OUTLINE

INTRODUCTION

The increased understanding of microbial biochemistry in recent decades, along with major advances in genetic and molecular techniques, has resulted in an expanding diversity of microorganisms entering the biotechnology arena. Be it novel uses for well-studied organisms, such as the commercial production of restriction endonucleases from many common bacteria and yeasts, or the potential for development of new applications from new species such as the unidentified hydrogen-producing bacterium FOX-1 (1), microorganisms, themselves, are integral components in the overall aspects of biotechnology from discovery, through research and development, to production.

For those biotechnologists not formally trained in classical microbial physiology, the too-prevalent assumption is that microorganisms function similarly to the purified re-

agents used in a well-documented chemical reaction. In reality, microorganisms (even authenticated and characterized strains) are heterogeneous conglomerations of multiple biochemical pathways with the potential for working antagonistically or synergistically, depending upon the environment in which the microorganism resides. For those strains under study in the laboratory or being potentially harnessed for bioprocess use, the microbial environment is the culture medium.

This article surveys elements of microbial media and other considerations of microbial nutrition that impact upon the general growth and metabolic activity of microorganisms. Although specific references are given for many useful compendia of microbial media formulations (2–7), the purpose here is not to further cite well-documented media and buffer formulations. The intent of this article and its specific examples is to illustrate general principles of controlled media design, formulation, and preparation for the cultivation of microorganisms.

ESSENTIAL NUTRITIONAL REQUIREMENTS

Water

Depending upon the physiological state of the organism, the chemical composition of bacteria is 70–90% water. As a polar solvent, water dissolves other compounds of similar chemical nature, which also happen to be the biologically important molecules such as amino acids, carbohydrates, and nucleic acids. The polarity of water helps to permit the hydrogen bonding necessary in the formation of the final working configuration of a cell's large macromolecules. As a polar solvent, water chemically forces nonpolar molecules such as lipids into hydrophobic aggregates that are integral in the formation cell membranes. The presence of water is critical to the existence of microorganisms. Under laboratory conditions, microorganisms are cultivated with liquid and solid media. In both situations, the adequacy and purity of water used in media preparation can drastically effect the performance and/or sustained viability of an organism.

Because the availability of high-quality, purified water has become increasingly affordable for even small laboratories, the use of tap water or marginally distilled water for the preparation of media and reagents is not a recommended option. For most municipalities, tap water is seasonably variable with respect to its chemical and microbial content. Hard water ladened with calcium and magnesium will precipitate many media formulations, with deleterious results. The terms *deionized* or *distilled* water with respect to water purity are merely euphemistic unless actual determinations of residual ion and organic levels are known. Water passed through spent deionization beds or boiled and condensed through a scale-clogged distillation system is hardly purified. At minimum, water used in the preparation of microbial media and reagents for general laboratory purposes should meet U.S.P. specifications for purified water; other organizations such as the American Society for Testing and Materials (ASTM) and the National Committee for Clinical Laboratory Standards (NCCLS) have similar criteria with respect to the conductivity, resistivity, and total organic content for Type II water (8). Point of use deionization systems available from many manufacturers (e.g., Barnstead/Thermolyne Corporation, Dubuque, Ia. and Millipore Corporation, Bedford, Mass.) easily produce Type I, 18 MΩ water. Some systems include ultrafiltration to reduce pyrogen levels. Purified water for highly regulated applications and processes (e.g., biopharmaceuticals) must meet U.S.P. specifications for water for injection (9). Water, unless sterilized, should not be held for any length of time in storage containers such as bottles or carboys or allowed to stand in uncirculated piping systems (e.g., dead-legs) because there is a good probability that the water will become populated with bacterial biofilms that grow on container and piping walls. Bacterial contamination will organically pollute water purity in addition to increasing endotoxin and pyrogens to unacceptable levels for certain procedures including product purifications or animal injections. Note that pyrogens are lipopolysaccharides from bacterial membranes. With respect to purified water, they indicate bacterial contamination. Their presence, of course, in bacterial cultures is a mute point. Use of plastics for water storage containers may be a consideration because plasticizer leaching can cause inhibition of sensitive organisms.

Energy

All microorganisms require an exogenous source of energy. The biochemical mechanisms involved with this aspect of metabolism are diverse. *Lithotrophic* organisms obtain energy from inorganic sources. Lithotrophs fall into two metabolic categories with respect to energy procurement. *Photolithotrophic bacteria* and *cyanobacteria* obtain energy from light in conjunction with, respectively, reduced sulfur (e.g., hydrogen sulfide) or water, to release energy for biosynthetic functions. Variations in microbial chlorophyll molecules create adsorption spectra that, in nature, limit a given species to a particular photic zone. Under laboratory conditions, the light requirements necessary for cultivation reflect this consideration. For example, the green and purple sulfur bacteria, such as *Chlorobium* and *Chromatium*, with adsorption peaks above 750 nm, are cultivated under the red wavelengths of tungsten light. Cultures, however, should not be placed too close to an incandescent light source because the heat emitted from the bulbs can quickly raise the temperature of the culture vessel beyond the upper growth limits for an organism. Cyanobacteria (e.g., *Anabaena*) adsorb blue wavelengths of light below 700 nm. This requirement can be satisfied by cultivating the bacteria under fluorescent tubes that emit light at this range of the visible spectrum. *Chemolithotrophic* organisms utilize inorganic compounds for energy. Examples within this second form of energy procurement are *Sulfolobus* spp., which oxidize elemental sulfur to sulfuric acid, and *Nitrobacter* spp., which biochemically exploit the oxidation of nitrites to nitrates. Numerous new genera and species of prokaryotic chemolithotrophs that obtain energy from various inorganic electron donors have been isolated in recent years, including *Archaeoglobus* spp., *Methanococcus* spp., and *Pyrodictium* spp. (10). Many obligate lithotrophs are inhibited by organically rich en-

vironments and are best cultivated under chemically defined media conditions.

Organotrophic organisms obtain energy more conventionally from organic compounds. As with the lithotrophs, organotrophs many be either phototrophic or chemotrophic. *Photoorganotrophs* are represented in nature by the anaerobically cultivated purple nonsulfur bacteria (e.g., *Rhodospirillum*), which utilize light in conjunction with organic compounds such as malate, pyruvate, or yeast extract, rather than O_2, as electron acceptors to release energy for growth and nutrition. *Chemoorganotrophs* encompass a vast number of organisms from all the microbial groups including archaea and bacteria, fungi, protozoans, and nonphotosynthesizing eukaryotic cells that obtain energy from the oxidation or other dissimilation of organic compounds.

Major Chemical Elements (C, H, N, O)

Unlike energy-procuring mechanisms, which vary widely between microbial genera and species, the anabolic or biosynthetic requirements of eukaryotic and prokaryotic cells are remarkably similar. Molecular mechanisms for intracellular communication and structural components share much chemistry whether they are bacterial *E. coli* cells or fungal *Aspergillus nidulans* cells. Whereas individual strains may vary in their ability to manufacture basic cell components and metabolites due to specific mutations at points within biochemical pathways, all known organisms share the same basic cellular needs for carbohydrates, lipids, proteins, and molecular combinations thereof. The elements carbon, hydrogen, nitrogen, and oxygen can be regarded as major essential elements of nutrition because they contribute in significant percentages to the biomass of cells. These major elements may be required in the gaseous form, as organically fixed compounds, or both. Iron, magnesium, phosphorous, potassium, sulfur, and other elements, although critically important to sustained growth and metabolic activity, are often termed minor or trace elements in that they collectively represent less than 2% of cellular dry weight.

Carbon. Nutritionally, carbon appears in cellular metabolism in two forms: carbon dioxide gas (CO_2) and organic molecules. CO_2 is required by all organisms for a number of biochemical functions including tricarboxylic acid (TCA) cycling and de novo fatty acid synthesis from acetyl-CoA. Although much of the carbon dioxide is metabolically recycled throughout the cell's biochemical pathways, an initial exogenous source of carbon dioxide is mandatory. Autotrophic organisms readily assimilate atmospheric carbon dioxide; yet, also, all heterotrophic organisms have some ability to fix this compound, although at a much-reduced capacity. Microbial cultures will sometimes experience long lag periods when subcultured at low-volume inoculum into fresh media. This phenomenon is often attributable to suboptimal CO_2 tension, which the culture slowly corrects with cellular respiration before any significant increase in biomass can occur. The term *CO_2 sparking* refers to the sudden increase in bacterial growth observed when a freshly inoculated culture is briefly sparged with the gas. An enriched atmosphere of 5% CO_2 is used for the cultivation of clinical (particularly for fresh isolates) bacterial strains. CO_2 incubators are most efficient for multipurpose cultivations, but the anaerobic gas-pack CO_2-generating systems offered by BBL (Becton Dickinson Microbiology Systems, Cockeysville, Md.) or Difco (Difco Laboratories, Detroit, Mich.) are recommended for small volume or infrequent use. Depending upon the absolute requirement, capnophilic (CO_2-requiring) bacteria can also be cultivated in jars in which inoculated test tubes or agar plates are placed along with a burning candle. The candle jar is then tightly sealed while the candle continues to burn until free oxygen in the jar is consumed. The resulting atmosphere achieves approximately 2% CO_2. Both the anaerobic gas-pack systems and candle jars have draw backs with respect to increased risk of culture contamination. Respiring cultures give off significant amounts of water, which raises the humidity within the sealed jars. As the jars themselves are normally not sterile at time of culture incubation, any environmental bacterial or fungal contaminant within the jar will proliferate in the additional moisture. Capillary action of excess water at the culture vessel openings (particularly petri dishes) can draw contaminating organisms or their spores into the culture vessel.

Autotrophs can use carbon dioxide gas as a sole source of carbon for biosynthesis. Although autotrophy is often regarded by nonbacteriologists as synonymous with photosynthesis, autotrophy and phototrophy are quite independent metabolic functions. For example, methanogenic archaea (e.g., *Methanobacterium* sp.), while nonphotosynthetic, are capable of utilizing carbon dioxide and hydrogen as sole sources of carbon and energy. Yet, as noted elsewhere, purple nonsulfur bacteria are photosynthetic but rely upon organic acids for metabolic reducing power and, ultimately, as the carbon source for biosynthetic functions. Whereas autotrophy is widely represented among prokaryotes, the ability to utilize CO_2 as a sole carbon source is not a general characteristic of fungi. Among filamentous fungi, *Cephalosporium* spp. and *Fusarium* spp. have been documented to be able to do so under long-term cultivation (11).

Heterotrophs obtain carbon principally from organic molecules such as carbohydrates, amino acids, or lipids. For heterotrophs, a compound utilizable for its carbon often also functions as an energy source. Although glucose is widely assimilated by many heterotrophic microorganisms, it is not necessarily the universal carbon source for culture medium supplementation. Many bacteria, whether their characteristics are genuswide or species-specific, show little or no stimulation by glucose and preferentially utilize amino or other organic acids. The marine genus *Oceanospirillum* falls into this category as do many individual species within the diverse genus *Clostridium*. In an extreme example, *C. aminovalericum* (ATCC 13725) appears to be limited to δ-aminovaleric acid as its singular assimilable source of both carbon and energy.

Some organisms can alternate between autotrophy and heterotrophy, depending upon environmental and nutritional conditions. For these cultures, biomass vigor and yield are most often greater with heterotrophic rather than

autotrophic conditions; however, secondary metabolites produced can vary considerably between the two conditions.

Hydrogen. Certain archaea and bacteria can grow by utilizing atmospheric hydrogen (H_2) as an electron donor and, depending upon the organism, assorted compounds including carbon dioxide, oxygen, nitrate, or sulfate as terminal electron acceptors (10). The hydrogen-oxidizing genus *Hydrogenophaga* (12) is facultative with respect to energy metabolism in that it functions chemoorganotrophically in a nutritionally heterotrophic aerobic environment by metabolizing various amino acids or sugars for sources of carbon and energy. However, in an atmosphere containing 60% H_2, 10% CO_2, 25% N_2, and 5% O_2, the organisms switch to chemolithoautotrophic pathways. *Methanobacterium thermoautotrophicum*, a strictly anaerobic archeaebacteria, metabolizes hydrogen and carbon dioxide as sole energy and carbon sources to yield methane and water (methanogenesis). For the anaerobic methanogens as well as the aerobic hydrogen bacteria, conditions favoring autotrophy require a high (60–80%) concentration of hydrogen for cultivation. Under all conditions, work with compressed hydrogen gas should be conducted with adherence to pertinent laboratory safety practices. Lower concentrations of H_2 (3–10%) are frequently included in gas mixtures for the cultivation of anaerobic bacteria in gas-generating systems and glove boxes where, in the presence of a palladium catalyst, trace amounts of inhibitory molecular oxygen are chemically reduced to water. The final form of hydrogen required for nutritional purposes is the molecularly combined element required by all organotrophic cells. Combined hydrogen originates from the catabolic metabolism of organic compounds assimilated by a cell as carbon and energy sources.

Oxygen. As already noted for combined hydrogen, the bulk of combined oxygen within cells originates from the complex nutritional compounds, including water, assimilated by the cell. If a medium provides enough matter to satisfy the carbon and energy requirements of a culture, then the combined oxygen requirements will also be met. However, molecular oxygen (O_2) is an important, often growth-limiting, variable in microbial nutrition. O_2 is the primary terminal electron acceptor for many aerobic and facultatively anaerobic organisms. In oxygen-depleted or diminished environments, cells with no other biochemical mechanisms for exploiting alternative electron acceptors stop metabolizing and cease multiplying. Facultative organisms switch to fermentative pathways. In either situation, the biochemical activity of the cells, as well as the secondary metabolites produced, is significantly altered by oxygen starvation. Be it large-volume fermentors or small-volume chemostats or Fernbach flasks, the need for O_2 sparging in bulk cultivation vessels is regarded as a basic cultivation requirement for aerobic organisms (13). Be that as it may, one should also be aware that significant O_2 gradients quickly form in liquid test tube cultures, particularly for those cultures that form surface mats or pellicles of growth. Various micrometabolies can occur within the cell population in a standing culture along the O_2 gradients from surface to bottom of the test tube that might, if unrecognized, cause undue problems in scale-up development. Cultures with strong O_2-requirements (even for those that do not form pellicles) may not grow to very high density in a test tube because of the limited liquid–air interface. Better liquid growth of these test tube cultures is effected by incubating the tube at a slant to increase the surface area of the culture, or by shaking.

Nitrogen. Cells can assimilate nitrogen by two methods. Nitrogen fixation is the ability to acquire elemental nitrogen from the air and to molecularly combine the element into chemical forms utilizable for biosynthetic processes. The bacterial genera *Azotobacter*, *Bradyrhizobium*, and *Rhizobium* are most recognized for this characteristic, although some facultative anaerobes as well as anaerobic bacterial species also have the capacity. Fungi are not recognized as competent nitrogen fixers. Nitrogenase activity is induced with cultivation on nitrogen-free media. Growth on chemically defined "nitrogen-free" media might presumptively select for potential nitrogen fixers; however, trace amounts of nitrogen from agars, chemicals, and glassware are present in sufficient concentration to permit effective scavenging and growth (albeit, less than optimal) by many non-nitrogen-fixing organisms. Conclusive nitrogen fixation is best determined by the acetylene reduction assay (14).

The second, and most widely utilized, microbial mechanism for nitrogen procurement is via combined nitrogen assimilation from inorganic or organic molecules. Media formulations satisfy combined nitrogen requirements either with inorganic salts [e.g., NH_4Cl; NH_4NO_3 or KNO_3; $(NH_4)_2SO_4$] or from organic compounds (e.g., amino acids). The ability to utilize inorganic salts as a nitrogen source varies widely even within species. The chemolithotrophs as a group effectively utilize inorganic ammonium or nitrate salts as sole sources for nitrogen. For other organisms, the inability to grow under chemically defined medium conditions with ammonium or nitrate salts as a sole nitrogen source is due not so much to the inability to assimilate the ion directly from the medium or to incorporate it as the glutamine precursor to all subsequent biosynthetic nitrogenous pathways, but to the specific need for additional nitrogenous growth factors such as purines, pyrimidines, amino acids, or small peptides. These kinds of nitrogenous nutritional requirements are discussed in greater detail in the section "Growth Factors".

Nitrate is not a preferentially assimilated or utilized source of nutritional nitrogen for many bacteria or fungi; concentrations as low as 0.2% are inhibitory to the growth of some bacteria. However, the use of nitrate in energy metabolism as a terminal electron acceptor is a widely used mechanism among bacteria and is termed dissimilatory nitrate reduction or denitrification. The biochemical pathways involved with nitrate assimilation for cellular syntheses and for dissimilatory nitrate reduction are different. Nitrate reduction occurs with either aerobic or anaerobic bacteria. Strains of *Clostridium perfringens*, for example, utilize nitrate as an electron sink, which causes a shift from butyrate to acetate fermentation and an increase in growth yield (15). All recognized species in the extremely

halophilic genus *Haloarcula* are capable of using nitrate as a sole nitrogen source and, in addition, are strong denitrifiers with the ability to readily tolerate and reduce 3 M concentrations of KNO_3 under either complex or chemically defined media conditions; aerobic growth of haloarculas with liquid media lacking nitrate supplementation is markedly limited compared to aerobic growth in media supplemented with 0.2% KNO_3 (R. J. Cote, unpublished data, 1995).

Minor and Microelements (Fe, Mg, K, P, S, and others)

Trace metal function and speciation have been extensively studied in bacteria and fungi (16,17). Nutritionally essential metal ions function metabolically as enzyme cofactors in membrane transport and in structural components. Microbial response to trace metals is detectable at extremely low concentrations (i.e., microgram or nanogram quantities, depending upon the metal). However, the bioavailability of a particular metal is markedly dependent upon proper speciation of the ion as it occurs in the culture medium (18). Depending on interaction with other medium components or methods of sterilization, metal valences can change to nonusable forms, or the ions can irreversibly bind as insoluble precipitates. Although problems with metal-binding phenomena are often directed toward the nutritionally essential metals, the potential for significant and irreversible binding of ions to media components must also be taken into consideration in studies of bacterial resistance to heavy metals. Reports of bacterial resistance to silver and selenium (19,20) could not be verified when the metals were added to culture media in a manner that eliminated their binding to peptones (R. J. Cote and R. L. Gherna, unpublished data, 1994). Similar observations made regarding media influence and metal sensitization of *Enterobacter cloacae* to silver sulfadiazine (AgSu) (21) are explained by heavy-metal binding under complex media conditions. Tilton and Rosenberg (22) discuss the issue of heavy-metal sequestration in a study of the effects of agar on silver inhibition.

Microelement supplementation is not normally required in media formulated with chemically complex components such as yeast extract or protein hydrolysate because the essential metals are naturally present in these materials in sufficient concentration to provide optimum culture growth and performance. Well-designed, chemically defined formulations include calcium, iron, magnesium, manganese, phosphorous (as phosphate), potassium, sodium, and sulfur (as sulfate) in the form of inorganic salts. Other micronutrients may be required in the medium, depending upon the nature of the metal function under study or, in the case of general culture propagation, the purity of the water and cleanliness of the glassware used to prepare the medium. Understanding of cell physiology, as well as any physical interactions within the culture system, is a basic requirement when working with nutritional trace metals. For example, although boric acid is often included in trace metal mixes, a boron deficiency is practically noninducible for cultures grown in borosilicate glass vessels because enough of the element leaches from the glass to satisfy nutritional needs. Table 1 lists metal mix formulations that are useful for chemically defined cultivation of numerous microorganisms. As noted elsewhere in this article, the use of tap water to satisfy trace element requirements is not recommended because regional and seasonal variability in water purity can introduce considerable ionic variation in a medium, with frequently deleterious results.

Table 1. Trace Metal Mixes for Bacteriological Media

Metal mix A: Balch's trace element solution

Nitrilotriacetic acid	1.5 g
$MgSO_4 \cdot 7H_2O$	3.0 g
$MnSO_4 \cdot H_2O$	0.5 g
NaCl	1.0 g
$FeSO_4 \cdot 7H_2O$	0.1 g
$CoCl_2 \cdot 6H_2O$	0.1 g
$CaCl_2$	0.1 g
$ZnSO_4 \cdot 7H_2O$	0.1 g
$CuSO_4 \cdot 5H_2O$	10.0 mg
$AlK(SO_4)_2 \cdot 12H_2O$	10.0 mg
H_3BO_3	10.0 mg
$Na_2MoO_4 \cdot 2H_2O$	10.0 mg
Distilled water	to 1.0 L

Suspend nitrilotriacetic acid in about 500 mL water and adjust to pH 6.5 with KOH pellets to dissolve. Add remaining salts one at a time. Bring final volume to 1.0 L with distilled water. Use 10.0 ml trace element solution per 1 L medium.

Metal mix B: modified Balch's trace element solution

To 1.0 L metal mix A add	
$NiSO_4 \cdot 6H_2O$	30.0 mg
Na_2SeO_3	20.0 mg
$Na_2WO_4 \cdot 2H_2O$	20.0 mg

These metals are included for the cultivation of methanogenic bacteria under chemically defined conditions.

Source: From Ref. 23, p. 158.

The whitish haze or precipitate that develops in some media upon standing or after autoclaving is frequently caused by imbalanced metal compositions. Divalent and trivalent cations (i.e., Ca^{2+}, Fe^{2+}, Fe^{3+}, and Mg^{2+}) will spontaneously bind with OH^- and PO_4^{2-} groups in the medium to form insoluble hydroxides and phosphate complexes. The condition is most evident at neutral to alkaline pH values and is intensified by heat, either boiling or autoclaving. Similarly, precipitation caused by metal binding to proteinaceous material in the medium and darkening of chemically defined agar media are also frequently encountered in poorly designed or manipulated formulations. All of these adverse metal interactions are generally regarded as deleterious and growth limiting. Depending upon the composition of the medium, these kinds of chemical interactions can be eliminated by sterile filtration or separate autoclaving of inorganic salts and any phosphate buffers, and separate autoclaving of agar.

The use of chelating agents can also help to selectively maintain the solubility of polyvalent cations. Care must be taken when using powerful chelators such as ethylenediaminetetraacetic acid (EDTA) or nitrilotriacetic acid

(NTA) because overchelation also depletes bioavailability of the metals. For microbial media, 0.5–2.0 mg/L EDTA or 15–150 mg/L NTA are reasonable concentrations. Mild chelation can be achieved with the use of specific amino acids (e.g., glycine, histidine) or carboxylic acids (acetate, citrate, succinate, tartrate). However, their use and concentration must be evaluated with respect to the function of the medium and the physiology of the microbial culture. For example, carboxylic acids are readily utilized carbon and energy sources for many microorganisms, and glycine is inhibitory at 1% concentration to many bacteria.

Under iron-deficient growth conditions, some bacteria produce and secrete chelators called siderophores to improve transport of ionic iron into the cell (24,25). Siderophores have been found in a number of diverse genera including *Aureobacterium (Arthrobacter) flavescens* (26), *E. coli*, *Klebsiella* (27), *Pseudomonas*, and *Mycobacterium avium* subsp. paratuberculosis (28). Other organisms rely upon the hemin molecule in blood as an easily assimilable iron chelate. A growth factor requirement for hemin is common among medically important bacteria. Hemin requirement (the X-factor) is diagnostic in the identification of *Haemophilus influenzae*. *Porphyromonas gingivalis* (29) and *Vibrio vulnificus* biotypes 1 and 2 require iron in the form hemin for growth and virulence (29,30). Whereas a number of classical media formulations (e.g., GC Agar) include crude hemoglobin as the source of the iron porphyrin molecule, use of hemin, instead, will produce a medium free of the heavy debris associated with hemoglobin. Hemin is used at a concentration of 0.5 mg/L medium. To improve solubility, initially suspend the compound in 1–2 mL 1 N NaOH, then add the hemin-NaOH solution to the bulk of the medium.

Many of the metals listed here that have been historically categorized as needed by microorganisms only in trace amounts have, in recent years, come to be evaluated on a different metabolic scale. Sulfur serves as an energy source for numerous species of bacteria, and thiosulfate seems to be utilized for energy by some fungi. While the role of sulfate as the terminal metabolic electron acceptor for the many anaerobic sulfate-reducing bacteria has been long recognized, new genera are currently being isolated that possess the ability to utilize one or more biologically important metals [(Fe (III), Mn (IV)], U (VI), and others] as terminal electron acceptors in biochemical dissimilatory metal reduction pathways (31). Because the function of terminal electron acceptor is not recyclable within the cell and bears a heavy metabolic load, the amounts of metal ion needed per liter for efficient energy transfer are orders of magnitude greater than those needed to satisfy trace element nutrition. One to four grams per liter is a guideline, depending upon the specific metabolism of the organism as well as the molecular weight and form of the metal salt selected for use.

Growth Factors

Given less than a dozen essential chemical building blocks and a source of metabolic energy to power the cellular machinery, some organisms, such as the wild-type *E. coli*, can synthesize every molecule needed for cell maintenance, growth, and reproduction. Many other microorganisms (even strains within the same species) are auxotrophic in that they have lost the ability to synthesize one or more key organic compounds essential to their physiology. These missing compounds are called growth factors and must be present in the culture medium if cell growth is to be vigorous, metabolically productive, and sustainable.

L-Amino Acids. L-Amino acids are common growth factor requirements for prokaryotes and eukaryotes. Many bacterial genera (e.g., *Lactobacillus* spp.) have multiple amino acid requirements. The requirement may be absolute or conditional and influenced by the presence and concentration of other amino acids (32–34). Similarly, a phenotypic amino acid requirement may disappear with the addition of an appropriate synthetic pathway intermediate. For example, a tryptophan "requirement" may actually be caused by a metabolic block earlier in the tryptophan pathway and might be satisfied by one of the earlier pathway intermediates (i.e., aspartic acid or indole). Because amino acids may share a common transport system, an excess of one amino acid can result in an increased need for a competing amino acid. Amino acid supplementation is not required in complex media containing peptones or other protein hydrolysates. In chemically defined media, the addition of 20–50 mg/L amino acid stimulates prokaryotic growth (100–200 mg/L for yeast), although adjustment of the concentrations is necessary for media optimization with multiple amino acid-requiring strains to chemically balance the formulation. The most notable exception is the requirement for glutamic acid, which, as precursor to all other amino acid biosyntheses, must be added at 200–500 mg/L to achieve optimal growth of a bacterial culture. Amino acids, except glutamine, are stable with autoclave sterilization at the working concentrations used in media. Glutamine in aqueous solution will spontaneously break down with time to ammonium and pyrrolidone carboxylic acid residues. This reaction occurs more rapidly at elevated temperatures (37 °C and above). The use of glutamine peptides in a medium can eliminate this problem, however, they are expensive for large-scale use. Concentrated stock solutions of amino acids may not be soluble, but neutralization of the stock solution with NaOH or KOH will increase solubility with the formation of amino acid salts for many of these compounds. Stock solutions of cysteine will autooxidize to cystine unless stored anaerobically (e.g., under N_2).

For many years, the perceived need by bacteria for combined amino acids (peptides or proteins) was satisfied by the argument that peptide transport utilized different systems than did amino acids; thus, the need for a specific peptide was actually an alternative cellular method for obtaining a specific amino acid contained within that peptide via a biochemically noncompetitive mechanism. However, increased knowledge of the role of peptides in protein trafficking suggests that peptide auxotrophies can affect cellular physiology and communication (35). Successful laboratory cultivation of *Thermoplasma acidophilum*, having no other known growth factor requirements, is dependent upon specific lots of powdered yeast extract containing a methanol-soluble growth factor, which purification re-

vealed to be a small 1,000-MW peptide (36). Similarly, recent laboratory cultivation of *Treponema maltophilum* also included the requirement for a methanol-soluble growth factor from yeast extract (37). The treponeme requirement has not been further purified. Finally, successful cultivation of the protozoan *Entamoeba histolytica* in complex media enriched with peptone, vitamins, and serum is nevertheless dependent upon an unknown growth factor found only in certain lots of powdered yeast extract (38). Whether the elusive yeast extract growth factor is the same for all these metabolically dissimilar organisms or whether the relatively gentle methods used in the manufacture of yeast extract simply yield a large pool of assorted intact peptides possibly required by some microorganisms poses an interesting question.

Whole Proteins. Whole proteins (e.g., albumin, blood, egg, meat, serum) are not known to be essential requirements for microbial growth, although they are an integral medium component for many nutritionally fastidious microorganisms. Clinical isolates of mycobacteria have been historically cultivated with Lowenstein–Jensen medium, containing whole egg and inspissated (coagulated by heating at 80–85 °C for 45 min) to form a solid matrix (39). Most mycobacteria, however, can be effectively cultured with Dubos medium or Middlebrook 7H9/or 7H10 media, in which the egg protein is replaced by the more defined components bovine serum albumin, catalase, dextrose, and oleic acid (40). Variations of chopped meat media (2) were for many years the recommended formulations for cultivation of pathogenic clostridia and similar bacteria, yet many of these strains give equal cell yield with the more defined, and more easily prepared, Reinforced Clostridial medium (40), although this basal medium frequently requires the addition of hemin and/or vitamin K_1 to satisfy the growth factor requirements of some strains; additionally, 0.5% cellobiose added to reinforced clostridial medium will enhance the growth of cellulolytic clostridia.

Defibrinated rabbit or sheep blood (5–10% v/v) is a common addition to media used for the cultivation of microorganisms pathogenic to animals. Human blood is not recommended for use for microbial culture work for health safety reasons and also because outdated blood obtained from banks is normally citrated. Citrated blood of any type should not be used in culture media because the anticoagulant may have negative effects on culture growth or hemolytic reactions. Although diagnostic hemolytic reactions differ between rabbit and sheep bloods, the ability to support microbial growth is generally the same. Human or sheep bloods, unless chocolated, are not used for the cultivation of *Haemophilus* spp. or other organisms requiring NAD because these fluids contain enzymes that inactivate the growth factor. Chocolate blood agar is prepared by heating the medium containing blood to 70–80 °C for 15 min. Purchase of whole animal blood should be from a reputable supplier and pooled from animals on an antibiotic-free diet. Well-collected and processed defibrinated blood is free from clots and cell lysis. Although commercial blood suppliers carefully collect their products, each lot of blood should be checked for sterility prior to use. Not all types of bacterial contaminants found in blood will grow well in either of the U.S.P.-recommended sterility test media (i.e., Fluid Thioglycollate and Soybean–Casein Digest). To broaden the screening procedure, the battery of media should be enlarged to include Brain Heart Infusion (BBL 11059 or Difco 0037) to enhance the recovery of somewhat fastidious contaminants, as well as HTYE (Trypticase peptone (BBL), 0.5%; yeast extract 0.2%; HEPES, acid, 0.4%; adjust to pH 7.2 $\pm$ 0.1 prior to sterilization at 121 °C for 15 min), which has wide versatility in the ability to cultivate diverse environmental heterotrophic organisms that do not grow well with conventional, general bacterial growth media. Whole blood should be stored under refrigeration (not frozen) and should be incorporated into media as soon as possible to help stabilize the fluid. Whole blood can not be stored longer than 2–3 weeks without significant deterioration. However, when stored at 4–8 °C, media containing blood can, for most media purposes, have a 4-month shelf life.

Serum (5–10% v/v) is an alternative to blood for the cultivation of pathogens. Horse, fetal, or newborn bovine sera are most frequently used for the cultivation of bacteria, whereas adult bovine serum is specified for the cultivation of many pathogenic protozoans. Sera vary in their intrinsic enzyme activity. For example, horse serum degrades glutamine, a necessary component in many animal cell line media formulations, and as already noted for chocolatizing whole blood, sheep and human blood can inactivate NAD. Preparation instructions for many media formulations call for serum heat inactivation (incubation of the serum at 56 °C for 30 min) to inactivate the protein complement. This temperature may not be high enough to eliminate adverse serum enzyme activity. Conversely, heat inactivation may not be a universally advantageous specification for all microbial growth and performance. A researcher should investigate types of sera as well as the effects of heat inactivation upon the performance of a microbial culture.

Whole proteins and their hydrolysates supply an eclectic and undefined mix of nutrients, detoxifiers, and other molecules that slowly release or absorb metabolites that may be required for cell nutrition in small amounts but quickly become toxic at elevated levels (e.g., fatty acids). Proteins hydrolysates supply a myriad of nutritional growth factors and help control physical parameters such as pH and osmolarity.

Be that as it may, the use of proteins and their derivatives in media formulations is becoming problematical with respect to biotechnology for two reasons: (*1*) Because many of the products of interest produced by microorganisms are proteins or substances with chemical affinity to proteins, presence of a complex proteinaceous medium component can significantly complicate a product purification process. (*2*) Biotechnology applications under regulatory compliance are facing increasing scrutiny about the potential presence of unidentified adventitious agents in media components. The international concern with bovine spongiform encephalopathy (BSE) is real and pervasive throughout the field of biotechnology, ranging from final product, to the type and source of medium components used in the preparation of a frozen or lyophilized master cell bank used in the manufacture of a product.

The European Commission decision 97/534/EC bans the importation of specified risk materials (SRM) into the European Union member countries (including Australia, Canada, and New Zealand). U.S. biotechnology companies wishing to deal with the European market must be able to provide a declaration to customs agents that assures their product does not contain, nor is derived from, the specified SRM as defined in 97/534/EC. The specified risk material, in this instance, is defined as "the skull, including the brain and eyes, tonsils and spinal cord of bovine animals over 12 months, ovine and caprine animals which are over 12 months or have a permanent incisor tooth erupted through the gum, and the spleen of ovine and caprine animals" (41).

Many of the peptone hydrolysates used in biotechnology are of animal (bovine) origin and are manufactured from "leftovers" of the slaughterhouse trade. As large-scale animal processing is not a clean operation, SRM contamination of raw material used in the manufacture of peptones is probable, particularly where source material is not directly traceable to government-regulated, clean herds.

The degree of concern with animal peptones with respect to 97/534/EC varies with industry and product. For example, from a regulatory perspective, the manufacture of biopharmaceuticals, especially direct injectables, demands high scrutiny for presence and elimination of any SRM. But the use of an animal peptone in a medium used solely for clinical diagnostic purposes (e.g., a peptone used clinically in MacConkey agar to differentiate *E. coli* from other normal intestinal flora), might be of lesser concern because the peptone never comes in direct contact with animals or humans at risk to BSE or similar prion agents. Acid-hydrolyzed animal peptones are generally of lower risk than enzymatic hydrolysates because the acid and heat associated with acid hydrolysis inactivates viral agents. Ultrafiltration of peptone solutions and sera has been proposed as a mechanism for eliminating possible BSE contaminants as well as reducing endotoxin levels. In any event, the concern with BSE and related animal/human pathogenic agents has caused an escalation of documentation requirements for the tracking of animal-derived media components. Certificates of origin for sera, meat, and milk peptones can, and should, be obtained from reputable vendors of these materials. Although certificates of analysis are now routinely supplied by raw material vendors to the biotechnology industry, certificates of origin are currently customer driven and are generally supplied only as requested.

BSE has fostered much current interest in the development of nonanimal peptones. With yeast, soy, or wheat as the source protein, some of these "veggie peptones" have interesting nutritional attributes but, nevertheless, still suffer the drawback of elevated intrinsic carbohydrate levels characteristic of plant peptones.

Difficulties in medium optimization and performance currently preclude wide use of serum-free or SRM-free media with animal cell lines. However, design of SRM-free media for most bacteria and yeast are feasible and cost-effective.

Vitamins. Vitamins are biochemical catalysts and appear in cellular metabolism as coenzymes or as the prosthetic group of enzymes. Vitamins elicit microbial growth response at very low levels, at nanogram concentrations for vitamins such as biotin and cyanocobalamin (vitamin B_{12}). Although many microorganisms are capable of synthesizing all of the required vitamins, many others are auxotrophic for one or more of these growth factors. The genus *Lactobacillus* characteristically has multiple vitamin requirements, and several strains within the group were widely used for many years in protocols for vitamin assays until replaced by instrumentation-based methodologies. The U.S.P. 23 still retains *Lactobacillus delbrueckii* subsp lactis (*L. leichmannii*) (ATCC 7830) as the assay organism for vitamin B_{12}. Marine bacteria frequently require B_{12}, whereas thiamine and biotin are necessary for the growth of many mycelial fungi. Menadione or its more active form, vitamin K_1, is a supplement for the cultivation of some clinical anaerobic bacteria. As noted with amino acids, a shift in medium composition can spare the need for a specific vitamin. *E. coli* (ATCC 10799; NCIB 8134) requires vitamin B_{12} when cultivated with a chemically defined minimal medium; when grown in the presence of 20 μg/mL methionine, the vitamin requirement is eliminated (42). Vitamin auxotrophies can appear as a need for the vitamin precursor, the intact vitamin, or as conjugates in coenzyme form. Koser noted, many years ago, that vitamin and amino acid auxotrophies in thermophilic bacilli are temperature variable (43). NAD and cocarboxylase (thiamine pyrophosphate) are coenzymes required by many pathogenic bacteria.

All of the vitamins are water soluble and heat stable at working concentrations used in media; coenzymes should be filter sterilized, as should concentrated vitamin stock solutions. Most vitamin stock solutions remain water soluble in significant concentrations, although biotin, folic acid, nicotinic acid, and riboflavin require neutralization with NaOH to retain solubility of the concentrate. Vitamin K and thioctic acid stock solutions are ethanol soluble. Ascorbic acid, used in microbial cultivation as an antioxidant, has a short life (about 3 weeks) in media; use of ascorbate salts rather than the free acid will improve stability. Table 2 lists a complete vitamin mix for the cultivation of bacteria and fungi. Yeast extract at a concentration of

Table 2. Balch's Vitamin Solution

p-Aminobenzoic acid	5.0 mg
Folic acid	2.0 mg
Biotin	2.0 mg
Nicotinic acid	5.0 mg
Calcium panothenate	5.0 mg
Riboflavin	5.0 mg
Thiamine HCl	5.0 mg
Pyridoxine HCl	10.0 mg
Cyanocobalamin	100.0 mg
Thioctic acid	5.0 mg
Distilled water	1.0 L

Mix all vitamins in distilled water. Adjust to pH 7.0, if necessary, to dissolve. Filter sterilize and store in brown bottle with refrigeration.

Source: From Ref. 44, p. 160.

0.1–0.5% is used as an undefined vitamin supplement for microbial growth in complex media; however, concentrations of yeast extract as low as 0.05% can elicit growth stimulation by organic growth factors, which may or may not be vitamins.

Nucleic Acid Precursors. Nucleic acid precursors are often required by nutritionally fastidious organisms when cultivated in defined or semidefined media. In some instances, the purine or pyrimidine will satisfy the requirement; more commonly, an organism needs preformed nucleosides or nucleotides. Organisms with these types of synthetic deficiencies will show a growth response to 5–50 μg/mL filter-sterilized additive.

Lipids. Lipids or their precursors are required by diverse organisms. Some pneumococci have a unique requirement for choline as a lipid precursor. *i*-Inositol is a structural component of some phospholipids. Inositol-deficient strains of *Neurospora crassa* and *Saccharomyces cerevisiae* have been used in studies of phospholipids and cell membrane structure. Fatty acids stimulate the growth of some fungi; certain mutants of *N. crassa* are auxotrophic for fatty acid synthesis (45). Rumen bacteria require short-chain fatty acids for growth. Many mycobacteria have a generalized requirement for exogenously supplied lipid. Various media formulations for nonglycerophobic mycobacteria include 2.0 mL/L glycerol, 0.05 g/L oleic acid, or 0.5 g/L Tween 80 to satisfy this requirement. Most of the bacterial mollicutes (anaeroplasmas, mycoplasmas, and spiroplasmas) require sterols. Cholesterol is a prevalent component in semidefined media formulations for these organisms, whereas fetal calf or horse serum supplies the growth factor in general-use complex mycoplasma media. *Eubacterium coprostanoligenes* (ATCC 51222) and *Eubacterium* sp. (ATCC 21408) represent a novel group of bacteria that use cholesterol and similar sterols as terminal electron acceptors (46,47). The former organism does not require cholesterol but metabolizes and requires phosphatidylcholine for growth, whereas the latter requires cholesterol as well as an alkenyl ether lipid for growth. These bacteria have been used in probiotic studies on decreasing the level of cholesterol in the digestive tract. All the lipids just mentioned are stable to autoclave temperatures. Short-chain fatty acids are water soluble; higher molecular weight lipids are soluble in less polar solvents such as ethanol or chloroform. In the presence of other media components at alkaline pH, some high-weight lipids can form growth-limiting soapy complexes. Separate sterilization of the fatty compounds helps to alleviate the problem.

Polyamines. Polyamines (e.g., putrescine, spermidine, spermine) are formed via the arginine pathway and have undefined functions in the cell. Research on polyamines has been done principally in vitro where the compounds bind to and neutralize charges on DNA and RNA. Although high concentrations of Mg^{2+} exert the same general ionic neutralization effect, only polyamines have the ability to influence correct tRNA conformation. Much of the cellular polyamine appears bound to ribosomes. In *E. coli*, putrescine and spermidine account for half the total product of the arginine pathway (48). Polyamine supplements as growth stimulants appear in media for the cultivation of *Ureaplasma urealyticum* (2p.530), *Haemophtlus parainfluenzae* (49), *Veillonella atypica* (50), and other bacteria. Where complex media are used, there is generally a sufficient polyamine content in yeast extract to satisfy the requirements of deficient strains.

Unique Growth Factors. Any organism has the possibility to, either spontaneously or through human intervention, develop mutations in biosynthetic pathways. Thus, unusual or strain-specific growth factors are always a consideration in the development of media for "unculturable" organisms. Deliberate mutation for the inability to synthesize the cell wall component diaminopimelic acid was engineered into early recombinant host strains of *E. coli* as an attenuation factor to reduce the possibility of survival outside of laboratory cultivation. Until recently, *Bacteroides forsythus* had only been culturable in cocultivation with other oral anaerobic bacteria, until its requirement for *N*-acetylmuramic acid was recognized (51). As noted earlier for the L-amino acids, the inability to synthesize functional signal and transport peptides may be limiting factors in the protein chemistry of some organisms.

PHYSICAL PARAMETERS

pH

pH is a strong selection factor for microorganisms. Although most bacteria have a wide pH range ($\pm$3.0 pH units) at which measurable growth occurs, optimum growth is limited to a narrow range. Minimum and maximum pH values can often be distinct and sharply defined. Members of the genus *Bacillus* will grow at pH 6.8 but not at pH 6.5. Extreme halophiles with a biomass yield optimum at pH 7.4 continue to grow slowly at pH 7.0 and exhibit little or no growth below pH 6.7. Eukaryotic and prokaryotic organisms shift their biochemistry according to the pH of their environment and thus change cellular characteristics as well as metabolic by-products. Such changes in cultivation parameters can be consciously directed toward a particular application such as secondary metabolite production. Unfortunately, the effects of pH shifts are too often not critically examined, particularly at the small-scale cultivation stage. For example, in an unbuffered test tube culture of anaerobic carbohydrate-fermenting clostridia, acid production can quickly drop the medium to below pH 4.0, well outside the pH minimum of 6.5 necessary for significant growth. Either the culture will sporulate (if medium conditions are conducive to the process) or viability quickly diminishes as acid concentration increases. Effective media design must be constructed around the pH at which the medium is developed and will be used. Radical adjustment to media naturally posed at a particular pH too often leads to precipitation of components or other problems with performance. Inclusion of buffers, as well as the types of buffers used, are important considerations in media design.

Incubation Temperature

Incubation temperature influences microbial metabolism both with respect to the rates at which cellular processes run and the rates at which nutrients are assimilated. Strains of *Serratia marcesans* produce pink-pigmented colonies at 26 °C but are colorless or slow to produce pigment at 37 °C. Temperature effects may sometimes be subtle. Bacteria alter the fatty acid compositions of their phospholipids according to temperature. The proportion of low-melting-point fatty acids increases as growth temperature decreases (52,53). Organisms may display fairly broad temperature tolerances within a range, but as with pH, optimum growth range is fairly narrow. Psychrophiles characteristically exhibit efficient metabolic rates at temperatures below 15 °C; the obligate psychrophilic bacterial species *Colwellia psychroerythrus* has a temperature optimum around 10 °C and lyses above 20 °C (54). Mesophiles are active between 20 °C and 40 °C. Free-living environmental strains are more tolerant of wider temperature ranges than are pathogenic strains that effectively function within only a few degrees of the body temperature of their hosts. Thermophilic microorganisms exist at temperatures above 40 °C. Although some fungi (e.g., *Mucor miehet* and *Sporotrichum thermophile*) can grow at temperatures as high as 50 °C, extreme thermophily, characterized by the ability to metabolize at temperatures above 70 °C, is restricted to members of the archaea and, to a lesser extent, the bacteria.

Oxidation–Reduction Potential

Oxidation–reduction (redox) potential of the culture environment determines the ability of a microorganism to initiate growth. Redox values of media and respiring cultures are measured with a pH meter set to the millivolt (mV) mode and a platinum electrode. Aerobic organisms require positive millivolt conditions. Obligate microaerophiles require 0 to −100 mV; clinical anaerobes less than −100 mV; obligate and extreme anaerobes less −200 mV. Actively metabolizing anaerobic cultures can drop redox levels below −300 mV. Media for obligate microaerophiles and anaerobes include reducing agents to lower the redox potential to a range optimal for a culture inoculum to be able to initiate metabolic activity. Subsequent cellular growth will maintain an overall redox condition reflecting the varying metabolic activities of the culture. Organic matter such as meat particles, yeast extract, and reducing sugars exert reducing effects in a medium. Filling a culture vessel almost to capacity with medium or adding 0.2% agar to the medium to retard diffusion of O_2 will be adequate to culture less fastidious microaerophiles. Anaerobic organisms with more stringent redox requirements need one or more chemical reducing agents included in the growth medium. Frequently used reducing agents, listed in terms of approximate redox potential in millivolts, include sodium thioglycollate (−100 mV), cysteine hydrochloride (−210 mV), titanium (III) citrate (−480 mV), sodium sulfide (−571 mV), and sodium dithionite (−600 mV). The overall redox level of a medium containing any of these reducing agents will, of course, be dependent upon the chemical interactions of all media components as well as the reducing agent. Media chemically reduced with any of these compounds should not be allowed to reoxidize, because the chemical structure of the reducing agents can be irreversibly altered by oxidation and lose effectiveness; in some instances, the oxidized forms of reducing agents can be toxic to cells (55). For some strict anaerobes cultivated under chemically defined conditions, it is best to add the reducing agent just prior to inoculation because reduced conditions are difficult to maintain under prolonged media storage. Ljungdahl and Wiegel (56), Breznak and Costilow (57), and Balch et al. (58) provide excellent detailed instructions for the cultivation of strict anaerobes.

Detoxifiers

Detoxifiers are required for the cultivation of some fastidious microorganisms. In the natural environment, metabolic by-products released by some organisms are enzymatically neutralized or utilized by other organisms for nutritional or other biochemical needs before the compounds accumulate to toxic levels. In vitro, for a pure culture lacking the appropriate enzymatic mechanisms to neutralize its own metabolic wastes, these metabolites can build to inhibitory concentrations before significant culture growth has occurred. The inability to break down hydrogen peroxide by organisms lacking catalase, and strain sensitivity to fatty acid accumulation are two common problems associated with metabolite accumulation in closed culture conditions. To cultivate these types of microorganisms, some media require the addition of detoxifiers, of which most are absorbents. Frequently utilized detoxifiers include blood/serum, bovine serum albumin (BSA, fraction V), catalase, and charcoal. More recently, liposomes have been utilized to slowly release lipid growth factors to deficient organisms, thus eliminating the toxic effects that a full "dose" of a medium lipid supplement would have for these organisms (59). Similarly, cylodextrins have been shown to effectively chelate and then slowly release potentially toxic, yet essential, nutrients for some clinical bacteria under semidefined growth conditions (60,61).

MEDIA DESIGN AND COMPOSITION

Optimal growth and performance of a microbial culture is most influenced by the design and composition of its growth medium. There is no one "best" medium for a particular application; however, there exist many examples of poorly designed and/or poorly manipulated media, or well-designed media being used for an inappropriate purpose, in which a microorganism manages to survive in spite of the medium and not because of it. Effective media design comes from an understanding of an organism's biochemistry and physiology, as well as the nutritional ecology of the environment from which the organism was isolated. Although isolation media are selective and frequently nutritionally suboptimal to limit the growth of unwanted organisms, general growth or maintenance media should provide conditions to sustain a culture at optimal morphology and physiology through repeated subcultures. Under microscopic examination, bacteria grown under favorable conditions do not have a misshapen or shriveled

appearance; cell inclusions are generally minimal or absent; and cell lysis and/or spheroplast development is minimal or absent. At logarithmic phase of growth, motility is detectable for motile strains. Depending upon its application, a medium may be further defined in terms of chemical composition or optimized to increase biomass or cell product yield. An organism exhibiting optimal growth in a nutritionally balanced maintenance medium may not give high yields of a much-wanted metabolic by-product. Thus, medium optimization is a process directed toward a specific application. With so many nutritional and physical variables impacting upon microbial physiology, attempts at media optimization can become unnecessarily expensive, time-consuming, and largely unproductive when blindly tackled one variable at a time. Statistical methods using modified factorial approaches have been developed to aid in systematic media optimization for large-scale development (62), but for general laboratory purposes, knowledge and understanding of an organism's metabolic pathways and physical growth parameters can indicate specific areas in which quick design improvements to an existing formulation can effect significant results.

Media formulations may be chemically defined, in which discrete compound identity and concentration of all components are known, or chemically undefined, in which ingredients include one or more chemically complex substances such as protein hydrolysates and extracts. The choice of defined or undefined medium is dependent upon its application. Chemically defined media are useful in biochemical or metabolic studies of organisms. These types of formulations are also sometimes used in large-scale bacterial or yeast fermentations to produce products which further require stringent purifications such as those from recombinant DNA technology. General laboratory growth media for heterotrophic microorganisms as well as industrial media for large-scale production of metabolites (e.g., antibiotics, alcohols and other solvents) are often chemically complex. Scale-up of any medium formulation must include considerations of availability, cost, performance and lot-to-lot reproducibility of components as balanced against the value of the product. Chemically defined media can be expensive, particularly if the ingredients include a lengthy list of growth factors.

Microorganisms can transport only small molecules across their membranes. Large molecules (e.g., DNA, starch, proteins) can be nutritionally utilized by a microorganism only if it can synthesize and secrete the appropriate extracellular enzymes to digest large molecules into subunits small enough for assimilation into the cell. Because this type of enzymatic activity is absent from many organisms, in vitro microbial cultivation relies upon predigested macromolecules in the form of hydrolysates, peptones, and extracts and simple carbon compounds as nutritional substrates.

Protein Hydrolysates (Peptones)

Protein hydrolysates supply a mixed source of nitrogen and growth factors in the form of amino acids, nucleic acid fractions, peptides, and salts to a complex growth medium. For organisms possessing the metabolic capacity, protein hydrolysates can also serve as complex carbon and energy sources. Industrial large-scale fermentations using bacteria and fungi effectively use by-products from other industrial processes as proteinaceous material for media, including cottonseed, yeast, and soy. Although these substrates are chemically undefined, published analyses of their nutritional content greatly help in determining the appropriateness of a product for inclusion in a medium (63). Manufacturers of refined media and media components offer water-soluble products with more controlled nutritional composition. Table 3 lists and briefly describes the extracts and hydrolysates frequently encountered in microbiological laboratory media. Meat, milk, and soy commonly serve as starting material for the manufacture of hydrolysates. Digestion of these proteins can be by acid, alkali, or enzymatic hydrolysis. The source protein and method and degree of hydrolysis determine the nutritional characteristics of a hydrolysate. Prolonged hydrolysis releases free amino acids; more gentle hydrolytic processes yield mixtures of amino acids and peptides. The strong conditions of acid or alkali hydrolysis destroy much intrinsic vitamin content of a raw protein, as well as some amino acids such as tryptophan, and reduce the levels of serine and threonine. Acid-hydrolyzed protein hydrolysates are high in salt content formed during the neutralization step; however, some manufacturers feature acid-hydrolyzed peptones with additional processing to reduce the amount of salt [e.g., Casamino Acids (Difco 0230)]. Enzymatic digests contain free amino acids as well as small peptides while maintaining the vitamin content of the original source material. Enzymatic casein digests, reflecting the amino acid composition of the starting material, are high in tryptophan and low in cystine. Peptones from plant proteins [i.e., Soytone (Difco); Phytone (BBL)] contain intrinsic carbohydrate and, while conducive to rapid heterotrophic growth, can cause quick culture decline due to substantial metabolic acid production. Because of the carbohydrate level, plant peptones are also unsuitable in basal media for fermentation or sole carbon source utilization studies. For routine growth, peptones are normally added to media at concentrations of 0.5–1.0%. Growth of microorganisms with diverse and multiple nitrogenous auxotrophies (e.g., the lactobacilli) is enhanced by elevated peptone concentrations as well as nutritional supplementation with peptones of mixed sources and degrees of hydrolysis.

Carbon and Energy Sources

Microorganisms other than autotrophs require organic compounds as a source of carbon and energy. These can include simple sugars, complex carbohydrates, alcohols, amino and other organic acids, and short-chain lipids. Some organisms (e.g., *Aspergillus, Pseudomonas*) possess the complex metabolic machinery that permits numerous classes of organic compounds for carbon/energy substrates. Other taxa exploit specific classes of molecules metabolically ignored by or toxic to general heterotrophs. Methylotrophs (*Methylobacterium* spp., *Methylomonas* spp., *Methylophaga* spp., and others) can extract energy from C_1 compounds such as methanol and formaldehyde, whereas

Table 3. Hydrolysates and Extracts

Hydrolysis method	Source	Product/manufacturer[a]	Characteristics
Acid	Casein	Acidicase (BBL) Casamino acids (Difco) Hy-Case (Sheffield)	Free amino acids; deficient in tryptophan and cystine; high intrinsic salt concentration unless designated salt-free
Enzymatic	Casein	Casitone (Difco) NZ-Amine (Sheffield) Trypticase (BBL)	Free amino acids and small peptides; high levels of tryptophan; low in carbohydrates
Enzymatic	Meat	Myosate (BBL) Thiotone (BBL) Primatone (Sheffield) Peptone (Difco) Proteose peptone (Difco)	Mixtures of amino acids and peptides; those designated proteose are hydrolyzed for a high peptide content; Thiotone high in sulfur
Enzymatic	Plant	Phytone (BBL) Soytone (Difco) Hy-Soy (Sheffield)	High in carbohydrates and vitamins
Mixed	Yeast/casein	Biosate (BBL)	Combines amino acids as well as vitamins lost during protein hydrolysis of peptones
	Casein/meat	Polypeptone (BBL)	
Autolysis	Yeast	Yeast extract (BBL; Difco; Sheffield)	High in amino acids, peptides, water-soluble vitamins, and carbohydrates

[a]Items listed are representative of of a manufacturer's product line. Consult manufacturers' technical manuals for more information, Refs. 39, 40, and 64.

the metabolic diversity of the bacterial genus *Pseudomonas* has allowed selection of strains that can utilize the long-chained hydrocarbons in crude oil or attack the degradation-resistant chemical rings of cresols and phenols as sole carbon/energy sources. Assorted fungal genera (*Cladosporium*, *Candida*, and others) have been found as actively growing contaminants in aircraft and diesel fuels (65). The type and concentration of a carbon substrate present in a medium will affect overall growth rates, morphology, and metabolites of a culture. Sole carbon utilization profiles are used in identification matrices for prokaryotes and yeasts.

Carbohydrates and related compounds are preferential carbon sources for many genera of microbes. Hexoses are most diversely utilized, followed by the disaccharides, trisaccharides, smaller polysaccharides (starch and glycogen), and pentoses. Glycerol, mannitol, and sorbitol are commonly utilized alcohols. Under laboratory conditions with defined media and mixed sugars at normal substrate levels (e.g., 2–10 g/L), microorganisms often exhibit diauxic growth, in which a culture first utilizes the carbon compound that supports the greatest rate of growth, with concurrent catabolic repression of other substrates (66–68). Enzyme systems then shift accordingly as the organism switches to and consumes each less-preferential carbon compound. This results in a biphasic growth curve. However, under carbon-limited (e.g., microgram to milligram per liter concentrations) chemostat conditions that mimic the low-nutrient conditions of the natural environment, a number of organisms use the components of carbon mixtures simultaneously (69).

Proteolytic organisms have the capacity to utilize L-amino acids and related compounds as sole carbon/energy sources. This metabolic characteristic is more common among bacteria than fungi and varies widely between species; identification keys for the genus *Clostridium* use saccharolytic versus proteolytic metabolisms for species differentiation. As a group, the helical/vibroid Gram-negative bacteria (e.g., *Aquaspirillum*, *Azospirillum*, *Camplylobacter*, *Oceanospirillum*) do not ferment or oxidize carbohydrates but satisfy carbon/energy requirements with amino acid catabolism. *Legionella* spp. also use amino acids as carbon/energy sources. Filamentous fungi vary in their ability to utilize amino acids as effective carbon sources; none, however are limited to nitrogenous sources of carbon. Glutamic acid, alanine, arginine, and proline are frequently utilized by many prokaryotes and yeasts. The aromatic rings of the amino acids tryptophan, phenylalanine, and tyrosine, as well as the purine and pyrimidine rings of the nitrogenous bases, are not readily attacked by many organisms. The ability to do so is used for taxonomic speciation. Degradation of any of these ring compounds, however, is not presumptive of an organism's ability to further use the breakdown products as a sole source of carbon/energy; in many cases, the compound is not so metabolized. Organisms that catabolize amino acids frequently utilize organic acids in the same fashion (e.g., *Oceanospirillum*). In addition, many carbohydrate-utilizing organisms are also capable of utilizing organic acids. For example, citrate and propionate utilizations are classical tests in the identification of the carbohydrate-metabolizing genus *Bacillus*. When used as sole carbon and energy sources, amino and organic acids may not be soluble at required substrate levels (2–5 g/L); however, neutralization with KOH or NaOH will form soluble salts of these compounds.

Some organisms have the capacity to utilize fatty acids and other nonpolar molecules as carbon and energy sources. In some instances, the requirement is absolute. The bacterial genus *Leptospira* requires long-chain fatty acids (70), which are supplied in complex growth media by rabbit serum. The anaerobic sulfate-reducing *Desulfovibrio* sp. (DSM 2056) oxidizes the fatty acids butyrate through stearate (71).

Simple sugars and other carbon compounds can undergo chemical changes when autoclaved with other media

components. Amino acids and organic acids, though heat stable at growth factor levels, may degrade at substrate concentrations. The characteristic darkening of autoclaved media containing glucose and peptones, called the Maillard reaction, is caused by an interaction of amino acids with the glycosidic hydroxyl group of the sugar. Darkening of autoclaved media can also be caused by the interaction of mono- and disaccharides, particularly glucose, with phosphates; the reaction is more intense at alkaline pH. Carlsson et al. (72) demonstrated that the glucose–phosphate reaction produces hydrogen peroxide at levels toxic to catalase-negative organisms. These types of adverse chemical reactions between nutrient components compromise the performance of a medium and are to be avoided either by autoclaving or filter sterilizing the reactive compounds separately from the balance of the medium. Not all commonly used carbon substrates can withstand autoclave sterilization. In particular, arabinose, fructose, lactose, pyruvate, ribose, and xylose should be filter sterilized. Light-weight alcohols and similar solvents are volatile at autoclave temperatures. Autoclaving of heat-stable alcohols can be done in tightly stoppered containers; alternatively, these compounds can be sterilized with appropriate solvent-resistant membrane filters. Long-chain hydrocarbons (e.g., oils and waxes) are hydrophobic and are not sterilizable by autoclaving because the sterilant (steam) cannot adequately penetrate the material. A good chemical reference text, such as the *Merck Index* (73), is invaluable for determining the heat stability, solubility, and other important characteristics of many chemical components used in media formulations.

Extracts

Spray-dried powders derived from infusions of meat, yeast, or other chemically complex proteinaceous materials provide a nutritionally useful but undefined source of water-soluble growth factors and sugars. Because they are not subject to the same harsh conditions as those used in the manufacture of peptones, meat or yeast extracts can supply those nutrients lost during the peptone hydrolysis (e.g., vitamins and certain amino acids). Extracts, in themselves, do not contain sufficient concentrations of essential nitrogen or carbon compounds to effectively function as the sole source of these nutrients in a medium. Meat extracts include appreciable amounts of glycolic and lactic acids, as well as creatine. Yeast extract is high in carbohydrates and, therefore, interferes with fermentation studies. The nutritional properties of the fresh yeast extract solution used in many media formulations for the cultivation of mycoplasmas is not replaceable by powdered yeast extract. Malt extract used in some media for fungi is composed primarily of carbohydrates (glucose, fructose, sucrose, maltose, dextrins) and small amounts of nitrogenous matter. Powdered extracts are generally incorporated in media at a concentration of 0.5–1.0%.

Aqueous extracts and infusions of various materials have historically been used to supply undefined nutritional factors in laboratory media. Concentrated liquid extracts generally are used at 10–20% v/v concentration as a medium supplement, whereas infusions will constitute the entire liquid base of a medium to which additional nutrients are added. As already noted, a filtered, aqueous solution prepared from autolyzed baker's yeast (150 g yeast/L) is a necessary ingredient in media for mycoplasmas and other mollicutes. The fresh yeast extract solution is then filter sterilized and incorporated into the mycoplasma media at 10% v/v concentration. Lactic acid bacteria from milk or milk products have been cultivated with infusions prepared from whole milk, whereas tomato juice or other fruit juice extracts have been used at 10–20% v/v in media for lactic acid bacteria isolated from plants. Potato infusions (200–300 g potatoes/L) serve as a nutritional base in many media for the cultivation of bacterial and fungal plant pathogens. Soil extracts prepared from fertile, chemically uncontaminated soils have been used to induce sporulation in many bacteria. Rumen fluid, containing partially digested nutrients from the first compartment of a cow's stomach, is a supplement in media for the cultivation of rumen microorganisms. Rumen fluid contains an undefined mixture of fatty acids, carbohydrates, peptides, vitamins, and metabolites. As rumen fluid is most commonly added to and autoclaved with basal medium components, any heat-labile nutrients are destroyed. Rumen fluid is obtained from fistulated dairy cows and can often be procured gratis from universities with departments of animal or dairy nutrition. Rumen fluid may or may not contain significant amounts of solid material, depending upon the length of time the material has been in the rumen. Centrifugation will effectively remove the bulk of debris; however, a series of filtrations down through 0.2 μm is necessary to remove dead cells of indigenous microflora that can confuse microscopic examinations of the organism being cultured. A defined mixture of fatty acids (Table 4) can effectively replace the need for rumen fluid for many bacteria; however, as with most chemically complex, undefined supplements, cell yield is frequently better when it is included in the medium.

Buffers

pH buffers are molecules that, in solution, resist fluctuations in hydrogen ion concentration. Weak acids, bases, and their corresponding salts in partial dissociation function as pH buffers. Buffering capacity is greatest when the

Table 4. Volatile Fatty Mix for Rumen Bacteria and Fungi

Acetic acid	17.0 mL
Propionic acid	6.0 mL
N-Butyric acid	4.0 mL
N-Valeric acid	1.0 mL
Isovaleric acid	1.0 mL
Isobutyric acid	1.0 mL
DL-α-Methylbutyric acid	1.0 mL

Pipette the given volumes of fatty acids into a container that has a tight-fitting closure and mix well. The objectionable odor of the free fatty acids can be reduced by neutralizing the pH of this solution with the addition of NaOH pellets. Use 3.1 mL of the fatty acid mix per liter of medium.

Source: From Ref. 44, p. 162.

compound is at 50% dissociation. The pH at which this occurs is equal to the pK_a value of the compound, and greatest buffering capacity falls between ± 1 pH unit of the pK_a. Thus, no one buffer can be used across the entire pH range of 1 to 14 (74). Some acids are zwitterions (compounds that can chemically behave as acids or bases) and have more than one pK_a. In an extreme example, glycine when titrated against HCl has pK_a 2.3; titrated against NaOH, pK_a 9.6. Other zwitterions include citric acid (pK_{a1} 3.06, pK_{a2} 4.74, pK_{a3} 5.40), succinic acid (pK_{a1} 4.19, pK_{a2} 5.57), and the Good buffers (see later). The perfect media buffer would be (*1*) completely effective at poising a desired pH throughout the metabolic flux of a culture's growth cycle, as well as any other chemical or environmental changes that may affect pH (e.g., metal ion interaction, temperature), (*2*) resistant to microbial enzymatic activity, (*3*) chemically inert with respect to other medium components, and (*4*) inexpensive. The perfect buffer does not exist.

Lacking perfect buffers, in vitro microbial cultivation relies, for better or worse, upon a standard array of buffering systems. Nevertheless, the choice of buffer must not be made haphazardly. No discussion of buffers could be complete without N. E. Good's comment: "It is impossible even to guess how many exploratory experiments have failed, how many reaction rates have been depressed, and how many processes have been distorted because of imperfections of the buffers employed" (75). The capacity to buffer well at a particular pH is only one of many criteria in the determination of an appropriate buffer for a particular application. Chemical interaction with other media components or culture metabolites will compromise both the buffering capacity as well as the nutritional balance of a medium. The effectiveness of a microbially metabolized buffer diminishes with culture growth. The pH of some buffers can vary, sometimes considerably, with concentration or temperature. Synthetic buffers, while very effective for bench-top laboratory needs, may become prohibitively expensive upon scale-up.

Natural Buffering Agents. Natural buffering agents are those compounds most frequently encountered in microbiological media; they are also the buffers subject to the greatest drawbacks in their use. Carboxylic acids (e.g., acetate, citrate, succinate) are effective buffers for the lower ranges (<pH 6) of biological activity. These compounds are metabolically catabolized for carbon and energy by many microorganisms. Also, at the concentrations needed for buffering, carboxylic acids can become cation chelators. The mixtures of amino acids in protein hydrolysates and extracts have significant buffering capacity. Thus, peptone-based complex media frequently do not require additional buffering agents when used at or about the initial pH of the medium. Many peptones are adjusted during manufacture to pH 6.8–7.0. Peptone solutions are stable to sterilization at 121 °C; however, they adversely interact at elevated temperatures with other medium components such as glucose, phosphates, and polyvalent cations. In addition, because peptones are nutrients, buffering capacity diminishes or shifts as the amino acids are microbially consumed.

Sodium bicarbonate–carbon dioxide buffers can maintain pH in the range 6.0–8.0. However, when used in conjunction with intrinsically buffered media, bicarbonate buffers have a working range of pH 6.8–7.2. Despite the necessity for closed systems to retain the gaseous CO_2 phase, bicarbonate buffers are widely used in the cultivation of anaerobic bacteria and eukaryotic animal cell lines. Bicarbonate buffers are nutritionally consumed. Also, carbon dioxide has minimal solubility in aqueous solutions, which somewhat limits its buffering capacity. Solid calcium carbonate (powdered) is used in various media for strongly acidifying organisms such as *Acetobacter, Clostridium*, and *Lactobacillus*. Ethanol-tolerant, acid-producing acetobactors can be isolated and differentiated from mixed-culture fermentations using a carbonate-ethanol medium (yeast extract, 3%; calcium carbonate, 2%; agar, 2%; filter-sterilized ethanol, 2%). Strongly acidifying acetobacter isolates able to grow in the presence of ethanol will also dissolve the carbonate and form a zone of clearing around the colony.

Although widely used in media formulations at pH 6–8, phosphate buffers suffer from a great number of drawbacks. Unless a medium is carefully designed and prepared with respect to metal speciation and concentration, phosphates will adversely bind to and precipitate polyvalent cations and proteinaceous material at neutral to alkaline pH. This chemistry creates two problems: (*1*) buffering capacity is diminished as cations complex with the phosphate anion, and (*2*) cations bound as precipitates are unavailable as nutrients. These unwanted chemical interactions are intensified by heat. The problem can be reduced by autoclaving the phosphate buffer separately from the balance of the medium and then combining both solutions when cooled to room temperature after autoclaving. The addition of a chelator such as EDTA may retard trace metal precipitation; however, overchelation will also restrict the availability of trace metals from the nutrient pool. Above pH 7.2, with poorly designed media formulations, precipitation can become spontaneous even at room temperature; the reaction may be immediate or may slowly develop over time and is often misinterpreted as bacterial contamination. Balanced phosphate-buffered salines (e.g., Dulbecco's, Hank's) containing calcium and magnesium salts are filter sterilized to avoid precipitation of the salts. When autoclaved together, phosphate and glucose will also adversely react at neutral pH and above; trace metals will intensify the reaction. Because soluble phosphates are nutrients, the effectiveness of these buffers can diminish with culture metabolism. Finally, phosphate buffers exhibit a concentration effect characterized by a rise of 0.2–0.3 pH unit with each 10-fold dilution.

Synthetic Buffers. Synthetic buffers were developed to alleviate the many problems encountered with the earlier generations of natural buffers. Tris [Tris(hydroymethyl)-aminomethane; pK_a 8.3 at 20 °C] was the first organic compound widely utilized for its improved buffer characteristics. Tris and Tris HCl can be combined for buffering between pH 7.0 and 9.0, with strongest activity between 7.2 and 8.0. Tris can also be paired with other acids such as acetate, borate, or phosphate for specific buffering ap-

plications. Tris does not precipitate calcium ions and helps to maintain the solubility of magnesium salts. Tris is, however, a chemically reactive amine and can penetrate cell membranes; some microorganisms (e.g., *Sporocytophaga myxococcoides* ATCC 10010) have shown growth inhibition by the compound. Tris exhibits marked concentration and temperature effects that can limit its effectiveness for certain biological purposes. Tris buffers fall approximately 0.1 pH unit per 10-fold dilution. At 0.05 M, a Tris buffer at 25 °C will be pH 7.20; at 5 °C, pH 7.76; at 37 °C, pH 6.91. Therefore, when used in culture media, Tris buffers should be constructed with the incubation temperature of the culture in mind and not upon the pH of the buffered medium at room temperature.

During the 1960s Good et al. (75) developed a number of zwitterionic compounds for use in biological systems to include as many as possible of the following desired buffer characteristics: (*1*) freely soluble in aqueous solutions to permit preparations of concentrated stock solutions, (*2*) buffering optima within the range of most biological systems, (*3*) biochemically nonreactive and chemically stable, (*4*) inert to microbial or other enzymatic attack, (*5*) minimal temperature and ionic effects upon buffer pH, and to further enhance their versatility to include postculture analytical procedures, (*6*) insoluble in organic solvents and (*7*) transparent to the ultraviolet wavelengths used in many biological spectrophotometric assays. Collectively these compounds have come to be known as the Good buffers, of which, HEPES (pK_a 7.5 at 25 °C) is most commonly recognized due to its prevalence in media formulations for the cultivation of animal cell lines. Other Good buffers useful for microbial media formulations include ACES (pK_a 6.8 at 25 °C), which is a component in the recommended cultivation medium for *Legionella*; buffered charcoal yeast extract (BCYE) (2p.518); MES (pK_a 6.1 at 25 °C), PIPES (Pk_a 6.8 at 25 °C), and TES (pK_a 7.5 at 25 °C).

HEPES has been implicated in the phototoxicity of RPMI medium for the cultivation of eukaryotic cells; however the effect was eliminated when sodium pyruvate was added to the culture medium (76). Other Good buffers have also shown various types of inhibition in certain cell lines (77). As with any buffering system or other media component, the Good buffers should be evaluated for applicability against the microorganism under study.

Biological buffers for cell growth purposes are commonly used at 0.01–0.05 M; chemical effectiveness of the buffer, initial pH of the medium without the buffer, production of acid or basic metabolites during culture growth, and enzymatic or other reagent optima are considerations in determining appropriate buffer ion concentration. Buffer tables can be found in numerous publications. Lacking a table, buffer solutions can be prepared with either of the two following methods and a calibrated pH meter:

1. Prepare a 2× solution of the buffer compound. Using HCl or NaOH, titrate the solution to the desired pH. Bring the solution to 1× volume with deionized or distilled water.
2. Prepare equimolar solutions of the acidic member and the basic member of the buffer pair. The molarity of these solutions is that of the final concentration needed for the working buffer. Choosing the solution of the buffer pair with a pH closest to that needed for the working buffer, titrate the solution to the desired pH with the equimolar solution prepared with the remaining component of the buffer pair.

Gelling Agents

Many microbial applications, such as strain isolation and purification, necessitate the use of solid media. Growth of aerobic organisms, in addition to specific morphologies, are often enhanced on solid media providing unrestricted gas exchange. The different gelling agents available to microbiologists each have attributes and drawbacks that one must consider before choosing a particular gelling agent to include in a medium formulation. Although agar is the most frequently encountered gelling agent in microbial culture media, it must be properly used in order to maintain the chemical and nutritional integrity of a formulation. Many chemolithotrophic organisms are inhibited by organics and will not grow on media solidified with agar. Conversely, a number of marine bacteria are agarolytic and can quickly dissolve or soften this support matrix. Other gelling agents, including carrageenan and Gelrite, are alternatives to agar, but each has its own chemical peculiarities that must be understood before they can be effectively used.

Agar. Agar is a polysaccharide complex extracted from a number of species of red algae (*Gelidium*, *Gracilaria*, and others) found in the Pacific and Indian Oceans and the Japan Sea. The agar complex can be separated into (*1*) agarose, a neutral gelling fraction, and (*2*) agaropectin, a sulfated, nongelling fraction. Depending upon the purity and gel strength of the agar, and also upon the chemical composition of the medium in which the agar is used, a molten 1.5% agar solution will set at temperatures between 32 and 39 °C. However, agar media with high concentrations of salt (e.g., those for the extreme halophiles, which contain >18% NaCl and 0.5% each of $MgSO_4$ and KCl) gel quickly at temperatures above 55 °C. The gelling capacity of agar is thermally reversible, however, repeated remelting of agar-containing media is not recommended because the chemical stability of many nutrients cannot withstand repeated exposure to elevated temperatures. Agar is subject to acid hydrolysis, which destroys the gelling capacity of the polysaccharide; the phenomenon is intensified by heat. Agar-containing media autoclaved at less than pH 5.0 will not gel when cooled. If a low-pH agar is required, it is advisable to prepare and sterilize the medium in two separate solutions: For 1 L of low-pH agar medium, (*1*) heat and dissolve agar, with stirring, in 500 mL water; (*2*) dissolve remaining medium components in 500 mL water; (*3*) sterilize each solution separately at 121 °C; (*4*) cool each solution to approximately 50 °C; (*5*) aseptically combine both solutions, mix well, and dispense into containers as required.

Agar products vary with respect to nitrogenous and inorganic salt contaminants. A number of manufacturers feature agars purified though repeated water and solvent washes. Some agar products contain significant amounts

of metals that can bind to and precipitate with phosphates in the medium, resulting in diminished growth yield with the solid medium as compared with that of the corresponding liquid medium. Similarly, autoclaving any agar in the same solution with the carefully balanced nutrient salts of a chemically defined medium, particularly at neutral to alkaline pH, will frequently give rise to a pronounced darkening or haze that can compromise the effectiveness of the medium. Under chemically defined conditions, component integrity is best preserved by autoclaving a purified agar separately from the autoclaved or filter-sterilized chemical portion of the medium, as already outlined for preparation of a low-pH agar medium. The use of electrophoretic grades of agarose would be more suitable than purified agars for gels in which a minimal level of trace metal contamination is required.

As with all gels, agar exhibits syneresis in that it will squeeze out solute as it contracts. The small puddle of liquid at the bottom of a freshly prepared agar slant is an example of this phenomenon. The amount of syneresis is dependent upon the concentration of the agar in the gel. Agar media can also lose water through desiccation during storage. Once water has been eliminated from the agar gel, it will not reenter the matrix unless the gel is remelted; however, melting of solid media for the purpose of rehydration not recommended because performance of the medium will be markedly reduced.

Agar is normally used at concentration from 1.0 to 2.0% for solid media; at 0.075 to 0.2% to create a viscosity that retards oxygen diffusion in media such as fluid thioglycollate medium U.S.P. and the classical oxidation–fermentation (O-F) medium of Hugh and Leifson (78); and at 0.5 to 0.75% for soft, top-layer agars in media for bacteriophage propagation.

Agarose. Agarose, the purified gelling fraction of agar, is used in some formulations for organisms that are inhibited by agar. Purified agarose products, particularly those grades used for electrophoretic work, are low in inorganic and organic contaminant and, therefore, react less with the phosphates present in a medium. Gel clarity is greater than for agar. Low gelling temperature agaroses melt above 65 °C and form gels at less than 30 °C. Agarose will form solid gels at 0.75–1.0%.

Gellan Gum. Gelrite, a gellan gum, is a heteropolysaccharide composed of glucuronic acid, rhamnose, and glucose, produced by bacterial fermentation, and commercialized as a gelling agent by Kelco (Merck & Co., Inc., Kelco Division, San Diego, Calif.). Sigma Chemical Co. (St. Louis, Mo.) distributes the material under the trade name Phytagel. Under either name, this gellan gum is somewhat difficult to work with for routine media solidification purposes, but nevertheless, its unique characteristics make the material the most practical solution to some unusual microbial cultivation requirements. Gelrite/Phytagel is a high-melting-temperature (~70 °C) gel, which makes it useful for the cultivation of thermophilic bacteria and fungi at 45–50 °C, temperatures at which agar shows considerable syneresis and softening. The gel is generally thermally reversible, although under some conditions, such as the elevated soluble salt concentrations of marine media, gelling can become permanent. Gelrite/Phytagel is subject to acid hydrolysis when autoclaved at low pH. The gellan is resistant to microbial attack by most organisms and so proves useful in the isolation of organisms such as the marine cytophagas, a group in which many strains characteristically possess the ability to degrade other biopolymer gels including agar, algin, carrageenan, and gelatin. Many chemolithotrophic organisms (e.g., *Nitrobacter*, spp. and *Thiobacillus ferroxidans*), although inhibited by agar and other organic gelling agents, can be grown successfully on a solid medium using the gellan. Full gelling capacity of this polysaccharide is cation dependent, and media formulations may need amending to include at least 0.1% $MgSO_4 \cdot 7H_2O$, or other magnesium salt to permit sufficient gelling. Under chemically defined media conditions, further chemical adjustments to other components may be necessary to retain chemical balance because of a modification in cation level. Recommended concentrations for Gelrite/Phytagel are in the 0.1–0.2% range, however experimentation will probably be needed to select the appropriate concentration for one's own needs. Table 5 provides a media formulation that has been successfully used as a solid medium for the cultivation of laboratory strains of *T. ferroxidans* (ATCC 21834 and others); the gel is rigid enough for the isolation and picking of colonies, and growth

Table 5. Solid Medium for *Thiobacillus ferroxidans*

Solution A	
$(NH_4)_2SO_4$	0.08 g
$MgSO_4 \cdot 7H_2O$	0.20 g
K_2HPO_4	0.04 g
Trace elements (see Table 1, mix A)	0.5 mL
Distilled water	40.0 mL
Adjust Solution A to pH 2.3 with concentrated H_2SO_4. Filter sterilize.	
Solution B	
Phytagel (Sigma P-8169)	0.5 g
Distilled water	40.0 mL
With constant stirring, heat Phytagel to boiling to dissolve. Sterilize at 121 °C for 15 min. Cool to no less than 80 °C.	
Solution C	
$FeSO_4 \cdot 7H_2O$	2.0 g
Distilled water	20.0 mL
Quickly dissolve ferrous sulfate with constant stirring. Immediately filter sterilize.	
Complete medium	
Warm solution A to about 50 °C. Add solution C to solution A and immediately combine with solution B. Mix well and pour plates. As this medium must be poured at a rather high temperature to avoid premature gelling of the Phytagel, it will be necessary to dry the plates before use by leaving the lids ajar in a sterile environment or by incubating them at 37 °C overnight to eliminate excess condensation.	

is rapid (3–5 days) at 20–30 °C. Preparation methods for this particular formulation illustrate many of the topics discussed in this article with respect to treatment of chemically incompatible salts, acid hydrolysis, and heat instability of media components.

Alginic Acid and κ-Carrageenan. Alginic acid (79) and κ-carrageenan (80,81) have been used microbiologically for specialized gelling needs. Gelling efficiency of alginate is Ca^{2+} dependent, whereas κ-carrageenan is K^+ or Na^+ dependent. Since all of these substances are easily degraded by assorted bacteria and fungi, their use as gelling agents is restricted. Microbial degradation of these substances is used for taxonomic purposes.

Silica Gel. A final solid substrate for the laboratory cultivation of obligate chemolithotrophic organisms is silica gel, first used by Weintraub and Hanks (82) in 1936 for the isolation of ammonia-oxidizing bacteria. Many authors have since attempted improvements on the tedious method (83–86). Preparation of any quantity of plates is laborious. Briefly, sodium silicate is reacted with strong HCl to produce silicic acid, NaCl and almost immediate gelling. Nutrient salts may be included in the formulation, or the surface of the silica gel may be later flooded with nutrients, with some absorption. Because the amount of NaCl is high (~8–10%), the gel may first need clearing of the salt, with repeated washings with water prior to flooding with a nutrient solution. Silica gels are translucent and rigid with a high degree of syneresis. The gels are autoclavable, with a tendency for cracking, and are not reversible. Table 6 provides simplified instructions for silica gel preparation adapted from Ref. 82.

Table 6. Simplified Silica Gel Plates

Stock solutions

Solution 1	
Concentrated HCl (~37%)	14.5 mL
Distilled water	to 100.0 mL
Solution 2	
$Na_2SiO_3 \cdot 9H_2O$	20.0 g
Distilled water	100.0 mL

Use slight heat and constant stirring to dissolve sodium silicate. Filter out any particulates or colloidal material with Whatman #1 paper.

Preparation of silica gel plate

1. Volumes given are for one 20 × 100 mm petri dish. Gelling will occur within 10–15 s of mixing solutions. Be prepared to work quickly.
2. Add 14.5 mL solution 1 to a 100-mL beaker and stir continuously. (A magnetic stirrer will work best.)
3. Quickly add 19.0 mL solution 2 into the beaker and mix well.
4. As soon as effervescence stops, quickly pour contents of beaker into a 20 × 100 mm petri dish. Use a glass dish if subsequent autoclaving is required.
5. Initial gelling will occur almost immediately. Gel strength will increase slightly over a half-hour period, at which time the gel may be washed to remove excess NaCl and then flooded with nutrient solution.

MEDIA STERILIZATION

With few exceptions, media and buffers used for microbial cultivation must be sterilized as soon as possible after preparation to limit proliferation of environmental contaminants that will alter the nutritional characteristics of the medium either by consumption of nutrients or by production of metabolites. Even nonnutritive buffers or trace metal stock solutions can give rise to unwanted fungal growth if stored unsterilized for any length of time at room or refrigerator temperatures. Sterile media and buffers are necessary for culture propagation; the presence of microbial contaminants, even at a low level, can invalidate any study or production process. The physical stress of sterilization, however, can compromise the nutritional and physiological characteristics of a medium or buffer. Consequently, one must choose a sterilization method that has the least negative impact upon the material being sterilized. Although steam sterilization had historically been the only form of sterilization accessible by many laboratories, the widespread availability and diversity of reasonably priced and reliable disposable filtration units offer more appropriate choices for media sterilization, even for small laboratories.

Steam Sterilization (Autoclaving)

Steam remains the most widely used sterilization method for rugged, heat-stable media and has the advantage of often being the terminal step in media preparation. With no additional manipulation of an uninoculated medium poststerilization, possibility of inadvertent introduction of contamination is reduced. The term *autoclaving* is often used synonymously for the definitional procedure: "sterilize at 121 °C for 15 minutes." This phrase *must* be applied in context to the volume of the medium being sterilized as well as to the efficiency of the autoclave being used. The precise meaning of the phrase infers that the contents of each container within an autoclave cycle must achieve an uninterrupted exposure to 121 °C for 15 min; it does not mean that the autoclave itself was set for that temperature and time. From a practical laboratory standpoint, this means that small volumes (e.g., test tubes) will require the minimal amount of autoclaving time, whereas large volumes (e.g., one or two flasks) will require additional autoclaving time. Fully loaded autoclaves may require longer run times. Under laboratory autoclave conditions, a 30–35 min sterilization cycle for 0.5 L liquid medium in a 1-L flask is a practical guideline; agar media that have been allowed to solidify before sterilization may require longer autoclave times. Large-scale fermentation volumes can require hours to sterilize; media processed in poorly maintained autoclaves might never be adequately sterilized. Where mechanical agitation of a medium is not possible during the autoclave cycle, maximum container volumes of media should not exceed the ratio of >1 L media in a 2-L vessel because the prolonged autoclave times required for heat conduction to raise the innermost portions of large volumes of media to 121 °C will subject the outer portions of the media to extreme overheating.

Autoclaves and their cycles should be validated for media sterilization. Ideally, this would include replicate au-

toclave run data from multiple thermocouple probes spaced strategically within the autoclave chamber and load configurations. While this technological expense is beyond the budget of many small research laboratories, quantified preparations of *Bacillus stearothermophilus* sterilization indicators, such as the Verify Biological Indicators (Steris Corporation, Mentor, Ohio), can indicate general "121 °C, 15 min" parameters. Chemical indicator strips or labels are not reliable indicators of sterilization and should be used only as visual aids to indicate that a particular item has been run through an autoclave cycle. Under the most elemental quality control conditions, media samples should be held at least 2 weeks at 26 °C and 37 °C, and also at conditions and temperatures conducive to the growth of the types of environmental bioburden normally encountered during media preparation and sterilization, to ensure that latent contamination does not subsequently proliferate. Unusual media formulations (e.g., extremes in pH, chemolithotrophic conditions, unusual energy sources) that may not allow proliferation of common microorganisms may require inoculation of lot samples into more conventional heterotrophic media (e.g., tryptic soy broth) to encourage the growth of common environmental contaminants.

Steam at pressures below 15 psi (121 °C) are used for sterilization of many media components not stable at 121 °C. Skim milk (used as a cryoprotectant in lyophilization and as a substrate in phenotypic characterization) is best sterilized at 116 °C for 20 min; the lower pressure reduces carmelization of indigenous lactose. Powdered sulfur (S^0) used as an energy source for microorganisms can be treated with Tyndallization (100 °C for 30 min for 3 consecutive days) to avoid melting the element into a solid mass that physically limits its availability to organisms. Tyndallization is also used as a method of bioburden reduction (it is *not* a sterilization process) for other extremely heat-labile media. In theory, vegetative cells are killed by the first day's boiling; quickly germinating spores are killed the second day; by the third day, late-germinating spores are killed, leaving a relatively clean preparation.

Filter Sterilization

Heat-labile media components should be filter sterilized. Any chemically balanced liquid buffer or medium can also be filter sterilized to ensure that chemical integrity will not be compromised by the elevated heat and pressure of steam sterilization. Membrane filters, rather than depth filters, are preferred for sterilization purposes because their uniform pore size permits absolute retention of particles down to a specified pore diameter when the membranes are stored, sterilized, and used according to manufacturer's instruction. Depending upon the polymer composition, membrane filters are available in porosities from 10 μm down through nominal molecular weight limit used for ultrafiltration. For general microbiological purposes, 0.2-μm filtration is used for sterilization of media and buffers because this porosity effectively traps many vegetative bacteria and spores. However, in serum-based media, because mycoplasmas are not always held back at 0.2 μm, filtration through a stack of three 0.2-μm membranes rather than a single membrane will increase the probability of retention of these common serum contaminants. In addition, membranes are now available in 0.1-μm porosity that can retain smaller-sized microbial contamination, but flow rates are slower and rate of membrane clogging increases as porosity decreases. In any event, the filtration method selected for sterilization should be challenged against the smallest microbial contaminants known to be present in the working environment and production stream (87). As pore size decreases to submicron diameters, there is the possibility of holding back large molecular weight nutritional components and aggregates.

Water-soluble hydrophilic microbial media, stock solutions, and buffers are most commonly filter sterilized with membranes composed of cellulose acetate or nitrate esters. Fastidious cultures may require initial washing of the membranes with hot water to remove residual organics prior to media filtration; filters and membranes specified for tissue-culture applications are also recommended for sensitive organisms. Nonaqueous media components such as ethanolic concentrates of antibiotics or dimethyl sulfoxide (DMSO) must be filter sterilized with hydrophobic polymer membranes designed to withstand organic solvents. Nylon and Teflon membranes are suitable for many organic-solvent based biological applications. These types of membranes can require initial washing with a weak nonpolar solvent such as methanol to condition them for filtration. Some membranes, such as Nylon, are protein binding; if specific proteins are key media components, choose a membrane specifically identified as low protein binding.

Membrane filters have limited loading capacity and will quickly clog. Consequently, effective membrane filtration with any large volume, especially with particulate-laden preparations, requires sequential filtration from larger through smaller porosities to clarify the medium of debris, as much as possible, prior to the final filtration step. Low-speed centrifugation may also be used to first clarify crude media preparations. Glass fiber depth filters are efficient prefilters for many media applications because they have great loading capacity; however, they do not always eliminate the need for sequential membrane clarification steps prior to sterilization. Sterile filtration can be a slow process. It may be necessary, for critical applications, to perform the entire operation in a cold room to retard environmental microbial or other denaturing activity upon the raw material.

Positive-pressure filtration with an inert gas such as nitrogen is used in most large-scale filtration applications. Positive pressure reduces foaming of the filtrate and possible denaturation of any essential protein components. For critical and regulatory applications, the gas supply must also be sterile filtered before it reaches the medium reservoir. In many laboratories, filter sterilization with vacuum is the only available option. With vacuum, foaming of proteinaceous material will be best reduced with sequential prefiltration through larger membrane porosities as well as with minimal vacuum applied to the process. For most bacterial applications, serum foaming is not a deleterious nutritional problem. However, do note that me-

dia foaming can be a serious source of environmental contamination if the foam is not trapped and collected before passing into the laboratory vacuum line.

Disposable, presterilized filtration systems are offered by a number of manufacturers (e.g., Falcon, Corning, Gelman, Millipore, Nalge) in small- to large-volume capacities. Capsule filters are available for small to medium inline batch processing (20–60 L). Filter/storage systems in the 200-mL to 1-L sizes offer the ease of vacuum-operated membrane sterilization and storage with minimal preparation and clean up. Syringe filters are most used for volumes of less than 50 mL; however some types can sterilize volumes up to 1 L without clogging.

Dry Heat Sterilization

Some materials with microbiological applications require dry heat sterilization. Whereas autoclaving is suitable only for heat-stable aqueous material, and filter sterilization is amenable to those materials capable of passage through membranes, dry heat is used for sterilization of nonaqueous, heat-stable material such as oils and waxes. It is also used for glassware or equipment depyrogenation and enzyme (RNase) elimination in many production as well as research protocols. A minimal standard for dry heat sterilization is 350 °C for 30 min, or 121 °C for 6 h (88). As with autoclaving, the time can vary considerably with the efficiency of the sterilization oven as well as with the volume and kind of material being sterilized. Sterilization oven validation is required for many production process. However, for basic laboratory needs, biological dry-heat spore indicators (*Bacillus stearothermophilus* and *B. subtilis*) such as Spore-O-Chex (PyMaH 00190) will give a better indication of actual oven operation than will chemical indicator strips that show only that a particular temperature has been reached, but not for how long, nor if any temperature interruptions occurred. Oils and waxes are best heat sterilized in shallow volumes in large containers to permit rapid and thorough heat penetration of the material because temperature lag is much longer with nonaqueous than with aqueous materials.

MEDIA STORAGE

Prepared microbial media should stored refrigerated at 4–8 °C and in the dark. Containers should be tightly sealed or, in the case of petri dishes, packaged in plastic bags to retard evaporation. Desiccated agar media are characterized by surface cracking and pulling of the agar away from container walls. Water evaporation from liquid or solid media concentrates solutes, which can result in permanent precipitation of some components, alters concentrations of critical nutritional factors or substrates, and increases osmolarity to possibly growth-limiting levels. The ability to freeze media is entirely dependent upon the formulation. As water freezes and concentrates the solutes, poorly soluble chemicals, such as tyrosine, or chemicals, such as phosphates, prone to complexing may not go back into solution when the medium is subsequently thawed. Phototoxicity of media can develop when light activates the glass or plastic containers, as well as media components, and initiates formation of free radicals; aerobic conditions intensify these deleterious reactions as do the blue wavelengths of light emitted by fluorescent tubes (89). The effects of light and free radical formation with respect to tissue culture media have been well studied. In one such mechanism, light at 360 nm and 450 nm activates riboflavin, resulting in a transfer of energy to tryptophan or tyrosine and the formation of cytotoxic free-radical products (90). Similar hydrogen peroxide formation in RPMI medium has been shown to be intensified by the presence of HEPES buffer. With bacteria, an inhibitory effect of light on growth-supporting properties of eosin methylene blue agar has been demonstrated (91). It is recommended that tissue culture media and media for those microorganisms sensitive to the presence of hydrogen peroxide or free radicals (e.g., anaerobic bacteria) be stored and cultured in the dark or in yellow wrappers to reduce the inhibitory effects of light on the media and growth of the organisms.

OUTLINE

INTRODUCTION

The aqueous environment to which cultured cells are exposed includes low molecular weight nutrients, hormones, transport proteins, buffers, and reagents intended to either reduce stresses imposed on the cultured cells in the bioreactor environment or stabilize the product. The medium, in many cases, also includes attachment proteins and/or hormones that adsorb to the surface(s) of the bioreactor and mediate interaction with the cultured cells. The cells rapidly modify the environment (both aqueous and substratal) by utilization of nutrients and secretion of proteins and metabolites. In many cases these secreted products can be detrimental to both the cells and the prod-

uct of interest. Thus it is common practice to include in media antioxidants, protease inhibitors, and buffers. The cell-specific rates of medium utilization and metabolite production impact many of the values for process control parameters, which are in turn influenced by the medium design. Media components that destabilize or copurify with the product must, of course, be avoided.

After a few days of culture in the bioreactor, the cells are exposed to a modified or "conditioned" medium, which differs considerably from the initial formulation. The levels of some amino acids such as alanine usually increase, while glutamine levels usually decrease. The metabolism of glutamine results in the secretion of ammonia (which can be cytotoxic at 1–2 mM), and glucose metabolism leads to lactic acid production (which causes medium acidification). Different clonal lines isolated from the same transfection, fusion, or primary isolate usually exhibit differences in growth characteristics and metabolism. This results in differences in the conditioned medium that frequently require "fine tuning" of the production process, initial medium, and supplemental feedstocks. Cells of comparable derivation generally do, however, perform well in similar bioreactor systems.

In developing any process utilizing animal cell culture, all of the aspects of upstream and downstream processing must be also considered. The goal is usually to consistently produce conditioned medium containing a high concentration of an intact, uniformly processed product, which can be readily isolated from other cellular products and medium components. The interrelationship between the cultured cells (and their associated metabolic activities), aqueous environment, substratum, bioreactor design (three-dimensional geometry, materials, mass transfer limitations, "shear stresses", etc.), and product of interest (including the associated downstream processing considerations) must be emphasized. This interrelationship dictates the approach for producing any product through mammalian cell culture technology. In Figure 1 many of the important parameters are grouped within these five categories to illustrate their interrelationships. The composition and range of aqueous environments utilized in mammalian cell culture are presented here, and further information can be found in discussions surrounding the other components of a bioreactor system.

While it is true that many factors of the production process influence medium design, it is, in practice, usually the case that the medium design dictates many aspects of the overall process strategy. In addition, the medium composition defines raw material requirements including their storage and quality control (QC). Accordingly, much of the overall cost of manufacturing the final product can depend on the medium composition and its degree of optimization. Therefore, a common first step toward process design is the definition of the hormonal, nutritional, and substratum requirements of the cell line. In most cases, these are independent of the bioreactor design and process parameters. Evaluation of these data in light of the restrictions defined by the desired product suggest appropriate conditions, bioreactors, processes, and the course for medium optimization. It should be noted that even small modifications in the medium can influence the cell line stability, the product quality/yield, operational parameters of the bioreactor, and downstream processing.

Medium Composition

The aqueous environment to which the cells are exposed results from a combination of many of the factors just discussed. Dissolved gasses and pH are monitored and controlled. Metabolites or other cell products may be either stimulatory or inhibitory to the cultured cells. Almost all of the medium components have both lower and upper limits within which the cells perform optimally, and these ranges are interdependent. The effective concentration range of a given amino acid, for example, is dependent on the concentrations of other amino acids that are taken up by the cells through the same uptake mechanism. The medium and process parameters must therefore be designed such that no component either exceeds or falls below its effective concentration range (both net utilization and biosynthesis of specific amino acids are observed, dependent on the metabolite and conditions). This concept of "metabolic balance" has been clearly expounded in relation to static culture systems (T-flasks) by Ham and his colleagues (1,2).

In practice, an analytical comparison of fresh and conditioned medium provides considerable insight in medium optimization (3). Most of the components routinely included in media are discussed here in detail and can be grouped into four categories: water, low molecular weight nutrients, proteins, and supplements of a nonhormonal/nonnutritional nature. Table 1 lists the components of six common medium formulations that are frequently used as a starting point in medium development.

Scrutiny of these formulations provides some insight into the complexity of media and the evolution of in vitro cell culture technology over the past 40 years. Dulbecco's Modified Eagle's (DME) medium (4–6) was designed for high-density culture of attachment-dependent cells in the presence of serum supplementation, whereas F-12 medium (7) represents an initial round of optimization for clonal (low-density) protein-free growth of CHO cells. The concentration of each component of F-12 was empirically determined through sequential concentration/growth response (C/GR) analyses. MCDB 302 medium was derived from F-12 via further C/GR analyses (8). RPMI medium was developed for suspension culture of lymphocytic cell lines in the presence of serum (9). Iscove's DME (10) and mixtures of DME/F-12 are commonly used to provide all the components necessary for low-density low-protein cultures, while also including high enough levels of nutrients to support mass cultures (11,12). The subsequent analysis of the amino acid and carbohydrate consumption by cells cultured in the specified bioreactor system utilizing a "good mixture" often suggests appropriate modifications of the basal nutrient formula.

Water Quality

It is recommended that water of at least the pharmaceutical "water for injection" (WFI) quality be utilized for mammalian cell culture, and it should be noted that such preparations are not necessarily pure; they simply meet

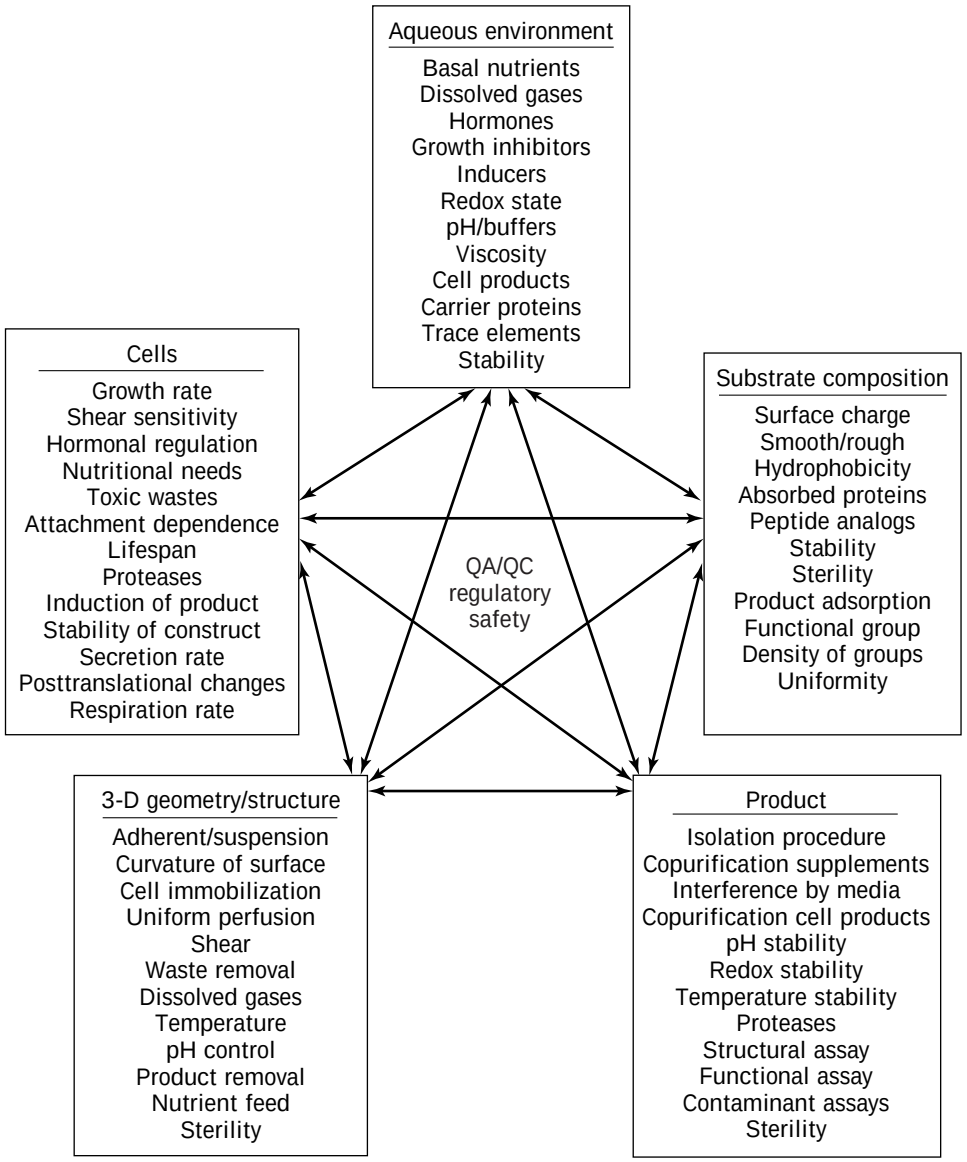

Figure 1. Bioreactor systems: interrelationship of components.

standards for injection. Agents present in water are diluted throughout the organism with injection, but remain in a relatively concentrated form in cell culture.

Water from any natural source is full of contaminants, and mammalian cells are exceedingly sensitive to many compounds that often contaminate the water used for media preparation (13). This is particularly noticeable with "reduced protein" formulations, and contaminants not removed during the purification process or introduced during storage are common causes of aberrant cultures. These contaminants can be either growth stimulatory or growth inhibitory (with the latter being more common). Unpurified water can contain organics (from detergents or degraded biomass), inorganics (such as chlorine and heavy metals), microorganisms (which often result in endotoxin/pyrogen contamination), or particles.

It is recommended that a multiple step purification is used to purify water for cell culture. In the authors' facility, water is filtered, deionized, adsorbed with carbon, purified by reverse osmosis, passed through a Milli-Q™ polishing unit (Millipore Corporation, deionization/carbon adsorption), depyrogenated via ultrafiltration, and then stored at 80 °C in stainless steel tanks until use. Routine maintenance and monitoring of the various stages of the purification stream are performed. Other techniques such as distillation and UV oxidation are commonly utilized.

Low Molecular Weight Nutrients

Bulk ions and trace elements should be considered nutrients because their absorption, secretion, and concentration in a given organism are finely controlled (14). The concentrations of these ions maintain the osmotic pressure of the microenvironment, and their distribution within the tissue (primarily Na^+ and K^+) maintains membrane potential. Therefore, both the absolute and relative amounts of sodium and potassium are important. The transient alterations in the availability of Ca^{2+} and Mg^{2+} mediate

Table 1. Media Formulations Commonly Used in Animal Cell Culture

Compound (g/mol)	DME	F-12	MCDB 302	RPMI 1640	Iscove's DME	Coon's DME:F12
Bulk ions and trace elements						
$CaCl_2$ (anh) (111.00)	1.80×10^{-3}	2.99×10^{-4}	6.00×10^{-4}		1.49×10^{-3}	1.36×10^{-3}

transmembrane signaling events, and these ions are also necessary for integrin-mediated cell adhesion. Among other biochemical roles, phosphate and bicarbonate ions buffer the acidity of the microenvironment. Other ions such as selenium, vanadium, copper, zinc, iron, molybdenum, and manganese are necessary as cofactors for certain enzymes. Depending on their concentration, trace elements can be either stimulatory or inhibitory in cell culture, and therefore must be used at optimal concentration.

Trace elements are contained as contaminants in the reagents used to prepare media, and care must be taken to assure that such unknown materials remain consistent throughout a production operation. In order to insure this consistency, it is common practice to "ball mill" large batches of powdered nutrients, and perform QC on random aliquots. The batch is then packaged in appropriately sized containers because the uniformity of the powder decays with time. Preparation of media from these large lots then requires minimal QC (provided a good source of water is utilized). Verification of osmolarity, pH, O_2 and CO_2, levels (blood gas analyzer), and sterility is usually sufficient.

There are two major energy sources utilized by cultured mammalian cells: six-carbon sugars and glutamine (15). Glutamine (2–10 mM) can serve both as a source of energy and carbon. However, ammonia produced from the conversion of glutamine to glutamic acid can be detrimental at concentrations exceeding 2 mM, and cultures of cells such as murine hybridomas tend to build up significant concentrations of this metabolite. Cell lines can sometimes be adapted to tolerate slightly higher levels of ammonia, but success in this endeavor has been limited with levels not exceeding about 10 mM. Glutamine is also unstable in aqueous solution at 4 °C (half-life is approximately 100 days), and ammonia is one of the principal degradants. Thus, long-term storage of media containing this amino acid should be avoided. If necessary, glutamine-free formulations can be supplemented with this amino acid just prior to use. Glucose is the most common carbohydrate (2–20 mM) provided as a source of energy, but many cell lines can be adapted to growth in galactose or other six-carbon sugars (16,17). In this case, a desirable reduction in the rate of lactate production and six-carbon sugar utilization is sometimes observed, presumably achieved via a decrease in the steady-state concentration of glycolytic intermediates. Concomitant reduction in growth rate is often seen. Pyruvate can also function as an energy/carbon source.

Amino acids provide the major nitrogen source in these cultures and have been grouped into two categories as a result of tissue culture experiments: the essential and nonessential amino acids (Table 1). However, most cultured cells perform better in the presence of the nonessential amino acids, and increases in the quantitative requirements for the essential amino acids are observed in cultures deprived of nonessential amino acids. An exception to this classification is the CHO-cell-derived lines that are auxotropic for proline (0.1–1 g/L generally required). Other amino acids such as serine and glycine have been shown to be beneficial supplements for low-density cultures but are relatively unimportant under conditions generally employed in large-scale mammalian cell cultures.

Vitamins have classically been grouped according to their solubility water soluble (B_{12}, biotin, folic acid, niacinamide, pantothenic acid, pyridoxine, riboflavin, and thiamine) or fat soluble (vitamins A, E, K). These compounds are enzymatic cofactors that are necessary for cellular metabolism and are reutilized (not metabolized and/or degraded) by the cells. The fat-soluble vitamins are usu-

ally added to the medium from a concentrated ethanolic stock and are not particularly stable in solution. Vitamin A (a retinoid) can have no effect, stimulate growth, or induce differentiation (dependent on the cell type and culture conditions). Vitamin E serves as an antioxidant, and vitamin K is necessary for the γ-carboxylation of proteins. The water-soluble vitamins function in multiple metabolic roles and are generally necessary components of a medium formulation. Vitamin C, a water-soluble antioxidant, has been demonstrated to be beneficial in culture, particularly with cells that tend to synthesize collagen. It is readily oxidized, and continuous supplementation is advisable if beneficial effects are to be observed (18).

Many cultured cells require supplementation with fatty acids, phospholipids (and/or their precursors), and other hydrophobic compounds such as cholesterol. The quantitative and qualitative requirements vary with cell type, culture conditions, and duration of exposure to the supplement (19). Much is still to be discerned about the interconversion and biosynthesis of lipids by cultured cells, but a few generalizations can be made. *cis*-Unsaturated fatty acids (for example, linoleic, oleic, arachidonic) have been shown to be beneficial for many cell lines, but are relatively insoluble and inherently unstable in aqueous solutions. They are usually supplied as conjugates with delipidated albumin or cyclodextrins, or added as unilamellar vesicles (liposomes). Certain lots of albumin or improperly prepared albumin conjugates can be quite toxic. Liposomes have been utilized to provide cells with both fatty acids and phospholipids such as spingomyelin, phosphotidyl choline, phosphotidyl ethanolamine, and phosphotidyl inositol. This approach is difficult to utilize in large-scale cell cultures; in many cases the need for supplementation with the more complex lipids can be circumvented by providing the cells with precursors such as choline, ethanolamine, and inositol. A few cells such as NS-1-derived hybridomas have a deficiency in cholesterol biosynthesis, and supplementation is usually necessary.

Nucleic acid precursors such as the nucleosides and nucleotides are usually not required in a medium formulation, provided at least one source of pyrimidine and purine is supplied. Therefore, hypoxanthine and thymidine are included in most media. Particular care must be taken with mutant lines lacking enzymes of the biosynthetic pathways or with cultures grown without glucose. In the latter case a source of five-carbon sugars or a small concentration of glucose is advisable. Hybridoma cell lines produced via NS0 (a cell line derived from NS1) fusions do not express functional glutamine synthetase (GS), and therefore this line has been used to produce cell constructs using GS as a selectable marker (20). Recombinant lines produced in this manner grow in glutamine-free medium, but this formulation is usually supplemented with adenosine, guanosine, cytidine, uridine, and elevated levels of thymidine.

Culture in glutamine-free medium results in a system where ammonia does not accumulate to toxic levels, and frequently, higher cell densities can be achieved. However, even after adaptation to glutamine-free medium, the proliferation rate is generally less than that seen in glutamine-containing media. NS0-derived lines usually need to be provided with a source of cholesterol unless considerable "weaning/adaptation" has been performed (21).

Proteins

The first cultures were established in mixtures of plasma and tissue extracts (22–24). More defined and reproducible nutrient media designed in the late 1950s to early 1960s were developed using cultures supplemented with dialyzed serum. We now know that serum provides a host of factors not contained in many basal nutrient formulations, including low molecular weight nutrients (sugars, lipids, vitamins, amino acids, trace elements, etc.), hormones, blood proteins, metabolites, and protective compounds. Significant inter-lot, seasonal, and source variation in serum composition exists.

Because quantitative analysis of all of the serum components is not yet possible (particularly for the proteins, lipids, and lipoprotein complexes), variation in the serum supplement is frequently cited as the principal source of variability between cultures. It is also the root of many problems associated with the production of mammalian tissue culture products. Supplementation with 10% serum results in the contamination of the product-enriched medium with a mixture of hundreds of proteins totaling about 4 g/L. This significantly complicates and increases the expense of downstream processing. In addition, serum is expensive, and the availability of high quality serum has been (and is likely to be) a problem for large-scale efforts.

It is now well accepted that the major role played by serum in cell culture is to provide hormones, growth factors, transport proteins, and attachment factors. Serum also has other beneficial effects in culture. It supplies "generic" protein that coats the system, preventing nonspecific adsorption of essential factors to the bioreactor walls and filters. Enzymes contained in serum modify media components, producing molecules the cells can more readily utilize, and also detoxify other materials. Serum also provides essential nutrients that are not included in the older, less-complex basal media. Recently, the importance of the numerous protease inhibitors present in serum has also become apparent, and several reports of increased product integrity in cultures supplemented with protease inhibitors are present in the literature (tPA/aprotinin). In addition, the physical properties of medium (colloid osmotic pressure, diffusion rates, viscosity) are altered by serum supplementation.

If serum is utilized in a culture system, extensive labor-intensive prescreening of several lots is usually necessary. This screening usually focuses on the growth and productivity of the cell line, and small-scale testing for interference in the product isolation. Long-term growth, cellular morphology, cellular productivity, and the possibility of adventitious contaminants must be examined. Once identified, a large lot of serum is usually purchased. Long-term storage of costly, unstable biologicals such as serum in a monitored freezer facility is expensive. Taken together, these factors have driven the development of the technology to reduce the need for serum supplementation in mammalian cell culture. In fact, with the recent concern about potential prion contamination (25), a major emphasis has

been placed on eliminating all animal-derived components from culture systems designed to produce parenteral pharmaceuticals.

Many of the useful growth promoting agents, attachment factors, carrier proteins, and protease inhibitors found in serum have been identified and characterized by investigators attempting to reduce the level of serum supplementation in their particular culture system by providing their cultured cells with purified molecules (26). In the last few years a significant industry has emerged to market recombinant proteins for health care, research, and cell culture manufacturing. Many proteins (or modified polypeptides exhibiting the same activity in vitro) can be obtained at a reasonable expense if ordered in quantity. In fact, most protein-containing serum-free formulations are significantly less expensive than medium supplemented with 5% serum. Proteins commonly utilized in these media formulations are discussed later and listed in Table 2 (along with other supplements).

Hormones and growth factors bind to cellular receptors and, in the process, signal the cells to perform specific tasks (growth factors are hormones that were discovered in tissue culture). Mammalian cells evolved in the presence of a mixture of these factors, only some of which are well characterized today. The many components of basal cellular physiology are regulated by the concentrations of hormones to which the cells are exposed (27). In addition, a given cell (depending upon the receptors that the cell expresses) can be signaled to grow, die (apoptosis), or differentiate by exposure to different regulatory factors. Hormones such as steroids, insulin, and thyroid hormone regulate basal metabolic activities. In many cases such signals are necessary for continued viability of cells in culture. In fact, nearly every cultured mammalian cell requires stimulation by insulin (or an insulin-like growth factor [IGE]) for survival (insulin, 0.5–10 μg/mL; IGF, 1–10 ng/mL).

Analogs of many of the proteins produced through recombinant DNA technology exhibit activities similar to those of native proteins in vitro (although pharmacokinetics, tissue distribution, and pharmacodynamics may differ in vivo). Some of such analogs are now available from commercial sources and provide the necessary regulatory signal(s) to the cultured cells when present at 1–10 μg/L. The quality and expense of such analogs can be consistent with the requirements of animal cell production systems for parenteral pharmaceuticals. Analogs of IGF and EGF, for example, are marketed for less than $50 per milligram when purchased in quantity.

Transport proteins such as albumin, transferrin, low- and high-density lipoproteins (LDL, HDL), transcobalamin, hemoglobin, and thyroid hormone binding protein bind necessary nutrients and hormones that would in their unbound form be toxic to the cultured cells at high concentrations. These compounds are either slowly released in a controlled manner (fatty acids, thyroid hormone) or are transported into cells via binding-protein-mediated or cell-receptor-mediated processes (Fe^{2+} and transferrin). In "reduced serum" cultures, most cells require supplementation with additional transferrin (0.5–10 μg/mL) unless frequent supplementation of the medium with ferrous citrate/sulfate and iron chelators is performed; some success utilizing hemoglobin as a transport moiety has also been reported. Transport proteins also serve to help detoxify medium by binding contaminants (heavy metals, detergents) and solubilizing essential nutrients that do not readily dissolve in aqueous solutions (cholesterol and other lipids and lipoproteins, and transcobalamin). Lipids, for instance, when added to cultures above the critical micellular concentration rapidly form micelles that can lyse cultured cells. Albumin and serum lipoproteins are frequently used to supply lipids and cholesterol to cultured cells (28). It should be noted that the lipid composition of these supplements can vary considerably between preparations, and care must be taken to select one appropriate for the cell of interest.

In the last decade many cytokines have been identified and are now available from commercial sources. Culture of blood and marrow-derived cells (i.e., for cell-based therapies) is essentially impossible in the absence of the appropriate mixture of cytokines, and the hormonal signals that direct the proliferation and differentiation of the early progenitor (stem) cells are not fully understood. Large-scale cultures of such cells are used to produce, isolate, and characterize new cytokines and have led to several that are being utilized in adjunctive therapy to cancer treatment to speed recovery after chemotherapy or radiation treatment. Reconstitution of the immune system through ex vivo expansion and posttherapy infusion of bone marrow cells (or mobilized peripheral blood progenitor [stem] cells [PBSC]) taken from patients prior to high-dose chemotherapy is currently being tested in clinical trials. The effectiveness of these cultures depends on the development of an appropriate balance of cytokine signals in the culture media (29). Several cytokines that are being examined in such medium formulations are listed in Table 2. The use of other recently discovered cytokines, for example IL-15, which stimulates T-cell proliferation, are likely to become more significant in the near future.

Attachment proteins (fibronectin, laminin, vitronectin) adsorb to culture surfaces and then interact with anchorage-dependent cultured cells via specific receptor molecules. The attachment, spreading, and growth of these cells is abnormal (and/or limited) in the absence of these proteins. These molecules (along with proteoglycans) are secreted by cells in vivo to form the extracellular matrix (ECM) with which the cell and its neighbors interact. The composition of the ECM varies with the tissue and has been shown to regulate certain aspects of cellular physiology (30). Thus, it is sometimes necessary to provide cultured cells with the appropriate molecules in order for the cells to perform specific desired tasks in vitro. These molecules can be either preadsorbed to the surfaces or added to the medium at concentrations of a few micrograms per milliliter during inoculation of anchorage-dependent cell cultures. Precoating microcarriers with serum proteins is also a common practice, and some success utilizing the attachment motifs in synthetic peptides has been achieved.

Synthetic polymers containing multiple copies of attachment motifs such as RGD (Arg-Gly-Asp) in many cases adequately substitute in culture systems for proteins derived from animal sources, and the expense and quality of

Table 2. Proteins/Polypeptides Used in Animal Cell Culture

Supplement	Tissue/cell source	Structure	Functions/activities
		Growth factors	
Nerve growth factor β (NGF-β)	Submaxillary	Two-chain protein, 26 kDa	Cell growth, neuron development, and survival
Epidermal growth factor (EGF)	Submaxillary, tumor-associated macrophages, prostate tumors	Polypeptide, 6.1 kDa	Stimulates broad range of responses including growth
Platelet-derived growth factor (PDGF)	Platelets, ovarian and lung tumors, melanomas	Dimeric glycoprotein, 28.6, 27.6 kDa (AA or BB)	Stimulates broad range of responses including growth
Insulin-like growth factor I (IGF-I)	Liver, breast tumors	Polypeptide, 7.6 kDa	Stimulates growth and insulin-like activity
Insulin-like growth factor II (IGF-II)	Liver	Polypeptide 7.5 kDa	Stimulates growth and insulin-like activity
Fibroblast growth factor (basic) (bFGF)	Brain, hypothalamus, pituitary, kidney	Monomeric protein 16.4 kDa	Stimulates growth of mesodermal cells
Fibroblast growth factor (acidic) (aFGF)	Brain, hypothalamus	Monomeric protein, 15.9 kDa	Stimulates growth of mesodermal cells
Liver cell growth factor	Plasma	Gly-His-Lys	Synergistic with Cu^{2+} to stimulate growth and survival
Transforming growth Factor β (TGF-β)	Kidney, platelets, and renal, breast, and prostate carcinomas	Two-chain protein, 25 kDa	Stimulation or inhibition of growth or differentiation
Transforming growth factor α (TGF-α)	Breast, neuroendocrine, and squamous carcinomas	Two-chain protein, 6.0 kDa	Similar to EGF
Vascular endothelial cell growth factor (VEGF)	Variety of tumors, tumor-associated macrophages	Dimeric protein, 28 kDa	Stimulate growth and survival of microvasculature cells
		Cytokines	
Erythropoietin (EPO)	Kidney	Glycoprotein, 45 kDa	Stimulates growth and differentiation, red cell precursors
Interferon α/β (IFN-α/β)	Fibroblasts, T and B cells, monocytes, macrophages	Monomeric protein, α 16–28 kDa, β 20 kDa	Inhibits growth of B and T cells and some tumors
Interferon γ (IFN-γ)	T cells	Homodimer, 40 kDa	Stimulate NK and T-cell growth, differentiate myeloid cells
Granulocyte colony stimulating factor (G-CSF)	Macrophage	Monomeric protein, 23 kDa	Growth and differentiation of granulocyte lineage
Granulocyte macrophage colony stimulating factor (GM-CSF)	Fibroblasts, T cells	Monomeric protein, 14 kDa	Growth and differentiation of granulocyte/macrophage lineage
Tumor necrosis factor β (TNF-β)	Macrophages	Monomeric, 19 kDa	Stimulates fibroblast growth and activates a variety of cells
Interleukin 1 (IL-1 [α/β])	Macrophages, monocytes, T and B cells, endothelial cells, fibroblasts	Monomer, 17.5/17.3 kDa	Stimulates inflammatory and T-cell growth
Interleukin 2 (IL-2)	T cells	Monomer, 15 kDa	Stimulates T cells, NK cells, and TIL cells
Interleukin 3 (IL-3)	T lymphoma, eosinophils, mast cells, keratinomas	Monomer, 16 kDa	Stimulates growth of megakaryocyte and myelocyte lineages, late stem cells
Interleukin 4 (IL-4)	T cells, stromal cells, mast cells, thymoma	Glycoprotein, 16 kDa	Stimulates B- and T-cell growth, isotype switching (IgG4 and IgE)
Interleukin 5 (IL-5)	T cells, eosinophils, mast cells	Glycoprotein homodimer, 45 kDa	Eosinophil proliferation and differentiation
Interleukin 6 (IL-6)	Monocytes, fibroblastoid cells, T, B, endothelial, and stromal cells, hepatocytes, fibroblasts	Monomeric protein, 16 kDa	Stimulates stem and B-cell growth, hepatic acute phase, hybridoma survival
Interleukin 7 (IL-7)	Stromal cells, spleen cells	Monomeric protein, 17 kDa	Stimulates progenitor B- and T-cell growth

Table 2. Proteins/Polypeptides Used in Animal Cell Culture (*continued*)

Supplement	Tissue/cell source	Structure	Functions/activities
Interleukin 8 (IL-8)	Neutrophils, monocytes, fibroblasts, T cells, endothelial and epithelial cells	Dimeric protein, 8 kDa	Stimulates angiogenesis, neutrophils, and chemotaxis
Interleukin 9 (IL-9)	T cells	Monomeric protein, 14 kDa	Proliferation of T cells and erythroid precursors
Interleukin 10 (IL-10)	B and T cells, monocytes, keratinocytes	Homodimeric protein, 37 kDa	Stimulates B-cell, mast cell, and thymocyte growth
Interleukin 11 (IL-11)	Fibroblasts and marrow stromal cells, osteosarcomas	Dimeric protein, 8 kDa	Stimulates growth of early and late megakaryoblastic and myeloblastic cells
	Attachment/substratal proteins and compounds		
Cell Tak™	Marine mussel	Polyphenolic protein	Effectively "glues" most cells to most surfaces
Collagen types I–IV	Most tissues, distribution specific for type	Multisubunit proteins	Binds and presents adhesion molecules and stimulates attachment and growth
Extracellular matrix (solubilized)	Extracts of EHS mouse sarcoma and human placenta available	Mixture of proteoglycans, collagens, and attachment factors	Promotes attachment, spreading, mitosis, and differentiation of many epithelioid cells
Fibronectin	Plasma	Dimeric protein, 440 kDa	Promotes attachment and spreading via RGD (Arg-Gly-Asp) and other motifs of most cells from mesenchyme
Laminin	Extracellular matrix	Dimeric protein, 900 kDa	Stimulates attachment and growth of cells derived from endoderm and ectoderm; stimulates neutrophil oxidative burst
Pronectin®F	Synthetic polymer	Polypeptide with multiple RGD motifs	Supports attachment of some cell lines (e.g., CHO, 3T3, BHK)
Poly-D-lysine	Synthesis	Polypeptide, polymers, mw > 50,000	Reduces net negative charge of surface-enhancing attachment
Vitronectin	Plasma	Monomeric protein, 70 kDa	Stimulates attachment and growth of many cell types
	Transport proteins		
Albumin	Plasma	Monomeric protein, 68 kDa	Carries fatty acids and trace elements and can detoxify
Ceruloplasmin	Plasma	Protein, 135 kDa	Transports copper
Hemoglobin	Red cells	Quaternary protein, 65 kDa	Binds oxygen, carbon dioxide and can detoxify
High-density lipoprotein	Plasma	Lipid, cholesterol and multiple protein subunits	Transports cholesterol, cholesterol esters, and other lipids
Low-density lipoprotein	Plasma	Particle containing lipid, cholesterol, and protein (Apoprotein B) subunits	Transports cholesterol, cholesterol esters, and other lipids
Transferrin	Plasma	Monomeric protein, 78 kDa	Carries iron and can detoxify

such polymers can also be consistent with the limitations imposed on manufacturing a pharmaceutical protein. Plasma and chemically treated culture surfaces are widely utilized to provide a surface that more closely mimics the ECM than untreated plastic or glass. Both small-scale plasticware and microcarriers that have surfaces with exposed attachment motifs have recently been introduced into the marketplace.

Nonhormonal and Nonnutritional Supplements

Other compounds are frequently included in medium formulations to reduce specific detrimental conditions that

are generated in the artificial microenvironment of the bioreactor, or to facilitate control and monitoring of the system. Also included in this group are antibiotics, which although frequently utilized are not necessary nor recommended. These compounds interfere with cellular metabolism and have been developed by selecting molecules that are more active with microbial enzymes than their analogous mammalian counterparts. Nevertheless, most antibiotics compromise some aspects of mammalian metabolism when present in their effective concentration range, and all are toxic at relatively high dosages. Serum and other supplements can, in some cases, reduce the detrimental effects of antibiotics on cultured cells, and the inhibitory effects of a specific antibiotic are greatly dependent on the cell type. Therefore, if antibiotics must be utilized in a specific culture system, an extensive dose–response analysis should be performed under conditions resembling (as close as possible) those of the bioreactor. Potential copurification with the desired product or interference with downstream processing must also be examined.

In the bioreactor, pH is stabilized with buffers (phosphate and bicarbonate) and usually maintained through control of dissolved CO_2 and base addition. Phosphate has a pK_a of 7.21 and is present in media (2–3 mM) both as a nutrient and as a buffer. The concentration of phosphate is limited by the solubility of calcium phosphate, and higher concentrations of phosphate are practical only in reduced-calcium formulations. The principle pH buffer in mammalian organisms is the bicarbonate–carbon dioxide system, and a similar control strategy is utilized with most bioreactor systems:

$$H_2O + CO_2 \rightarrow H_2CO_3 \rightarrow H^+ + HCO_3^-$$
$$pK' = 6.1 \text{ at } 37\ ^\circ\text{C and } 760 \text{ mmHg}$$

Where $[H_2CO_3]$ (mM) = 0.0308 PCO_2 (mmHg). Applying the Henderson–Hasselbalch equation ($pH = pK' + \log \{[HCO_3^-]/[H_2CO_3] = 6.1 + \log \{(\text{total } CO_2) - 0.0308\ PCO_2\}/0.0308\ PCO_2$) it is apparent that increases in the partial pressure of CO_2 result in decreases of pH. Equilibrium in a bioreactor is essentially dependent on the rate of CO_2 dissolution, diffusion, and bulk mixing because the rate of formation of H_2CO_3 from water and dissolved carbon dioxide is rapid ($T_{1/2}$ = 11.5 s) (31). At pH 7.4 the relative ratios are approximately 20,000:1000:1 (HCO_3^-:CO_2:H_2CO_3).

The amount of bicarbonate present in the medium is chosen to be close to equilibrium conditions for the specified pH operating condition. This amount is usually about 23 mM (similar to circulating blood) and will be at equilibrium with 5–10% CO_2. Bicarbonate in excess of this equilibrium point is used to titrate acid produced by the cultured cells. Carbon dioxide is also a nutrient, and aqueous solutions equilibrated with air at 37 °C contain only 0.21 mm CO_2 (7 μM). Therefore, if air equilibrated cultures are desired, it is recommended to use an additional organic buffer like HEPES (*N*-2-hydroxyethylpiperazine-*N*′-2-ethanesulfonic acid) and 1–2 mM bicarbonate to maintain adequate concentrations of dissolved CO_2.

Although relatively expensive, HEPES is frequently used as an additional buffer because, unlike bicarbonate, its p*K* falls in the physiological range (7.31 at 37 °C). The pK_a is, however, extremely temperature sensitive (-0.014 per change of 1 °C), and thus a room temperature solution at pH 7.55 would be pH 7.31 when warmed to operating temperature. HEPES is utilized at concentrations ranging from 10 to 50 mM. The concentration of sodium chloride needs to be reduced to compensate for changes in osmolarity at the higher levels, and a reduction in the level of potassium ion should be made to maintain similar Na^+/K^+ ratios. At concentrations of HEPES more than 15 mM the buffer is sometimes growth inhibitory (dependent on cell type via stimulation of the production of detrimental oxygen metabolites).

3-(*N*-Morpholino)propanesulfonic acid (MOPS) (pK_a = 7.20 at 20 °C) is also used for this purpose. The temperature sensitively is less (-0.006 per change of 1 °C), but the pK_a is slightly more acidic (which can be advantageous or detrimental, depending on the cell type).

Phenol red has classically been included in culture media as a pH indicator. There is no compelling reason for its use with instrumented systems and in fact has been shown to have estrogenic activity with cultured cells (C127, MCF-7) and to copurify with proteins (tPA, IFN-γ).

Many protective agents are often added to the medium to protect the cells from damage caused by osmotic gradients, shear, and interaction with air–liquid interfaces (bubble damage). The agents include dextran (30–50 g/L, 80,000 MW); polyethylene glycol (20,000 MW), methyl cellulose (0.1–0.2% w/v), and pluronic polyol F-68 (0.025–0.3%). The latter, a block copolymer of polyoxpropylene and polyoxyethelene of 8,300 MW, has been demonstrated to reduce bubble-induced cell damage and is the most frequently used protective agent (32).

Antioxidants are sometimes beneficial. Superoxide radicals and hydrogen peroxide are generated by normal cellular metabolism and enzymes such as xanthine oxidase present in serum supplements. These compounds can also be generated by photooxidation of compounds such as tryptophan and riboflavin, and their production can be stimulated by several factors such as hyperoxic conditions, general cell stress, and compounds such as HEPES. These highly reactive metabolites can cause damage to both the cultured cells and the cell products. Enzymes (superoxide dismutase, catalase), vitamins (C, E, and β-carotene), carrier proteins (transferrin, hemoglobin), amino acids, trace elements (Se^{2+} as a cofactor for glutathione peroxidase), bilirubin, and reduced glutathione are all antioxidants useful in mammalian cell cultures. All except the enzymes and glutathione are components of serum.

Reducing agents (β-mercaptoethanol) can help to prevent oxidative damage, primarily by restoring the reduced form of glutathione. When added to cultured cells, increases in cystine uptake (presumably by the mixed disulfide) and in antibody secretion rates (hybridomas) have been observed.

Many cells actively synthesize and secrete proteases, and even limited cell death (inherently a part of the microenvironment of any bioreactor) causes the release of intracellular protease into the medium. Therefore, supple-

mentation with protease inhibitors specific to proteases generated in a particular culture system is recommended. Cultures that have been established or maintained in serum-supplemented medium are particularly sensitive due to large quantities of adsorbed plasminogen (which is readily activated to plasmin by a variety of proteases). Ten to 40 kIU of aprotinin will effectively inhibit plasmin (and kallikrein) activity. ϵ-Amino caproic acid also inhibits plasmin at 2–7 mM concentrations (higher levels are somewhat toxic). Several other biocompatible inhibitors are now commercially available at nonprohibitive costs (see Table 3). Pepstatin inhibits acid proteases (at 0.7–1 μg/mL). Leupeptin is a reversible, competitive, polypeptide inhibitor of serine and thiol proteases that shows little toxicity at 5 μg/mL. In addition, both soybean and egg white trypsin inhibitors inhibit serine proteases, are effective between 10 and 100 μg/mL, and cost only a few cents per liter. Pefabloc® SC [4-(2-aminoethyl)-benzenesulfonyl fluoride] is relatively nontoxic (compared with phenylmethylsulfonyl fluoride or diisopropyl fluorophosphate) and blocks serine proteases (trypsinlike and chymotrypsin-like) when present at 1–2 mM concentrations. However, it is hydrolyzed relatively rapidly in medium at pH 7.0 (half life ~6 h) and is less stable in more basic environments ($t_{1/2}$ at pH 7.5 ~ 2 h).

Heparin or heparin sulfates (10–100 μg/mL) can help to reduce cell clumping when a normally adherent cell line is grown in suspension. Heparins also stabilize certain growth factors and enhance their bioactivity (endothelial cell growth factor, bFGF, VEGF). Heparins are crude mixtures available from many vendors and are not likely to be identical. Preparations are available with different nominal molecular weights, and those below 5,000 lack some of the biological activities present in other preparations.

MEDIA SELECTION

The most common goal of large-scale animal cell culture is the production of conditioned media with the highest possible titer of a homogeneous protein for subsequent isolation as a functionally active, pure product. In other cases the product can be an inactive proenzyme, a mixture of proteins from nonrecombinant cells, or even the cells themselves. Media selection is therefore highly dependent on the particular product and cellular system and is influenced by the design and composition of the bioreactor. A medium suitable for production of a specific cell product in a batch system is usually not ideal for producing the same product (with the same cells) in a highly instrumented perfusion system. The impact of medium components on downstream processing should guide medium development.

In vivo cells function differently depending on their environment (consider fibroblasts in wounds, osteoblasts, neutrophils, etc.). A given cell line can be cultured in different medium formulations. Metabolism can be modified by providing specific hormonal signals (e.g., insulin), providing physical signals (e.g., shear stress and endothelial cells), and/or altering the availability of nutrients (e.g., the scavenger pathways for nucleotide biosynthesis in hypoxanthine-aminopterin-thymidine selection). Cultures starved of glucose can utilize glutamine as an energy source, and lipid-depleted medium forces cultures into de novo lipid synthesis. The rate of lactic acid production can frequently be reduced by substituting other sugars for glucose (see the section "Low Molecular Weight Nutrients"), but concomitant reductions in proliferation rate are usually observed. Changes in the fatty acid composition of the medium can alter cell membrane fluidity and result in changes in signal transduction, oxidative damage, and other membrane-associated cellular processes (33). In cultures with a transport phenotype (i.e., differentiated cultures of intestinal origin), media nutrients can enhance the transport function (34).

Cellular metabolism alters in response to changes in the environment, and this process is referred to as *adaptation*. Large changes are usually inconsistent with cell viability and proliferation. Cells are generally adapted through

Table 3. Biocompatible Protease Inhibitors

Inhibitor	gm/mol	mg/L	Properties
Albumin	68,000	1,000	Serves as a nonspecific substrate
Aprotinin	6,511	6.8	Inhibits serine proteases (trypsin, kallikren, 40 U/mL = 6.8 μg/mL); at pH 7–8 aqueous solutions are stable for only 1 week at 4 °C
ϵ-Aminocaproic acid (EACA)	131.2	920	Inhibits plasmin
Egg white trypsin inhibitor	28,000	50	At 10–100 μg/mL inhibits serine proteases (trypsin, plasmin, coagulation factor Xa, kallikrein, no antichymotrypsin activity)
Leupeptin	460	2.0	Reversible competitive inhibitor of serine and thio proteases; plasmin, trypsin, kallikrein, cathepsin b, thrombokinase; 2 γg/mL nontoxic, plasmin inhibition 50% at 8 μg/mL
Ovoinhibitor		2.5	Inhibits tyrpsin and chymotrypsin equally on a weight basis; 5 μg/mL usually nontoxic
Pefabloc® SC	239.5	250	100–1,000 μg/mL inhibits serine proteases (daily addition in batch cultures due to rapid hydrolysis in medium)
Pepstatin	685	0.7	Inhibits acid proteases, especially pepsin, renin, cathepsin D, chymosin (make 2 mM stock in alcohol)
Bovine pancreas trypsin inhibitor		2.0	Inhibits trypsin and chymotrypsin. Usually 2–5 μg/mL, nontoxic
Soybean trypsin inhibitor	20,100	50	At 10–100 μg/mL inhibits serine proteases (trypsin, plasmin, coagulation factor Xa, kallikrein, no antichymotrypsin activity)

gradual changes made to a medium, which is selected based on the constraints of the product, the bioreactor system, and the nutritional requirements of the cell line. Further optimization is then performed. The composition of the final formulation depends on initial medium choice and the order in which components are optimized.

A considerable component of the cost of a product can be the medium cost (either directly or indirectly). Some media components are relatively expensive and in many cases not justifiable by the small incremental increases in product titer (e.g., nucleosides). The addition of some costly components can be supported by enhanced culture performance (e.g., insulin). Many examples of increasing product titer by more than an order of magnitude through medium optimization have been documented, and it is likely that no published formulation is "optimal" for a particular purpose. The potential for optimization can be limited by the availability of time, other resources, and the suitability of the current performance of the culture system.

Optimization is therefore highly dependent on the product and the tissue culture system and can result in reduced-serum formulations, a serum-free medium, a chemically defined formulation, or a combination that involves a medium exchange. In the latter case the cell mass is usually generated in medium supplemented with serum or a reduced-serum formulation in which the cells proliferate rapidly. The production of conditioned medium for product isolation then proceeds in more a defined, generally less expensive, formulation. This strategy also addresses downstream processing concerns by eliminating serum from the production phase. Although impractical in batch mode processes, perfusion systems can be utilized for this approach. A potential drawback of a medium exchange process is a reduction of cell mass with time. Also, cell damage can occur if a washing step is included in the process (resulting in the release of intracellular contents, including proteases, into the conditioned medium).

Reduced Serum and Serum-Free Formulations

The addition of serum or plasma to cell culture media dates back to the early years of cell culture (22–35) and logically follows the attempt to mimic the environment of cells in vivo, which are nourished from interstitial fluids that resemble blood plasma. Serum is the liquid phase remaining after the clotting of whole blood and, as such, is similar in composition to blood plasma (the noncell component of blood), except for the absence of fibrinogen and other clotting factors and increased levels of serotonin. Serum is thus a complex mixture of proteins, vitamins, inorganic salts, amino acids, hormones, lipids, and other components in an aqueous solution. Serum provides cells with hormonal, nutritional, and stromal (attachment) factors (36). In addition, serum proteins can act as carriers for other factors that are necessary for cell viability and function. Serum proteins also help protect cells (and product proteins) from hydrodynamic stress (impeller or bubble damage) and proteases secreted by the cultured cells or released during cell lysis. Serum acts as a sink to bind and detoxify the formulation (e.g., deleterious trace elements).

In spite of all these benefits of serum supplementation of the culture medium, the goal is usually to reduce or eliminate this supplement. Because of its biological nature, there are wide fluctuations in serum composition and ability to support cell growth/function, and consistency between batches is hard to maintain (purchases of serum should be preceded by lot testing to demonstrate its growth-supporting function and product generation with specific cells of interest).

Even small amounts of residual serum can complicate filtration, concentration via precipitation or ultrafiltration, and chromatographic processing steps. Reduction or elimination of serum therefore reduces cost of media and simplifies downstream processing. It also reduces foaming in the bioreactor, decreases the possibility of adding adventitious infectious agents to the culture, increases the consistency of medium preparations while decreasing the complexity of QC, and may help maintain expression levels of recombinant proteins or antibodies. A formulation is considered serum-free if sufficient factors have been added to the media to eliminate the need for whole serum.

Most of the classic formulations were designed to be used with serum and to support relatively low-density small-scale cultures (billion cells per liter), for example Eagle's Minimum Essential medium, Dulbecco's Modified Eagle's medium, and M199 (1). Some formulations were developed specifically for clonal growth, such as F-12 medium, which was tested to support clonal growth and serial propagation of two Chinese hamster cell lines for cultures of less than 10^5 cells/mL (1,7). Therefore, while such formulations support the proliferation of low density cultures, essential nutrients are rapidly depleted by higher-density cultures.

Table 1 compares the composition of many widely used media: DME, Ham's F-12, Coon's DME/F-12, MCDB 302, RPMI 1640, and Iscove's DME. These formulations typically require further optimization for most cell types. A proven strategy is to mix commercially available media to determine appropriate mixtures empirically (36–38). Subsequently, the analysis of consumed metabolites in cell-conditioned media can lead to the fine tuning of a formulation for a particular cell type.

Thus, many factors encourage reduction or elimination of serum supplementation: medium expense, downstream processing, the lot-to-lot variation and incomplete characterization, and the potential for introduction of contaminating agents (i.e., mycoplasma, viral pathogens, or prions). Reduction of serum from 10% to 1% can save approximately $25/L in serum costs, not including the savings associated with growth testing, storage at $-20\ ^{\circ}C$, heat inactivation and filtration, and the costs associated with additional purification steps.

The movement toward serum-free media was championed in a series of publications by Sato and his colleagues in the mid-1970s. They demonstrated that serum could be replaced by mixtures of defined and/or partially defined factors, and that the necessary replacements were qualitatively and quantitatively different, depending on the cell type (38). Most cell lines have been established with medium containing a relatively high level of serum supplementation. The key to reducing or eliminating serum is to determine which components of serum the cells are responding to or utilizing for both growth and product ex-

pression. The cells must then be adapted to an alternative environment, or these components need to be provided independent of the serum supplement. Thus, a first step toward serum-free media is to determine, by weaning (adapting) the cells from the serum-supplemented environment in small increments, the level of supplementation where culture performance is significantly reduced (i.e., changes in proliferation and product expression rates, morphology, etc.).

The next step is supplementation with serum components to restore culture performance. This is a reiterative process. Examples of these supplements include many of the proteins and other compounds listed in Tables 1–3. This process may be accelerated by the use of multivariant analysis such as the Plackett–Burmann method (39). Enrichment of the medium with amino acids which are depleted during culture has been shown to increase growth rates and productivity (40). Depending on the process, other substitutions can be beneficial, for example, lactalbumin hydrolysate, bovine colostrum, or bovine whey (41) instead of albumin, ferric citrate (42), or aurintricarboxylic acid/citrate/EDTA (43) to replace transferrin.

Because cells in reduced serum and serum-free cultures are generally more sensitive to environmental conditions, it may be necessary to optimize media for different reactor configurations and modes of operation (44). This may include the addition of protease inhibitors to counteract the effect of increased cell lysis and/or reduced concentrations of nonspecific proteins, which taken together increase the incidence of destruction of the protein product from cell-released proteases.

Some cultures at higher cell densities no longer require serum due to the presence of beneficial autocrine factors. This may be one of the major factors accounting for the success of culture strategies that involve a switch to serum-free or reduced-serum formulations for the production phase after high cell densities are achieved. Once the cells adapt to conditions more consistent with the desired process, it is useful to prepare a frozen cell bank of adapted cells. Recent reports (45,46) recommend cryopreservation media based on nonnutritional polymeric additives in place of serum.

Chemically Defined Media and Protein-Free Media

Beyond the reduction or elimination of serum is the need for chemically defined media or protein-free media. The feasibility for chemically defined media increases as the critical components necessary for many varied culture systems become defined. Several of these defined systems are utilized in large-scale cultures today. The impetus for chemically defined media partially stems from regulatory considerations because such formulations provide greater lot-to-lot consistency. Similar reasons support the use of recombinant proteins rather than those isolated from animal tissue (with potential contaminating agents). From a regulatory viewpoint, defined formulations help to demonstrate control of all aspects of the synthesis and processing of proteins destined for licensing as pharmaceutical agents. The practicality of this approach will increase as more purified factors become available (at significantly reduced prices) through recombinant technology. Even today, many hormone-supplemented, chemically defined formulations can be prepared at less expense than medium supplemented with 10% serum.

EXAMPLES OF MEDIA

Choosing the most appropriate medium for a particular cell type and desired function is a fundamental decision. There are a wide variety of expression systems for recombinant proteins, and each system has its own requirements, for example, the necessity of proline in CHO cell culture, the ability of NS0 cells to proliferate in glutamine-free media (see the section "Low Molecular Weight Nutrients"), and the requisite fatty acids for BHK proliferation. The challenge is not only to find the medium conditions that enhance cell growth and/or production, but also to choose economical components that will not bring contaminating agents to the media or interfere with purification of the product. Culture conditions for cell lines at low density and small scale typically do not support high-density, large-scale production. As medium requirements have become more stringent (from serum-containing to serum-free to chemically defined), whether from economic, scientific, or regulatory concerns, there are more and more medium options on the market, many of which are proprietary and developed for a single cell type. Therefore, a commercially available cell line is often offered with an "optimized medium formulation." Although this medium may work well for the specific cell line, it is not likely to be the best choice for other cell lines, nor will it be economical.

Two types of media are reviewed next, one for attachment-independent (hybridoma) cells and the other for attachment-dependent (endothelial) cells. Media for hematopoietic cell culture systems have recently been reviewed and are also good examples of the targeted cell population the formulation being defined by (29,47,48).

Hybridoma Media

The media requirements of hybridoma cells have been extensively studied, and many formulations and variations thereof can be found in the literature. Hybridomas are attachment-independent cell lines of mixed hematopoietic origin. Media formulations based on DME, RPMI 1640, IMDM, and DME/F-12 (among others) have been used with serum supplementation. However, the potential for copurification of serum proteins (albumin and antibodies) with hybridoma-produced antibodies is a tremendous incentive to utilize serum-free media. Serum-free formulations of basal media supplemented with insulin, transferrin, ethanolamine, and selenium (ITES) are commonly used, along with the variations and (ITES with β-mercaptoethanol (βITES) or ITES with hydrocortisone (HITES) (49,50). Amino acid supplementation has been shown to enhance cell growth and antibody production; however, full optimization of amino acid supplementation is specific to a particular cell line (40,51–53). A fed-batch bioreactor study that aimed to maintain nutrient concentrations with a process control strategy based on stoichiometric consumption rates and total cell number has lead

to impressive improvements in cell density, culture life, and antibody titer for a specific hybridoma cell line (54). Because ammonia is toxic to hybridoma cultures (55), the use of glutamine-based dipeptides as a substitute for glutamine is being investigated. The dipeptide is stable in storage, preventing the spontaneous degradation of glutamine to ammonia; however during culture glutamine is released by hydrolysis of the dipeptide. In selected cell lines, higher cell yields are observed coincident with a significant reduction of accumulated ammonia (56,57). In a move toward more defined and ultimately protein-free culture media, the use of ferric citrate (50–500 μM) has been demonstrated to be a substitute for transferrin (42,58).

Endothelial Cell Media

Endothelial cells, the cells that line the blood vessels, are a rich source of enzymes of pharmaceutical interest and are used as components of in vitro assays for cardiovascular, inflammation, and oncology research. They are attachment dependent and are typically utilized as primary or low-passage-number (P5–P20) cultures, with a strong dependence on proper culture conditions for retaining function, morphology, and life span. Optimized culture media are specific for origin of the cells, including both the species and the location in the vasculature. Human endothelial cells are the most difficult to grow in culture, but perhaps the most important for pharmaceutical and biotechnology applications. Human umbilical vein endothelial cells (59,60) and human dermal vascular endothelial cells (61) can be cultured in similar medium. A basal medium of M199, DME or MCDB 131 (62–64) is typically used, supplemented with fetal bovine and/or human serum in the range of 2–50%, with a typical value of 10–20%. Because of the primary nature of typical endothelial cultures, it is not unusual, although not completely necessary either, to add both antibiotics (penicillin, streptomycin, neomycin, and/or gentamicin) and antifungal agents (i.e., Fungizone®). Endothelial cells require glutamine, which should be added to the medium no more than one week before feeding to the cells.

Primary cultures at a proper seeding density typically grow without additional growth factors; however, subcultured cells require a mitogen such as fibroblast growth factor (FGF) or endothelial cell growth factor (ECGF), which is potentiated by the glycosaminoglycan heparin (65). The advent of commercially available endothelial cell cultures has led to the availability of commercially prepared complete media. These media provide the advantage of being optimized for individual types of cells; however, a potential disadvantage is cost. Endothelial cells in vivo grow on a basement membrane that contains laminin and type IV collagen. In vitro endothelial cells benefit from treatment of the growing surfaces with an attachment factor such as collagen, gelatin (denatured collagen), fibronectin, or attachment peptides (i.e., the RGD sequence).

MEDIA PREPARATION AND OPTIMIZATION

There are three major forms in which medium can be supplied: bulk powder, media concentrates, and bulk liquid. Each has its own advantages and disadvantages, as described later. The choice of powder, concentrate, or liquid will vary depending on convenience, cost, storage space (or lack thereof), and availability of a reliable water supply. Whatever the starting configuration, quality control measures are required to ensure lot-to-lot consistency and conformity to standards. Some quality control techniques (i.e., amino acid analysis by HPLC) can also be used for media optimization.

Media Preparation from Powder

Typically the most common medium used for large-scale animal cell culture is that prepared in the end-user laboratory from a powdered formulation. The advantages are cost (both in the cost of the media and the required amount of storage space at 4 °C), increased shelf life of powdered media versus liquid media (years versus months, respectively), flexibility of preparation (i.e., it is relatively easy to modify the formulation at the time media is prepared), large lot sizes for custom and standard formulations, control over the type of container used for the final, prepared media (for ease of use in filling and/or perfusion of reactors), and customized quality control (samples can be taken at any step or every step during the process and run in as few or as many assays as required).

The requirements for media preparation from powder are good source of water (see section “Water Quality”), adequate storage at 4 °C for the bulk powder and the reconstituted media, storage at −20 °C or −70 °C for other media components, mixing vessels and agitation or mixing equipment, sterilization equipment (i.e., filters and pumps for submicron filtration, and autoclave or steam-in-place for media holding tanks), and equipment for quality control (i.e., pH meter or blood gas analyzer for pH, vapor pressure osmometer for osmolarity, scale or volumetric containers for volume). Bulk powder (after checking for any discoloration or unusual odor) is added to water (approximately 90% of final volume) and mixed thoroughly. Other ingredients are added one at a time to ensure complete dissolution. Volume and pH adjustments are made and the medium filtered. Quality control checks on pH, osmolarity, and volume should be made prior to sterile filtration, with the caveat that pH usually increases a few tenths during filtration. In addition, a sterility check from the final material pumped through the filter should be performed (37 °C overnight). After the quality control checks are passed, the reconstituted medium can be released for use. Over time glutamine-containing media will build up significant amounts of ammonia, even at 4 °C (see the section “Low Molecular Weight Nutrients”). As an alternative, medium can be prepared glutamine-free, with glutamine supplemented just prior to use or prepared with glutamine-containing dipeptides to extend shelf life.

Powdered medium is produced by the ball milling process, in which ingredients in powdered form are added to a mixing unit along with ceramic particles or balls. The drum-shaped mixing unit is rotated, which results in mixing of the contents. This process has its drawbacks, notably the ball mill batch size before blending is limited to the size of the mixing drum, heat is generated during ball mill-

ing, which can degrade heat sensitive components, and the ceramic balls can chip and break into the medium, resulting in ball mill particles in the packaged product. BioWhittaker has recently introduced a micronization process in which the powdered media is continuously mixed without the use of ceramics. They claim increased lot size to a 6,500-kg blended lot, elimination of the possibility of ceramic chips in the powdered media, quicker production time, and the potential for a completely enclosed automated process.

Media Concentrates

Life Technologies, Inc. has introduced media concentrates, which offer some of the convenience of liquid media while retaining some of the flexibility and cost savings of powdered media. As a substitute for bulk powder, concentrates require less mixing and filtering but similar QC strategies. The advantages lie in reducing the amount of time and effort spent weighing out individual ingredients, increasing the shelf life over complete bulk liquid media (concentrates are segregated into 3–4 component mixtures, each of which is more stable than the complete liquid media itself), and the potential for automated mixing (66). Concentrates, by definition, also require less storage space than bulk liquid media. However, using concentrates to reconstitute full-volume media is not their only or even their best use. Concentrates can be utilized as perfusion supplements, adding back key components to high-density reactors without greatly effecting the volume (67,68). This is ultimately done to increase the productivity of the reactor. However, another reason to add supplements is to provide a minimally required level of nutrients to prevent apoptosis (programmed cell death), which has been shown to occur when even a single essential nutrient is limiting (69,70). Cell death, whether by apoptosis, hydrodynamic damage, or other mechanisms, leads to increased levels of cell-released proteases as well as a reduction in cell density. Nutrient feeding by concentrates can occur along with $1\times$ media perfusion, which, in addition to adding nutrients, dilutes waste products such as lactate and ammonia.

Bulk Liquid Media

Bulk liquid media is the most expensive form of media but the least time-consuming for the end user. The media is mixed, filtered, and QC checked at the vendor, reducing or eliminating the need for the end-user to provide a water supply, mixing and filtration equipment, and QC instruments. However, the extra labor and processing adds to the cost of the media. In addition, shipping costs increase. Another cost to the end-user is storage in the appropriate temperature-controlled environment. A drawback of bulk liquid media has been its availability in bottles (0.5–1 L), which require transfer to other vessels for filling or perfusion of the bioreactors. This concern has been addressed by the sale of liquid in drums and large bags (50–100 L), which can be equipped with custom fittings. However, special handling equipment may be necessary to move these large containers around the end-user facility.

Quality Assurance

The goal of quality assurance is to provide consistency between lots and to provide a level of confidence that the media meets the necessary conditions. Vendor-supplied certificates of analysis for media in powder, concentrate, or liquid form provide a list of components and their mass or concentration. Simple tests, such as pH, osmolarity, sterility, and volume, can provide additional information about reconstituted media and should be routine. Other tests can provide additional information such as ammonia and glutamine (especially for media close to the expiration date) levels, amino acid analysis (for new lots of media to verify formulation), and endotoxin levels (for any media, but especially those containing albumin, which binds endotoxin). Individual components of the media, especially serum and growth factors, should be lot tested with the appropriate cell lines for their ability to support growth.

Optimization

Media for individual cell lines or groups of cell lines can be optimized for cell growth, specific production rates, attachment (in)dependency, cost of media, or other factors critical to a project. This optimization is especially important for larger-scale and/or longer-term projects.

There are two major approaches to optimization of fed-batch reactor schemes: bottom-up and top-down (67). The bottom-up approach refers to adding back components that are determined to be depleted. This approach can range from a simple addition of glutamine or glucose feed, or be based on an extensive study of cellular metabolism (71). The analysis required then can range form a single measurement in a metabolite analyzer (such as a YSI glucose or glutamine analyzer, or a Kodak Biolyzer) to complex analytical methods (i.e., HPLC) for detecting trace compounds. The specificity of a particular media supplement has the advantage of enhancing that feature that is most important for a particular production project, but this specificity also has the disadvantage of not translating to other cell lines or optimization conditions. The optimized formulation may be valid for only a narrow range of cell density and is likely to be cell-line specific.

The top-down approach uses complete media supplementation with either $1\times$ media or concentrates. This is a simple approach that does not require elaborate metabolic studies, but does increase the cost of the actual media supplement, a factor that must be weighed against the time savings in development of a bottom-up type of supplement. Top-down strategies require the identification of at least one key nutrient (i.e., glucose), which is monitored to control the supplementation rate through a stoichiometric or heuristic model.

POSTTRANSLATIONAL MODIFICATION AND MEDIUM COMPOSITION

Proteins, whether produced in vivo or in vitro, undergo posttranslational modifications that ultimately effect the biological properties of the protein. Although some posttranslational modifications occur extracellularly in vivo,

(i.e., activation of the complement system or proteolysis of prothrombin to thrombin during blood coagulation), many posttranslational modifications occur prior to release of the protein from the cell. These modifications include hydroxylation, phosphorylation, sulfation, adenylation, carboxylation, acetylation, methylation, and glycosylation (72). Of these modifications, glycosylation has been most extensively studied in cell culture because the ability to properly glycosylate proteins is an advantage of mammalian recombinant expression over prokaryotic systems. Altered glycosylation patterns may effect clearance rates, specific activity, further processing of the protein, solubility, and immunogenicity. The cell type is a major contributing factor to glycosylation patterns of proteins made in cell culture; however, there is evidence that environmental factors, including cell culture media, can influence glycosylation.

Glycosylation

Oligosaccharides attached to asparagine residues are referred to as N-linked, whereas those attached to serine or threonine hydroxyls are O-linked. More studies have been conducted on N-linked oligosaccharides due to their more complex nature. Glucose starvation has been shown to reduce the incidence of glycosylation at asparagine residues and lead to aberrant oligosaccharide structures (73,74). An individual assessment of the result of such deviant glycosylation on the recombinant protein properties is warranted, and if necessary the cell culture medium should be adjusted to ameliorate the problem. Other cell culture components that have been reported to disrupt glycosylation include hormones, DMSO, acidotropic amines, EDTA, HEPES buffer, the antibiotic tunicamycin, and the ionophore monensin (74). If it is determined that important protein properties are altered by the media composition, media optimization for production of the appropriate glycoform is required.

OUTLINE

INTRODUCTION

Escherichia coli and *Bacillus subtilis* (later to include other species of the genus *Bacillus*) were the first microbial tools used in studies of biochemical pathways and genetics because of their undemanding needs for cultivation as well as their general lack of pathogenicity. Consequently, more is known about the workings of the metabolic processes of these organisms than all others, and this knowledge has

been successfully applied in the era of biotechnology. Whether by human-directed and human-enhanced natural strain selection or by genetic manipulation, these prokaryotic organisms have provided a wealth of molecular information that has much accelerated biotechnology's scientific and industrial growth.

The purpose of this article is not to belabor basic nutritional considerations required to propagate these organisms: most wild-type strains are so metabolically versatile that they will grow in a simple medium containing only 1% peptone. Microbial growth alone, however, is rarely the ultimate goal in scientific pursuit. Strain isolation, enhancement, genetic stability, performance, and reproducibility are all entangled aspects of cultivation for these as well as other microorganisms. Unfortunately, there are no universal road maps to guide a biotechnologist to success in manipulating a microorganism; the best solutions are often strain specific as well as need specific. Thus, this article highlights broad discussions of media considerations involved with the growth and manipulation of these metabolically incredible bacteria.

NUTRITIONAL REQUIREMENTS

E. coli and *Bacillus* spp. have complete anabolic and catabolic biochemical pathways. This metabolic complexity allows the cultivation of these organisms with relatively simple media containing an organic source of energy, the nutritionally essential minerals (N, C, H, O, PO_4^{2-}, SO_4^{2-}), and trace elements (Ca^{2+}, K^+, Na^+, Mg^{2+}, Mn^{2+}, Fe^{2+}, Zn^{2+}, Cu^{2+}, Co^{2+}, Mo^{2+}, BO_3^{3-}). Auxotrophies for amino acids, vitamins, or other growth factors do occur for some strains whether deliberately engineered into a genome or naturally occurring.

These bacterial strains are organotrophs and can utilize heterogenous organic compounds as sources of carbon and energy including alcohols, amino acids, carbohydrates, fatty acids, hydrocarbons, organic acids, and polysaccharides. *E. coli* is facultative and can respire aerobically or anaerobically depending upon the carbon–energy source and other growth parameters. However, secondary metabolites produced by the organism vary tremendously between aerobic and anaerobic conditions. With the exception of the anaerobic species *Bacillus infernus* (DSM 10276) (1), the genus *Bacillus* is strictly aerobic or facultative. Morphological and physiological characteristics can be influenced by media conditions with these metabolically responsive bacteria, and care should be taken to standardize media conditions as well as other growth parameters to ensure reproducibility in research or production.

GENERALIZED MEDIA

Bacteriological media may be either defined or undefined with respect to chemical composition. The type of medium selected is entirely dependent on the ultimate goal of the cultivation process.

Chemically Defined Media

In a chemically defined formulation, each component is discretely identifiable as to chemical identity and concentration. The mineral salt-based formulations used in studies of biochemical pathways or gene function are examples of chemically defined media. Auxotrophs can be screened on this type of mineral medium when it is amended with appropriate concentrations of amino acids, vitamins, or other other growth factors (2). Such formulations can also be modified for selectivity by the incorporation of specific carbon or nitrogen sources, inhibitory compounds, or adjustment to physiochemical parameters (e.g., pH, salinity). Chemically defined media are also employed, where possible, in the large-scale production of high-value recombinant DNA-derived biopharmaceuticals. Because product yield is often low for such types of fermentation protein and peptide products, isolation and purification procedures are rigorous. Use of chemically defined media eliminates interfering proteinaceous matter present in the peptones and extracts of complex formulations that further complicates product recovery.

Chemically defined media are not particularly forgiving in use if poorly designed and balanced or poorly prepared. For example, growth inhibition caused by amino acid antagonism is a well-studied phenomenon observed under chemically defined, mineral media conditions. In particular, valine inhibition of *E. coli* K12 has been studied in detail (3). Chemical imbalance, such as an excess of phosphates used as medium buffering agents, can cause deleterious binding and precipitation of trace element divalent cations (e.g., Ca^{2+}, Fe^{2+}, Mg^{2+}) necessary as enzyme cofactors for key metabolic functions. Use of a trace metal in a nonmetabolically active valence or in medium conditions that alter metal speciation (4) can also lead to chemical imbalance in a mineral medium. Sometimes, trace metal and other growth factor requirements in mineral media can be spared. Iron limitation will induce the production of siderophores (iron-binding transport molecules) in *Bacillus megaterium* (ATCC 19213) as well as other bacteria (5) to increase cellular uptake of the required ion. The requirement for Mn^{2+} for sporulation in *B. subtilis* can be bypassed in mineral media by properly balancing the ratio of carbon sources (glucose to malate) entering the metabolic pathway above and below the manganese-requiring enzyme phosphoglycerate phosphomutase (PGA mutase) (6). The vitamin B_{12} requirement in *E. coli* (ATCC 10799; NCIB 8134) can be spared by high levels of methionine (20 μg/mL) added to a mineral growth medium (7).

For nutritionally fastidious microorganisms, such as many animal and human pathogens, development of a good chemically defined medium with respect to the identification of key nutrients, as well as the important balancing of their concentrations, can be laborious and most often necessitates a lengthy list of growth factors. Fortunately, wild-type *E. coli* and *Bacillus* spp. can generally be cultivated with rather simple chemically defined formulations such as M9 medium (see final section, "Media Formulations") composed of a few mineral salts and an organic carbon source. With M9, those essential trace elements and microelements not deliberately represented in the formulation are spuriously supplied as poorly defined contaminants in the distilled water or from the glassware used to prepare the medium. Neidhardt et al. (8) developed a more nutritionally complete defined mineral medium

suitable for use in rigorous biochemical studies of the enterobacteria.

Undefined (Complex) Media

Undefined media, also called complex media, provide many of the nutritional elements as mixtures of protein hydrolysates (e.g., peptones) or extracts (e.g., yeast extract) in which the exact chemical identity and concentration of essential nutrients, trace elements, and growth factors are not known. The demands of the biotechnology industry have influenced the manufacturers of these raw media components to provide detailed lot analyses of hydrolysates and extracts (9) but, for critical needs, any new lot of peptone or extract must be qualified by performance testing before use.

Complex media formulations, rather than those chemically defined, will generally give greater cell yield for most strains of *E. coli* and *Bacillus* spp. Commonly available laboratory media such as soy bean casein digest broth manufactured under different trade names (e.g., Trypticase Soy Broth [BBL]; Tryptic Soy Broth [Difco]) will support vigorous growth for most strains with growth optima close to neutral pH. For general purposes, a combination of 1.0% peptone, 0.5% yeast extract, and 0.2% utilizable carbon source will adequately satisfy the nutritional needs for these heterotrophic organisms as well as for many auxotropic mutants. Complex nitrogen and carbon substrates (e.g., cottonseed meal, molasses) are frequently used in large-scale fermentation media for the microbial production of enzymes and antibiotics; however, lot-to-lot variation in these raw materials can be significant issues in maintaining consistency in media performance.

Although any number of generalized formulations, either chemically defined or complex, will support growth of these microorganisms, strain-specific characteristics, product desirability, enzyme induction or increased expression, or other investigational needs will necessitate optimization of a medium. Greasham and Inamine (10) highlight many of the considerations and decisions that must be made with respect to optimization. The design of media for *E. coli* and *Bacillus* spp. must also take into account a variety of media-induced phenomena that can affect growth or other biochemical activities of the organisms as well as the quantity and types of secondary metabolites produced.

Catabolite Repression

Catabolite repression of carbon or nitrogen metabolism is frequently encountered in both *E. coli* and *Bacillus* spp., although the exact biochemical mechanisms differ between genera. In general, a readily metabolized substrate (such as glucose) can repress the activity of enzymes acting on similar substrates, thereby affecting the nature of secondary metabolite production. For example, α-amylase activity in *B. subtilis*, normally expressed when the organism is grown on starch, is repressed when glucose is present; bacitracin synthesis in *Bacillus licheniformis* is repressed by glucose but unaffected by citrate (11). In *B. subtilis*, the expression of the histidine-inducible, histidine-degradative pathway (*hut* operon) is repressed by rapidly metabolized carbon compounds including glucose, glycerol, and malate (12) as well as by amino acid mixtures (13). Derepression of the *hut* operon occurs when histidine is added to the medium (14).

Diauxic Growth

Under nonlimiting media conditions with mixed carbon–energy sources, bacteria can exhibit diauxic growth in which substrates are preferentially consumed on the basis of ease of assimilation and catabolism while utilization of other substrates is repressed (15). The metabolic shift from one substrate to another is accompanied by a lag in growth. However, using carbon-limited chemostat cultures of *E. coli* ML30 (DSM 1329), Lendemann et al. (16) demonstrated that this phenomenon does not occur under the low nutrient (e.g., μg/L) concentrations frequently encountered in natural environments. Using combinations of as many as six sugars (glucose, galactose, maltose, ribose, arabinose, and fructose), the authors demonstrated that, regardless of the mixture combination or dilution rate, *E. coli* simultaneously utilized all the sugars.

Effects of Nutrient Fluctuations

With media designed to maximize culture growth, care must be taken to ensure that media parameters do not deteriorate in terms of either nutrient depletion or accumulation of inhibitory metabolites. While the need for maintenance of an overall nitrogen–carbon balance of a medium is generally recognized, the effects of minor nutrient depletion can be subtle, but important. For example, under conditions of methionine deprivation, *E. coli* will substitute norleucine in tRNA (A.S. Lubinecki, personal communication, 1994), a potentially serious anomaly in the production of a biopharmaceutical peptide. Phosphate limitation has been shown to cause the loss of the plasmid pBR322 from *E. coli* (17). With respect to metabolic byproducts, rapidly growing aerobic cultures of *E. coli* accumulate acetate to growth-inhibiting levels. Acetate formation in *E. coli* has been shown to limit expression of recombinant growth hormone (18) as well as to limit induction of human interleukin 2 expression in fermentor cultures (19). Kleman and Strohl (20) have studied acetate metabolism in *E. coli* under chemically defined nutritional conditions.

ENRICHMENT AND ISOLATION MEDIA

Obtaining a pure culture of a specific type of bacterium, particularly for the general heterotrophs discussed here, often requires both general and selective enrichment. When the organism of interest is present only in small numbers or as a nonrobust population of the total microbial flora, an initial general enrichment of the sample may help to enhance the presence of the desired organism. With *E. coli* and *Bacillus* spp., almost any general bacteriological growth medium (e.g., tryptic soy broth) can often support enrichment of the desired organism as well as proliferation of any other general heterotroph in a mixed sample. Under such conditions, selective enrichment tech-

niques can help to increase the numbers of the organism or phenotype of interest while suppressing the growth of nondesirable cells in a mixed population.

In some instances, raw samples may include physiologically stressed organisms that might be best recovered with a slightly less nutritious medium such as R2YA (21), or with HTYE (see final section) developed for cultivation of a broad spectrum of "heterotrophically delicate" bacteria (e.g., *Caulobacter, Cytophaga*) and stressed cells, while also being supportive to the growth of general heterotrophs. Clavero and Beuchat (22) determined that heat-stressed *E. coli* 0157:H7 was best recovered with tryptic soy agar rather than with modified sorbitol MacConkey agar.

If strain selection is intent upon a particular phenotypic characteristic (e.g., utilization of heptane as a sole carbon source) rather than upon taxonomic concern, isolation may be done directly by inoculating sample material into nutritionally complete defined media or into dilute complex media supplemented with a substrate compound of interest. Cultivation of sample material under a physiological parameter (alkalophilic or acidophilic conditions) of interest is also a selective pressure. The judicious incorporation of antibiotics in a medium will also keep many of the unwanted organisms in a mixed culture to low levels. In general, prolonged incubation or multiple transfers of any microbial growth that develop in the selection media will eventually give rise to a culture expressing the desired characteristic. Continuous fermentation methods can be used to the same effect to select for a phenotype from a heterogenous cell population, but often the resulting dominant or selected population phenotype is not necessarily genetically stable once selection factors are relaxed (23).

Isolation is accomplished from an enrichment culture generally by spatially separating the cell of interest from other cells in the enrichment culture. This is most conveniently done by streaking aliquots on agar or other solid gel plates with the aim to have discretely separated bacterial colonies to pick, or by serial dilution in liquid media with the hope that the desired cells, being dominant in the population, will eventually be isolated by increasing dilutions of the original enrichment culture.

Because *E. coli* is an indicator organisms of fecal contamination, many versions of media have been developed to quickly isolate and identify the bacteria in potable and nonpotable waters, food, etc. This organism can be isolated using a variety of commercially available selective media (e.g., brilliant green broth, EC broth, lauryl tryptose broth, MacConkey agar). These media contain bile salts (0.15–0.5%) to inhibit the growth of competative gram-positive as well as some gram-negative organisms in a sample mixture. Dyes such as crystal violet or brilliant green are included in some of these formulations to further selectivity for coliforms. The inclusion of lactose (0.5–1.0%) in these media as a fermentable carbon source helps to differentiate *E. coli* from other bile- and dye-resistant organisms. Lactose fermentation is detected either by the presence of gas in an inverted Durham vial contained in a test tube of liquid medium or, with agar media, by differential colony color caused by acid production from lactose and a chemical pH indicator (such as neutral red) included in the medium. Based on the work of Feng and Hartman (24) and Robison (25), the accurate detection of *E. coli* with the classical selective media can be significantly increased by the inclusion of 4-methylumbelliferyl-β-D-glucuronide (MUG) at 50 mg/L. Most *E. coli* strains are β-glucuronidase positive and cleave the substrate to free the methylumbelliferyl moiety, which can then be detected by fluorescence under 365-nm ultraviolet light. Similarly, 5-bromo-4-chloro-3-indolyl-β-D-glucuronide (X-Gluc) can be incorporated as a chromogenic substrate targeting *E. coli*. Gaudet et al. (26) recently evaluated some of these selective media for their usefulness in enumerating *E. coli* from nonpotable waters and concluded that lauryl tryptose agar supplemented with MUG or X-Gluc gave the best sample recovery.

Isolation of spore-forming bacilli can frequently be accomplished by allowing culture growth in a generalized growth medium to proceed until nutrient depletion induces sporulation (see next section). Deliberate limitation of a key nutrient such as a carbon or nitrogen source can often quicken sporulation. Media selectivity can be introduced for pH parameters, salinity, substrate utilization, etc. as desired. As spores of *Bacillus* spp. are among the most heat-resistant of endospore-forming bacteria, heat can be used as a selective factor to eliminate vegetative cells as well as weakly thermal-resistant spores from a sporulated culture. Exposure of the culture to 70–80 °C for a minimum of 10 min is one general method for *Bacillus* spp. selection. Harvest and purification of the spores from remaining vegetative cells and other debris should be performed with gentle procedures, either enzymatically or by density gradient, because strong mechanical methods such as high-speed centrifugation can damage the spores. A single spore isolation can then be attempted by germinating aliquots of the spore sample using agar streak plates.

SPORULATION MEDIA FOR *BACILLUS* SPP.

Bacillus spp. tend to form spores in any suitable growth medium providing a sufficient incubation period. With complex media formulations containing peptones and yeast extract, the incubation time required for depletion of nutrients and stimulation of sporulation is frequently manipulated by a simple reduction of total nutrients as demonstrated with the laboratory medium, sporulation broth (see final section). Increased rates of sporulation can be achieved with the addition of appropriate cations (Ca^{2+}, Mg^{2+}, Mn^{2+}) at assimilable trace metal (millimolar, mM) concentrations (27). Classical media formulations include these trace elements as poorly defined organic chelates supplied in crude soil extracts as in SEY medium (see final section). Many strains of *Bacillus cereus, B. coagulans, B. megaterium, B. subtilis,* and others sporulate well with media based on potato infusions supplemented with yeast extract and 2.5 g/L glucose (28). The pH of these media should be adjusted to approximately 7.2 for pH-neutral strains; sporulation media for alkalophilic and acidophilic strains should be adjusted to a pH supporting optimal growth. If the optimum pH for the sample is known, adjust the pH of the sporulation medium to that of the habitat where the sample was collected. Highly aerobic strains

may require aeration in liquid cultures to obtain a high yield of spores. Elevated glucose levels in a medium during the stationary phase of culture growth can repress sporulation.

As with all microbial processes, the optimal medium and growth conditions for sporulation is strain specific. Similarly, sporulation conditions for optimum chemical resistance may not be the same as those of temperature resistance (29). One should should evaluate more than one medium to find conditions that provide both a high degree of sporulation as well as adequate resistance. Wild-type *B. subtilis* can sporulate in chemically defined media with glucose as a sole carbon source. In studies on transduction with *Bacillus thuringiensis*, LeCadet (30) used media containing peptones to satisfy nitrogen and amino acid requirements, inorganic salts to supply cations, glucose as a carbon and energy source, and potassium phosphate as a buffer for a high yield of heat-stable spores. Setlow and Kornberg (31) noted that small additions of trace metals and glucose to nutrient agar greatly increased hydrogen peroxide resistance of *B. subtilis* spores. Although spore production in *B. stearothermophilus* and *B. thuringiensis* is readily achieved at commercial scale, successful in vitro sporulation of the insect pathogen *B. popilliae* remains elusive, thereby limiting its prospects in biocontrol.

The important enzymes of commercial interest secreted by *Bacillus* spp., as well as many of the antibiotic secondary metabolites produced by the genus, appear at the onset of sporulation. To maximize product yield, a culture must be able to be held in this physiological state without completing the sporulation process. Development of sporulation-deficient strains rather than media design is the more frequent approach to solving this dilemma.

MOLECULAR BIOLOGY MEDIA

A number of excellent manuals such as those of Sambrook et al. (32) and Miller (33) detail the fundamentals of molecular biology work with *E. coli* and *B. subtilis*. This section discusses only the general media most frequently encountered for the manipulations of these organisms.

General Growth

LB (Luria–Bertani) medium (see final section of this article) is the general workhorse formulation used in many molecular biology protocols involving the maintenance and propagation of genetic bacterial stocks. NZCYM medium and its variations (NZYM, NZM) are also used when nutritionally rich formulations are required such as in the propagation of bacteriophage. Similarly, TB (terrific broth) medium (see final section) supports increased bacterial growth and is used to prepare high-yield plasmid DNA or recombinant products from *E. coli, B. subtilis,* and other organisms. Powdered basal media for many of these formulations are available from Sigma.

λ-Bacteriophage Propagation

Because λ-phage tail fibers bind specifically to the *lamB* (maltoporin; maltose-binding protein) receptor on the outer membrane of *E. coli* K12, LB medium supplemented with filter-sterilized maltose at a concentration of 0.2% will induce the receptor in a bacterial culture and help maximize phage adsorption. Glucose in the medium acts as a catabolite repressor. Divalent cations are also required for phage adsorption and integrity, and LB media for λ can be further supplemented with filter-sterilized 2 mM $MgSO_4$. Adsorption by other phage may be enhanced by calcium salts rather than magnesium. However, for the preparation of λ stocks, particularly when liquid media are used, the medium components are adjusted to reduce the amount of adsorption because the lysed phage remain in prolonged contact with bacterial cell debris and thus readsorption to debris can occur, which will reduce overall phage titer when the lysate is centrifuged to remove the cell debris. Thus, the use of LB or NZYCM supplemented with a low concentration of glucose (0.3%) to slightly repress *lamB* and 0.075 mM $CaCl_2$ as a less efficient divalent cation is an effective way to reduce readsorption problems in the preparation of λ stocks from liquid culture.

Recombinant Detection

LB agar supplemented with 5-bromo-4-chloro-3-indolyl-β-D-galactoside (X-Gal) provides an easy way to detect bacterial colonies containing plasmid DNA. The method is used for vectors encoding for the operator-proximal portion of the β-galactosidase (*lacZ*) gene and hosts containing the carboxy-terminal portion of the gene. When a normal plasmid is incorporated into a bacterial cell, α-complementation of gene fragments between the vector–host permit the formation of the functional β-galactosidase enzyme. When the chromogenic substrate X-Gal is included in the medium, the Lac^+ bacterial colonies turn blue. Plasmids containing foreign DNA inserted at the polycloning site located within the vector β-galactosidase fragment do not allow α-complementation with the host gene fragment. Thus, a recombinant bacterial colony arising from a cell transformed with a plasmid containing foreign DNA does not develop the blue color associated with β-galactosidase activity on X-Gal; recombinant colonies remain white. X-Gal is generally used at a concentration of 40 mg/L when incorporated into LB agar. X-gal is not heat stable and must be added to LB agar after the medium is autoclaved. X-gal is not water soluble and is normally prepared as a stock solution in dimethylformamide (20 mg X-Gal/1 mL DMF). The stock solution can be sterilized through a solvent-resistant (e.g., nylon) 0.2-μm membrane filter. The stock solution is light sensitive and should be stored frozen.

Some host strains contain the *lac* repressor, which prevents β-galactosidase activity until derepressed. In this capacity, isopropyl-β-D-thiogalactopyranoside (IPTG) is used as an inducer for enzyme activity. IPTG is also used to induce the TAC promoter. Because it is heat labile, IPTG is added to sterile LB medium to a final concentration of 0.5 mM from a filter-sterilized aqueous stock solution.

Competent Cells and Transformation

Although transformation is not a universal trait in bacteria, strains of *Bacillus subtilis* demonstrate the competent

ability to take up extracellular DNA via a complex membrane-mediated, nonnutritional mechanism considered to be a natural means of genetic exchange for these organisms (34). Only a small percentage of cells within a culture possess the capacity for transformation, and the generation of a competent subpopulation is best achieved with a minimal salts liquid medium amended, as necessary, with growth factors specific to the strain. Although the competent state arises with the stationary phase of culture growth, media conditions that induce maximum sporulation are not necessarily those which support a maximum population of transformation-competent cells because the two functions are physiologically unrelated.

For organisms lacking the ability to develop natural competence, or for which the natural occurrence is low (35), preparation of competent cells can be achieved chemically. For example, competent cells of *E. coli* are commonly prepared by growing a culture overnight in LB broth at 37 °C followed by treatment with highly concentrated solutions of $CaCl_2$ to increase membrane permeability to DNA. Be that as it may, the success of generating a high rate of competent cells is strain dependent as well variable with preparation batch.

THE USE OF ANTIBIOTICS IN MEDIA

Antibiotics are incorporated into culture media to eliminate the growth of contaminants or to select for an antibiotic-resistant population of cells. As antibiotic resistance is often plasmid mediated, the incorporation of a specific antibiotic into a medium that selects for plasmid-containing cells helps to prevent the spurious loss of important genetic elements carried on plasmids which can occur with constant culturing or with further genetic or physiological manipulations.

In general, antibiotics are heat labile and must be added aseptically to media from filter-sterilized or other types of cold-sterilized stock solutions. Although some antibiotics, such as penicillin-G, are stable at room temperature in powdered form, chemical degradation of these compounds begins to occur quickly once an antibiotic is in solution. The rate of degradation increases with temperature and, as noted in Table 1, many of the commonly used antibiotics lose their effectiveness within 3 days at the 37 °C incubation temperature frequently used for bacterial cultivations. In addition, tetracycline is light sensitive, and ampicillin is degraded from media by resistant bacteria. Thus, to maintain antibiotic effectiveness, it is more prudent to add the agent from a freshly prepared stock solution at time of culture inoculation rather than to incorporate the compound during the preparation and aseptic fill of the basal growth medium, especially if the medium is to be stored, even under refrigeration, for any prolonged length of time.

Table 1. Frequently Used Water-Soluble Antibiotics Used in Bacterial Media

Antibiotic	Stability at 37 °C (days)	Working concentration
Ampicillin	3	50–100 mg/L
Chloramphenicol	5	5 mg/L
Gentamycin sulfate	5	50 mg/L
Kanamycin sulfate	5	100 mg/L
Penicillin-G	3	100,000 U/L
Streptomycin sulfate	3	100 mg/L
Tetracycline	4	10 mg/L

Note: Chloramphenical and tetracycline are also ethanol soluble.

MEDIA FOR CULTURE PRESERVATION BY FREEZING OR LYOPHILIZATION

Any medium that gives sufficient growth with robust cell appearance and maintains the important characteristics of the strain is a candidate for a medium used in culture preservation. *Bacillus* spp. retain greatest viability when preserved as spores, and thus strains should be cultivated, if possible, under conditions conducive to sporulation. For nonsporulating bacilli and for strains of *E. coli*, cultures should be grown in an appropriate growth medium and harvested at the late logarithmic phase of growth. Genetically engineered strains may require the addition of a selective agent (e.g., antibiotics) to the medium to retain unstable genotypes. Previous preservation studies on plasmid containing strains of *E. coli* and *B. subtilis* indicated that plasmids were best retained with liquid nitrogen preservation. Plasmids in *E. coli* and in *B. subtilis* spores were also not affected by freeze-drying. However, freeze-drying of vegetative cells of *B. subtilis* resulted in loss of cell viability by an order of magnitude and also resulted in the requirement of a lengthy postlyophilization rehydration period before full plasmid-coded antibiotic resistance returned. Thus, the *B. subtilis* culture grown from vegetatively harvested lyophilized cells required an antibiotic-free medium for initial growth (36).

Cells of either bacilli or *E. coli* can be frozen in liquid nitrogen in growth medium supplemented with either 10% glycerol or 5% dimethyl sulfoxide (DMSO) as the cryoprotectant. This is most easily done by adding 20% sterile (autoclaved) glycerol to an equal volume of cells suspended in the culture medium or by adding filter-sterilized DMSO to cells suspended in the culture medium to a final concentration of 5%. If the culture is to be lyophilized (freeze-dried), cells should be harvested from the growth medium and suspended in an appropriate cryoprotectant such as 20% skim milk (sterilized in test tubes at 116 °C for 20 min) or the growth medium to which separately autoclaved 24% sucrose is added to a final concentration of 12%. A more complex cryoprotectant medium is a filter-sterilized reagent composed of trypticase soy broth (BBL 11768); sucrose, 100 g; bovine serum albumin fraction V, 50 g; and distilled or deionized water to 1.0 L.) Actual preservation methods are detailed in a number of publications (37,38).

MEDIA FORMULATIONS

1. HTYE Medium
   Trypticase peptone (BBL 11921), 5.0 g
   Yeast extract, 2.0 g

HEPES, 4.0 g
Distilled water, 1.0 L

Dissolve ingredients one at a time in distilled water. Adjust to pH 7.1 with NaOH. Sterilize by autoclaving at 121 °C for 15 min.

2. SEY Medium
Difco yeast extract, 1.0 g
K_2HPO_4, 0.2 g
Agar, 15.0 g
Soil extract (see below) 1.0 L

Adjust medium for final pH 7.0 and sterilize at 121 °C for 15 min.

Soil extract: Autoclave 500 g air-dried, sifted garden soil of high fertility with 500 ml tap water in a 2-L flask for 30 min. When cool, decant the supernatant, filter through paper, and bring to 500 ml with additional tap water.

3. Sporulation Medium
Yeast extract, 1.0 g
Beef extract, 1.0 g
Tryptose, 2.0 g
$FeSO_4$, 2.0 mg
Glucose, 10.0 g
Agar, 15.0 g
Distilled water, 1.0 L

Adjust medium for final pH 7.2. For broth, eliminate agar and reduce concentration to one-third of the given quantities. Sterilize at 121 °C for 15 min.

4. LB (Luria–Bertani) Medium
Tryptone (Difco 0123), 10.0 g
Yeast extract, 5.0 g
NaCl, 10.0 g
Distilled water, 1.0 L

Sterilize by autoclaving at 121 °C for 15 mins. Final pH 7.0.

5. NZCYM Medium
NZ amine (Sigma C 0626), 10.0 g
NaCl, 5.0 g
Bacto–yeast extract (Difco 0127), 5.0 g
Casamino acids, 1.0 g
$MgSO_4 \cdot 7H_2O$, 2.0 g
Distilled water, 1.0 L

Adjust to pH 7.0 with NaOH. Sterilize at 121 °C for 15 mins. Variations: NZYM (NZYCM without casamino acids); NZM (NZYM without yeast extract).

6. Terrific Broth
Bacto-tryptone (Difco 0123), 12.0 g
Bacto-yeast extract (Difco 0127), 24.0 g
Glycerol, 4.0 mL
Distilled water, 900.0 mL

Sterilize at 121 °C for 15 mins. Cool to room temperature and add sterile buffer solution (as below), 100.0 mL

Sterile buffer solution: KH_2PO_4, 2.31 g; K_2HPO_4, 12.54 g; distilled water, 90.0 ml. Sterilize at 121 °C for 15 min.

7. M9 Medium
Basal medium
Na_2HPO_4, 6.0 g
KH_2PO_4, 3.0 g
NaCl, 0.5 g
NH_4Cl, 1.0 g
Agar (for solid medium), 15.0 g
Distilled water, 990.0 mL

Adjust basal medium to pH 7.4. Autoclave at 121 °C for 15 min and cool to less than 50 °C. Aseptically add the additives listed next. If agar is needed, autoclave mineral salts and agar separately as 2× solutions and aseptically combine after sterilization.

Additives (sterilized by autoclaving as separate solutions at 121 °C for 15 min)
1 M $MgSO_4$, 2.0 mL
20% glucose, 10.0 mL
1 M $CaCl_2$, 0.1 mL

OUTLINE

INTRODUCTION

The key to the successful development of a chromatographic procedure for the industrial-scale purification of proteins is to establish a high-productivity method that delivers the product in sufficient purity. Laboratory-scale protocols are usually set up with special regard to resolution, which is maximized by choosing high-performance methods based on small adsorbent particles and high-pressure equipment. On the process scale, however, high throughput seems to be the major goal, so during scale-up the small particles usually have to be replaced by larger ones due to pressure drop limitations at high-flow velocity in large columns. Additionally capacity per unit volume of adsorbent becomes an issue, thus requiring the use of porous adsorbents, which offer a high internal surface area for product adsorption. When using comparatively large porous adsorbents (d_p = 50–200 μm) the process performance is mainly determined by the velocity of protein transport to the binding sites situated on the internal surface. Because large (protein) molecules are characterized by small diffusion coefficients in free solution ($D = 1 - 50$

$\times 10^{-12}$ m^2/s) and because "hindered" transport within a porous structure leads to even lower "effective" diffusion coefficients, protein chromatography in these media has been described as being limited by slow intraparticle transport (1). Large-scale operations therefore seem to be characterized by the compromise between low pressure drop at high flow velocity and slow mass transport employing larger adsorbent particles.

The driving force for new developments in stationary-phase design has been the need to reduce the limitation by intraparticle mass transport. This may be achieved by increasing the influx velocity into the particle by enhancing diffusive transport (2) or by perfusing the stationary phase in order to support (or even replace) diffusive movement of the solutes to the ligands by convection. Perfused particles with very short diffusive pores are one option to accomplish this (3). An even more consequent way is the use of a continuous stationary phase, where the internal surface is completely accessible by convection, thus removing the necessity for diffusive motion. Adsorbents manufactured accordingly may be short in length (L) because the concept of convective solute transport essentially speeds up the sorption process and permits short residence times, t_C ($= L/v$). Sufficient capacity (adsorbent volume) is supplied by units of increased diameter, which has up to now resulted in a membrane type of design characterized by a low L/d ratio. This concept has first been realized employing modified microfiltration membranes of variable design (hollow fiber, flat sheet or membrane stack [4]), therefore the description *membrane chromatography* is justified despite the fact that a microfiltration membrane is not the only possible stationary phase fulfilling the criteria just discussed. The increasing importance of membrane adsorbents is demonstrated by two recent reviews (5,6). In this article the basic ideas behind membrane chromatography are elucidated from a conceptual point of view, supported by a short theoretical analysis. Possible limitations of the technology are discussed, followed by an attempt to position the membrane concept within a train of protein purification methods. Finally applications of adsorptive membranes on small and pilot scale are used to demonstrate the large potential of this technology as a highly productive method of purifying proteins on the process scale.

THE BASIC CONCEPT

Improved Mass Transport

As discussed earlier, membrane adsorbents try to overcome the diffusion limitation present in porous particles by allowing convective transport of solutes to the ligands. This is achieved by attaching ligands to the internal surface of stationary phases, which contain mainly through-pores and only few or no dead-ended pores. The underlying picture is the modification of the internal pore surface of microfiltration membranes with ligands in a way that, by pumping the feed solution through the membrane, the solutes are convectively transported to their binding site. Slow diffusion in dead-ended pores, as is the case with porous adsorbents, is thus avoided. The situation is depicted schematically in Figure 1. Additionally, a continuous stationary phase is used, so packing problems, which are common with particle-based media and necessitate a minimum bed length in order to neutralize packing irregularities, are circumvented. As a result, from these characteristics, adsorbents of low L/d ratio may be built, which stand for high productivity at short residence time due to fast mass transport in a continuous matrix. Prerequisite, however, is that the adsorbate solution be homogeneously distributed over the whole frontal area of the membrane, otherwise flow irregularities will neutralize the advantages mentioned. This is discussed in more detail in the following sections.

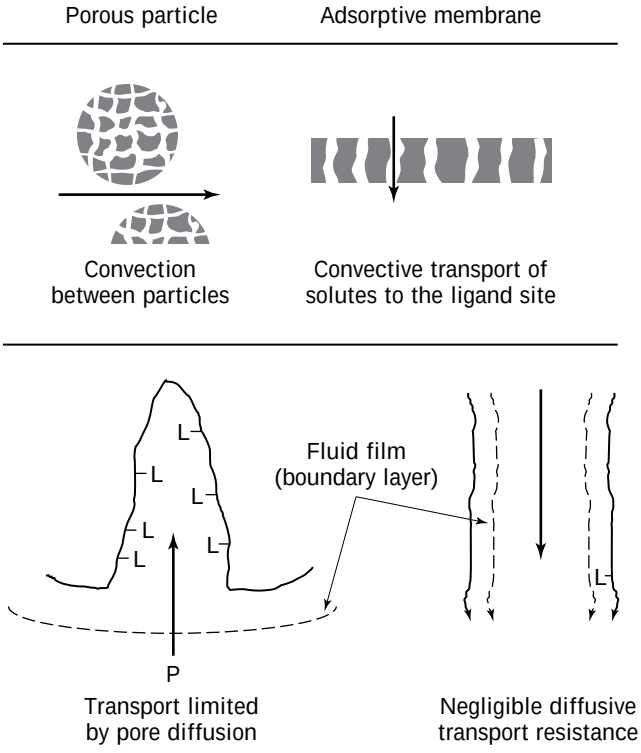

Figure 1. Schematic representation of the major transport characteristics of adsorptive membranes and porous particles.

Geometric Formats

Adsorbents fulfilling the criteria developed may be arranged in different formats. As shown in Figure 2, it is possible to differentiate between four basic concepts: single or stacked flat-sheet membranes (A), hollow-fiber modules (D), radial-flow cartridges containing spiral-wound membranes (C), and cartridges packed with continuous stationary phases in the form of membranes or rods (B). All these arrangements are commercially available; a complete list of available products, however, is difficult to compile because the life-span on the market of some of these products has been limited. The reader is referred to the information provided by Langlotz et al. (7), Roper and Lightfoot (5), and Thömmes and Kula (6).

Single-sheet membranes may be employed in suitable filter holders, as long as sufficient care is taken to equally distribute the process liquid across the frontal membrane

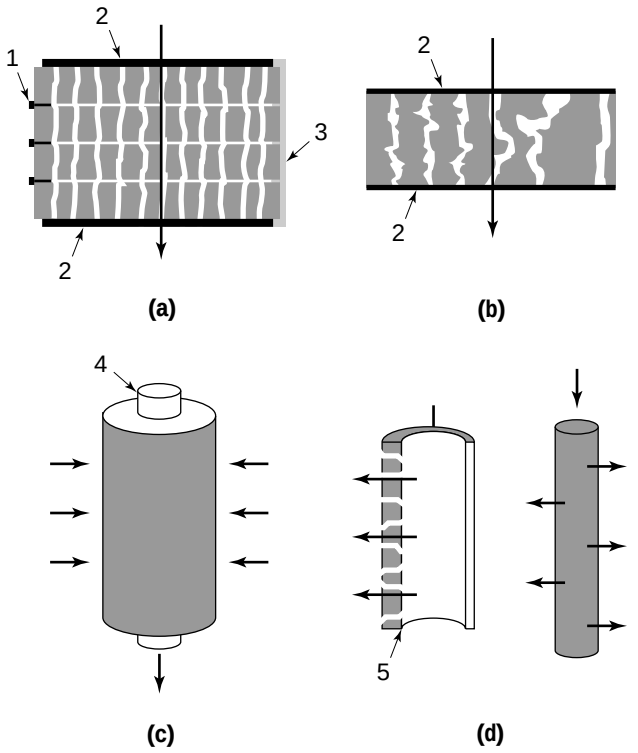

Figure 2. Schematic representation of the four major classes of membrane adsorbents: (**a**), stack of flat sheet membranes; (**b**), continuous cartridge with through-pores; (**c**), radial flow unit with spiral wound membranes; (**d**), hollow-fiber membrane; 1, individual gasket; 2, distributor and collector plate; 3, complete sealing around a membrane stack (e.g., silicone); 4, central tube for liquid collection; 5, cross-cut through an individual hollow-fiber.

area and to efficiently collect the liquid after passage through the membrane. The arrangement of membranes in stacks allows the increase of the capacity of an individual unit as well as an adjustment of the length of the adsorbent bed. The sheets must be separated by proper sealing in order to avoid fluid flow around the membranes instead of through them. This may be achieved by single gaskets or by embedding the stack in a suitable sealing substance (e.g., silicone). Alternatively a continuous adsorbent packing with thoroughgoing pores may be used, thus making the stacking of individual sheets obsolete. Radial-flow cartridges contain an internal tubing for fluid collection, which is surrounded by a spiral-wound membrane sheet. The liquid is transported in a radial direction from outside to inside, thus keeping the column aspect ratio, L/d, small, as is the case in a flat-sheet membrane. The same is true for hollow-fiber modules, where the fluid passes the membrane perpendicular to the influx direction. L is defined here as the wall thickness of a single fiber. These modules may be operated in a dead-end mode with the column outlet sealed, so that all the liquid must pass through the membrane; alternatively a cross-flow mode may be chosen with the possibility to recycle the process solution. The total capacity of a hollow-fiber adsorption module can be adjusted by bundling several fibers in a single module.

Static Capacity

As already discussed, on a preparative scale the capacity per unit volume of adsorbent available for a certain purification task becomes an important issue because adsorbent cost as well as plant space requirements of the whole purification unit have to be taken into account in economic considerations. Because the ligands are attached to the internal surface of stationary phases, their specific surface area, $a(m^2/m^3)$, determines the equilibrium capacity in a first approximation. Champluvier and Kula measured a for nylon membranes ($d_p = 1.2\,\mu m$) as 250 m^2/m^2 of frontal area (8). Assuming an average membrane thickness, L, of 200 μm we obtain a as 1.2×10^6 m^2/m^3. Conventional porous particles for protein chromatography have a specific area, which is significantly larger than this value (e.g., 1.5×10^7 m^2/m^3, our own measurements with the silica-based matrix Bioran CPG, Schott, Germany, 200-μm average particle diameter, 100-nm average pore diameter), so this seems to be a major drawback of membrane-based stationary phases. In fact membrane adsorbents with a monolayer coverage of ligands on their internal pore surface have suffered from reduced static binding capacity, as has been summarized by Roper and Lightfoot in their review (5). An approach to circumvent reduced capacity is the introduction of a three-dimensional binding layer on the pore surface. This is achieved by graft polymerization of monomers containing functional groups, which may be derivatized to protein-binding ligands. The resulting functionalized polymer layer works as a three-dimensional binding space with a gellike structure, which is able to take up adsorbate molecules in multiple layers, as depicted schematically in Figure 3. This technique has been applied to hollow-fiber membranes with great success (9–19) and is also used in commercially available flat-sheet membrane adsorbents (Sartobind, Sartorius, Göttingen, Germany) yielding a capacity comparable to porous adsorbent particles (20). The increase in static capacity for standard proteins compared with (theoretical) monolayer coverage has been reported to be between 4- and 20-fold for hollow-fiber modules (16) and up to 100-fold for flat-sheet membranes (21). Wang et al. compared the static capacity of polymer

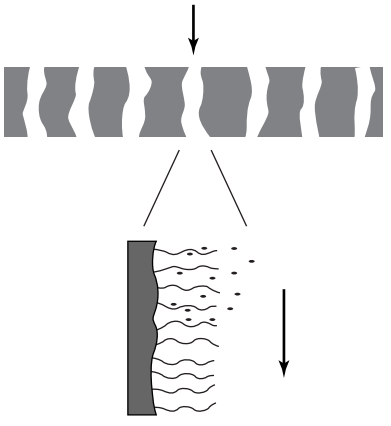

Figure 3. Schematic representation of the modification of the internal pore surface with grafted polymer ligands.

coated membranes for cytochrome *c* to membranes with monolayer ligand coverage, as well as to porous particles, and found the three-dimensional ligand layer to yield significantly higher values (22). However, as is discussed later, the gellike structure of the layer may change the mass transfer characteristics of the membrane adsorbents, a fact that has to be included in the analysis of the sorption performance.

Process Performance

When the suitability of a new adsorbent design for the large-scale purification of proteins is to be estimated and compared with established stationary phases, a benchmarking method must be defined. On the process scale, an important question is, how much product may be obtained within a certain period of time with a given amount of adsorbent? Additionally, the product should have sufficient purity in order to reduce the overall number of process steps in a purification train. Summarizing, the basic questions are the following:

- Which throughput is possible with a given set-up as a result of the permeability of the stationary phase (mechanical limitation)?
- Which throughput is possible with a given set-up as a result of the efficiency of the sorption process (dynamic limitation), in other words, is the static capacity of the adsorbent used well enough under the process conditions chosen?
- Which product purity is achieved with a given set-up under the process conditions chosen (resolution limitation)?

The permeability, B, of a membrane adsorbent is a function of the adsorbent's pore diameter and of the overall porosity of the matrix; typical values may be calculated from pressure-drop data available from the literature. Values ranging from 7×10^{-16} m^2 for continuous phases from methacrylate block polymers with 0.4-μm pore diameter (23), to 2×10^{-15} m^2 for 1.2-μm d_p hollow fibers with grafted polymer ligands (24), and 2.5×10^{-14} m^2 for commercially available stacks of flat-sheet membranes (average $d_p = 15\ \mu$m) (20) may be found. The pressure drop in the adsorption unit may then be calculated for a given set of operating conditions (L, v, η), after equation 1.

$$\Delta p = \frac{v \cdot L \cdot \eta}{B} \tag{1}$$

The dynamics of the sorption process may be determined from frontal adsorption experiments. The deviation of measured breakthrough curves from the ideal step function shows how efficiently the static capacity of the adsorbent is used. Measuring the breakthrough capacity, Q_D, (at 1, 5, or 10% breakthrough) under different experimental conditions (e.g., by varying L and v) allows the definition of the process conditions that make the best use of the static capacity of the adsorbent. In addition, a theoretical analysis will yield characteristic quantities (e.g., numbers of transfer units, plate heights, or transport and dispersion coefficients) that allow a prediction of the process performance according to standard models (21,25–27).

The overall performance, however, must take washing, elution, and regeneration into consideration; this can be expressed as the total number of bed volumes required for all of these operations, α. The product yield is considered by the recovery ratio, R_E. Productivity may be defined as amount of product per unit time and unit adsorbent volume, as shown in equation 2 (21).

$$P = R_E \frac{1}{\left(\frac{Q_D}{C_0} + \alpha\right)} \left(Q_D \cdot \frac{v}{L}\right) \tag{2}$$

Finally the product purity should be addressed by introducing the resolution, R_s, of the membrane-based separation under process conditions. An attempt to optimize R_s will often show that a compromise has to be found between maximizing the throughput at low L/d and maintaining high resolution, because the short bed lengths make adsorptive membranes into typical low-plate-number systems (28). Coffman et al. have shown, however, that most protein separations may be run successfully by employing membrane adsorbents because separation will occur according to an on–off separation mechanism that requires no separation by differential migration in long columns (29).

To summarize, the quality of a membrane adsorption method will be defined by the product purity it delivers at maximized productivity. A significant increase of this quality compared with standard methods using porous particles is anticipated due to the fact that the improved mass transport capability allows high throughput at low L/d at maintained resolution under on–off separation conditions. The factors that may limit the achievement of this ambitious goal are discussed next.

LIMITING FACTORS IN MEMBRANE ADSORPTION PROCESSES

As with all processes based on fixed beds, sorption dynamics of adsorptive membranes may be limited by mixing, mass transport, and the kinetics of the binding reaction. In order to discuss these effects precisely, one must attempt to define them according to the specific details of membrane adsorption units. Kinetic limitations arise from the rate of formation of the adsorbate–ligand complex, which is described by the forward reaction rate constant, k_a. Together with the rate constant of dissociation of the complex, k_d, we obtain the dissociation constant of the binding equilibrium, K_D (k_d/k_a). Further limitations are caused by slow transport of adsorbate molecules from the bulk solution to the binding site (e.g., diffusive motion through the fluid boundary layer above the binding surface). Although the concept of throughgoing pores in membrane adsorbents has been invented to overcome slow diffusion in dead-ended pores, the membrane production process may result in adsorbents with some pores of that kind, so in specific cases pore diffusion has to be considered in the description of sorption dynamics. Additionally, as

already mentioned, the attachment of a three-dimensional adsorbing layer to the internal pore surface must be regarded as a potential mass transport barrier. Mixing in adsorptive processes should be split into three major effects: fickian dispersion, nonideal fluid flow within the adsorbent, and extracolumn mixing (30). The first effect describes the dispersive motion "against" the direction of convective flow, the second effect accounts for irregularities within the adsorbent, leading to uneven fluid flow through the packing, whereas the third summarizes contributions of tubing, extracolumn dead volumes, liquid distributors and collectors, zone broadening, and so forth. Very often these different contributions are lumped together in a single dispersion coefficient, D_{ax}, which is then characteristic for the whole experimental set-up rather than for the adsorbent itself. In the following the respective importance of these limitations is discussed in detail in order to provide a basis for the prediction of the performance of adsorptive membranes in the purification of biomolecules.

Mixing

Roper and Lightfoot (30) analyzed peak broadening in stacked flat-sheet membranes under nonbinding conditions with a specific flow-reversal technique in order to differentiate between fickian dispersion, nonideal fluid flow within the adsorbent, and extracolumn mixing. They used the height equivalent of a theoretical plate (HETP) concept to determine the individual contributions to the overall peak broadening and found the plate heights, h, resulting from fickian dispersion to be 1–5 μm for a range of flow velocity, v, between 0.5 and 4 cm/min. These values were in accordance with theoretical considerations, which predicted h as a function of the dispersion coefficient D_{ax} and of v according to equation 3.

$$h = \frac{2 \cdot D_{ax}}{v} \tag{3}$$

Values for h reported in literature for adsorptive membranes, however, were between 20 and 200 μm and showed a slight increase with linear velocity. This difference could be attributed to extracolumn effects and nonideal fluid flow. Peak broadening by a factor of 1.7 occurred due to extracolumn dispersion; the additional difference between h measured in this work and h in the literature data arose from uneven flow distribution in the stack. Similar results were reported by Gebauer et al. (21), who found the mixing in stacks of commercially available flat-sheet membranes (represented by an overall D_{ax}) to be 10-fold higher compared with an estimation based on literature correlations. This difference was attributed to extracolumn effects as well. Enlarged overall mixing may be a significant influence on the performance of membrane adsorbents. This was demonstrated in a scale-up study on the isolation of human serum albumin from plasma using stacks of ion exchange membranes (20). The increased mixing found with large-scale modules compared with laboratory-scale units led to a more than threefold reduction of the productivity of the process. Josic et al. (31) investigated the influence of liquid distribution at the column inlet of cartridges with a continuous stationary phase of type B (compare Fig. 2). In the case of nonoptimized inlet design, a significant part of the fluid passed through the central region of the unit, thus leaving large parts of the membrane unreachable by convective transport. The uneven flow distribution led to a significant loss of performance of chromatographic separations employing these units. With optimized inlet design, resolution was comparable with established HPLC methods. Reif and Freitag (32) demonstrated the importance of reduced dead volume behind the membrane; a large mixing zone led to deteriorated resolution in the analytical separation of standard proteins.

Nonuniform flow distribution may be caused by variations in the pore size of adsorptive membranes. Suen and Etzel (26) as well as Liu and Fried (33) demonstrated by computer simulations that a wide pore-size distribution may lead to significantly flattened breakthrough curves during frontal protein adsorption and thus to a strongly reduced useful capacity of the adsorbents. Similar effects were shown for variations in membrane thickness. As a consequence, stacking of membranes was recommended to reduce these effects. Kim et al. described the modification of hollow fibers with grafted polymer chains bearing phenylalanine and tryptophan as pseudoaffinity ligands for immunoglobulin adsorption. The deviation of protein breakthrough from ideal behavior with these adsorbents was also attributed to a wide distribution in pore length (12). The distribution in pore diameter in protein A modified-hollow-fiber modules was described by Klein et al. as the reason for incomplete use of the static capacity of these adsorbents in immunoglobulin capture (34). The influence of overall mixing on performance during frontal adsorption was investigated in a theoretical study by Suen and Etzel (26). These authors used the dimensionless column Peclet number, Pe, to quantify dispersion according to equation 4 (v_e is the interstitial flow velocity).

$$Pe = \frac{v_e L}{D_{ax}} \tag{4}$$

Peclet numbers above 40 were described to be sufficient to exclude a deteriorating influence of mixing on the breakthrough behavior during frontal adsorption to membrane stacks. Because Pe is proportional to the bed length, augmented mixing (represented by increased D_{ax}) may be compensated for by increasing L. Similarly Liu and Fried (33) reported a Pe above 25 to be sufficient to neglect dispersion as a possible limitation of the sorption process. It is important to note that these considerations were set up for frontal adsorption of a one-component system; stronger boundary conditions may be required for the separation of a multicomponent system.

To summarize, as long as sufficient care is taken during process design to minimize extracolumn effects as well as nonuniform flow, mixing phenomena are unlikely to be the limiting factors in membrane chromatography. However, it has to be kept in mind, that adsorptive membranes are used in a chromatographic process; therefore standard criteria of filtration module design will not meet the requirements of a sorption process and may possibly lead to a loss of the advantages of the membrane-based process.

Mass Transport

When dealing with porous particles for protein purification, there are two potential sources of transport resistance to adsorption: transport of adsorbate from the bulk of the solution to the external particle surface, and transport within the particle to the binding site. In this case the general perception is that fluid-side transport is an order of magnitude faster than transport within the adsorbent; therefore film transport resistance is often neglected in a simple analysis. Band spreading in frontal analysis, as well as peak broadening during chromatography, then is attributed to slow, often hindered, intraparticle diffusion. The concept of using membranes with throughgoing pores for protein adsorption was supposed to remove the transport resistance by reducing the characteristic length for protein diffusion to the ligands. Brandt et al. (4) provided a general estimation of the importance of mass transport for the efficiency of an adsorptive membrane by relating the characteristic diffusion time in a membrane pore, t_D ($t_D = d_p^2/D$), to the contact time, t_C ($t_C = L/v$), during passage through the membrane. Efficient usage of the static capacity was supposed to take place if $t_C \gg t_D$. Inserting standard values for adsorptive membranes into this equation ($d_p = 3 \times 10^{-6}$ m, $L_{\text{single sheet}} = 2 \times 10^{-4}$ m, $v = 8.3 \times 10^{-4}$ m/s) and assuming an average diffusion coefficient, D, of 5×10^{-11} m^2/s we obtain $t_D = 0.18$ s, whereas t_C even for a single membrane is 0.24 s. Therefore a stack of 10 membranes, which is often found in commercially available modules, easily fulfills the condition, which allows us to neglect diffusive transport resistance. This is in contrast to standard porous particles, where t_D is based on the particle radius and therefore can be estimated as 40.5 s for the same protein in a particle 9×10^{-5} m in diameter.

The absence of dead-ended pores and the concomitant disappearance of the intraparticle transport resistance should make diffusion through the fluid boundary layer above the ligands the only transport step (see Fig. 1) in membrane chromatography. The rate of transport through this layer is dependent on the free diffusion coefficient of the adsorbate as well as on the thickness of the layer. Because interstitial flow velocities in narrow pores of microfiltration membranes are comparably high and boundary layer thickness thus may be low, this transport resistance commonly is regarded as not likely to limit the sorption process. Suen and Etzel (26) demonstrated the validity of this approach for membranes with small pore diameter by comparing the characteristic time needed to diffuse through the fluid boundary layer with the average residence time in a module. They were able to show that even for very small diffusion coefficients (i.e., large protein molecules) the residence time in a correctly designed membrane stack is much higher than the diffusion time through the fluid film, so the importance of this transport resistance is low compared with other possible limitations. In cases of much larger pore diameters these considerations may no longer be valid. Adisaputro et al. (35) measured the dynamics of whey protein uptake to membranes of very large pore diameter (50–300 μm) and found reduced capture efficiency with decreasing residence time. Calculation of the fluid film diffusion time for an average protein showed that, with these large pore diameters, film transport was a likely candidate for the dominant limitation of sorption efficiency.

As mentioned earlier, the introduction of a three-dimensional ligand layer to the pore surface may also introduce a mass transport resistance. Gebauer et al. (21) investigated commercially available ion exchange membranes with respect to their sorption dynamics and found a limitation of sorption efficiency by a diffusion mechanism. Depending on the length and density of the ligand layer a pore or solid diffusion mechanism of protein transport was identified. The breakthrough capacity, however, could be maintained on a very high level for a wide range of flow velocities, a fact that was attributed to convection-aided mass transport into the flexible chains of the ligand layer. Attaching polymer-grafted ligands to the internal pore walls of hollow fibers also yielded stationary phases with three-dimensional adsorbing layers. Here no dependency of breakthrough behavior from residence time in the module was detected, thus supporting the thesis of fast protein influx into the ligand sphere (12,15–17,24).

Mass transport limitations are not as dominant in membrane adsorption as they are in standard protein chromatography using porous particles. The complete neglecting of transport resistance, however, is possible only under certain conditions. Therefore transport in adsorptive membranes should be analyzed carefully during process design based on these stationary phases.

Binding Kinetics

If axial mixing and mass transport may under certain circumstances be excluded as potential limiting factors of sorption efficiency, the kinetics of the protein–ligand interaction becomes the focus of attention. Brandt et al. (4) used a second-order rate expression to estimate the reaction time, t_R, for interaction of BSA with a monoclonal antibody (MAb) affinity ligand. They obtained $t_R = 5$ s, a significantly higher value than the average diffusion time in membrane pores, which was calculated earlier. From this estimation it can be deduced, that slow association kinetics may limit the performance of affinity-membrane adsorbents. A similar situation was predicted by Suen and Etzel (26) from a thorough theoretical analysis, which was later experimentally verified with the pepstatin A/pepsin affinity system (36). Kinetic limitations were also found to be responsible for deviations of protein breakthrough from an ideal step function in dye ligand/dehydrogenase pseudoaffinity systems employing stacks of flat-sheet membranes (37). Briefs and Kula (38) reported the onset of peak broadening due to kinetic limitation with a similar pseudoaffinity interaction from t_C below 20.5 s. For ion exchange interactions, however, no kinetic limitation could be verified within the range of experimental conditions ($t_C = 5.1$ to 20.5 s). An investigation on kinetically limited membrane chromatography was performed by Nachman et al. (39–41) employing hollow-fiber modules with affinity ligands attached to the internal pore surface. In this study it was shown that reducing the residence time in the module in turn reduced the capture efficiency of the adsorbents. In addition, under all experimental conditions, t_C was well

above t_D, which had been calculated based on the membrane geometry and the diffusion coefficient of the adsorbate. Also the capture efficiency was independent from initial concentration, as can be predicted for kinetic limitation under conditions of a rectangular isotherm (21). Kinetically limited adsorption may be exploited in membrane chromatography to separate adsorbate molecules that have identical binding isotherms but different association rate constants. In standard porous adsorbents these pairs cannot be separated due to the fact that slow diffusion in the pores leads to the formation of a local equilibrium between adsorbate in the pore liquid and bound adsorbate. Membrane adsorbents are sensitive to differences in adsorption kinetics, provided neither mass transport nor mixing are "hiding" the kinetic differences. This was theoretically predicted (27) and proven experimentally (36) for an affinity interaction based on stacks of flat-sheet membranes.

Adsorptive membranes offer a rare opportunity to investigate effects of binding kinetics in adsorptive processes. The fact that this is possible underlines the excellent mass transport characteristics of these matrices, which allow very fast protein purification under conditions of protein–ligand interactions as the rate-limiting step in the sorption process. However, this seems to be limited to affinity interactions, which show comparatively slow association rates with ligands attached to planar surfaces due to higher steric requirements. With fast ion exchange interactions, even adsorptive membranes have not been able to demonstrate kinetic effects during protein sorption.

POSITIONING OF MEMBRANE ADSORPTION IN A PURIFICATION TRAIN

Now that adsorptive membranes have been characterized according to their basic properties, where should they be introduced into a standard protein purification scheme? Wheelwright differentiated between initial recovery, low-resolution purification, and high-resolution purification in a downstream process (42). Initial recovery is supposed to deliver a clarified product solution of reduced volume, whereas low-resolution purification should lead to a significant enrichment of the target molecule and to the removal of major contaminants. High-resolution purification refers to the removal of minor impurities with properties similar to those of the desired product, as well as final polishing (e.g., separation of correctly processed molecules from false variants, multimers, etc.). Depending on the design of the adsorption unit, adsorptive membranes can accommodate any of these tasks.

Krause et al. demonstrated that application of dye–ligand affinity membranes in a cross-flow mode allowed the purification of malate dehydrogenase from *E. coli* homogenate (43). A clarified, concentrated, and initially purified product solution was obtained after elution, thus demonstrating the feasibility of membrane adsorption for integration into primary recovery. Additional support for the use of membrane-based adsorption in this early process stage comes from the isolation of proteins from unclarified whey, which was accomplished with large-pore membrane stacks (35).

A second assignment in the area between initial recovery and low-resolution purification is the use of adsorptive membranes for product capture from diluted but already clarified solutions. Good mass transport characteristics together with fast binding kinetics make ion exchange membranes a successful candidate; hydrophobic interaction and pseudoaffinity ligands are also suitable for this task (11,17,18,44–46).

Low-resolution purification is achieved when membranes are used for the separation of proteins in order to initially fractionate clarified product solutions (32,47–50). Sequential arrangement of membrane units for different separation mechanisms allows the development of a multidimensional separation concept (51).

The use of membranes for high-resolution purification was realized in high-performance membrane chromatography (HPMC) (23,31,52). Here the properties of continuous stationary phases of type B (Fig. 2) are used with ion exchange, hydrophobic interaction, and reversed-phase ligands. Affinity (34,53,54), immunoaffinity (40), and receptor affinity membranes (41) also belong to this category, although they may be used early in a purification train in order to introduce a high selectivity step in the very beginning of the downstream process. Fast binding kinetics favor the use of very dilute feed solutions because high-affinity adsorption may be operated with large throughput in membrane devices, even if the feed concentration is on the order of magnitude of the dissociation constant, K_D, of the adsorbate–ligand interaction (39).

The versatility of adsorptive membranes in serving the needs of the different stages of a downstream process is summarized in Figure 4.

OPTIMIZING THE PERFORMANCE OF ADSORPTIVE MEMBRANES

If we define the performance of a membrane adsorption unit according to the parameters described earlier ("Process Performance") as the realization of a desired product purity at maximized productivity, then the optimization task has two main goals: the achievement of a certain resolution and the simultaneous increase of throughput. The problem of maximizing throughput requires information on mechanical stability of the stationary phase, the quality of fluid flow through the unit, and knowledge of the overall kinetics of the sorption process. The latter point may in a first approximation be reduced to the question of residence time within the adsorbent phase. As discussed in the section "Mass Transport", adsorptive membranes are supposed to have superior transport properties even if the static capacity is increased by introducing a three-dimensional ligand layer on the internal membrane surface. This fact in turn reduces the residence time ($t_C = L/v$) that is needed for efficient usage of the available capacity. An indicator of this efficiency often used in protein chromatography is the breakthrough capacity, which increases with residence time and is dependent on the performance of the stationary phase with regard to the overall dynamics of the sorption process, be it limited by transport processes, dispersion, or binding kinetics. The better the

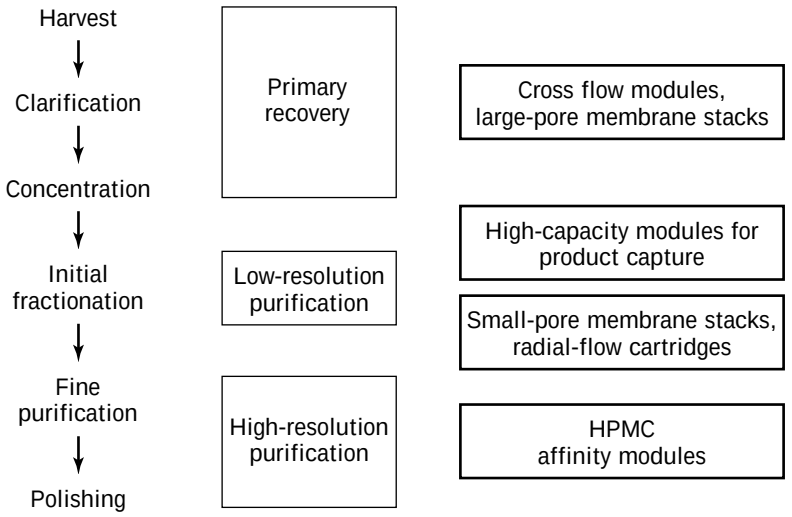

Figure 4. Positioning of membrane adsorbents in a purification train.

dynamic properties of the adsorbent, the shorter the residence time can be without compromising the breakthrough capacity. In the case of adsorptive membranes this allows using adsorbent beds that are short in length (L) and can be operated at high fluid velocity (v). The work of Yamamoto and Sano (55) as well as equation (2) predict the productivity to increase with the breakthrough capacity, and to decrease with t_C. As breakthrough capacity increases with t_C, there is an optimum in t_C with respect to productivity. The advantage of adsorptive membranes is that efficient usage of the static capacity is already obtained at short t_C; therefore a high productivity of membrane-based adsorption methods can be anticipated.

A sophisticated way of predicting the dynamic behavior of membrane adsorbents has been presented by Suen and Etzel (26,27). A numerical solution of the equations describing membrane adsorption was used to analyze the influence of operating parameters on performance. In addition to breakthrough behavior, the separation of two proteins in kinetically limited chromatography on membrane stacks was simulated and proven experimentally. As shown by Gebauer et al. (21) productivity of membrane adsorption systems can also be analyzed based on analytical solutions of the equations describing protein breakthrough, if a single limiting step can be identified for the process under investigation.

Similar considerations are necessary if the dependency of resolution on the operating parameters is estimated. From the fact that membranes may be regarded as low-plate-number systems, a minor performance in the separation of proteins could be predicted. As shown by Coffman et al. (29), however, most protein separations are operated in an on–off mode during elution chromatography. This means that the selectivity of the separation relies on the differences in the interaction between the proteins to be separated and the adsorbent at various concentrations of the eluting agent. Separation by differential migration, which is caused by the different retardation of the individual molecules during their movement through the adsorbent, plays only a minor role. Therefore only a few theoretical stages are needed for the satisfactory separation of proteins by ion exchange, hydrophobic interaction, or reversed-phase methods; the intrinsic separation factor of the different proteins is high enough to justify separation according to an on–off mechanism. Consequently, short membrane adsorbents allow very good separations, and the resolutions obtained are mostly comparable to HPLC separations, where long columns yield very high plate numbers under high-pressure conditions. Coffman et al. reported that about 50 stages is sufficient for most separation tasks, so HETP values between 20 and 200 μm, which have been found for adsorptive membranes, necessitate bed lengths of 10 mm for good resolution in protein separation. Similar findings on the bed length necessary for satisfactory results in protein separation using adsorptive membranes were presented by Dubinina et al. (56). In their analysis the authors demonstrated, that only a short bed is needed if proteins are separated according to an on–off mechanism. In an extended study the influence of gradient steepness, flow velocity, and bed length was investigated, and it was shown that short adsorptive membranes may be used for high throughput separation with good resolution.

Because increasing throughput (either by increasing the load or by reducing t_C) must be suspected to reduce resolution, the same criteria for optimizing L/v apply as in the case of the breakthrough capacity of membrane adsorbents. The good mass transport capabilities then allow the use of high flow rates at retained resolution when using well-designed membrane units. This is supported by the findings of many workers, who reported excellent resolution over a wide range of flow velocities during the separation of proteins with these devices (23,31,32,47,49, 52,57–59).

A major problem of adsorptive membranes (introduced earlier in "Mixing") is a direct consequence of the improved transport properties. Operating at short t_C results in configurations of small column aspect ratio (L/d). Ensuring an even fluid flow through an adsorbent bed of large diameter is a major task during module design for application of

membrane chromatography, especially on a large scale. Part of the problem arises from the difficulty of distributing liquid evenly over a large diameter. In the case of adsorption to particle-shaped stationary phases, uneven distribution of fluid at the column inlet will be neutralized during passage through the comparatively long beds; the lower part of a column will act as an additional distribution unit. In the case of membrane adsorbents this is not possible because the very short bed length, which can be chosen without compromising the performance, is the major advantage of this concept. Thus a very careful design of the distribution unit of large-scale equipment is essential. Up to now, commercially available units have not taken this into consideration, a fact that can be considered as one of the main reasons why membrane adsorption has not lived up to its preparative potential in protein purification. Furthermore the fabrication of the membrane adsorbent itself has to be taken into account. Wide distribution in pore size will lead to a preferential passage of fluid through certain regions of the membrane, resulting in a broad distribution of residence times with the respective consequences for process performance. This was analyzed theoretically by Suen and Etzel (26), who demonstrated that stacks of flat-sheet membranes are suited to achieving a homogenized flow through membranes with a large variance in porosity. It must be pointed out that hardware problems (uniform membranes and proper housing design) presently are the major limitation of a further success of membrane adsorption on the process scale. Until these problems are solved this promising technique will remain the "eternal talent" within the large variety of stationary phases for protein adsorption that are available on the market.

APPLICATIONS

As described earlier, adsorptive membranes may be used at several positions in a purification train. The scope of this section is to discuss applications from each of the positions within a purification scheme, but the selection provided here is not intended to be a complete collection of membrane-based adsorption methods. Therefore the reader is referred to recent review articles for additional applications (5,6,60). The examples were selected in order to test the prediction that processes employing membrane adsorbents have superior productivity at retained resolution.

Primary Recovery

Because microfiltration membranes are suitable for the clarification of culture broth or homogenates, the attachment of ligands to the internal pore surface allows a combination of protein adsorption and solid–liquid separation in a single step. This approach has been realized by Krause et al. (43), who used Cibacron blue–modified microfiltration membranes (Sartobind Blue, Sartorius, Göttingen) for the isolation of malate dehydrogenase directly from unclarified *E. coli* homogenate. The membrane adsorbent had a static capacity similar to commercially available particles with the same ligand and was used in a cross-flow mode with recycling of the filtrate (i.e., a batch adsorption mode). The overall productivity was 1,200,000 U/(L h) and combined clarification, capture, and initial purification in a single step. Data on long-term stability of this method are lacking, however; therefore the influence of traditional shortcomings of microfiltration membranes due to fouling, layer formation, and so forth cannot be judged.

A different field of application is the capture of whey proteins from unfiltered whey, employing large-pore membrane stacks (35) (Productiv S and QM, BPS Separations, Spennymoor, U.K.). Adisaputro et al. replaced the traditional method of batch adsorption of whey proteins with membrane stacks. Based on their results the authors predicted an increased productivity of the membrane method at the short residence times, which become possible due to fast mass transport characteristics. The size of the pores, however, was a point of concern because, on one hand, a large pore size was required to allow the use of unfiltered whey as an initial recovery operation, but on the other hand, too-large pore diameters cause fluid-side boundary layer problems, as already discussed.

Capture

If the use of clarified solutions as a feedstock for adsorptive processes is preferred to the whole-broth scenario just outlined, then the situation after removal of particulate matter is characterized by a large volume of product at a comparatively low concentration. This is especially valid for the production of recombinant proteins, so the primary goal at this point is the reduction of process volume. Usually, a concentration step such as ultrafiltration or precipitation is introduced, but this may, as well, be a perfect task for membrane adsorption. The efficient capture at short residence time is coupled with the selectivity of an adsorption process, so concentration may be combined with a high-productivity initial purification.

A typical process example is the purification of MAb from hybridoma cultures. The product concentration usually does not exceed 1 g/L even with highly efficient cell lines; the range of titers found is instead on the order of a few hundred milligrams per liter. Additionally the growth medium has physiological ionic strength (13–15 mS/cm), which requires diafiltration or dilution of the feedstock in order to allow sufficient capacity if an ion exchange step is chosen as the initial purification method. Ion exchange membrane adsorption has been described as an efficient method to capture MAb directly from clarified broth, possibly preceded by dilution to reduce ionic strength. Jungbauer et al. (61) used Zetaprep QAE radial flow cartridges (LKB, Bromma, Sweden) for this purpose and performed a scale-up study from 50 mL to 930 mL total adsorbent volume. The productivity reported was 0.2 g/(L h); a certain enrichment of the MAb was demonstrated by SDS gel electrophoresis. Cation exchange membrane stacks as well as a pleated module were used by Lütkemeyer et al. for the isolation of IgG from diluted hybridoma supernatant on a laboratory scale (28 mL of adsorbent, feedstock volume 5.5 L) (58). The high static capacity of the adsorbent (50 mg/mL) together with short residence times in the short adsorbent bed yielded a productivity of 75.2 g/(L h),

a value that was 13 times higher compared with the same process performed using a packed bed of porous cation exchange particles. In a later publication a similar process was shown on the pilot scale with undiluted hybridoma supernatant. Even at the high ionic strength, the overall productivity was 29 g/(L h). During the experiments, 100 L of supernatant was processed in 2 h in a unit with a 4-mm bed length (Sartobind S, Sartorius, Göttingen, Germany; $V = 220$ mL); the process volume was reduced 44-fold at 100% recovery (62). A similar approach was chosen by Wang et al. for the purification of a recombinant immunofusion protein secreted by *E. coli* (22). The same stack of cation exchange membranes was used for capture of the target protein from 200 L of clarified and 10-fold-diluted culture broth. The reported productivity was up to 1.5 g/(L h) at 10-fold reduction of process volume. Capture of urease to a hollow fiber, which had been modified to a tentacle type of adsorbent by grafting polymer chains with anion exchange ligands to the internal pore surface, was described by Matoba et al. (17). The productivity (expressed as urease collection rate) found in these investigations was up to 200 g/(L h). These examples show how the efficiency of membrane adsorbents may be exploited for high-productivity capture of target proteins from diluted culture supernatants.

Low-Resolution Purification

Because even during capture processes with adsorptive membranes a separation of the target molecules from impurities is achieved, there is no simple borderline to low-resolution purification. One way of differentiating between the processes is with regard to their main tasks, which are reduction of process volume and isolation of the main component from major impurities. During capture mainly ion exchange membranes are used, but hydrophobic interactions as well as pseudoaffinity ligands may be applied during low-resolution purification. At this point the considerations for optimizing t_C with regard to resolution under high-throughput conditions, which have been discussed, become important.

A typical example of low-resolution purification is the isolation of HSA in a plasma fractionation process based on ion exchange adsorbents. This was first described by Lacoste-Bourgeac for the valorization of fraction IV paste, which originated from the traditional ethanol precipitation during plasma fractionation (63). A series of anion exchange and cation exchange spiral-wound membrane cartridges (Cuno, Cergy-Pointoise, France) was used to recover albumin at 66% yield from the paste. Thus the high content of protein in this fraction, which otherwise was reported to be of only little value, could be exploited. A process for the isolation of HSA employing stacks of flat-sheet membranes was presented by Gebauer et al. and was compared with the well-established ion exchange process based on porous beads (20). Here a series of strong anion and cation exchange steps was used with a productivity of up to 220 g/(L h) on the laboratory scale. This value was six to eight fold higher than the traditional process based on a porous ion exchange matrix (Sepharose FF, Pharmacia, Uppsala, Sweden). The procedure was increased in scale based on commercially available equipment to 110 mL of adsorbing volume; the results, however, showed a drop in productivity of a factor of 3 compared with the small scale. Additionally a significant dilution of the product was observed. The deteriorated performance of the large-scale module could be attributed to overall mixing effects in the module, which originally was a filtration unit and had not been optimized with regard to chromatographic needs. This supports the earlier conclusion that neglective column design will lead to a dramatic loss of performance due to the sensitivity of short-bed adsorbents to extracolumn effects. A series of anion exchange and hydrophobic interaction was presented by Luksa et al. for the purification of recombinant tumor necrosis factor α from clarified *E. coli* extract (64). Comparison of the results obtained with commercially available cartridges of type B (Quick Disk, Knauer, Berlin, Germany) with a conventional method based on porous particles showed a similar product purity at half the process time, thus demonstrating that increased throughput at retained resolution may be obtained with adsorptive membranes. The performance of another commercially available stack of anion exchange membranes (Memsep DEAE, Millipore, Bedford, Mass.) was evaluated by Gerstner et al. (47). The authors were able to separate three component mixtures of standard proteins at a productivity of 58 g/(L h). Reif et al. published the use of immobilized metal ion chromatography on membrane stacks for the purification of a $(His)_6$-tagged recombinant protein (65). In this example it could be shown that, contrary to ion exchange membrane chromatography, the slow association kinetics of the pseudoaffinity interaction may limit the throughput with regard to resolution. Additionally it was shown that step gradients give better results in protein separation on membrane adsorbents than linear gradients—a universal phenomenon that may be due to the fact that the short membrane bed is not sufficient to allow the development of the self-sharpening effects of the linear gradient, which favorably influences the resolution in particle-based chromatography. The separation of whey proteins in strong ion exchange membranes was reported by Splitt et al. (66). In this work the influence of bed length was shown in the separation of the two genetic variants of β-lactoglobulin from whey, which became possible when a minimum bed length of 2 mm was chosen by the coupling of commercially available flat-sheet units. The capture of whey proteins from diluted solutions was achieved at a productivity of 45.5 g/(L h) with more than 60-fold reduction of the feed volume. Champluvier and Kula used Dye ligand membranes to isolate dehydrogenases from clarified yeast extracts. A productivity of 150,000 U/(L h) was found for glucose-6-phosphate dehydrogenase with Cibacron blue immobilized to nylon flat-sheet membranes (37). In this case the throughput was described to be limited by the kinetics of the association reaction. In a sequential arrangement of ion exchange and dye-ligand-modified membranes, formate dehydrogenase was purified with a productivity between 24 and 37 g/(L h). The protein was purified 4.6-fold with 27% overall yield by this the sequence; the eluate from one step was directly applied to the next membrane without intermediate buffer exchange (51). An interesting application was

reported by van Huynh et al. with the isolation of plasmid DNA from crude cell lysates using stacks of flat-sheet membranes (DEAE Memsep, Millipore, Bedford) (67). Because these comparatively large bioproducts provide some challenge to conventional particulate matrices due to their size, membranes with throughgoing pores are an interesting alternative for the processing of these potentially large-scale products (e.g., for gene therapy).

Table 1 summarizes the productivity obtained during the applications described here. This selection from a much larger number of low-resolution purification operations described in the literature shows that membrane adsorbents can be used efficiently at this stage of a downstream process. They also elucidate, that the scale-up of this method must be based on solid considerations with regard to the needs of an adsorption process, otherwise the impressive results on the laboratory-scale with regard to high throughput at retained resolution are not transferable to the process scale.

High-Resolution Purification

Membrane-shaped stationary phases were introduced into high-resolution purification with the concept of high-performance membrane chromatography (HPMC) (23,31, 52,59,68). By choosing continuous stationary phases of a membrane type of geometry, separations could be performed at resolutions comparable to HPLC methods. The improved transport characteristics of the continuous phase allowed higher throughput in spite of the low L/d ratio, which was used to obtain reduced pressure drop along the columns. A thorough analysis of the parameters influencing the performance of HPMC was provided by Tennikova and Svec (23). An interesting result of their investigations was an increased resolution of anion exchange HPMC during the separation of standard proteins, with increasing flow velocity; the separation in hydrophobic interaction chromatography (HIC) mode was not affected. Compared with low-resolution purification employing adsorptive membranes, step gradients yielded better separations than a linear gradient.

Attaching affinity ligands to membranes offers another opportunity to use them in high resolution purification. As shown by Nachman et al. (39–41), affinity membrane adsorbents are well suited for the fast purification of complex molecules from diluted feedstock. By coupling of receptors or antibodies to commercial hollow-fiber modules (Sepracor, Marlboro, Mass.) automatic separations were performed at high productivity (2–6 g/(L h)). Similar results were obtained with protein A–modified hollow-fiber modules from the same manufacturer (34). A dimensionless analysis of IgG adsorption to this matrix revealed a kinetic limitation of the sorption efficiency; breakthrough capacity increased with t_C but was independent from C_0 (69). As an alternative to hollow fibers, flat-sheet membranes were modified with protein A by Langlotz et al. (53) and were used to purify IgG from hybridoma supernatant. In this work it could be demonstrated that high resolution by affinity ligands and high productivity may be obtained at the same time (10.8 g/(L h)).

CONCLUSION

From the existing literature some important features of adsorptive membranes may be extracted, making them a very interesting candidate for stationary phases for the process-scale purification of proteins. Despite this fact, large-scale applications of the technology have not been undertaken. This may partly due to the traditional reluctance to use new matrices for the industrial-scale purification of proteins, where the proof of long-term stability and reproducibility is essential for the success of the downstream process. Additionally, creative solutions for the practical realization of large-scale units with very low L/d have not been developed. At this point the manufacturers have to prove that the demands of an adsorptive process with regard to regular fluid flow, reduced extra column effects, and so on can be served on the process scale. Currently there are only few examples of pilot-scale processes available in the literature; it is hoped that the near future will bring many more successful applications of adsorptive membranes. The technology certainly has potential for process-scale separations, as has been demonstrated by theoretical analysis and laboratory-scale experiments.

Table 1. Some Typical Productivity Values Obtained with Membrane Adsorbents

Ligand	Geometric format	Target protein	Productivity (g/(L h))[a]	Ref.
Q	Stack	Formate dehydrogenase	36	51
Q	Pleated module	Antithrombin III	21.5	58
Q	Stack	HSA	220	20
DEAE	Hollow fiber	Urease	200	17
S	Pleated module	IgG	72.5	58
S	Stack	IgG	29	62
MAb	Hollow fiber	Recombinant interferon α2a	2.7	40
Histidin	Hollow fiber	IgG	6.7	46
Procion yellow	Stack	Pyruvate decarboxylase	40.3	38
Procion red	Stack	Formate dehydrogenase	24	51
Cibacron blue	Cross-flow module	Malate dehydrogenase (from unclarified broth)	1.1	43
Protein A	Hollow fiber	IgG	35	34
Protein A	Stack	IgG	10.8	53

Productivity was calculated from the cited references by calculating the total time of the respective purification cycles (including washing and elution, when available) and relating the amount of product purified to the cycle time and the adsorbent volume used.

NOMENCLATURE

a	Specific surface area (m^2/m^3)
α	Number of bed volumes required for wash, elution and regeneration during chromatographic cycle
B	Permeability of a packing (m^2)
C	Initial concentration (kg/m^3)
D	Diffusion coefficient (m^2/s)
D_{ax}	Axial dispersion coefficient (m^2/s)
d	Adsorbent bed diameter (m)
d_p	Pore diameter (m)
ϵ	Void fraction (−)
η	Dynamic viscosity (kg/(m s))
HETP	Height equivalent of a theoretical plate (m)
k_a	Second-order association rate constant (l/(mol s))
k_d	Dissociation rate constant (s^{-1})
L	Adsorbent bed length (m)
L/d	Column aspect ratio (−)
n	Plate number in HETP concept (−)
P	Productivity (g/(L h))
Pe	Peclet number (−)
Q_{max}	Static capacity (kg/m^3)
Q_D	Breakthrough capacity (kg/m^3)
R_E	Recovery ratio
R_S	Resolution
t_C	Residence time (s)
t_D	Diffusion time (s)
t_R	Reaction time (s)
V	Adsorbent volume (m^3)
v	Flow velocity (m/s)
v_e	Interstitial flow velocity (m/s)

OUTLINE

INTRODUCTION

The term *filtration* refers to the separation of two or more components from a liquid or gas. Generally, it refers to the separation of solids from either liquids or gases. In membrane separations, one goes beyond the classical separation of solids from the other phases. Membranes can be and are used to separate dissolved solutes in a solution from one another and also to remove the solutes from the liquid in which they are dissolved. In this manner, membranes are used to either purify products or to concentrate them. This is particularly advantageous in biotechnology where the products of biological origin are very often protein-

aceous in nature and are heat labile. The membranes offer a means of separation that occurs at or below ambient temperatures. This gives the biotechnologist a separation or purification technique that provides maximum assurance of product stability. In membrane-based separations, the membrane acts as a barrier to the passage of certain components while others move freely across the membrane. Therefore, the end result of a simple membrane separation is the concentration in the upstream fraction of the components that do not cross the membrane barrier. This fraction is referred to as the *retentate*. The fraction that passes across the membrane is called the *permeate* or *filtrate* and contains the components of the solution in essentially the same concentration as the starting fluid. This is the simple basic *membrane separation*.

THREE MAJOR APPLICATIONS OF MEMBRANE SEPARATIONS

Product Purification

Product purification is the most important application for membrane separations in biotechnology. Membranes are made of different materials, and the biotechnologist needs to make a choice based on the goal of the application and the suitability of the membrane for the application. This article aims at providing the biotechnologist with information that will help select the best membrane and the manner in which to use the membrane to accomplish the separation and purification task easily. Membrane separations are an important part of both the upstream and downstream processing in biotechnology. A typical process can include a number of steps, such as centrifugation followed by membrane-based clarification of the supernatant, one or more chromatographic procedures, final membrane processing steps to accomplish further purification, and finally concentration.

Sterile Filtration

One of the most critical steps in the manufacture of injectable therapeutic agents is the sterilization of the product. The simplest method of sterilizing solutions is the one that uses heat, and autoclaving is a typical example of such methods. However, products of the biotechnology industry are most often thermolabile and therefore cannot be heat sterilized. Membranes provide an excellent alternative. Membrane filters are used for filtering out bacteria and other microorganisms from the final formulations, rendering the products very safe for injection. This step is followed by lyophilization of products that are marketed as solid powders. Those products marketed as liquid formulations are filled straight into ampules, vials, or other appropriate containers after sterile filtration through membrane filters.

Virus Removal by Membrane Filtration

This is the most recent application of membrane separations in the biopharmaceutical industry. A new generation of membranes is today used to remove viruses from biological preparations. Therapeutic agents manufactured from blood, by cell culture processes, or by the most modern method using transgenic animals can contain dangerous viral contaminants from the source materials. These products can be filtered through membrane devices to remove most viral contaminants, including HIV and the viruses known to cause different forms of hepatitis.

There is a point of differentiation here from the previously mentioned sterile filtration in which there is complete or total removal of microbiological contaminants from the solution. In virus filtration, the removal is not complete, especially when the viruses are very small. Therefore, for complete viral safety, the practice is to use membrane filtration as a method complementary to the longer known generic methods of viral inactivation, such as treatment with a combination of solvents and detergents, other chemical inactivating agents, and pasteurization by mild heating for prolonged periods of time.

CLASSIFICATION OF MEMBRANES AND MEMBRANE PROCESSES

The more commonly used membrane processes in the biotechnology industry are microfiltration, ultrafiltration, and reverse osmosis. All three are pressure-driven processes and differ from each other in the size of the components they retain. The membrane itself, under the influence of applied pressure, controls the retention and passage of individual components of the solution being processed.

Microfiltration

Microfiltration processes retain particles in the submicron range that are suspended in the process fluid. The membranes are also used in removing particles and microorganisms from air and gases, as in the fermentation processes in biotechnology and other industries. The particles removed by membrane filtration range in size from 0.1 μm to 10 μm. Conventional filtration processes such as those using pad filters and filter presses in the more conventional pharmaceutical industry are generally capable of retaining particles only above the 10 μm size.

Ultrafiltration

Ultrafiltration membranes generally retains macromolecules or particles from about 0.001 to 0.2 μm in size. By choosing one or more of the available membranes, one can separate larger macromolecules from smaller ones within the above size ranges. For example, separation of large proteins or polysaccharides from smaller molecules is a typical application for ultrafiltration membranes in the biotechnology industry.

Reverse Osmosis

Reverse osmosis is one of the oldest known applications for membrane separations. This is the process where membranes are capable of retaining even smaller molecules than ultrafiltration membranes. Salts and other molecules with a molecular weight below 1,000 Da that are not normally retained by ultrafiltration membranes are retained

by the reverse osmosis membranes. The first use of these membranes was in desalting sea water. The membranes are today used for concentrating small molecules, and ultrafiltration is used for fractionation and purification of macromolecules with molecular weights between 1,000 and 1 million Da. Figure 1 summarizes the use of membrane filters in biotechnology. Table 1 gives examples of products that can be retained by the three types of membranes. In a typical biotechnology process, microfiltration is the first membrane-based step, and it is used to separate suspended material such as cells from a bioreactor and other particulate matter, including cell debris, from the multitude of dissolved substances, which very often includes the specific product of interest expressed by the cell line. In many instances, clarifying filters made of a variety of materials are used for preclarification of the process stream before microfiltration. This usually helps to improve the performance of the microfiltration step and extends the life of the membrane filter. Honig and Schwartz (1) have written an excellent review of this subject. The filtrate or permeate from the microfiltration step contains the desired product elaborated by the process along with other proteins, carbohydrates, and smaller molecules such as salts from the culture medium as well as those produced during the process. To separate the product of interest from these contaminants, the ideal membrane separation step is ultrafiltration. Membranes with the appropriate nominal molecular weight cutoff, a term used to identify and differentiate ultrafiltration membranes from one another, are next used in successive purification steps to facilitate recovery of the desired product of high purity. Quite often, the manufacturing process also includes chromatographic or other suitable process steps in between membrane separations to achieve an overall process advantage in terms of product quality and yield. Figure 2 illustrates how membrane and chromatography procedures are integrated together step-by-step for upstream and downstream processing in the biotechnology industry.

MEMBRANE CHEMISTRY, STRUCTURE, AND FUNCTION

The high-volume microfiltration in the biopharmaceutical industry requires removal of particulate and colloidal substances in an economical and efficient manner. The nature of these particles and the interplay of filtration dynamics contribute to the difficulty of the task. It is important to balance filter performance against process costs to arrive at a system that provides the ideal separation solution at a low operating cost. In general, the filtration process starts out with passing the process stream through a porous medium that entraps the solids in its matrix or retains them on its surface. The materials used in the manufacture of these filters are porous or fibrous, such as paper, felt, woven yarns, and fabrics, and other materials. Depending on the basic filtration mechanisms, particle retention mode and construction characteristics, the different filters used in the biologicals industry are classified as *depth filters*, *surface filters*, and *screen filters*. Figures 3, 4, and 5 show the mechanism of retention of particulates by these three types of filters.

Depth filters consist of fibrous, granular, or sintered materials that produce a random porous structure. When a

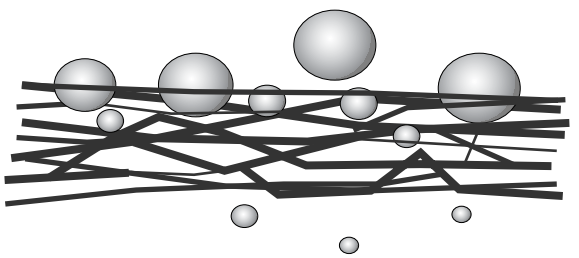

Figure 4. Mechanism of particle retention by surface filters.

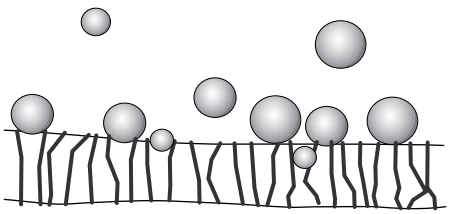

Figure 5. Mechanism of particle retention by screen filters.

fluid passes through a depth filter, particles become entrapped in its tortuous network of flow channels. Particle retention mechanisms are random adsorption and mechanical entrapment throughout the depth of the filter matrix. The filtration media of these filters can be wound cotton, rayon, or polypropylene as well as resin bonded laminates such as cellulose and fiberglass.

Surface filters are made up of several layers of media, such as glass or polymeric microfibers. During filtration, particles larger than the spaces within the filter matrix are retained primarily on the filter surface. Other smaller particles can get entrapped within the matrix. Thus, these filters have the property of both depth and screen filters. The surface filters are generally made of polymeric materials, resin-bonded paper, or fiberglass and paper.

Screen filters have a geometrically regular porous matrix, and particles are retained on its surface primarily by a sieving or size exclusion mechanism. Small particles and

microorganisms larger than the pore size are retained on the surface. The filtration process here is absolute because everything larger than the rated pore size cannot get through the filter. Examples of such filters include cast polymeric membranes used for all critical submicronic and macromolecular separations in the biotechnology industry. The structure of the filter material is more rigid, and the manufacture is much better controlled than for the other types of filters.

Screen filters made of *microfiltration membranes* have a well-defined pore size in the range of 0.1 to 1 μm. Because particles and microorganisms are retained at or near the surface of the membrane, there is very little possibility of the so-called grow through phenomenon taking place when these filters are used for sterile filtration applications in the manufacture of parenteral drugs. This is a truly major application for the microfiltration membranes in the general pharmaceutical and biotechnology industries. They also find use in another biotechnology application, the harvesting of cells from bioreactors.

Ultrafiltration membranes are the second major group of screen filters and are often called *asymmetric* or *skinned* membranes. The skin of the membrane does the job of retaining the dissolved solutes larger than the membrane rating. The skin is supported by a more rigid support layer or backing. Unlike microfiltration membranes, ultrafiltration membranes are not designated by their pore size but according to the molecular weights of the dissolved solutes that the membrane will *retain* or *reject*. This, as mentioned before is called the nominal molecular weight cutoff of the membrane.

METHODS OF MEMBRANE MANUFACTURE

Most membranes are made of organic polymers such as the natural polymer, cellulose, and its derivatives (e.g., cellulose acetate) and certain other synthetic polymers (e.g., polyethylene, polycarbonate, polysulfone) and their derivatives. Some membranes are also made of inorganic materials such as zirconium and aluminium oxide. These are often referred to as *ceramic membranes*.

In the manufacture of polymeric membranes, the organic polymers are dissolved in an appropriate solvent and combined with the nonsolvent or swelling agent. This makes up the membrane casting solution. The membranes are cast on casting machines, which are almost always made by the membrane manufacturers themselves. Most membranes are made in the form of flat sheets, but some are cast on the module support as in the case of tubular module membranes. Some membranes are also made directly in the form of hollow fibers. The membranes are then annealed.

Flat sheet membranes are subsequently incorporated into flat membrane plate and frame modules or made into spirally wound or pleated cartridges. Critical details of membrane manufacture are well-guarded secrets and are proprietery processes developed and owned by membrane manufacturers.

Microfiltration membranes are made to a thickness of about 100 to 120 μm, and the retention of particulate material takes place at the membrane surface or within the first few micrometers of the tortuous length of the membrane pores. *Ultrafiltration membranes* consist of a very thin skin that performs the task of separation of the solutes in solution. This skin is supported by a much thicker support material that contains voids, often referred to as finger voids because of their fingerlike shape. These voids facilitate the rapid flow of the fluid once it gets past the fine skin of the ultrafiltration membrane. *Reverse osmosis membranes*, as per their classical definition, are meant to retain all solutes other than the solvent itself. These were originally developed for sea water desalination to make potable water. This is still by far the largest industrial application for reverse osmosis membranes. These membranes have since been made into somewhat modified versions that can retain smaller molecular weight solutes that are generally not retained by the ultrafiltration membranes with a low nominal molecular weight cutoff. The molecules retained are larger than the salts that can pass more easily through the membrane. These new-generation reverse osmosis membranes find a niche application in the concentration of low molecular weight solutes, such as peptides, antibiotics, and other products in the biopharmaceutical industry. Table 2 summarizes the characteristics of the three membrane processes described.

Track-Etch Membranes

As described earlier, most polymeric membranes contain tortuous pores in a spongy material. The pores of these membranes can have a fairly wide pore size distribution as a result of their method of manufacture. A different type of membrane is made by a two-step process that includes the manufacture of the polymer sheet membrane of a certain thickness followed by bombardment of the membrane sheet with massive energetic nuclei in a beam of ^{235}U fission fragments. These nuclei go through the membrane, leaving tracks that are then the pores formed in the membrane. After the bombardment step, the membrane undergoes further process steps to make it antistatic and to modify its surface characteristics such as either hydrophobicity or hydrophilicity. It is natural and quite logical to assume that such a process of making pores in a membrane would produce a membrane with highly uniform pore diameters and with a sharp nominal molecular weight cutoff. However, in actual practice, the random bombardment can as well result in two or more pores being formed close together, thus giving rise to much larger pores than the individual pores. This problem of overlapping pores is supposedly avoided if the nuclear bombardment takes place at an angle of 29° between the particle beam and the membrane sheet (2). There are also some other disadvantages to these membranes. Their extreme thinness of only about 15 μm makes them difficult to handle. Also, if the bombarding particles fail to penetrate completely through the membrane sheet, the apparent pores in the membrane are not true pores.

Virus Removal Membranes

The biotechnology industry, which has benefitted more from membrane processes than the conventional phar-

Table 2. Characteristics of Membrane Processes

Process	Permeate	Retentate
Microfiltration[a]	Solvent with all dissolved solutes	Particulates in suspension, colloidal material
Ultrafiltration[b]	Water with dissolved solutes of lower molecular weight	Dissolved solutes of higher molecular weight and colloidal material
Reverse osmosis	Solvent, typically water	Solutes

[a]In microfiltrator, particulate retention generally depends on the pore size of the membrane.
[b]In ultrafiltration, the passage or retention of solutes depends on the nominal molecular weight cutoff of the membrane.

maceutical industry, has constantly changing requirements. These are the result of the development of new biologicals by newer and rather very innovative processes as well as the more and more stringent regulatory requirements that call for high product quality and safety. An excellent example here is the need for biologicals to be rendered free of both relevant and adventituous viral contaminants. The membrane manufacturers who have regularly kept up with the demands of the biotechnology industry have come up with special membranes for this application that are being used by the industry to make virus-free biologicals.

HOW MEMBRANE PROCESSES ARE OPERATED

Membrane processes are driven by pressure, which is a great advantage to the biotechnology industry, in which large majority of products are heat labile. The processes also consume less energy because they do not require either heat transfer or heat generation. They call for a pump to run the process fluid through the membrane under pressure, as illustrated in Figure 6. Some of the processes can, however, be run with either compressed air or nitrogen and do not need pumps. Most membrane processes are run at ambient temperature, with few exceptions such as those processes where extremely heat-labile products call for the processes to be run at lower-than-ambient temperatures. Low temperature membrane processing is also common when the process time is long, and there is the accompanying risk of product degradation or microbial contamination of the process fluid. At the other extreme, higher temperatures are used when a fluid is very viscous, and the product of interest is not quite heat sensitive. The higher temperature reduces the viscosity of the process stream and increases the rate of filtration with the overall advantage of significant reduction in process time.

In a well-developed process in the biotechnology industry, it is quite common to find membrane filtrations operating in tandem with one or more chromatographic purification steps or other methods of separation and purification. Further, one may also use more than one membrane separation step (i.e., microfiltration, ultrafiltration, and reverse osmosis) at appropriate points in the downstream process just as different chromatography procedures, such as ion exchange, size exclusion, or affinity methods, are used in a complementary fashion. One single membrane separation step is not always enough to accomplish the end result. Centrifugation is sometimes used before the membrane processes for clarification of fluids containing a high biomass, as in fermentation processes. The supernatant of the centrifugation is then better handled by other methods of purification, including membrane-based processes.

Two Methods of Operation of Membrane Processes

The processes are run according to two distinctly different methods. Figure 7 illustrates these two methods of filtration. The first is the classical method of filtering a solution containing suspended particulates either to recover the particulates themselves, as in the recovery of a product crystallized from a solution, or to obtain a clear filtrate when the product of interest is in the filtrate. This method is known as *dead-end filtration* or *normal-flow filtration*.

When the solution being filtered contains a high concentration of particulates or bioburden, the filter can quickly get clogged because of the accumulation of solids at the surface of the membrane. This usually ends up with the deposition of a boundary layer at the membrane surface, which then acts as a secondary membrane. This prevents free passage of the liquid and eventually the mem-

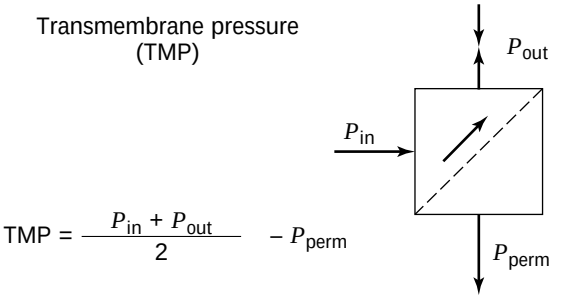

Figure 6. Basic scheme of a tangential-flow filtration process.

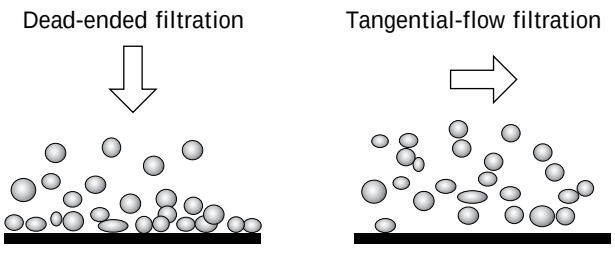

Figure 7. The two methods of using membrane filters.

brane is completely clogged. When this happens, filtration cannot be continued, and the only solution is to stop the process and replace the membrane filter with a new one. Such stoppages are time consuming and often result in loss of valuable product, which affects the economics of the overall process.

A practical and often successful alternative to the classical dead-end filtration is the use of the membrane filters by a method known as *tangential-flow filtration* or *cross-flow filtration*. Figure 6 illustrates the circulation of the complete process fluid in a direction parallel to the membrane surface.

Different types of pumps are used in the process. The advantage of the method is that the particulates that would accumulate at the membrane surface in dead-end filtration are now kept in the body of the fluid. They stay away from the membrane surface, permitting the liquid to flow relatively unhindered through the membrane pores. If the rate of filtration or *flux* drops significantly, the process fluid can be diluted by adding an appropriate pure solvent such as water or a buffer. This procedure helps to recover much of the original flux, and the filtration can be continued as before. The addition of the diluting fluid can take place without stopping the process. This step of *in-process dilution* is referred to as *diafiltration*. A typical tangential flow filtration process scheme is illustrated in Figure 8. If the desired product is in the filtrate, which is now more dilute, the filtrate can be reconcentrated to the desired concentration by either ultrafiltration or reverse osmosis, choosing the appropriate membrane according to the molecular weight of the product of interest. The concentration and further purification can also be performed by a chromatographic method.

Equipment Employed in Membrane Filtration

Membrane filters in different configuration are required for different processes depending on the method of filtration used. The choice of a particular type of filter depends on several considerations, such as process fluid composition; goal of the process, which would either be to recover the particulates or the filtrate; and, of course, the economics of the process.

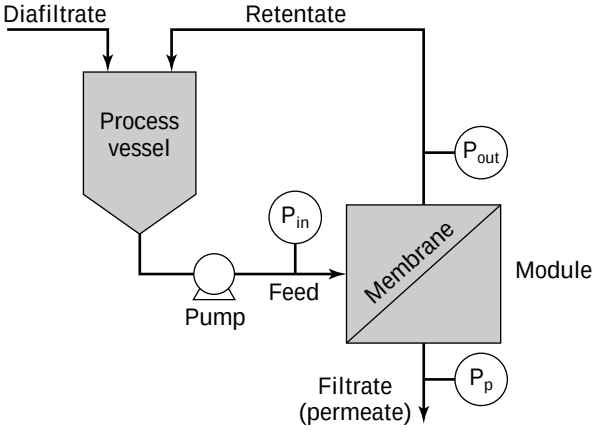

Figure 8. Schematic of a tangential-flow filtration operation (clarification, concentration, and diafiltration).

Equipment for Microfiltration in the Dead-End or Normal-Flow Filtration Mode For clarifying small volumes of solutions as in a research and development environment, small filter disks of different diameters and pore sizes are used. The filter disks are placed in appropriate holders of plastic materials or stainless steel. The stainless steel holders can be autoclaved for sterility before the filtration and can be used over and over again.

These less-expensive filters are also quite useful in determining what type of filters are appropriate for a certain application. Filters are also available in the form of fabricated devices that can be placed at the end of a syringe. Such filters are ideal for filtering volumes from 1 mL to about 100 mL. For applications where large volumes of process fluids need to be filtered, as in an industrial environment, cartridge filters placed in suitable stainless steel holders are ideal. The filters placed in such holders are easy to handle; thus can be autoclaved or steam sterilized and sometimes cleaned for reuse.

Quite often, the particulate level in filtrations is high, and the membrane filters can quickly get clogged. The common solution to this problem is to place in the filtration step prefilters and clarifying filters before the membrane filters. The economic advantage of extending the life of the usually more-expensive final filter is far greater than the cost of the prefilters. In well-designed processes, the filters are used in a sequence as follows:

$$\text{Clarifying filter} \Rightarrow \text{Prefilter} \Rightarrow \text{Membrane filter}$$

Each filter removes the suspended or colloidal material for the process stream to improve the performance of the filter next in line (1).

Equipment for Small-Scale Ultrafiltration, Including Tangential Flow Filtration For concentrating small volumes of 1- to 20-mL protein solutions, centrifugal filtration units (Fig. 9) fitted with ultrafiltration membranes are available. Other devices such as the stirred cell (Fig. 10), which can be used with a wide range of ultrafiltration membranes, are also marketed by filter suppliers. These devices are ideal for processing volumes of a few milliliters to about half a liter. A stirring bar helps to stir the fluid above the membrane and keeps the foulants moving in the body of the solution, reducing filter clogging and increasing filtration rates. Although this device will help to achieve small laboratory-scale separations or protein concentrations, it will not give indications of the membrane area or process conditions to use when the process is eventually scaled up to large volume operations.

Because large-scale ultrafiltration processes are usually conducted in tangential-flow filtration systems, it is better to start with a device that operates in this mode at the research and development laboratory. Small-scale devices for these applications are available from filter suppliers. Devices that hold single sheets of membrane or small filter modules with more membrane area are also available. It is important to proportionately increase the membrane

area of the filtration device as the volume of the process fluid increases. When the process is scaled up to the pilot plant level or to full-scale manufacture, large surface area modules and systems are available and offer the convenience of proper scale-up. Membrane filters in the following configurations are available from suppliers: *hollow fiber modules*, *spiral wound modules*, *plate and frame devices using flat sheet membranes*, and *tubular filters*. All these configurations have been developed by individual manufacturers based on sound hydrodynamic principles and rather complex mathematical models for module and system performance. The idea behind the development of each type of device is to improve its performance and ultimately reduce processing costs for the end user. The decision to use a particular device for a given application is usually made by taking into consideration the properties, and more specifically, the composition of the process stream, the goal of the application, and the results of the initial small-scale trials. The impact of the filtration step on the overall process economics is undoubtedly an important factor.

Small devices operated on bench tops are ideal for early studies in the research and development laboratories. Properly performed experiments help to determine which membranes and membrane devices are best suited for a particular application and also for correct optimization of the process. Most filter manufacturers help in proper planning of these studies, which are critical when one needs a quick answer to a bioseparation problem. (Some companies even offer hands-on training for the operators.) The result of the studies is the knowledge of which membrane pore size (in case of microfiltration membranes) or what nominal molecular weight cutoff (in case of ultrafiltration membranes) is best for the application.

Hollow fiber modules are sometimes used in ultrafiltration processes. The active membrane that participates in

the separation process is on the inside of the hollow fiber of a uniform bore diameter. The process fluid is pumped through the hollow fiber, and the solvent and molecules that cross the membrane appear on the outside of the fiber. Bundles of many fibers, from 50 to 3,000 based on the internal diameter, are sealed inside a transparent cylindrical cartridge with the two ends sealed with epoxy sheets. Each cartridge has permeate ports at either end as well as feed and retentate ports. The ports can be connected to the piping of the system in which the module is installed by standard triclover clamps. Hollow fiber modules carrying ultrafiltration membranes of different cutoffs and surface area are available from several suppliers.

Spiral wound modules offer the biotechnology industry the most compact and least expensive of the ultrafiltration devices. The device is constructed of the same flat sheet membranes used in plate and frame devices. Each cartridge is made by wrapping alternate layers of membrane and separator screens concentrically around a hollow core, as shown in Figure 11. The flow schematic in a spiral wound ultrafiltration membrane cartridge manufactured by Millipore Corporation is shown in Figure 12. The product to be processed enters one end of the cartridge under pressure and flows tangentially down the central axis. The

ultrafiltrate containing salts, water, and molecules not retained by the membrane flows through the membrane into the permeate channel and spirals all the way to the central core of the cartridge. The permeate is continuously removed from the central core while the retentate containing the rejected material exits through the retentate port.

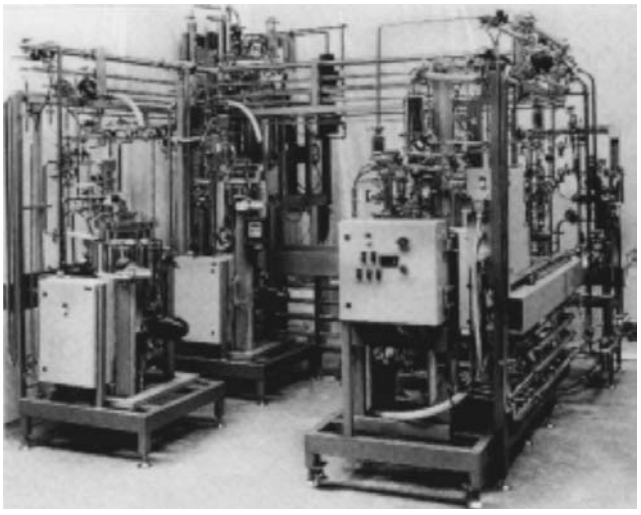

Figure 19. A fully automatic system used in downstream processing. *Source*: Photo courtesy Millipore S.A., Molsheim, France.

Spiral cartridges made with different ultrafiltration membranes with varying cutoffs are available from filter suppliers.

Flat sheet cassettes and *plate and frame modules* are a frequently employed configuration in tangential-flow filtration, and devices offered by suppliers contain microfiltration membranes of different pore sizes and ultrafiltration membranes with several cutoffs. The microfiltration membranes are the same ones offered in cartridges used in the dead-end mode. Small devices that can be operated in the tangential-flow filtration mode with single sheets of membranes or modules are ideal. The work at this scale will help the user to understand problems of filter clogging or membrane polarization and fouling phenomena and how to address the problems rapidly by either choosing another type of membrane or changing the process conditions.

The cassette filter devices are made by stacking and bonding together identical membrane sheets and separator screens together in parallel. Devices with identical membranes contain the same materials of construction. Therefore, development of a process can start with a small minicassette for the small-volume experiment and is eventually scaled up to a several hundred liter process by simply stacking together many larger surface area cassettes in stainless steel or acrylic holders.

As a process moves from the small bench-top experiment in the research laboratory to the floor of the manufacturing plant, the industry needs equipment to process large volumes of process streams. The filter suppliers have responded to this need of the biotechnology and other industries by developing modules that not only carry large membrane areas of several square meters but are extremely robust. These can be used repeatedly after proper cleaning and sanitization for several years. Typical examples of such devices are the Prostak membrane modules available from Millipore Corporation. These are tangential-flow stacked plate devices. The modules are solvent bonded and contain neither adhesives nor compression-dependent membrane seals. The modules containing Millipore's Durapore range of microporous membranes can be steam sterilized dozens of times. Figure 13 shows the flow path of the process fluid in the Prostak modules, which are shown in Figure 14. Because these are available in both the microfiltration and ultrafiltration versions, it is possible to use the same hardware for both steps in a downstream process, giving a significant reduction in capital investment. Most filter suppliers offer either manually operated or fully automatic systems that contain the membrane devices. A small bench-top filter evaluation module in a stainless steel holder is illustrated in Figure 15. Figure 16 shows how a number of plate and frame membrane modules can be put together in several stainless steel holders and plumbed together to form an assembly of membrane modules that can be part of a large process system. Figures 17, 18, and 19 illustrate a variety of typical small and large membrane systems used in the biotechnology industry. The systems carry the different membrane configurations described earlier.

CONCLUSION

The information provided above will give present and potential users of membranes for bioseparations a clear picture of how best to approach the task to achieve the desired end results. The manufacturers of membranes and membrane devices are always ready to give the users the necessary help in choosing the right product for each application. For detailed information on membrane separations, the readers can also refer to numerous review articles and textbooks on the subject, such as the one on ultrafiltration by M. Cheryan (3). Another useful book edited by McGregor (4) includes articles on a variety of specialized topics written by persons practicing the art of membrane separations in biotechnology. The use of microfiltration in the tangential mode in the recovery of intracellular products has been reviewed by Le and Atkinson (5), whereas Short and Webster (6) have authored an excellent article on the use of ultrafiltration in the pharmaceutical industry.

OUTLINE

INTRODUCTION

Mold, a typical filamentous microorganism, is utilized widely in the field of biotechnology. Although molds are usually cultivated either by submerged liquid cultures and agitation or by solid-substrate cultures, these conventional methods may have various difficulties (1). Membrane surface liquid culture (MSLC) is one of the promising methods that has recently been developed by Nakanishi and his coworkers to solve difficulties associated with conventional cultivation methods (2–7). Although MSLC is very simple in principle, it has advantages of both the conventional submerged liquid culture and solid-substrate culture. Molds cultivated with MSLC sometimes produce metabolites in a larger quantities and are stable against autolysis.

PROBLEMS OF THE CONVENTIONAL CULTIVATION METHODS

Molds are difficult to cultivate because they are obligate aerobes and their growth is characterized by long, thin, branched threads of mycelium. Molds are usually cultivated either by submerged liquid cultures, such as shake-flask cultures and culture using an agitated vessel, or by solid-substrate cultures. However, these conventional methods include several severe problems for cultivation of molds. Because molds are obligate aerobes, it is of crucial importance to keep a sufficiently high dissolved oxygen level in the medium. In a shake-flask culture or a culture using an agitated vessel, molds take on either a pulpy state or a pelletlike morphology (aggregated forms) (8). In a pulpy state, molds may be damaged, suffering from shear stress caused by high agitation of the medium and spurging of air. The culture broth is highly viscous particularly at a high cell concentration, and accordingly, it becomes more difficult to supply oxygen to the cells. Also, the cells existing in the center of a pellet are apt to be autolyzed because of oxygen deficiency. On the other hand, in a solid-substrate culture, molds are grown statically on a solid substrate, such as unprocessed agricultural products or by-products, facing the air (9). Thus, in the solid-substrate culture, molds grow as they do in their natural habitats. Many researchers have reported that enzymes are sometimes produced at higher levels by solid-substrate cultures than by shake-flask or agitated vessel cultures (1–15). These findings might be partly ascribable to the fact that molds that are statically cultivated by the solid-substrate method do not suffer from fluid shear and low oxygen levels, although details of the mechanisms are not known. On the other hand, features of the solid-substrate culture is disadvantageous because the medium is restricted to natural agricultural products and thus control of the medium composition and pH is difficult. Furthermore, the production rate of metabolites is sometimes limited by mass transfer rates inside the solid substrate. Handling of the fine particles of the solid substrate during cultivation and a low yield of the product after cultivation are also serious problems.

PRINCIPLES AND CHARACTERISTICS OF MSLC

In MSLC, molds are grown on the surface of a microporous membrane, one side of which faces the air and the other side of which is in contact with liquid medium (2–7) (Fig. 1.) Although MSLC is very simple in principle, it has the advantages of both the solid-substrate culture and the conventional submerged liquid culture. In MSLC, molds are grown on the surface of a solid material (a porous membrane) facing the air, as in the case of solid-substrate culture. Moreover, MSLC is a static culture without vigorous agitation or shaking of the medium and spurging of air. Thus, the molds do not suffer from fluid shear. However, in contrast to the solid-substrate culture, liquid medium is used in MSLC, as in conventional submerged liquid cultures, which allows easy control of composition and pH during cultivation.

In MSLC, mycelia or hyphae do not pass through the membrane pores and thus do not invade the liquid medium side. If the hyphae should pass through the membrane pores, they would adhere onto the backside of the membrane, which in turn would block the pores and obstruct

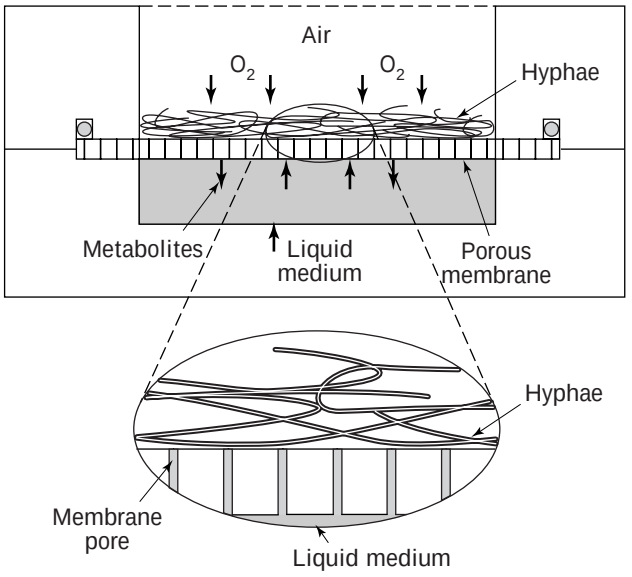

Figure 1. Conceptual scheme for MSLC. A porous membrane is set on the surface of liquid medium on one side and faces humidified air on the opposite side (upper surface). Molds are grown on the upper surface of the membrane, taking oxygen directly from the air and at the same time absorbing the liquid medium existing in the membrane pores. The enlarged figure below shows that the liquid medium rises up through the pores to the upper surface.

the transfer of medium components and metabolites. Thus, it is important to select a porous membrane with appropriate pore size, structure, and material. The membrane pore size should usually be smaller than 0.2–0.4 μm, with no appreciable mass transfer resistance (9). The membrane should be hydrophilic so that liquid medium can reach the top of the membrane pores at the outer surface where molds are grown, as shown in Figure 1. For example, an SE20 membrane made of polysulfone with hydrophilic treatment (Fuji Photo Film Co., Tokyo, Japan) cellulose membranes from Millipore (Bradford, Mass.) having a molecular weight cut-off of 5,000–300,000 could be used. Because the hyphae do not enter the membrane pores, the medium remains clear and uncontaminated with cells, which may contribute to simplification of the downstream processing.

Furthermore, MSLC is energy saving because it does not require shaking, agitation, or spurging.

Table 1 summarizes some major differences among MSLC, solid-substrate culture, and submerged liquid culture.

APPARATUS AND MODES OF CULTIVATION

Apparatus

Various types of apparatus are available for MSLC. For preliminary experiments such as screening of strains for production of a specific metabolite and optimization of medium composition, a plastic dish can be used. Liquid medium that has been autoclaved is poured into a plastic dish and then a porous membrane is set onto the surface of the liquid medium and held in place by appropriate supports, as shown in Figure 2 (4). Spores are inoculated uniformly onto the membrane surface, and cultivation is carried out statically in a thermostat-controlled and humidified aseptic box.

In experiments for the optimization of cultivation conditions, an apparatus made of heat-resistant plastic, such as polycarbonate, equipped with a peristaltic pump and a medium container is available, as shown in Figure 3 (2,4,6). The MSLC apparatus shown in Figure 3 is composed of an upper plate with a circular openings and a lower plate with a cylindrical groove. The membrane is set between the upper and lower plates with an O-ring. Spores are inoculated uniformly onto the membrane surface, and cultivation is allowed to start statically. The liquid medium can be circulated between the groove in the lower plate of the apparatus and an outside container. Medium components and pH can be controlled in the container. The medium in the groove may be gently stirred if necessary.

To conduct MSLC on a large scale, a cylindrical MSLC apparatus, shown in Figure 4 (7), or a plate-type apparatus in which two plates face each other at a short distance are available. In the cylindrical apparatus, the liquid medium is pumped up from a reservoir to the top of the cylindrical membrane and spouted toward the inner surface of the cylinder. The medium runs down along the inner surface of the cylindrical membrane module as in a wetted wall column. The medium is collected into the reservoir and circulated. Pumping should not be constantly, but instead intermittent. In continuous operation, fresh medium is supplied from a medium container and withdrawn using pumps with holding cells on the membrane surface. The entire cultivation system should be placed in a thermostat-controlled aseptic box or room equipped with an aseptic filter. Spores may be inoculated uniformly onto the membrane surface with a paintbrush or sprayed from a nozzle. Again, pH and medium components can be easily controlled in a container placed outside the membrane module.

Table 1. Some Major Differences in the MSLC, Solid-Substrate Culture, and Submerged Liquid Culture

	MSLC	Solid-substrate culture	Submerged liquid culture
Oxygen uptake	Mostly from gaseous phase	Mostly from gaseous phase	Soley from dissolved oxygen
Agitation	Not essential	Not essential	Strongly required
Medium	Liquid medium	Solid substrate	Liquid medium
Growth	Grown on surface of membrane	Penetrated deep into the solid substrate	Grown in a pulpy or pelletlike form
Recovery of extracellular product	Directly from the liquid medium	Extracted with liquid	Recovered after cell separation

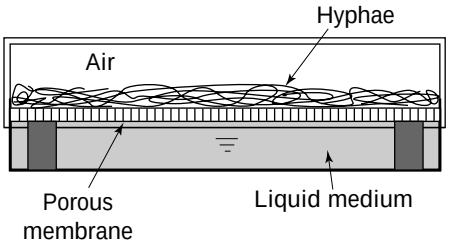

Figure 2. Schematic diagram for an MSLC apparatus using a plastic dish. A porous membrane is set on the surface of liquid medium and held in place by appropriate supports.

Cultivation Modes

Any cultivation mode can be applied to MSLC, including batch, fed-batch, repeated-batch, repeated fed-batch, and continuous. In every mode, molds are cultivated with holding cells on the membrane. In fed-batch MSLC, some components of the medium can be added at appropriate time intervals or added continuously into the medium container during the batch cultivation using the apparatus shown in Figures 3 and 4. In continuous MSLC, fresh medium is continuously fed into the apparatus and withdrawn at the same rate, with an appropriate retention time. The cells are held on the membrane surface during cultivation, in contrast to the ordinary continuous cultivation using an agitated vessel in which the steady state is attained in such a way that the amount of cells grown in per unit time in the fermentor is equivalent to that withdrawn from it.

EXPERIMENTAL RESULTS

Production of Neutral Protease Using Aspergillus oryzae IAM2704

A. oryzae usually produces neutral protease when grown in an appropriate liquid medium such one containing 4 g casein, 15 g glucose, 1 g K_2HPO_4, 0.5 g $MgSO_4 \cdot 7H_2O$, 0.5 g NaCl, and 0.01 g $FeSO_4 \cdot 7H_2O$ in 1 L of ion exchange water, pH 7.0 (3,4). Casein is an inducer for production of protease as well as a nitrogen source. Glucose is the carbon source. Figure 5 shows a comparison of courses of cultivation at 30 °C with respect to changes in glucose concentration, total protease activity in 20 mL of culture medium, and total dry cell weight in shake-flask culture, liquid-surface culture, solid-substrate culture, and MSLC. In all cases, cultivation was started by inoculating spores. In the shake-flask culture, 100-mL shake flasks were used. Liquid-surface culture was carried out statically on the surface of the medium. In the solid-substrate culture, cultivation was carried out on a 1.5% (w/v) agar containing every component of the medium. In MSLC, an SE20 membrane having a nominal pore size of 0.2 μm was used, and culture was carried out statically. A neutral protease activity was expressed as the amount of enzyme determined by the method using 0.6% casein as a substrate. One unit of enzyme activity was defined as the amount of enzyme that solubilizes 1 mg protein at pH 7.0 and 30 °C in 1 min, measured by Lowry's method with bovine serum albumin as a standard (16).

In the shake-flask culture and liquid-surface culture, the amount of protease reached its maximum after several days of cultivation and then rapidly decreased to a low level. The maximum amount of protease produced in both cultures was around 5 U/mL. In the solid-substrate culture on an agar medium, the highest amount of protease produced was about 25 U/mL of agar medium, which was 5 times higher than obtained with the shake-flask culture and liquid-surface culture. Furthermore, the amount of enzyme decreased more gradually after it reached a maximum in the solid-substrate culture. With MSLC, the amount of enzyme produced was higher than 50 U/mL, twice as high as by solid-substrate culture on an agar plate. As shown in Figure 5, both the consumption rate of glucose and the mycelial growth rate were also higher at the initial stage of MSLC than in the shake-flask culture,

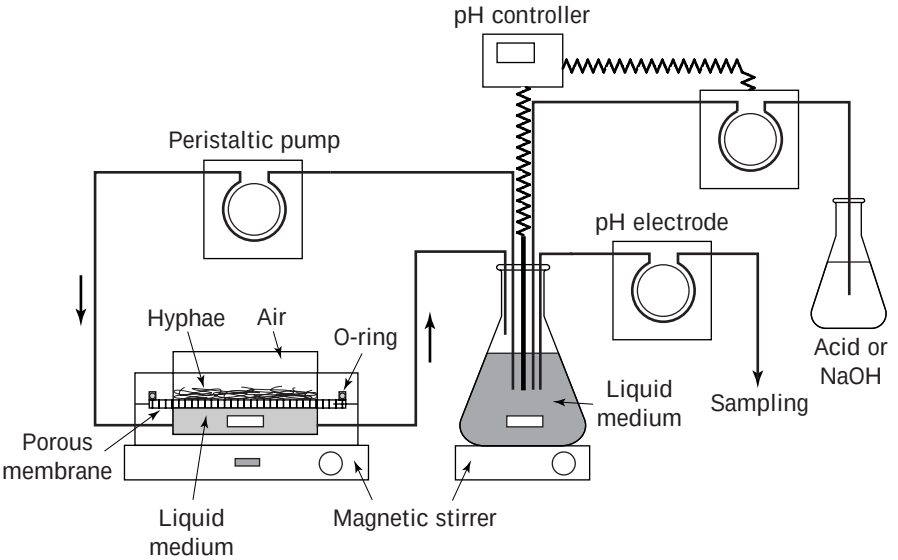

Figure 3. Schematic diagram for a disc-type MSLC system with a medium container, pH controller, and peristaltic pumps (7). The MSLC apparatus is composed of an upper plate with circular openings and a lower plate which is cylindrical, shallow, and contains liquid medium. A porous membrane is set between the upper and lower plate with an O-ring.

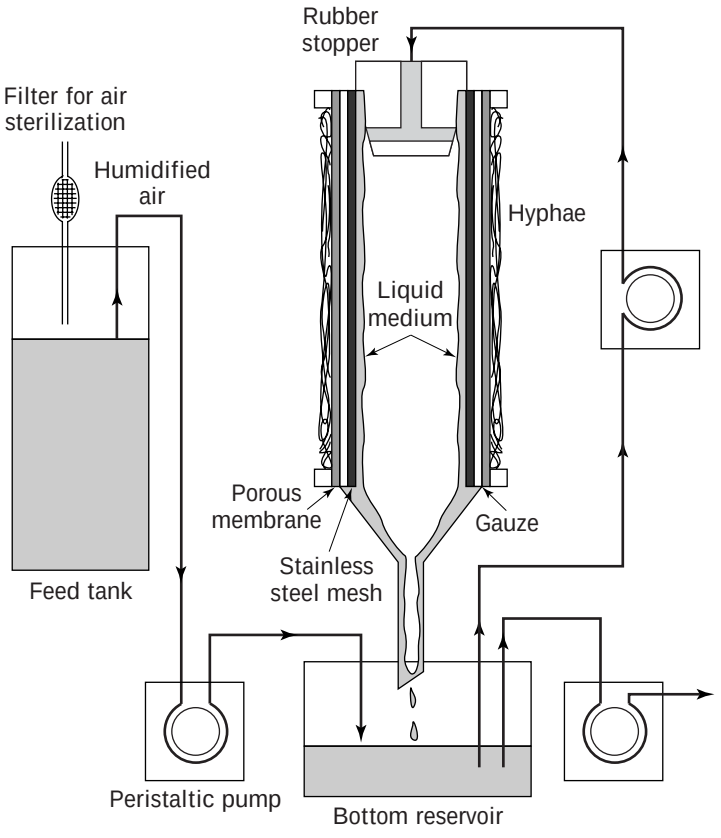

Figure 4. Schematic diagram of an MSLC system using a cylindrical membrane module (8). Liquid medium is intermittently circulated between a cylindrical membrane module and the bottom container. Liquid medium flows down along the inner surface of the module. In continuous MSLC, fresh medium is supplied from the feed tank to a bottom reservoir and withdrawn. The liquid medium is circulated, as in a batch MSLC.

probably because of higher efficiency of oxygen uptake. However, the reason why the enzyme was produced in a larger quantity by MSLC compared with the other cultures may not be due to the larger amount of the molds produced. The highest value for the specific amount of enzyme produced by the shake-flask culture, liquid surface-culture, solid-substrate culture, and MSLC in Figure 3 was around 1.1, 1.2, 4.0, and 6.3 U/mg, respectively.

In MSLC, the effects of the composition and concentration of medium on the production of metabolites were usually different from those in the shake-flask culture. Thus, it is important to optimize the composition and concentration of the medium by using a plastic dish, as shown in Figure 3. In Figure 6, a typical example is shown in which the glucose concentration in the medium for MSLC affects the amount of protease produced in a quite different fashion than seen in shake-flask culture. In MSLC, the maximum amount of protease and specific amount of protease per dry cell weight were increased by lowering the glucose concentration from 1.5% to 0.2%, and in shake-flask culture, the tendency was opposite. It seems that glucose was more effectively utilized to produce the enzyme in the MSLC than in the shake-flask culture.

The molds are stabilized to a greater extent in MSLC. Usually, it is very difficult to conduct a repeated-batch culture or a long-term continuous culture with cell holding in a shake-flask set-up. In MSLC, cultures with cell holding are easy to maintain because of the increased stability of the mold. Keeping the cells on the membrane surface, one can conduct cultures either in a repeated-batch or continuous mode. As shown in Figure 7, repeated batch culture of *A. oryzae* IAM2704 to produce neutral proteases could be effectively carried out by MSLC (5); the liquid medium was exchanged with fresh medium every day except in the first batch. In the first batch, it took a longer time for the molds to germinate and to grow over the whole membrane surface. Once the membrane surface was covered with hyphae, production of the proteases occured satisfactorily. As shown in Figure 7, the cumulative amount of protease increased almost linearly with cultivation time at the initial stage of cultivation. Although the amount of protease produced in each batch gradually decreased, even in the 27th batch it was about 7 times the amount produced in the shake-flask culture.

Production of Kojic Acid Using *A. oryzae* NRRL484

Most molds can produce secondary metabolites, particularly organic acids such as citric acid, erythorbic acid, and kojic acid. *A. oryzae* NRRL484 produced kojic acid in a quite large amount by MSLC (5–7). In the production of kojic acid, molds exhibited behaviors different from those for production of neutral protease. Molds were active in production of kojic acid even when the concentration of carbon and nitrogen sources was in the high range. Figure 8 shows the effect of glucose and yeast extract concentrations on the production of kojic acid using *A. oryzae* NRRL484 in MSLC and shake-flask culture at 30 °C, with culture medium containing 0.75 g $(NH_4)_2SO_4$, 0.25 g K_2HPO_4, 0.25 g $MgSO_4 \cdot 7H_2O$, and 0.5 g of 300 g/L HCl

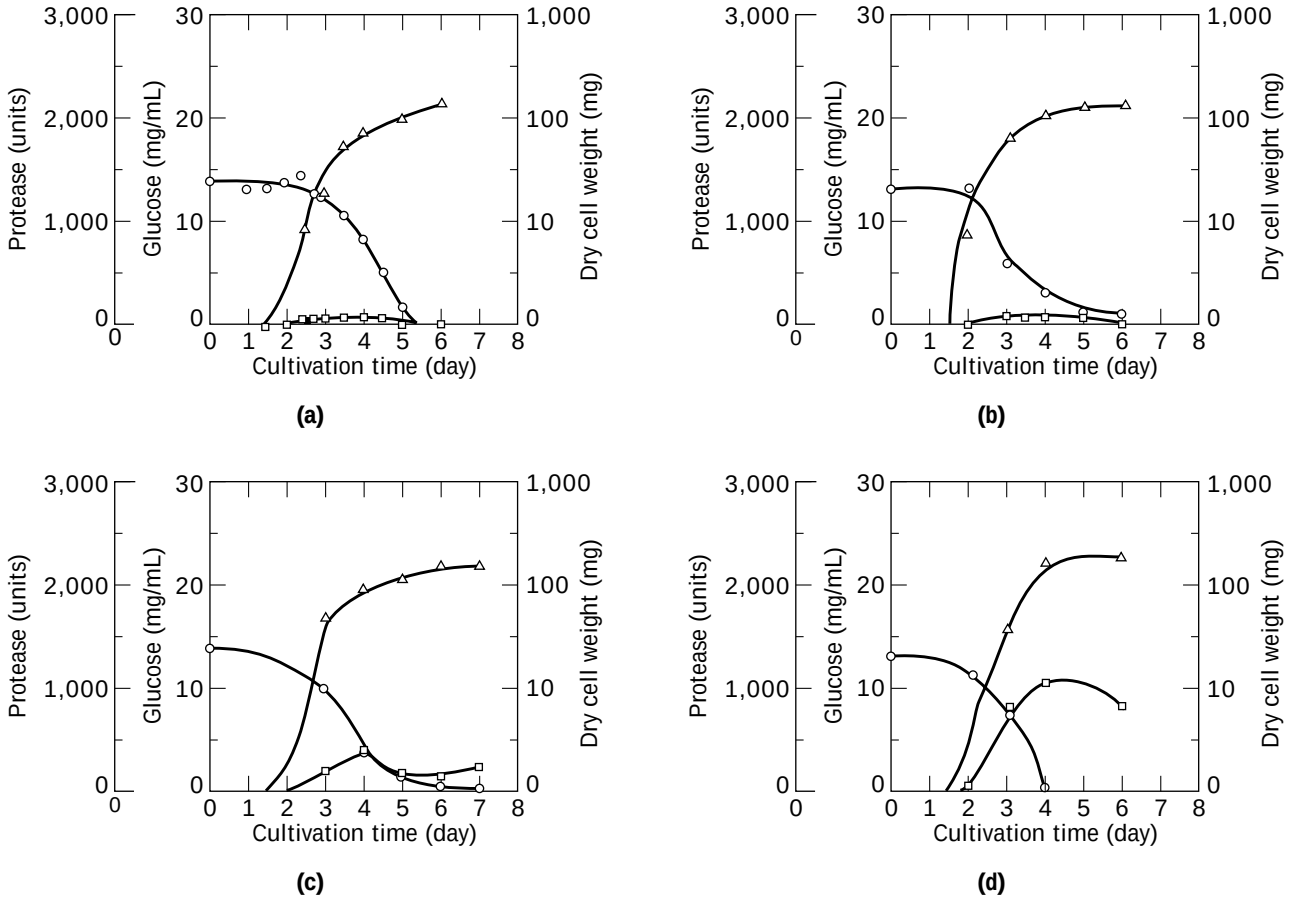

Figure 5. Change of concentrations of dried cell mass (△), glucose (○), and protease (□) during cultivation of *Aspergillus oryzae* IAM2704. (**a**) Shake-flask culture; (**b**) liquid-surface culture; (**c**) solid-substrate culture on agar plate; (**d**) MSLC (4).

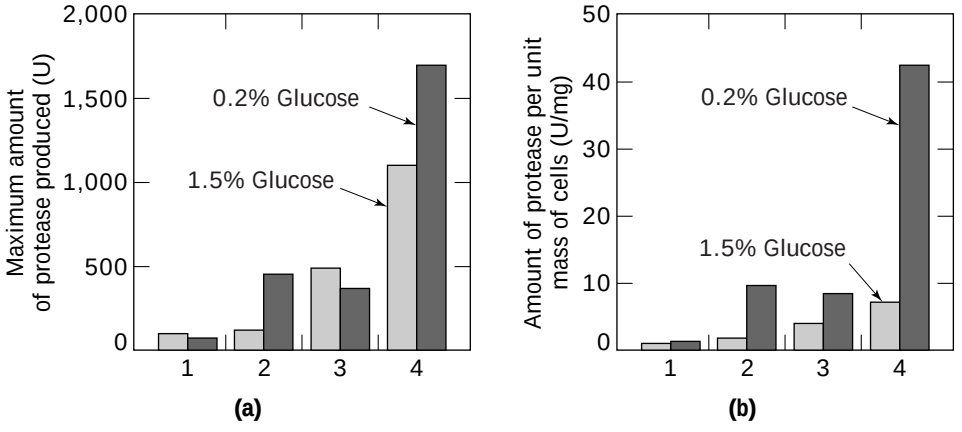

Figure 6. Maximum amount of protease produced (**a**) and specific amount of protease (**b**) during batch cultivation of *Aspergillus oryzae* IAM2704 using 0.2 and 1.5% glucose. 1, Shake-flask culture; 2, liquid-surface culture; 3, solid-substrate culture on agar plate; 4, MSLC (4).

solution containing 20 g/L $SO_4 \cdot 7H_2O$, 20 g/L $FeSO_4 \cdot 7H_2O$, and 30 g/L $ZnSO_4 \cdot 7H_2O$ in 1 L of ion exchanged water, pH 6.0, in addition to 50–400 g/L glucose and 0.2–10 g/L yeast extract. Glucose was a carbon source as well as the substrate for production of kojic acid. Yeast extract was the most suitable nitrogen source. The amount of kojic acid produced can be measured either by Bentley's method (17) or by high-performance liquid chromatography (HPLC). As shown in Figure 8 for a wide range of glucose and yeast extract concentrations, the maximum amount of kojic acid produced by MSLC was higher than by shake-flask culture (7).

Because molds were quite stable in MSLC, repeated fed-batch culture of *A. oryzae* NRRL484 was possible to

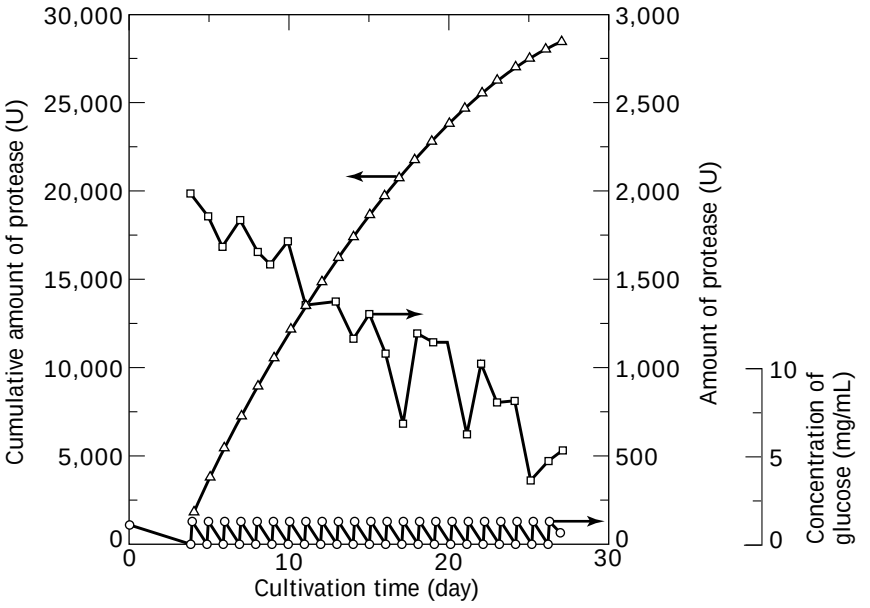

Figure 7. Changes of amount of protease produced in each batch (□), cumulative amount of protease (△), and concentration of glucose (○) during long-term repeated-batch culture by MSLC. The medium containing 0.2% glucose and 0.4% casein was exchanged every 24 h after 4 days of cultivation (first batch).

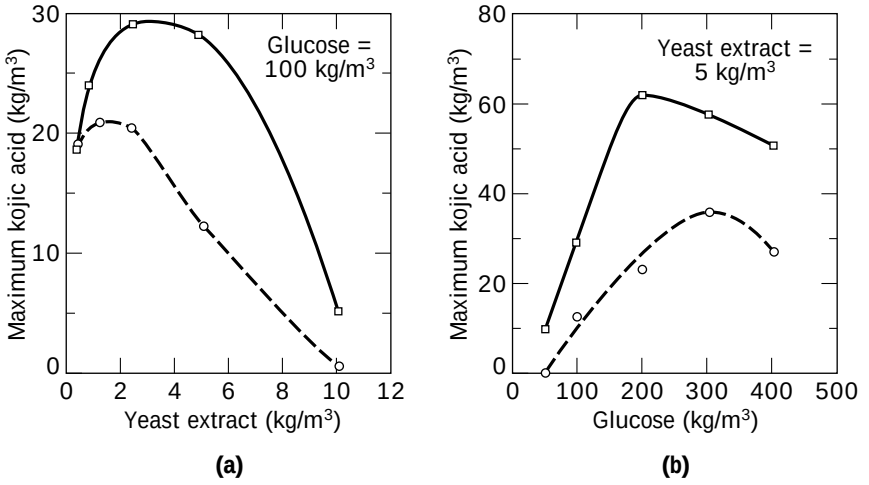

Figure 8. Effects of the concentrations of yeast extract (**a**) and glucose (**b**) on kojic acid production by MSLC (□) and shake-flask culture (○).

produce kojic acid as shown in Figure 9, in which powder glucose was added three times during one batch cultivation and the whole liquid medium was exchanged every 4 days, except the first batch (5). It took a longer time in the first batch until the molds had germinated and grown over the entire membrane surface, as was the case for production of neutral protease. Once the membrane surface was covered with hyphae, there was substantial production of kojic acid. In Figure 9, 12 fed-batch cultures are plotted. For batches 2 through 10, the kojic acid concentration in every batch reached 75 g/L or more, and it precipitated as fine crystals in the medium. In the batches 11 and 12, the production rate was greatly decreased. One possible reason for this decrease is that the amount of mycelia mat formed on the membrane surface increased, which might suppress oxygen transfer into the inside of the mat. Thus, some mycelia that were exposed adjacently on the membrane surface may have been autolyzed.

Continuous production of kojic acid was also possible using *A. oryzae* NRRL484 in a tubular-type MSLC apparatus with cell holding (7). In the cylindrical MSLC apparatus shown in Figure 4, a vertical cylinder 4 cm in diameter and 24 cm in length made of stainless steel mesh is surrounded by a sheet of gauze and then by an SE20 membrane sheet. The top end of the vertical cylindrical membrane module was sealed with a silicon rubber stopper. Typical results for continuous MSLC are shown in Figure 10. In this case, the effective membrane surface area was around 220 cm^2. The volume of medium in the entire system for recycling was 700 mL. At the start of cultivation, about 3 mL of a suspension of spores (5,000/mL) was inoculated uniformly onto the membrane surface using a paintbrush. During cultivation, medium was pumped up from a reservoir at a flow rate of about 6.6 mL/min using a peristaltic pump, and it flowed toward the inner surface of the cylinder through four small holes bored inside the

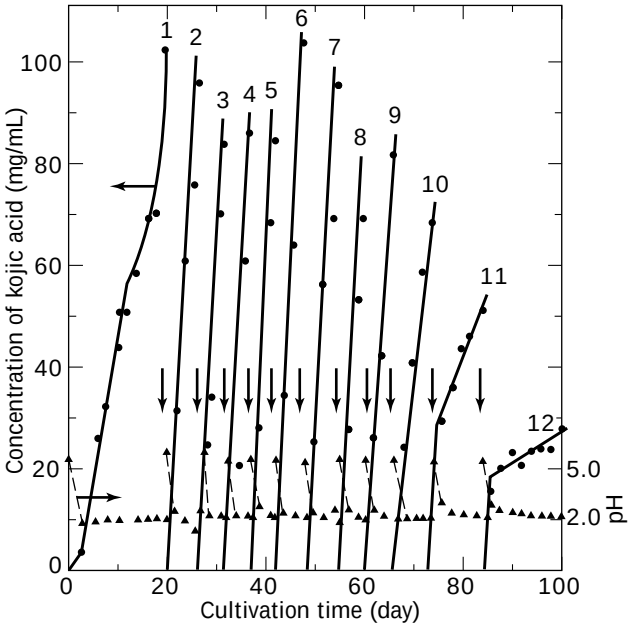

Figure 9. Changes of the concentration of kojic acid produced in each batch (●) and pH (▲) during repeated fed-batch MSLC using the exchange medium containing 0.25% yeast extract and 10% glucose. During each batch culture, powdered glucose was added to a final concentration of about 10% usually twice (batches 1 through 9) and three times (batches 10 and 12). Arrows show the times at which the entire medium was exchanged with fresh medium.

stopper. The pump was driven for 5 min every 15 min using a timer, and thus medium circulation was repeated. Fresh medium was supplied from a medium container and withdrawn using peristaltic pumps. The pumps for medium supply and withdrawal were driven for 1 min every 1 h at a flow rate of 1.25 mL/min. Thus, an average flow rate was 30 mL/day. As shown in Figure 10, after 12 days of cultivation, an almost steady state was attained, although glucose still remained. The steady-state concentration level of kojic acid was in the range of about 40 to 50 g/L for about 65 days. The yield of kojic acid on the basis of glucose consumed was evaluated to be around 70–80%, which is higher than that produced by shake-flask culture (30–40%). The glucose concentration gradually decreased even after 15 days of cultivation, probably because of maintenance metabolism. The fact that long-term continuous MSLC is possible, as shown in Figure 10, may indicate the increased stability of the mold.

PROBLEMS AND FUTURE PERSPECTIVES

In MSLC, molds tend to efficiently produce enzymes and secondary metabolites, and their stability against autolysis seems to be increased. Molds are typical aerobes with a strong oxygen requirement. Molds grow on a solid surface in their natural habitats. Such properties of molds probably favor MSLC, in which molds are grown on the membrane surface, obtaining oxygen directly from the atmosphere while taking liquid medium through the membrane pores with negligibly small mass transfer resistance. In conventional submerged liquid cultures using a shake-flask or an agitated vessel, mold cells are surrounded by the liquid medium, which contains a low amount of dis-

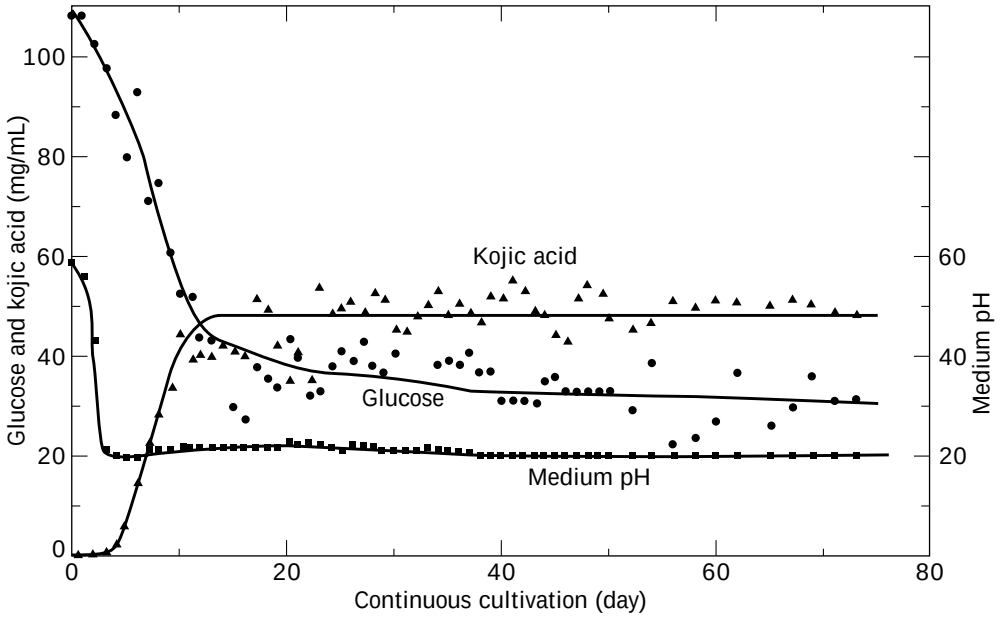

Figure 10. Continuous MSLC using a cylindrical membrane module at 30°C, holding molds on the membrane. About 30 mL of fresh medium was supplied semicontinuously per day, and the same amount was withdrawn while the medium was circulated between the membrane module and bottom container.

solved oxygen; in addition the cells suffer from shear stress, which may promote autolysis. In fact, a long-term operation with cell holding is quite difficult in conventional submerged liquid cultures. On the other hand, MSLC resembles liquid-surface culture (18), in which molds are suspended on the surface of liquid medium without a porous membrane at the interface. Liquid-surface culture is in principle very simple and an energy saving method. Liquid-surface culture was successfully applied to the production of citric acid using molds (19). However, there are some difficulties in conducting liquid-surface culture. In the production of neutral protease by liquid-surface culture using *A. oryzae* IAM2704, the amount of enzyme produced was slightly more than that by shake-flask culture but much less in comparison with that by MSLC. Furthermore, the cell mat is apt to sediment with increasing size. On the other hand, in kojic acid production using *A. oryzae* NRRL484, the cells formed a dense mat on the surface of the liquid medium and did not sediment; however, kojic acid production was less than that obtained by the MSLC. Thus, behaviors of the molds in liquid-surface culture seem to depend on the kinds of mold and cultivation conditions.

Sudo et al. have recently reported (20) that α-amylase is produced at a higher level by solid-substrate culture using rice bran than by agar-plate culture due to better growth of submerged mycelia, which mainly produce the enzyme. Thus, it may be interesting to compare the cells cultivated by MSLC with those obtained from other cultures (such as solid-substrate culture, agar-plate culture, liquid-surface culture, and shake-flask culture) from a stand point of the differences in respiratory activity, the amounts of related enzymes and, also gene expression. It may also be interesting to examine the effect of the gas composition on cultivation of molds by MSLC.

MSLC is an energy-saving process because the amounts of energy required for agitation and aeration are negligible, and downstream processing is simplified because the medium is not contaminated with cells. However, to utilize MSLC industrially some technical problems should be solved, such as those in spore inoculation, removal of the cells, and sterilization of the apparatus. The properties of the membrane are an important factor. The membrane should be reusable, resistant to autoclaving, and show appropriate hydrophilicity.

MSLC is an interesting method for investigating the physiological properties of molds, as well as a promising method for effective production of metabolites using molds.

OUTLINE

The versatility of microbial biosynthesis is enormous. Today's products of the microbe vary from the simplicity of

methane and acetic acid to the complexity of vitamin B_{12} and proteins. The importance of the fermentation industry resides in five characteristics of microorganisms: *(1)* a high ratio of surface area to volume, which facilitates the rapid uptake of nutrients required to support high rates of metabolism and biosynthesis; *(2)* the tremendous variety of reactions microorganisms are capable of carrying out; *(3)* a facility to adapt to a large array of different environments, allowing a culture to be transplanted from nature to the laboratory flask or the factory fermentor, where it is capable of growing on inexpensive carbon and nitrogen sources and producing valuable compounds; *(4)* the ease of genetic manipulation, both in vivo and in vitro, to increase production of the products, to modify structures and activities, and to make entirely new products; and *(5)* an ability to make specific enantiomers, usually the active ones, in cases where normal chemical synthesis yields a mixture of active and inactive enantiomers.

Microorganisms are important to us for many reasons, but one of the principal ones is that they produce things of value to us. These may be very large materials such as proteins, nucleic acids, carbohydrate polymers, or even cells, or they can be smaller molecules, which we usually separate into metabolites essential for vegetative growth and those that are inessential (i.e., primary and secondary metabolites, respectively).

The power of the microbial culture in the competitive world of commercial synthesis can be appreciated by the fact that even simple molecules (e.g., L-glutamic acid and L-lysine) are made by fermentation rather than by chemical synthesis. Although a few products have been temporarily lost to chemical synthesis (e.g., solvents such as acetone and butanol), it is obvious that most natural products are made by fermentation technology. Despite the efficiency of the chemical route to riboflavin, much of the production of this compound is carried out by fermentation; chemical processes to vitamin C and steroids still employ microbial bioconversion steps. Most natural products are so complex and contain so many centers of asymmetry that they probably will never be made commercially by chemical synthesis.

Although microbes are extremely good in presenting us with an amazing array of valuable products, they usually produce them only in amounts that they need for their own benefit; thus, they tend not to overproduce their metabolites. Regulatory mechanisms have evolved in microorganisms that enable a strain to avoid excessive production of its metabolites so that it can compete efficiently with other forms of life and survive in nature. Some of the important control mechanisms are induction, feedback regulation, and nutrient (catabolite) regulation. The fermentation microbiologist, however, desires a "wasteful" strain that will overproduce and excrete a particular compound that can be isolated and marketed. During the screening stage, the microbiologist searches for organisms with weak regulatory mechanisms. Once a desired strain is found, a development program is begun to improve titers by modification of culture conditions, mutation, and recombinant DNA technology. The microbiologist is actually modifying the regulatory controls remaining in the original culture so that its inefficiency can be further increased and the microorganism will excrete tremendous amounts of these valuable products into the medium.

The main reason for the use of microorganisms to produce compounds that can otherwise be isolated from plants and animals or synthesized by chemists is the ease of increasing production by environmental and genetic manipulation. Thousandfold increases have been recorded for small metabolites. Of course, the higher the specific level of production, the simpler the job of isolation. Consider the case of *Ashbya gossypii*, which has been forced into making over 40,000 times more riboflavin than it needs, or *Pseudomonas denitrificans*, which produces a 100,000-fold excess of vitamin B_{12}. The original Oxford strain of *Penicillium notatum* produced 5 mg of penicillin per liter; today's strains make over 60,000 mg/L, a figure higher than the dry weight of the cells in the fermentor.

Primary metabolites are the small molecules of all living cells that are intermediates or end products of the pathways of intermediary metabolism, are building blocks for essential macromolecules, or are converted into coenzymes. The most industrially important are the amino acids, nucleotides, vitamins, solvents, and organic acids. Primary metabolites vary in size from hydrogen gas (2 Da) and methane (16 Da) to vitamin B_{12} (1,355 Da). It is not unexpected that amino acids and vitamins are used in human and animal nutrition, that ethanol, acetone, and butanol are used as fuels and solvents, and that citric and acetic acids are used as acidulants. However, many of these general metabolites are used in novel ways: the sodium salts of glutamic, 5′-inosinic, and 5′-guanylic acids as flavor enhancers, sodium gluconate as a sequestering agent to prevent the deposition of soap scums on cleaned surfaces, and fumarate in the manufacture of polyester resins. Organisms that produce such products are fantastic in their degree of overproduction.

For many years, microbial products have been used to enhance the quality, appeal, and availability of food and drink. A list of primary metabolites that have been or are being used in the food and feed industries is shown in Table 1.

About 1 million tons of amino acids are produced annually. In amino acid production, feedback regulation is

Table 1. Some Primary Metabolites Used in the Food and Feed Industries

Class	Examples
Alcohols	Ethanol
Amino acids	Glutamic acid (monosodium glutamate), lysine, threonine, tryptophan, phenylalanine
Nucleotides	5′-Guanylic acid, 5′-inosinic acid
Organic acids	Acetic acid, propionic acid, succinic acid, fumaric acid, lactic acid, malic acid, tartaric acid, citric acid, gluconic acid
Polyols	Glycerol, mannitol, erythritol, xylitol
Polysaccharides	Xanthan, gellan
Sugars	Fructose, sorbose
Vitamins	Riboflavin (B_2), cyanocobalamin (B_{12}), biotin

bypassed by isolating an auxotrophic mutant and partially starving it of its requirement. A second means to bypass feedback regulation is to produce mutants resistant to a toxic analog of the desired metabolite (i.e., an antimetabolite). Combinations of auxotrophic and antimetabolite resistance mutations are common in primary metabolite producing microorganisms. Permeability is very important in the production of L-glutamic acid, the major amino acid of commerce. About 1.2 billion pounds of monosodium glutamate, a potent flavor enhancer, are made annually by fermentation using various species of the genera *Corynebacterium* and *Brevibacterium* (e.g., *Corynebacterium glutamicum*, *Brevibacterium flavum*, and *B. lactofermentum*). Today, these glutamate producers are classified as subspecies of *Corynebacterium glutamicum* (e.g., *C. glutamicum* ssp. *flavum* and *C. glutamicum* ssp. *lactofermentum*). The major route of glutamate production from glucose is via the Embden–Meyerhof pathway and the early steps of the tricarboxylic acid cycle (Fig. 1). α-Ketoglutarate, which would normally be converted to succinyl coenzyme A in the cycle, is instead reductively aminated to glutamate by glutamate dehydrogenase. Molar yields of glutamate from sugar are 50–60%, and broth concentrations reach more than 100 g/L. Normally, glutamic acid overproduction would not occur because of feedback regulation. However, due to a modification of the cell membrane, glutamate is pumped out of the cell, thus allowing its biosynthesis to proceed unabated. The membrane alteration is intentionally effected by biotin limitation (all glutamic acid bacteria are biotin auxotrophs), glycerol limitation of glycerol auxotrophs, oleate limitation of oleate auxotrophs, or addition of penicillin or fatty acid derivatives to exponentially growing cells. Apparently all of these manipulations result in a phospholipid-deficient cytoplasmic membrane. Also required for effective production are a high level of carbon and energy source as well as growth inhibition. The actual excretion is carried out by a specific efflux system involving a carrier that is dependent on membrane potential (1).

The bulk of the cereals consumed in the world are deficient in the essential amino acid L-lysine. Lysine supplementation converts such cereals into balanced food or feed. Lysine is a member of the aspartate family of amino acids. It is produced in bacteria by a branched pathway that also produces methionine, threonine, and isoleucine. This pathway is controlled very tightly in an organism such as *Escherichia coli*; this organism contains three aspartate kinases, each of which is regulated by a different end product. In addition, after each branch point, the initial

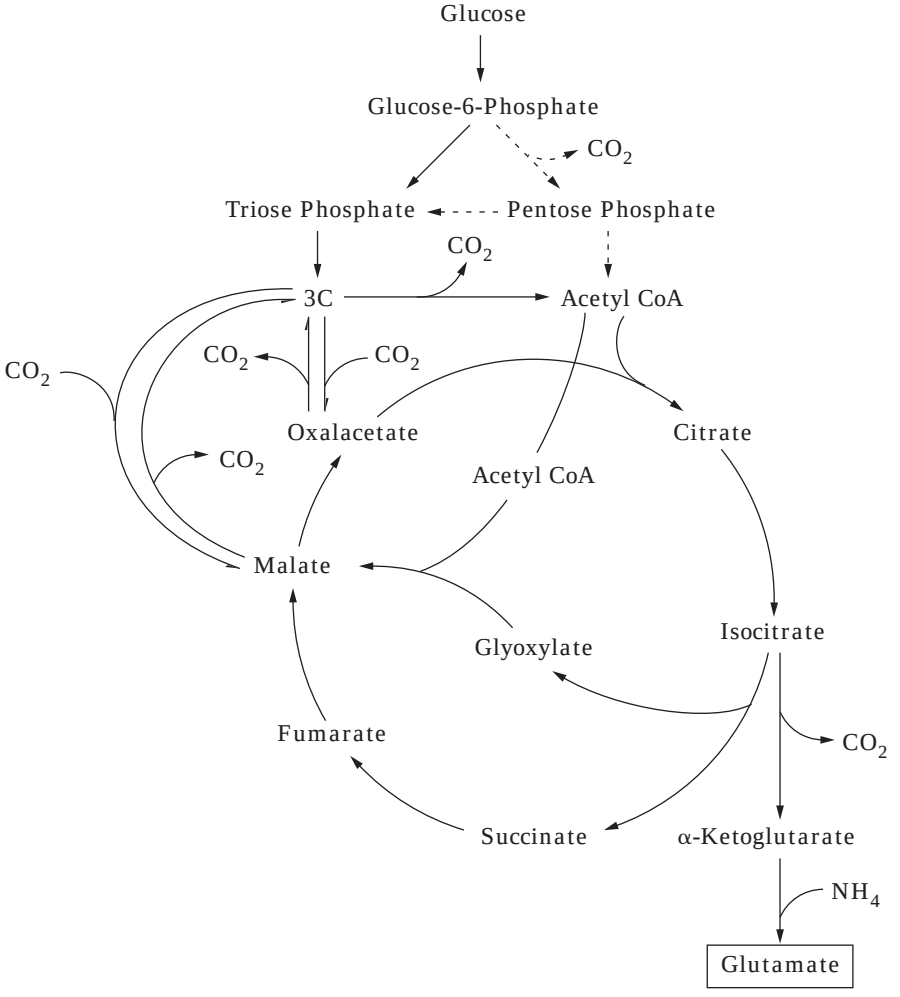

Figure 1. Pathway of glutamic acid production from glucose by *Corynebacterium glutamicum*.

enzymes are inhibited by their respective end products and no overproduction occurs. However, in lysine fermentation organisms (e.g., various mutants of *C. glutamicum* and its relatives), there is a single aspartate kinase, as shown in Figure 2. This aspartate kinase is regulated via concerted feedback inhibition by threonine plus lysine. By genetic removal of homoserine dehydrogenase, a glutamate-producing wild-type *Corynebacterium* is converted into a lysine-overproducing mutant that cannot grow unless methionine and threonine are added to the medium. As long as the threonine supplement is kept low, the intracellular concentration of threonine is limiting and feedback inhibition of aspartate kinase is bypassed. Other enzymes in the aspartate family biosynthetic pathway such as aspartate semialdehyde dehydrogenase and threonine synthetase are unregulated. In addition to the difference in the mode of aspartate kinase feedback inhibition, lysine overproducers differ from *E. coli* in the following ways: (*1*) no feedback repression of aspartate kinase or aspartate semialdehyde dehydrogenase occurs in lysine overproducers;

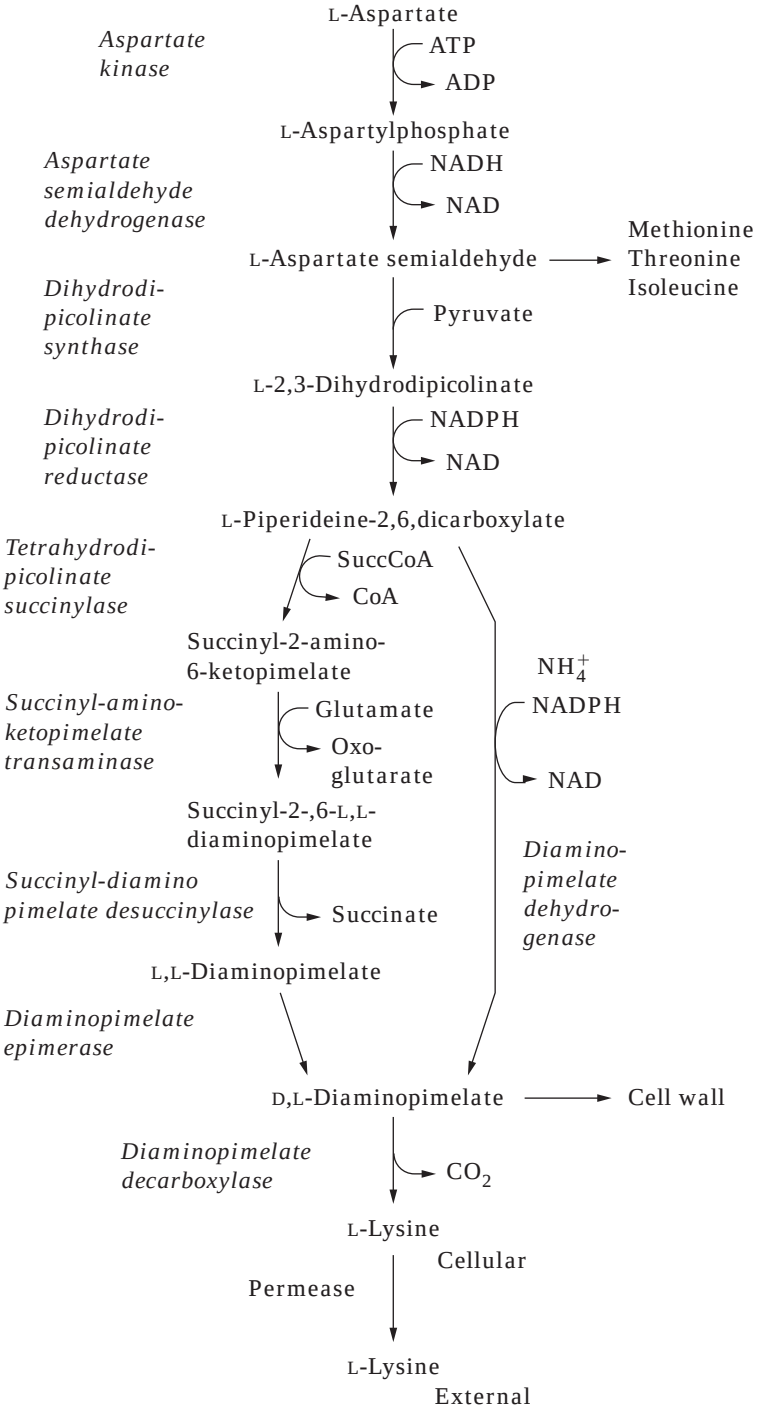

Figure 2. Biosynthesis of L-lysine by *Corynebacterium glutamicum Source:* From Ref. 2.

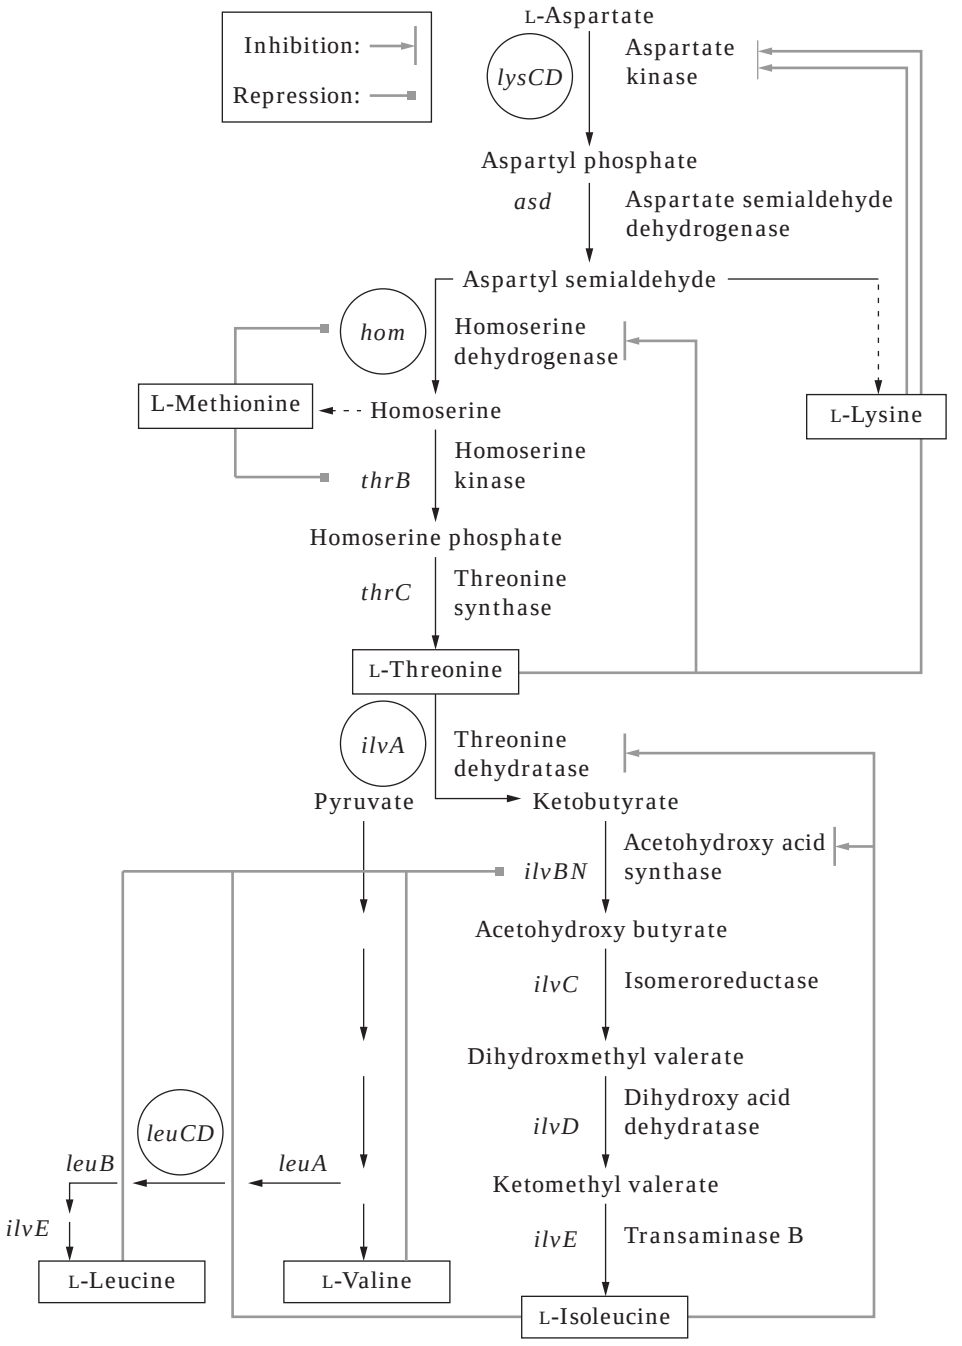

Figure 3. L-Isoleucine biosynthesis in recombinant *Corynebacterium glutamicum* strains. Repression on the DNA level (shaded lines with square ends) and inhibition of enzymes (shaded lines with arrowhead ends). The last four enzymatic steps are the same for L-isoleucine and L-valine biosynthesis. *Source*: Ref. 7.

(*2*) the first and second enzymes of the lysine branch (dihydrodipicolinate synthetase and dihydrodipicolinate reductase) are neither inhibited nor repressed by lysine in lysine overproducers; (*3*) L-lysine decarboxylase is absent in lysine overproducers. The pentose phosphate pathway is of much greater importance in lysine production than in glutamate formation due to the greater need of NADPH for the former path (3). Lysine excretion is by active transport involving a carrier and is driven by membrane potential, the lysine gradient, and the proton gradient. Excretion

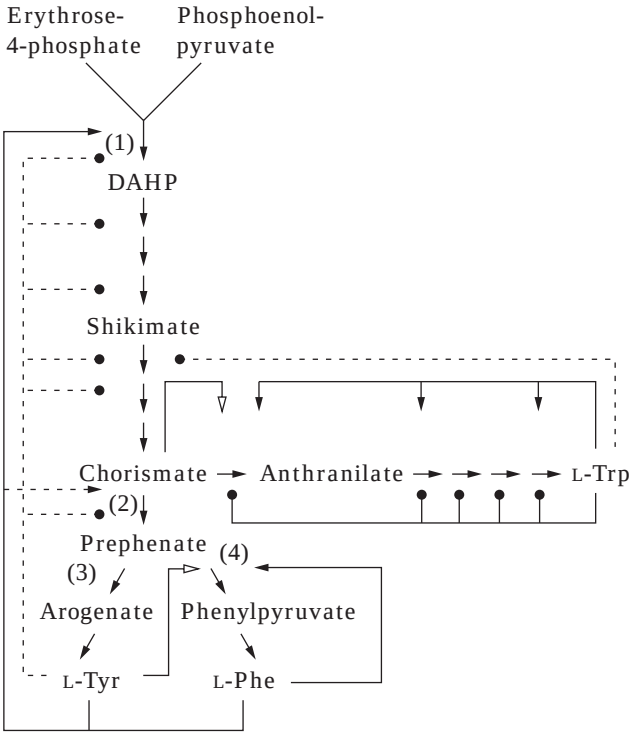

Figure 4. Biosynthetic pathway of aromatic amino acids and their regulatory mechanisms in *Corynebacterium glutamicum* sp. *lactofermentum*. 1, 3-deoxy-D-arabino-heptulosonate-7-phosphate (DAHP) synthase; 2, chorismate mutase; 3, arogenate aminotransferase; 4, prephenate dehydratase; ◀—, inhibition; ◀---, partial inhibition; ◁—, activation; ●—, repression; ●---, weak repression. *Source*: From Ref. 8.

uses a 2 OH/lysine symporter and is catalyzed by a dipetide uptake system dependent on electromotive force, not ATP (4).

Recombinant DNA techniques have made their way into the amino acid production area (5). *E. coli* and *Serratia marcescens* strains have been constructed with plasmids bearing amino acid biosynthetic operons. Plasmid transformation has been accomplished in *C. glutamicum*, so that recombinant DNA technology is now used to improve these commercial amino acid–producing strains. The major manipulations have involved gene cloning to increase the levels of feedback-resistant aspartate kinase and dihydrodipicolinate synthase (6). As a result, lysine industrial production yields 120 g/L and 0.25–0.35 g L-lysine·HCl per gram glucose used (molar yield of 0.25–0.35 mol L-lysine per mole of glucose used). The market for L-lysine·HCl is 360 million pounds per year (6).

Recombinant technology and traditional mutagenesis and selection have been major influences in constructing bacterial strains capable of producing 100 g/L L-threonine, 40 g/L L-isoleucine, 34 g/L L-leucine, 31 g/L L-valine, 28 g/L L-phenylalanine, 55 g/L L-tryptophan, 26 g/L L-tyrosine, 100 g/L L-proline, 65 g/L L-arginine, and 40 g/L L-histidine. The relationship between the lysine biosynthetic pathway and that for threonine, methionine, isoleucine, valine, and leucine in *C. glutamicum* is shown in Figure 3. The pathway to the aromatic amino acids (phenylalanine, tryptophan, and tyrosine) is given in Figure 4.

The commercial interest in nucleotide fermentations is due to the activity of two purine ribonucleoside 5′-monophosphates, namely guanylic acid (GMP) and inosinic acid (IMP), as enhancers of flavor (9,10). Some 2,500 tons of GMP and IMP are produced annually in Japan alone. Three main processes are used: (*1*) hydrolysis of yeast RNA by fungal nuclease to AMP and GMP followed by enzymatic deamination of AMP to IMP; (*2*) fermentative production of the nucleosides inosine and guanosine by *Bacillus subtilis* mutants followed by chemical phosphorylation, and (*3*) direct fermentation of sugar to IMP by *C. glutamicum* mutants plus conversion of guanine to GMP by salvage synthesis using intact cells of *Brevibacterium ammoniagenes*. Titers of IMP by direct fermentation have reached 27 g/L (10).

The pathway of purine ribonucleotide biosynthesis (Fig. 5) is virtually identical in all living systems. In the first specific step, 5′-phosphoribosyl pyrophosphate (PRPP), derived from ATP and ribose-5-phosphate, is aminated with glutamine to form 5′-phosphoribosylamine (PRA). By a series of nine known enzymic steps, PRA is converted to IMP, the first purine ribonucleotide formed. This pivotal intermediate is the precursor of both AMP and GMP. IMP is then converted to adenylosuccinate (S-AMP), aspartate acting as the succinyl donor and GTP as the energy source. Adenylosuccinate is then converted to AMP by adenylosuccinate lyase, a bifunctional enzyme that also catalyzes an earlier step. Inosinic acid is oxidized by IMP dehydrogenase using NAD^+ as a cofactor to form XMP. The latter is aminated by XMP aminase to GMP. In this reaction, ATP is the energy source, and, depending on the organism, the amino donor is either glutamine or ammonia. Both AMP and GMP can be used for synthesis of nucleic acids after being converted to their respective di- and triphosphates. Alternatively, GMP can be reduced to IMP in a reaction catalyzed by GMP reductase (which utilizes NADPH as an electron donor) and AMP can be converted to IMP by deamination. These reactions permit a cyclic regeneration of intermediates common to both purine nucleotides from an accumulated excess of either. All of the purine ribonucleotide interconversions occur via their 5′-isomers.

With such a complex series of biosynthetic reactions, it is essential to the economy of the cell that there be regulation of the rates of the individual reactions. This regulation is accomplished by negative feedback inhibition of enzyme action and repression of enzyme synthesis. Figure 6 shows an example of a typical feedback control system for nucleotide biosynthesis. Usually both AMP and GMP exert feedback repression and inhibition on the common pathway and on their respective branches. An important control site is step 1, catalyzed by PRPP amidotransferase. In some microorganisms, AMP and GMP each inhibit action of the enzyme completely at high concentrations. In other organisms, a cumulative type of regulation is observed. Synthesis of the amidotransferase, as well as many of the other enzymes of the common pathway, is also re-

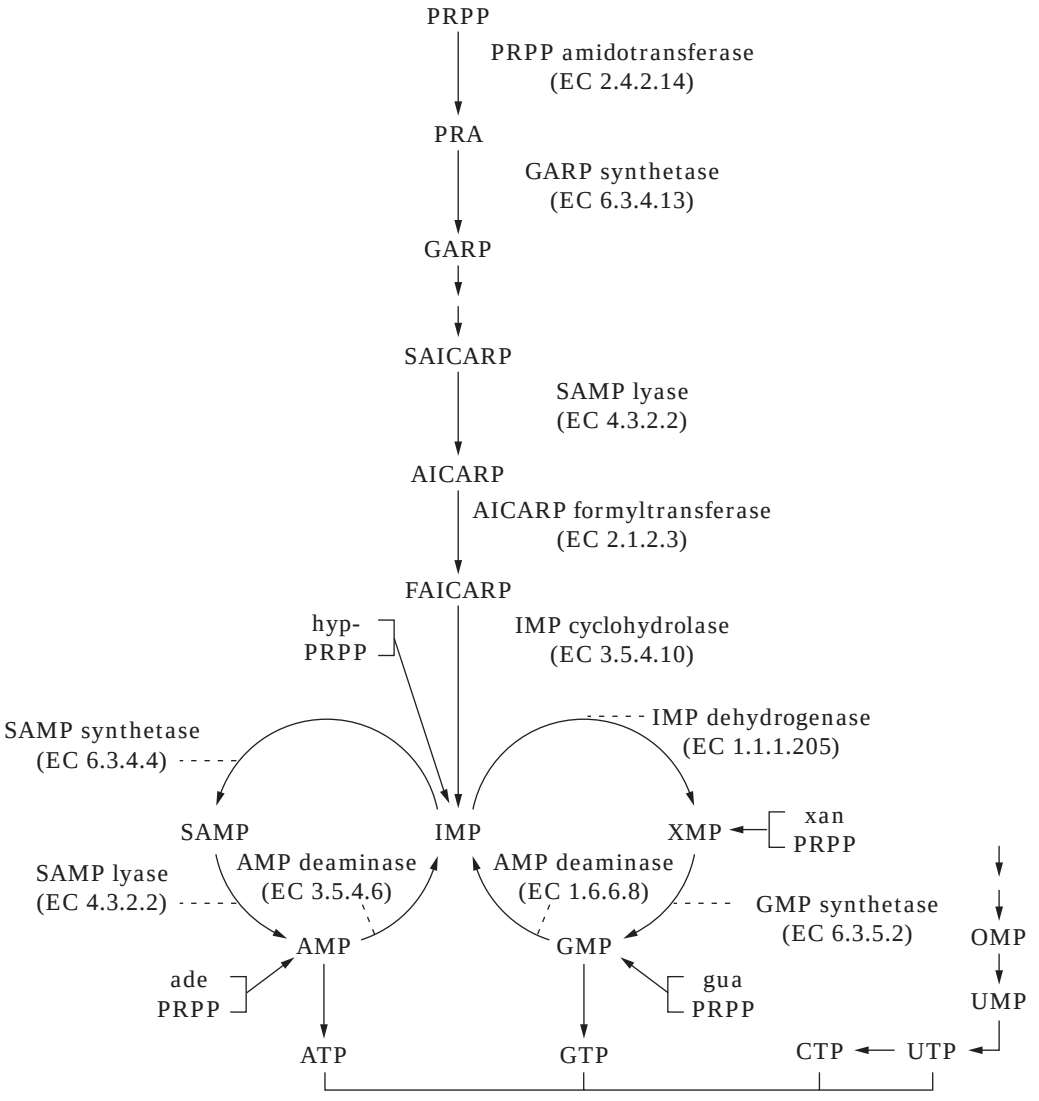

Figure 5. Biosynthetic pathway to purine nucleotides. pressed by AMP and GMP. Another important control site is IMP dehydrogenase, which is usually inhibited and repressed by GMP. The conversion of IMP to S-AMP (catalyzed by adenylosuccinate synthase) is usually repressed and inhibited by AMP.

The key to effective purine accumulation is the limitation of intracellular AMP and GMP. This limitation is best effected by restricted feeding of purine auxotrophs. Thus, adenine-requiring mutants lacking adenylosuccinate synthetase (see Fig. 7) accumulate hypoxanthine or inosine that results from breakdown of intracellularly accumulated IMP. Because of the strong inhibition and repression of IMP dehydrogenase by GMP, the accumulation does not proceed past IMP into the GMP branch of the pathway. Certain adenine auxotrophs of *Bacillus subtilis* excrete more than 10 g/L inosine. These strains are still subject to GMP repression of enzymes of the common path. To minimize the severity of this regulation, the adenine auxotrophs are further mutated to eliminate IMP dehydrogenase. These adenine–xanthine double auxotrophs show a twofold increase in specific activity of some common-path enzymes and accumulate up to 15 g/L inosine under conditions of limiting adenine and xanthine (or guanosine). Further deregulation is achieved by selection of mutants resistant to purine analogs. Thus, mutants requiring adenine and xanthine and resistant to azaguanine produce more than 20 g/L inosine. Insertional inactivation of the IMP dehydrogenase gene in another *B. subtilis* strain yielded a culture producing 35 g/L inosine (11). Genetic engineering of the inosine monophosphate dehydrogenase

gene in a *B. subtilis* strain, which was producing 7 g/L guanosine and 19 g/L inosine, changed production to 20 g/L guanosine and 5 g/L inosine (12). Other *B. subtilis* mutants produce as much as 23 g/L guanosine (10). With regard to pyrimidine production, another recombinant strain of *B. subtilis* produces 18 g/L cytidine, and a mutant lacking homoserine dehydrogenase (which increased the concentration of the precursor aspartate in the cell) produces 30 g/L cytidine (13).

Riboflavin (vitamin B_2: Fig. 8) is produced commercially by both fermentation and chemical synthesis (15). Riboflavin overproducers include two yeastlike molds, *Eremothecium ashbyii* and *Ashbya gossypii*, which synthesize riboflavin in concentrations greater than 20 g/L. Production of riboflavin amounted to 4 million pounds in 1992 (16). A riboflavin overproducer such as *A. gossypii* makes 40,000 times more vitamin than it needs for its own growth. The biochemical key to riboflavin overproduction appears to involve insensitivity to the repressive effects of iron. Ferrous ion severely inhibits riboflavin production by low and moderate overproducers, such as clostridia and *Candida* but has no inhibitory action against *E. ashbyii* and *A. gossypii*. In normal microorganisms, it appears that iron represses almost all of the riboflavin biosynthetic enzymes, whereas riboflavin or a derivative inhibits the first enzyme of the pathway, GTP cyclohydrolase II. New processes using *Candida* sp. or recombinant *B. subtilis* strains that produce 20–30 g/L riboflavin have been developed in recent years.

Vitamin B_{12} (Fig. 9) is industrially produced by *Propionibacterium shermanii* or *Pseudomonas denitrificans* (16,18). Such strains used for industrial production make about 100,000 times more vitamin B_{12} than they need for their own growth. The key to the fermentation is avoidance of feedback repression by vitamin B_{12}. The early stage of the *Propionibacterium shermanii* fermentation is conducted under anaerobic conditions in the absence of the precursor 5,6-dimethylbenzimidazole. These conditions prevent vitamin B_{12} synthesis and allow for the accumulation of the intermediate, cobinamide. Then the culture is aerated and dimethylbenzimidazole is added, converting cobinamide to the vitamin. In the *Pseudomonas denitrificans* fermentation, the entire process is carried out under low oxygen conditions. A high level of oxygen results in an oxidizing intracellular environment that represses formation of the early enzymes of the pathway. The key to *Pseudomonas denitrificans* fermentation is the addition of betaine (19). Vitamin B_{12} overproduction by *Pseudomonas denitrificans* is totally dependent on betaine, but the mechanism of control is unknown. Production of vitamin B_{12} has reached levels of 150 mg/L (18).

In production of biotin, feedback repression is caused by the enzyme protein acetyl-CoA carboxylase biotin holoenzyme synthetase, with biotin 5-adenylate acting as corepressor (20). Strains of *Serratia marcescens* obtained by mutagenesis, selection for resistance to biotin antimetabolites, and molecular cloning produce 600 mg/L in the presence of high concentrations of sulfur and ferrous iron (21).

Such a titer is high enough to economically compete with the traditional chemical process. The pathway is shown in Figure 10.

A novel process for vitamin C (ascorbic acid) synthesis involves the use of a genetically engineered *Erwinia herbicola* strain containing a gene from *Corynebacterium* sp. The engineered organism converts glucose into 2-ketogulonic acid, which can be easily converted by acid or base to ascorbic acid (23). Another process devised independently converts 40 g/L glucose into 20 g/L 2-keto-L--gulonate (24). This process involves cloning of the gene encoding 2,5-diketo-D-gluconate reductase from *Corynebacterium* sp. into *Erwinia citreus*. Plasmid cloning of the genes encoding L-sorbose dehydrogenase and L-sorbosone dehydrogenase from *Gluconobacter oxydans* back into the same organism yielded a strain capable of converting 150 g/L D-sorbitol into 130 g/L 2-keto-L-gulonate (25).

Filamentous fungi have been widely used for the commercial production of organic acids. About 1 billion pounds of citric acid are produced each year. This organic acid is produced via the Embden–Meyerhof pathway and the first step of the tricarboxylic acid cycle (Fig. 11). The major control of the process involves the inhibition of phosphofructokinase by citric acid. The commercial process employs *Aspergillus niger* in media deficient in iron and manganese. Manganese deficiency has two beneficial effects in the citric acid fermentation: *(1)* it leads to high levels of intracellular NH_4, which reverse citric acid inhibition of phosphofructokinase, and *(2)* it brings on the formation of small mycelial pellets, which are the best morphological form for citric acid production. The morphological effect is due to a change in cell wall composition caused by growth in low Mn^{+}. A high level of citric acid production is also associated with a high intracellular concentration of fructose 2,6-biphosphate, an activator of glycolysis (27). Other factors that contribute to high citric acid production are the inhibition of isocitrate dehydrogenase by citric acid and the low pH optimum (1.7–2.0). Higher pH levels (e.g., 3.0) lead to production of oxalic and gluconic acids instead of citric acid. The low pH level inactivates glucose oxidase, which normally would yield gluconic acid (26). In approximately 4 to 5 days, the major portion (80%) of the sugar is converted to citric acid, titers reaching about 100 g/L. Because citric acid is easily assimilated, is palatable, and exhibits low toxicity, it is widely used in the food and pharmaceutical industries. It is employed as an acidifying and flavor-enhancing agent, as an antioxidant for inhibiting rancidity in fats and oils, as a buffer in jams and jellies, and as a stabilizer in a variety of foods. The pharmaceutical industry uses approximately 16% of the available supply of citric acid. Processes have been developed for the production of citric acid by *Candida* yeasts, especially from hydrocarbons. Such yeasts are able to convert *n*-paraffins to citric and isocitric acids in extremely high yields (150–170% on a weight basis). Production of citric acid instead of isocitric acid is favored by selecting mutants that are deficient in the enzyme aconitase. Titers as high as 225 g/L have been reached (26).

Cloning of the aldehyde dehydrogenase gene from *Acetobacter polyoxogenes* on a plasmid vector into *A. aceti* sp. *xylinum* increased the rate of acetic acid production by more than 100% (from 1.8 to 4 g L^{-1} h^{-1}) and titer by 40% (from 68 to 97 g/L) (28).

Ethyl alcohol is a primary metabolite that can be produced by fermentation of a sugar or a polysaccharide that can be depolymerized to a fermentable sugar. Yeasts are preferred for these fermentations, but the species used depends on the substrate employed. *Saccharomyces cerevisiae* is employed for the fermentation of hexoses, whereas *Kluyveromyces fragilis* or *Candida* species may be utilized if lactose or pentoses, respectively, are the substrates. Under optimum conditions, approximately 10 to 12% ethanol by volume is obtained within 5 days. Such a high concentration slows down growth and the fermentation ceases. With special yeasts, the fermentation can be continued to alcohol concentrations of 20% by volume.

However, these concentrations are attained only after months or years of fermentation. At present, industrial ethanol is mainly manufactured by fermentation, but there are still considerable amounts made by the petrochemical industry from ethylene. Bacteria such as clostridia and *Zymomonas* are being reexamined for ethanol production after years of neglect. *Clostridium thermocellum*, an anaerobic thermophile, can convert waste cellulose directly to ethanol. Other clostridia produce acetate, lactate, acetone, and butanol and will be utilized as petroleum becomes depleted in the world. Fuel ethanol produced from biomass would provide relief from air pollution caused by the use of gasoline and would not contribute to the greenhouse effect. Because of the elimination of lead from gasoline, ethanol is being substituted as a blend to raise gasoline's octane rating. *E. coli* has been converted into an excellent ethanol producer (43%, v/v) by recombinant DNA technology (29). Alcohol dehydrogenase II and pyruvate decarboxylase genes from *Zymomonas mobilis* were inserted in *E. coli* and became the dominant system for NAD regeneration. Ethanol represents more than 95% of the fermentation products in the genetically engineered strain.

In addition to the multireaction sequences of fermentations, microorganisms are extremely useful in carrying out biotransformation processes in which a compound is converted into a structurally related product by one or a small number of enzymes contained in the cells (30). Bioconverting organisms are known for practically every type of chemical reaction. One of the earliest and most famous is the biotransformation of progesterone to 11 α-hydroxyprogesterone (Fig. 12). The reactions are sterospecific, the ultimate in specificity being exemplified by the steroid bioconversions. This specificity is exploited in the resolution of racemic mixtures when a specific isomer rather than a racemic mixture is desired. Bioconversions are characterized by extremely high yields (i.e., 90 to 100%). Other attributes include mild reaction conditions and the coupling of reactions using a microorganism containing several enzymes working in series. There is a tremendous interest in immobilized cells to carry out such processes. These cells are usually much more stable than either free cells or enzymes and are more economical than immobilized enzymes. Recombinant DNA techniques have been useful in developing new bioconversions. For example, the cloning of the fumarase-encoding gene in *Saccharomyces cerevisiae* improved the bioconversion of malate to fumarate from 2 to 125 g/L in a single manipulation (31). The conversion yield using the constructed strain is near 90%.

Microbially produced secondary metabolites are extremely important to our health and nutrition (32). As a group that includes antibiotics, other medicinals, toxins, pesticides, and animal and plant growth factors, they have tremendous economic importance. In batch or fed-batch culture, secondary metabolites are usually produced after growth has slowed down. They have no function in growth of the producing cultures (although they contribute to survival of producing organisms in nature), are produced by certain restricted taxonomic groups of organisms, and are usually formed as mixtures of closely related members of a chemical family. From 1990 to 1994, more than 1,000 new secondary metabolites were characterized from actinomycetes alone (33).

The best known of the secondary metabolites are the antibiotics (Figs. 13 and 14). This remarkable group of compounds form a heterogeneous assemblage of biologically active molecules with different structures and modes of action (Table 2). In 1996 the antibiotic market involved 160 antibiotics and a $23 billion market (36). Since 1940 we have witnessed a virtual explosion of new and potent antibiotic molecules that have been of great use in medicine, agriculture, and basic research. However, the search

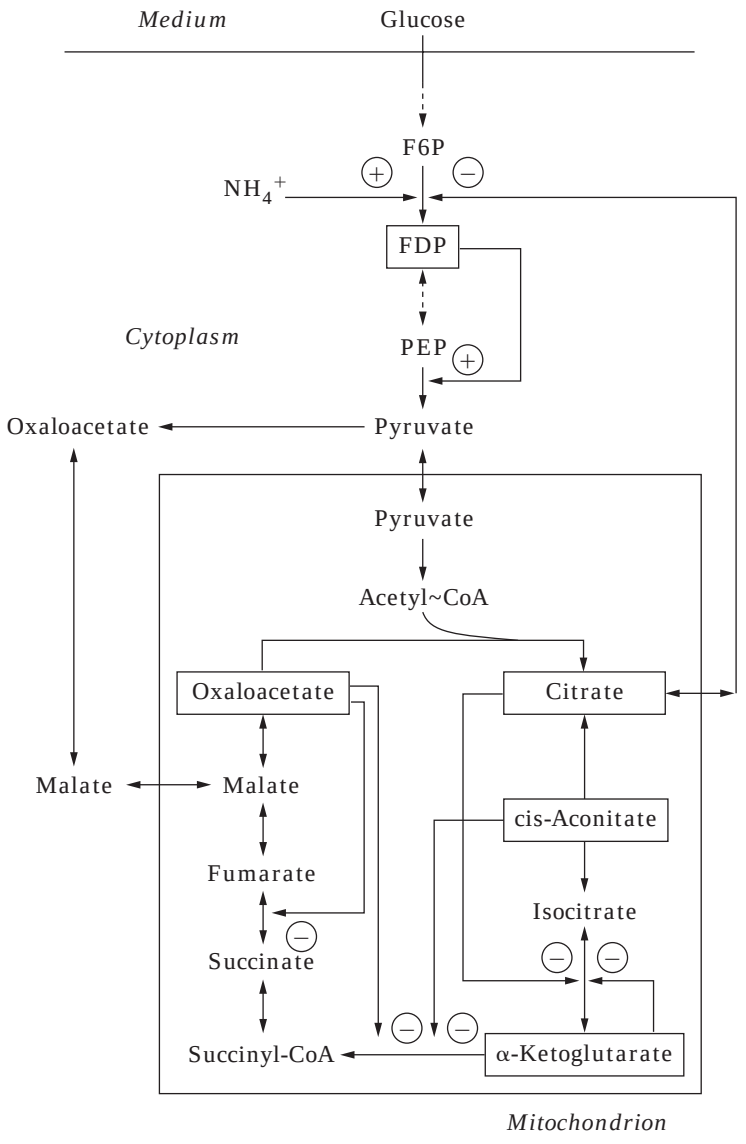

Figure 11. Metabolic scheme of citric acid overproduction. +, activation by the respective metabolite; −, inhibition. *Source*: From Ref. 26.

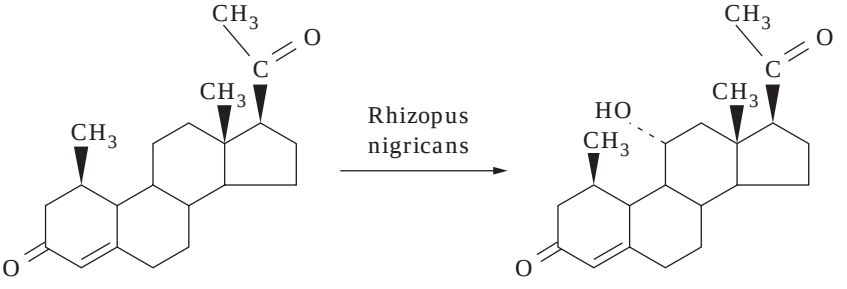

Figure 12. 11α-Hydroxylation of progesterone by *Rhizopus nigricans*.

for new antibiotics continues in order to combat evolving pathogens and naturally resistant bacteria and fungi and previously susceptible microbes that have developed resistance; improve pharmacological properties; combat tumors, viruses, and parasites; and discover safer, more potent, and broader spectrum compounds. About 6,000 antibiotics have been described, 4,000 from actinomycetes alone, and they still are being discovered at a rate of about 300 per year. *Streptomyces griseus* strains produce more than 40 different antibiotics and *Bacillus subtilis* more than 60 different antibiotics. Strains of *S. hygroscopicus* make almost 200 antibiotics. One *Micromonospora* strain

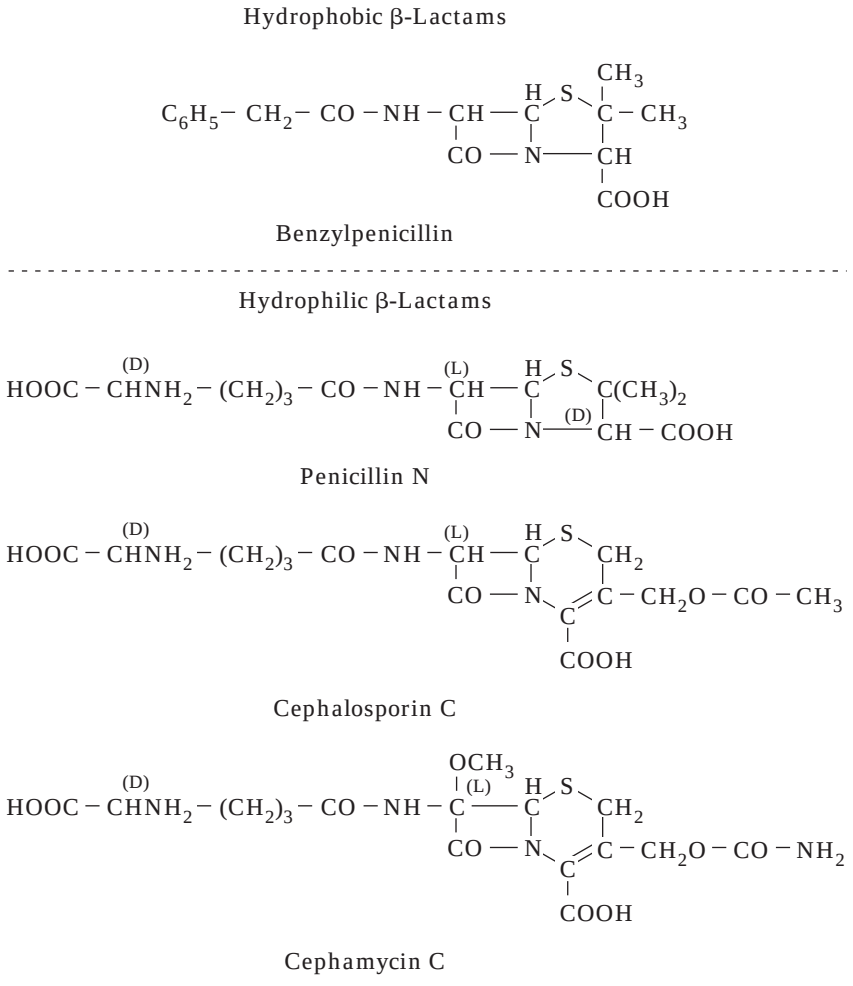

Figure 13. Some *β*-lactam antibiotics. Benzylpenicillin is also known as penicillin G.

can produce 48 aminocyclitol antibiotics. The antibiotics vary in size from small molecules such as cycloserine (102 Da) and bacilysin (270 Da) to polypeptides such as nisin, which contains 34 amino acid residues. They attack virtually every type of microbial activity, including DNA, RNA, and protein synthesis; membrane function; electron transport; sporulation; germination; and many others. In the search for new antibiotics, many of the new products are made by chemists by modification of natural antibiotics; this process is called semisynthesis. By 1974 more than 20,000 semisynthetic penicillins, 4,000 cephalosporins, 2,500 tetracylines, 1,000 rifamycins, 500 kanamycins, and 500 chloramphenicols had been prepared. In 1980 worldwide antibiotic production amounted to about 25,000 tons. Included were 17,000 tons of penicillins, 5,000 tons of tetracyclines, 1,200 tons of cephalosporins, and 800 tons of erythromycins. Antibiotics are used not only chemotherapeutically in human and veterinary medicine but also for growth promotion in farm animals and for the protection of plants.

In nature, secondary metabolites are important for the organisms that produce them, functioning as *(1)* sex hormones; *(2)* ionophores; *(3)* competitive weapons against other bacteria, fungi, amoebae, insects, and plants; *(4)* agents of symbiosis; and *(5)* effectors of differentiation (37). For years, the major pharmaceuticals (such as hypertensive and antiinflammatory agents) used for noninfectious diseases were strictly synthetic products. Similarly, major therapeutics for nonmicrobial parasitic diseases in animals (e.g., coccidiostats and antihelmintics) came from the screening of synthesized compounds followed by molecular modification. Despite the testing of thousands of synthetic compounds, only a few promising structures were uncovered. As new lead compounds became more and more difficult to find, microbial broths filled the void and microbial products increased in importance in treatment of nonmicrobial diseases. Today, microbially produced polyethers (38) such as monensin, lasalocid, and salinomycin dominate the coccidiostat market and are also the chief growth promotants in use for ruminant animals. The avermectins (Fig. 14), another group of streptomycete products with a market of more than $200 million per year, have high activity against helminths and arthropods (39). Indeed, their activity is an order of magnitude greater than previously discovered antihelmintic agents, the vast majority of which were synthetic. Known pharmacological activities of microbial secondary metabolites are shown in Table 3.

Many microbial products with important pharmacological activities were discovered by screening for inhibitors

Channel formers	Linear gramicidin	Peptide
Mobile carriers	Monensin	Polyether

using simple enzymatic assays (40). One huge success has been lovastatin (mevinolin), a fungal product of the compactin group (41) that acts as a cholesterol-lowering agent in animals. Lovastatin is produced by *Aspergillus terreus*. In its hydroxy acid form (mevinolinic acid), mevinolin is a potent competitive inhibitor of 3-hydroxy-3-methylglutaryl-coenzyme A reductase from liver. Another enzyme inhibitor on the market is acarbose, a natural inhibitor of intestinal glucosidase (42), which is produced by an actinomycete of the genus *Actinoplanes*. It decreases hyperglycemia and triglyceride synthesis in adipose tissue, liver, and the intestinal wall of patients suffering from diabetes, obesity, and type IV hyperlipidemia.

Also in commercial or near-commercial use are biopesticides including fungicides (e.g., kasugamycin, polyoxins), insecticides (*Bacillus thuringiensis* crystal, nikkomycin, spinosyns), herbicides (bialaphos), antihelmintics and coccidiostats as mentioned earlier, ruminant growth promoters (monensin, lasalocid, salinomycin), plant growth regulators (gibberellins), immunosuppressants for organ transplants (cyclosporin A, FK-506, rapamycin [Fig. 15]), anabolic agents in farm animals (zearelanone), uterocontractants (ergot alkaloids), and antitumor agents (doxorubicin, daunorubicin, mitomycin, bleomycin) (43,44). A remarkable aspect of this development is that many of the compounds were first isolated as poor or toxic antibiotics (e.g., monensin, cyclosporin, rapamycin) or as mycotoxins (ergot alkaloids, gibberellins, zearelanone) before they were put to work for our benefit. Following in their footsteps are many secondary metabolites with potent activities that are under investigation right now. Indeed, antibiotic activity is merely the tip of the iceberg, a mere scratching at the surface of the potential of microbial activity.

In batch culture, some secondary metabolite processes exhibit a distinct growth phase (trophophase) followed by a production phase (idiophase). In other fermentations, trophophase and idiophase overlap; the timing depends on the nutritional environment presented to the culture, the growth rate, or both. Secondary metabolite production in nature probably allows organisms to differentiate and to compete effectively with other forms of life. Delay in antibiotic production until after trophophase aids the producing organism, because the microbe is usually sensitive during growth to its own antibiotic. Resistance mechanisms in producers include enzymatic modification of the antibiotic, alteration of the cellular target of the antibiotic, and

Table 3. Some Pharmacological Activities of Microbial Secondary Metabolites

ACTH-like	Diuretic	Erythematous	Leukemogenic
Anabolic	Edematous	Estrogenic	Motility inhibition
Analeptic	Emetic	Fertility enhancing	Nephrotoxic

decreased uptake of excreted antibiotic. The raw materials of secondary metabolism are primary metabolites, which often exert a negative or positive effect on secondary metabolism.

Manipulation of culture media in any development program often involves the testing of hundreds of additives as possible limiting precursors of the desired product. Occasionally, a precursor that increases production of the secondary metabolite is found. The precursor may also direct the fermentation toward the formation of one specific desirable product; this is known as *directed biosynthesis*. Examples of the latter include phenylacetic acid in benzylpenicillin fermentation, specific amino acids in the production of actinomycins and tyrocidins, and substituted benzoic acids in the formation of novobiocins. In many fermentations, however, precursors show no activity because their syntheses are not rate limiting. In such cases, screening of additives has often revealed dramatic effects, both stimulatory and inhibitory, of nonprecursor molecules on the production of secondary metabolites. These effects are usually due to interaction of these compounds with the regulatory mechanisms existing in the fermentation organism.

The regulatory mechanisms prevalent in secondary metabolism are essentially the same as found in primary metabolism (45). Thus chloramphenicol limits its own synthesis by repressing arylamine synthetase, and ergot alkaloids limit their production by inhibiting dimethylallyl transferase; these are the initial enzymes unique to the secondary pathway. Glucose, a sugar usually used rapidly for growth, exerts carbon catabolite repression of secondary metabolite synthesis. Similarly, ammonium ion or rapidly used amino acids exert nitrogen metabolite regulation on secondary metabolism. Inorganic phosphate exerts a strong negative effect in secondary metabolite fermentations. Enzyme induction is evident in the production of alkaloids and antibiotics. In actinomycetes, γ-butyrolactones function as autoinducers of secondary metabolism. Besides the specific types of regulation mentioned earlier, the onset of secondary metabolism is also controlled by growth rate. Generally, secondary metabolites are not produced at growth rates near the maximum specific growth rate. In fact, the idiophase can be shifted into the trophophase when media that support only low rates of growth are used. Antibiotic biosynthesis ends via the decay of antibiotic synthetases or because of feedback inhibition and repression of these enzymes. Because the regulatory mechanisms are genetically determined, mutation has had a major effect on the production of secondary metabolites (46). Indeed, it is the chief factor responsible for the hundred- to thousandfold increases obtained in production of antibiotics from the time of their initial discovery to the present.

Environmental manipulations have proven to be quite useful for bringing on metabolite overproduction. Optimization of fermentation parameters such as temperature, pH, oxygen transfer, and nutrients is of course extremely important. If a process is inducible, inducers are added. They include methionine for cephalosporin C formation, valine for tylosin production, and tryptophan for ergot alkaloid production. Virtually all fermentation processes operate, after the initial growth stage, under conditions of unbalanced growth, and from the start of any development program, the microbiologist must find the key to this unbalanced growth. The key is often a specific nutrient limitation that restricts growth and brings on product accumulation.

Genetics has had a long history of contributing to the production of microbial secondary metabolites, such as antibiotics (47). The tremendous increases in fermentation productivity and the resulting decreases in costs have come about mainly by mutagenesis and screening for higher-producing microbial strains. Mutation has also served to *(1)* shift the proportion of metabolites produced in a fermentation broth to a more favorable distribution, *(2)* elucidate the pathways of secondary metabolism, and *(3)* yield new compounds. The medically useful products demethyltetracycline and doxorubicin (adriamycin) were discovered by simple mutation of the cultures producing

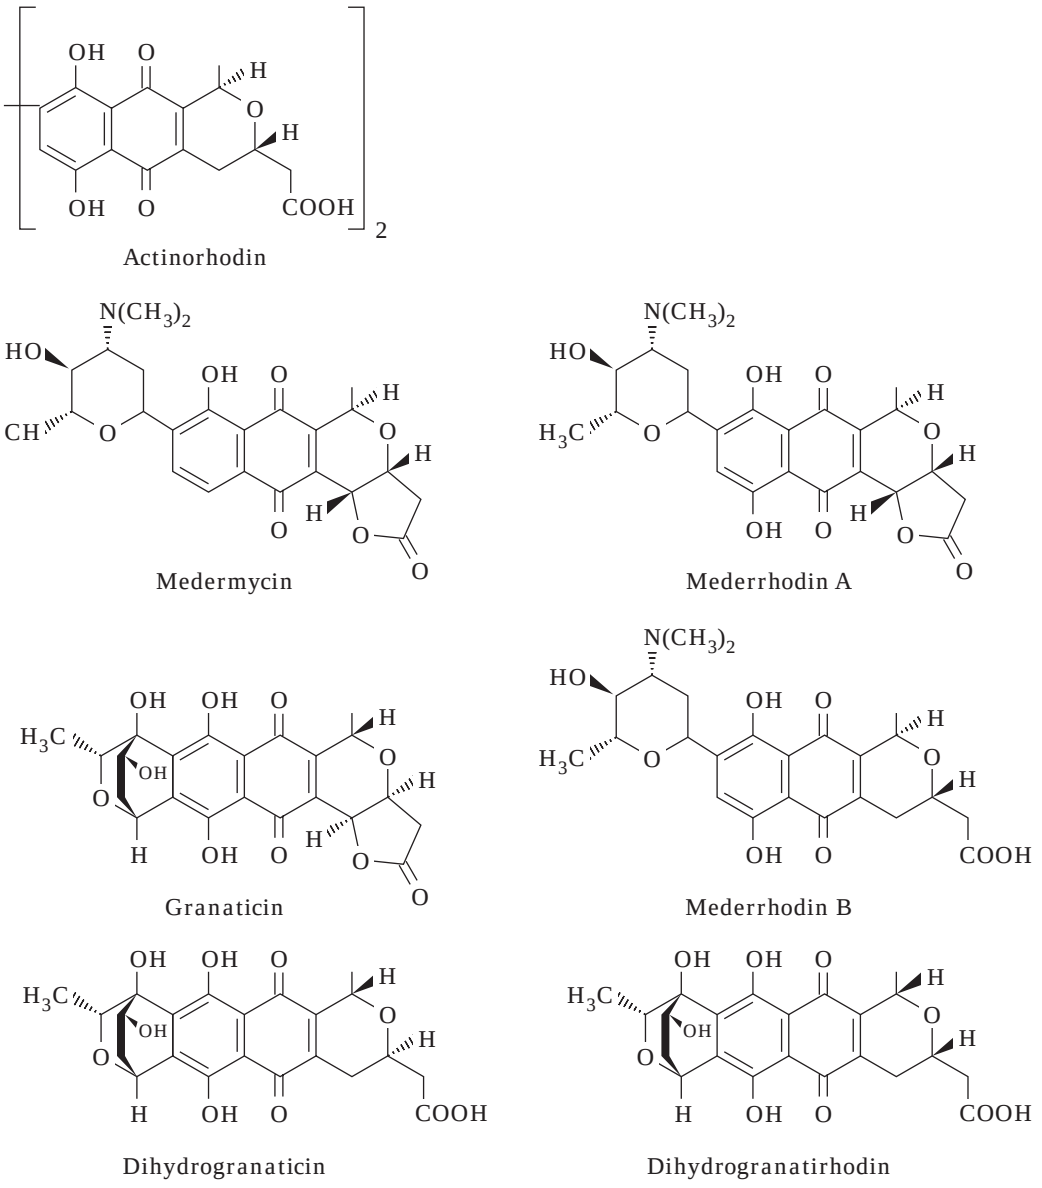

Figure 16. Hybrid antibiotics. Left, structures of the natural isochromane quinone antibiotics: actinorhodin, granaticin, dihydrogranaticin, and medermycin. Right, structures of new hybrid antibiotics: mederrhodin A and B and dihydrogranatirhodin produced by genetically engineered organisms (the absolute stereochemistry of dihydrogranaticin at C-1 and C-3 is tentative). *Source*: From Ref. 52.

tetracycline and daunorubicin (daunomycin), respectively. The technique of mutational biosynthesis has been used for the discovery of many new aminoglycoside, macrolide, and anthracycline antibiotics. It has recently been successfully employed in producing a new commercial avermectin (48).

The use of protoplast fusion has facilitated genetic recombination of different strains from the same or different species to yield new antibiotics. Protoplast fusion has also been useful in elimination of an undesirable component from penicillin broths.

Recombinant DNA technology has been applied to the production of antibiotics (49). Many genes that encode individual enzymes of antibiotic biosynthesis have been cloned and expressed at high levels in heterologous microorganisms. Continued efforts in the application of recombinant DNA technology to fermentations have led to overproduction of limiting enzymes of important biosynthetic pathways, thereby increasing production of the final products. This has been accomplished in the area of cephalosporin biosynthesis (50). In addition, many antibiotic resistance genes from antibiotic-producing organisms have been cloned and expressed. Some antibiotic biosynthetic pathways are encoded by plasmid-borne genes (e.g., methylenomycin A). Even when the antibiotic biosynthetic pathway genes of actinomycetes are chromosomal (the

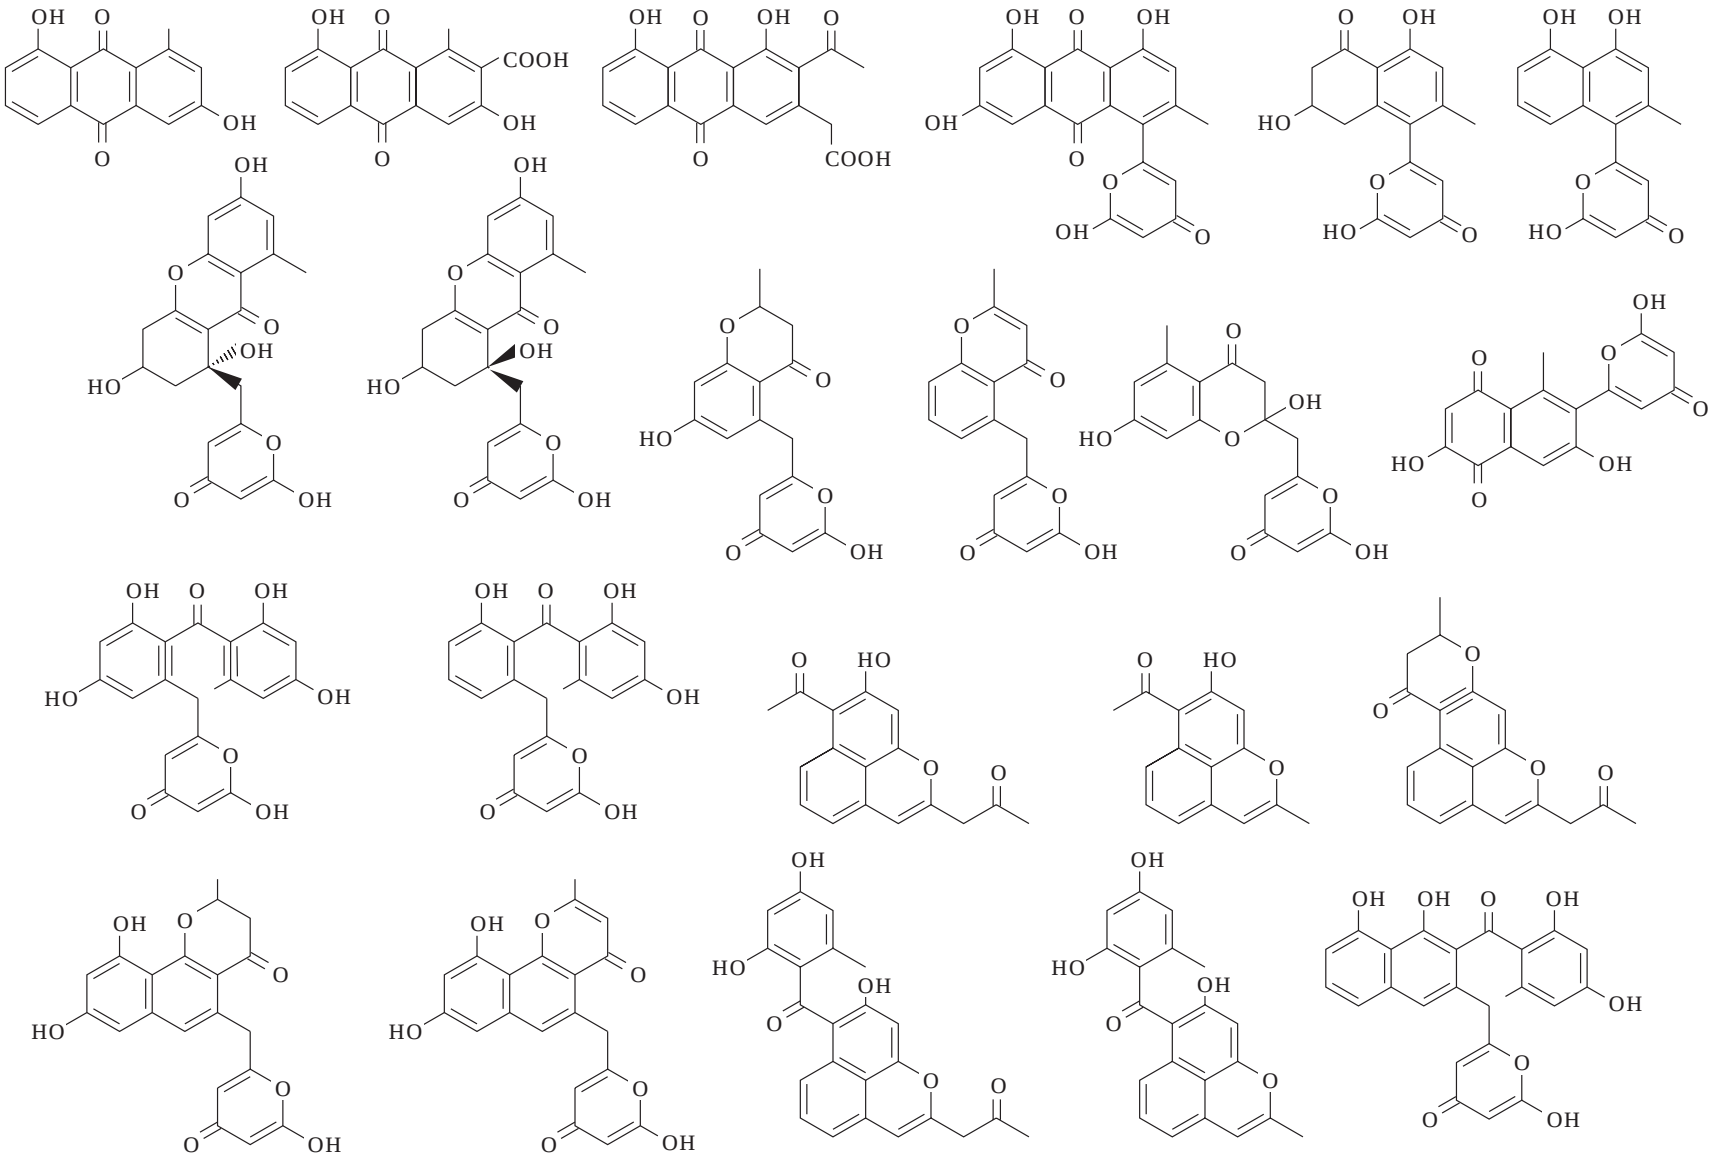

Figure 17. Novel polyketides produced by the actinorhodin (*act*), frenolicin (*fren*), and tetracenomycin (*tcm*) PKS gene clusters. *Source*: From Ref. 47.

usual situation), they are clustered, which facilitates transfer of an entire pathway in a single manipulation. The genes of the actinorhodin pathway, normally clustered on the chromosome of *Streptomyces coelicolor*, were transferred en masse on a plasmid to *S. parvulus* and were expressed in the latter organism. The presence of the bialophos (a herbicidal antibiotic) resistance gene in the bialaphos biosynthetic cluster allowed cloning of the entire 13-enzyme pathway of this herbicidal antibiotic from *S. hygroscopicus* into *S. lividans*. Here, the resistance gene is also one of the biosynthetic genes, coding for demethylphosphinothricin acetyltransferase. Even in fungi, pathway genes can be clustered such as the penicillin genes in *Penicillium* or the aflatoxin genes in *Aspergillus*. However, the genes that code for cephalosporin biosynthesis in *Cephalosporium* are distributed among different chromosomes.

For the discovery of new or modified products, recombinant DNA techniques can be used to introduce genes that code for antibiotic synthetases into producers of other antibiotics or into nonproducing strains to obtain modified or hybrid antibiotics. Gene transfer from a streptomycete strain producing the isochromanequinone antibiotic actinorhodin into strains producing granaticin, dihydrogranaticin, and mederomycin (which are also isochromanequinones) led to the discovery of two new antibiotic derivatives, mederrhodin A and dihydrogranatirhodin (51,52; Fig. 16). A hybrid antibiotic, isovalerylspiramycin, was obtained by introducing the *carE* gene from the carbomycin producer *S. thermotolerans* into the spiramycin producer *S. ambofaciens* (53). These are both 16-membered macrolides, but one of the two sugars in carbomycin is isovalerylmycarose and the corresponding sugar in spiramycin is mycarose. When the acylating gene was cloned into the nonmacrolide producer *Streptomyces lividans*, the recombinant was capable of converting spiramycin to isovalerylspiramycin. Many novel polyketide secondary metabolites have been obtained by cloning DNA fragments from one polyketide producer into various strains of other streptomycetes (54,55). Figure 17 shows some of these novel polyketide molecules.

OUTLINE

INTRODUCTION

Methane oxidizing bacteria (methanotrophs) are defined as those bacteria that can grow on methane as their sole source of carbon and energy. They are therefore a subgroup of methylotrophs (bacteria that can grow on one-carbon compounds). Methanotrophs are generally regarded as obligate in nature, growing only on methane and usually on methanol but not on multicarbon substrates. Methanotrophs have attracted considerable interest over the past 25 years due to their potential for the production of bulk chemicals, single-cell protein, and use in biotransformations (1–3). Their ability to degrade the groundwater pollutant trichloroethylene and other chlorinated compounds has also been examine in detail (reviewed in Refs. 4 and 5). There is considerable interest in methanotrophs because they appear to be ubiquitous in nature (6–8) and are likely to be a major sink for methane in the natural environment (reviewed in Refs. 9 through 12).

In a pioneering study, Whittenbury and colleagues isolated and characterized a large number of different methanotrophs from soils, sediments, and aquatic environments (6). More recently, Bowman and colleagues (7) isolated more than 100 strains of methanotrophs from many different environments and carried out a detailed chemotaxonomic study on these isolates. This study reinforced the view that these bacteria are widespread in nature and are important in the global cycling of methane in the natural environment.

Methanotrophs are all Gram-negative bacteria and can be classified into two groups. Type I methanotrophs of the genera *Methylomonas*, *Methylobacter*, *Methylomicrobium*, *Methylococcus*, *Methylosphaera*, and *Methylocaldum* utilize the ribulose monophosphate (RuMP) pathway for the assimilation of formaldehyde into cell carbon, possess bundles of intracytoplasmic membranes (Fig. 1), and are members of the γ-subdivision of the purple bacteria (class Proteobacteria). Type II methanotrophs, such as *Methylosinus*, *Methylocystis*, and *Methylosporovibrio*, utilize the serine pathway for formaldehyde fixation, possess intracytoplasmic membranes arranged around the periphery of the cell (Fig. 1), and fall within the α-subdivision of the

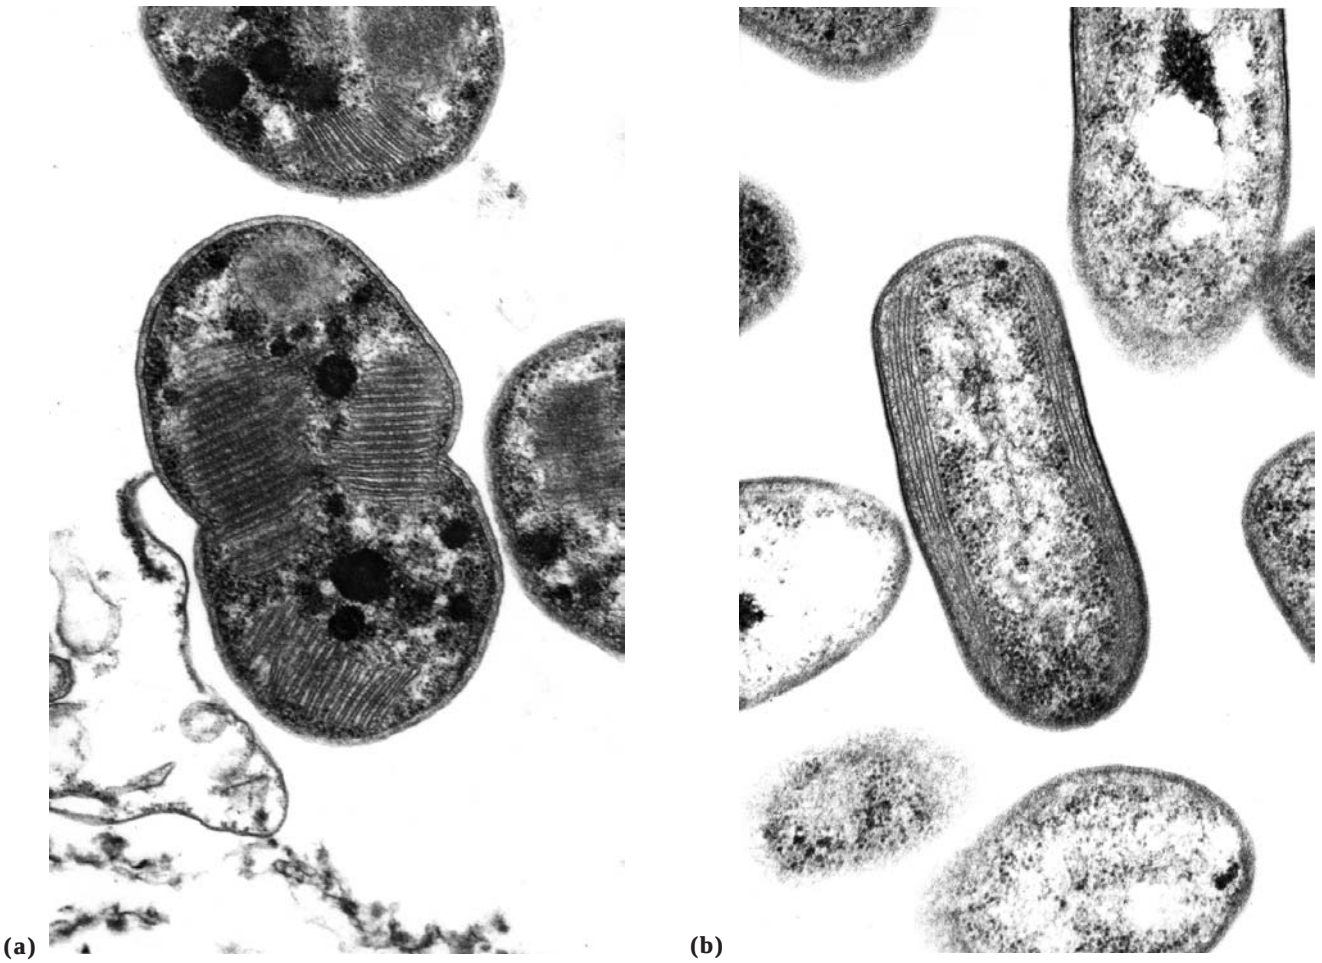

Figure 1. Electron micrographs. (**a**) Section of *Methylomonas methanica* (NCIMB 11130), showing a Type I membrane system. (**b**) Section of *Methylocystis parvus* (NCIMB 11129), showing a Type II membrane system. Magnification, all ×68,800.

Proteobacteria. Some methanotrophs, such as *Methylococcus capsulatus* (Bath), appear to have some properties of both Type I and Type II methanotrophs and are sometimes termed Type X methanotrophs. The taxonomy of methanotrophs has been reviewed in some detail (7,13). Classification schemes, based on pheno- and chemotaxonomic studies have been strengthened as a result of the nucleotide sequencing of both 5S and 16S ribosomal RNA (rRNA) from a large number of methanotrophs and methylotrophs. Type II methanotrophs such as *Methylocystis parvus*, *Methylosinus trichosporium*, and *Methylosporovibrio methanica* appear to cluster in the α-2 subdivision of the class Proteobacteria and form a separate cluster from other serine pathway methylotrophs. Type I methanotrophs such as *Methylomonas methanica*, *Methylomicrobium album*, *Methylomonas rubra*, and *Methylomonas luteus*, together with the Type X methanotroph *Methylococcus capsulatus*, are found in the γ-subdivision of the purple bacteria (reviewed in Refs. 8 and 14). The key features of representative genera of methanotrophs are summarized in Table 1. Properties such as mol% G + C content of DNA, membrane fatty acid composition, nitrogen fixation, and morphological features can be used to discriminate between Type I and Type II methanotrophs.

PHYSIOLOGY AND BIOCHEMISTRY OF METHANOTROPHS

Methanotrophs grow by oxidizing methane using the pathway shown in Figure 2. The key feature of all methanotrophs is their ability to oxidize methane to methanol (see later). Methanol, the oxidation product of methane, is further metabolized to formaldehyde by the pyrolloquinoline quinone (PQQ)-linked enzyme methanol dehydrogenase (MDH). This is an enzyme that is found in all Gram-negative methylotrophic bacteria and has been extensively studied at the biochemical and molecular level (15–17). There are a large number of genes involved in methanol oxidation, and there are complex regulatory networks controlling their expression. The majority of work in this area has been carried out using methanol utilizers rather than methanotrophs (18). The oxidation of methanol yields formaldehyde, a central intermediate in the methane

Table 1. Characterization of the Most Well Studied Methanotrophs

	Methylomonas	Methylobacter	Methylomicrobium	Methylococcus	Methylosinus	Methylocystis
Phylogeny	Gamma Proteobacteria	Gamma Proteobacteria	Gamma Proteobacteria	Gamma Proteobacteria	Alpha Proteobacteria	Alpha Proteobacteria
Membrane type	Type I	Type I	Type I	Type I	Type II	Type II

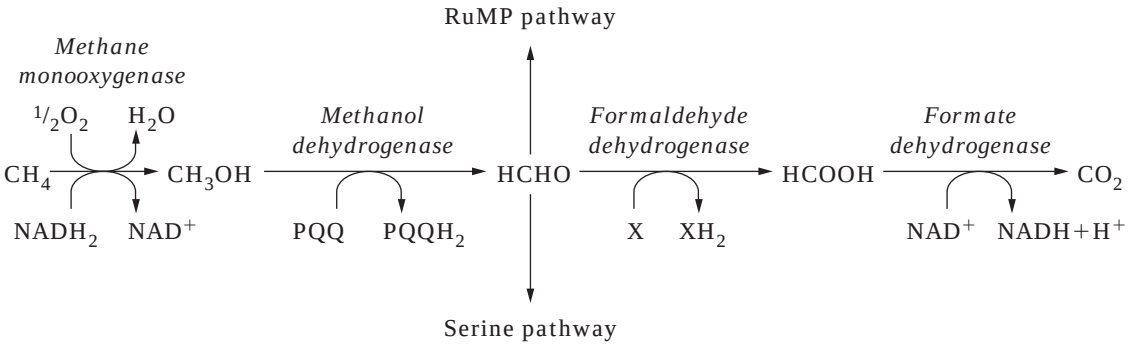

Figure 2. Pathway for the oxidation of methane and the assimilation of formaldehyde.

oxidation pathway. Approximately half of the formaldehyde produced is further oxidized by the enzymes formaldehyde dehydrogenase and formate dehydrogenase to yield carbon dioxide. This results in the generation of reducing power for biosynthesis and the initial oxidation of methane. The CO_2 is not fixed into cell carbon in significant amounts but is lost to the atmosphere. The remainder of the formaldehyde is assimilated into cell carbon by one of two pathways. In Type I methanotrophs, formaldehyde is condensed with ribulose phosphate into hexulose-6-phosphate in the RuMP pathway. The key enzymes of this pathway are hexulose-6-phosphate synthase and hexulose-phosphate isomerase. Subsequent rearrangement reactions result in the net incorporation of glyceraldehyde-3-phosphate into cellular material (Fig. 3). Type II methanotrophs utilize the serine pathway for the incorporation of formaldehyde into the cell. Key enzymes of this pathway include serine hydroxymethyl transferase, hydroxypyruvate reductase, malate thiokinase, and malyl CoA lyase (Fig. 4). The biochemistry of these methylotrophic pathways has been extensively reviewed by Anthony (15,16).

Methane oxidation is carried out by the enzyme methane monooxygenase (MMO). A membrane-bound, particulate methane monooxygenase (pMMO) appears to be present in all methanotrophs grown in the presence of relatively high concentrations of copper ions. Studies on this enzyme have been hampered by its lability in cell-free extracts and difficulties in purification from the membranes of methanotrophs. Biochemical and biophysical studies have shown that pMMO activity is directly related to the copper/total membrane protein ratio in membrane fractions from *Methylococcus capsulatus* (Bath) grown at different copper concentrations. pMMO appears to consist of at least three polypeptides of approximately 46, 23, and 20 kDa, and EPR studies suggest the presence of a number of copper clusters. Recently, the pMMO enzyme complex has been isolated in active form from *M. capsulatus* (Bath) using a variety of detergent treatments (19). An active preparation of pMMO from *Methylococcus* has been reported to contain three subunits (47,27, and 25 kDa) and iron and copper atoms (probably involved in catalysis at the active site) and uses duroquinol as the in vitro electron donor (20). Further characterization of pMMO at the biochemical level is ongoing in a number of research groups.

In some methanotrophs, a second form of MMO, a cytoplasmic, soluble form (sMMO), is synthesized when the growth conditions are such that the culture copper-to-biomass ratio is low (less than 1 μM/g dry weight). This sMMO is structurally and catalytically distinct from the pMMO and has a broad substrate specificity, oxidizing a

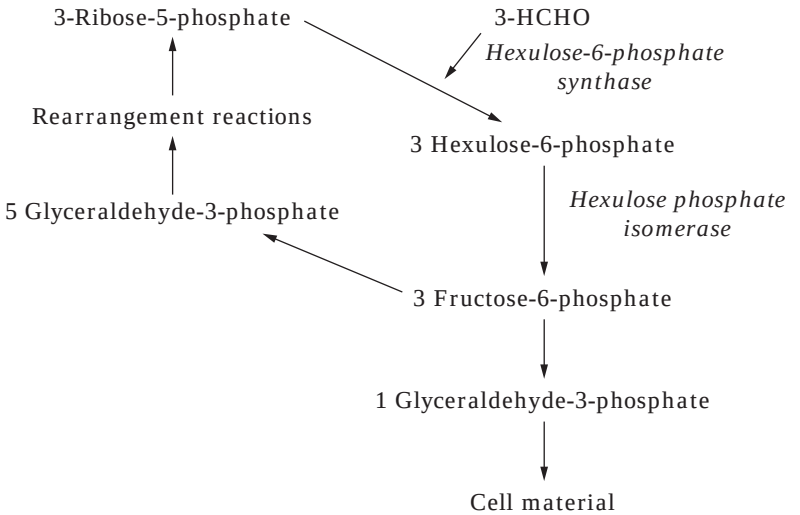

Figure 3. RuMP pathway for formaldehyde fixation.

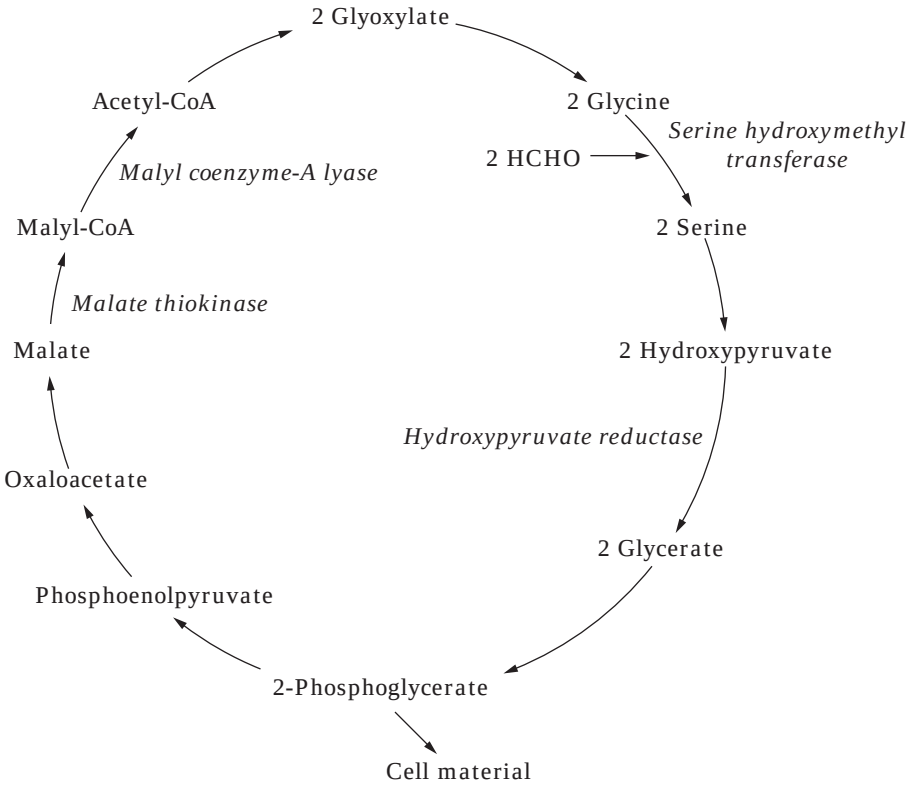

Figure 4. Serine pathway for formaldehyde fixation.

wide range of aliphatic and aromatic compounds. Probably the most extensively characterized sMMOs are those isolated from the Type II methanotroph *Methylosinus trichosporium* OB3b (reviewed in Ref. 21) and the Type X methanotroph *M. capsulatus* (Bath) (reviewed in Ref. 22). sMMO has also been characterized from the Type II strains *Methylosinus sporium* 5 and *Methylocystis* strain M. sMMO has also been reported in the Type I methanotroph *Methylomonas methanica* 68-1.

The sMMO complex of *M. capsulatus* (Bath) and *M. trichosporium* OB3b have very similar properties and both consist of three components: A, B, and C. Protein A is made up of two copies of each of three subunits, α, β, and γ, with molecular masses of 60, 45, and 20 kDa and is the hydroxylase component of the enzyme complex. Protein A contains a binuclear iron-oxo center believed to be the reactive center for catalysis (21–23). Protein B, 16 kDa, is a single polypeptide containing no metal ions or cofactors and functions as a regulatory or coupling protein (21). Protein C is a 39-kDa NADH reductase containing 1 mol each of FAD and a 2Fe2S cluster that accepts electrons from NADH and transfers them to the diiron site of the hydroxylase component of the Protein A component of sMMO. The mechanism of action of sMMO has recently been reviewed (21–23). The X-ray crystal structure of the hydroxylase component of sMMO from *M. capsulatus* (Bath) has been reported, which has further stimulated research on the mechanism of oxidation of methane by this unique enzyme (23).

GENETICS OF METHANOTROPHS

A significant problem in the development of genetic systems for methanotrophs has been the lack of suitable ways of introducing and maintaining heterologous vector DNA in these organisms. Coupled with their relatively slow growth on plates, this has meant that fairly slow progress has been made in this area. Bacteriophages specific for methanotrophs have been isolated from a wide range of environments, including groundwater, fermentors, soils, rumen of cattle, fish, and oil and gas installation waters. They have been characterized in terms of their plaque morphology, ultrastructure, antigenic properties, nucleic acid content, restriction enzyme analysis, and lytic spectrum. *Methylosinus*- and *Methylocystis*-specific phages are particularly prevalent in nature, but few attempts to use them for transduction experiments with methanotrophs have been reported (reviewed in Ref. 24).

A number of large plasmids, ranging from around 50 to 190 kbp have been detected in a number of methanotrophs including *Methylomonas*, *Methylocystis*, *Methylosinus*, and *Methylobacter*. Of 10 representatives examined, only *M. capsulatus* (Bath) did not contain any detectable plasmid DNA (25). Some cross-hybridization with plasmid DNA from different *Methylosinus* species was noted, and a rudimentary restriction endonuclease map of the 55-kbp plasmid from *M. albus* was constructed. However, difficulties in the large-scale isolation of plasmid DNA from these organisms have hampered their development as potential

cloning vectors. There is currently no evidence for the presence of antibiotic or metal resistance genes, nitrogen fixation genes, or methane oxidation genes on these plasmids, but because these plasmids represent "significant potential coding" regions, their presence should not be disregarded in any molecular genetics work with these organisms.

There are no good conventional transformation systems for methanotrophs, and several workers have tried electroporation of plasmids into methanotrophs with little success. Transfer of broad-host-range plasmids into methanotrophs has been the most successful route to gene transfer in these organisms. Lidstrom and colleagues have transferred the Inc P1 broad host range cosmid cloning vector into *Methylomonas*, *Methylocystis*, and *Methylosinus* species at frequencies ranging from 10^{-2} to 10^{-8}. The mobilizing plasmid used in these filter matings was pRK2013 (26). Similar results using similar IncP and IncQ plasmids have been achieved in the authors' laboratory with *M. trichosporium* OB3b and *M. capsulatus* (Bath). Kanamycin and streptomycin appear to be good genetic markers for methanotrophs because the rate of spontaneous mutation for resistance to these antibiotics is very low (less than 10^{-8}). Plasmids carrying kanamycin and streptomycin resistance have been successfully transferred to *M. capsulatus* (Bath) at frequencies of 10^{-3} to 10^{-9} per recipient.

The major obstacles to the development of mutagenesis procedures for the obligate methanotrophs are probably their relatively slow growth on agar plates and the fact that they rely on methane as their sole source of carbon and energy. A consequence of this is that selection of methane oxidation mutants may be difficult. This can usually be overcome because most methanotrophs can be adapted to grow on methanol, thus allowing the selection of an MMO^- phenotype. Conventional mutagenesis procedures using chemical mutagens have not been particularly successful. However, mutants lacking the ability to grow on methane have been isolated using the "suicide-substrate" dichloromethane (DCM). This is cooxidized by MMO to the potentially toxic product carbon monoxide, and therefore methanotrophs growing on methanol agar plates that are DCM resistant are potential methane monooxygenase mutants. Screening of methanotrophs for the presence or absence of a functional sMMO has also been made easier due to the development of a quick, reliable plate assay. This is based on the work of Hanson and colleagues (27) and relies on the conversion of naphthalene to naphthols by soluble MMO but not particulate MMO. The naphthols thus formed can be reacted with tetrazotized *O*-dianisidine to form purple diazo dyes with intense color. This method now allows the assay of soluble MMO activity on plates. The procedure does not kill potential mutants, which can subsequently be recovered and streaked onto fresh agar plates under the appropriate growth conditions (28).

A similar naphthalene assay, coupled with DCM selection, has recently been used to isolate and characterize MMO mutants of *M. trichosporium* OB3b (29). *M. trichosporium* OB3b mutants defective in only the particulate form of MMO were isolated by *(1)* suppressing sMMO expression by the presence of high concentrations of copper in selection plates, *(2)* adding excess methanol with DCM to inhibit possible sMMO-mediated activation of DCM to toxic products in any colonies where sMMO might be expressed, *(3)* adding low concentrations of yeast extract to enhance growth and plating efficiency on methanol, and *(4)* carrying out mutagenesis selection over a long period (5 weeks). Although DCM resistance was unstable in many mutants (a phenomenon observed in other laboratories, including the authors'), mutants that were deficient in pMMO and expressed sMMO constitutively in the presence of elevated copper concentrations (up to 12 μM, which inhibits expression of sMMO in the wild-type organism) were isolated. These mutants had lost the ability to express pMMO activity and concomitantly failed to form the intracytoplasmic membranes characteristic of wild-type *M. trichosporium* OB3b expressing pMMO. Subsequent detailed analysis of these sMMO-constitutive *M. trichosporium* OB3b mutants suggested that either a defect in copper metabolism affecting copper assimilation causes lack of pMMO expression, or that a more general copper-dependent regulatory system that may control pMMO induction, sMMO repression, copper uptake, and production of the intracytoplasmic membranes associated with pMMO has been inactivated (30). Such mutants would clearly be useful for in situ bioremediation processes involving sMMO where the external concentration of copper ions cannot be controlled.

MOLECULAR BIOLOGY OF THE METHANE OXIDATION PATHWAY

Research, primarily in the laboratories of Lidstrom, Hanson, Goodwin, and Harms, has resulted in the identification and cloning of a number of genes involved in methanol oxidation from the Gram-negative methylotrophs *Methylobacterium extorquens* and *Paracoccus denitrificans* (reviewed in Refs. 17, 31, and 32). One of these genes, *mxaF*, from *Methylobacterium*, encoding the large subunit structural gene of methanol dehydrogenase, has been used as a heterologous hybridization probe to identify and clone the corresponding *mxaF* genes from *M. capsulatus* (Bath) and *M. albus* BG8. Methanol oxidation structural genes have also been isolated from the marine methanotroph *Methylomonas* strain A4. Molecular characterization of these genes suggests that they are similar to those that have been extensively characterized in Gram-negative methylotrophs (17), although their regulation may be somewhat different (33).

The genes encoding the sMMO enzyme complex have been cloned from *M. capsulatus* (Bath) and are clustered on the chromosome of this methanotroph. DNA sequencing of this gene cluster has revealed that the genes encoding the α-, β-, and γ-subunits of Protein A (*mmoX*, *Y*, and *Z*), Protein B (*mmoB*), and Protein C (*mmoC*) are all linked on the chromosome. The sMMO gene cluster of *M. capsulatus* (Bath) has been used to probe for sMMO genes in a number of representative strains of methanotrophs. sMMO homologues were detected only in *Methylococcus* and *Methylosinus* strains. sMMO appeared to be absent from the Type II methanotroph *Methylocystis parvus* OBBP or Type I representatives of *Methylomicrobium album*, *Methylomonas*

methanica, *Methylomonas agile*, and *Methylobacter capsulatus*.

Subsequently, sMMO gene probes from *Methylococcus* were used to clone the sMMO gene cluster from *M. trichosporium* OB3b (reviewed in Ref. 34) and *Methylocystis* sp. strain M (35). These gene clusters have also been DNA sequenced, and the genes are arranged in the same order as in *Methylococcus* (Fig. 5). The function of *orfY*, which lies between *mmoZ* and *mmoC*, is unknown at present. Derived polypeptide sequences of sMMO components from all three methanotrophs showed a high degree of identity, highlighting the conserved nature of this enzyme complex (35). Amino acid sequences within the α-subunit of Protein A align well with the four-helix iron coordination bundle of the R2 protein of ribonucleotide reductase and is characteristic of a family of proteins that contain a catalytic carboxylate-bridged diiron center. The diiron center in sMMO is now well defined by X-ray crystal structure analysis (23). The N-terminal region of Protein C also exhibited extensive homology with reductase components of other oxygenases that contain a ferredoxin-like 2Fe-2S center. Protein B, the coupling protein of sMMO, has some sequence identities with other oxygenase-coupling proteins (36), but all other polypeptides of sMMO including the derived sequence of *orfY* appear to be novel.

Expression of functionally active Proteins B and C has been achieved using a T7 polymerase expression system in *Escherichia coli*. Attempts to express the hydroxylase components in *E. coli* in the authors' laboratory have proved unsuccessful, but expression of sMMO genes has recently been achieved using other heterologous hosts including methanotrophs that contain only pMMO (37), which will facilitate further studies on the structure, function, and catalytic mechanism of methane monooxygenase by site-directed mutagenesis.

Use of the cloned sMMO genes has also been made in the construction of sMMO mutants of *M. trichosporium* OB3b. A reverse-genetics approach has been taken using marker exchange mutagenesis, a method first used successfully by Toukdarian and Lidstrom (38) for the construction of nitrogen-fixation mutants of *Methylosinus* sp. strain 6. A DNA fragment containing *mmoX* of OB3b was cloned into pBR325. An *Xho*I fragment internal to the *mmoX* gene was replaced with a kanamycin resistance cassette, and the *mob* fragment was also inserted into pBR325 to facilitate transfer by conjugation of the resulting recombinant plasmid pHM32 from *E. coli* S17-1 to OB3b. Homologous recombination of the mutated *mmoX* gene with the wild-type *mmoX* gene in the chromosome and subsequent loss of the unstable pBR325-based plasmid allowed the isolation of kanamycin-resistant OB3b colonies. These were DCM resistant on methanol-agar plates and grew only in the presence of Cu^{2+} on methane, that is, they had the expected $pMMO^{+}$, $sMMO^{-}$ phenotype (39). These mutants have now been complemented by transfering the sMMO gene cluster from wild-type *M. trichosporium* OB3b back into these mutants by conjugation.

M. trichosporium OB3b is a better organism than *M. capsulatus* (Bath) in which to study the regulation of expression of sMMO because OB3b will also grow well on methanol agar plates. The physiological growth conditions under which OB3b switches between using pMMO and sMMO, in response to the Cu^{2+}-to-biomass ratio are also now well defined and have been the subject of several studies (40,41). Differential expression of sMMO and pMMO is regulated by the amount of copper ions available to the cells; sMMO is expressed at low copper-to-biomass ratios, whereas pMMO is expressed at high copper-to-biomass ratios. The transcriptional regulation of the sMMO gene cluster in the methanotrophic bacterium *M. capsulatus* (Bath) has been investigated (42). Using Northern blot analysis and primer extension experiments, it was shown that the six open reading frames of the sMMO gene cluster are organized as an operon, and the transcripts produced upon expression of this operon have been identified. The synthesis of these transcripts was under the control of a

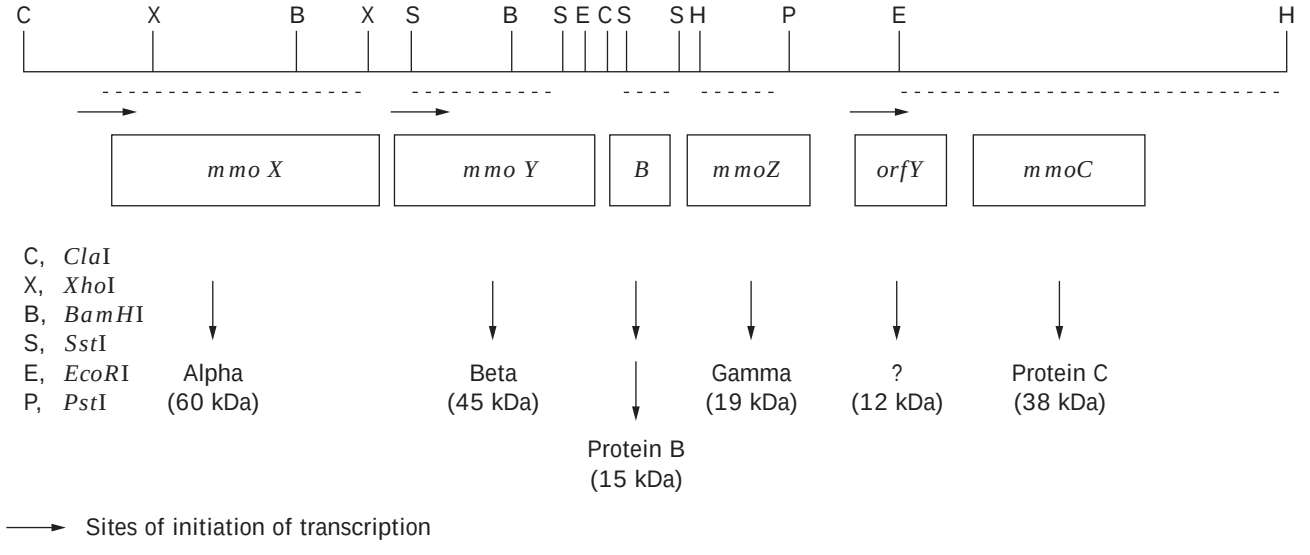

Figure 5. sMMO gene cluster of *Methylosinus trichosporium* OB3b.

single copper-regulated promoter, which has not been precisely defined. In both *M. capsulatus* and *M. trichosporium*, transcription of the sMMO gene cluster is negatively regulated by copper ions. Data suggest that transcription of the *M. trichosporium* OB3b sMMO gene cluster is directed from a σ^{54}-like and a σ^{70}-like promoter. The pMMO (*pmo*) genes of *M. capsulatus* (Bath) are transcribed into a polycistronic mRNA of 3.3 kb. The synthesis of this mRNA was activated by copper ions. Activation of *pmo* transcription by copper ions was concomitant with repression of sMMO gene transcription in both methanotrophs. This suggests that a common regulatory pathway may be involved in the transcriptional switch between sMMO and pMMO gene expression (42,43).

MOLECULAR ECOLOGY OF METHANOTROPHS

The difficulties in using traditional culture-based techniques to study the ecology of methanotrophs have been discussed previously (44). In particular the slow growth of methanotrophs, together with scavenging of nonmethanotrophs on agar plates, has hampered studies.

Phospholipid analysis of natural environment samples or enrichment cultures is one approach to assessing the types of methanotrophs present, because they contain more unusual fatty acids; the technique has been used successfully for the wetland environment (45). The detection and identification of methanotrophs in environmental samples can also be attempted using antibodies either to whole cells of culturable methanotrophs or to key enzymes such as methane monooxygenase or methanol dehydrogenase (reviewed in Ref. 44). However, these methods do not guarantee that all methanotrophs may be detected, and extensive control experiments with large numbers of extant methanotrophs are necessary to validate antibody probes. Estimates of the biomass and activities of methanotrophs can be made by measuring the release of $^{14}CO_2$ and incorporation of $^{14}CH_4$ added to environmental samples. However, this technique needs to be coupled with further experiments designed to analyze bacterial community structure.

Application of molecular biology techniques to methanotrophs has been aided considerably by the sequencing of a number of 16S rRNA genes of methanotrophs and methylotrophs (7,8) and the cloning of several methanotroph-specific genes (34,46). Hanson and colleagues have used 16S rRNA sequence data to examine phylogenetic relationships within genera of methanotrophs and methylotrophs. Type I methanotrophs such as *Methylomonas*, *Methylomicrobium*, and *Methylobacter*, together with the Type X *Methylococcus*, cluster in the γ-subdivision of the class Proteobacteria, whereas Type II methanotrophs *Methylosinus* and *Methylocystis* are found in the α-2 subdivision of the Proteobacteria (8). Hanson and colleagues have used this information to design oligonucleotide probes having a broad specificity for methanotrophs and methylotrophs in the natural environment (47). When coupled to suitable fluors, probes 9α and 10γ were successfully used to differentiate between mixed cultures of Type I and Type II methanotrophs by in situ hybridization (14).

16S rRNA technology has also been used to study the ecology of methanotrophs in blanket bog peat from the north of England. DNA was extracted from several 1-cm sections of a 30-cm-depth peat core covering various depths throughout the core, including the most active methane-oxidizing layer. Total 16s rRNA libraries from each section were screened with 16S rRNA probes specific for the genera *Methylococcus* (Mc 1005), *Methylomonas* (Mm 1007), *Methylobacter* (Mb 1007), and *Methylosinus* (Ms 1020). Results suggested that *Methylosinus* and *Methylococcus* were probably the dominant methanotrophs present in the peat environment. Two clones that hybridized to the *Methylosinus* probe were sequenced. Their 16S rDNA sequences, when analyzed, suggested that they branched closest to the *Methylosinus / Methylocystis* cluster of methanotrophs but were distinct from these sequences (48).

The 16S rRNA data coupled with polymerase chain reaction (PCR) technology have also been used successfully in analyzing methanotrophs in the marine environment. Seawater samples were enriched for methanotrophs by addition of essential nutrients and methane. The change in composition of the bacterial population was then monitored by analysis of 16S rDNA libraries constructed from DNA taken before and after enrichment, using universal eubacterial 16S rRNA primers and PCR. The dominant 16S rRNA sequence that was present in samples after enrichment on methane was recovered from 16S rRNA gene libraries, sequenced, and found to show a close phylogenetic relationship to *Methylomonas*, indicating that novel methanotrophs related to extant *Methylomonas* spp. were present in enrichment cultures (49). Based on the 16S rDNA sequence of this putative marine methanotroph, two oligonucleotides (Mm 650 and Mm 850, Table 1) were synthesized with rhodamine groups attached to their 5′ terminus. These fluorescently labeled probes have been used to determine the response of this marine methanotroph to changes in cultural conditions, thereby allowing optimization of enrichment and isolation methods for this organism (50).

FUNCTIONAL GENE PROBES FOR METHANOTROPHS

Genes unique to methanotrophs include those encoding sMMO and pMMO polypeptides. Another potentially useful marker is *mxaF*, encoding the large subunit of methanol dehydrogenase (the second enzyme of the methane oxidation pathway), which is present in virtually all Gram-negative methylotrophs (51). *mxaF* appears to be highly conserved in all Gram-negative methylotrophs (e.g., methane and methanol utilizers) and is therefore a good indicator of the presence of these organisms in the natural environment. PCR primers designed to specifically amplify a 550-bp fragment of *mxaF* have been successfully used to extend the database of *mxaF* sequences and to identify methylotroph sequences in peat core samples (49,52,53).

The high degree of identity between sMMO genes has enabled the design of PCR primers that specifically amplify each of the five sMMO structural genes (52) such that amplification of each of these genes is now possible from cultured methanotrophs containing sMMO. In addition,

when total DNA from a variety of different freshwater, marine, soil, and peat samples was used as a template with these sMMO-gene-specific primers, a PCR product of the correct (predicted) size was obtained. Subsequent DNA sequencing of a number of these PCR products from peat samples has proved that methanotroph-specific sMMO-encoding DNA had been amplified from environmental DNA samples, and that these genes are very similar but not identical to known sMMO gene sequences. This suggested that there was considerable diversity of methanotrophs in these peat samples, and also that sMMO-containing methanotrophs were present in significant numbers (52). This is further supported by the observation that sMMO-containing methanotrophs have been enriched for and isolated from the same peat core samples, and that 16S rRNA/PCR experiments described earlier also revealed the presence (dominance) of *Methylosinus*- and *Methylococcus*-like organisms.

The PCR technology developed with sMMO genes is useful for studying environments such as peat or contaminated aquifers where methanotrophs containing sMMO might dominate in a copper-depleted environment. However, a better functional gene probe for these organisms would be one based on the pMMO present in all extant methanotrophs. Sequence data on *pmo* and *amo* (the ammonia monooxygenase gene, which codes for a related enzyme found in nitrifying bacteria) has allowed the design of degenerate PCR primers that will specifically amplify a 525-bp internal DNA fragment of *pmoA* or *amoA* from a variety of methanotrophs and nitrifiers. Analysis of the predicted amino acid sequences of these genes from representatives of each of the phylogenetic groups of methanotrophs (α- and γ-Proteobacteria) and ammonia oxidizing nitrifiers (β- and γ-Proteobacteria), revealed strong conservation of both primary and secondary structure. These new sequence data suggest that pMMO and ammonia monooxygenase may be evolutionarily related enzymes, despite their different physiological roles in methanotrophs and ammonia-oxidizing bacteria (54).

These observations are particularly important in the study of the ecological role of these organisms because ammonia oxidizers can also oxidize methane (with MMO also cooxidizing ammonia). The degenerate oligo PCR primers just described have now been used successfully to specifically amplify *pmo/amo* sequences from DNA isolated from a wide variety of environments including seawater, freshwater, agricultural and forest soils, and peat (J.C. Murrell and I.R. McDonald, unpublished data, 1997). Sequencing of these PCR products and examination of derived amino acid sequences of PmoA and AmoA now allows identification of these sequences as those originating from an α- β-, or γ-representative of the methane-oxidizing Proteobacteria (55), and an extensive database of sequences from extant methanotrophs and nitrifiers is also being established, which will aid further molecular ecological studies.

BIOTECHNOLOGY

The unique ability of the MMO enzyme in methanotrophic bacteria to catalyze some reactions of environmental and possibly commercial importance has generated interest in these organisms. The discovery that methanotrophs can degrade halogenated hydrocarbons that are ubiquitous in nature and also toxic pollutants has resulted in research that may lead to greater commercial exploitation (4,5,56).

The most ubiquitous of the groundwater pollutants are trichloroethylene (TCE), 1,2-dichloroethane, and chloroform. Bacteria that utilize TCE or chloroform as a sole carbon and energy source have not been discovered. However, several bacteria that contain nonspecific oxygenases, such as MMO, cause the mineralization of these compounds by cometabolism (cooxidation).

The capacity of methanotrophs to convert halogenated compounds was recognized by Colby et al. (57), who showed that methyl bromide could be used as a model substrate for the MMO reaction. Further work was stimulated by the observation of Wilson and Wilson (58), who demonstrated that methane could stimulate biological TCE degradation in soil. Since then, various pure cultures of methanotrophic bacteria have been found to be capable of cometabolic transformation of halogenated hydrocarbons (27,41,56,59–61). Large differences between various cultures were observed, and high TCE degradation rates were found with *M. trichosporium* OB3b cultivated under conditions of copper limitation and incubated with formate instead of methane as a source of reducing equivalents (60). Cells grown under copper limitation express exclusively the soluble MMO (40,62), and the conclusion that it is this form of the enzyme that is responsible for TCE oxidation was confirmed by in vitro incubations with the purified enzyme (63). Much lower rates of TCE oxidation have been reported for methanotrophs that possess only pMMO (64).

The feasibility of in situ bioremediation by stimulation of the growth of indigenous populations of methanotrophs has been investigated by Semprini and McCarty (65). They reported that biodegradation of TCE occured within an aquifer, at the Moffett Naval Air Station, after it had been supplied with methane and oxygen to stimulate indigenous methane-oxidizing bacteria. The initial results from a further study, at the Savannah River site, indicated that a substantial increase in Type II methanotrophic bacterial populations occurred in some areas of the aquifer, and an increase in the frequency of bacteria that contained DNA with sequences complementary to the *mmoB* gene at different sites was observed (66).

The second biotechnological application of the methanotrophs has been as single-cell protein (SCP). Methane, as natural gas, is available inexpensively and in large amounts; however, as a substrate for SCP production, it has many drawbacks. These include explosive hazards and the low aqueous solubility of methane. Therefore methanol has been the preferred substrate because it is easily derived from methane and highly soluble in water. Methanol is also easily removed from the SCP product in downstream processing. Not surprisingly it was the substrate of choice for the only self-contained SCP business in the United Kingdom, the Pruteen process of ICI (67), which utilized the methylotroph *Methylophilus methylotrophus*. Methanol was also used in two smaller-scale processes by Probion (Hoechst-Uhde, Germany) and Norprotein (Norsk-

Hydro, Sweden), both of which utilized *Methylomonas* species (for reviews see Refs. 2 and 3).

Methanotrophs have also been used for the conversion of propylene to propylene oxide, a high-value product. However, even though high rates of propylene oxidation were obtained, these rates fell dramatically after 3–4 min due to loss of biocatalytic activity (68). sMMO and pMMO both have the potential for cooxidation of a wide range of other compounds. sMMO will cooxidize compounds including alkanes, haloalkanes, alkenes, alicyclics, and aromatics (69); recently pMMO has been shown to cooxidize chlorinated ethenes at yields that are greater than those of sMMO (70). These cooxidations may have future biotechnological applications. Finally the recent characterization of thermophilic/thermotolerant methanotrophs also opens up further avenues for the exploitation of methanotrophs in biotechnological processes (71).

OUTLINE

INTRODUCTION

Methane and methanol are cheap, readily available carbon sources for microbial growth, and their metabolism involves specialized routes of assimilation and dissimilation. Consequently, considerable work has gone into exploring potential applications of organisms capable of growth and product formation from these substrates, particularly on methanol. Because the attraction of methylotrophs derives primarily from substrate costs, most of the work has been directed toward the higher volume–lower price end of the fermentation market, in particular single-cell protein

(SCP). However, SCP from methanol proved to be uneconomical, although an unexpected benefit arose from the early SCP program, namely the application of methylotrophic yeasts as hosts for expression of recombinant proteins.

The full potential of methanol as a fermentation substrate has yet to be realized. Future applications could arise from the use of methanol to supplant carbohydrates in existing fermentation processes for metabolite (e.g., amino acid and vitamin) production. However, the benefit of lower substrate costs needs to be balanced against the (generally) increased oxygen requirements of methanol- compared with carbohydrate-based processes.

MICROBIOLOGY AND ECOLOGY

Methylotrophs are organisms that grow on carbon substrates more reduced than carbon dioxide but with no carbon–carbon bonds (reduced C_1 substrates). Although some aerobic methylotrophs have been shown to oxidize reduced C_1 substrates to carbon dioxide and fix carbon by typical autotrophic routes (autotrophic methylotrophs), most aerobic methylotrophs assimilate carbon at the oxidation level of formaldehyde (true methylotrophs). The primary metabolism of these organisms is thus fundamentally distinct from that of autotrophs and heterotrophs, and some "obligate" methylotrophs are unable to use heterotrophic substrates containing carbon–carbon bonds as the sole carbon source.

Methane, the most reduced C_1 compound, is a key link between the processes of anaerobic degradation and the aerobic food chain. The activity of anaerobic and aerobic methanotrophic bacteria (i.e., methylotrophs that can use methane as a sole source of carbon and energy) significantly reduces the potential release of methane to the atmosphere arising from the activity of methanogens. Many of the methanogens are also methylotrophic, being able to use substrates such as methanol and formate to drive methanogenesis (methylotrophic acetogens are also known). Methanol arises from methyl esters and methoxy groups found in plant materials (e.g., lignin and pectin) and also through chemical oxidation of methane in the troposphere and its subsequent deposition in rainfall. The ability to utilize methanol as the sole source of carbon and energy is found in representatives of all three taxonomic domains: methanogenic methylotrophs belonging to the Archaea and other anaerobic and aerobic methylotrophic prokaryotes belonging to the eubacteria (with both Gram-negative and Gram-positive representatives); a number of methanol utilizing yeasts (Eucarya) and filamentous fungi have also been isolated. Methane utilizing yeasts have also been described (1), but these have exceptionally long generation times and are currently of no more than academic interest. There is strong evidence for anaerobic methane oxidation associated with sulfate reducing and/or methanogenic activity (2). However, the organisms responsible have been difficult to culture axenically. Hence most of the work on methanotrophic organisms has concentrated on the methane utilizing aerobic (eu)bacteria (2).

In addition to the more obvious reduced C_1 substrates methane and methanol, nature provides a wide range of compounds based on methylated heteroatoms such as methylamines, methyl sulfides, methyl sulfonates, methoxy compounds, and halogenated methanes. Oxidation or hydroxylation of these methyl groups results in the release of formaldehyde, which can feed directly into the dissimilatory and assimilatory pathways of C_1 metabolism. Some of these organisms play an important role in nutrient cycling in the environment and probably contribute to the natural degradation of toxic compounds.

GROWTH ON C_1 COMPOUNDS

Bacterial growth on methane and methanol was first described nearly a century ago. However, the subject lay fairly dormant until the 1960s and 1970s, when research activity driven partly by academic studies on the relationship between methylotrophic and autotrophic biochemistry and, in no small way, by the perceived applications of methylotrophs increased dramatically. The latter originated from the interest in producing SCP (i.e., microbial biomass) from methane or methanol as an animal or human food supplement, a venture in which a number of companies became involved to a greater or lesser extent but that was ultimately shown to be uneconomic. Despite this uncertain start the basic principles on which the choice of C_1 substrates was made remain valid, namely that substrates such as methane and methanol are cheap and because they are highly reduced should give high growth yields. As substrate costs become an increasingly important factor with increasing production volume (and decreasing unit price of the product), the potential applications of methylotrophs are likely to be in bulk products. Alternatively, the enzymes or metabolic sequences unique to methylotrophic metabolism may offer some possibilities not available in heterotrophs. The biotechnological application of methylotrophs can therefore be conveniently categorized under three headings:

1. Processes highly dependent on substrate economics
2. Processes based on C_1-specific enzymes or metabolism
3. Processes or products incidentally associated with C_1 metabolism

Although these subdivisions are not mutually exclusive they are nonetheless useful in explaining the rationale behind the development of certain C_1-based processes.

Metabolic Biochemistry and Energetics

The pathways of carbon assimilation affect both the efficiency of growth and the types of products that might feasibly be produced from methylotrophs. In aerobic (true) methylotrophic bacteria two fundamentally different routes of carbon assimilation have been demonstrated: the ribulose monophosphate (RuMP) pathway and the serine pathway (3,4). The RuMP pathway (Fig. 1) has similarities to the Calvin Benson cycle of CO_2 fixation in the sense that 3 C_1 units (formaldehyde) are added to C5 acceptors (ribulose monophosphate) that subsequently undergo a se-

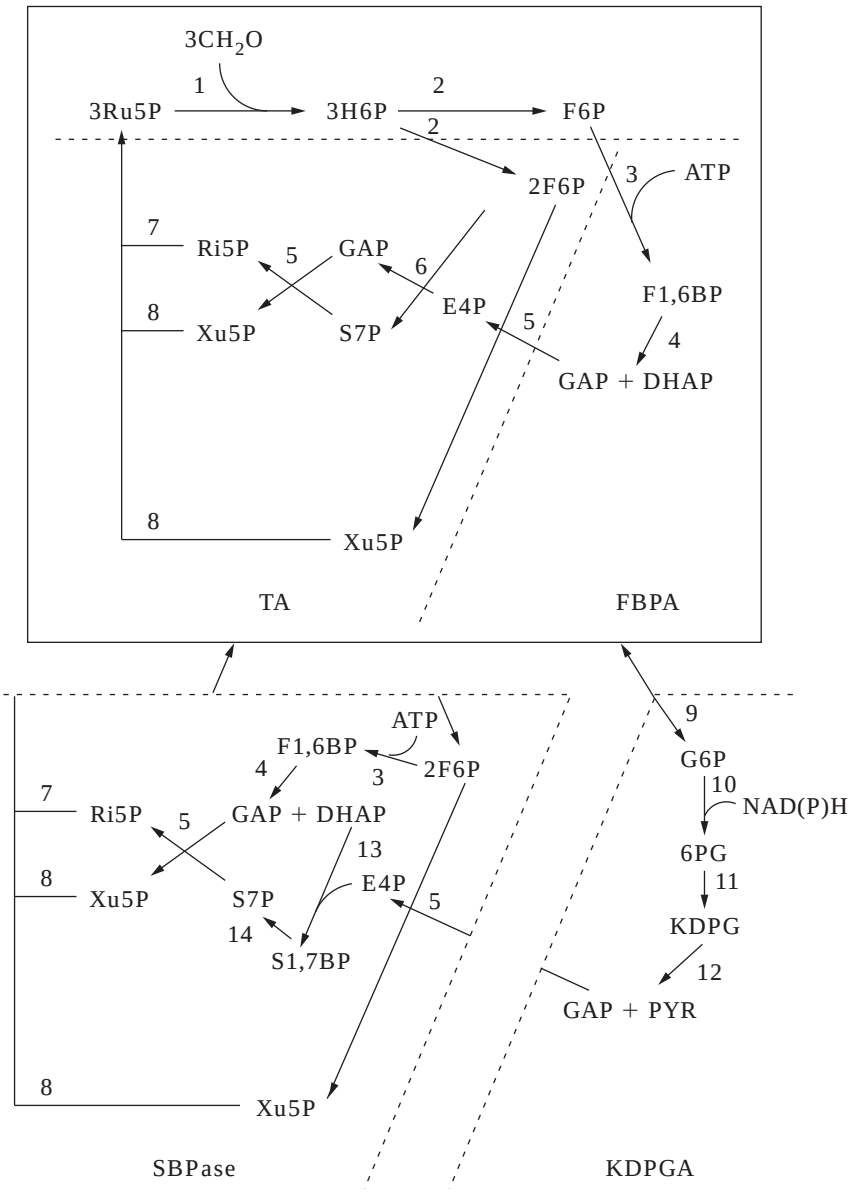

Figure 1. Intermediates and enzymes in the ribulose monophosphate pathway of formaldehyde fixation. Intermediates: Ru5P, ribulose-5-phosphate; H6P, hexulose-6-phosphate; F6P, fructose-6-phosphate; F1, 6BP, fructose-1,6-bisphosphate; DHAP, dihydroxyacetone phosphate; GAP, glyceraldehyde-3-phosphate; E4P, erythrose-4-phosphate; Xu5P, xylulose-5-phosphate; S7P, sedoheptulose-7-phosphate; Ri5P, ribose-5-phosphate; G6P, glucose-6-phosphate; 6PG, 6-phosphogluconate; KDPG, 2-keto-3-deoxy-6-phosphogluconate; PYR, pyruvate; S1,7BP, sedoheptulose-1,7-bisphosphate. Enzymes: 1, H6P synthase; 2, H6P isomerase; 3, phosphofructokinase; 4, F1,6BP aldolase; 5, transketolase; 6, transaldolase (TA); 7, Ri5P isomerase; 8, Pentose phosphate 3-epimerase; 9, phosphoglucose isomerase; 10, G6P dehydrogenase; 11, 6PG dehydratase; 12, KDPG aldolase (KDPGA); 13, S1,7BP aldolase; 14, S1,7BPase (SBPase).

ries of rearrangements yielding a C3 intermediate for cell biosynthesis and regenerating the acceptor molecules. Two variations of both cleavage reaction (fructose-1,6-bisphosphate aldolase [FBPA] and 2-keto-3-deoxy-6-phosphogluconate aldolase [KDPGA]), which generates the C3 biosynthetic intermediate, and the rearrangement stage (transaldolase [TA] and sedoheptulose-1,7-bisphosphatase [SBPase]), which regenerates the acceptor molecule, have been recognized and give four possible combinations. A comparison of the energetics of assimilation based on the production of a common C3 intermediate, pyruvate, shows that the FBPA/TA combination which is found in a number of Gram-positive methylotrophs, is the most efficient (Table 1).

The xylulose monophosphate (XuMP) pathway found in methylotrophic yeasts (5) has similarities to the RuMP pathway, being based on carbohydrate transformations and involving condensation of C_1 and C5 units and subsequent rearrangements based on transaldolases and transketolases (Fig. 2). However, the serine pathway found in bacteria is fundamentally different, involving assimilation of a C_1 unit into serine and subsequent rearrangements based on hydroxy acids and amino acids (Fig. 3). It also involves a CO_2 fixation step. Neither the XuMP nor serine pathway is as energetically efficient as the RuMP pathway but may offer advantages over the RuMP pathway organisms for the accumulation of certain metabolites.

Most of the yeasts, nonmethanotrophic serine pathway, and Gram-positive RuMP pathway organisms are facultative methylotrophs (3) able to use a range of heterotrophic substrates (e.g., carbohydrates). All of the methanotrophs appear to be obligate C_1 utilizers, some being very sensitive to excess methanol; many of the Gram-negative RuMP organisms are restricted facultative methylotrophs, growing poorly on some heterotrophic substrates. For me-

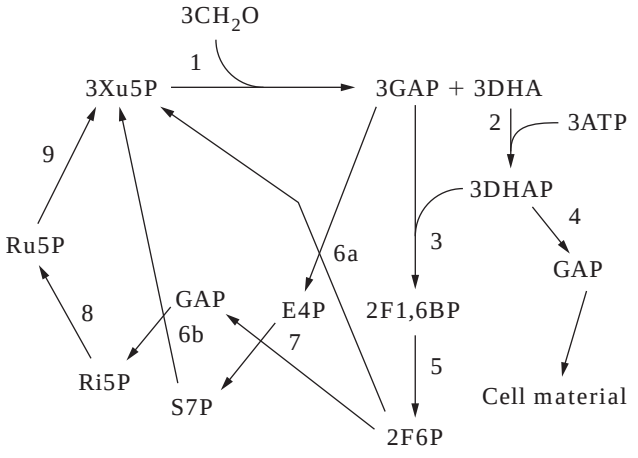

Figure 2. Intermediates and enzymes in the xylulose monophosphate pathway of formaldehyde fixation. Intermediates: Xu5P, xylulose-5-phosphate; GAP, glyceraldehyde-3-phosphate; DHA, dihydroxyacetone; DHAP, dihydroxyacetone phosphate; F1,6BP, fructose-1,6-bisphosphate; F6P, fructose-6-phosphate; E4P, erythrose-4-phosphate; S7P, sedoheptulose-7-phosphate; Ri5P, ribose-5-phosphate; Ru5P, ribulose-5-phosphate. Enzymes: 1, DHA synthase; 2, triokinase; 3, F1,6BP aldolase; 4, triose phosphate isomerase; 5, F1,6BPase; 6, transketolase; 7, transaldolase; 8, Ri5P isomerase; 9, pentose phosphate 3-epimerase.

tabolite overproduction, facultative methylotrophs can offer significant advantages because the ability to grow on heterotrophic substrates allows the isolation of mutants and genetic manipulation of methylotrophic metabolism.

Biomass Production

Despite the demise of C_1-based SCP processes, any future process adopted on the basis of substrate cost will inevitably involve growth of methylotrophs on a large scale. A retrospective consideration of the development of large-scale C_1-based processes is therefore warranted.

Table 1. Energetic Requirements of the Different Variants of the RuMP Cycle for the Production of Pyruvate ($3CH_2O \rightarrow$ Pyruvate), Chosen as a Typical Metabolic Intermediate

RuMP variant	NAD(P)H	ATP
KDPGA/SBPase	+1	−1
KDPGA/TA	+1	0
FBPA/SBPase	+1	0
FBPA/TA	+1	+1

KDGPA, 2-keto-3-deoxy-6-phosphogluconate aldolase; SBPase, sedoheptulose-1,7-bisphosphatase; FBPA, fructose-1,6-bisphosphate aldolase; TA, transaldolase.

Growth Yields and Energetics. A summary pathway for bacterial methane oxidation is shown in Figure 4. The pathway for methanol oxidation in Gram-negative methylotrophic bacteria that do not use methane is essentially the same, with the omission of the first step, although in some organisms formaldehyde is oxidized in a cyclic manner (6) after fixing in the initial steps of the assimilation pathway. Some methylotrophs may not use an NAD-linked formaldehyde dehydrogenase. However, those that do should give the highest growth yields and are therefore more likely to be adopted in a commercial process. $PQQH_2$ in methanol dehydrogenase is reoxidized by passing electrons via a periplasmic cytochrome c_L to the respiratory chain with energy conservation via chemiosmosis yielding approximately 1 ATP/$PQQH_2$ (7). Gram-positive methylotrophs use an NAD-linked methanol dehydrogenase (8). In principle, reoxidation of the resulting NADH via the respiratory chain should yield more ATP than gained from methanol oxidation in Gram-negative bacteria, which should translate into higher growth yields. For a wide range of substrates the yield of cells is proportional to the reduction level of the substrate, because biochemical oxidation yields proportionate amounts of ATP and cell yield is proportional to the ATP yield from substrate oxidation (9). Thus, one might expect that cell yields on methane

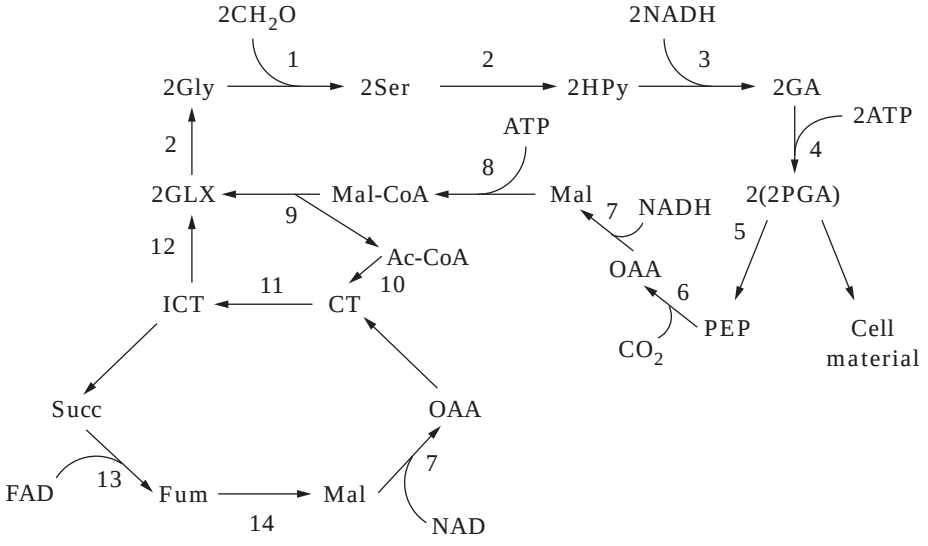

Figure 3. Intermediates and enzymes in the serine pathway of formaldehyde fixation. Intermediates: Gly, glycine; Ser, serine; HPy, hydroxypyruvate; GA, glycerate; 2PGA, 2-phosphoglycerate; PEP, phosphoenolpyruvate; OAA, oxaloacetate; Mal, malate; Mal-CoA, malyl-CoA; Ac-CoA, acetyl-CoA; CT, citrate; ICT, isocitrate; Succ, succinate; Fum, fumarate; GLX, glyoxylate. Enzymes: 1, serine transhydroxymethylase; 2, serine-glyoxylate aminotransferase; 3, hydroxypyruvate reductase; 4, glycerate kinase; 5, enolase; 6, PEP carboxylase; 7, malate dehydrogenase; 8, malate thiokinase; 9, malyl-CoA lyase; 10, citrate synthase; 11, aconitase; 12, isocitrate lyase; 13, succinate dehydrogenase; 14, fumarase.

would be higher than those on methanol. However, this relationship breaks down for highly reduced substrates; Figure 4 demonstrates the causes for methane oxidation. The biological oxidation of methane requires an energy input in the form of NADH, thus making methanol a potentially higher yielding substrate than methane (this is borne out in practice [10]). A number of other factors also mitigate against the use of methane as a substrate:

1. Flammability
2. Lack of compressibility
3. Low aqueous solubility
4. High oxygen demand (from Fig. 4 it is evident that the minimum oxygen demand would be 1.5 O_2/CH_4) resulting from the operation of methane monooxygenase

It should also be recognized that natural gas contains higher saturated and unsaturated hydrocarbons that can be partially oxidized by methanotrophs, resulting in the accumulation of inhibitory by-products. Therefore, except in circumstances in which the activity of methane monooxygenase (MMO) is required, bulk product formation from methylotrophs is likely to be based on methanol as substrate. Methanol can be derived from methane or a variety of other fossil fuels or renewable energy sources via synthesis gas (Fig. 5). The latter has also been proposed as a substrate for bulk product formation using carboxidotrophic bacteria (11) that use CO as a carbon source. However, despite the higher solubility of CO compared with methane, the problems of handling large volumes of a toxic substrate mitigate against this proposal.

Biomass Production from Methanol. A number of companies developed pilot-scale processes for biomass production from methanol (Table 2), with Imperial Chemical Industries (ICI) in the United Kingdom going on to full-scale

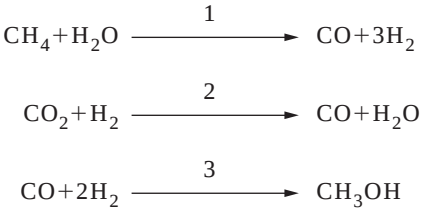

Figure 5. Imperial Chemical Industries process for the catalytic synthesis of methanol from methane 1, 15–20% Ni catalyst on Al_2O_3 or SiO_2, 700–900 °C, 1–25 bar; 2, Ni catalyst; 3, Cu/Zn catalyst, 250–280 °C, 70–110 bar.

production in a 1,500 m^3 continuous bioreactor using a Gram-negative bacterium. This was a significant technical achievement, the largest aseptic continuous culture process ever to operate.

The oxygen demand for growth on methanol (0.6–0.7 O_2/CH_3OH), although significantly less than that for methane, is still high compared with growth of heterotrophs on glucose (approximately 0.4 $O_2/[CH_2O]$). This high oxygen demand is a consequence of the relative inefficiency of energy conservation of periplasmic methanol dehydrogenase. For large-scale processes this inefficiency results in significant heat generation and oxygen transfer problems. The ICI solution to these problems was to use the moderately thermotolerant (t_{opt} = 40 °C) bacterium *Methylophilus methylotrophus* and a high aspect ratio (42 m × 7 m) pressure cycle reactor (17). This design also minimized the number of mechanical seals in the reactor, which were the most likely routes of contamination in long-term continuous operation. Gas transfer and mixing were achieved according to the airlift principle, with pressurized air being introduced at the base of the riser. However, the height of the liquid was such that the oxygen dissolved almost completely as it entered the reactor. To avoid toxicity or nutri-

Table 2. Full- or Pilot-Scale SCP Processes Using Methanol as Substrate

Company	Capacity (m^3)	Product (organism)	Reference

Norsk-Hydro, Sweden	45	Norprotein *(Methylomonas methanolica)*	15
Mitsubishi Gas-Chemical Co., Japan	2	(*Pseudomonas* sp.)	16

ent limitation methanol was introduced through a series of nozzles placed at various points up the riser. To achieve a product of the right composition as an animal feed, the reactor was run at a dilution rate of 0.16–0.19 h^{-1} (μ_{max} = 0.55 h^{-1}) with a cell density of 30 g dry wt L^{-1} and a projected annual production capacity of 50,000–70,000 tons. *M. methylotrophus* uses the KDPGA/TA route of C_1 assimilation (18), which, as discussed earlier, is marginally less efficient than the FBPA/TA route. It was also found to assimilate ammonia solely via the less energetically efficient glutamine synthase–glutamine oxoglutarate aminotransferase (GS/GOGAT) route. By knocking out this route and expressing glutamate dehydrogenase (GDH) from *Escherichia coli* in this organism a 7% improvement in yield from methanol was achieved (19). However, the latter construct was never used for commercial production.

Phillips Petroleum (later Provesta Corporation) in the United States opted for a process using the methylotrophic yeast *Pichia pastoris*, a decision based on the greater public acceptability of yeasts in nutrition. Methanol dissimilation in yeasts occurs by an energetically inefficient route involving an alcohol oxidase and catalase (Fig. 6). Not only is there no energy conservation arising from the conversion of methanol to formaldehyde but the oxidase mechanism involves stoichiometric amounts of oxygen. Although some oxygen is subsequently released through the action of catalase, the net requirement is $0.5O_2/CH_3OH$. Because inefficient energy conservation results in excessive heat generation the low optimum growth temperature (30 °C) was also a disadvantage, as was the long generation time (5.5–6 h). Nevertheless, through medium optimization and bioreactor design the Phillips process managed to achieve oxygen transfer rates of 0.8–1 mol L^{-1} h^{-1}, allowing operation at very high cell densities and producing a continuous slurry containing 125–150 g dry wt L^{-1} cells that could be spray-dried directly without concentration (14).

POTENTIAL APPLICATIONS

Processes Dependent on Substrate Economics

With the exception of SCP three other types of bulk product have been or are currently being considered as products from methylotrophs: poly-β-hydroxyalkanoate–based biodegradable plastics, polysaccharides, and amino acids. Although the driving force for all of these programs is substrate economics, in the last case the mode of carbon assimilation may predispose certain methylotrophs toward production of particular classes of amino acids.

One practical benefit from the research arising from the SCP programs was a detailed understanding of metabolic pathways and the energetics of carbon assimilation and dissimilation in methylotrophs. Using this information, Linton and Niekus (20), Collins (21), and Ackermann and Babel (22) have compared the likely carbon conversion efficiencies and oxygen requirements for conversion of methanol to these three bulk products. Predictions for amino acid production were based on glutamate. For polysaccharides and glutamate the predicted yields (w/w) from glucose and methanol are similar (Table 3), indicating that, for equally high yielding organisms, methanol would offer a cost advantage. However, the higher oxygen demand for methylotrophs is a significant disadvantage. In the case of exopolysaccharides the yield on oxygen is predicted to be 10-fold lower than that on glucose. Because polysaccharide volumetric productivity from glucose is often limited by the efficiency of oxygen transfer into increasingly viscous media the substrate cost advantage is more than offset by this disadvantage. Therefore, exopolysaccharides produced from methanol would have to have some unique characteristics to justify commercial production. A few years ago, Celgene Corporation marketed Poly-54/Methylophilan, an exopolysaccharide produced by continuous culture of *M. viscogenes*. Several uses were envisaged, but of particular note was its high viscosity at 80 °C (higher than xanthan gum), which, unlike xanthan, was maintained for extended periods. This suggested a possible role in enhanced oil recovery and in oil drilling muds. However, production has subsequently ceased (D. Stirling, personal communication, June 1997).

Amino Acid Production. Glutamate production from methanol has a threefold disadvantage compared with glucose in terms of yield from oxygen. Thus, production of glucose or other bulk amino acids from methanol has more realistic prospects than polysaccharide production. Indeed, methanol was being examined as an alternative substrate for glutamate production in the early 1970s. It is interesting to note that yields of up to 33 g/L were obtained in these early studies using metabolically ill-defined Gram-negative methylotrophs (23), which probably used the RuMP pathway. Similar yields have been reported more recently (24) using mutants of the Gram-negative RuMP organism *Methylobacillus glycogenes* (formerly classified as *Pseudomonas insueta* and *Protaminobacter thiaminophagus*). However, Ackermann and Babel have pointed out (22) that, despite their lower growth yields, serine pathway organisms should potentially give higher yields of glu-

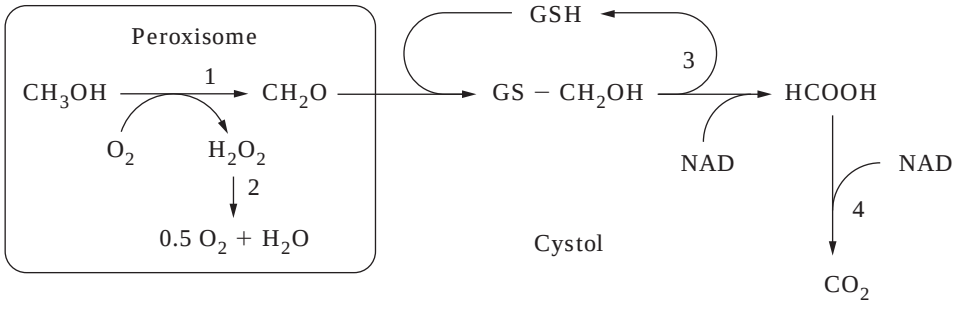

Figure 6. Linear (noncyclic) pathway for methanol dissimilation in methylotrophic yeasts.

Table 3. Predicted Product Yields (Y_s) from Methanol and Glucose, and the Associated Yield from Oxygen (Y_{O_2}).

Product[a]	Carbon source	Substrate requirement	Y_s (g/g)	Y_{O_2} (g/g)
EPS ($C_6H_{10}O_5$)	Methanol	$6.14CH_3OH + 3.21O_2$	0.82	1.58
	Glucose	$1.05\ C_6H_{12}O_6 + 0.3O_2$	0.86	16.3
Glutamate ($C_5H_9O_4N$)	Methanol^R	$6CH_3OH + NH_3 + 4.5O_2$	0.76	1.02
	Methanol^S	$5CH_3OH + NH_3 + 2.5O_2$	0.92	1.84
	Glucose	$C_6H_{12}O_6 + NH_3 + 1.5O_2$	0.82	3.06
PHB ($C_4H_6O_2$)	Methanol	$5.5CH_3OH + 3.75O_2$	0.49	0.72
	Glucose	$C_6H_{12}O_6$	0.48	[b]

Note: Yields are based on the known metabolic pathways between substrate and product and their associated energy requirements; substrate required for biomass formation is not considered. EPS synthesis from methanol is based on the RuMP pathway (20); glutamate synthesis from methanol (20,22) is based on both the RuMP pathway (^{R}) and the serine pathway (^{S}); PHB synthesis from methanol is based on the serine pathway and makes the same assumptions as cited in Ref. 21 regarding efficiency of methanol usage.

[a]EPS, extracellular polysaccharide (hexose); PHB, poly-β-hydroxybutyrate.

[b]Conversion of glucose to PHB generates ATP and NAD(P)H. There is therefore no additional ATP required for PHB synthesis, so the yield based on oxygen usage is, technically, infinite.

tamate from methanol; it should be borne in mind that high yields of amino acids may also depend on the type of organism being used.

Glutamic acid has traditionally been produced from *Corynebacterium* or *Brevibacterium* spp., which, as Gram-positive organisms, appear to be disposed toward this sort of application, partly because of the lack of an outer membrane and partly because of efficient glutamate efflux systems. Although the majority of Gram-positive methylotrophs isolated use the RuMP pathway (3) they may offer a greater possibility for realizing the theoretical yields of glutamate than the Gram-negative organisms previously studied. Furthermore, the isolation of stable mutants from Gram-negative methylotrophs is known to be difficult. Bearing in mind this difficulty and the cooling requirements for large-scale production, Schendel and coworkers (25) have isolated lysine overproducing mutants of a thermotolerant (t_{opt} = 50 °C), methylotrophic *Bacillus* sp. Process modeling and optimization (26) have demonstrated that production is primarily growth associated and optimal productivity should be obtained in a variable-feed, constant-volume fed-batch process. A final concentration of greater than 45 g/L lysine, which also included a significant amount of by-products (mainly glutamate and alanine) has been reported (27). Therefore, there is further room for improvement in control of metabolic flux to lysine. Abouzeid and coworkers (28) are examining the possibility of aromatic amino acid production (e.g., phenylalanine) from the Gram-positive *Amycolatopsis methanolica* (formerly *Nocardia* sp. 239). In the latter case, there is also a strong precedent for starting with a RuMP (or XuMP) pathway organism because erythrose-4-phosphate, a precursor for aromatic amino acid biosynthesis, occupies a central position in the RuMP and XuMP pathways.

Serine and methionine have also been considered for methylotrophic fermentative production. The former is required as a precursor in tryptophan production and is also included in some cosmetics. Its catalytic production from glycine and methanol by methylotrophs was an obvious target because serine hydroxymethyltransferase (SHMT) catalyzes the first step in carbon assimilation by serine pathway organisms and should therefore be expressed at high levels. Mutants of *Hyphomicrobium methylovorum* were reported (29) to produce 34 g/L serine from 100 g/L glycine and 48 g/L methanol, while resting cells of a strain of *Methylobacterium extorquens* produced 54 g/L serine (30). However, considerably higher concentrations have been achieved (31) in an enzyme bioreactor using a recombinant SHMT (from *E. coli*), and it is unlikely that a methylotrophic whole organism process will supplant this concentration. Unlike the previous examples, methionine for animal feeds is currently produced chemically from acrolein and methanethiol. Hence, the economic feasibility of fermentative whole cell biocatalytic production by methylotrophs is more difficult to assess than in the previous cases. Biosynthesis requires L-homoserine (from aspartate), serine, sulfide, and the C_1 carrier 5-methyl-THF, suggesting that serine pathway organisms would also be the obvious candidates. This suggestion was made valid by the studies of Yamada and coworkers on ethionine-resistant mutants of RuMP and serine pathway organisms (32,33). However, none of the yields were commercially significant, and the lack of any recent literature on this topic suggests that it is not being pursued.

Biodegradable Plastics from Methanol. Marlbrough Biopolymers, a subsidiary of Monsanto, now produces a biodegradable plastic under the tradename Biopol by fermentation using *Alcaligenes eutrophus* grown on glucose as the carbon and energy source (34). The plastic is a derivative of poly-β-hydroxybutyrate (PHB), a high molecular weight polyester produced by many bacteria as a carbon and energy storage compound. *A. eutrophus* was selected because PHB can comprise up to 80% of its dry weight under appropriate conditions and also because, when supplied with propionic acid, the organism produces a random copolymer of 3-hydroxybutyrate and 3-hydroxyvalerate, P(3HB-3HV), which is tougher and more flexible than pure PHB. Current production runs at about 1,000 tons per annum. However, it has been predicted that even at a 10-fold higher level the cost of P(3HB-3HV) would be about $5/kg, similar to that of other biodegradable plastics but considerably higher than synthetic plastics derived from petrochemicals (35). Glucose accounts for 35–40% of this price. Therefore, at present, microbially derived plastics are still in the category of niche products.

Two underlying research trends are evident in this area. For truly bulk production of PHB-based plastics at a price similar to synthetics it has been recognized that production in plants such as rapeseed or soybean represents the way forward, and some progress in this area is being made (35). Production in bacteria, due to its higher cost, is more likely to concentrate on niche products. In that light, the evidence that PHB is just one of a family of polyhydroxyalkanoates (PHAs) and that some PHA synthases will accept hydroxyacyl CoAs derived from a wide range of derivatized carboxylic acids supplied to the medium opens up a potentially fruitful avenue for the production of specialist biodegradable polymers (36). The greater ease of physiological and genetic control of metabolic flux in bacteria would favor production by fermentation.

Because substrate costs represent a significant proportion of the selling price of PHAs, substitution with a cheaper substrate could offer some short- and long-term benefits for P(3HB-3HV) and specialist PHA production, respectively. Collins (21) calculated that the maximum theoretical yield from methanol would be 0.18 g/g compared with 0.33 g/g from glucose. Although the price differential between the two substrates would still favor methanol, the cost savings are marginal. In the early stages of Biopol development methanol was apparently considered as a substrate but not pursued because the product was of low molecular weight and extraction was difficult. More recent research by a number of groups has shown that high molecular weight PHB can be produced from methylotrophs and that P(3HB-3HV) can be produced in methylotrophs by supplementing the fermentation with *n*-amyl alcohol or valeric acid (propionic acid was less effective). However, the 66% of dry weight (136 g/L PHB) achieved by Suzuki et al. (37) using computer-controlled fed-batch fermentation is the highest reported yield for any methylotroph. This apparent limit probably reflects a restriction of metabolic flux to the PHB precursors, which suggests that genetic manipulation of flux control mechanisms may be necessary to match the yields currently achieved with *A. eutrophus*. PHB synthesis in methylotrophs appears to be restricted to *Methylobacterium* spp. ("pink-pigmented facultative methylotrophs") and the autotrophic methylotrophs (38). *Methylobacterium* spp. assimilate carbon via the serine pathway and have a complete TCA cycle, unlike restricted facultative methylotrophs that use the RuMP cycle. It is evident that, without a complete TCA cycle, acetyl CoA resulting from the breakdown of PHB would be of limited benefit. Hence, the latter organisms have evolved to accumulate extracellular polysaccharide rather than PHB. Recent work on the cloning from *A. eutrophus* and heterologous expression of genes required for PHB biosynthesis (39) is extending the range of potential strains for PHB production. Thus, RuMP pathway methylotrophs may be considered in the future.

Processes Based on C_1 Metabolism

Although the pathways of carbon assimilation in methylotrophs are specialized, few of the enzymes involved are unique. In the RuMP pathway only the hexulose phosphate synthase and isomerase are peculiar to C_1 metabolism. Therefore, beyond the observation that certain routes of C_1 assimilation might provide a higher flux of precursors for amino acid biosynthesis, for example, the assimilatory enzymes of C_1 metabolism have not been exploited. However, there has been considerable interest in the development of processes based on C_1 dissimilatory enzymes, in particular methane monooxygenase, methanol dehydrogenase, methanol oxidase (from yeasts), and formate dehydrogenase.

Methane Monooxygenase. Two types of MMO have been recognized: a nonheme iron-soluble (cytoplasmic) enzyme (sMMO) and a membrane-associated enzyme (pMMO; p, particulate) that requires copper for activity and has some similarity to ammonia monooxygenase (40). Soluble MMOs from *Methylococcus capsulatus* (Bath) and *Methylosinus trichosporium* OB3b have been extensively studied, and crystal structures of the oxygenase component from both enzymes are available (41). Additionally, the genes encoding sMMO from a number of sources have been cloned, sequenced (42), and expressed in heterologous hosts (43). Both sMMO and pMMO insert oxygen into a range of substrates other than methane, with sMMO having a very low substrate specificity (44,45). Initially this observation led to interest in the use of cells expressing MMO as biocatalysts for synthetic biotransformations, particularly in the conversion of propene to propene oxide. Although a bulk product, the chemical synthesis of propene oxide is not straightforward, and there was considerable interest in the possibility of a one-step biological process that did not yield by-products (46). However, the dual requirements of high catalytic rates and extended biocatalytic lifetimes could not be realized, primarily because the process of propene epoxidation actually inactivated the MMO (47). Other potential applications as a synthetic biocatalyst have also foundered, partly because sMMO has a low stereoselectivity and therefore has little value for the synthesis of chiral chemicals. Another limitation is that with many substrates it exhibits poor regioselectivity, producing, for example, mixtures of alkan-1-ols and alkan-2-ols from the oxidation of straight chain alkanes (44).

More recently the interest in MMO has focused on applications in biotreatment, particularly of the priority pollutant trichloroethene (TCE) and other low molecular weight partially halogenated hydrocarbons (e.g., dichloroethene, vinyl chloride). In fact, MMO is only one of a number of mono- and dioxygenases that have been shown to fortuitously co-oxidize these compounds (48). Cometabolism processes typically yield no benefit to the host organism and, in the case of co-oxidation, represent an energy drain, requiring an additional energy source for continued operation of the oxygenase. In the case of methane oxidizing bacteria, methanol is an obvious energy source, although growth on methanol may have undesirable physiological consequences (see later section). Oxidation of TCE by methane oxidizing bacteria leads to the transient accumulation of TCE epoxide (49), which is chemically unstable. As a consequence, TCE epoxide and some of the derived breakdown products are also highly reactive and can give rise to toxicity. This result has been demonstrated with both purified sMMO (49) and whole cells expressing

sMMO (50). However, it seems that the toxicity can be alleviated by continued supply of reducing power and particularly by the use of mixed rather than axenic cultures (51). In the latter, it is probable that other members of the bacterial consortium assist in the removal of toxic intermediates, thus prolonging the life of the primary biocatalyst.

Studies with pure cultures have demonstrated that oxidation of TCE is fastest with bacteria expressing the sMMO (2). The ability to express sMMO is restricted to certain types of methanotrophs: primarily the type II (serine pathway) and type X bacteria such as *Methylosinus trichosporium* and *Methylococcus capsulatus*, respectively. Furthermore, in these organisms, production of sMMO is regulated by the availability of copper in the medium. With a copper-sufficient medium these organisms preferentially produce the pMMO (which results in a higher growth efficiency). Therefore, to get high rates of TCE oxidation, it is necessary to grow these organisms in a copper-deficient medium. Although this condition may be feasible in laboratory experiments it may be more difficult to achieve in operational biotreatment plants and impossible to control for in situ biotreatment operations. However, with increasing access to the molecular genetics of methanotrophs (42), the generation of stable mutants (e.g., by reverse genetics [52]) unable to synthesize pMMO presents an interesting prospect. Regulatory mutants that constitutively produce sMMO would also circumvent another physiological problem, which is that growth of type II and type X organisms on methanol, even under copper limitation, results in production of pMMO (53) (at very low copper concentrations this is produced as an apo-enzyme). Mutants that constitutively produced sMMO could be supplied with methanol as a growth substrate and also to drive the co-oxidation reaction, without the risk of switching off sMMO synthesis.

Several reports (2) have described the practical applications of methanotrophs for TCE and other chlorinated hydrocarbon degradation, both in controlled bioreactors and in situ. Bioreactor studies have mainly been based on *Methylosinus trichosporium*, which was shown, in laboratory studies using copper-limited growth conditions, to have the highest reported specific activity of TCE degradation of any of the oxygenase-based systems that have been examined. Because of the problems of sMMO expression using methanol as growth substrate, these reactors have usually been supplied with methane to sustain the active biomass and formate to drive the biotransformation. However, with a continuously fed bioreactor, methane and TCE compete for the sMMO, which reduces rates of biodegradation. A practical alternative is the use of sequencing reactors (54) that are alternately supplied with methane and TCE. The feasibility of in situ biotreatment (55) of contaminated aquifers by stimulating indigenous methanotrophic activity has also been investigated. Injection of methane–air mixtures was shown to stimulate growth of methanotrophs, particularly type II methanotrophs, which have the potential to produce sMMO. In one study, degradation of TCE was shown to increase after this treatment, which suggests that these organisms were also expressing sMMO. However, without the ability to control the availability of copper for growth, it is more difficult to optimize expression of sMMO activity and hence TCE biodegradation in in situ treatment.

Whole cells of methanotrophic bacteria have also been considered as methane sensors (56) (using oxygen uptake as the mode of detection) and methane filters (57) for use in the mining industry. However, neither of these potential applications has been developed beyond the laboratory stage.

Methanol Dehydrogenase. Methanol oxidation in Gram-negative aerobic methylotrophs involves a periplasmic methanol dehydrogenase (MDH) that uses pyrroloquinoline quinone (PQQ, or methoxatin) as a cofactor. Reducing equivalents from MDH would normally be passed to a soluble cytochrome c (7) but can also be passed to artificial electron acceptors such as ferrocenes, which are used as mediators in biosensors. Higgins et al. (58) developed a sensor based on MDH that had a rapid response time and useful sensitivity range (1–100 μM). However, MDH oxidizes a number of primary alcohols in addition to methanol. Although the enzyme from *Rhodopseudomonas acidophila* has a higher affinity for ethanol than for other primary alcohols (59), this lack of specificity limits the usefulness of MDH in diagnostics. In contrast, the broad substrate range may present opportunities for use in synthetic biotransformations (60). In Japan there also appears to be a market for PQQ, the MDH cofactor, as a health food (61).

Methanol or Alcohol Oxidase. Methanol oxidase is the enzyme used by eukaryotic methylotrophs to catalyze the first step in methanol metabolism. It produces formaldehyde (from methanol) and hydrogen peroxide and is normally found in association with catalase, which degrades the peroxide (5). As with MDH, methanol oxidase also oxidizes a range of higher alcohols and is therefore often referred to as alcohol oxidase (AOX). In methylotrophic yeasts AOX and catalase are expressed at very high levels and are located in organelles known as peroxisomes. Peroxisomes can be seen in thin sections to occupy most of the intracellular volume. This very high level of expression has been exploited for the development of eukaryotic expression systems, which are discussed later.

As with MDH, AOX has been considered for use in biosensors but with detection based on oxygen uptake rather than through direct or indirect electron transfer reactions (62). Similar to MDH, the enzyme also has a broad substrate range. Methylotrophic yeasts and AOX have also been considered for the production of formaldehyde, where it has been demonstrated that surprisingly high concentrations (0.95 M) could be accumulated by mutants of *Candida boidinii* (63) and for production of hydrogen peroxide. The latter is toxic to most AOX enzymes, but that from *Pichia pastoris* NRRL Y-4290 appears to be remarkably resistant (64). The production of peroxide using methanol oxidase from methylotrophic yeasts has been patented by Unilever, although there is no evidence that it has been put into commercial practice.

Formate Dehydrogenase. The formate dehydrogenases (FDH) from methylotrophic bacteria appear to be surprisingly complex given their apparently simple function.

However, those from methylotrophic yeasts are simpler. The enzyme from *C. boidinii* is a homodimer with subunits of approximately 36 kDa; it is both oxygen insensitive and moderately thermostable (65). Because the end product of formate oxidation is gaseous and can therefore be easily removed from the reaction, the combination of formate and FDH is ideal for reduced nucleotide recycling. The enzyme is produced commercially and has been used with great effect for continuous biotransformation reactions requiring NADH (66).

Applications Fortuitously Associated with C_1 Metabolism

Heterologous Gene Expression in Methylotrophic Yeasts. One of the fortuitous and enduring aspects of the various SCP programs resulted from the discovery that the methanol or alcohol oxidase of the yeast *P. pastoris* was expressed at very high levels (5), essentially from a single chromosomal copy of the AOX gene (there are actually two AOX genes, but *AOX1* is expressed much more strongly than *AOX2*). One of the problems with the use of *Saccharomyces cerevisiae* as a host for heterologous expression of eukaryotic proteins is the lack of a strong, yet tightly regulated, inducible promoter. During growth on methanol, methanol oxidase can comprise up to 30% of the soluble cell protein in *P. pastoris* (67), with the enzyme being localized in specialized microbodies (peroxisomes) together with catalase and dihydroxyacetone synthase, the first enzyme involved in formaldehyde assimilation. As mentioned earlier, these peroxisomes occupy most of the cell contents of methanol grown cells, but when grown on glucose, peroxisomes are virtually absent. A similar situation is found with another well-studied methylotrophic yeast, *Hansenula polymorpha* (68). The strong inducible *AOX1* promoter has been exploited by Provesta Corporation for the development of a powerful expression system that is now commercially available in a variety of forms (69). For production purposes, the system of choice involves cloning into an integrative additive or transplacement vector. Transplacement involves replacement of the *AOX1* locus by the cloned construct giving a strain with an aox1AOX2 phenotype, capable of only slow growth on methanol. Additive integration at the *AOX1* or *HIS4* locus will leave a functional *AOX1*, allowing continued growth on methanol.

Higher levels of heterologous gene expression are usually obtained with the transplacement system. Chromosomal integration yields stable expression systems; however, multiple copies of the expression cassette, usually associated with expression from plasmid vectors, result in higher levels of expression. Scorer and coworkers (70) have shown that, by including a kanamycin resistance gene in the integration cassette and selecting for high levels of resistance to the antibiotic G418, it is possible to select for multicopy integration, which occurs naturally in about 5–10% of transformants. In this way it has been possible to achieve expression levels comprising up to 32% of total cell protein (Table 4); by combining this technique with techniques for high cell density culture developed during the SCP program (71), yields of up to 12 g/L recombinant protein have been recorded. The highest protein yields have been obtained in cytosolic form. However, secreted proteins can be obtained using either native (including prokaryotic) secretion signals, the leader sequences from prepro-α mating factor, or invertase from *S. cerevisiae*. As with *S. cerevisiae, P. pastoris* also carries out some typical eukaryotic posttranslational modification including N- and O-linked glycosylation.

Table 4. A Selection of Heterologous Proteins Produced in *Pichia pastoris* (Pp) and *Hansenula polymorpha* (Hp)

Protein (MW)	Host/system	Yield (g/L)
HBsAg (23)	Pp (FB) + Hp	0.4 (Pp)
Human TNF (17)	Pp (FB + CC)	10
Human EGF (6)	Pp (FB)	0.5
Streptokinase-*Se* (47)	Pp (CC)	0.077
Aprotinin (6.5)	Pp (FB)	0.93
Tetanus tox. frag Cs*Ct*(50)	Pp (FB)	12
Pertactin-*Bp* (69)	Pp (FB)	3
Human PN-2 (6.8)	Pp	1
HIV gp120 (54)	Pp (FB)	1.25
HSA (67)	Pp (FB) + Hp	
Human IGF-1 (7.5)	Pp (FB)	0.5
Human lysozyme (14)	Pp	0.7
Human SOD (16)	Pp	0.75
IL-2	Pp	4
Human tPA	Pp	
Invertase-*Sc* (58)	Pp (FB) + Hp	2.5 (Pp)
Glucose oxidase-*An* (75)	Hp	2.25

Note: These proteins were chosen to illustrate the range of yields obtained with therapeutically important proteins. For a fuller list see Ref. 68. FB, fed batch; CC, continuous culture; *Se, Streptococcus equisimilis; Ct, Clostridium tetani; Bp, Bordetella pertussis; Sc, Saccharomyces cerevisiae; An, Aspergillus niger.*

Expression in *H. polymorpha* (Table 4) offers the same features seen with *P. pastoris*, potentially coupled with more efficient production because the optimum growth temperature is 37–43 °C, reducing the cooling requirements of large-scale processes, and growth on methanol is faster (68). However, because *H. polymorpha* has only one *AOX* gene, transplacement constructs are unable to grow on methanol as the sole carbon source. Usually glucose is used for growth, with methanol added to induce heterologous gene expression at the appropriate time. The inducible formate dehydrogenase (FMD) promoter has also been used.

Recent studies with a number of organisms have started to unravel the processes of peroxisome (and other microbody) proliferation and protein targeting. Given the dramatic increase in peroxisomes associated with methanol induction and the peroxisomal location of AOX, it has been suggested (68) that methylotrophic yeasts may offer an additional advantage for heterologous gene expression: namely, targeting to peroxisomes as a mechanism for compartmentalizing toxic or proteolytically susceptible proteins.

Production of Vitamins and Coenzymes. Although they do not command the high prices of recombinant proteins and other pharmaceutical products, vitamins and coenzymes occupy a price range dictated more by productivity than substrate economics. Nevertheless, various methylotrophs have been found to produce relatively high levels

of potentially valuable products such as cytochrome c, coenzyme Q_{10}, and vitamin B_{12}. Methanol oxidation occurs in the periplasm of aerobic Gram-negative methylotrophic bacteria and links directly to the respiratory chain via a soluble cytochrome c (7). Some wild-type strains have been observed to release significant quantities of this cytochrome into the culture medium during growth (71); cyanide- and glycine-resistant mutants accumulate levels higher than those of wild-type strains (72). The high respiratory capacity associated with aerobic methanol oxidation also underlies the ability of some mutant facultative methylotrophs to produce high levels of coenzyme Q_{10}. Both of these products have applications in cardiotherapy, with Q_{10} also finding an increasing market in dietary supplements, but face competition from sources such as spent brewing yeast or bovine or equine heart, neither of which incur specific production costs.

Vitamin B_{12} is produced commercially by fermentation using *Propionibacterium* spp. However, anaerobic methylotrophic methanogens and acetogens have been shown to accumulate high concentrations of corrinoids, including vitamin B_{12}. Despite the low biomass productivity and cell yields of these anaerobes, potential production with these organisms remains an active area of research (73).

CONCLUDING REMARKS

Despite the commercial failure of methanol-based SCP production, the rationale for adopting methylotrophic organisms for processes in which substrate costs form a significant part of overall production costs still holds true. The early work on methylotrophic bacteria was dominated by studies of Gram-negative organisms, and our understanding of the biochemistry of these organisms is now relatively advanced. Work on Gram-positive methylotrophs has lagged behind. However, given that Gram-positive organisms are favored for fermentation processes to produce low molecular weight metabolites such as amino acids (which increasingly fall into the high volume–low price category of products), it is probable that Gram-positive organisms will receive increasing attention. As far back as the early 1970s the potential of methylotrophs for producing such metabolites was appreciated. Given the increasing access to the molecular genetics of methylotrophic bacteria, it would not be surprising to see this area develop.

Substrate costs also underlie the high degree of interest in producing polyhydroxyalkanoates in methylotrophs. However, even if methanol could supplant carbohydrate in the current processes, PHA production costs could still not compete with those of bulk plastics. Thus, at least for the foreseeable future, PHAs are likely to remain a specialized product; as such, the fermentation substrate is likely to be dictated by the nature of the process and product required rather than the opposite.

Finally, it is probable that some of the specialized applications of methylotrophs will continue to develop. The *P. pastoris* expression system appears to be well established, and the more recently developed *H. polymorpha* system could provide a useful complement. Methanotrophic bacteria (or recombinant methane monooxygenase), on the other hand, may yet find an application in biotreatment plants. Certainly the practice of stimulating the proliferation of methanotrophs to boost their cometabolic contribution in natural ecosystems is a rational approach and may offer a cost-effective solution to some problems of environmental contamination.

OUTLINE

INTRODUCTION

Microalgae have been cultured commercially for about 50 years for applications in secondary wastewater treatment (1) and use as animal feeds (2,3) as fertilizers (4), in production of chemicals (5,6), and in secondary metabolites with pharmaceutical potential (7), as well as other purposes. The early interest in using microalgae as a significant source of protein has waned because of the relatively low biomass productivities. Now the focus of algal mass cultures is on relatively specialized niche applications; nevertheless, progress remains slow relative to biotechnological use of bacteria, yeasts, and animal cells. Cost-effective culture of microalgae requires substantially improved biomass productivity, better utilization of the available light, and more efficient use of carbon dioxide, the principal carbon source.

Open outdoor mass culture systems, such as ponds and raceways, typically operate at low cell densities (0.01 to 0.06% w/v); consequently harvesting is expensive and economic returns are low. In addition, species control is difficult in open systems, and much of the incident radiation is wasted. The low productivity of open systems has prompted the development of enclosed photobioreactors (PBRs) (i.e., transparent tubes or containers in which the culture may be circulated by various devices). Enclosed PBRs allow a more controlled culture environment, including improved temperature control. Successful design of PBRs relies on attaining a proper balance of engineering and biological factors that are interdependent and depend also on the species being cultured. Of course, from a commercial perspective, reliability and the costs of construction and operation are also important. The physical rate processes of concern are the light delivery, the gas–liquid mass transfer, temperature control, fluid dynamics, and mixing. The biological rate processes of concern are photosynthesis, growth, and production of metabolites.

This article details the major types of bioreactors used in mass culture of microalgae. The basic requirements for successful outdoor culture are noted, and the physics and biology of mass cultivation are discussed.

BIOREACTORS FOR MICROALGAE MASS CULTURE

Three microalgae—*Chlorella*, *Dunaliella*, and *Spirulina*—are currently produced commercially on a relatively large scale (approximately 1,000 tons each per annum). The current commercial production systems for these species are mostly open raceway ponds. Many commercially useful algae are difficult to cultivate in open systems because they require a mild culture environment that is highly susceptible to contamination by other algae, bacteria, protozoa, and fungi. The inability to cultivate desirable algal species that contain valuable products (e.g., astaxanthin, aquaculture feeds, polysaccharides, and polyunsaturated fatty acids) in open ponds has increased interest in closed systems. The closed systems in use include (*1*) bag culture, which is widely used for culture of algae for aquaculture; (*2*) alveolar panels and other flat plate reactors of various designs (8–10); (*3*) stirred tank reactors with internal illumination (11,12); (*4*) airlift reactors (13,14); and (*5*) tubular reactors. Tubular reactors may be arranged in a horizontal position relative to the land or they may be inclined (15–22). Some of the major types of photobioreactors are discussed in the following.

Open Raceways

Open raceways, or shallow mixed ponds, for microalgal production were introduced in the 1950s and early 1960s by Oswald and coworkers (23). The principles of design and construction of shallow paddle-stirred raceways for microalgal culture have been reviewed by Dodd (24) and Oswald (25). The pond is set in a meandering configuration. Various designs are used to promote flow and low shear mixing. A simplified open raceway is depicted in Figure 1. Selection of a suitable bottom lining and construction of walls are important to the success of the open pond. The lining may be made of concrete or sheets of plastic and rubber material. Sheets of polyvinyl chloride 1–2 mm thick, are commonly used. The size of commercial ponds varies from 1,000 to 5,000 m^2; one or two paddle wheels per pond are used for stirring. A larger wheel (ca. 2 m in diameter) revolving slowly (e.g., 10 rpm) is preferable to a smaller, faster wheel, which could produce shear damage and foam.

Supply of Carbon Dioxide. The method of supplying carbon dioxide is an important aspect of the raceway design, particularly for species that grow near neutral pH. Several systems have been developed to efficiently supply CO_2 to shallow suspensions. In most cases the gas is supplied as fine bubbles. Because of the shallow depth of culture, the residence time of the bubbles is not sufficient for complete absorption of the CO_2; hence, some gas is lost to the atmosphere. To avoid this, Märkl and Mather (26) used a

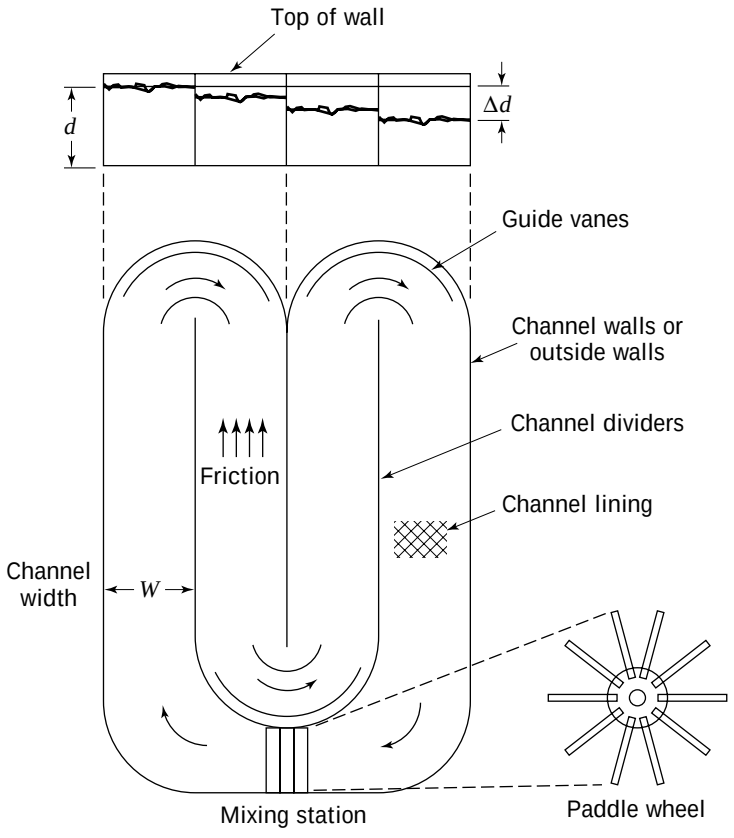

Figure 1. Open raceway with a paddle wheel mixing device. The channel length is the distance traveled by the culture from the discharge side of the paddle wheel to its upstream side. *Source*: Adapted from Oswald (25) and Dodd (24), with permission.

pump to push the algal suspension through a nozzle to a chamber in which the CO_2 was added. High CO_2 transfer rates were obtained. The jet produced an additional flow in the pond. The most effective method currently available for transferring CO_2 to algal cultures is countercurrent carbonation (25), in which the gas is injected as minute bubbles into a column of downcoming culture. The culture velocity is adjusted to that of the small bubbles of CO_2 rising against the current. Using this technique, Laws et al. (27) reported a 70% utilization of the supplied CO_2 compared with 13 to 20% if conventional bubbling was used (28).

Mixing. Mixing is necessary to prevent settling of cells and to avoid thermal stratification of the culture. Properly designed paddle wheels are by far the most efficient and durable pond mixers. The engineering of a raceway equipped with paddle wheels has been comprehensively described by Oswald (25). As shown in Figure 1, the depth, d, of culture in a channel of finite width, w, varies along the channel. The mean channel velocity, v(m s^{-1}) is given by

$$v = \frac{1}{n} R^{2/3} \cdot s^{1/2} \tag{1}$$

where n is the Manning friction factor (s m$^{-1/3}$), R is the hydraulic radius (m), and s is the rate of loss of energy in the channel per unit length. The channel length, L, that corresponds to the assumed change in depth for a given friction factor, hydraulic radius, and velocity (v) is given as (25)

$$L = \frac{\Delta d(dw/(w + 2d))^{4/3}}{v^2 \cdot n^2} \tag{2}$$

The value of n varies according to the relative roughness of the channel. Experimentally determined n values in algae growth channels vary from 0.008 to 0.030 (25). The lower value is for smooth, plastic-lined channels, and the higher one is for relatively rough earthen channels. The channel velocity, v, affects the paddle wheel's power requirements; hence,

$$P = \frac{Q \cdot \rho \cdot \Delta d}{\eta} \tag{3}$$

where P is the power (kW), Q is the volumetric flow rate of culture ($Q = v \cdot d \cdot w$) (m^3 s^{-1}), ρ is the density of culture (kg m^{-3}), Δd is the change in depth (m), and η is the efficiency of the paddle wheel. Because $\Delta d = s \cdot L$ and s is a function of v^2, P increases as the cube of velocity; therefore, velocity should be minimized whenever energy is a major cost factor. Typically, the flow rates range between 15 and 30 cm s^{-1}. Velocities greater than 30 cm s^{-1} result in large values of Δd in long channels and may require high channel walls and higher divider walls. Note that for a finite value of the channel width, w, the permissible mixing channel length, L, and thus the mixable area, $a = L \cdot w$, is strongly dependent on depth, d.

Contamination and temperature are difficult to control in open pond systems. Also, the culture depth cannot be reduced below 12 to 15 cm or a severe reduction of flow and turbulence would occur. Hence, areal volumes tend to be large, about 120 to 150 L/m^2 (29), requiring maintenance of a rather low cell concentration (around 500 mg/L). A low cell concentration in turn increases the cost of harvesting the biomass, and ponds are expensive to maintain. These problems could, in principle, be minimized by photobioreactor designs that employ shallower cultures, maximize cell densities, allow better process control, and minimize contamination. Closed photobioreactors achieve these objectives, as described in the next section.

Enclosed Photobioreactors

PBRs can be defined as algal culture systems that do not allow direct contact of the culture with the atmosphere. PBRs generally may be grouped into two classes: tubular and flat plate. These groups can be further classified into several categories, depending on orientation of tubes, the type of gas exchange system, and the arrangement of the individual growth units. The materials of construction provide additional variations. For example, in the case of flat plate reactors, most work has been carried out with alveolar systems in which the flat plate is divided into many individual cells. Another example is the use of flexible plastic bags. A major factor in the design of these systems is the depth of the culture, which ultimately determines the biomass concentration and productivity. Lee (30) and Borowitzka (31) provided comprehensive summaries of the state of the art of the closed PBRs, none of which are in widespread commercial operation.

Conventional mass culture ponds covered with inexpensive plastic sheets have been used in several algal mass culture projects, but they provide few benefits beyond an increased temperature during early spring or fall in temperate climates. Also, their design and operation are essentially identical to those of the conventional open pond systems described earlier. Here, only tubular reactors capable of operation outdoors with natural sunlight and with high surface-to-volume ratios (>10 m^{-1}) are considered.

In vertical column reactors, bubble columns or airlifts, aeration, and agitation are provided by injection of CO_2-enriched air through a sparger at the bottom of the column. In practice, a vertical column can extend for only a few meters or an expensive structure is needed for support. James and Al-Khars (13) studied the growth and productivity of *Chlorella* and *Nannochlropsis* in a vertical airlift photobioreactor. Contreras Gómez (14) showed that the average annual volumetric productivity of a draught tube airlift was about 1 g L^{-1} per day in culture of *Phaeodactylum tricornutum*. A major advantage of tower reactors is that oxygen does not accumulate in the growth medium because the residence time of the gas phase is quite small in a relatively short reactor. Also, tower bioreactors are potentially easy to keep sterile compared to other tubular systems. A major drawback of any tubular system positioned vertically is that in the summer the reactor is always at a large angle to the sun's rays; hence, the amount of solar energy absorbed during the midday hours is lower than for horizontally placed tubular devices.

The earliest described outdoor tubular reactor was made of 3-cm-diameter glass tubes arranged in a serpentine configuration (32). The tubular loop was immersed in water. The culture was recirculated in the system by a motor-driven pump. The flow velocity was 15 to 30 cm s^{-1}. The culture circulated through a bubble column that was injected with 5% CO_2 at a rate of 1–1.5 cm^3 min^{-1}. The total culture volume was 40 L. The more recent systems are essentially identical to that first design. Thus, Chaumont et al. in France (33) employed tubes placed parallel to ground and Pirt et al. in England (15) used a vertically placed loop. Both systems used pumps to circulate the culture. Because fragile cells can be sensitive to mechanical pumping, the authors recommended the use of airlift devices for both culture recirculation and CO_2 supply.

Although other designs of tubular reactors have been proposed—including the two-plane tubular reactor (16), the near-horizontal tubular reactor (21), the helical bubble reactor (34), the α-tubular reactor (35), and the parallel flow tubular photobioreactor (18)—they are essentially the same as the ones used by Pirt et al. (15) and Chaumont et al. (33).

Figure 2 shows a fully instrumented tubular photobioreactor similar to those described by Chaumont and coworkers. The system shown consists of a vertical external-loop airlift pump that drives the culture fluid through the horizontal tubular solar receiver. The airlift section (riser, downcomer, and degasser) has a height of 3.5 m. The gas-injected riser and the downcomer sections (Fig. 2) are extensions of the solar receiver tube. The solar receiver is made of transparent Plexiglas® tubes (0.05-m internal diameter, 0.005-m wall thickness) joined into a loop configuration by Plexiglas® joints to obtain a total horizontal length of 98.8 m. The solar receiver is submerged ($\sim$0.05 m) in a shallow pool of water that is maintained at 21 $\pm$ 2 °C by cooling with a heat pump when needed. The bottom and inside walls of the pool are painted white to improve reflectance. The surface area of the pool is 21.4 m^2. The total culture volume in the bioreactor is 0.200 m^3.

The exhaust gas from the top of the degasser zone is analyzed for oxygen (paramagnetic analyzer) and carbon dioxide (infrared analyzer). Filter sterilized culture medium is fed in at the degasser zone. A port located on the side of the degasser section is used to continuously harvest the culture (Fig. 2). The temperature, the dissolved oxygen, and the pH measurements are made via sensors located in the degassing zone, in addition to a dissolved oxygen sensor located at the end of the external loop. The sensors are connected to a control unit and a computer for data acquisition.

The air supply point is located at the entrance of the riser, whereas the CO_2 is injected at the entrance of the solar receiver in response to a signal from the pH sensor. The photosynthetically active radiation (PAR) is determined at the ground level and inside the photobioreactor. In the previously described microalgae mass culture facility, the irradiance inside the thermostatic pond was higher than the incident radiation on the surface of the water because of the light reflected by the walls and the bottom of the pool. This phenomenon of radiation enhancement is quantified in terms of the albedo of a system.

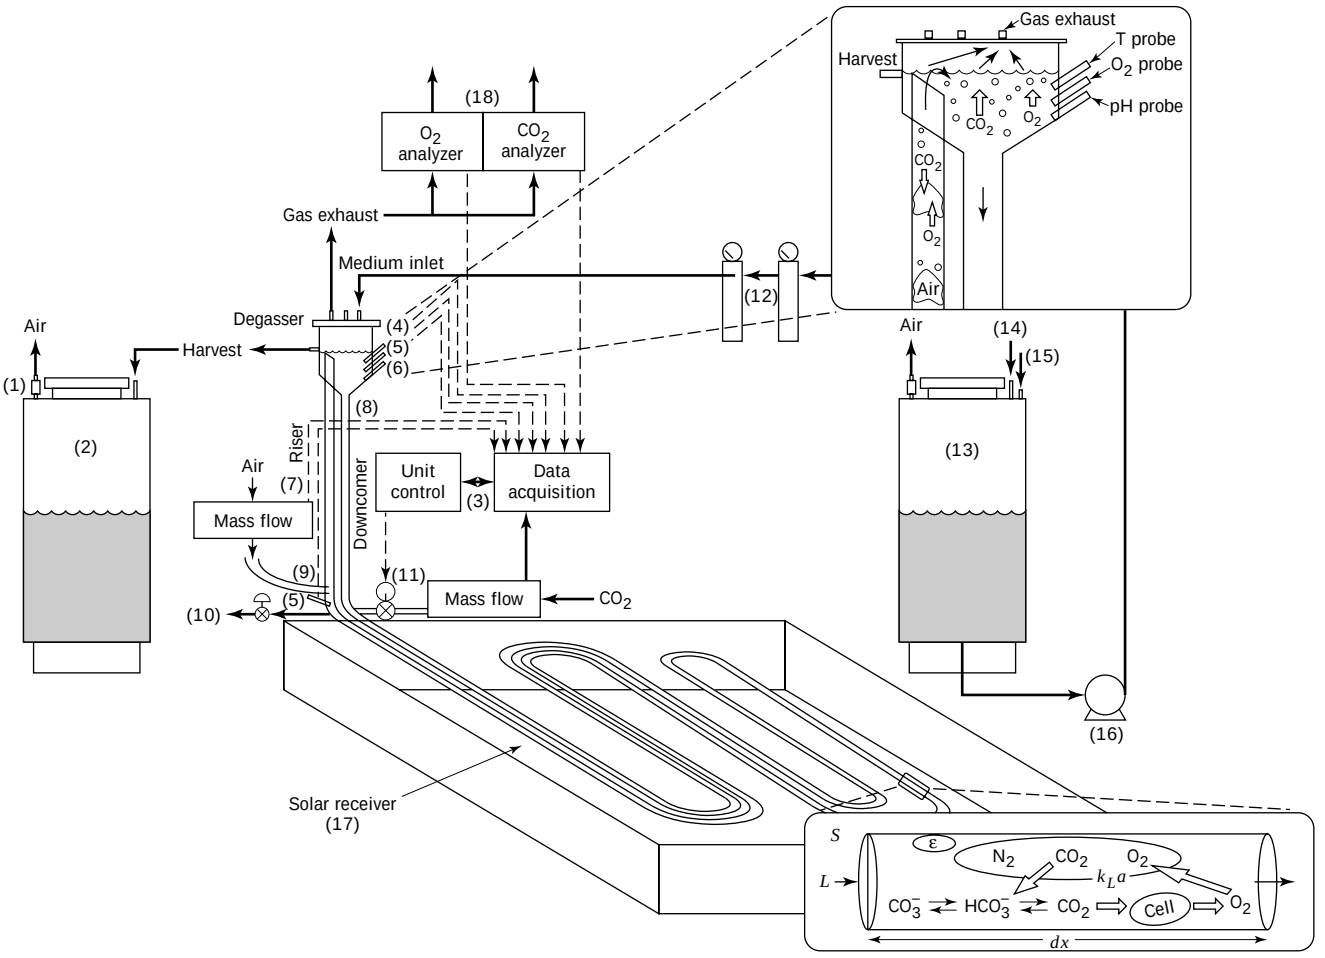

Figure 2. Tubular photobioreactor: (1) air filters, (2) harvest tank, (3) control unit, (4) temperature sensor, (5) dissolved oxygen probe, (6) pH probe, (7) riser, (8) downcomer, (9) air injection, (10) sampler, (11) CO_2 injection, (12) medium sterilization filters, (13) fresh medium, (14) nutrient inlet, (15) seawater inlet, (16) pump, (17) thermostated water pool, (18) gas composition analyzer.

For efficient and reliable large-scale culture of microalgae in PBRs, several operational, environmental, and design variables need to be assessed. A summary of some of the main variables and their impact on the various aspects of a reactor's performance are depicted in Figure 3. Of these, an important design criterion is the efficiency of light utilization, which in turn is related to the productivity of the system. Also important are the costs of construction and operation (36).

As indicated in Figure 3, the on-line data acquisition of dissolved oxygen, pH, and temperature inside the culture allows for rapid characterization of the physiological state of the cells. The measurement of CO_2 and O_2 molar flows at the gas inlet and outlet enables estimation of the mass transfer capability of the system and efficiency of CO_2 utilization. The measurement of the biomass concentration and the product content allows the estimation of the biomass and product productivities. Finally, the biomass productivity, P_b, and the photon flux absorbed per unit of volume, F_{vol}, may allow the assessment of the efficiency of a system in harvesting energy and converting it into biomass.

PHYSICAL FACTORS THAT INFLUENCE BIOMASS PRODUCTIVITY

Biomass productivity in any culture system depends on the degree to which the culture conditions match the requirements of the selected strain. Because mineral nutrient limitation is easily avoided in microalgal mass culture (29,37), light availability inside the photobioreactor and temperature are the main factors that determine productivity. Once the temperature is suitably controlled, light availability becomes the only limiting factor (22,38).

The interrelations among the various factors that influence productivity in outdoor conditions are shown in Figure 4. Productivity is determined by the growth rate, which, for fixed fluid dynamics and temperature, is a function of the light profile within the reactor and the light regime to which the cells are subject. The average irradiance (I_{av}) within the reactor depends on the external irradiance (I_0) on the surface of the reactor and its geometry (22,39,40). I_0 is a function of time, the geographic location, and environmental factors (41). Although temperature is relatively easily controlled, the available solar radiation at

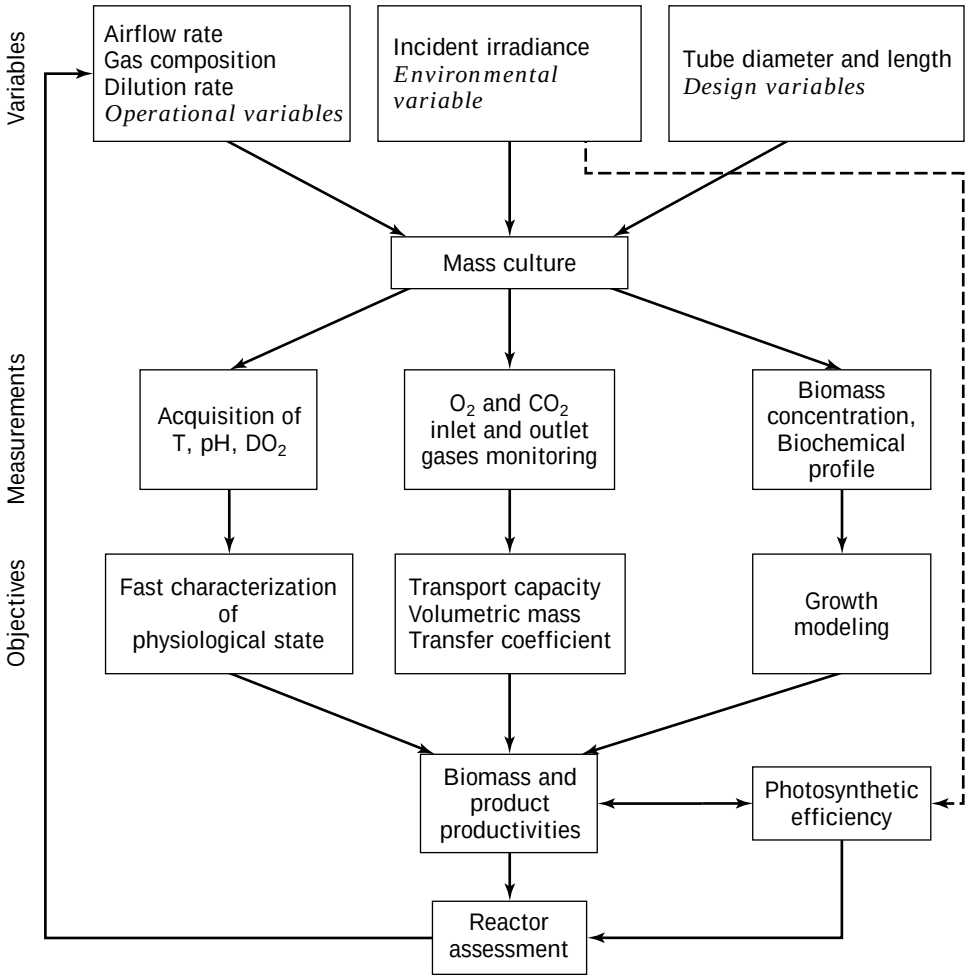

Figure 3. Relationships among bioreactor design and operational variables.

any location cannot be controlled. The self-shading effect of the cells also affects the radiation profile inside the culture (40). In addition, the fluid dynamics inside the reactor also influence the light regime seen by the cells because, depending on the nature and intensity of fluid movement, the cells spend different amounts of time in zones of different illumination (42–44). Fluid mechanics also affect the transport behavior and availability of certain nutrients. In an optimal system where no other factors limit, light availability determines the rate of photosynthesis and productivity. However, excessive light can be harmful and is known to produce a photoinhibitory response (45). The issues relating to light availability are discussed in the following sections for photobioreactors located outdoors.

Light Availability inside a Photobioreactor

For commercial-scale culture, sunlight is usually the preferred source of light because artificial light is too expensive for all but the most valuable products. The effects of natural outdoor light on cultures are not entirely clear because most studies on characterizing the photosynthetic response to light (e.g., 46–48) were conducted under carefully controlled indoor laboratory conditions. The irradiance levels used in such studies were significantly lower than the peak solar irradiance that typically occurs outdoors. Cultures grown outdoors experience large variations in light availability: Within a few hours the irradiance increases from 0 at dawn to more than 2,000 μE $m^{-2}s^{-1}$ at noon (i.e., a rate several times above saturation); within a few additional hours, the irradiance declines to 0 again as evening sets in. Because of this rapid change, the culture may go from being light limited in the morning to being photoinhibited at noon and light limited once again during the late afternoon and evening.

Information concerning light distribution in microalgal mass culture systems is scant, but recently a comprehensive model for light distribution and average irradiance inside a horizontal tubular outdoor photobioreactor has been proposed (40). That model has been further generalized for use with other configurations of photobioreactors (49). The mathematical model determines the distance traveled by an incident ray of light to any point inside the culture and estimates the local irradiance by taking into account the light attenuation due to biomass. The incident total radiation is divided into direct and disperse radiation. The former is characterized by having a direction defined as a function of the position of the sun at any given mo-

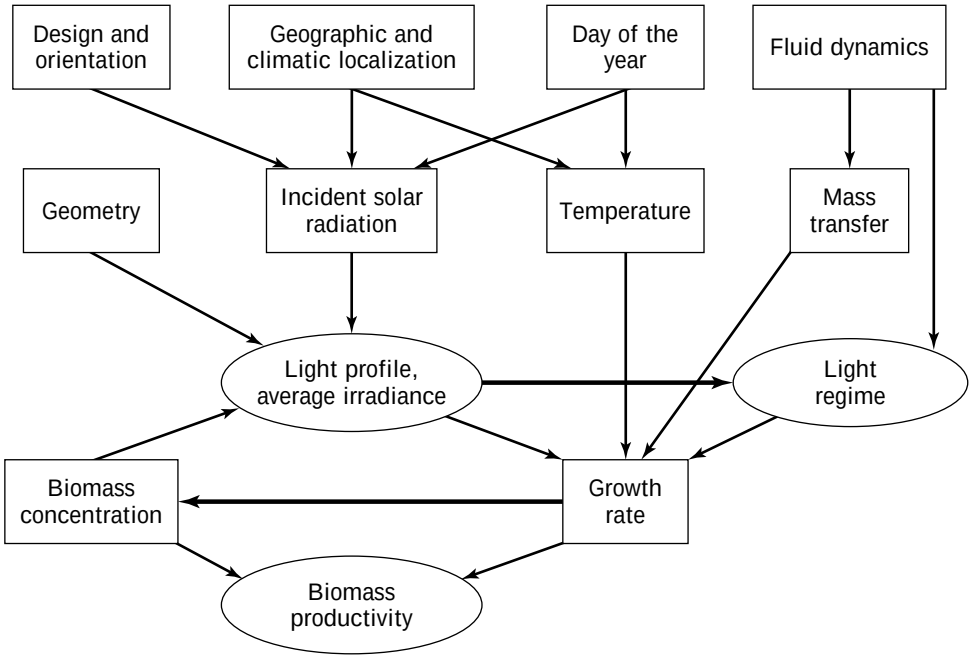

Figure 4. Relationships among parameters that influence biomass productivity in outdoor culture.

ment, and the latter, being reflected radiation, has no specific direction. The model is mathematically complex. For example, the angle of incidence of direct radiation on the photobioreactor surface is a function of five variables: day of year, solar hour, geographic latitude, surface slope, and surface azimuth angle (i.e., the deviation of the projection on a horizontal plane of the normal to the surface from the local meridian, with zero due south, east negative, and west positive) (50,51). Detailed information for estimating the angle of the incidence of the solar radiation, the irradiance impinging on the reactor surface, and the path traveled by the ray of light inside both horizontally and vertically placed tubular reactors has been reported (40,49,52).

Local and Average Irradiance inside the Culture. In a well-mixed microalgal mass culture system, light attenuation by biomass gives rise to a heterogeneous illumination profile inside the culture bulk for which mathematical evaluation is essential to estimate the average irradiance on which the growth of the microalgae depends (53). This attenuation is usually represented by Lambert–Beer's law. The incident radiation on the culture surface may be considered as consisting of the sum of two contributions: direct radiation, which has a direction defined by the position of the sun, and the disperse radiation. The latter is the sum of the diffuse radiation and that reflected by the surface surrounding the reactor.

The local direct irradiance inside the culture may be estimated using Lambert–Beer's law, as described elsewhere (40). The disperse radiation coming from all spatial directions can be determined by an integration over all the angles of incidence (40). Thus, it is possible to determine the light profiles and average irradiance inside the culture. Figure 5 shows the modeled local irradiance at two radial positions in a horizontal or vertical arrangement at 8 and 12 solar hours. As expected, as solar hour changes, curves of local irradiance at the same internal ratio adjust to the sun's position. In the morning (8 solar hours) in the vertical reactor, the side facing the sun had much higher direct irradiance values than the opposite side; this difference was lower in the horizontal reactor. However, at noon, the irradiance distribution in the vertical reactor, unlike the horizontal tube, was practically homogeneous. This profile results because during midday, the contribution of disperse irradiance to the total irradiance is very large in the vertical arrangement. Therefore, the level of irradiance for each internal radius and for any hour of the day is higher in the horizontally placed reactor tube than in the vertically placed reactor tube. The irradiance distribution inside the culture and the patterns of cell movement inside the photobioreactors are also different.

The Light Saturation Constant and the Photoinhibition Phenomenon

Algal growth is related to light intensity. According to Goldman (54), the generalized curve relating algal growth to light intensity has the shape shown in Figure 6. The curve has four main features: (*1*) at some low growth rate, the growth is balanced by decay, and the net growth rate is zero; (*2*) the initial slope of the curve represents the maximum efficiency of growth in response to light; (*3*) there is a saturating light intensity at I_s for which $\mu = \mu_{max}$; (*4*) at some light intensity $I_p > I_s$, the growth is inhibited and $\mu < \mu_{max}$.

Because most algal species become light saturated at a fraction of the peak solar light intensity, much potentially useful solar energy is essentially wasted. The light satu-

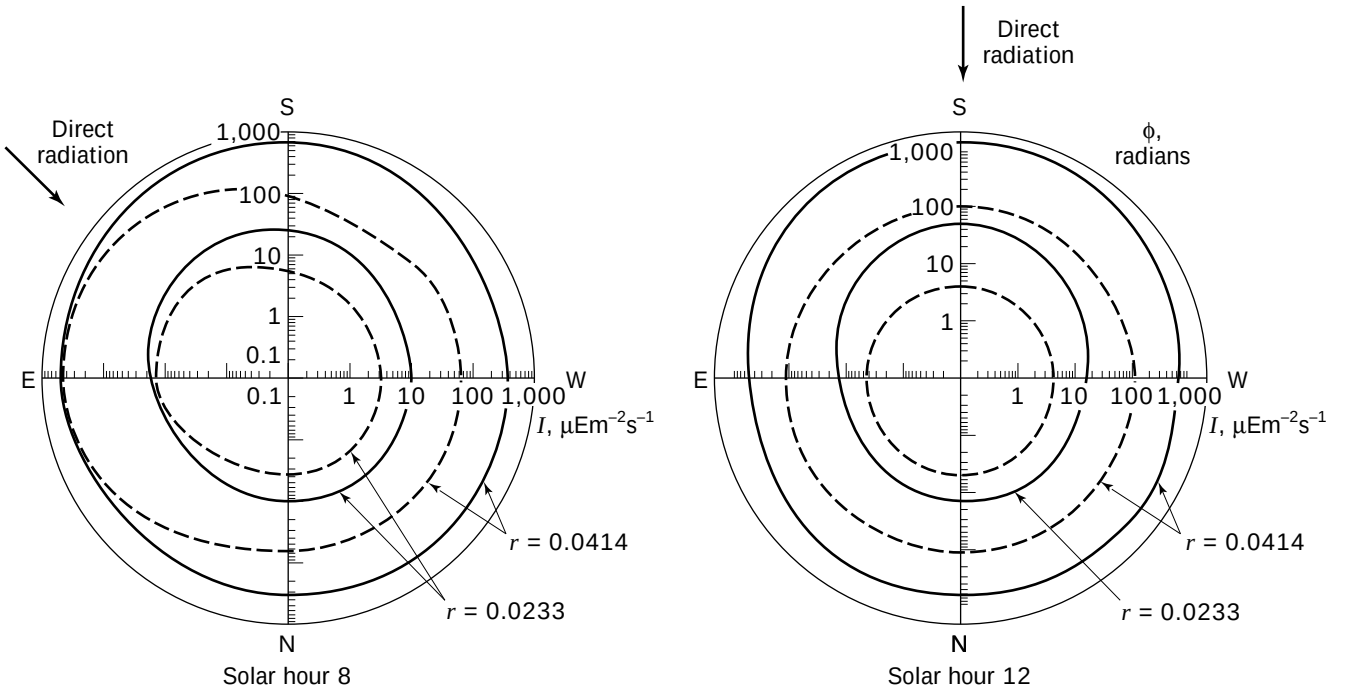

Figure 5. Calculated radial irradiance profiles in the cross section of a bubble column (dashed lines) and a photobioreactor placed parallel to the ground (solid lines) at 8 and 12 solar hours. In both cases the parameters were 0.1-m tube diameter; 1.9 g L^{-1} biomass concentration of *Phaeodactylum tricornutum*; dilution rate of 0.033 h^{-1}; and pigment content, $X_p = 2.21\%$.

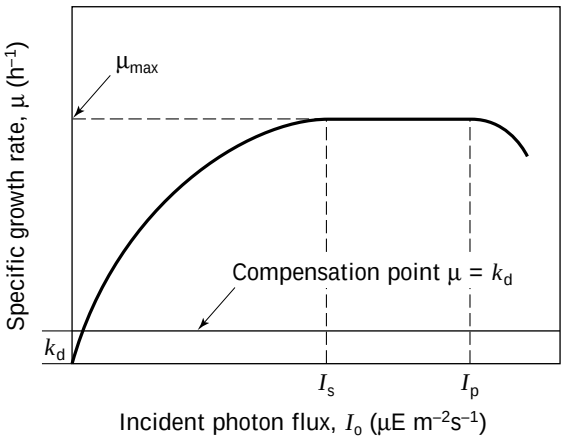

Figure 6. Dependence of the growth rate (μ) on the incident photon flux (I_0). *Source*: From Goldman (55), with permission.

ration constant is a measure of the intrinsic capacity of cells to utilize light energy. A high saturation constant is advantageous because it increases the efficiency of light use and reduces photoinhibition.

Photoinhibition—a decline in the photosynthetic capacity due to light intensities in excess of those required to saturate the photosynthesis (29)—has been studied often in algae. Shading the culture with shad nets is commonly used to protect against inhibitory levels of light during midday hours. The kinetics of photoinhibition and its recovery in *Porphyridium cruentum* have been studied (56). A linear relationship was found between the specific rate of photoinhibition and the specific light absorption rate. The temperature was reported to have a pronounced modifying effect on photoinhibition. At 15 °C, no damage was detected at 2,300 μE $m^{-2}s^{-1}$ light intensity, even after 45 min of illumination. In contrast, at 35 °C, 84% inhibition of the photosynthetic activity was observed within 10 min of exposure. *P. cruentum* cells recovered readily when transferred to low light (90 μE $m^{-2}s^{-1}$) or darkness; the specific rate of recovery was independent of the light intensity to which the cells had been exposed during the inhibitory treatment.

The existence of photoinhibition in continuous outdoor cultures of *Phaeodactylum tricornutum* has also been documented (52). Figure 7 shows how the average irradiance, I_{av}, inside the culture varies with dilution rate, D, regardless of the tube diameter, indicating that the cultures adapt mainly to the average irradiance. At $D = 0.025\ h^{-1}$, the I_{av} increased only slightly with increasing external irradiance, I_0, on the reactor surface. The mean value of I_{av} for the whole range was $84 \pm 9\ \mu E\ m^2\ s^{-1}$. With a smaller tube diameter or higher external irradiance, the biomass concentration increased as expected for self-shaded light-limited growth. However, the slight increase in I_{av} with increasing I_0 points to some photoinhibition by external irradiance, although this is not very extensive due to the high biomass concentrations. At $D = 0.040\ h^{-1}$, I_{av} values are higher ($163 \pm 20\ \mu E\ m^{-2}\ s^{-1}$) than at $D = 0.025\ h^{-1}$ because of the lower steady-state biomass concentrations. The greater light availability gives rise to a higher specific growth rate and photoinhibition because of the greater in-

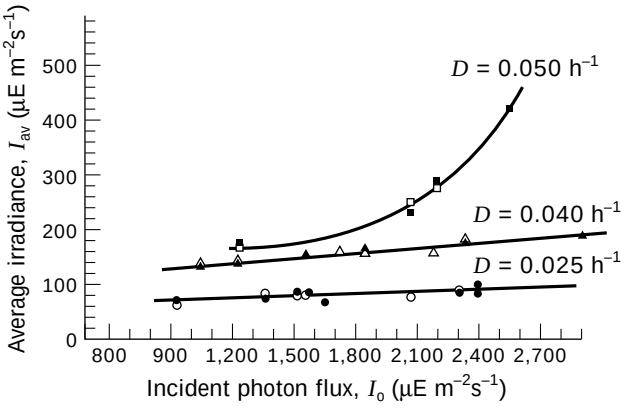

Figure 7. Variation of the average irradiance (I_{av}) inside a tubular photobioreactor during culture of *Phaeodactylum tricornutum* UTEX 640. Data are shown as functions of the mean daily photosynthetic irradiance (I_0) on the reactor surface for various dilution rates and two different tube diameters. Open symbols are for 3-cm tube diameter; filled symbols are for 6-cm tube diameter.

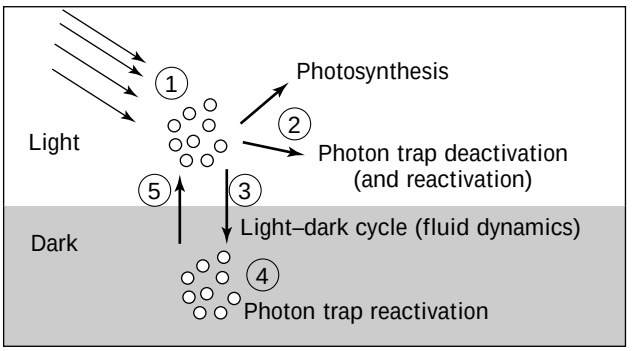

Figure 8. A simplified mechanistic representation of photosynthesis. (1) photon capture → biomass synthesis; (2) photon capture → photon trap deactivation (reactivation); (3) cell transfer to the dark; (4) photon trap reactivation; (5) cells return to the illuminated zone. Photon trap recovery is zero order with respect to unrecovered photon trap, and the recovery time is species dependent. *Source*: From Merchuk et al. (59), with permission.

crease in I_{av} with I_0. At 0.050 h^{-1} dilution rate, the exponential increase in I_{av} with I_0 caused by the low steady-state biomass concentration underlines the existence of photoinhibition; hence, the one-to-one relationship between μ and I_{av} no longer applies.

Photoinhibition is caused by oversaturation of photosystem II, which damages the D1 protein that carries the binding site of the electron carrier (57,58). This photoinhibition effect is quite distinct from that of temperature rise that occurs in uncontrolled systems as a function of the photon flux density (PFD). Whereas a single cell of microalgae cannot be simultaneously photolimited and photoinhibited, in bioreactors photolimited and photoinhibited cell populations may coexist because of variations in photointensity in different zones. At low light intensities the few damaged D1 protein molecules are replaced rapidly and the net damage to the photosynthetic apparatus is negligible. In this situation, a dark period reduces growth rate (photosynthesis) because fewer photons are captured but no gain is obtained from the dark time. In contrast, under conditions of intense illumination, part of the light energy impairs the photosynthetic apparatus. Repair and damage proceed simultaneously, and the observed growth is the sum of the two processes. If a dark period is introduced in this situation, the duration of the photosynthetic period declines, but the damaging period is also reduced; the photon trap repair continues during the dark time. Consequently, during the next light period, a substantially rejuvenated photon trap compensates for the loss in photosynthetic time. Under these circumstances, alternating light and dark periods do not reduce growth, which may in fact be slightly enhanced. Nevertheless, the length of the dark period is important: lengthening the light period beyond an optimal value will produce loss of growth. The optimal or critical dark period is not a fixed quantity; instead it depends on the PFD of the previous light period and the fluid residence time in zones of different irradiance. Figure 8 outlines a mechanism of photosynthesis that takes into account the steps noted in the foregoing (59). Clearly, therefore, the principal problem of designing or choosing a photobioreactor is ensuring, for any species with preestablished photosynthetic characteristics, that the largest possible fraction of cells experiences optimal exposure to light in the largest possible reactor volume.

Biomass Productivity

Many studies on the influence of environmental variables on biomass productivity have been carried out in laboratories (20,32,60,61), but few have been performed under outdoor conditions. Some models have been proposed specifically for outdoor algal ponds (41,62–64). Thus, Incropera and Thomas (41) present a model for determining the mean irradiance in an open pond as a function of climate and geographic location parameters. Starting from estimated irradiance values, a six-parameter growth model is proposed (41). The model does not consider photoinhibition and predicts maximum productivities of about 34 g m^{-2} per day. A five-parameter mathematical model for biomass productivity in outdoor systems has been proposed by Sukenik et al. (62,63). According to this model, the cells adapt to mean irradiance inside the culture; however, photoinhibition is not taken into account, and the results are not valid at low biomass concentration. The model yields productivities of 10.2 to 27.2 g m^{-2} per day. By using mean temperature and irradiance data, Guterman et al. (64) propose a growth model for open systems. The model estimates the variation of culture parameters such as dissolved oxygen, temperature, pH, and biomass concentration through empirical linear relationships and does not consider photoinhibition. The estimated maximum productivity was 38 g m^{-2} per day at irradiances of 2,500 μE m^{-2}s^{-1}. According to these models the maximum productivities are reached at low biomass concentration, when the mutual shading effect is negligible and the culture may be considered light saturated. The estimated productivities from these models have not been experimentally verified. In fact, such cultures cannot be carried out, because

photoinhibition in the middle of the day decreases growth rate and may even lead to culture washout.

A macromodel for estimating the yearlong biomass productivity of microalgal cultures in outdoor tubular photobioreactors has been developed by Acién Fernández et al. (52). In this model the solar irradiance impinging on the reactor surface I_0 is initially determined as a function of the day of the year and the location. Then, by taking into account the geometry of the system, the average irradiance to which the cells are exposed inside the culture, I_{av}, is determined. Finally, the specific growth rate, μ, is correlated with I_{av} as follows:

$$\mu = \frac{\mu_{max} \cdot I_{\alpha v}^{(n_2 + n_3/I_0)}}{\left(I'_k\left(1 + \left(\frac{I_0}{K_I}\right)^{n_1}\right)\right)^{(n_2 + n_3/I_0)} + I_{\alpha v}^{(n_2 + n_3/I_0)}} \quad (4)$$

where I_0 is the irradiance on the surface of the reactor. The characteristic parameters of this equation were obtained by fitting the experimental results to the equation. The parameter values were $\mu_{max} = 0.063\ h^{-1}$, $I'_k = 94.3\ \mu E\ m^{-2}\ s^{-1}$, $K_I = 3426\ \mu E\ m^{-2}\ s^{-1}$, $n_1 = 3.04$, $n_2 = 1.209$, and $n_3 = 514.6$. Equation 4 has been used to simulate the biomass productivity in a continuous outdoor culture of *Phaeodactylum tricornutum* (52). The measured data agreed with the simulations within 20%. The simulated biomass productivity over the annual cycle is shown in Figure 9. The approach described can in principle be extended to other strains. If photoinhibition were not taken into account as in earlier models (41,62–64) the experimental results could be fit to a hyperbolic model that considers only photolimitation (61):

$$\mu = \frac{\mu_{max} I_{\alpha v}^n}{I_k^n + I_{\alpha v}^n} \quad (5)$$

however, the scatter of the data would significantly exceed ±20%. In equation 5 I_k is the affinity cells have for light and n is a fitting parameter of the model.

In view of the observations discussed, several conclusions can be made regarding biomass production by microalgal mass cultures: (*1*) the optimum dilution rate varies over the year as a function of incident radiation and the diameter of the bioreactor tube; (*2*) the larger the tube diameter, the more extensive the photoinhibition effect, although the simultaneous existence of photolimitation and photoinhibition permits growth to be maintained and a quasi steady state is still attained.

Fluid Dynamics and Mixing

To achieve high productivity, algal cultures need to be mixed. The method of mixing (turbulence) is critical because some algae are quite shear sensitive (65,66). When light is the limiting factor for growth, stirring has been suggested as the most practical means by which to attempt to distribute solar energy evenly to all cells in the culture. The stirring is associated with a flashing light effect. The duration for which the cells are exposed to the light and dark zones of the reactor is a function of agitation intensity. The flashing light effect has been intensively investigated by Laws et al. (67). The flashing light effect or agitation has been associated with increased photosynthetic efficiencies. Laws and coworkers (67) introduced a simple technique for utilizing the flashing light effect in shallow but optically dense outdoor algal cultures by inserting an array of small foil segments across the width of a continuous

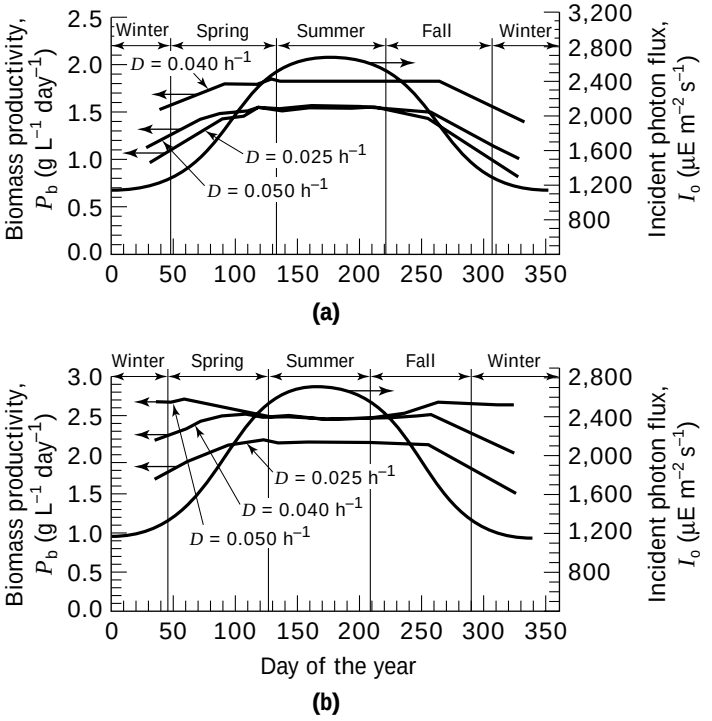

Figure 9. Variation of the estimated biomass productivity with the day of the year for a continuous culture of *Phaeodactylum tricornutum* UTEX 640 in two tubular photobioreactors: (**a**) 0.06-m tube diameter, (**b**) 0.03-m tube diameter. Simulations are shown for three dilution rates.

flume at intervals of 1.2 m along the length of the flume. The wing-shaped foils created a vortex circulation that produced an ordered pattern of vertical stirring. By using these devices, Laws and coworkers obtained photosynthetic efficiencies (based on the PAR) of 9.6 and 7.5, respectively, with and without the foils in place.

In tubular photobioreactors and ponds, higher flow rates generally enhance productivity. Typically, flow rates range between 20 and 30 cm s^{-1}. As noted, the flow can be generated by various methods such as paddle wheels and pumps. In closed tubular photobioreactors the flow is commonly driven by airlift systems, which are generally less damaging to cells than the mechanical devices. The velocity in the tube controls the turbulence and shear rate, determines the mixing behavior and the mass transfer capacity, and greatly influences the axial oxygen concentration profile in the tube. The liquid velocity, U_L, may be estimated by an extension of the well-known and widely tested model developed by Chisti (68); thus,

$$U_L = \left[\frac{g h_D \varepsilon_r}{2f \dfrac{L_{eq}}{D}} \frac{A_r}{A_d}\right]^{0.5} \quad (6)$$

where f is the Fanning friction factor that can be calculated using the Blasius equation,

$$f = 0.0791 \mathrm{Re}^{-0.25} \quad (7)$$

where Re is the Reynolds number, or $(\rho_L U_L D)/\mu$, D is the tube diameter, and ρ_L and μ are the density and the viscosity of the liquid, respectively. As shown in equation 6 the superficial liquid velocity in a tubular photobioreactor is a function of gas holdup in the riser, ϵ_r, the height of the dispersion, h_D, and the ratio between the cross-sectional area of the riser and the downcomer.

Gas–Liquid Mass Transfer

In addition to availability of light, the availability of carbon dioxide (the carbon source) affects the productivity of a photosynthetic culture. The cells combine carbon dioxide and water to generate carbohydrates and cell biomass. Photosynthesis generates oxygen, which is released into the extracellular fluid. Because large amounts of oxygen can inhibit photosynthesis, oxygen must be removed to prevent buildup. Similarly, carbon dioxide must be provided such that availability of carbon does not become a limiting factor. Removing oxygen and supplying carbon dioxide are problems of gas–liquid mass transfer. Therefore, modeling of an algal reactor must consider gas–liquid mass transfer and how it is affected by hydrodynamics.

The mass transfer from the gas phase to the culture suspension in open ponds has been extensively studied (26,69). According to Märkl (70), the critical CO_2 concentration in an algal suspension of *Chlorella vulgaris* in an open pond is very low. A concentration as low as 10^{-6} M assures unlimited photosynthesis. Experiments with the same strain and with different oxygen concentrations in the medium show that the photosynthetic reaction rate is enhanced by 14% when there is almost no oxygen in the algal suspension and reduced by 35% when the medium is saturated with pure oxygen. In technical systems an oxygen content no higher than the saturation concentration with air (21%) is desirable (26). Mathematical expressions for longitudinal profiles of CO_2 and dissolved oxygen in algal cultivation units have been derived by Livansky et al. (71). The mass transfer issues relating to tubular photobioreactors have been treated by Camacho Rubio et al. (72).

Because carbon dioxide tends to be expensive one consideration is minimizing its loss; hence, quantitative transfer of CO_2 from the gas to the liquid phase is aimed at but normally not achieved. The dissolved carbon dioxide is in equilibrium with carbonate and bicarbonate species. These equilibria are pH dependent. Loss of dissolved carbon dioxide due to uptake into algal cells is partly compensated for by regeneration from carbonates and bicarbonates. Consequently, carbon dioxide uptake is accompanied by changes in pH. The relevant equilibrium and the corresponding equilibrium constants (73) that need to be considered are

$$H_2O \leftrightarrow H^+ + OH^- \quad K_w = [OH^-] \cdot [H^+] = 10^{-14} \quad (8)$$

$$CO_2 + H_2O \leftrightarrow H_2CO_3 \leftrightarrow HCO_3^- + H^+ \quad K_1 = [HCO_3^-] \cdot [H^+]/[CO_2] = 10^{-6.381} \quad (9)$$

$$HCO_3^- \leftrightarrow CO_3^{2-} + H^+ \quad K_2 = [CO_3^{2-}] \cdot [H^+]/[HCO_3^-] = 10^{-10.377} \quad (10)$$

As noted (72), models based on mass balances and gas–liquid mass transfer phenomena can be used to predict the various culture variables such as dissolved oxygen concentration, the carbon content within the culture, the composition of the outlet gas, the carbon dioxide losses and requirements, and the pH of the culture. As shown in Figure 10, through any 24-hour period, the simulated data closely agree with the measurements.

Temperature

Many studies in both open ponds and closed reactors have shown that temperature is an important factor affecting productivity. The highest biomass growth rate can be obtained only at the optimal temperature for growth. Although this effect is obvious and well documented under laboratory conditions, the magnitude of the effect on the annual production of biomass outdoors seems not be sufficiently appreciated. The diurnal variation in temperature to which cultures in open raceways are exposed results in temperature-limited growth during a significant fraction of the day. Lee et al. (48) showed that the light yield (g biomass kJ^{-1}) increased some three- to fivefold with increasing temperature in cultures of *Chlorella*, an effect that may be readily observed with other microalgae. The temperature of the culture at night is yet another important factor that affects the net output rate of biomass. The effect of temperature on dark respiration is, of course, very well documented (16,52,53).

Compared with open ponds, enclosed reactors generally warm up faster in the morning, thus reaching the optimum temperature for algal photosynthesis earlier in the day

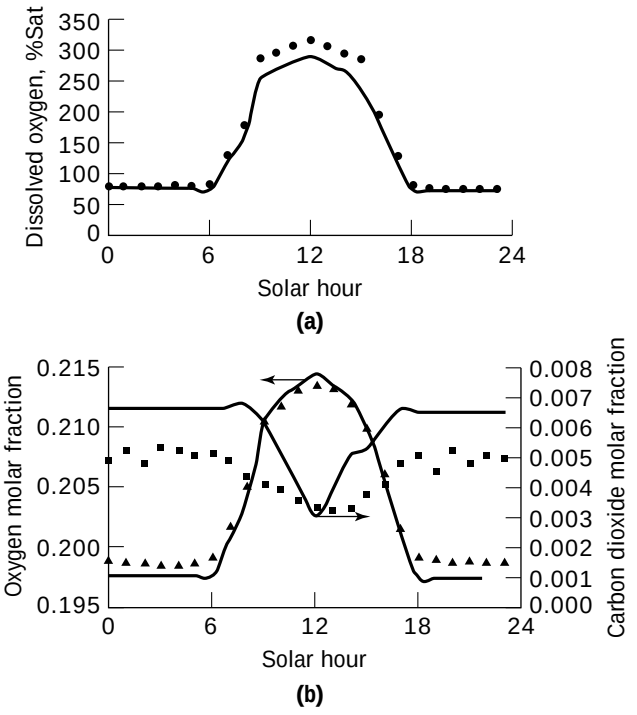

Figure 10. Daily variation of (**a**) the culture dissolved oxygen in the photobioreactor solar receiver tube (●) and (**b**) concentrations of O_2 and the CO_2 in the gas phase coming out of the photobioreactor (■, oxygen molar fraction; ▲, carbon dioxide molar fraction). The continuous lines represent simulations. Data are for a culture of *Porphyridium cruentum*.

(38). Closed reactors, however, can also overheat and thus require some sort of temperature control systems. In closed systems this control is achieved by either incorporating a heat exchanger into the design or evaporative cooling of water sprayed on the surface of the reactor. Economic considerations generally favor evaporative cooling.

PHOTOSYNTHETIC EFFICIENCY

The photosynthetic efficiency (PE) of biomass growth is defined as the energy stored in biomass per unit of light energy absorbed (74). This parameter is of fundamental importance in biomass production, because the microalgal production should aim to achieve the maximum attainable PE so as to produce the most biomass possible per unit land area (open ponds) or volume (enclosed systems). According to Richmond (74), microalgae use only the PAR, which constitutes about 43% of the total solar radiation at the Earth's surface and has an energy input equivalent to that of monochromatic light at a wavelength of 575 nm. Because one Einstein of 575-nm light contains 49.74 kcal of energy, and assuming that free energy of photosynthesis is 114 kcal mol^{-1} of reduced CO_2, the theoretical maximum energy efficiency for the photosynthetic reduction of CO_2 to glucose with white light is $114/(8 \cdot 49.74) = 0.286$, or approximately 29% (75). This estimation assumes that eight photons of light are needed for the requisite transfer of four electrons. Under field conditions, much lower photosynthetic efficiencies have been obtained. The maximum practical photosynthetic efficiency is a problem still to be resolved (76); however, a theoretical photosynthetic yield of 6 to 7% of the total solar energy seems possible (77). A 6–7% efficiency represents a biomass productivity of 35 to 70 g m^{-2} per day depending on the geographic locations. A photosynthetic efficiency of 10% during a period of 122 days has been reported (78). Nevertheless, producing biomass on large scale under outdoor conditions with an efficiency similar to that obtained under controlled laboratory conditions remains a challenge.

Information on algal yields reported over 30 years has been summarized by Goldman (54). Although the early attempts at mass culture produced no better than 10 to 15 g dry wt biomass m^{-2} per day over short periods, today it is not uncommon for sustained yields to reach 20 to 25 g m^{-2} per day. Goldman presented a thorough analysis of maximum yield potential of algae based on the thesis that algal production under the proper conditions is limited only by light (55). Goldman's equation can be written as

$$P_b = \frac{1}{Q_b} \cdot I_s\left(\ln \frac{0.45 \cdot I_0}{I_s} + 1\right) \qquad (11)$$

where P_b is the productivity of the system (g m^{-2} s^{-1}), I_0 is the total irradiance at the culture surface (μE m^{-2} s^{-1}), I_s is the saturating light intensity for which the growth rate is the maximum (i.e., when $\mu = \mu_m$, see Fig. 6) (μE m^{-2} s^{-1}), and Q_b is the heat of combustion of the biomass (μE g^{-1}). The maximum available intensity of sunlight at the Earth's surface is about 2,000 μE m^{-2} s^{-1}. Equation 11 predicts that, for a range of I_s values between 60 and 180 μE m^{-2} s^{-1}, as is typical for microalgae culture, the upper limit of algal yield is 30 to 60 g dry wt m^{-2} per day. According to this model, the factor that most strongly influences the algal yield is I_s. By contrast with the laboratory experiments, most outdoor algal production systems report productivities in the range of 15–30 g m^{-2} per day (79). These figures are far different from those observed in carefully controlled indoor cultures.

The laboratory work reported previously was carried out under conditions of low intensities, at or below saturation for photosynthesis. In practice, when dealing with sunlight, the major problem is not the maximal quantum efficiency but the fraction of absorbed photons that can actually be used in photosynthesis. The problem, well described by Benemann (80), is that if algal photosynthesis saturates at low light intensities, and algal cells have a high extinction coefficient (high pigment content), then more light will be absorbed than can be used in photosynthesis. Depending on the actual saturating and incident light intensities, the extinction coefficient, K_a, and the biomass concentration, the maximum efficiency (regardless of the minimum quantum requirement) will be reduced by about two- to fivefold from that possible at low light levels (80). The only solution to this problem is to increase the light intensity at which photosynthesis saturates, which means reducing the antenna and accessory pigment level of the cell without affecting the rest of the photosynthetic apparatus.

A new procedure for calculating yields in microalgal mass cultures at high incident irradiances has been proposed by Molina Grima et al. (81). This approach is based on an averaged irradiance for assessing the photon flux absorbed by the biomass. The starting point of the procedure (81) is the definition of the quantum yield, Ψ_E. The quantum yield is defined as the amount of biomass generated per unit of radiation (usually photons or Einsteins) absorbed by the culture. Because it represents the ratio of biomass generation to absorbed photon flux, the quantum yield can be calculated by the expression

$$\Psi_E = \frac{P_b}{F_{vol}} \tag{12}$$

where P_b is the volumetric biomass productivity and F_{vol} is the photon flux absorbed per unit volume. The quantum yield can be converted to energy units, commonly denoted as Ψ_{kJ}, by taking into account the average energy of the light used (kJ E^{-1}). The bioenergetic yield, Ψ, quantifies the percentage of light energy that is converted to chemical energy; Ψ can be calculated as the product of Ψ_{kJ} and the biomass heat of combustion, Q_b:

$$\Psi = \Psi_{kJ} Q_b \tag{13}$$

Because P_b in steady-state continuous culture can be calculated as the product of biomass concentration, C_b, and the dilution rate, D, any of the growth yield defined in equations 12 and 13 can be evaluated as long as the absorbed photon flux can be found.

Absorbed Photon Flux

The quantification of the absorbed photon flux is a complicated matter, especially when the flux must be evaluated in geometries other than flat reactors. Many factors such as light scattering effects may lead to a misevaluation of the absorbed flux. In every case the flux needs to be evaluated by direct measurement of the light leaving the photobioreactor (82). The light absorbed can be evaluated by integrating the local volumetric rate of energy absorption over the total reactor volume (83). This integral can be readily obtained from the extinction coefficient of biomass, K_a, and the average irradiance, I_{av}.

$$F_{vol} = I_{\alpha v} K_a C_b \tag{14}$$

Calculation of the absorbed photon flux by the preceding procedure has several advantages: the calculation is independent of the system geometry once I_{av} is known and can thus be applied to any type of photobioreactor as long as I_{av} can be determined. Photon flux losses due to reflection of light off the reactor walls that cannot be neglected (82) are automatically taken into account if the irradiance is measured inside the culture. The validity of equation 14 for assessing the absorbed photon flux has been checked experimentally in a culture of *Isochrysis galbana* (81) and using data published by Lee and Erickson (84) for *Chlorella* in a flat photobioreactor. *Isochrysis galbana* showed a maximum efficiency of light conversion into biomass of 0.6 g E^{-1} at $I_0 = 820$ μE $m^{-2}s^{-1}$ and a dilution rate of 0.030 h^{-1}. The maximum capacity of the biomass to metabolize light was found to be 13.1 μE $g^{-1}s^{-1}$ (81). Above this value a significant drop in system efficiency occurred.

OPERATIONAL CONSIDERATIONS

Successful maintenance of a microalgal culture facility requires continuous monitoring to prevent the development of nonoptimal conditions. As shown in Figure 3, the on-line information typically monitored includes the dissolved oxygen (DO), temperature, and pH. In addition, daily microscopic observations are important for characterizing the physiological state of the culture. Measurement of growth should be routinely accompanied by detailed microscopic evaluations. Any increase in number of contaminating organisms in the culture is a warning signal: the temperature may have deviated from the optimal, or the concentration for a particular nutrient may have gone out of the optimal range. Monitoring of the nitrogen content is another useful indicator of the state of continuous cultures and may give information about the possible depletion in mineral nutrient in the culture. This information can be used as a guideline for adding, in equivalent amounts, the entire formula of the elements making up the growth medium. The concentration of DO is another reliable and sensitive indicator of conditions that relate to growth and productivity. There are many indications that early detection of an inexplicable decrease in DO concentration or a decline in the normal rate of the daily increase of DO in outdoor mass culture serves as a reliable warning signal that the culture is stressed and may quickly deteriorate (74).

Reliability of the microalgal mass culture systems and the ability to easily clean them are other important operational considerations. Closed reactors may experience fouling of the walls by biomass. For continuous cleaning of tubular photobioreactors, Chaumont et al. (85) have developed and patented a system that consists of balls that continuously circulate through the tubes. Such systems are effective for fouling control.

Tubular photobioreactors are also reasonably reliable. They have been used to continuously culture many species including the marine algae *Phaeodactylum tricornutum*, *Tetraselmis chuii*, and *Isochrysis* sp. for periods in excess of 3 months (19,53). These systems are particularly suited to continuous or semicontinuous culture, which permits superior control over the culture conditions and provides a product of consistent quality. As an additional operational advantage, the cell concentration reached is much greater in most closed systems than values achieved in open systems; consequently, the harvesting cost is lower for closed systems. However, the actual cell density needs to be managed carefully to maximize productivity (Fig. 11). At low cell densities, especially in outdoor systems, the algae may be severely photoinhibited, whereas at very high cell densities self-shading can reduce productivity as individual algal cells do not receive an optimal level of light.

In summary, culture management aims to achieve and sustain an optimal state of the culture. For maximum biomass productivity, solar irradiance should be the sole lim-

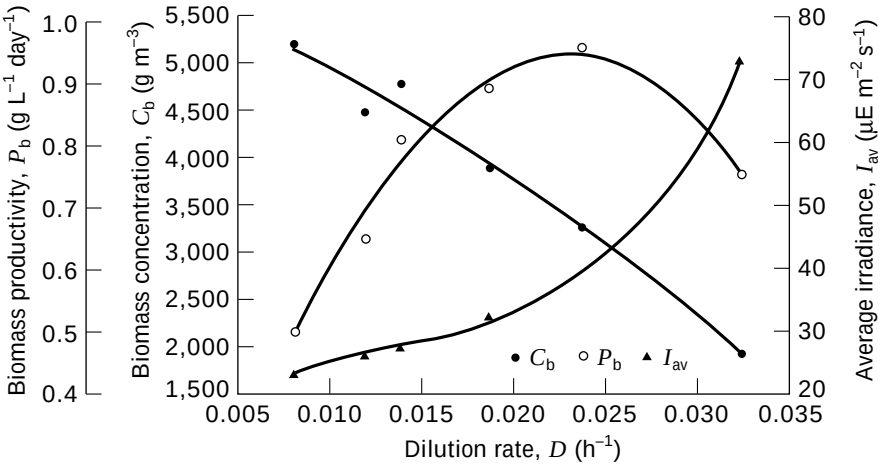

Figure 11. Effect of dilution rate, D, on the steady-state biomass concentration, C_b, the biomass productivity, P_b, and the average irradiance inside a photobioreactor, I_{av}. Data were obtained in an outdoor continuous culture of *P. tricornutum*, in a concentric tube airlift bioreactor. *Source*: From Refs. 14 and 49, with permission.

itation; however, when a metabolite is the desired product, the operational conditions for maximal productivity might be different from those for biomass productivity.

CONCLUDING REMARKS

Microalgae represent an important but little known resource with the genetic potential to provide valuable compounds. Future development of algal biotechnology will depend largely on what unique high-value products microalgae can provide. Algal products or processes must have some unique attribute, either biochemical or engineering, that would make them superior to heterotrophic microbes. Current commercial use of microalgae is restricted to a few niche applications.

Based on a comparison of the major types of algal culture systems (Table 1), the open systems are clearly deficient in several aspects. Despite this deficiency, open raceway systems are in commercial use. A principal advantage of open culture systems is the relatively small capital investment needed. Open systems are simple, but their productivity is low relative to the theoretical maximum. Much improvement in photosynthetic activity could be effected by genetic engineering of the photosynthetic complex to raise the light intensity threshold at which the photosynthetic machinery is light saturated. Also, resistance to photoinhibition may be introduced by genetic modifications.

Enclosed photobioreactors, which allow better control of operational conditions, are better suited to producing high-value products. These bioreactors permit culture of a greater diversity of algae than possible in open ponds. The potential of enclosed outdoor tubular photobioreactors has been demonstrated with high-productivity culture of microalgal species such as *Porphyridium*, *Isochrysis*, and *Phaeodactylum*. Because of better control of culture parameters, enclosed culture allows for manipulation of the biochemical composition of the algal biomass for various purposes (86–89). Although the enclosed culture technology is more capital intensive than the open pond systems, the additional cost may be recoverable. Temperature increase and fouling are the major problems with closed photobioreactors. The choice of a suitable mass culture system depends on several factors including geographic location, the microalgal species, and the metabolite to be produced. The following factors should be considered in making a selection: *(1)* the culture system should permit the culture of several species; *(2)* the culture system should provide uniform illumination and high rates of mass transfer that are attained by means that do not damage the culture; *(3)* the reactor must prevent or minimize fouling, particularly of

Table 1. Comparison of Properties of Different Large-Scale Algal Culture Systems

Reactor type	Mixing	Light utilization efficiency	Temperature control	Gas transfer	Hydrodynamic stress	Species control	Sterility
Unstirred ponds	Very poor	Poor	None	Poor	Very low	Difficult	None
Open raceway	Fair to good	Fair to good	None	poor	Low	Difficult	None

its light transmitting surfaces; and *(4)* the volume of the nonilluminated parts of the reactors should be minimized.

NOMENCLATURE

A_d	Cross-sectional area of the downcomer (m^2)
A_r	Cross-sectional area of the riser (m^2)
C_b	Biomass concentration (g L^{-1} or g m^{-3})
d	Depth channel (m)
f	Fanning friction factor
F_{vol}	Photon flux absorbed in unit volume (μE m^{-3} s^{-1})
h_D	Height at which the degasser is situated (m)
I	Hourly incident photosynthetic radiation (μE m^{-2} s^{-1})
I_{av}	Photosynthetically active hourly average irradiance inside culture (μE m^{-2} s^{-1})
I_0	Solar irradiance impinging on the reactor surface (μE m^{-2} s^{-1})
I_s	Saturating light intensity for which the growth rate is maximum (μE m^{-2} s^{-1})
K_a	Absorption coefficient (m^2 g^{-1})
K_1	First equilibrium constant for bicarbonates buffer (mol m^{-3})
K_2	Second equilibrium constant for bicarbonates buffer (mol m^{-3})
K_W	Dissociation constant of water
L	Channel length (m)
L_{eq}	Equivalent length of the solar receiver (m)
n	Manning friction factor (s $m^{-1/3}$), or characteristic parameter of the hyperbolic growth model
n_1	Characteristic parameter of the photolimitation–photoinhibition model
n_2	Characteristic parameter of the photolimitation–photoinhibition model
n_3	Characteristic parameter of the photolimitation–photoinhibition model
P	Power consumption for the culture flow in the channel (kW)
P_b	Biomass productivity (g m^{-3} h^{-1})
Q_b	Heat of combustion of biomass (μE g^{-1})
S	Cross section of the tube (m^2)
s	Rate of loss of energy in the channel (dimensionless)
U_L	Superficial liquid velocity in the tube (m s^{-1})
v	Mean culture flow velocity channel (m s^{-1})
w	Width channel (m)
ψ	Bioenergetic yield coefficient (%)
ψ_E	Quantum yield (g E^{-1})
ψ_{kJ}	Energetic yield (g kJ^{-1})
η	Efficiency of the paddle wheel (−)

ACKNOWLEDGMENTS

I wish to acknowledge the contribution of all my colleagues of the Marine Biotechnology Group of the University of Almería, who have worked with me on this subject. Thanks are also due to Prof. Y. Chisti for helpful comments and assistance with the final manuscript. Some of the work reported was financially supported by the Plan Andaluz de Investigación (Junta de Andalucía), Comisión Interministerial de Ciencia y Technología (C.I.C.Y.T.), Spain, and the European Union.

OUTLINE

INTRODUCTION

In biotechnology, the denominator is biomass, for example, yield is the desired product per unit of biomass. Biomass concentration is one of the major determinants to identify the stage of the culture cycle. It is necessary to understand the controlling points in the physiology of the bacterial growth. Biotechnologists have talked extensively about growth phase and idiophase as the key measures of fermentation technology. There are a number of approaches for biomass measurement, but they are not very good and have significant limitations. The reader should supplement the treatment presented here with a previous article (1) that details a number of procedures and leads back to the earlier literature. Another useful overview is provided by Sonnleitner et al. (2). The former paper comes from the approach of a physiologist, and the latter is from the point of view of biotechnologists. For historical interest, the collected source is by Dawson (3).

Principles

Principles of bacterial growth are discussed in microbial physiology texts. I would particularly recommend that by White (4). Although there are many books on bioprocessing, most do little to discuss biomass measurements. The book by Pirt in 1975 (5) was a milestone in the field of microbe growth for product formation; newer publications are now available (6,7), but they do little for the estimation of biomass.

Definitions of Growth

To measure biomass and bacterial growth rate, precise definitions are needed. Although biomass is fundamental to carrying out technology, we have to consider first the growth process that makes the biomass and examine its

several definitions. The most basic definition of growth is based on the ability of individual cells to multiply, that is, to repetitively initiate and complete cell and organismal division. This definition implies monitoring the increase in total number of discrete bacterial particles. There are three basic ways to do this: by microscopic enumeration of the particles, by electronic enumeration of the particles passing through an orifice (Coulter counter) and by modern flow cytometry. Assessment of particle number would falsely include dead cells and detritus, which would tend to lower estimations of growth rate. The rate would be artificially raised by the progressive dissolution of aggregates of bacteria and the fragmentation of nongrowing filamentous organisms. An increase in cell number need not correlate exactly with an increase in biomass or useful product. Commonly, at the end of an exponential growth phase, cell division overshoots biomass production and the cells become smaller.

A second definition of growth involves determining the increase in colony-forming units (CFU). Because some cells may be dead or dying, this definition of growth may be different from the one based on the detection of discrete particles as a function of time. Although in the long run, the increase in the number of organisms capable of indefinite growth is the only important consideration for the physiologist, this is not so for the biotechnologist, for several reasons. First, for strain purity, each new production run starts afresh from starter cultures; these cultures would had been specially treated much differently than the cells in the actual production run. This care is to avoid contamination and the buildup of unwanted mutants. Second, dead, dying cells and stationary cells may be the productive members of the culture in terms of product formation. This second definition is the reason that colony counting and most-probable-number (MPN) methods of measurement are so important. It must be noted that viable counting methods, which seem so natural to a bacteriologist, are really quite special in that cultures are diluted so highly that individual organisms cannot interact. For example, these methods cannot in principle be applied to obligate sexually reproducing organisms requiring male–female interaction or to colonial organisms such as myxobacteria that in certain conditions need to be part of a large mass of organisms that produces sufficient exoenzymes in order to grow. Even when applied to the prokaryote, there are special restrictions and limitations, for example, CO_2 must be available in sufficient concentration, although this need not be supplied if many organisms are present generating CO_2. This and possible detoxification of the medium can lead to a lower count than would have occurred in the more concentrated actual culture. To illustrate, consider a single bacterium and an isolated mammal, both introduced into an environment without any individuals of their own kind. The former would produce a colony, whereas the latter could only produce a viable colony if the founding individual was a pregnant female.

A third definition of growth (and the practical one) is based on an increase in biomass. Macromolecular synthesis and increased capability for synthesis of cell components are the obvious basis for the measurement of growth by everyone interested in microbes and what they can do. From our point of view, the whole process of chromosome replication and cell division is an essential but minor process that seldom limits growth; what usually limits growth is the ability of enzymatic systems to use available resources to form biomass. Moreover, the restriction of growth of the culture is usually the result of the depletion of resources or degradation of the local environment.

A fourth definition of growth is based on the organisms' action in chemically changing their environments. This category can be considered as simply a different consequence of the increase in biomass. But it allows the rate of the growth process and the biomass production to be estimated in indirect ways. Most important in industry, the gases coming from the fermentation are analyzed, and the consumption of oxygen and production of carbon dioxide are used as effective and efficient means to follow growth. Especially important is the use of mass spectrometer methods, because of their precision and the ability to automate measurements, growth of cultures can be followed usefully and effectively.

Biomass is the result of growth; it has variously different definitions according to purpose. In most biotechnology, biomass is organic material that is cheap and can be converted into fuel, or heat, or structural materials. It is necessary that such sources be self-generating, cheap, and available. Whether biomass is alive or dead is less relevant; the assumption is that it was, or at least once was, alive. If one has a mixture of coal and fresh plant material, the term biomass is fully ambiguous. For product formation there is less ambiguity; microbial biomass requires the expenditure of resources, and useful product may be produced by organisms that may be living or dead according to which of the definitions of growth is used.

Balanced Growth

These four definitions of growth become equivalent under a single circumstance: the state of balanced growth (8). This is certainly an academic concept, but its practicality is clear. An asynchronous culture can be said to be in balanced growth when all intensive properties are constant in time. An intensive property is one that does not matter how big the system is. An extensive property is another term from physical chemistry and refers to those properties of the system that are proportional to the amounts of substances of various kinds in the system. Thus, biomass and cell number are extensive properties of a culture and proportional to the volume of culture considered. These properties increase regularly and exponentially with time during balanced growth. However, temperature or ratios (such as DNA, RNA, or product per cell) are intensive properties that do not change during balanced growth. The application of this physical–chemical principle to bacteriology lies in the thought that if a culture is grown for a long-enough duration (usually with many subcultures) so that the biomass is sparse enough to not alter the environment significantly, sooner or later the organisms will come to achieve the same growth state for any particular constant environment, no matter what the cell's condition was initially—be it log, lag, or the stationary state. Once this balanced growth state has been achieved, if the conditions

remain the same, the culture will remain in balanced growth indefinitely. This would be true of a culture that had grown in a continuous culture or one that was diluted manually periodically, avoiding entry into either lag or the stationary state. However, if a nutrient is exhausted, or if the culture is altered by mutation and selection, or if the physical nature of the environment is changed, then balanced growth would cease and the culture would be in some nonbalanced state of growth.

The criteria given above are too stringent to be fully met with any practicality, but it is readily possible to study cultures that are substantially in balanced growth by growing cultures maintained at low density by dilution and using arbitrarily any one measure to follow growth, for example, biomass assayed turbidimetrically. If the doubling time remains constant over an extended period of time, then it is a good assumption that growth is balanced. Studies of these cultures can lead to an understanding of the properties of individual cells in the idealized state of balanced growth. But they would not bear on the properties of aggregates or clumps of cells or of cells reacting to some calamity or catastrophe in their environment.

Although we may consider any extensive property of a culture in balanced growth, let us first focus on biomass and call it X for tradition's sake. The rate of formation of biomass will be proportional to the amount of biomass. Call the proportionality constant, μ, then:

$$dX/dt = \mu X$$

Through the laws of calculus, this equation can be integrated and a boundary condition ($X = X_0$ when $t = 0$) imposed, yielding the well-known equation for exponential growth:

$$X = X_0 e^{\mu t}$$

However, every cellular substance, or even an extracellular product of the cells, could be substituted for our X. Thus, after growth becomes balanced, the increase of any component or group of components will be exponential in time. If the ratio of one substance to every other is to remain constant, the same proportionality constant must apply for every component. This common value of μ is called the *specific growth rate* or *growth rate constant*. Not only will any substance increase exponentially, but any combination of substances or the rate of change of any substance also will increase exponentially with this same specific growth rate, μ. Practically, this allows the rate of oxygen uptake, heat production, or production of an internal or external metabolite to be used as an index of growth. It will also allow growth to be monitored by the depletion of some medium component or the change in conductivity of the medium.

Intensive properties, such as μ and the ratio of the concentrations of different cell substances, must necessarily remain constant under conditions of balanced growth. In addition, the distribution of cell sizes and the average number of chromosomes will stay constant. An average cell will have a time-independent constant rate of carrying out every cellular process, and newly arisen daughter cells will have a constant probability of being able to form a colony (i.e., the percentage of nonviable cells will remain constant). Therefore, under these special conditions, no matter what measure of growth is used (whether it is particle counting, colony formation, chemical determination of a cell substance, or consumption or excretion of a substance), the same specific growth rate will be obtained and that rate will be constant through time.

Changes in Cell Composition at Different Growth Rates of Balanced Growth

Organisms respond to environmental conditions, both physical and chemical, by altering their own composition. These changes have been well documented for certain enteric bacteria but may occur with all prokaryotes (9). In general, favorable growth conditions mean faster growth, which requires a higher concentration of ribosomes and associated proteins. In terms of gross composition, the most obvious difference comparing a faster culture with a slower culture is a greater RNA content in the former (10). Also, under favorable growth conditions, the cells can lay down reserve materials such as glycogen and poly-β-hydroxybutyric acid. These changes in composition lead to the possible pitfall of the bacteriologist falsely relating one measure of growth to others when comparing growth in different environments.

Unbalanced Growth

Although balanced growth conditions lead to reproducible cultures, much of physiology deals with the responses of organisms to changes in their environment that lead to progressive changes in the organism (i.e., to the study of unbalanced growth). When a stationary culture is inoculated into fresh medium, the properties of organisms change drastically through the course of the batch culture cycle. Though only very well documented for certain enteric bacteria, similar changes probably apply with other prokaryotes. The exact course of changes in composition and morphology depends on the medium and on the age and condition of the inoculum. Culture cycle phenomena have relevance to growth measurements. These phenomena are particularly important in ecological studies, where the conditions under which the organisms grow are critical and, to a large degree, uncontrollable. The changes in characteristics are also involved in response to the fluctuations in natural conditions (11,12). For biotechnology purposes, it is the progression of changes in the so-called idiophase of growth that are paramount.

Noting that a typical bacterial culture generally means one of *Escherichia coli* (13), a typical bacterial culture cycle progresses as follows. When a stationary culture is diluted into rich medium, macromolecular synthesis accelerates. The components of the protein-synthesizing system (i.e., ribosomal proteins and ribosomal RNA) are made first. Only after considerable macromolecular growth has ensued does cell division take place. During this lag phase, the average size of cells increases greatly. When the capacity of the medium to support rapid balanced exponential growth is exceeded, metabolic processes (both intermediate metabolism and macromolecular synthesis) slow down. Different processes slow differentially in a way to

make small, RNA-deficient cells. Finally, the cells die and may eventually lyse.

Pitfalls in Measuring Growth

Errors in measuring bacterial growth fall into four classes. The first major pitfall is the general tendency of most organisms toward clumping or a filamentous habit of growth. This can occur even under mildly toxic conditions with bacteria that ordinarily divide regularly. The second pitfall is the differential viability of injured bacteria under different culture conditions. Repair processes may permit the recovery of viable cells under some, but not other, conditions. A third major pitfall is the possible development of resistant stages. Bacteria known to form resistant stages, such as spores, pose no problem because the controls and measurements to correct for such differentiated forms are well known; but when resistant stages are not suspected, error can arise. The fourth pitfall pertains to the way in which the inoculum is exposed to the new environment. Different results may be obtained if the concentration of an agent is raised gradually, if it is raised discontinuously, or if a high concentration is temporarily presented and then removed or lowered, such as when a concentrated solution of a nutrient is added and the mixing is not rapid. The cell concentration at the time of challenge can be critical. Bacteria may have special ways, sometimes inducible mechanisms or sometimes unknown ones, to protect themselves against toxic agents. Finally, the protection may be dependent on the number of organisms cooperating in detoxification.

Mycelial Habit of Growth

The evaluation of mycelial growth (the first pitfall) is both easier and much more difficult than that of well-behaved organisms that engage in binary fission and then promptly separate. The problems and methods for colonial growth have been discussed by Calam (14) and will be briefly dealt with here. Filtering filamentous cells, with or without drying, is easier than with smaller nonfilamentous cells.

The rate of increase in size of the colony in one, two, or three dimensions depends on the rate of elongation of those terminal hyphae that happen to be growing perpendicular to the surface of the colony, but the mobilization of resources into the mycelial mass depends on the surface area of the colony (15,16). Therefore, particularly with shake cultures, the results depend on the nature and size of inoculated fragments; with large fragments, growth becomes limited at an earlier stage by diffusion of nutrients into the mycelial mass. Thus, the major pitfall with the mycelial habit of growth is that the growth is quickly deviates from exponential growth and depends on the geometry of growth and the nature of the inoculum. In shake cultures, the apparent growth may depend on the shape of the vessel and on the shaking speed, its character (circular or reciprocal), and the distance moved, because all of the above can affect the tendency of the mycelia to break into smaller pieces. An important aspect of biotechnology is controlling the filamentous versus pellet conformations.

Cell Differentiation

The change of enteric bacteria from large, RNA-rich forms in the exponential phase to small, RNA-poor forms in the stationary phase has many of the aspects of differentiation. Bacteriology, however, has much clearer examples of cell differentiation in the cases of transition of rod to coccus, of vegetative bacillus to endospore, and in the formation of exospores, cysts, and buds. The tendency to form filaments in certain circumstances can also be considered a differentiation. These changes and their reversal pose potential pitfalls for all approaches to growth measurement.

Adsorption of Cells to Surfaces

Many bacteria naturally adhere to certain surfaces or can adapt and mutate to achieve a high avidity for solid surfaces, including glass. Many experiments with chemostat culture have failed to achieve their primary goal because the organisms adhered to the vessel walls. It is for these reasons that plastic or Teflon should be used whenever there is long-term contact of the organism with a culture vessel (16) Other approaches to minimizing the effects of growth on vessel walls include the use of large culture volumes in large containers, the use of violent agitation, and the frequent subculture of the bacteria into fresh glassware. These are the conditions in large biofermenters, but not during the production of the starter cultures. In addition, the use of detergents, vegetable oils, silicone coatings, and a high-ionic-strength medium may to some degree alleviate this problem.

This problem is particularly pertinent during dilution of the culture for measurement by highly sensitive means, such as microscopic and plate counts. It is, therefore, given consideration in the discussion of those methods (1,17,18).

DIRECT PARTICLE COUNTS

For many biotechnology purposes, the counting methods that can be used are limited because the growth medium generally contains particulate matter. This does not preclude their use in the development of strains and other phase of biotechnology.

Microscopic Enumeration

Microscopic enumeration is a commonly used technique that is quick and cheap and uses equipment readily available in the bacteriological laboratory. The technique is subject to gross errors, however. These can be overcome to a large degree using improvements suggested by the work of Norris and Powell (19). Precise details are given in my earlier review of this subject that are a further modification of this method (1), and some versatile techniques that have some of the characteristics of viable counts or metabolic measurements are given in the work by Murray et al. (20).

Methods and equipment, some linked to computer programs, are now available to record, scan, and view a microscope field. Software and hardware are available that enable a sample to be placed in a counting chamber viewed by a microscope, and then an electronic count can be made from the image. The computer can distinguish between cells adhering side by side and between a long cell and a pair of sister cells that have completed division but have

not separated. The capability exists to measure the biomass from the density of the pixels since the phase contrast (see later text) is a measure of the biomass. For filamentous organisms, the computer could output the total length of hyphae and convert that into biomass (21,22). Direct enumeration from charge-coupled device (CCD) images with highly intelligent computer filtering will allow distinguishing the bacteria or fungi from the particulate matter in the brew in many cases.

Electronic Enumeration

The Coulter Counter (Coulter Electronics, Hialeah, Fla.), its commercial competitors, and particularly the laboratory-built versions have been important in the development of bacterial physiology in the past 50 years. Such instruments are used routinely in clinical hematology. They are also very useful in the enumeration of nonfilamentous yeasts and protozoa, but not of mycelial or filamentous organisms.

The principle of electronic enumeration is as follows. A fixed volume of diluted cell suspension is forced to flow through a very small orifice connecting two fluid compartments. Electrodes in each compartment are used to measure the electrical resistance of the system. Even though the medium conducts electricity readily, the orifice is so small that its electrical resistance is very high. Consequently, the electrical resistance of the rest of the electrical path is negligible by comparison. When a cell is carried through the orifice, the resistance further increases because the conductivity of the cell is less than that of the medium. This change in resistance is sensed by a measuring circuit and converted into a voltage or current pulse. The counting rates can be very high, but beware of coincidence errors. The pulses are counted by an electronic circuit similar to that used in counting radioactivity. Very small pulses are eliminated by a discriminator circuit. Very high pulses, which might result from dirt or other irrelevant particles, are eliminated by an upper discriminator. In advanced models, the pulses may be analyzed by size and stored in a multichannel analyzer; later, the data can be recovered and plotted in a histogram, and the numbers, mean size, and standard deviation can be calculated. All the data may be collected, and the discrimination against pulses that are too high or too low can be carried out as the data are analyzed. The instruments have some method of forcing an accurately known volume through the orifice during the counting period. This is usually done by displacing the fluid in contact with a mercury column past triggering electrodes that conduct effectively through the mercury, but not through the diluent medium.

The major problem areas in electronic enumeration are three. The first problem concerns the size and shape of the cells. Some bacterial cells are very small (less than 0.4 μm^3), and the resistance pulses produced as they pass through the orifice are comparable to the noise generated by the turbulence that develops in the fluid flowing through the orifice. One can set the discriminator dial on the instrument to reject the turbulence noise, but one loses sample information, particularly about newly divided cells. One can run blanks and subtract the blank values, but blanks are particularly variable for small cell sizes. In addition, a pattern of turbulence can become established, remain for a while, and then be replaced with another pattern. This can cause major interference. Determining the size of cells has many difficulties, including the effect of the path that the particle takes through the orifice and the resistance of the various layers and compartment of the cell. Therefore, this potential use of the instrument is not discussed in this article. Finally, the overall error increases when the blank has large statistical variation. This is not a major problem for biotechnology because currently used microbes are relatively large.

The second major problem for physiological studies in electronic counting results from the failure of cells to separate promptly from each other after cell division. This, and the tendency to form filaments and aggregates, can be minimized by careful choices of the organism and the conditions. Possibly it can be reduced by vortexing or sonicating the sample. It was fortuitous for the advancement of microbial physiology that *E. coli* was chosen for physiological and genetic studies in the 1940s and 1950s because only a relatively small number persists in pairs or chains or in the form of aggregates. There is the related problem of coincidence, which is the passage of more than one cell through the orifice in a short enough time so that a single larger cell is registered by the electronic equipment. This problem can be dealt with by increasing the dilution so that the probability of coincidence is reduced.

The third major problem is technical: the clogging of the orifice in electronic counting. The resistance change is a smaller proportion of the total electrical resistance of the orifice when the orifice diameter is larger. Consequently, for small rod-shaped bacteria such as *E. coli*, orifices with diameters in the range of 12 to 30 μm must be used. The exact choice is a tradeoff between the increased signal strength of small apertures and the increased noise and probability of becoming clogged. Clogging is best prevented by ultrafiltration of all reagents. Alteratively, the diluent can be prepared and allowed to settle for a long time (months) in a siphon bottle so that the particulate-free solution can be withdrawn from above. Additional information about this technique can be found in the works by Drake and Tsuchiya (23) and Kubitschek (24).

Flow Cytometry

Flow cytometry became an extremely powerful method for the studies of many aspects of the biology of eukaryotes two decades ago. The instruments are now common in hospitals and clinical research laboratories. Because prokaryotes are smaller, it is only more recently that the instrumentation and methods have been refined and are only now coming into their own in the study of bacteria. The instruments operate by forming a small-diameter stream of the sample suspension. This is encased in a stream of particulate-free fluid. The tube through which they flow constrict in such a way that the stream of the sample is made still narrower in diameter. This process is called hydrodynamic focusing. The flowing stream is examined with laser light with various frequencies and angles, and the output of the detection circuits is used to detect when a

particle passes through and determine its characteristics. The design permits the analysis of biomass by light-scattering methods and by fluorescent staining of chemical components such as DNA. This will be discussed in "Flow Cytometry." The electronic circuits allow cells to be counted very rapidly. Growth can be followed by the increase in counts in samples counted at intervals. The problems for the application to prokaryotes is in sensitivity and background noise.

The original designs were made for study of problems in immunology. Applications, including microbiology, have been previously described (25–27).

Another quite different instrumental design was developed in Norway (28,29). It depends on flow directly on a microscope slide on an inverted microscope. This instrument uses an inverted microscope essentially operated in the dark-field mode. It uses a high-intensity mercury arc. Now with commercially available equipment, it has been utilized to study a variety of problems. Clever applications have been described (30,31).

The instrument of the first type uses a well-collimated laser source and fiberoptics. Great care is needed to maintain the instrument and its calibration. Routinely, polystyrene beads are mixed with the biological sample in a fixed amount. They have a uniform size and serve to quality control the electronics. By relating the biological count to the bead count, the concentration of biological particles can be determined. These kinds of controls can be used with the second type of instrument, which is cheaper and is now in use in many laboratories for many microbiological purposes. It is also capable of counting at very fast rates.

COLONY COUNTS EQUAL VIABLE COUNTS

Bacteriology really became an experimental science when Herr Dr. Robert Koch listened to Frau Fannie Hesse and developed the agar plate. This allowed not only the cloning of pure strains but also the enumeration of colonies arising from individual viable cells. Many variations have been developed and used in the ensuing century: (*1*) spread plates, (*2*) pour plates, (*3*) thin-layer plates, (*4*) layered plates, and (*5*) membrane filter methods. Although these techniques are very useful in the development of industrial strains, they take too much time and cannot be used on-line.

These techniques are described in many places (1). The pour-plate methods have variations in which the cells are grown in roller tubes or microtubes (32) and are examined with low-power microscopes when the colonies are small (33). There are many individual variations of techniques, sometimes resulting from historical accidents and sometimes resulting from special bacteriological circumstances. Automation of colony counting has put additional special restrictions on techniques, but allows colonies on the Petri dishes to be counted rapidly without operator error.

It must be emphasized again that mycelial organisms pose special problems. To some degree they can be overcome by sonication or shearing. A practical approach is to conduct a pilot study to find the amount of ultrasound that produces the maximal count that optimizes the separation of propagules from each other and minimizes the destruction of them by the physical treatment.

In the future, the development of growth media that is perfectly clear and can be solidified in uniform layers on a new generation of microscope slides will permit the analysis by telometering and computer analysis after only a few hours of incubation. In some cases, observation will be repeated and the difference in the images used to compute the growth rate as well as the initial CFU and viable biomass. Selectivity and identification of special properties with dyes and chemical reactions could be used as well. Again, particulate matter can be a problem, but less severe as the microcolonies grow to be larger than the detritus in the medium.

Spread Plates

The sample is pipetted onto the surface of solidified agar medium in a Petri dish, and then the cells are distributed with a wire, glass, or Teflon spreader. In the spread-plate technique, the growth forms surface colonies. It is reliable when methods to transfer all of a defined volume of cell suspension to the surface of the agar are used. The method is additionally useful because surface colonies are required to produce the proper color responses with many indicator agars that depend on the redox state of the colonies. In many cases, different colors are given from subsurface colonies because the oxygenation is different, and, therefore, the acid production and reducing potential are different than on the surface, and the selectivity is usually much less. (See Murray et al. [20] for recent improvements in technique.)

Pour Plates

An aliquot sample of diluted cells is pipetted into an empty sterile Petri dish; molten, but cool (45 °C), agar medium is poured onto the sample; and the contents are mixed by swirling and then allowed to harden. The pour-plate technique is a standard technique. Its main advantages is that most colonies are subsurface. They are, therefore, small, making it possible for a plate to have many colonies and still be countable. This method has a large dynamic range, and automation can be very useful.

Thin-Layer Plates

The use of thin-layer plates came out of virology. The sample is pipetted into a tube containing a small volume (2.5 to 3.5 mL) of molten but cool (45 °C) soft agar (0.6 to 0.75%) medium. This is then poured onto previously poured and hardened (1.5 to 2% agar) medium in a Petri dish, and the overlay is allowed to harden. This was the technique developed to measure virus plaques in the 1940s.

Layered Plates

Layered plates are like thin-layer plates except that an additional layer of agar medium is poured onto the newly congealed soft agar medium containing the cells so that all colonies are subsurface, but in the same plane. It is very useful because all colonies are subsurface and, therefore,

much smaller and compact. Under the right conditions they can be intensely colored because they are highly anaerobic. Many more colonies may be present, and yet the coincidence by fusion of colonies is small; this means that several thousand colonies per plate can be used and give meaningful results. This approach is especially recommended because the main difficulty with usual surface colony counting method is its lack of dynamic range. Rules have been issued that between 30 and 300 colonies are required for spread plates. The lower limit is set by statistical accuracy, and the upper limit is set by coincidence limitations. This 10-fold range is inconvenient for many purposes, because in many cases one cannot predict the number within a factor of 10 when choosing the dilution factor. The extra care needed to prepare the overlay plates is justified because it allows the counting in a larger range of 30 to 2,000 colonies. A second major advantage is flexibility for nutrient supplementation. Minimal agar can be used to pour the basal layer in a large number of Petri plates for indefinite storage. Stock supplies of the minimal soft agar can also be kept on hand. Then, 10- to 50-fold excesses of needed special nutrients can be added to the aliquots used for the molten top agar. In some cases, dyes and chromogenic substrates can be added as needed to the soft agar to allow screening of the colonies. Toxic substances can be incorporated to measure frequencies of resistant mutants.

Membrane Filter Methods

The diluted cells are filtered onto an appropriate membrane filter, which is then placed on an agar medium plate or onto blotter pads containing liquid medium. Sometimes it is necessary to carefully prewash the membranes and the pads with water or medium and then sterilize them. It is also necessary to supply nutrients at a higher level because they must diffuse to where the cells are located.

Automation

Several articles and books have been devoted to attempts to speed and automate growth measurement (34,35).

Special Situations

Certain organisms are very sensitive to substances present in agar. Meynell and Meynell (36) presented an excellent discussion of these problems. Injured organisms may have additional special requirements, and the entire 26th symposium of the Society for General Microbiology (37) was devoted to these problems. Genetically defective organisms pose individual problems that can be research problems on their own, such as the ability of various repair mutants to form countable colonies (38).

The problem of quantitating the number of organisms in cultures of strict anaerobes is discussed by Holdeman et al. (39) and Hungate (40).

Most Probable Number Method

The most probable number (MPN) method consists of making a number of replicate dilutions in a growth medium and recording the fraction of tubes showing bacterial growth. The tubes exhibiting no growth presumably failed to receive even a single cell that was capable of growth. Because the distribution of such cells must follow a Poisson distribution, the mean number plated at this dilution can be calculated from the formula $P_o = e^{-m}$, where m is the mean number and P_o is the ratio of the number of tubes with no growth to the total number of tubes. The mean number, estimated by $-\ln P_o$, is then simply multiplied by the dilution factor and by the volume inoculated into the growth tube to yield the viable count of the original sample. The MPN method is a very inefficient method from the point of view of statistics, because each tube corresponds to a small fraction of the surface of a Petri dish in a plate count. Consequently, many tubes or wells in a titer plate must be used, or the worker must be prepared to settle for a very approximate answer.

It is important to understand when the MPN method is of advantage. It can be used if there is no way to culture the bacterium on solidified medium, and it is preferred for mixed cultures if the kinetics of growth of the individual types are markedly different. Suppose some cells grow immediately and rapidly and end up making a large colony on solid agar that spreads over and obscures colonies of the organism of interest that form later. The small colony formers may be more numerous but unmeasurable on plates because of the fewer but highly motile or rapidly growing bacteria. Another use of the method is when other organisms that are not of interest are present in the sample, and no selective method is available to prevent their growth. Thus, the method has utility when the bacterium of interest produces some detectable product (e.g., a colored material, specific virus, or antibiotic). Then, even though contaminating organisms may overgrow the culture, the numbers of the bacterium in question can be estimated by the fraction of the tubes that fail to produce the characteristic product. Finally, if agar and other solidifying materials have some factors (such as heavy metals) that may alter the reliability of the count or interfere with the object of the experimental plan, then the MPN method can be used to avoid these difficulties.

Modern developments in laboratory techniques currently available can be used to speed the execution of the MPN method and make it more efficient. Machines are available to fill the wells of plastic trays that have as many as 144 depressions. However, it may be better to use 96-well trays because most apparatus, such as hand-held pipets, currently use them. Scanning devices designed for other purposes can be used to aid in counting the number of wells with no growth. Similarly, automatic and semiautomatic pipets can be used to fill small test tubes. Because these procedures make it possible to examine many more cultures, the classical tables of fixed numbers of tubes and fixed dilution series are obsolete and should be abandoned. A different more flexible approach and method of calculation has been provided (1). It may easily be optimized for the purpose at hand.

DIRECT BIOMASS MEASUREMENTS

Some measure of the bacterial cell mass or numbers of a culture is almost always used as the reference basis for

measurements of cellular metabolic activities, the types of morphological characters, or the amount of chemical constituent; biomass and cell numbers are the two basic independent parameters of bacterial growth. The methods for measuring biomass seem obvious and straightforward, but in fact they are complicated if accuracy if sought. Furthermore, the results may be expressed in different ways and, in some of these ways, the values may be more relative than absolute.

Wet Weight

A nominal wet weight of bacterial cells originally in liquid suspension is obtained by weighing a sample in a tared pan after separation and washing the cells by filtration or centrifugation. In either case, however, diluent is trapped in the interstitial (intercellular) space and contributes to the total weight of the mass. The amount of interstitial diluent may be substantial. A mass of close-packed, rigid spheres contains in its interstices 27% of space. This is independent of sphere size. A mixture of sizes packs more densely, and close-packed bacterial cells may contain an intersticial volume of 5 to 30 %, depending on their shape and amount of deformation. This is a problem that is readily solved if the washing step can be carried out with pure water.

Simple weighing or just measuring the packed volume of cells can be an excellent and rapid method with filamentous organisms or those that grow as pellets. Then filter, wash and weigh or centrifuge, and measure the height of the pellet. Both can be very rapid, and the procedures can be calibrated to correct for the exogenous water or shapes of centrifuge tubes. Because the particulate matter in the medium has different physical properties, it can be possible to separate the cells from the particulates and estimate the cell volume directly. This correction could be established with radioactive or fluorescent dextrans or other molecules that are too big to enter the cells.

Dry Weight

A nominal dry weight (solids content) of bacterial cells originally in a liquid suspension is obtained by drying a measured wet weight or volume in an oven at 105 °C to constant weight. The cells could be washed with water (possibly extracting cell components), or (better) a correction could be made for medium or diluent constituents that are dried along with the cells. Separating the cells by filtration poses particular problems. More problems arise if volatile components of the cells can be lost by oven drying, or if some degradation and volatilization occurs, evidenced by discoloration (particularly if a higher temperature is used). Some regain of moisture occurs during the transferring and weighing process in room atmosphere, so this should be done quickly within a fixed time for all replicate samples, especially if the relative humidity is high. It is best, of course, to use tared weighing vessels that can be sealed after drying.

It is possible that more accurate determination can be made by drying the sample to constant weight in a desiccator vessel with P_2O_5 and under oil-pump vacuum at 80 °C or by lyophilization. Results with the three methods are indistinguishable within 1% for certain cases (41). An excellent discussion of dry weight procedures and errors is given by Mallette (42).

The dry weight of cells may be reexpressed on a wet weight basis (grams of solids per gram of wet cells) or on a wet volume basis (grams of solids per cubic centimeter of wet cells or per cubic centimeter of cell suspension).

Because the drying can be a time-consuming process, and adequate knowledge about the possibility of volatilization of some cell components is not known, in the future, adequate drying quickly at lower temperature could be done in specially designed vacuum ovens. Such procedures could also be calibrated for the residual water content. Often, a practical method is to dry the cells in a microwave oven.

BIOMASS BY LIGHT SCATTERING

Light-scattering methods are the techniques most generally used to follow the growth of pure cultures. The major advantages are that they can be performed quickly and nondestructively. However, they may give information about a quantity not of primary interest to the investigator. Although they can be powerful and useful, they can lead to erroneous results. Under a range of conditions, they give information about macromolecular content (dry weight) and not about the number of cells or the state of hydration.

To understand their use in biomass determination, only the basic principle of Huygens is needed. Electromagnetic radiation interacts with the electronic charges in all matter. When the light energy cannot be absorbed (colorless materials), a light quantum of the same energy must be reirradiated. This light photon may emerge in any direction. This means that all atoms in a physical body serve as secondary sources of light. Those photons that happen to go in the direction of the original wave will stay in phase with the wave arriving directly from the light source, but light reirradiated from different points in the body that go in other directions will differ in phase at an observation point. The phase will differ depending on the distance that the photon must travel throughout the object because light going through matter is slowed. (The degree of slowing is measured by the index of refraction.)

It is refraction that controls how light is bent and focused in large bodies such as prisms, lenses, raindrops, or a pane of glass. In the last case, all the light that is scattered in any direction except straight ahead cancels, leaving only a beam of light going in the original direction. However, it is slightly retarded relative to a light ray not going through the pane; this is the basis causing the index of refraction of substances to be greater than 1. For the present purposes, the deflection of the light into different directions is the basis for the three types of useful techniques outlined next.

Theoretical Aspects

When the particles are very small, the light scattered is given by the Rayleigh equation:

$$\mathbf{I} = \frac{8\pi^4 r^6 \eta_0^4}{R^2 \lambda} \frac{[(\eta/\eta_0)^2 - 1]^2}{[(\eta/\eta_0)^2 + 2]^2} v\mathbf{I}_0 v[1 + \cos^2(\theta)] \quad (1)$$

In this equation, **I** is the intensity of the scattered light at a given direction and distance; r is the radius of the spherical equivalent of the actual particle; η_o is the index of refraction of the suspending medium; η is the index of refraction of the particle; v is the volume illuminated; $\mathbf{I}_o$ is the intensity of the incident light; v is the concentration of particles; θ is the angle of observation; R is the distance of the observer from the sample; and λ is the wavelength of light in vacuo. The factor depends on the angle of observation, θ, relative to the forward direction of the illuminating beam. The $[1 + \cos^2(\theta)]$ factor takes into account the two mutually perpendicular beams of plane-polarized light that comprise unpolarized light. For a given physical setup, most of these factors can be combined into an empirical constant.

In studies of bacteria, the biomass is commonly measured by turbidity. Turbidity is the amount of light scattered away from the forward direction and is thus a measure of the integral of all the scattered light. Similarly, for the flow cytometer applications, **I** must be integrated over the directions that are collected by the instrument's optics. This integral will be designated by **F**. In nephelometry only light scattered at 90° to the primary beam is recorded. This measure is actually a mixture involving on one hand the size shape and orientation of the particles and on the other the inhomogeneities inside the particle.

The range of very small particles where the equation 1 holds is called the Rayleigh domain. For this domain, the actual volume, index of refraction, shape, and orientation of the particles are irrelevant to the total light scatter. Most viruses are sufficiently small for their total scattered light to belong to this domain. For such small particles, the total light scatter integrated over all angles is proportional to the square of the volume, V^2. This results because the Rayleigh equation contains the radius, r, raised to the sixth power, which is equivalent to the volume squared. From the relative index of refraction, $m = \eta/\eta_o$ of the cells and the refractive index increment, the particle dry mass, q, and the wet weight can be calculated as discussed next, but only if all the parameters in equation 1 are known.

For somewhat larger particles with low index of refraction, such as most bacteria, which typically range from 0.3 to 3 μm in linear measure, light scattered from different parts of the particle can interfere both destructively and constructively as a result of phase differences. This defines the Rayleigh-Gans domain and is the relevant case for most microbes. The shape and orientation of the particles become important for this domain, where the particle's radius is comparable to λ', the wavelength of light in the suspending medium which is equal to λ/η_o. For particles in this domain, it is sufficient to take only the constructive and destructive interference into account, whereas phase shifts as the light traverses the particle can be neglected. The light scattering in this domain can be treated relatively simply, and for calculation, equation 1 need only be amended by multiplication with quantities called P functions. These functions are specific for shape, size, and orientation. Thus

$$I_{RG} = I(P(\theta)) \quad (2)$$

where I_{RG} is the light scattered as corrected by the Rayleigh-Gans method. The P functions are given and discussed in a variety of sources (see Ref. 1).

The mathematics of the third, the Mie, domain applies to particles of any size and index of refraction and are computer intensive. The computations can be carried out much more easily if the particles are spherical. For pigment-bearing cells, such as green and blue-green algae, the computations are very elaborate.

Although the Rayleigh-Gans or Mie mathematics apply as well to the simpler cases, we have defined the Rayleigh-Gans domain as the region in which interference, but not phase, must be taken into account, and the Mie domain is where both interference and phase shifts must be taken into account for accuracy. The choice of the appropriate mathematics depends on both the size and the index of refraction of the particle relative to the medium above that of the medium (i.e., on $\eta/\eta_o - 1$).

Bacteria (e.g., *Escherichia coli* growing in minimal medium) belong to the Rayleigh-Gans domain and not the Rayleigh domain because they are large enough to require correction for interference; however, they do not belong to the Mie domain because they have only a small dry mass, being mostly, water, and have an index of refraction only slightly larger than the aqueous growth medium and thus do not elicit phase shifts. Typically the index of refraction relative to the growth medium of many bacteria is 1.04. In any case, a relative index of refraction between 1.00 and 1.05 ensures that most bacteria suspended in their growth medium will fall in the Rayleigh-Gans domain (43–47).

Studies (48) show that dilute suspensions of most bacteria, independently of cell size, have nearly the same apparent absorbance per unit of the dry weight concentrations. Measurements at various angles (49) show that light is collimated mainly in the first few degree from the primary beam and at high angles almost purely measures the inhomogeneity of the bacterial cells.

Very different absorbancies (turbidities) are found per particle or per colony-forming unit with different sizes of bacterial cells. An approximate rule commonly assumed is that the dry weight concentration is directly proportional to the absorbance. This rule applies roughly to both cocci and rods and is a first approximation to a more precise rule, that is, that the light scattered out of the primary beam is proportional to the four-thirds power of the average volume of cells in the culture. Objects smaller than bacteria, such as suspensions of viruses, will not obey these rules. The rules also fail to apply when the suspensions of very small bacteria have a bluish cast. Larger objects (yeasts and filaments and aggregates of bacteria) may still appear cloudy and not necessarily colored, but may not obey the rule. Where the rule applies, the proportionality constant relating the absorbency measurement to the dry weight concentration is the same for any good, well-collimated photometer.

Turbidimetry

Bacterial suspensions are in between the size limits of atoms and objects like window panes. Consequently, most of

the scattered light is deviated only slightly; it is directed almost but not quite in the same direction as was the incident beam. The light scattered from an atom or a very small particle depends inversely on the fourth power of the wavelength of light. For a pane of glass, there is no light left uncancelled in any but the original direction, so the light retains its original hue and the pane appears transparent. If the glass was powdered to the size of bacteria, a suspension of powdered glass or bacteria (like a cloud) would appear white but not transparent nor colored. Because bacterial suspensions appear cloudy or turbid, instruments to measure the phenomenon are called turbidimeters (*turbidus* = confused or disturbed).

The common practice in bacteriology is to use any available colorimeter or spectrophotometer to measure turbidity. Ideally, such instruments measure only the primary beam of light that passes without deviation through the sample and reaches the photocell. Usually, the measurement is made of the light intensity relative to that which reaches the photocell when a sample of the suspending medium has replaced the cell suspension. From what has been said, an ideal photometer must be designed with a narrow beam and a small detector so that only the light scattered in the forward direction reaches the photocell. That is, the instrument must have well-collimated optics. Such an ideal instrument gives larger apparent absorbance values than simple instruments with poorly collimated optics, because in the latter a large percentage of the light scattered by the suspension is still intercepted by the phototube. Therefore, the measuring system responds as if there were less light scattered than is actually deviated from the forward direction.

If the instrument or the size of organism does not meet these criteria, valid measurements in many cases can be made by establishing a standard curve on either a relative or an absolute basis. Difficulty arises only as physical or biological conditions vary with the samples to be compared, since then the experimenter cannot be sure that the same standard curve applies.

These considerations apply only to dilute suspensions. Deviation from Beer's law must be applied after the absorbance exceeds about 0.3 when light of 500 nm or shorter is used. A good discussion of this question is given by Kavenagh (50). Failure to take this deviation into consideration is the most common difficulty encountered in the microbiological literature that involves turbidimetry. One way to avoid this problem is to restrict culture densities and use only dilute cultures for measurement (i.e., keep the absorbance below 0.3). It is usually better to make measurements at higher densities and correct for deviations from Beer's law. The longer the wavelength of light used, the less important the need for the Beer's law correction.

Nephelometry

Although most of the light scattered by bacteria is nearly in the forward direction, instruments that measure the light scattered at 90° from the primary beam have been used to measure bacterial concentrations. Instruments designed to make right-angle measurements of light scattering are called nephelometer (*nephelos* = cloud). Bacterial concentration may be measured with this nephelometric principle in a spectrofluorometer when the dials are set so that the excitation monochromator and the emission monochromator are at the same wavelength.

Nephelometric measurements can be ultrasensitive, so that very small concentrations of bacterial cells can be measured. If it is known which factors are important and whether elongated particles are oriented or randomly distributed in space, then light-scattering measurement over a range of angles can give information about several aspects: the state of aggregation of the protoplasm, such as whether the ribosomes are in polysomes or as monosomes within the living cell; the thickness of the cell envelope (46, 49, 51, 52); and the distribution of cell mass from the center of the cell

Wyatt (52) has developed an apparatus to measure the angular dependency of the light-scattering signal from 30° to 150°. In this range, different organisms, different treatments of a culture, and cultures in different phases of growth give characteristic patterns. These may be of some use as a fingerprint technique for the diagnosis and study of drug action. For the reasons stated above, the light-scattering signals in the high-angle range cannot be used reliably for growth measurement because they are sensitive to details of subcellular structure.

Light-scattering measurements made over a range of angles from 0° to 20° are relatively independent of these three factors, but are more critically dependent on overall size. Measurement in this range could nondestructively yield the biomass concentration, the number concentration, the average axial ratio, and a measure of average biomass distribution around the center of the cells for bacteria in balanced growth.

It may be easily possible to build a device in which an inexpensive neon laser illuminates a flow through a cuvette or a series of cuvettes of different path lengths. It would be so constructed that little stray light from the laser arrives at the detectors. One detector monitors the input beam, and a second monitors the light scattered a few degrees from the direction of the primary beam, say at 4°. A third measures the light scattered at right angles, and software outputs the dry weight biomass and intracellular heterogeneity that is a measure of the physiological state of the cells. It would avoid problems of the failure of Lambert's law by having multiple path lengths and would usually neglect the signals from the path length cuvettes in which deviations from the Beer-Lambert law were important. A variation would have several laser beams. The appropriate choice would depend on the color of the surrounding medium and the size of the microbes. The farther into the infrared that can be used, the less the Beer's law correction is needed, but there may be more interference from medium constituents.

It is possible to put probes into the fermentation apparatus for light scattering, turbidity, and nephelometry that have light sources and light detectors. These methods usually fail because the organisms grow on the optical surfaces. It is possible to remove, sterilize, and reinsert the probes, but this could lead to contamination. There are some ways around the surface-growth problem that may

be effectively implemented in the future to essentially by cleaning the optical surfaces in situ.

Flow Cytometry

For the conversion of forward scatter measurements in flow cytometry, the intensity of light pulse from a passing particle must be converted to volume or wet biomass or dry biomass. Our analysis (53) showed that in the Rayleigh region the biomass is related to the intensity raised to the 0.5 power, and in the Rayleigh-Gans region the power is approximately 0.75 for the usual bacteria and is somewhere in between for the very small bacteria that we are studying. Rules have been developed to establish the exact power. The results are applicable to bacteria and very small bacteria (0.02 to 0.6 μm^3) that are not usually spherical. The physical limitations and the mathematical basis of the calculations have been justified for the application of the proposed formula for practical use in microbial ecology and physiology of extremely small aquatic bacteria as well as the more well-studied forms. Although the method was developed for the small bacteria present in natural populations that are difficult to size by alternative methods, it will also be useful for industrial cultures of bacteria.

The major problem with both types of instruments discussed earlier is to convert the forward scattered light into a value proportional to the biomass of the particle. Although complicated, this problem has been solved for the first type of instrument (53). Consequently, the number of the channel of the multichannel analyzer can be related to biomass through a power law function. As of yet, a reliable way to do the same for the second class of instrument that uses an inverted microscope is not available. This does not prevent the instrument from being a very valuable instrument, but it will be more valuable when accurate sizes can be developed.

It may not be possible to theoretically analyze the light-scattering pulses from the second type of instrument and to convert them into dry weight biomass, but it is not impossible to imagine that something akin to the polystyrene latex beads that have become so useful in medical technology will be developed that have precisely defined size and an index of refraction in the range that includes most bacteria. Then, the second type of instrument will become useful for biomass determinations. As with light-scattering measurements, aggregation, clumping, and failure of cells to separate will remain problems to be coped with.

SAMPLING

Attention must be paid to analyzing an appropriate sample. Although this just takes attention to detail, it is so important that it should be emphasized again and again. During bioprocess technology, it is important to sample from a number of parts of the system. Pooling and mixing and then analyzing are appropriate, but in many cases, analysis of each part individually and the body of data analyzed statistically are efficient and useful.

ACKNOWLEDGMENT

I would like to thank George Hegeman and Matt Hilton for help in preparing this article.

OUTLINE

INTRODUCTION

Most recombinant DNA–derived mammalian cell culture products are manufactured using cells grown in suspension. Commonly used cells include Chinese hamster ovary (CHO), baby hamster kidney (BHK), hybridoma, and myeloma cells. Those cells can be cultivated in fermentors similarly to microorganisms. However, the vast majority of cells grown in research laboratories, and many of those used in the manufacturing of viral vaccines for human and veterinary use, are anchorage-dependent or anchorage-preferred cells. This means that they need to attach to a compatible surface to survive and multiply, or, if given a compatible surface, they will readily attach to it and multiply rather than stay in suspension. Frequently used anchorage-dependent cells include MDCK, vero, mouse L, fibroblasts such as MRC-5 and WI-38, and almost all differentiated primary cells from nonblood tissues, such as hepatocytes, neuronal cells, and chondrocytes. These cells are grown on petri dishes, flasks (T-flasks), and roller bottles in research laboratories. Traditionally roller bottles are used in the production of biologics, such as cytokines and viruses, derived from those cells. In a typical production plant of those biologics, it is common to see tens of thousands of roller bottles being used for cell cultivation. The amount of labor requirement for roller bottle handling is daunting. Many of those processes manufacture products that were approved by regulatory agencies long ago. If the products were developed more recently, many, if not most, would have been manufactured with an alternative and improved method.

The need to establish a better method of culturing anchorage-dependent cells in large scale prompted the development of microcarriers. The first microcarrier culture was demonstrated by van Wezel in 1967 with diethylaminoethyl (DEAE) Sephadex A50 particles originally designed as column packing for ion exchange chromatography (1). The first industrial-scale product (inactivated polio vaccine) produced in microcarrier cultures was subsequently introduced by van Wezel in 1972 (2). This new way of culturing anchorage-dependent cells spurred other investigators to discover novel techniques to improve cell attachment to the beads, to test new types of microcarriers, and to increase the cell density. Serum coating of DEAE Sephadex beads (3), electric corona discharge for treatment of plastic (polystyrene) beads, and use of dextran microcarriers with a lower charge density (4) led to improvements in microcarrier technology. Since then, a variety of microcarriers have been developed and much research has provided insights into optimization of culture conditions. Table 1 presents a list of the most commonly used commercial microcarriers. The advantages of microcarrier culture over conventional monolayer culture methods (e.g., roller bottles, stacking flat plates) are numerous. Using microcarriers to provide a surface for cell attachment, a large surface area can be contained in a given reactor volume with a relatively uniform environment. Using a reactor similar to conventional fermentors, environmental monitoring and control become possible, thus opening up the possibility of further process optimization.

Most conventional microcarriers have a diameter of approximately 200–250 μm when suspended in medium and

Table 1. Commercially Available Conventional and Macroporous Microcarriers

Microcarrier type	Supplier
Conventional microcarriers	
Biosilon (polystyrene based)	Nunclon
Cytodex 1 (DEAE dextran)	Pharmacia
Cytodex 2 (DEAE dextran)	Pharmacia
Cytodex 3 (gelatin)	Pharmacia
Glass-, collagen-, and hydroxyapatite-coated plastics	Solohil Engineering
Macroporous microcarriers	
Cultisphere (collagen or gelatin)	Hyclone
Cytoline (polyethylene)	Pharmacia
Cytopore (cellulose)	Pharmacia

a specific density of 1.02–1.03 g/cm^3, slightly higher than that of the medium. This higher density allows a minimum agitation to be used to keep the microcarriers in suspension. It also allows for ready settlement after agitation is turned off, which is ideal for culture harvest or exchange of medium for supporting higher cell growth. A typical culture uses a microcarrier concentration equivalent to a settled bead volume 5–15% of total culture volume. This gives a surface area of about 0.5–1.5 m^2/L culture volume. Each liter of culture is equivalent to 5–150 roller bottles. The potential of increasing cell growth surface area was further advanced by the development of macroporous microcarriers (5). These are highly porous convoluted spheres with internal cavities for cell attachment and growth. Macroporous microcarriers can be used for culturing both anchorage-dependent and suspension cells.

Over the past 30 years, microcarrier culture technology has developed and matured to its present-day status. It allows for an easy way of producing a large quantity of cells both in laboratories and for industrial manufacturing. The ease of cell retention in microcarrier cultures also facilitates the employment of a perfusion system, which increases the maximum achievable cell density significantly. For large-scale cultivation of anchorage-dependent cells, microcarrier culture is still the best method.

CONVENTIONAL MICROCARRIERS

The microcarriers developed in the 1970s were initially based on cross-linked dextran. Soon after their introduction they were used successfully for the production of various vaccines and biologicals (6). Further development led to the use of other materials as microcarrier supports. These materials include polystyrene (7), glass (8), cellulose (9), and gelatin (10). The original dextran-based microcarriers require tedious procedures for detachment of cells (11) for subsequent inoculation, which is not the case for some of the other materials developed (8). Several studies have been directed at the effect of surface charge on cell attachment (12,13) and the kinetics of attachment (12).

Cell Surface Interactions and Attachment Kinetics

A microcarrier culture is typically initiated by trypsinizing cells that are adherent on a surface, either on tissue culture flasks or on microcarriers. Sometimes cells for inoculation are cultivated in suspension, and the production scale is conducted with microcarriers. Inoculation from a suspension culture eliminates the need for trypsinization. Once inoculated into a microcarrier suspension, the cells can either attach to the microcarriers or agglomerate to each other to form aggregates. It is essential that the rate of cell attachment to the microcarriers follows rapid kinetics to prevent them from agglomerating. The need for rapid attachment is even more pronounced in cases of primary cells such as hepatocytes or in case of other adherent cell lines that lose their viability if maintained in suspension over extended periods of time. For single cell populations, several studies have demonstrated that the initial rate of attachment of cells to microcarriers is essentially a first-order process, meaning the rate of increase in attached cells is proportional to the concentration of unattached cells, provided that the surface area available for attachment is not limiting (12). The process of cell attachment to any foreign surface can be viewed as a combination of two separate processes: initial adsorption of cells to the microcarrier surface followed by adhesion molecule–mediated attachment and cell spreading. The affinity of the binding of the cells to the microcarriers depends on the cell line, the microcarrier characteristics, the growth phase of the culture, the medium composition, and the cell loading per microcarrier. Cells initially adsorbed can possibly desorb from the microcarrier surface without really developing cell adhesion; the surface should therefore have sufficient affinity so as to allow the cells to remain attached to develop a firm grip by cell adhesion molecule–mediated interactions.

The initial adsorption of cells onto the microcarrier surface is a physical process and is believed to be facilitated by various attractive or affinitive interactions between the cell surface and the microcarriers. Cells in general fail to attach to unmodified crossed-dextran beads such as Sephadex but attach readily to DEAE Sephadex, although the optimal charge density for cell spreading and growth is less than that in DEAE Sephadex (4). Plastics such as polypropylene and polystyrene, in their native state, have a lower surface energy and are therefore incompatible for cell attachment. When treated with an electric corona discharge, their surface energy rises to that of tissue culture dishes, which enhances their ability for cell attachment. It has been demonstrated that corona discharge leads to the unmasking of carboxylic groups on the polystyrene surface, leading to this increase in surface charge density (14). Also, the attachment of cells has been shown to be affected by the length of the carbon chain on the unmasked surface groups (15). The cell surface is negatively charged due to the presence of negatively charged residues on the side chains of membrane-associated cell surface proteins. The interaction of the cell surface with positively charged surfaces can be attributed to the electrostatic interactions. The attachment of cells to negatively charged surfaces is likely due to Lewis acid type reactions in which short-range electron donor–acceptor interactions lead to coupling. In some cases microcarriers coated with cell adhesion factors, such as fibronectin, collagen, and laminin (16), have also been used to facilitate cell adhesion. It is interesting to note that for many cell types the initial attachment rate to charged microcarriers such as DEAE-modified cross-linked dextran beads (Cytodex-1) is faster than to those coated with collagen, which is an excellent surface for cell adhesion on petri dishes.

Furthermore, although serum provides many factors that promote cell adhesion, the initial attachment to charged microcarriers is often faster in the absence of serum (12). These observations suggest that electrostatic interactions between the surfaces of cells and microcarriers is a dominant factor for initial cell attachment. The provision of adhesion molecules, either covalently bound to microcarriers (16) or in soluble form in medium (17), promotes subsequent development of firm grips of cells on microcarriers and facilitates cell spreading. In many cases, no exogenous adhesion molecules are necessary because

cells synthesize their own. For some cell types the omission of these factors impedes cell spreading despite successful cell attachment to microcarriers (16). It is possible then to coimmobilize charged groups and cell adhesion molecules on the microcarriers to promote both initial physical attachment and subsequent biological events of development of adhesion plaques and cell spreading. Irrespective of the surface charge and the hydrophobicity or hydrophilicity of the microcarriers, it is essential that the surface have good wettability characteristics (18).

It has also been shown that a correlation exists between the exchange capacity of the microcarriers and the rate of cell attachment. A higher exchange capacity of the microcarriers leads to a higher first-order rate constant for cell attachment. However, at physiological pH, a higher exchange capacity is not correlated to a higher charge density. Moreover, a difference in cell spreading is observed at different exchange capacities (12). It appears that higher exchange capacities lead to increased cell attachment, but one must be cautioned that a higher exchange capacity may not lead to optimal growth of cells. The optimum exchange capacities for cell attachment and for cell growth are thus very different, and it is advisable to perform preliminary experiments to determine what exchange capacity is best suited for a particular cell type and a particular microcarrier type.

Inoculum Cell Density

After inoculation, cells attach to microcarriers randomly and the number of cells per microcarrier is distributed over a range. Once the adhesion plaques are developed and spreading occurs, most cells do not detach readily and reattach to other microcarriers. They grow until they cover the surface of the bead. For cells subject to contact inhibition, growth ceases then. Many cell types can form multiple layers, but growth rate often slows down after reaching confluence. Therefore, cells on beads with more cells initially reach confluence and stop growing or slow their growth rate faster while others are still growing. Once this happens the overall growth rate in the culture slows. The initial cell distribution on microcarriers thus affects the overall growth kinetics of microcarrier culture. The narrower the initial cell distribution is, the better the growth kinetics will be. Furthermore, microcarriers that do not receive any cells initially will remain barren. Thus, the initial cell distribution after inoculation also affects the maximum cell concentration attainable in the culture.

The initial random distribution of cells on the microcarriers can be simulated by a Poisson distribution, which predicts the probability of a microcarrier having a certain number of cells given the average number of cells per microcarrier (19). Ideally the average number of cells that attach per bead should be such that the fraction of beads without any attached cells is kept at a minimum. It has been shown that a minimal average of about five to six cells per microcarrier is a necessary inoculum size (19,20). With this inoculum ratio, the percentage of microcarriers without any cells attached to them is less than 1%, as estimated from the Poisson distribution.

Cell Shear

Adequate agitation in microcarrier cultures is critical for providing a homogeneous environment and thus facilitates oxygen transfer. The hydrodynamic forces that result from agitation can be detrimental to cells grown on microcarriers. Cells grown microcarrier culture are more shear sensitive than those grown in suspension. The dominant cell damage mechanism in microcarrier bioreactors is believed to be due to forces generated by the collision of microcarrier beads with each other and by small turbulent eddies, which are motions generated by the random variations of fluid direction and velocity in a turbulent flow field (21). In general, except in the spinner flasks used in laboratories, a pitch-blade or marine-type impeller is used for agitation. The ratio of impeller diameter to tank diameter is typically larger than that used in microbial fermentation. The larger impeller provides a larger capacity in liquid pumping for suspending the microcarriers. Because of the low solubility and mass transfer rate of oxygen in culture medium, external aeration is needed at larger scale. In many cases oxygen is supplied indirectly through membrane or silicone rubber tubing, which has a high permeability for oxygen. Use of such tubing is practical even up to a reactor of hundreds of liters. Direct sparging with air or oxygen is used in large stirred tank bioreactors. It is well known in suspension cultures that shear force from rupturing bubbles in a sparged system is the most dominant cell damaging mechanism. This is also likely the case in microcarrier cultures (22). With direct sparging surface active agents, such as Pluronic F-68, are used to reduce the attachment of cell-laden microcarriers to rising bubbles. Attaching to these bubbles and rising with them at a high velocity is often detrimental to cells attached to microcarriers. Furthermore, it is necessary to employ antifoaming agents. Otherwise, cell-laden microcarriers may rise to the top of the foam layer and accumulate there, eventually losing viability.

MACROPOROUS MICROCARRIERS

The cell concentration achievable in a conventional microcarrier system is limited by the available surface for growth. Increasing the microcarrier concentration beyond a certain limit does not lead to an increase in cell concentration because the increased agitation needed to suspend the microcarrier slurry becomes damaging to cells. Macroporous microcarriers were developed with an aim of circumventing some of these limitations of conventional microcarriers.

Macroporous beads are essentially convoluted spheres with relatively large pores for cell attachment and growth. The commonly used materials are gelatin (5), collagen (23), cellulose, glass, polyethylene (24), and polystyrene. The desirable properties of the materials of construction for macroporous microcarriers were discussed earlier. After inoculation of cultures, the cells attach to the external surface of the microcarriers and subsequently migrate inward to populate the interior of the beads. If large open channels leading to internal pores exist, cells may also populate the interior soon after inoculation. Thus, these macroporous

microcarriers provide extended surface area in the interior and potentially support a higher cell concentration with an equivalent number of beads. Also, the cells in the interior of the macroporous microcarriers are shielded from fluid flow and are hence not susceptible to detrimental shear effects (22). However, there are two areas for potential concern. First, in contrast to conventional microcarriers the surface of the macroporous microcarriers is full of cavities and is highly irregular. This irregularity interrupts the flow pattern in the bulk fluid in the immediate vicinity of the beads and gives rise to local microeddies that may damage the cells attached on the surface. Therefore, to avoid shear damage, once attached cells need to migrate inward at a relatively fast rate or the internal pore must be relatively open to allow for cells be carried into the interior by fluid convection during the cell attachment period after inoculation. The second cause for concern is the potential gradients of nutrients, oxygen, and metabolites along the radius of the microcarrier which may cause growth limitation. As a result, necrotic core could be induced within the beads (24,25). Use of intraparticle convection has been postulated as a method to overcome the formation of heterogeneous environment. Numerous cell types have been successfully cultivated on macroporous microcarriers for purposes of product production and virus production (26). Apart from stirred tank reactors, fluidized-bed reactors (27) are also used for cultivating cells in macroporous microcarriers.

Spatial Distribution of Cells and Cell Viability

To ensure efficient use of macroporous microcarriers the internal pores should be open to the exterior through open channels that allow for cell movement into the interior. Some collagen-based microcarriers have leaflike interiors with open and flat surfaces, and others have open pores interconnected by tortuous channels. The materials that the microcarriers are made of also affect the rate of cell movement. Thus, both the structure and the material may affect the performance of the culture. Ideally, macroporous microcarriers should have very open structures to allow cell penetration into the interior immediately after inoculation. Architectural staining of paraffin-embedded thin sections of cell-laden macroporous microcarriers with hemotoxylin and eosin (H&E) indicate that the distribution of cells in the interior is usually not uniform. Some of the internal cavities are packed to confluency, whereas others are devoid of cells.

Traditional methods of examining the pore structure and cell behavior in the interior require fixation and sectioning, which cause aberation. Furthermore, reconstruction of the three-dimensional image is difficult. By digitizing sectioned macroporous culture in three colors, it is possible to classify pixels as conforming to either background, cytoplasmic, microcarrier matrix, or nuclear parameters, based on a set of classification rules determined by statistical analysis (28). When relating the number of pixels occupied by cellular material to the total number of pixels in the sectioned microcarrier, quantification of cell growth can be generated. To examine the accessibility and geometrical features of the pores, confocal laser scanning microscopy (CLSM) can be used to optically section the beads (29). CLSM requires fluorescent samples. Most microcarriers can be rendered fluorescent by appropriate staining techniques. It is also possible to stain cells with a vital dye that has different excitation wavelengths than the dye used for microcarrier staining. This dual stain allows simultaneous observation of cells and microcarriers. Individual beads can be optically sectioned serially through their depths. A three-dimensional image can be reconstructed by combining the sections for examination of the openness and connectivity of the pores. To further evaluate the geometry of the pores, the solid structure of the beads can be removed from the reconstructed three-dimensional images to allow for direct visualization of the pores. Cell distribution, divisional, and other morphological characteristics can be observed directly. This confocal microscopic technique for direct evaluation of pore structure of macroporous beads is noninvasive and requires minimal sample preparation. It can easily be adapted for in situ observation of cell behaviors and to provide information to optimize the structure of those microcarriers.

MICROSPHERE-INDUCED AGGREGATES

A possible way to increase cell concentration in conventional microcarrier systems is by increasing the microcarrier concentration. However, a potential drawback of this scheme is the large ratio of settled bead volume to the culture volume. This large volume of settled beads calls for sophisticated methods of agitation to keep the microcarriers in suspension. Compared with these systems, the settled volume of cell aggregate with an equivalent cell concentration is relatively small, and the agitation requirements parallel those of simple suspension cultures. Also, some adherent cell lines have been engineered to grow in suspension or as aggregates by processes of adaptation or media adaptation. It has been demonstrated that agglomeration can be induced by lectin, concanavalin A, and wheat germ agglutanin (30). However, these processes are relatively slow, and a significant number of the cells initially inoculated lose their viability because of the duration required for aggregate induction.

Microspheres made of DEAE-derivatized Sephadex beads with diameters of 20–50 μm have been demonstrated to increase the rate of aggregate formation (31). Hence, this process can be thought of as a process similar to nucleation and growth in crystallization. After the initial attachment phase, these cell-laden microspheres come into contact with each other to form larger clumps, which serve as nucleation sites for aggregate formation via growth of these attached cells. Over time, aggregates emerge, each consisting of a few microspheres surrounded by multiple layers of cells.

A variety of cells, including CHO, vero, human embryonic kidney cells (293 cells), and swine testicular cells have been successfully grown on these microspheres (31) for virus and protein C productions (31). The drawback of employing aggregate cultures is that little is known about controlling the size of aggregates. As the aggregate size increases, nutrient limitation and a decreased viability can be expected.

CONCLUSION

Microcarrier processes, because of their ease of operation and control, are ideal for cultivating anchorage-dependent cells in both the laboratory and in manufacturing. The bioreactor operation requirements are virtually identical to those for a typical suspension culture in fermentors except that the upper limit for agitation is lower. Operating modes such as batch, fed batch (32), and perfusion are routinely being used in microcarrier cultures. The prevailing use of microcarriers in industrial scale is for the manufacture of viral vaccines and reagents. Depending on the cell type, serum-free cultivation is also possible. Because most newly developed cell culture processes for rDNA products employ suspension cells, microcarrier culture processes will see only moderate growth in the future. However, with increased efforts in research and product development employing differentiated cells, we may see microcarriers play an increasingly important role in small to moderate scales. This technology—developed three decades ago—is still intriguing to cell culture technologists. Its versatility in supporting the growth of a variety of anchorage-dependent cells ensures it a unique place in bioprocessing.

OUTLINE

INTRODUCTION

The immobilization of active biological substances or living cells has become a universal tool in biotechnology over the past decades. Immobilization can be defined as any procedure that confines substances or cells inside a given system and limits its free diffusion or migration. In biotechnology, the concept of microencapsulation is related to a special immobilization system, where the biological material is confined inside particles, beads, or hollow spheres.

Spherical particles can be considered to be the best-suited immobilization system for use in bioreactors, due to their optimal hydrodynamic properties and abrasion resistance. Because microencapsulation is a very powerful and universal tool, the applications for microencapsulated systems cover a very wide field. To date, it has been used to improve the relatively outdated biotechnological processes in the food industry (1,2), wastewater treatment (3), leaching (4), and environmental detoxification (5). In modern biotechnology it has been applied to cell culture processes for the production of high-value substances such as antibodies (6,7), erythropoetin (8), and the anticancer drug taxol (9), as well as for the production of artificial seeds (10,11) and cryopreservation (12). In medicine, microencapsulated cells have been used as artificial organs to treat diabetes (13,14), as a delivery system for gene therapy (15,16), as an intermediate step in cancer therapy (17), and for the treatment of Parkinson's disease (18,19), to name a few. Furthermore, microencapsulation can serve as a controlled release system for drugs in medicine (20–22) and pesticides in agriculture (23,24).

MICROCAPSULES

Although there are a variety of encapsulation techniques and suitable materials, the resulting microcapsules can be divided into only three main groups: beads, coated beads, and hollow spheres.

Beads

Beads can be produced by cooling liquid drops of gelling agents (gelatine, agarose) under their melting point, thus transforming the polymer solution into a stable cryogel by internal hydrogen bonding, or by chemically or ionically cross-linking polymers to produce a hydrogel. Because bead formation is a simple one-step process, it is relatively easy to develop a large-scale production process (25). The most common bead formation system is alginate cross-linked with calcium ions or any other divalent metal ions.

The fully developed three-dimensional internal network structure enables the beads to withstand extreme mechanical stress. Permeability of hydrogel beads is excellent, and they are often used for culturing cells and microorganisms. The disadvantage is their lack of a real barrier on the surface, so cells can expand during cultivation.

Coated Beads

Providing beads with one or several additional walls leads to the formation of coated beads, which have been developed to overcome the problems associated with the open porous structure of bead surfaces. To produce a membrane, the beads from charged polymers (e.g., alginate, agarose) are treated with a diluted solution of an oppositely charged polyelectrolyte (e.g., poly-L-lysine, poly(ethylene imine), poly(*N*-vinylamine), chitosan) thus forming a simplex membrane on the bead surface. The use of several alternatively charged electrolytes leads to multilayer membranes (26–28). Alternatively, beads can be soaked with a photosensitive substance that cross-links when irradiated (29–31).

A proper coating process produces an additional membrane without incorporation of the material to be immobilized and has the advantage that the membrane properties can be engineered independently with respect to diffusion, molecular weight cut-off, cell retention, or immunoprotection from the internal bead structure and material. Possibly the most well-investigated clinical application of microencapsulation is based on poly-L-lysine-coated calcium alginate beads in the treatment of diabetes (32,33), which has recently been applied to humans (34,35).

Hollow Spheres

Hollow spheres can be produced in a one-step process using two membrane-forming materials that cannot penetrate each other due to diffusional limitations. The cross-linking reaction is then limited to the interface area of the hollow sphere, forming drops and producing a stable membrane around a liquid core. Typical hollow-sphere-forming materials are all polyelectrolyte combinations, for example, cellulose sulfate (CS) and poly(diallyl dimethyl ammonium chloride) (PDADMAC), and CS and poly(ethylene imine) (PEI), able to produce a simplex membrane (36). Another method for the production of hollow spheres is the use of two materials such that the cross-linking material of the drop can diffuse into the surrounding solution. The membrane starts forming at the surface of the droplets and then proceeds outward, creating cell-free membranes. The membrane thickness can be controlled by the electrolyte concentration of the droplet. In principle it is a reversal of the bead-forming process (37). Of course, hollow spheres can also be obtained from a multistep process in which the

core of the coated beads is solubilized. This method has been used for controlled release systems in agriculture and the pharmaceutical industry. It is applied on shear-sensitive compounds such as animal cells in particular (38,39).

Recently simplex membrane systems have gained importance for medical applications such as artificial liver support (40) and gene therapy (41). Considerable progress has been made through a U.S. National Aeronautics and Space Administration study in which over a thousand combinations of polyanions and polycations were tested to identify new polymer candidates that could be suitable for the encapsulation of living cells, especially pancreatic islet cells for treatment of diabetes in humans (42,43).

FUNDAMENTAL METHODS IN MICROENCAPSULATION

The basis of all microencapsulation processes is the formation of a liquid drop followed by gelation (44,45), a cross-linking reaction, or membrane formation. The liquid drops can be obtained from extrusion of a liquid through a small needle or orifice, or from emmulsification of the drop-forming solution in a second immiscible solution by use of dynamic or static mixers. Scale-up ability of the process and a uniform microcapsule size and shape are the main parameters in encapsulation technology (46).

Dropping Methods

A liquid ejected with low velocity from a needle will break into individual drops. If the velocity is increased, drop formation increases until the maximum velocity is reached and the liquid begins to form a jet. The maximum velocity can be calculated from the following formula using the liquid velocity, v, interfacial tension, γ, liquid density, ρ, and the inner needle diameter, d_i:

$$v < 2\ (\gamma/\rho d_i)^{0.5}$$

Simple Dropping. The two main factors affecting drop size are the force of gravity trying to tear the drop from the needle tip, and the resisting product of the interfacial tension and the tip perimeter. Other forces interacting with drop formation are resistance power and inertial force, but these can be neglected in computations. The drop mass can be calculated from the equilibrium of the two main forces with the mass, m, gravity acceleration constant, g, external needle diameter, d_e, interfacial tension, γ, and the liquid density, ρ:

$$mg = \pi d_e \gamma \text{ and } m = \frac{\rho \pi d^3}{6}$$

The drop mass must however be corrected by a factor of 0.85 to get the true mass, because drops stretch out and leave a small portion behind when dropping from the needle. Even if very thin needles are used, it is very difficult to obtain droplets with a diameter of 1 mm or less (47,48).

Dropping with a Superposed Air Jet. The droplet size obtained from simply dropping can be reduced by superposing the drop forming process with an additional air jet. For calculating the droplet mass, the dragging forces of the airflow have to be taken into account. The viscous drag force is the laminar effect of the fluid, and the kinetic energy dissipation term represents the impact of the turbulence on the drag. Assuming that the drop diameter is larger than the tip, that there are no lateral fluid effects, and that the nascent drop has a spherical shape, the mass, m, of the generated droplet can be calculated using the gravity acceleration constant, g, liquid viscosity, μ, fluid velocity, v, droplet diameter, d_D, external needle diameter, d_e, the surface tension, γ, and the density of the fluid, ρ (49):

$$mg = \pi d_e \gamma - (3\pi\mu v d_D + 0.055\ \rho v^2 d_D^2)$$

Depending on the immobilization material used, uniform droplets from 2 to 6 mm can be produced. Droplet production can be scaled up by use of several needles at once and has been successfully performed for the encapsulation of IgG-producing hybridoma cell cultures and yeasts (50). However, the increasing airflow influences the line of flight of the droplets, which becomes important if several adjacent needles are used simultaneously. As long as the superposed airflow is laminar ($Re < 0.3$, Stokes' area), droplets will fall in a perfectly vertical line. For turbulent superposed airflow producing periodical eddies ($1{,}000 < Re < 10^5$, Kármán vortex street), the diversion can be neglected up to $Re < 1{,}080$. Stronger turbulence may cause collisions of the falling drops but can be avoided if the distance between the needles is increased. At any rate, small satellite drops are formed and site distribution increases significantly.

This method uses an airstream that is concentric with respect to the droplet-forming needle. Excentric air sleeve positioning combined with a beveled droplet-forming needle facilitates the generation of very small droplets. The distal end of the needle is beveled at an angle of about 15 to 45°; the beveled end is disposed facing the central axis

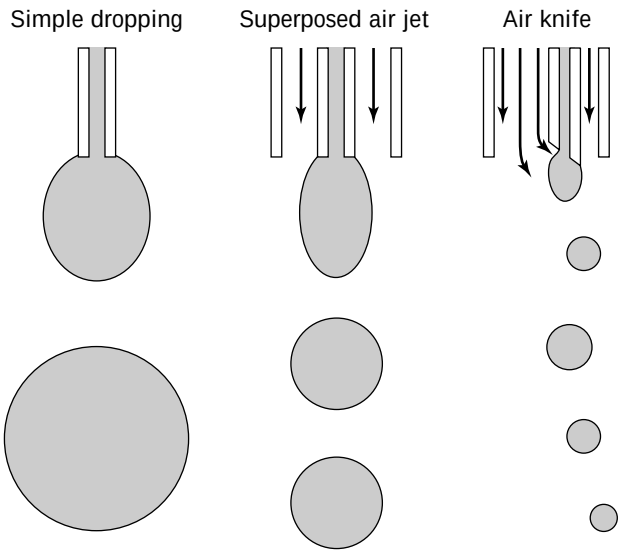

Figure 1. Monoaxial extrusion technologies based on simple dropping.

of the sleeve for the airstream. This arrangement leads to the formation of an air knife that generates droplets of 25–300 μm in diameter. The distribution of size is quite high due to the fact that the airstream not only drags the nascent drops but also breaks up the drop into smaller droplets. The rate of production is limited to 0.1–3.0 mL/min; the preferable limit is 0.3 mL/min (51,52).

Coaxial Dropping with a Superposed Air Jet. All of the systems mentioned so far include the mixing of the microcapsule-forming polymer with the material to be immobilized. This material is distributed evenly in the immobilization matrix and affects the membrane-forming process. In particular, if animal cells are immobilized in hollow spheres from polyelectrolyte complexes, the cells will be incorporated into the membrane. Because these membranes are very thin (1–5 μm) compared with those of animal cells (10–18 μm), several gaps result when these cells disintegrate. Complete cell and product retention or immunprotection cannot therefore be achieved. Coaxial dropping can be used to overcome this problem. This system uses one needle for the membrane-forming polymer solution and a second one, which is fixed in the center of the first, for the cell suspension. Both needles are of the same length. The nascent drop formed at their ends has a core containing the cell suspension and is enveloped with the polymer solution. While falling, the polymer solution completely surrounds the cells that comprise the core. The membrane-forming process in the precipitation bath is not affected. The core may have a volume of up to 25% of the whole drop. The droplet diameter can be varied from 1 to 5 mm. All the equations of the previous section are still valid.

This system has been scaled up to a productivity of 4 L/H by the simultaneous use of 24 concentric needles. To date this system has been successfully used for the immobilization of hybridomas (53), insect cell cultures (54), and the treatment of rheumatoid disease in mice, where microcapsules have been used intraperitoneously in mice containing a hybridoma cell line secreting antirheumatoid monoclonal antibodies (55).

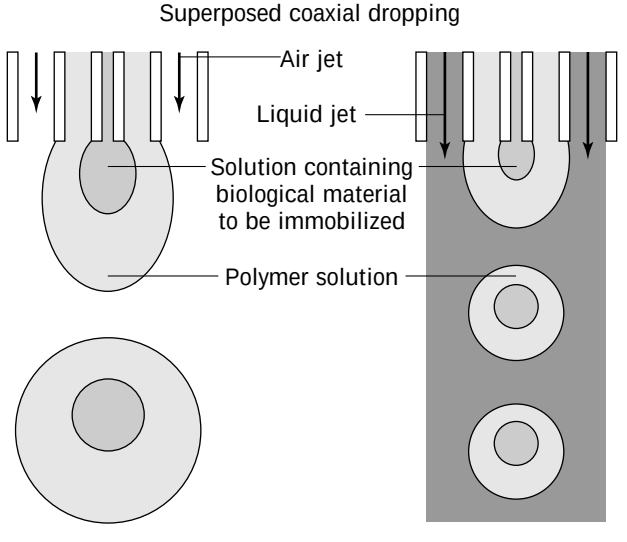

Figure 2. Coaxial extrusion technologies based on simple dropping.

Coaxial Dropping with a Superposed Liquid Jet. Superpositioning is not restricted to the use described in the last section; it can be used with any liquid immiscible with a drop-forming solution along with a precipitation bath. There are two main advantages to this method. Fluids still flow in a laminar fashion at higher velocities as compared with gases, and the viscous drag force is much higher. Both effects enable the production of hollow spheres from polyelectrolytes with a diameter ranging from 500 to 1,000 μm. This is considerably less compared with the previous system. Unfortunately this system is restricted to a productivity of 150 mL/h, and scale-up by use of multiple devices is problematic.

Electrostatic Extrusion. The application of a high static potential between the capillary and collecting solution has been used to improve droplet formation with respect to reducing the droplet size. The electric field force effectively pulls the forming droplet off the tip of the needle at a much lower mass (and hence size) compared with the simple dropping method. A series of small droplets (as small as

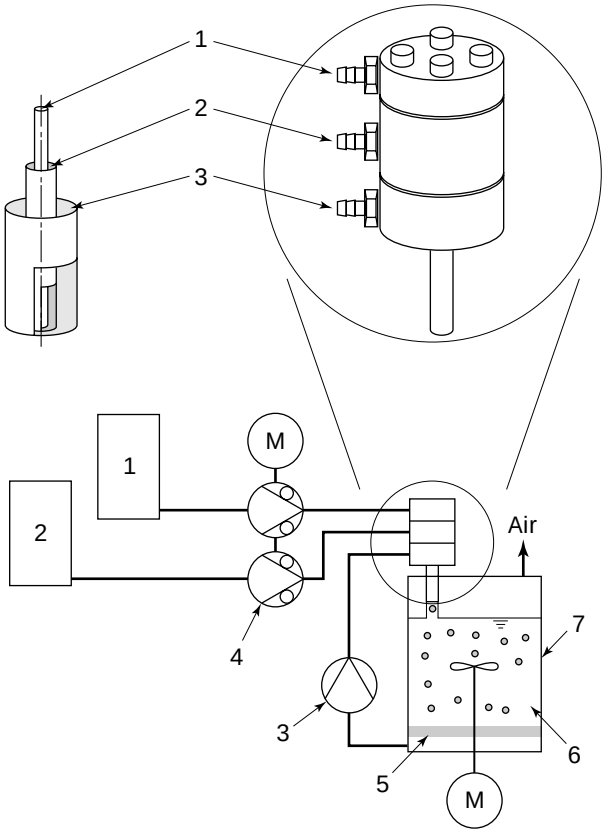

Figure 3. Schematic representation of the coaxial encapsulation apparatus (Torsten Steinau Verfahrenstechnik Berlin): (1) cell suspension, (2) cellulose sulfate solution, (3) inert carrier fluid, (4) multichannel peristaltic pump, (5) sieve for capsule retention, (6) polyDADMAC precipitation bath, and (7) stirred tank reactor.

26 μm in diameter) is generated with a comparably low standard deviation. The average microbead size can be easily adjusted from 2.5 to 0.2 mm by decreasing the concentration of the polymer solution, by using a higher-gauge needle, and by increasing the applied voltage. However there is a limit to how much the size can be reduced. In very high electric fields, droplets are no longer formed, and the solution pours from the needle in a steady stream. Charged molecules accumulate at the nascent drop's surface and counteract the surface tension. According to Lippmann's theory, the size of the drops can be determined with the electrostatic force, Fe, electric permitivity, ε, droplet diameter, d, the applied electrostatic potential, U, surface tension, γ, mass, m, and gravity acceleration constant, g:

$$mg = \pi d\gamma - Fe$$

$$mg = \pi d(\gamma - (k\varepsilon U^2/d))$$

$$d = 1/(6\ m/\pi\rho)^{1/3}$$

The correction factor, k, is difficult to evaluate. It depends on system design and may be a function of the form of the pending drop and of the electrostatic potential. This system has so far been applied to the encapsulation of cells in alginate beads (56,57), pancreatic islets in coated beads to study the influence of diameter and membrane compactness integrity and immunoprotection (58), and to the production of protein-loaded ethylene vinyl acetate beads for controlled-release purposes (59).

Rotating Disk. A liquid can be sprayed into a precipitation bath by using a rotating disk or a dish rotating at a high speed. The liquid for dispersion emerges from an orifice at the center of the axisymmetric rotating disk. The liquid leaves the disk in the form of small jets or ligaments, which form drops prior to falling into the precipitation bath. Droplet diameters, d, can be determined from the surface tension, γ, rotation speed (per second) of the disk, w, disk radius, r, and the liquid density, σ (60,61):

$$d = 0.425\ (\gamma/(w^2 r\sigma))^{0.5}$$

This system can be improved by applying a well-designed wave on the liquid flowing on the spinning disk. The ligaments are broken into uniform droplets with a standard deviation lower than 5%. Typically, a disk of 1 cm in diameter rotating at 2,000 rpm forms about 60 ligaments, which then form droplets of 500 μm at a flow rate of 6 L/h. Equations describing this process are much more complex than those for classical jet rupture. Physical properties of the liquid, design of the rotating disk, and wave frequency and amplitude must be adjusted to achieve correct particle size. This method is currently being used for experimental research and agriculture (62).

Rotating Nozzles. Instead of a rotating disk, a perforated rotating cylinder can be used. This cylinder can be placed in a reactor, with the reactor serving as the precipitation bath and the culturing vessel. Monodisperse and spherical drops are produced by rotating the cylinder at a velocity that hurls the drops directly down into the reactor liquid. The size of the beads is a function of the cylinder's rotation velocity, with a size of 1–3 mm and a deviation of up to 10%. The diameter and number of holes drilled in the cylinder can be varied according to the desired capacity, which can be up to hundreds of liters of alginate beads per hour. The volume, V, of the droplets can be calculated from the hole diameter, d, surface tension, γ, density of the liquid, ρ, gravity acceleration, g, and a correction factor, k, which depends on the shape of the holes:

$$V = (2\pi d)/(k\rho g)$$

The variation in bead diameter, d, for gelled alginate beads can be expressed as a function of the rotation velocity, ω:

$$d = (1/\omega^2)^{1/3}$$

As has been observed for simple dropping, the diameter, d, has to be corrected by a factor of 0.84 to 0.95, depending on the rotation velocity used, because the drop leaves behind a portion of the pendant drop upon breaking. The landing radius of the drops on the liquid surface must be taken into account to avoid splattering of the drops on the reactor walls. The landing radius, r, is dependent on the velocity, v, of the drops when leaving the hurler, the height, h, of the holes above the liquid surface, and the acceleration force, g:

$$r = v(2h/g)^{0.5}$$

Figure 4. Liquid-Jet-Based Methods

Dropping methods can be scaled up only by the parallel use of several needles, because drop formation depends on a relatively slow liquid velocity. Hence, dropping methods are limited to about 200 mL/h per needle. To overcome this problem, several methods for producing droplets from liquid jets have been developed, and several liters of microcapsules can be produced. The maximum productivity of these systems is limited due to the fact that the pressure needed to ensure flow increases with the second power of the liquid velocity, and with increasing liquid viscosity and decreasing orifice diameter. Pressure can be calculated using the following equations with pressure, P, resistance coefficient, χ, liquid density, ρ, liquid velocity, v, needle diameter, d, needle length, I, Reynold's number, Re, and the liquid viscosity, η:

$$\Delta P = (\chi \rho v^2/2)(l/d)$$

$$Re = v\rho d/\eta$$

and

$$\chi = 64/Re \text{ for } Re < 2{,}320 \text{ (laminar flow)}$$

or

$$\chi = 0.3164/Re^{0.25} \text{ for } 3{,}000 < Re < 10{,}000 \text{ (turbulent flow)}$$

or

$$\chi = 0.0054 + 0.3964/Re^{0.3} \text{ for } 20{,}000 < Re < 10^6 \text{ (turbulent flow)}$$

Dipping Jet. The dipping jet method is the simplest process for producing a large amount of microcapsules. It depends on the fact that a liquid jet at high velocity disintegrates into many drops when penetrating a fluid. Drop formation depends on irregular dynamic processes and leads to drops with a large size distribution (63,64). This method has been used to immobilize the fungi *Claviceps purpurea* in alginate particles for further production of alcaloids in a gas–solid fluidized-bed reactor. Researchers produced 110-L capsules with a mean diameter of 2.5 mm (65).

Vibrating Jet Breakage. Lord Raleigh influenced liquid jets with tuning forks in the late nineteenth century. He observed that vibration can force a liquid jet to disintegrate into equal drops if the wavelength of the vibration is greater than the perimeter of the liquid jet. He showed that the frequency, f, for maximum instability is related to the jet velocity, v, and the wavelength, λ (66):

$$f = v/\lambda$$

When a laminar-flowing jet is mechanically disturbed at this frequency, uniform drops are formed. The optimum wavelength, λ_{opt}, for breakup can be calculated with the needle diameter, d, dynamic viscosity, η, liquid density, ρ, and the surface tension, σ (67):

$$\lambda_{opt} = 2^{0.5}\,\pi d(1 + (3\eta/(\rho\sigma d)^{0.5}))^{0.5}$$

By considering that the jet will break into liquid cylinders with the wavelength λ, each of which will form uniform droplets, the diameter of the droplets, d, can be calculated:

$$d = (1.5\ d^2\lambda)^{1/3}$$

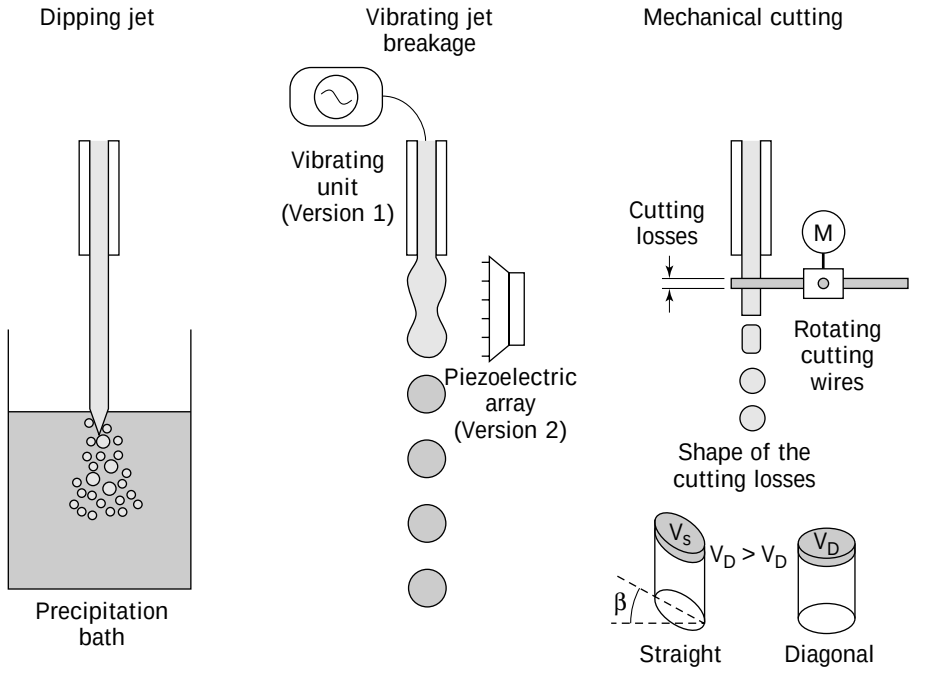

Figure 5. Liquid-jet-based extrusion technologies.

Mechanical Cutting. The principle of the mechanical cutting encapsulation method is to cut a liquid jet with a rotating wire into a series of uniform liquid cylinders behind the cutting wire. Due to surface tension, the liquid cylinders form drops immediately as they fall down into the precipitation bath. The bead build volume, V, of the cylinder can be calculated from the cutting angle, β, which is a function of the liquid velocity, v, and the local velocity of the wire, w, at the cutting point. Other relevant parameters are the thickness of the wire, d_w, the number of revolutions, n, of the cutting wire, the number of wires, z, and the nozzle diameter, d.

$$V = 0.25\ \pi d^2((v/(nz)) - (d_w + d\ \sin\beta)/\cos\beta))$$
$$\text{with } \beta = \arctan(v/w)$$

Because the wire used for cutting cannot be infinitesimally small, and its size is also determined by the material, it slings away about 10–20% of the liquid jet; this can be considered lost material. This cutting loss, V_L, can be determined as follows:

$$V_L = 0.25\ \pi d^2(d_w/\cos\beta + d\ \tan\beta)$$

When the cutting device is arranged at an optimal angle, α, depending on the liquid jet's velocity, the the drop volume is affected, and cutting loss can be reduced further:

$$\alpha = \arcsin(v/w)$$
$$V = 0.25\ \pi d^2((v/nz) - d_w)$$
$$V_L = 0.25\ \pi d^2 d_w$$

The cutting loss can also be reduced by use of a thinner wire for cutting. However, if a stainless steel wire becomes thinner than 0.2 mm, distortion effects of the wire can be observed when using fluids of high viscosity. Therefore, special stabilized wires 0.06 mm in diameter have been designed; in combination with diagonal cutting, they reduce cutting loss to only 3.3% (68,69).

This method is especially suited to produce beads from high-viscosity polymer solutions, with high productivity rates of up to 20 kg/h for 1-mm beads. This method has been used to immobilize a variety of microorganisms for further use in wastewater treatment experiments.

Liquid–Liquid Emulsification

Microcapsules can be obtained from dispersion of one liquid into another followed by a membrane-forming process. Generally, dispersions can be obtained from static and dynamic mixers. However dynamic mixers are preferred for microencapsulation because of the need to stabilize the dispersion until microcapsule formation has taken place, otherwise coalescence leads to increasing drop size.

Dynamic Mixer. It is advantageous to use an impeller that disperses the lighter liquid in both the center and the periphery at the same impeller speed. The optimum impeller diameter, d, depends on the vessel diameter, D, and presence of baffles:

$$d = D/3 \text{ (impeller)}$$

or

$$d = 0.4\ D \text{ (impeller in baffled vessels)}$$

The minimum agitation speed, n, required to disperse a dispersed (index D) liquid into a continuous (index C) liquid by using a four-paddled stirrer centered in a flat-bottomed cylindrical vessel with a liquid height equal to the vessel diameter, D, can be calculated from the liquid densities, ρ, and the viscosity, η_H, of the continuous phase:

$$n = 750\ D^{-2/3}\ (\eta_c/\rho_c)^{1/9}\ ((\rho_c - \rho_D)/\rho_c)^{0.26}$$

The viscosity of the dispersed phase and the interfacial tensions can be neglected (70). Calculating the mean particle size is fairly difficult and depends on type and diameter of the stirrer, agitation rate, and the physical properties of the liquids and their relative amounts (71). Generally, droplet size and size distribution decreases with increasing agitator speed. Droplet sizes ranging from a few micrometers to several hundreds of micrometers have been reported. A variety of correlations have been published relating the Sauter mean diameter, d_{32}, of the droplets to the vessel geometry and the physical properties of the dispersion system. The most well known correlation is derived from the impeller diameter, d_I and speed, n, the Weber number, N_{We}, liquid density, ρ, interfacial tension, η, the dispersed phase volume fraction, φ, and two correlation factors, b and c (72):

$$d_{32}/d_1 = b(1 + c\varphi)\ N_{We}^{-0.6}$$

$$N_{We} = \rho n^2 d_1^3/\eta$$

Due to the considerable internal sheer forces applied during dispersion, this method is especially suited for microencapsulation of inanimated matter (73–75) or viruses and microorganisms (76,77), but it can also be adjusted to the needs of cell cultures (78,79).

SELECTED MICROCAPSULE-FORMING MATERIALS

There are many microcapsule-forming materials available, indicating that there is no such thing as an all-purpose material. Hence, various materials have been proposed as carriers. They are based on either natural polymers, such as the polysaccharides alginate, carrageenan, agarose (80), and chitosan (81,82), and proteins such as gelatin (83,84) and collagen, or synthetic polymers such as polyacrylates, polyurethane and its less-toxic derivates (85), and polyethers. Each material has its pros and cons with respect to physicochemical stability, biodegradability or degradation into units small enough for renal excretion (86,87), and influence on the entrapped cells. Sulfated polyanions, for example, have been successfully used to obtain and maintain stable single-cell suspensions of insect cells (88), whereas these polymers exhibit the opposite effect: the formation of multicellular spheroids on mammalian cells (89). Technical considerations such as simplicity of preparation, availability, and cost also have to be taken into account.

Calcium Alginate

Alginic acid is a polyuronic acid extracted from brown seaweeds and some bacteria, mostly derived from the genus *Pseudomonas*. Chemically, alginates are block copolymers of 1,4-linked β-D-mannuronic acid (M) and α-L-guluronic acid (G). The mannuronate residuals of the bacterial alginate are acetylate to some extent at positions O-2 and/or O-3. The residues, occuring in varying proportions, depend on the source, and the residues are arranged in block patterns comprising homopolymeric regions (MM blocks and GG blocks) linked with alternating regions of heteropolymeric regions (MG blocks). Divalent cations, such as Ca^{2+}, bind preferentially between GG blocks, which appear to have preferred binding sites. Therefore, the composition (20–75% G content) and molecular size of the polymer impacts on the porosity, stability, gel strength, and swelling behavior (90–93).

Interfacial polymerization of alginate and Ca^{2+} is instantaneous, with precipitation of calcium alginate followed by a more gradual gelation of the interior as calcium ions penetrate through the alginate. During formation of gel beads, the biopolymer localized at the bead center moves gradually to the bead surface by attracting the ionotropic cations, which induce gelation. Consequently, the immobilized material flows with the macromolecules to the periphery of the bead, producing a superficial crust. At the same time the bead volume is reduced due to cross-linking of the macromolecules and expulsion of water. The interior of the bead consists of a fluffy core surrounded by a medium gelled zone containing supramolecular structures such as shafts and cavities. These structural inhomogeneities originate from gradients of local concentrations of components during the gelling process or the presence of chemically inert substances such as PEG. They remarkably affect the strength of beads and their permeability for low and high molecular weight components (94,95).

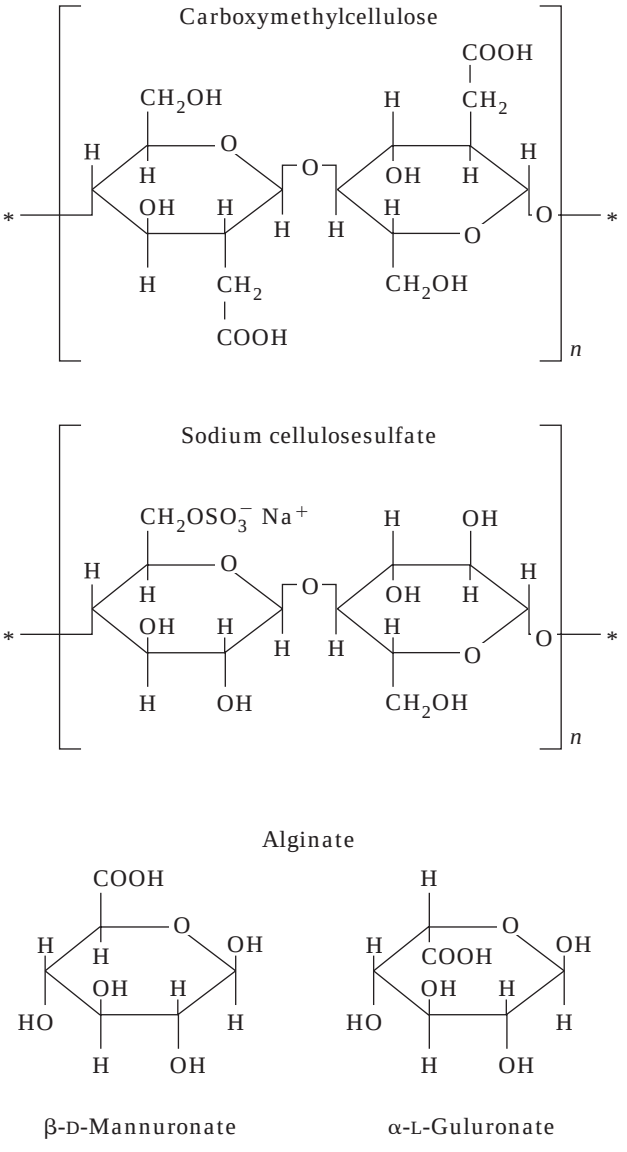

Figure 7. Polysaccharides used for encapsulation (I).

Calcium alginate beads are very stable for long periods and can tolerate a pH range from 3 to 10 at 25 °C. Thermal stability is also good, and beads can withstand incubation temperatures of up to 85 °C at pH 7.0. Destabilization of calcium alginates is promoted by chelating agents, which remove divalent cations. Phosphate, citrate, or EDTA should be avoided. The breaking of beads during fermentation of microorganisms is mainly caused by low initial alginate and/or high initial cell concentration, whereas the length of incubation has only a minor impact (96,97).

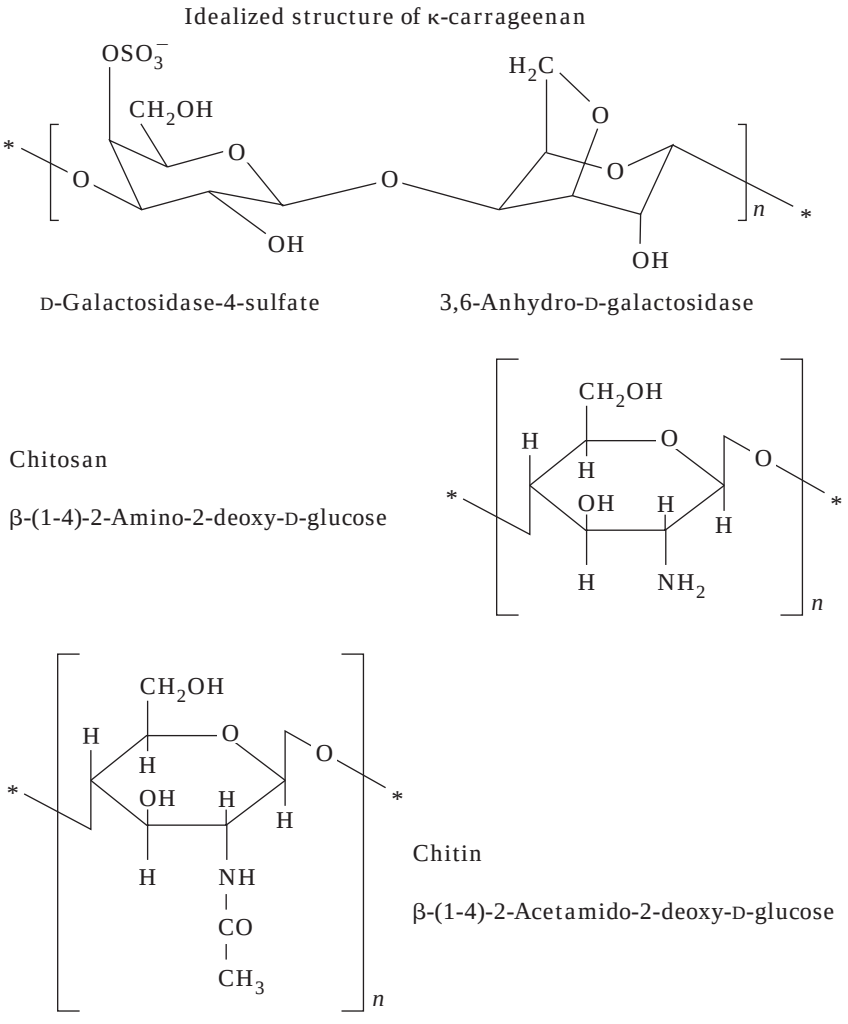

Figure 8. Polysaccharides used for encapsulation (II).

Microencapsulation in alginate beads is an inexpensive, versatile, and nontoxic method. It is used in food process industries to enhance fermentation productivity and cell stability. Costs for downstream processing are reduced by facilitating cell recovery and recycling (98). In the beverage industry, several processes including several different microorganism species have been developed for producing beer (99), wine (100), cider, (101) and ethanol (102).

Coating with Poly-L-Lysine

To prevent cell leakage from alginate beads in general and to provide immobilized cells with a semipermeable immunisolation barrier in particular, the coating of alginate beads with poly-L-lysine (PLL) has been introduced. This system is currently the best investigated and by far the most widespread microencapsulation system used in medicine.

First, viable cells are immobilized within an alginate bead. The bead is washed and transferred to another precipitation bath containing a PLL solution. Because the alginate is a negatively charged polymer, simplex membrane formation with the positively charged PLL is instant, decreasing the molecular weight cut-off of the system to about 100 kDa. Finally, the now-coated capsules are washed again and transferred to another precipitation bath containing a dilute solution of more oppositely charged polymers, with respect to the outer PLL surface. This final polyanion may be PEI (103) or alginate (104). The purpose of the additional coating is to neutralize nonreacted PLL and to mask the PLL that otherwise might provoke unwanted immune or fibrotic response. Because the outmost layer consist of alginate, purification of the alginate prior to use improves biocompatibility. Bioincompatibility is influenced by the chemical composition and, to a greater extent, by individual imperfections of the capsules; it has been clearly shown that fibrotic response against implanted capsules is associated with the presence of PLL around the capsules (105,106).

The stability of the PLL layer is governed mainly by the composition of the alginate, where alginate with a high M content ensures both more rapid binding of the PLL during the coating step and much thicker PLL layers. Because the reaction between the polymers is very fast, the rate-limiting step is the diffusion of PLL into the alginate gel. The free diffusion of the PLL is determined by gel porosity and the relative molecular weight of the polycation. Therefore the PLL layer can be improved through an increased concentration of PLL and by using a lower molecular

weight sample of PLL. However, a certain minimum polymer length is necessary to obtain stable capsules, so optimum PLL molecular weight is believed to be around 18 kDa (107,108).

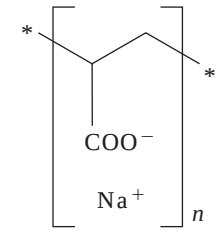
Improper performance of the microcapsules can be caused by a distorted coating process due to the presence of living cells on the surface area of the alginate bead. As previously pointed out, immobilized material has the tendency to be concentrated in the outer areas of alginate beads. The consequence is that small alginate beads are even more liable to improper coating caused by protruding cells than large beads, while cells in large beads are more likely to suffer from mass transport limitations. The additional entrapment of microspheres within a larger sphere can cover undesirable cell protuberances and debris integrated or exposed on the surface of the microsphere with a complete spherical shell of calcium alginate prior to the following coating process (109). Because only a small fraction of the alginate may diffuse throughout the coacervate membrane, the capsules are liable to osmotic swelling under physiological conditions because the cross-linking divalent ions of the bead are exchanged with monovalent ions. This swelling can also lead to capsule breakage. Strategies to reduce swelling include strengthening of the PLL layer by simply letting more polycations bind to the capsule surface, exchanging of a fraction of the calcium ions with ions with higher affinity toward the G blocks such as strontium or barium, using more alternate PLL–alginate layers, and decreasing capsule diameter. PLL-coated alginate capsules have been successfully used to treat diabetes in humans for periods of over one year (110–114).

Polyelectrolytes

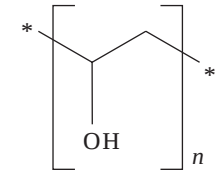
Polyelectrolytes are polymers that contain a charged group in their monomer repeating unit. They have been used as a flocculent in water purification, protein precipitation, and membrane technology. When brought into contact, aqueous solutions of oppositely charged polyelectrolytes immediately form water-insoluble but highly swollen precipitates or membranes. Membrane formation is completed within minutes.

Although there are is a vast number of possible polyanion polycation combinations, only a minority can be used for microencapsulation. For the encapsulation of living cells, it is strongly recommended that a polyanion be used for the inner polymer. This is in contact with the cells during capsule formation. The reason for this is that polycations are cytotoxic, especially those that contain quarternary ammonium groups such as PDADMAC. Polycations interact with the negatively charged phosphate groups of the cytoplasmic membrane, which finally leads to membrane rupture and cell death. This has been extensively studied with liposomes (115). Additionally, polycations form stable complexes with DNA and proteins (116,117). Membrane-bound polycations do not show these effects at all.

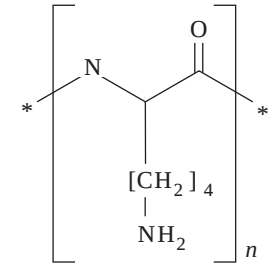
The best-suited polyanions to form a cell suspension containing drop are highly charged polysaccharide derivates with a molar mass in the range of 10^6 Da, with a cyclic backbone and pH-dependent charge. Typical examples are cellulose sulfate, carboxymethyl cellulose, and alginate. The corresponding polycation should contain either permanently charged quarternary amonium groups (PDADMAC) or a tertiary amine. The charge density should be between 50 and 100 mol%. The molecular mass may range from 10^3 to 10^6 Da, with high molecular weight species requiring a higher charge density to compensate for the lower diffusion coefficient (118–121).



Poly(acrylic acid)



Poly(vinyl alcohol)



Poly(L-lysine)

Figure 9. Polymers used for encapsulation.

Microcapsules from CS and PDADMAC exhibit immense mechanical stability up to 7 N per 3-mm capsule (122). About 0.3 N is required for this type of capsule to withstand the stress occurring in a heavily stirred tank reactor. The capsules typically possess a thin but very compact primary layer (a few microns) followed by a less densely packed region joining the inner layers of high porosity. The membrane properties mainly depend on the primary layer; therefore distortion of the membrane-forming reaction leads to microcapsules with very different properties. The molecular weight cut-off can be finely tuned according to the needs of the application. It can be as low as 5,500 Da for complete product recovery (123) or immunoprotection (40,124), in the range of 4.4×10^5 to 2.0×10^6 Da for continuous production of monoclonal antibodies

(53,125), or within the range of several microns to allow free virus passage for some gene therapy (126) and insect cell culture (54) applications.

Poly(Vinyl Alcohol)

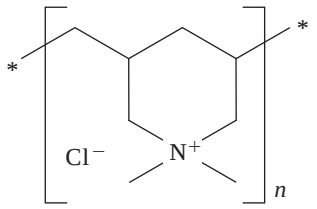
An aqueos poly(vinyl) alcohol (PVA) can be cross-linked through hydrogen bonding by a freeze–thaw process with hydroxyl groups on PVA molecules. The typical freezing temperature is around −20 °C. The mechanical strength of the cryogel greatly depends on the thawing rate, and shear modulus increases with decreasing thawing rate (preferably slower than 0.2 °C/min). During slow thawing, the system resides in the temperature range from −4 °C to −1 °C for a long time, and numerous hydrogen bonds are linked. It is important to consider that such interactions occur relatively slowly due to the high viscosity of the liquid microphase and the low temperature of the frozen system. Stability can be further increased by using a more highly concentrated PVA solution and storage in a frozen state. The ability of the gel to melt depends strongly on the preparation process. Thermoresistance is excellent, and immobilized thermophiles in PVA beads have operated at 65 °C for a period of 1 year and longer (127).

As a result of the formation of ice crystals during freezing, the cryogel has a high micro- and macroporous structure, which is necessary for nonhindered mass transport of any solutes for cultivation purposes. The polymer itself is nontoxic and biocompatible and is not degraded by most enzymes and microbes (128). The gel beads are stable in any biotechnology liquid media; swelling or softening can occur only under harsh conditions such as extreme pH or high concentration of chaotropic substances such as urea. Physiological concentrations of most compounds do not affect the gel or cause it to shrink, which increases stability (129,130). Apart from the freeze–thaw method, PVA can be cross-linked chemically by additions of compounds such as aldehydes or borates to form a hydrogel. Chemical cross-linking creates a gel of a comparable low strength; it can be described as having an appearance and strength similar to common gelatine (131). It is a very suitable method and, with the exception of the cross-linking reaction, nontoxic biomaterial has been studied extensively as membranes in artificial kidneys and as materials for skin replacement and contact with blood (132). It is therefore especially suited for coating beads. Microcapsules from PVL cryogels seem to be especially useful for use in wastewater treatment for removal of nitrogen (133,134), heavy metals (135), and environmental decontamination (136,137).

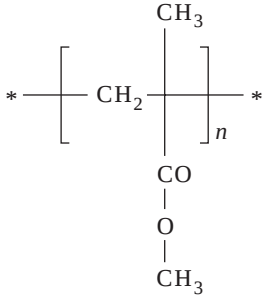
Poly(Methylmethacrylate-Hydoxyethylmethacrylate)

Poly(methylmethacrylate-hydroxyethylmethacrylate) (HEMA-MMA), which is 75–80% HEMA and 25–20% MMA, is a nonionic random copolymer. The polymer is water insoluble, which makes encapsulation more difficult. However water insolubility is considered an advantage because this is presumed to be a key factor leading to greater biocompatibility.

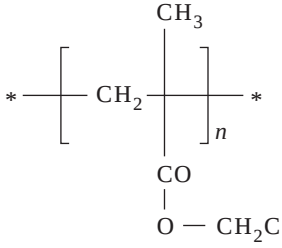
The cell suspension and the polymer are mixed together in a biocompatible solvent such as polyethylene glycol (PEG), and droplets are formed by jet extrusion or emulsification in another liquid. The membrane formation is initiated upon removal of the polymer solvent. This can be achieved easily by transferring the droplets in a phosphate-buffered saline (PBS) precipitation bath. The PEG is also soluble in the PBS solution, thus rapidly depleting the polymer solvent at the interface of the droplets, leading to a dense outer layer that provides all the resistance to the mass transfer. Below the dense layer are macroporous "trabecular" layers, similar to asymmetric phase-intervention membranes. Typically the membrane thickness ranges from 20 to 150 μm, with an average of 60 μm. The molecular weight cut-off of the membrane is above 52 kDa, possibly above 340 kDa, but can be influenced by the polymer composition, whereas the permeability of the membrane increases with higher HEMA content of the polymer and when the solubility parameters of the solvent and the precipitate are both high. Furthermore, the precipitation media influences the permeability of the microcapsule membrane with Tris-buffered glycerol, leading to denser



Poly(diallydimethylammonium chloride)



Poly(methylmethacrylate)



Poly(2-hydroxyethylmethacrylate)

Figure 10. Synthetic polymers used for encapsulation.

membranes that reflect the slower rate of precipitation in PBS or unbuffered glycerol. The membrane-forming process is not absolutely reliable with respect to complete membrane formation, and procedures to screen and remove capsules containing pinholes or flaws might be necessary for certain applications (138–140).

OUTLINE

INTRODUCTION

Most fermented foods are produced by mixed cultures acting on various substrates. Cheese, yogurt, pickles, whiskey, and sake (Japanese rice wine) are some examples of fermented foods (1). Numerous interactions occur between microbial communities, plants, and animals. The field of mixed culture is too broad to be reviewed completely in a short article. Of course, it is our belief that models, simulations, and stability analysis used for mixed culture systems are important aids in planning various experiments and interpreting the results (2). Pioneering works in this direction had been done by Henry Tsuchiya and Arnold Fredrickson. For example, we can see their careful results by referring to their review articles in this field (3,4). However, in spite of their extensive efforts, when using these aids general close agreement with data on the dynamic behavior of a complicated mixed culture has yet to be obtained. Thus we stress here applications of mixed culture and discuss case studies that demonstrate how these techniques can contribute to the design, operation, and control of mixed culture systems.

INTERACTION BETWEEN TWO SPECIES

Interactions between two species can be classified into three types: neutral (0), positive, and negative (5). Moreover, positive interactions are characterized into two interactions in detail: one is necessary for the survival of microorganisms (+*) whereas the other has an enhancing effect but is not obligatory for the life of these microorganisms (+). Negative interactions are also divided into two interactions: one directly affects other microorganisms (−*) and the other indirectly affects them (−).

Combination of these interaction categories results in more than nine groups classified under the following headings: neutralism (0, 0), mutual inhibition competition (−*, −*), competition—resource use type (−, −), amensalism (−, 0), parasitism (+, −), predation (+, −), commensalism (+, 0), proto-cooperation (+, +), mutualism (+*, +*). The first symbol in the parentheses shows the relationship of species 1 to species 2 and the second symbol shows the reverse relationship. The difference between parasitism and predation is only with respect to the size of species 1; that is, in parasitism, the size of species 1 is smaller than that of species 2 whereas in predation species 1 is larger than species 2.

Sometimes, of course, the actual relationship between two microorganisms cannot be classified into these nine groups because the relationship cannot be defined clearly. Nevertheless, the nine-group classification is useful for building a mathematical model and understanding the relationship between two species through simulation because a rough overview of the interaction between two microorganisms is possible based on this classification.

There are several examples of interactions belonging to these nine groups, but here only three examples that have been studied by the author are given. One is a mixed culture system of lactobacilli and propionibacteria in a bioreactor, the interaction of which is classified under proto-cooperation (+, +); the second example is a mixed culture system of lactobacilli and yeast classified as mutualism under a limited initial medium condition; and the last example is that of an activated sludge process consisting not of two microorganisms but of two competing groups of microorganism populations because of the convenience of the stability analysis and application of the result to the operation of the system.

One of the aims of this article is to show how models, simulations, and stability analysis are important aids in interpreting results of laboratory experiments or interacting phenomena and for the operation and control of a mixed culture system. Another aim is to demonstrate that the mixed culture system can be utilized for effective bioproduction. Mixed culture systems are encountered frequently in nature, but artificially constructed mixed culture systems can also contribute to the microbial production of various bioproducts such as bacteriocins.

MIXED CULTURE OF LACTOBACILLI AND PROPIONIBACTERIA

Bacteriocins are peptides produced from bacteria such as lactate-producing microorganisms, that is, lactobacilli, and effective antibiotics. Nisin is a typical bacteriocin effective against gram-positive microorganisms (6). Lactobacilli grow at pH higher than 4.0 and their growth is affected by the lactate produced, that is, product inhibition. Thus, the removal of lactate during fermentation is an effective way of optimizing nisin production, but the method of removal of lactate is a difficult problem to solve to assure optimal nisin production. In this study, we try to remove lactate by coculture of lactobacilli with propionibacteria, which can assimilate lactate efficiently.

Growth and Lactate Fermentation Characteristics of *Lactococcus lactis*

Figure 1 shows a typical result of the anaerobic batch culture of *Lactococcus lactis* subsp. *lactis* ATCC11454, a homolactate-producing bacterium. Without pH control, the pH decreased from 7.0 to 5.0 after 2 h of culture and to 4.5 after 3 h. Cell growth as well as nisin production stopped

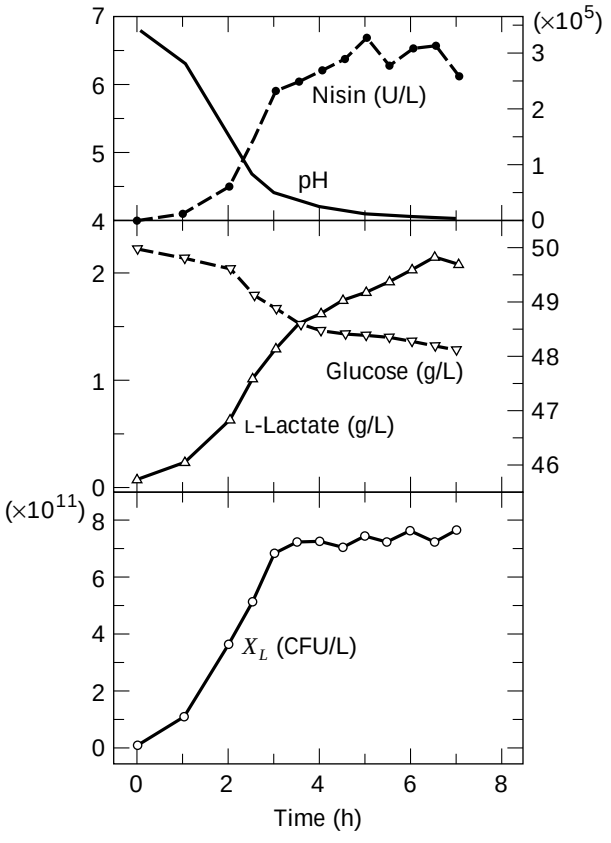

Figure 1. Time course of a batch culture of *Lactococcus lactis* without pH control. *Circles*, cell concentration; *inverted triangles*, glucose concentration; *triangles*, lactate concentration; *solid circles*, nisin concentration.

at 3 h after the start of culture. Lactate was produced at a level of approximately 1.5 g/L and was still produced at a decreased rate until 7 h later. Thus, control of pH to a value greater than 4.5 is essential for achieving a high cell growth rate. Also, nisin production is strictly associated with cell growth. Thus, for effective nisin production, the pH of the medium should be controlled to a value greater than 4.5. Finally, 300 U/mL nisin was produced in this batch culture without pH control.

To improve this low productivity of nisin, pH was controlled and lactate concentration was kept at a fairly low level by diluting the cultivation medium by adding fresh medium. This cultivation method is called repeated dilution culture. Using the method of repeated dilution culture, about 2,000 U/mL of nisin was produced after 10 h of operation. Cell growth, however, stopped at about 15 g/L of lactate. Thus, the control of lactate concentration kept to a level less than 15 g/L is also required for effective continuous production of nisin.

Growth Characteristics of Propionate Bacteria

Propionibacterium freudenreichii IFO12424 was used as a propionate-producing microorganism that can assimilate lactate. Figure 2 shows a typical result of anaerobic batch culture of *P. freudenreichii*. Lactate and glucose were used as carbon sources. From the figure, it can be seen that this

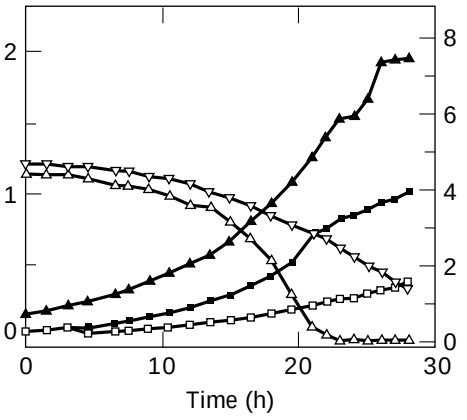

Figure 2. Time course of a batch culture of *Propionibacterium freudenreichii*. *Solid triangles*, cell concentration; *inverted triangles*, glucose concentration; *triangles*, lactate concentration; *open squares*, acetate concentration; *solid squares*, propionate concentration.

microorganism assimilates lactate. However, glucose was also assimilated, which is disadvantageous for the control of lactate concentration because glucose, the main carbon source for *L. lactis*, can be assimilated by *P. freudenreichii*. The glucose is competitively assimilated by both *L. lactis* and *P. freudenreichii*. If the population balance of these microorganisms is destroyed by the deficiency of glucose for *L. lactis* or by accumulation of lactate, stable operation of the mixed culture system will be difficult. Acetate was also produced by *P. freudenreichii*.

Interaction between Two Microorganisms

The interaction between the two microorganisms, *L. lactis* and *P. freudenreichii*, is illustrated in Figure 3. Lactate produced by *L. lactis* can be assimilated by *P. freudenreichii*. Without removing lactate, *L. lactis* cannot grow to a high density because of inhibition by low pH and by lactate itself. In this mixed culture system, the interaction between the two microorganisms is termed proto-cooperation.

Propionate and acetate produced by *P. freudenreichii* contribute somewhat to microbial contaminants in their

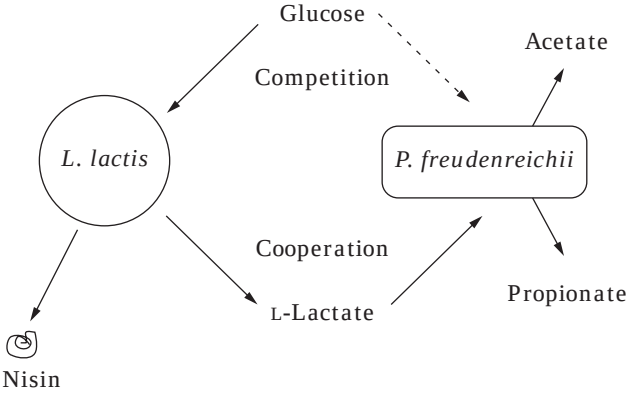

Figure 3. Interaction between *L. lactis* and *P. freudenreichii*.

capacities as antibiotics when they are used for food additives. However, these organic acids also contribute to the decrease in medium pH. Glucose, a carbon source for *L. lactis*, can be assimilated competitively by *P. freudenreichii*. In this sense the interaction between the two microorganisms is classified under competition. Thus, the interaction between the two microorganisms is a mix of cooperation and competition, that is, (±, ±), in glucose-rich medium. However, if we can control the glucose concentration to a level at which it is utilized by *L. lactis* but not by *P. freudenreichii*, the system can operate as a cooperation system. The most important issue is to manipulate or manage the system so as to represent the interaction (+, +), in practice, and to maintain a low supply of glucose, as well as preventing pH decrease of the medium. For this, mathematical modeling and simulation of the system are important tools.

Simulation Model of the Mixed Culture

Based on the kinetic data for cultivation, the following mathematical model was proposed under the assumption that the mixed culture can be described by use of the kinetic data of individual pure cultures.

Dynamics of the mixed culture system can be written by the following equations. To control the growth rate of *L. lactis* at a level comparable to that of *P. freudenreichii* by limiting glucose concentration, a fed-batch culture was employed. The cell growth rate for *L. lactis* in fed-batch culture is written as

$$\frac{dX_L}{dt} = \left(\mu_L - \frac{F}{V}\right)X_L \tag{1}$$

and the rate for *P. freudenreichii* is written as

$$\frac{dX_P}{dt} = \left(\mu_P - \frac{F}{V}\right)X_p \tag{2}$$

where X_i ($i = L,P$) and μ_i are viable cell concentration and specific growth rate, respectively. In these equations, the subscripts L and P represent *L. lactis* and *P. freudenreichii*, respectively, and F and V indicate the flow rate of the feeding medium and the liquid volume in the tank, respectively. Nisin (N, U/mL) production by *L. lactis* is written by

$$\frac{dN}{dt} = \rho_N X_L - \frac{F}{V}N \tag{3}$$

Propionate (P, g/L) production by *P. freudenreichii* is written as

$$\frac{dP}{dt} = \rho_P X_P - \frac{F}{V}P \tag{4}$$

Also, acetate (A, g/L) production by *P. freudenreichii* is written as

$$\frac{dA}{dt} = \rho_A X_P - \frac{F}{V}A \tag{5}$$

where ρ_k is the specific production rate of product k ($k = A,L,N,P$). Lactate production by *L. lactis* and its assimilation by *P. freudenreichii* can be summarized as

$$\frac{dL}{dt} = \rho_L X_L - v_{LP}X_P - \frac{F}{V}L \tag{6}$$

As a result of glucose assimilation by both organisms, the dynamics of glucose concentration (S, g/L) can be written as

$$\frac{dS}{dt} = -v_{SL}X_L - v_{SP}X_P + \frac{F}{V}(S_F - S) \tag{7}$$

where v_{ji} is a specific uptake rate of substrate j by microorganism i ($j = L,S$; $i = L,P$).

The dynamic pH change should be described by a mathematical model in which the following three types of equations are necessary. For example, for lactate concentration, one equation describes the equilibrium between dissociation and association for ionization of lactate such as

$$K_L = \frac{[L^-][H^+]}{[LH]} \tag{8}$$

where K_k is a dissociation constant for product k ($k = A,L,P$).

The second equation describes the total balance between ionized lactate and nonionized lactate $[LH]$ as

$$L_{MT} = [L^-] + [LH] \tag{9}$$

where L_{MT} is the mole-based total lactate concentration. From equation 8, nonionized lactate $[LH]$ is described by other variables, $[H^+]$ and $[L^-]$, and is substituted into equation 9 to give

$$L_{MT} = [L^-] + \frac{[L^-][H^+]}{K_L} = [L^-]\left\{1 + \frac{[H^+]}{K_L}\right\} \tag{10}$$

Then,

$$[L^-] = \frac{L_{MT}}{\left\{1 + \frac{[H^+]}{K_L}\right\}} = \frac{L_{MT}}{(1 + 10^{-pH+pK_L})} \tag{11}$$

where pK_L is defined in the same way as pH and $pK_L = -\log_{10}(K_L)$. In a similar way, ionized propionate $[P^-]$ can be written as

$$[P^-] = \frac{P_{MT}}{(1 + 10^{-kpH+pK_P})} \tag{12}$$

Also, the ionized acetate $[A^-]$ can be written as

$$[A^-] = \frac{A_{MT}}{(1 + 10^{-kpH+pK_A})} \tag{13}$$

These mole-based concentrations can be related to the weight-based concentrations as

$$L_{MT} = \frac{L}{MW_L}, \; P_{MT} = \frac{P}{MW_P} \text{ and } A_{MT} = \frac{A}{MW_A} \quad (14)$$

Here MW_k ($k = A,L,P$) is the molecular weight of chemicals k.

Finally, the following total ion balance should be considered.

$$[H^+] + X_B = [OH^-] + [L^-] + [P^-] + [A^-] + X_A \quad (15)$$

where X_A and X_B are the concentrations of strong acid and base in the medium, respectively. By substituting equations 11, 12, and 13 into equation 15 and using the definition of pH:

$$X_A - X_B = 10^{-pH} - 10^{pH-14} - \frac{L_{MT}}{1 + 10^{-pH+pK_L}} - \frac{P_{MT}}{1 + 10^{-pH+pK_P}} - \frac{A_{MT}}{1 + 10^{-pH+pK_A}} \quad (16)$$

By differentiating this equation with respect to time t:

$$\frac{d(X_A - X_B)}{dt} = \frac{\partial f}{\partial pH}\frac{dpH}{dt} + \frac{\partial f}{\partial L_{MT}}\frac{dL_{MT}}{dt} + \frac{\partial f}{\partial P_{MT}}\frac{dP_{MT}}{dt} + \frac{\partial f}{\partial A_{MT}}\frac{dA_{MT}}{dt} \quad (17)$$

where f represents the right-hand side of equation 16. If we can assume that

$$\frac{d(X_A - X_B)}{dt} = 0 \quad (18)$$

then

$$\frac{dpH}{dt} = \frac{1}{\left(\frac{\partial f}{\partial pH}\right)}\left\{-\left(\frac{\partial f}{\partial L_{MT}}\right)\frac{dL_{MT}}{dt} - \left(\frac{\partial f}{\partial P_{MT}}\right)\frac{dP_{MT}}{dt} - \left(\frac{\partial f}{\partial A_{Mt}}\right)\frac{dA_{MT}}{dt}\right\} \quad (19)$$

Now

$$\frac{\partial f}{\partial L_{MT}} = \frac{-1}{(1 + 10^{-pH+pK_L})}, \frac{\partial f}{\partial P_{MT}} = \frac{-1}{(1 + 10^{-pH+pK_P})}, \frac{\partial f}{\partial A_{MT}} = \frac{-1}{(1 + 10^{-pH+pK_A})} \quad (20)$$

and

$$\frac{\partial f}{\partial pH} = \mathrm{Ln}10\left[-10^{-pH} - 10^{pH-14} - \frac{L_{MT}\cdot 10^{-pH+pK_L}}{(1 + 10^{-pH+pK_L})^2} - \frac{P_{MT}\cdot 10^{-pH+pK_P}}{(1 + 10^{-pH+pK_P})^2} - \frac{A_{MT}\cdot 10^{-pH+pK_A}}{(1 + 10^{-pH+pK_A})^2}\right] \quad (21)$$

can be easily derived. Taking into account that equation 8 is not always valid, a correction term was introduced into the denominator of equation 19 as 1/230, which was determined using experimental data of the mixed culture system and resulted in the following equation (22). Finally, the pH change can be described by

$$\frac{dpH}{dt} = \left\{-\frac{1}{(1 + 10^{-pH+pK'_L})}\frac{dL_{MT}}{dt} - \frac{1}{(1 + 10^{-pH+pK'_P})} \cdot \frac{dP_{MT}}{dt} - \frac{1}{(1 + 10^{-pH+pK_{AL}})}\frac{dA_{MT}}{dt}\right\} \div \left\{\frac{1}{230} + \mathrm{Ln}10\left[10^{-pH} + 10^{pH-14} + \frac{L_{MT}\cdot 10^{-pH+pK_L}}{(1 + 10^{-pH+pK_L})^2} + \frac{P_{MT}\cdot 10^{-pH+pK_P}}{(1 + 10^{-pH+pK_P})^2} + \frac{A_{MT}\cdot 10^{-\&pH+pK_A}}{(1 + 10^{-pH+pKA})^2}\right]\right\} \quad (22)$$

where the dynamic change of L_{MT}, P_{MT}, and A_{MT} can be calculated using equations 4, 5, 6, and 14. Finally, the kinetic parameters such as μ_i, v_{ji}, and ρ_k ($i = L,P$, $j = L,S$, $k = A,L,N,P$) are given as a function of pH as well as substrate concentration, and the dynamic behavior of the fed-batch culture can be simulated using the mathematical model described by equations 1 through 7, 14, and 22.

Control of pH by Adjusting an Appropriate Initial Population

To maintain the culture pH at a value higher than 5.0 for a long period, *P. freudenreichii* should grow at a fast rate so that lactate is assimilated well. By comparing the specific growth rates of both microorganisms, it can be seen that *L. lactis* grows at a much faster rate than *P. freudenreichii*. This result means that lactate produced in correlation with *L. lactis* growth will accumulate in the fermentor if there is no control of the growth of *L. lactis*. For control of the growth rate of *L. lactis*, a fed-batch culture was employed. By manipulating the exponential feeding rate of glucose (in this case, μ_L was set at 0.2 h^{-1}; initial tank volume at 1.5 L, and initial glucose concentration at 2 g/L), the growth of *L. lactis* can be controlled. The mathematical model proposed here can be used for simulation of this exponential fed-batch mixed culture system. The kinetic parameters of *L. lactis* that depend on the pH were determined from the data for the pure batch culture. Other kinetic parameters were also determined from the experimental data.

By changing the initial cell populations of *L. lactis* and *P. freudenreichii*, the dynamic behavior of the mixed culture can also be altered. In this way the most appropriate initial cell populations were selected. After several simulation studies, an appropriate initial ratio of cell concentration of *L. lactis* to that of *P. freudenreichii* was determined as 1:14. The simulation result is shown in Figure 4. Here, to easily compare the simulation and experimental data, the cell concentration of *L. lactis* is represented by cell number whereas that for *P. freudenreichii* is by dry cell weight, because in the experiment the cell concentration of *P. freudenreichii* was calculated by subtraction of the

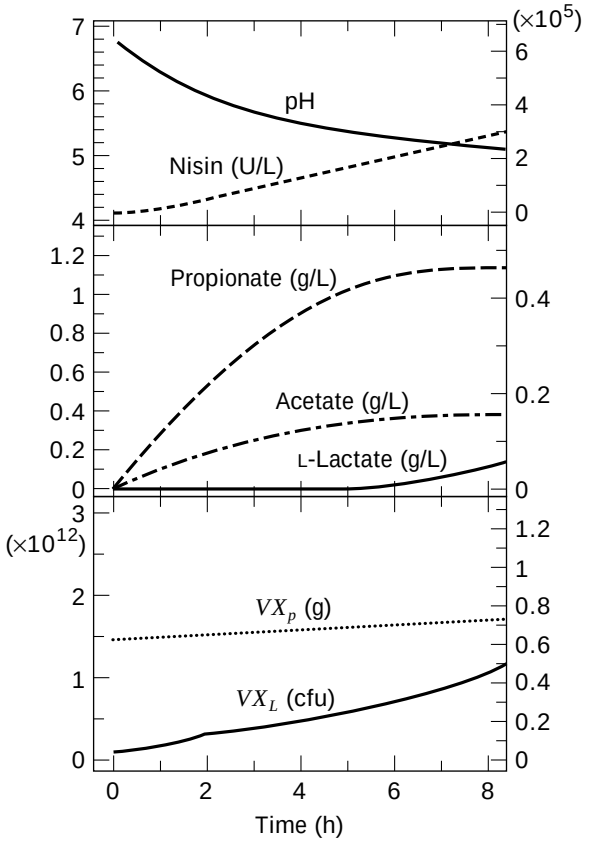

Figure 4. Simulation of a mixed culture for effective nisin production.

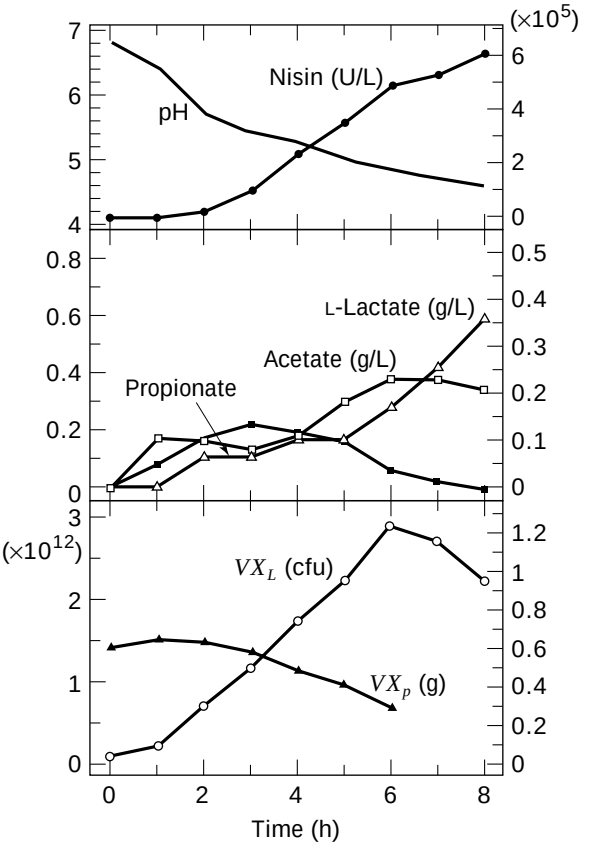

Figure 5. Experimental result of a mixed culture of *L. lactis* and *P. freudenreichii*. *Circles*, cell concentration of *L. lactis*; *solid triangles*, cell concentration of *P. freudenreichii*; *triangles*, lactate concentration; *open squares*, acetate concentration; *solid squares*, propionate concentration; *solid circles*, nisin concentration.

amount of dry cell weight of *L. lactis* converted from the cell number counted by plate colony from the total dry cell weight. It is shown that pH will be maintained at a value higher than 5 for a period of 5 h and that nisin will be produced much more effectively than for a given specific growth rate of *L. lactis*.

Experimental Result for the Mixed Culture

Figure 5 shows an experimental result of the mixed fed-batch culture with the same initial cell concentrations of both microorganisms, *L. lactis* and *P. freudenreichii*, as those in Figure 4. The pH could be controlled until 5 h from the start of cultivation. However, under these conditions *P. freudenreichii* could not grow well, whereas *L. lactis* grew faster than the estimated rate shown in Figure 4. The reason why there is a large difference between dynamic simulation using the mathematical model and experimental data is not clear at this point. However, the simulation model at least can be used for forecasting the dynamics of the mixed culture and for adjusting the initial cell concentrations of both species so as to achieve effective production of nisin by this mixed culture. Finally, the experimental data for the mixed culture show that the final nisin concentration was improved twofold.

In the near future, the process will be improved further after determination of the reason for the difference between the experimental data and the simulation data.

MIXED CULTURE OF LACTOBACILLI AND YEAST

To enhance bacteriocin productivity, a mixed culture system was employed as outlined in the previous section. However, the propionibacteria can assimilate glucose, which in the system described is the main carbon source of lactobacilli. Thus the glucose was competitively assimilated by both microorganisms, which may result in the need to use a fed-batch operation. One improvement that can be made to the system is use a main carbon source of lactobacilli which cannot be assimilated by another microorganism. Only the lactate produced by the lactobacilli should be a carbon source of the second microorganism. From this aspect, maltose was chosen as a carbon source of lactobacilli, and a microorganism that can assimilate lactate but not maltose was selected. From kefir, a type of yogurt, such a microorganism, *Kluyveromyces marxianus*, was isolated. The following mixed culture system was then constructed.

Interaction between *Lactococcus lactis* and *Kluyveromyces marxianus*

Kluyveromyces marxianus MS1, isolated from a type of yogurt (kefir), can assimilate lactate as a carbon source. *K.*

marxianus cannot assimilate starch and maltose directly whereas *L. lactis* can grow on maltose. Whether *L. lactis* could grow and produce nisin under aerobic conditions had to be determined because *K. marxianus* grows under aerobic conditions. The results indicated that there is no significant difference in the productivity of nisin and growth rate of *L. lactis* between aerobic and anaerobic conditions. Thus, the mixed culture system can be operated under aerobic conditions. The interaction of the two microorganisms is illustrated in Figure 6. *L. lactis* can assimilate the maltose and produce lactate, which can be assimilated by the yeast, *K. marxianus*. This cooperative interaction results in a very low or undetectable lactate concentration, which may enhance the growth of *L. lactis* as well as nisin production. Thus, the relationship between these microorganisms can be termed proto-cooperation or mutualism because their relation can be summarized by (+, +*).

Mixed Culture of *L. lactis* and *K. marxianus*

From the characteristics of the interaction, it is expected that a high growth rate of *L. lactis* as well as high productivity of nisin will be achieved. In Figure 7, the experimental data indicated that the system worked as desired because the lactate concentration can be kept at almost zero or at least at an undetectable level and *L. lactis* grew significantly. The monoculture of *L. lactis* using maltose as a carbon source stopped at 7 h because of low pH (Fig. 7a). Under mixed culture, pH could be maintained well around 6.0 (Fig. 7b) even by a manual dissolved oxygen (DO) concentration control. The role of DO control is explained later. Also, *L. lactis* as well as *K. marxianus* could grow at a level fourfold higher than the monoculture of *L. lactis*. The yeast also grew well and the nisin yield reached 1,400 U/mL at the end of fermentation after only 8 h operation (Fig. 7c), similar to the amount obtained in the pH-controlled repeated batch culture, which was fourfold higher than the level in the monoculture of *L. lactis*.

The pH level of the culture medium can be controlled by the lactate uptake rate linked with the growth of *K. marxianus*. On the other hand, the growth of *K. marxianus* can be controlled by the DO level. Then, the DO level can control the pH level in this mixed culture system. Finally, it is clear that a setpoint for the DO control by changing the agitation speed can control pH level. This is a so-called cascade controller. Based on this cascade controller concept, the pH level could be maintained almost completely automatically at a constant level by manipulating the agitation speed of the fermentor. Finally, the result of this mixed culture experiment with cascade control of pH is shown in Figure 8; the product nisin concentration was enhanced more and reached about 4,000 U/mL after 11 h of operation, which was almost 10 fold that by anaerobic monoculture of *L. lactis* without pH control and about twice as much as by anaerobic monoculture of *L. lactis* with pH control by NaOH addition.

The system developed here functions successfully. However, it should be stressed that a simple and reliable method for the measurement of individual cell concentrations should be developed. One way is to use a flow cytometer that can count individual cells if the cell size of each population is significantly different. One example of flow cytometry measurement of the concentration of lactobacilli and yeast in the mixed culture is shown in Figure 9. The abscissa of the figure represents the cell size, and one dot indicates one cell. Thus, densely clustered points means there are many cells. In this case, the lactobacilli cells are small compared with yeast cells. Using the scale of the abscissa, it may be possible to count each population. However, to identify the two populations of microorganisms more effectively, staining of their DNA using a dye such as propidium iodine (PI) also aids in discriminating the yeast and lactobacillus by cell size as well as by DNA content under two-dimensional plotting as shown in the figure. The ordinate indicates the DNA contents represented by strength of PI staining. In Figure 9, the clustering between lactobacilli and yeast cells becomes evident because the two populations separate like two islands.

DYNAMICS OF AN ACTIVATED SLUDGE PROCESS AS A MIXED CULTURE SYSTEM

An activated sludge process is a typical mixed culture system. The formation of activated sludge flocs as a result of the overgrowth of filamentous microorganisms results in a phenomenon known as bulking, which is a major problem in the operation of the activated sludge process. Wastewater composition, sludge loading, DO concentration, the feeding pattern of the aerator, and pH are some of the factors involved in the bulking phenomenon. The objective of this work is to develop a simple mathematical model describing the bulking phenomenon caused by high sludge loading, including the growth kinetics of microorganisms in an aeration tank in terms of a mixed culture system and the ability of the sludge to settle, and to obtain some means of preventing and controlling bulking. In our experiment, only the sludge loading rate was changed; the other operating conditions such as pH and temperature were kept constant. The DO concentration in the aeration tank was maintained at a high level so as not to induce the bulking phenomenon. The model system selected for examination is a mixed culture of two groups of microorganisms, one having the ability to induce the formation of flocs and the

other inducing bulking. The interaction between the two groups is classified under competition with respect to the utilization of the same substrate (7).

A continuous flow biochemical reactor in which a mixed culture of microorganisms is grown very often exhibits multiple steady states. The analysis of the stability of these steady states has been the subject of research. The techniques most frequently employed in determining the stability characteristics of a steady state are based on Liapunov's first method, which consists mainly of a linearization of the differential equations around the steady state and an examination of the eigenvalue of the Jacobian matrix. Here, the dynamic behavior of the activated sludge process, in which competition occurs with respect to assimilation of the substrate, is analyzed based on a mathematical model utilizing phase plane analysis and computer simulation. The results including those pertaining to the conditions that result in the system reaching the bulking steady state are very informative and useful for the practical operation of activated sludge processes.

Kinetics of Substrate Uptake and Cell Growth

The kinetics in two synthetic media, one in which the carbon source is glucose and polypeptone (medium A) and the other in which the carbon source is glucose (medium B), were studied experimentally using batch culture. In this system, the chemical oxygen demand (COD) concentration, S, is considered to be a limiting substrate for describing the kinetics of the process. Both groups of microorganism populations, that is, the floc-forming and the bulking-inducing groups, were cultured by feeding different types of synthetic medium into a batch reactor on a fill-and-draw basis. Two synthetic media were used to purify and main-

tain each population of microorganisms for more than 2 months. Using medium A in which the initial COD concentration was about 110 mg/L, the sludge settled well and was called floc-forming sludge. On the other hand, using medium B in which the initial COD concentration was about 450 mg/L, the sludge did not settle well, that is, it had a high sludge volume index. The sludge could be kept stable for more than 1 month by the feeding of medium B and was called bulking sludge. From the results of microscopic observation, it was determined that the bulking sludge was composed of filamentous microorganisms such as *Sphaphaeroutilus* sp., while the floc-forming sludge did not contain such microorganisms.

A 1-L jar fermentor equipped with automatic temperature control, an air flow rate indicator, DO sensors, and a magnetic agitator was used. The kinetics of floc-forming and bulking populations were analyzed from the batch experiments using medium A or B with various initial COD concentrations. A typical result (Fig. 10) shows the time courses of floc-forming sludge concentration X_F and the COD concentration S with medium A. From this figure, it was shown that the specific growth rate μ_F and the substrate uptake rate v_F could be represented by a linear relationship with respect to substrate (COD) concentration S and that the yield coefficient of the sludge from COD was constant. Similar results for growth rates and uptake rates as described here were obtained for both types of sludge and for both types of media. The mathematical forms of growth rates and uptake rates thus are as follows:

$$\mu_j = K_j(S - S_j) \tag{23}$$

and

$$v_j = \frac{-1}{Y_j}\mu_j \quad j = F, B \tag{24}$$

where F and B mean floc-forming and bulking sludge, respectively. The solid lines in Figure 10 show the calculated values using the estimated parameters. The kinetic model described by equations 23 and 24 is generally acceptable in the low COD concentration range.

The ability of the activated sludge to settle in the sedimentation vessel was also studied experimentally. An empirical description of the concentration of the sedimenting sludge related to the ratio of X_F/X_B was obtained. The ratio of the concentration of the settled sludge, X_g, to the con-

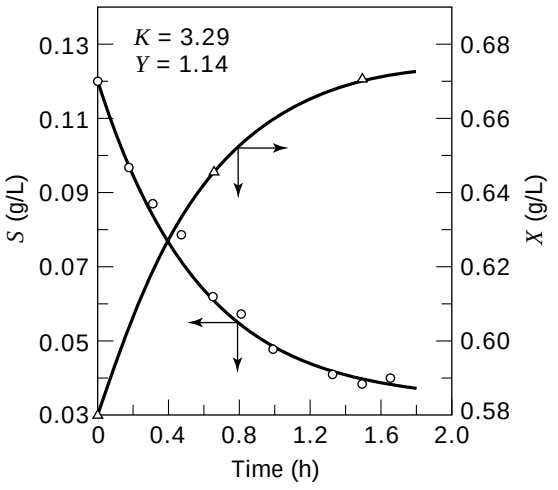

Figure 10. Batch culture of floc-forming sludge using medium A. *Circles*, chemical oxygen demand (COD) concentration; *triangles*, cell concentration.

centration of the sludge to be settled, X, which is denoted by χ, can be represented by

$$\chi = \frac{X_R}{X} = \alpha\left(\frac{X_B}{X_F} + \beta\right)^{-\gamma} + 1 \qquad (25)$$

Interaction between Bulking and Floc-Forming Sludges

It is assumed that there is competitive use of substrate between the bulking and floc-forming sludge. This assumption could be partially verified by the following experiment and computer simulation. When a fill-and-draw-type batch experiment is conducted from the point at which the ratio of the bulking to the floc-forming sludge is very small, the ratio of the bulking sludge to the total sludge increases gradually using medium B, and its ability to settle becomes poorer after more than 4 days from the start of the experiment. This experimental result can be simulated as shown in Figure 11 by the mathematical model given in equations 23 and 24. After 4 or 5 days from the start of the experiment, χ becomes almost 1.0; that is, the state of the sludge approaches bulking, which is reflected by the experimental data.

Mathematical Model of the Activated Sludge Process

For an activated sludge process in a completely mixed aeration tank and sedimentation vessel, a mathematical model of the system is derived. The mathematical model of the activated sludge process considered here is as follows:

$$\frac{dX_j}{dt} = \{(\chi - 1)q_r - q_i + \mu_j\}X_j, \quad j = F, B \qquad (26)$$

$$\frac{dS}{dt} = q_i(S_i - S) - \frac{\mu_F}{Y_F}X_F - \frac{\mu_B}{Y_B}X_B \qquad (27)$$

$$\mu_j = \begin{cases} K_j(S - S_j) & \text{for } S \geq S_j \\ 0 & \text{for } S < S_j, \end{cases} \quad j = F, B \qquad (28)$$

and

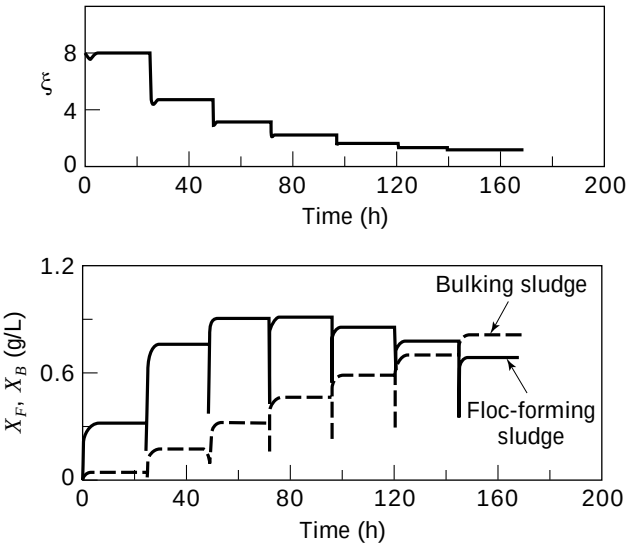

Figure 11. Simulation of fill-and-draw-type batch culture using medium B. After more than 4 days, the concentration ratio χ approached 1.0. After that, the bulking phenomenon was observed.

$$\chi = \alpha\left(\frac{X_B}{X_F} + \beta\right)^{-\gamma} + 1 \qquad (29)$$

where X_F, X_B, and S are the outlet concentration of the floc-forming sludge and the bulking sludge and the COD in the aeration tank, respectively, and S_i is the inlet COD concentration in the system; q_i and q_r are the inlet flow rate and recycled flow rate divided by the tank volume, respectively. Equations 26 through 29 are analyzed to obtain information about the bulking phenomenon caused by high organic loading. One of the important characteristics of process equations is that the growth rates of the bulking and floc-forming sludges intersect (Fig. 12). This result means that the interaction between the two sludges can be classified as competition for assimilation of the same substrate (COD). Using medium B, the relationship between the specific growth rates of both sludges becomes similar to those using medium A.

The intersection in Figure 12 defines the value of the COD concentration S_c at which both types of sludge, bulking and floc-forming, can coexist. As shown in Figure 12, in the region where COD is smaller than S_c, the specific growth rate of the floc-forming sludge is higher than that of the bulking sludge; that is, the floc-forming sludge may become dominant. On the other hand, in the region where COD is larger than S_c, the bulking sludge is dominant.

Another distinguishable feature of the mixed culture system employed here is the existence of the cell recycle stream. Reflecting on this feature, the coexistence of both sludges should be taken into account at a certain dilution rate, although the coexistence state does not occur without the cell recycle stream.

Dynamics of an Activated Sludge Process

Equilibrium Points. We next analyzed the dynamic behavior of equations 26 through 29 when the organic load-

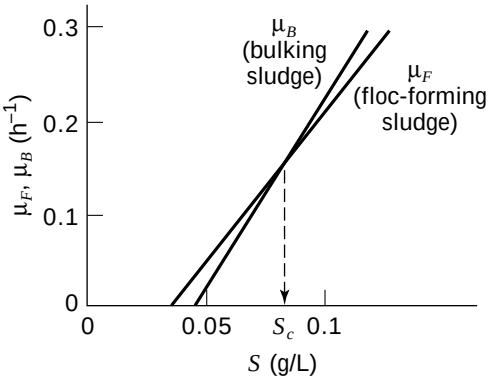

Figure 12. The specific growth rates of floc-forming sludge and bulking sludge using medium A.

ing rates S_i and q_i are changed. As the characteristics of a mixed culture system using medium B are similar to those using medium A, analysis is based on the parameters obtained using medium A. First, the possible steady states should be clarified.

It can be shown that there are, in general, four equilibrium points: normal state E-1 ($X_F \neq 0$, $X_B = 0$); bulking state E-2 ($X_F = 0$, $X_B \neq 0$); coexistence state E-3 ($X_F \neq 0$, $X_B \neq 0$); and washout state E-4 ($X_F = 0$, $X_B = 0$). The normal state, E-1, is the only desirable state for stable operation, and the bulking state, E-2, should be avoided. Figure 13 shows the relationship between these four equilibrium points in the state space. These points are given as intersections of three planes, called "isoclines," and the plane $X_B = 0$ or $X_F = 0$. An isocline is defined here as the curve or the plane along which the first derivative of

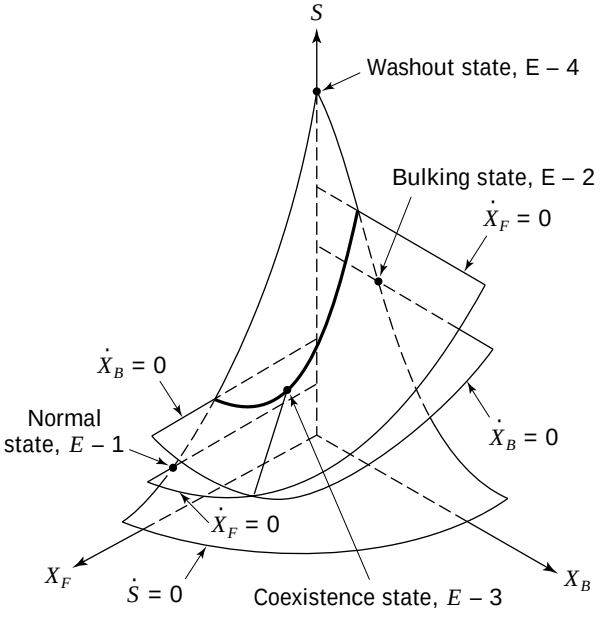

Figure 13. The possible independent equilibrium points, which are shown as intersection of isoclines and $X_F = 0$ or $X_B = 0$. Four possible points are shown as E-1 to E-4.

the state variables with respect to time t is zero excluding $X_B = 0$ and $X_F = 0$. Then, the isoclines are three planes that satisfy $dX_F/dt = 0$, $dX_B/dt = 0$, and $dS/dt = 0$ in equations 26 through 29. From the definition, the intersections of these planes are equilibrium points. For example, point E-1 is given as the intersection of both isoclines of $dX_F/dt = 0$ and $dS/dt = 0$, and the plane $X_B = 0$. The number of possible equilibrium points under a given operating condition is counted using the shapes and interconnections of these isoclines.

The trajectory of the state from a given initial condition to a final state is roughly estimated using these three isoclines because an isocline divides the gradient of a state variable into two regions having negative and positive values. From the gradient of the three state variables, the gradient of the trajectory in the state space is estimated. Finally, the maximum number of possible equilibrium points is four, as shown in Figure 13, and normal state E-1 is the only desirable state for the stable operation of the activated sludge process. The other states should be avoided. To make it possible for normal state E-1 to exist, parameters such as input flow rate q_i or recycled flow rate q_r and input COD concentration S_i must satisfy the following equations:

$$S_F \leq S_e \leq S_i \tag{30}$$

where

$$S_e = \frac{\{q_i - (\chi^* - 1)q_r + K_F S_F\}}{K_F} \tag{31}$$

Here χ^* is the value of χ at $X_B/X_F = 0$. This constraint was deduced from the assumption that normal state E-1 really exists. The same type of analysis can be performed with respect to the other equilibrium points.

Locally Stable Conditions of the Activated Sludge Process. The activated sludge process should be operated under conditions guaranteeing that the equilibrium point E-1 exists and is locally stable. The term locally stable means that the equilibrium point is asymptotically stable in the linearized system. The occurrence of the locally stable condition can be determined by checking the sign of the real part of the eigenvalues of the characteristic equation in the linearized system (8). Stability is guaranteed only in the vicinity of the equilibrium point. Of course, in practical operation, whether the system reaches the state E-1 from a given initial state depends on global stability, based not only on local stability but also on the global dynamic behavior. However, locally stable conditions provide useful information with respect to the stable operation of the activated sludge process. Using the locally stable condition, the domain of stable operation in the operating space consisting of S_i, q_i, and q_r can be obtained.

The locally stable conditions of four equilibrium points were deduced analytically as functions of the operating conditions S_i, q_i, and q_r. We showed that the coexistence state E-3 is unstable under all operating conditions. The locally stable conditions and the existence conditions of the four equilibrium points divide the domain of the operating

conditions into many regions. Such an analysis can be used to identify the existence and stability of an equilibrium point.

Figure 14 shows the region described by q_i, q_r, and S_i in which E-1 exists and is locally stable. Under the locally stable condition at E-1, S_e defined in equation 31 is as follows:

$$S_F \leq S_e \leq S_c \tag{32}$$

where S_c is the intersection of μ_F and μ_B as shown in Figure 12; that is, $\mu_F \geqq \mu_B$ in this region, and the floc-forming sludge becomes dominant. The well-known fact that high organic loading will cause the bulking phenomenon is verified using the model employed here (Fig. 14). This figure can also be utilized to determine the strategy required to obtain locally stable conditions. When the state of both sludges and COD concentrations does not change substantially from E-1, the system will be operated in a stable way as long as the operating condition is maintained in the region indicated in Figure 14. If the flow rate of wastewater q_i increases, the recycled flow rate q_r should be increased, as in Figure 14, to maintain the conditions in this locally stable region.

Figure 15 shows the region in which the bulking equilibrium E-2 is unstable or does not exist. In the domain of the operating conditions indicated in Figure 15, only E-1 is locally stable. Even though the bulking sludge increases slightly, based on the local stability it can be said that the desired operating state will be restored as long as the operating condition is maintained in this region. These conditions coincide with the well-known rule that the sludge loading rate should be kept low. The kind of deviation in the operating and initial conditions that renders the normal state E-2 unstable was clarified.

The locally stable conditions are not sufficient to maintain a stable operation that prevents the occurrence of the bulking phenomenon. This is because in practice locally stable conditions are valid only in the vicinity of equilibrium points. Therefore, the manipulating variables should be changed dynamically to maintain the system in normal state E-1 when disturbances have been introduced. The control problem has been solved (7). Finally, the interaction between the two sludges has been classified as competitive, and a mathematical model has been proposed and simulations as well as a stability analysis have been performed to determine the manner in which to operate the activated sludge process in a stable way.

OUTLINE

INTRODUCTION

Mutations are heritable changes in the genome that arise "spontaneously" or are induced by chemical or physical means. Mutational changes include deletions, duplications, translocations (transpositions), and base-pair substitutions. Base-pair substitutions are subdivided into transitions (a purine substituted for a purine, or a pyrimidine substituted for a pyrimidine) and transversions (a purine substituted for a pyrimidine and vise versa). There are two types of transitions (GC to AT and AT to GC), and four types of transversions (GC to CG, GC to TA, AT to CG, and AT to TA). Mutagenesis is an important aspect of fermentation process development for the production of primary metabolites (e.g., amino acids and vitamins) and secondary metabolites (e.g., antibiotics, antitumor agents, antihelmintic agents, and immunomodulators). Mutagenesis can be used to increase the levels of important precursors, cofactors, and enzymes involved in the biosynthesis of the desired product. It can also be used to eliminate competing nonessential biosynthetic pathways or to modify other parameters important in the fermentation process (e.g., culture viscosity, oxygen transfer, culture stability). There are two general approaches to mutagenesis, both of which are important at different stages of process development. The first approach is random chemical or physical mutagenesis. This is an indispensible approach to improve the production of complex secondary metabolites, because a priori it is essentially impossible to deduce what factors will be most important in the fermentation to improve the yield. The key to success with random mutagenesis is to identify procedures that give the optimum yields of mutants exhibiting the desired features. The second type of approach is more directed and can be focused specifically at rate-limiting steps in biosynthesis or at key regulatory elements. This generally requires more sophisticated molecular genetic tools and more knowledge about the genetics and biosynthesis of the product of interest. I discuss some key elements of the random and directed mutagenesis approaches, using secondary metabolite production in actinomycetes as models. Many of the methods and approaches can be adapted for other prokaryotes and for lower eukaryotes that have a haploid sporulation stage.

APPROACHES TO RANDOM BASE-PAIR SUBSTITUTION MUTAGENESIS

Comparative Mutagenesis

A number of chemical mutagens and UV light have been compared for their efficiencies of induction of mutations to spectinomycin resistance in *Streptomyces fradiae* (1,2). Of the mutagens tested, *N*-methyl-*N'*-nitro-*N*-nitrosoguanide (MNNG) was the most efficient, and UV light (UV) was the least efficient. The mutagens ranked in efficiency of mutation induction as follows: MNNG > 4-nitroquinoline-1-oxide (NQO) > methyl methanesulfonate (MMS) > ethyl methanesulfonate (EMS) > hydroxylamine (HA) > UV (Fig. 1). The efficiency of MNNG mutagenesis was enhanced by carrying out mutagenesis in the presence of chloramphenicol (4).

Optimizing Mutagenesis

The objective in optimizing mutagenesis conditions is to obtain the highest frequency of survivors containing single mutations altering secondary metabolite production. Higher levels of mutagenesis are not desirable because most mutations that alter product yields have negative effects (2). Therefore higher levels of mutagenesis will result in the coupling of gain mutations with loss-of-yield mutations. The optimum level of mutagenesis can be identified by statistical analysis of the progeny of mutagenesis. Because mutations, under ideal conditions, will be distributed among individual cells according to the Poisson distribution (2), the optimum condition giving a multiplicity of one mutation affecting secondary metabolite production per cell is obtained when 37% of the survivors of mutagenesis produce control yields (i.e., the null fraction of the Poisson distribution, $P_0 = e^{-m} = 0.37$, where the multiplicity (m) = 1). At this multiplicity, the fraction of cells containing only one mutation is also 37% (i.e., $P_1 = 1 \times e^{-1}/1!$). In *S. fradiae* the only mutagen capable of achieving

a mutational multiplicity of as high as 1 is MNNG. However, MNNG plus CM (4) gives much too high levels of mutagenesis to be a useful procedure for random mutagenesis.

Mutagen Specificity and Limitations of Current Protocols

The specificity of base-pair substitutions induced by mutagenic agents has been studied extensively in *Escherichia coli* (5–7). MNNG induces mutations by the transition pathway 99% of the time, and 95% of these are GC to AT transitions (5,7). EMS induces GC to AT transitions almost exclusively, and NQO induces mutations by this pathway about 90% of the time (5). UV induces a wider variety of transition and transversion mutations, but it appears to be too weak to be very useful in actinomycetes. Because MNNG, NQO, and EMS are among the most potent mutagens to choose from for streptomycetes, the spectrum of base-pair substitutions obtainable by chemical mutagenesis is almost completely limited to GC to AT transitions.

Streptomycetes and other actinomycetes have DNA containing very high G + C content (~70%). The G + C content in the third position in codons is generally >90%. Recently, the spectrum of potential amino acid substitutions induced by different transition or transversion mutation pathways at dominant streptomycete codons (those containing G or C in the third position) has been analysed (3). The GC to AT transition pathway cannot induce mutations at phenylalanine-, isoleucine-, asparagine-, or lysine-prevalent codons, nor can it generate codons for alanine, glycine, or proline. Of the other base-pair substitution pathways, the AT to CG transversion pathway is strikingly complementary to the GC to AT transition pathway. Thus AT to CG mutations can occur at phenylalanine-, isoleucine-, asparagine-, or lysine-prevalent codons and can also generate alanine, glycine, and proline codons (3). Twenty-six different amino acid substitutions can be generated by GC to AT transitions at prevalent codons, and 25 can be generated by AT to CG transversions. Importantly, none of the specific amino acid substitutions induced by one pathway can be induced by the other. Therefore, the simplest way to broaden the spectrum of base-pair substitution mutations for yield improvement would be to develop a mutagenic protocol that is specific for AT to CG transversions.

Approach to Expand the Range of Base-Pair Substitution Mutagenesis

No chemical mutagen induces AT to CG transversions as the primary pathway. However, in *E. coli* the *mutT* mutation causes ~1,000-fold enhancement in spontaneous AT to CG transversions (5,8). Because the *mutT* gene is highly conserved in bacteria, it should be present in streptomycetes. A system for reversible gene disruption has been proposed that would allow for the screening of mutants containing spontaneous AT to CG mutations in a *mutT* background, followed by direct selection of $mutT^+$ recombinational revertants that would have normal spontaneous mutation rates (3). The implementation of such a system awaits the cloning of an actinomycete *mutT* gene.

OTHER APPROACHES TO MUTAGENESIS

Gene Duplications by Genetic Engineering

Although gene duplications can arise as spontaneous or induced mutations at low frequencies, the process has not been harnessed as a general technique to improve product yields. In some cases, gene duplications or amplifications have been recognized after the fact as being associated with yield enhancement (9–12). Gene cloning methodologies and chromosomal insertion methods have provided the means to carry out directed gene duplications. These approaches can be used to alleviate rate limitations in secondary metabolite biosynthetic pathways, thus improving product yields and product quality (3,13–15).

The general approach for directed gene duplication is to identify a neutral site in the chromosome where genes can be inserted without changing the product yield or the fermentation properties of the production strain. The neutral site can be cloned, and a gene of interest can be inserted within the neutral site on a plasmid vector. The vector is introduced into the streptomycete host by transformation or by conjugation from *E. coli*, and the gene is inserted into the chromosomal neutral site by a homologous double crossover (Fig. 2), resulting in a gene duplication and loss of the delivery plasmid (13–15). In practice, the individual single crossover can be selected sequentially. The first crossover, which integrates the plasmid into the chromosome, is selected using the antibiotic resistance marker (AR) on the plasmid. This can be accomplished with a temperature-sensitive plasmid replicon that can be readily cured at elevated temperature in the absence of homologous recombination into the chromosome. The second crossover can be screened or selected using a counterselectable marker (CSM), such as the *rpsL* gene (16). In this

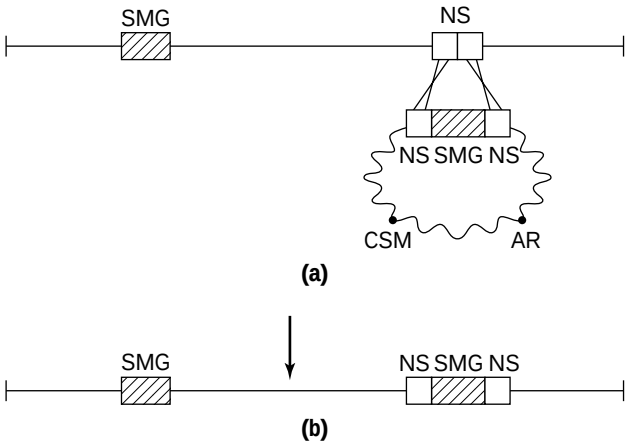

Figure 2. Gene duplication by homologous recombination of a secondary metabolite gene (SMG; crosshatched) into a predetermined neutral site (NS) from a plasmid (wavy line) containing markers for antibiotic resistance (AR) and counterselection (CSM).

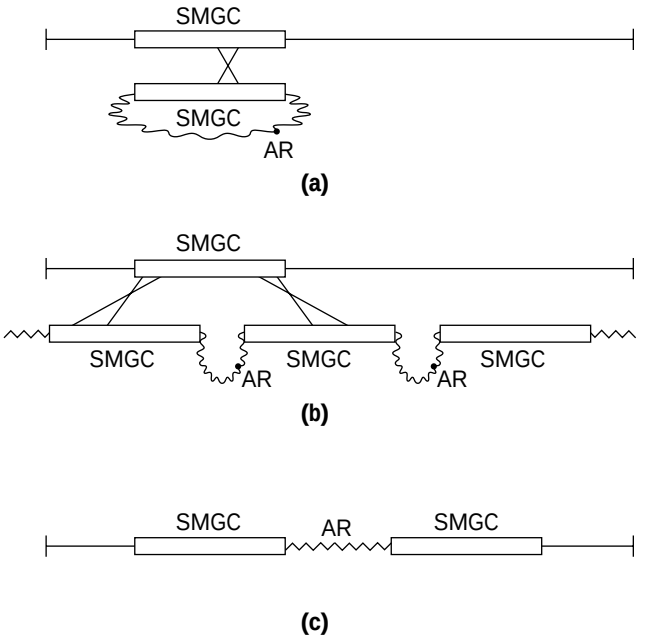

Figure 3. Gene duplication by homologous recombination of plasmid DNA into a secondary metabolite biosynthetic gene cluster (SMGC). A, Single crossover of a circular plasmid containing cloned SMGC into the chromosomal SMGC, selecting for an antibiotic resistance marker (AR); B, double crossover of a linear plasmid concatemer containing cloned SMGC into the chromosomal SMGC; C, recombinant containing SMGC duplication flanking plasmid DNA (wavy line).

case the wild-type *rpsL* gene encoding dominant streptomycin sensitivity is located on the plasmid, and the recessive streptomycin-resistant mutant allele of *rpsL* is located on the chromosome. Thus recombinants that have undergone a second crossover, deleting the plasmid, can be selected for streptomycin resistance at the temperature nonpermissive for plasmid replication. A good example of this neutral site cloning approach was the duplication of the *tylF* gene that encodes a rate-limiting step in the biosynthesis of the antibiotic tylosin in *S. fradiae*. In this case the neutral site was identified by transposon mutagenesis and cloned by selecting for the transposon marker that was expressed in streptomycetes and in *E. coli* (17,18).

Another variation of this method is to introduce the cloned gene into a plasmid that can insert site specifically into a plasmid or phage chromosomal insertion site, providing that the insertion site is neutral (15). A good example of this was the duplication of a gene involved in a rate-limiting step in pristinamycin biosynthesis by inserting a copy of the *snaAB* genes under the transcriptional control of the strong promoter *ermEp** into the plasmid pSAM2 *attB* site (19).

Duplication of much larger blocks of genes (~40 kb) can be accomplished by delivering the genes on a conjugal cosmid cloning vector lacking actinomycete replication functions (15,20). Recombinants are formed by homologous single crossovers of circular plasmids, or double crossovers of linear plasmid concatemers (Fig. 3), duplicating the complete ~40-kb region of interest. In this case, it is not predictable a priori if the insertion will be neutral, but in many cases it is, because ~50% of chromosomal sites in streptomycetes may be neutral (17). With this method of gene cluster duplication, the recombinants retain the plasmid sequences in the chromosome.

These methods also have the advantage that the recombinants are generally stable and lack self-replicating plasmids, which often reduce the productivity of the fermentation (13–15). Furthermore, the neutral site insertion method by double crossover results in a recombinant containing no heterologous DNA, so this method is in effect a directed gene duplication and directed translocation procedure that can give a very high frequency of the desired mutant that might otherwise occur randomly at an exceedingly low frequency, if at all.

Insertional Inactivation of Regulatory Elements by Transposons

Both positive and negative regulatory elements can influence the levels of production of secondary metabolites (21,22). Because transposons can be used to insertionally inactivate genes, they should be useful to disrupt regulatory genes. Disruption of negative regulatory genes should cause enhanced production of the desired products, whereas disruption of positive regulatory genes should cause reduced production. In both cases, the regulatory gene can be isolated by cloning the transposon and the flanking chromosomal DNA. This approach has been facilitated in IS*493*-derived transposons (17,23,24) by using markers that are selectable in streptomycetes and in *E. coli* (e.g., hygromycin resistance or apramycin resistance). In the case of negative regulatory genes, the cloned genes can then be used to make deletion mutants. Cloned positive regulatory genes can be used to make directed gene duplications to enhance production, as discussed in the previous section.

Random Insertion of Promoters by Transposition

The concept of using transposons as portable promoters was first proposed by Kleckner et al. (25). Several transposons are now available for streptomycetes, and those derived from IS*493* have outward reading promoter activity (18). Therefore this concept can now be tested using the natural promoter activity or by cloning stronger or regulatable promoters into a transposon. A preliminary study in the *Streptomyces roseosporus* indicated that Tn*5099* can induce mutations that cause enhanced daptomycin production (26). It has not been determined if the phenotype of these mutants is due to the portable promoter, to the inactivation of negative regulatory elements, or to both mechanisms. The data indicate, however, that transposon mutagenesis could become an important adjunct to robust industrial mutagenesis programs.

Biosynthetic Pathway Amplification

A somewhat more speculative approach to yield enhancement is by the duplication or amplification of the complete biosynthetic pathway. Because many secondary metabolite biosynthetic gene clusters are very large (e.g., 50 to 100 kb), it is not possible to duplicate them using standard cosmid cloning vectors. Recent genetic mapping experiments indicate that a number of secondary metabolite gene clusters are located close to one end of their respective linear chromosomes (3). In *Streptomyces rimosus*, which has a linear chromosome and a linear plasmid (11,27), the oxytetracycline biosynthetic genes are located about 600 kb from one end of the chromosome. One strain with improved oxytetracycline production contained 3 to 4 copies of a 1-Mb chimeric plasmid containing one plasmid end, one chromosomal end, and the complete oxytetracycline gene cluster. The strain also had one copy of the oxytetracycline gene cluster on the chromosome. In terms of classical mutagenesis, this strain harbors a duplication, translocation, and amplification because of the multicopy nature of the chimeric plasmid. This example of secondary metabolite pathway amplification has suggested a more directed homology-driven recombinational approach that might be applied to other secondary metabolite biosynthetic pathways clustered near the ends of linear chromosomes (3). Because linear plasmids are relatively common in streptomycetes (21,28), this could be a fruitful approach to assure that the secondary metabolite biosynthetic enzymes are not limiting, thus allowing other beneficial mutations influencing the flow of precursors into the pathway to be fully expressed phenotypically. Much more work is needed to fully develop this approach, but the potential benefits would appear to justify the additional studies needed to test this concept in other actinomycetes.

OUTLINE

INTRODUCTION

Myxobacteria are Gram-negative, rod-shaped, strictly aerobic soil bacteria that move by gliding or creeping and are famous for their cell–cell interactions, culminating in fruiting body formation. Until now, no actual technical process has been performed with myxobacteria, but they have already been grown in industrial-scale bioreactors for the production of certain secondary metabolites. Myxobacteria certainly have a potential for technical applications. They could be used as producers of enzymes, for example, proteases to be applied for milk clotting (1,2); enzymes degrading xylan, chitin, cellulose, or yeast cell wall β-glucans (sometimes with unusual cleavage patterns, such as converting starch into trisaccharides) (3); or unusual enzymes for biochemical research such as restriction endonucleases (4,5), reversed transcriptases (6,7), or protein kinases (8). All these possibilities have been very little explored because relatively few scientists have studied myxobacteria in the past, and very few study them at present on a broader scale for such applications. As myxobacteria have efficient export systems for exoenzymes and proteins, *Myxococcus xanthus* was investigated for some time as a host of foreign genes coding for useful proteins (9,10). The advantage in this application was seen in the fact that myxobacteria are nonpathogenic and apparently free of endotoxin. Also, less obvious applications are conceivable. Thus, an anticoagulant, myxalin, has been described from *M. xanthus* that could be useful in medicine (11,12). Lectins have been isolated from myxobacteria and might be further explored (13,14). However, the most promising application of myxobacteria may be in the field of secondary metabolites. So far, about 80 different basic structures have been isolated and elucidated from these organisms, with roughly 350 structural variants (1,15–18). Two compounds, soraphen and epóthilon, proceeded to the stage of an industrial development project. Although soraphen had to be given up as a fungicide for plant protection because of its intolerable side effects (19), epóthilon still is under investigation as a cytotoxin for antitumor application (20).

WHAT KIND OF ORGANISMS ARE MYXOBACTERIA?

Several up-to-date reviews about myxobacteria in general (21,22) and, more specifically, about their isolation, cultivation, preservation, and taxonomy are available (23–25). These facts, therefore, need be only briefly summarized here. Also, citations of the older literature are given in the recent reviews. Only fermentation of myxobacteria is discussed in some detail in this article.

Distinguishing Characteristics of the Myxobacteria

The myxobacterial cells are relatively large, between 3.5 and 12 μm long and from 0.6 to 1 μm wide, depending on the species and, to some extent, on growth conditions. Two morphological types, representatives of two suborders, can readily be distinguished under the microscope: the cells are either slender with tapering ends (*Cystobacterineae*) or are cylindrical with rounded ends; the latter are usually in the shorter size range and often more stout (*Sorangineae*).

The cells move by gliding over or within the substrate. Therefore the colonies spread, sometimes over the whole culture plate within a couple of days, and are named swarm colonies or swarms. Gliding motility is much reduced or totally suppressed on media with a high nutrient content, such as those containing 1% or more peptone. When transferred into a liquid medium, myxobacteria grow at first as a film along the walls of the container or, when shaken, as nodules or flakes suspended in the medium. After several transfers, often homogeneously growing strains can be obtained. To achieve this, transfers should be made from the supernatant, avoiding clumps as much as possible, at short intervals and using small volumes (20 mL in 100-mL flasks). Also, the composition of the medium may play a role. In general, strains belonging to the suborder *Sorangineae* are more recalcitrant than those of the *Cystobacterineae*. For these, weeks and months may be required before a specific strain grows as single cells, and sometimes this stage is never obtained. For this reason, until the 1960s it was generally believed that myxobacteria cannot be grown in liquid media, an opinion that definitely delayed their research.

While gliding bacteria are found in most branches of the bacterial phylogenetic system, two other characteristics of the myxobacteria are exceptional and even unique. Myxobacterial cells seem to communicate with one another with the aim to stay together. This can be seen in the behavior of the swarms. While individual cells can move much faster than the swarm expands, they still keep together, returning whenever they push beyond the swarm edge or waiting for the other cells to catch up. Small swarms may even migrate as a whole, like a pseudoplasmodium. Within the swarm, patterns of veins, rings, and parallel rows of cells in a ripplelike arrangement may develop. The cells in the ripples appear to move back and forth, creating in this way the illusion of oscillating waves, particularly striking when seen in time-lapse films but also recognizable by the patient observer under the microscope. The culmination of intercellular communication is the production of fruiting bodies. Under unfavorable conditions, especially starvation, hundreds of thousands to millions of cells aggregate at certain sites within the swarm. They often mill around for some time on a ring-shaped path and pile up. From such cell masses, fruiting bodies may differentiate. The simplest types are just knobs of cells and soft slime (*Myxococcus*); the most sophisticated ones consist of an excreted slime stalk, which may even be branched, with clusters of sporangioles at the end (*Chondromyces*). These sporangioles consist of a tough wall enclosing hardened slime and cells. In other genera, sporangioles are also found single on a stalk or sitting directly on or within the substrate, often in large, dense clusters. The size of the fruiting bodies varies between 10 and 1,000 μm, and most of them can readily be recognized with the naked eye. They usually are brightly colored (yellow, orange, red, brown, black), and are often produced in large numbers. The biological significance of the fruiting bodies is apparently to guarantee that a new life cycle is started with a community rather than a single cell. Why this strategy would be favorable will be seen when the physiology of the myxobacteria is discussed.

Inside the maturing fruiting body, the vegetative cells convert into myxospores. In the suborder *Cystobacterineae*, the vegetative cells always change their shape dramatically. They shorten and fatten—in the family *Myxococcaceae* they even become spherical—and turn optically refractile. They surround themselves with a capsule, which in most cases, however, is seen only under the electron microscope. In the suborder *Sorangineae*, the shape change is less spectacular; no capsule seems ever to be developed, but the cells also become optically refractile. Myxospores are fully desiccation resistant, in contrast to vegetative cells that are rather sensitive to drying. Temperature resistance is only mildly increased: wet myxospores may survive at 58–60 °C for 30–60 min, just long enough to get rid of contaminants in many cases. Dry myxospores may be heated to 140 °C for 1 h and still germinate. Thus, myxospores clearly are the myxobacteria's survival strategy, and fruiting must have some other significance.

There Are Two Physiological Types of Myxobacteria

All myxobacteria are specialized in the decomposition of biomacromolecules. Most species are bacteriolytic, that is, they excrete a host of hydrolytic enzymes—proteases, nucleases, lipases, polysaccharidases—that decompose living and dead, sometimes only dead, bacteria, yeasts, and other microorganisms, and of course also organic matter coming from higher organisms. One group, the genus *Sorangium* and a second as yet unnamed related genus, decompose cellulose. These organisms seem to attack only dead microorganisms, such as autoclaved *E. coli* and baker's yeast. Because a population obviously is more efficient than a single cell in the decomposition of environmental macromolecules by creating high enzyme levels, minimizing diffusion losses, and maximizing recovery of solubilized monomers, it becomes understandable why myxobacteria developed a social behavior.

Myxobacteria of both physiological types can, as a rule, be cultivated, and most of them in pure culture. A few, seemingly rare myxobacteria have never been grown in culture, mainly the *Haploangium* species, *Polyangium parasiticum* (discovered on the freshwater green alga *Cladophora*), and a few other species that have never been seen again by anybody after their original description from collected samples or crude cultures. A case of obligatory symbiosis has recently been reported for *Chondromyces crocatus* (26,27). Most strains of that species in our collection grow only if a companion is present. As the companion, too, cannot grow without *Chondromyces*, both could be cultivated together in large bioreactors, where they keep themselves automatically in balance (28). The companion could be characterized by 16*S* rRNA sequencing. It belonged, in all our *Chondromyces* strains, to the same species, a new member of the *Flavobacterium* group, regardless from where the *Chondromyces* had been isolated. The intimacy of the relationship is emphasized by the fact that the companion can even be seen within the sporangioles of the *Chondromyces* fruiting body (27), whereas normally the interior of myxobacterial fruiting bodies is free of contaminants for some time after their production.

All myxobacteria, the cellulose degraders included, can be grown on yeast agar, such as VY/2 agar (baker's yeast, 0.5% by fresh weight of yeast cake; $CaCl_2 \cdot 2H_2O$, 0.1%; vitamin B_{12}, 0.5 mg/L; agar, 0.5%; pH adjusted to 7.2 with KOH; autoclaved). On this medium, spreading colonies are obtained; the cultures stay alive for at least 2–3 weeks (30 °C) and often produce fruiting bodies. Fruiting bodies are useful when the strain is to be preserved by lyophilization, because vegetative cells cannot reliably be dried. Further, fruiting bodies are required for classifying an isolate (see following). Fresh isolates usually form fruiting bodies, but during cultivation fruiting body formation usually is lost after three to eight transfers. Fruiting body formation can be maintained, if cultures are started from fruiting body preserves. Those can be prepared by streaking swarm material onto small pieces of filter paper placed on water agar. After incubation for 2–3 days at 30 °C, often fruiting bodies are produced. They are allowed to mature for another 4–6 days. The filter papers are then inserted into sterile medicine bottles and dried in a desiccator under vacuum for a week. From dry filter paper preserves stored at room temperature, fruiting cultures can still be started after 8–20 years. The fruiting cultures must then be used after one to

two transfers to make fresh preserves; otherwise, fruiting may be lost.

The bacteriolytic myxobacteria usually also grow well on peptone-containing media, for example, CY agar (Casitone, Difco, 0.3%; yeast extract, Difco, 0.1%; $CaCl_2 \cdot 2H_2O$, 0.1%; agar 1.5%; pH adjusted with KOH to 7.2; autoclaved). On this medium growth often is heavier, but the swarms stay more compact, are often more slimy, rarely produce fruiting bodies, and die sooner (after 8–10 days) than on VY/2 agar. The reason for early death could be the production of ammonia and the concomitant shift of pH to alkaline conditions. The pH range of myxobacteria is 6.8 to 7.8. Of course, the media could be buffered. A useful buffer is HEPES, which is tolerated without adverse effects up to at least 100 mM. Several bacteriolytic myxobacteria seem to grow only on peptone, proteins, or amino acids and seem not to utilize carbohydrates at all (the genera *Myxococcus*, *Corallococcus*, and *Nannocystis*). However, there may be some unorthodox ways of carbohydrate utilization. Thus, *Myxococcus* degrades yeast cell wall β-glucan, and *Nannocystis* corrodes agar, so why should they leave the valuable decomposition products to other organisms? At least some *Corallococcus* strains decompose starch to tri- and oligosaccharides; those are utilized, while glucose and maltose remain untouched (3). (For more media recipes, see Ref. 24.)

Incidentally, in spite of their name of "slime bacteria," myxobacteria are poor producers of slime on plates and in liquid media. Only rarely colonies are somewhat raised and liquid media become recognizably viscose. Ropy liquids have never been reported. The slime of the swarm sheet, however, may become extremely tough, rubberlike, and almost impossible to divide with the inoculation loop.

For the cellulose degraders, too, alternative media are available (24), for example, filter paper on mineral salts agar with KNO_3 as the only nitrogen source (e.g., ST21 agar), on which they often form huge numbers of fruiting bodies, or mineral salts–glucose agar (e.g, CA2 agar). The organisms seem to prefer NO_3^- to NH_4^+ as the nitrogen source, grow even better in the presence of low peptone concentrations, but often are absolutely dependent on a carbohydrate (e.g., glucose, starch, cellulose) for carbon and energy. All myxobacteria can be grown in liquid media. This aspect is discussed in connection with fermentation in the next section.

Taxonomy and Genetics of the Myxobacteria

The taxonomy of the myxobacteria rests almost exclusively on morphological characteristics. Only very few useful physiological traits have been found; thus, cellulose degradation in *Sorangium* and synthesis of lanosterol in *Polyangium* (29) distinguish the two genera. A bright yellow fluorescence at 366 nm of the swarm colonies caused by the production of phenalamid (30,31) helps to distinguish *Myxococcus stipitatus* from *M. fulvus* when typical fruiting bodies are lacking. While suborders, families, and most genera can usually be identified without problems because the morphology of their vegetative cells, myxospores, and swarm colonies is sufficiently typical and can normally reliably be registered, differentiation of species is often not possible, because it requires typical fruiting bodies and those may be degenerate or completely lacking. In such cases, one can only guess what species one has. Today, molecular taxonomy could be applied to solve the problem (DNA–DNA hybridization).

Presently about 40 different species are recognized, but there certainly are more species in nature, at least another 20 to 30. They are classified in 12 genera, 4 families, and 2 suborders in the order *Myxococcales*. As already mentioned, the suborders can easily be distinguished by the shape of the vegetative cells. As demonstrated by 16*S* rRNA sequencing studies, the order is phylogenetically coherent and belongs to the δ-branch of the Proteobacteria (32). Complete 16*S* rRNA sequences are available for about 40 strains of many different genera and species, but the resulting picture does not much modify the established structure of the order. Clearly, the resolution of the technique is not particularly helpful at the species and genus level.

It should be mentioned that formerly, before it was appreciated that gliding motility is not a useful taxonomic characteristic, the genera *Cytophaga, Sporocytophaga*, the *Cytophaga*-like bacteria, and *Flexibacter* were classified as nonfruiting myxobacteria. In fact, they belong to a phylum of their own and are not related to the myxobacteria at all. This is of some practical importance, because several fish-pathogenic and allergenic species are known in that group, while no pathogenic myxobacteria have ever been reported. Another group, later recognized as a new genus, *Lysobacter*, was even classified as *Myxobacter* and *Sorangium* for some time. Those names can still be found occasionally in the current literature. *Lysobacter* comprises biotechnologically useful strains—suppliers of well-known antibiotics, such as myxin, and of interesting enzymes—but has nothing to do with myxobacteria. Phylogenetically the genus belongs into the γ-branch of the Proteobacteria.

The DNA of myxobacteria has a high G+C content of 66 to 72 mol%. The genomes are large for bacteria, between 9,500 and 10,000 kbp. Physical genome maps are available for *Myxococcus xanthus* (33) and *Stigmatella aurantiaca* (34). Two myxobacteria, *Myxococcus xanthus* and *Stigmatella aurantiaca*, have been analyzed with genetic methods as model systems for questions of morphogenesis, cell signaling, gliding motility, carotenoid synthesis, protein export, etc. (for details, see Refs. 21,22). Several gene transfer techniques have been developed: *E. coli* phage P1 suicide vectors, conjugation with *E. coli*, myxobacterial generalized transducing phages, and electroporation (21). Transposon mutagenesis has successfully been applied to gene tagging (35). In a few cases, those techniques have also been used for other myxobacteria, for example, *Sorangium cellulosum* (36,37), but there is always need of an adaptation.

Myxobacteria Are Very Common Soil Organisms

One might expect that organisms that are so unusual and fascinating as the myxobacteria, yet are so little investigated, are rare and difficult to obtain. The contrary is the case. Myxobacteria are found worldwide in all climate zones and vegetation belts and are very common every-

where. They live in soil, on rotting plant material, on decaying wood, on bark of living and dead trees, and on dung of various herbivores, especially rabbits, hares, deer, goats, and sheep; in general, wherever there is a rich microbial flora. The most diversified myxobacterial communities are found in warm, semiarid areas, like Egypt, the southwestern United States, or northern India, probably because, with their myxospores and fruiting bodies, they are beautifully adapted to such environments. Myxobacteria also seem to live in freshwater and to survive for some time in marine sediments; they can be isolated from marine sediments but are not halotolerant and thus probably cannot live there. They seem not to be able to grow at a low pH, and acid soils are the one habitat free of myxobacteria. Alkalophilic myxobacteria, however, have been obtained from alkaline lakes in Africa. Myxobacterial are typical mesophiles, although psychrophilic strains have been isolated from Antarctic samples.

Isolation and Maintenance of Myxobacteria

The relevant methods of maintenance of these bacteria have relatively recently been described in great detail (24), so a brief summary may suffice here. Because Myxobacteria have a rather generalized metabolism, a highly selective enrichment is not possible. The isolation techniques make use of gliding motility, the ability to attack living bacteria or cellulose, and resistance to certain antibiotics. There are essentially three ways to start enrichment cultures. In the first procedure, materials collected in nature are incubated in a moist chamber at 30 °C. Suitable sources are rotting wood, bark, or the dung of herbivores. To suppress growth of fungi, cycloheximide (50 mg/L) may be added to the water used to wet the source material. The cultures are inspected under a dissecting microscope with incident light at magnifications of 20–80×. Fruiting bodies may form within 2–8 days on the surface of the substrate and can be used to make transfers. From soft slimy *Myxococcus* fruiting bodies, myxospores can be transferred directly to a growth medium such as CY agar by cautiously touching the top of the fruiting body with the sharp tip of a needle on a 1-mL syringe. The young fruiting bodies are normally free of contaminants, so that often a pure culture is obtained in one step. In a similar way, sporangioles can be removed from the ends of the long stalks of *Chondromyces* fruiting bodies. The fruiting bodies of all other myxobacteria cannot be harvested without touching the heavily contaminated substrate and transferring pieces of it together with the fruiting bodies. Therefore, in these cases the fruiting bodies are transferred to streaks of living *E. coli* on water agar plus cycloheximide for further enrichment. The developing swarms usually expand quickly beyond the streak of the feed bacteria, and either uncontaminated sections from the swarm edge or fruiting bodies can be inoculated on growth medium. Often the procedure has to be repeated several times before a pure culture is obtained, which typically takes 2 weeks to 3 months. Sometimes special purification steps have to be included, such as heating fruiting bodies, suspended in water, at 58–60 °C for 10–60 min; shaking fruiting bodies overnight in a rich medium (in which they will not germinate) with high doses of suitable antibiotics; or gassing cultures with ammonia vapors to eliminate soil amoebae.

In the second approach, cultures are started by inoculating circular spots of living *E. coli* (about 2 cm in diameter) on water agar plus cycloheximide with small samples of soil or rotting plant material. After 2–3 days at 30 °C, swarm colonies and soon also fruiting bodies may develop, and transfers and purification steps are performed as described in the first approach. With this method, different types of samples can be processed, and myxobacteria with small, inconspicuous fruiting bodies are also obtained. Incidentally, on such plates often other gliding bacteria such as *Cytophaga*-like bacteria, *Flexibacter*, *Taxeobacter*, and *Herpetosiphon* also develop and can be recognized by their spreading colonies. In the third method, the cellulose degraders are isolated by inoculating filter paper pads on mineral salts plus cycloheximide agar with soil, rotting wood, decaying plant material, or dung of herbivores. After 10–14 days at 30 °C, bright yellow, orange, brown, or black spots around the inoculum indicate growth of *Sorangium* strains. Those usually produce huge numbers of densely packed fruiting bodies, which in fact are responsible for the colored areas. Transfers are made first to small pieces of filter paper on mineral salts agar, then on VY/2 agar. All *Sorangium* strains appear to be resistant to high doses of kanamycin, so that the antibiotic can be used for purification (50 mg/L kanamycin sulfate). Cellulose degraders are more tedious to purify, and it may take 1–2 years before the last contaminant is eliminated. Fortunately, pure strains are usually obtained within 1–3 months. In crude cultures for cellulose degraders, noncellulolytic myxobacteria always also develop. The inoculum, the solubilized cellulose, and other saprophytic bacteria supply sufficient nutrients for their growth. In particular, *Nannocystis*, *Polyangium*, and *Chondromyces* strains are often found in this way. They must, of course, be transferred to *E. coli* streaks on water agar.

Preservation of strains is done best by freezing 0.5- to 1-ml suspensions of cells in a 1% Casitone (Difco) solution at −70 °C in a deep freeze or in liquid nitrogen. The organisms appear to stay alive for many years (about 20 years has been experimentally proven). Freezing at −20 to −25 °C in ordinary household freezers seems not to work. In our experience, myxobacteria survive that at best for a couple of weeks. Drying of fruiting bodies has already been mentioned.

FERMENTATION OF MYXOBACTERIA

Fermentation of myxobacteria at a 5- to 50-m^3 scale has only been performed for the production of secondary metabolites. Data are available from many publications. Process descriptions are also found in a large number of published patents. Consequently, the following discussion centers upon this topic.

General Principles

With homogeneously growing strains, typical growth curves can be obtained. The generation times are long, typically between 4 and 14 h. The faster growing species are

normally those of the suborder *Cystobacterineae*. On the other hand, those species usually show short stationary phases; that is, soon after the end of the log phase is reached, the culture breaks down. This collapse can be really dramatic. Cultures of *Stigmatella aurantiaca* strains in peptone medium without carbohydrate become pitch black within 2–3 h, probably because of the activity of phenol oxidases from lysed cells, and are then dead. Therefore, transfers are best made in the upper log phase, and extended production in the stationary phase is usually not possible. Species of the suborder *Sorangineae*, in contrast, often are under stationary conditions for days and may continue to produce secondary metabolites during this period. With these species it is also advisable to make transfers in the upper log phase, because later the inoculum may result in a very long lag phase or will no longer start growing. Obtainable cell densities typically are 10^8–10^{10} cells/mL depending on the strain and the medium. It should be remembered, however, that myxobacterial cells are larger than those of most other myxobacteria. The biomass thus is often between 4 and 12 g wet weight/L, corresponding to 1–3 g dry weight. As already mentioned, slime production is normally not seen.

Liquid media suitable for bacteriolytic myxobacteria are all based on peptones or proteins, while those for the cellulose degraders can be varied in wider limits. Enzymatically digested casein peptones are the substrates of choice, for example, Difco Casitone or Marcor peptone from casein, tryptically digested. Peptones from meat and acid-hydrolyzed peptones are much less useful or outright inhibitory, possibly because of elevated phosphate concentrations (38) or an imbalance in amino acid composition. Yet some myxobacteria can also be grown on casamino acids (e.g., Ref. 39). Examples of simple media suitable for many bacteriolytic myxobacteria are CAS lm (Casitone, Difco, 1%; $MgSO_4 \cdot 7H_2O$, 0.1%; pH 6.8; autoclaved); if the peptone concentration is too high, which is the case with quite a few myxobacteria, MD1 lm may be used (Casitone, Difco, 0.3%; $CaCl_2 \cdot 2H_2O$, 0.07%; $MgSO_4 \cdot 7H_2O$, 0.2%; cyanocobalamin, 0.5 mg/L; standard trace element solution; pH 7.0; autoclaved). For liquid cultures of *Sorangium* strains, AMB lm (40) could be used (Casitone, Difco, 0.25%; soluble starch, 0.5%; $MgSO_4 \cdot 7H_2O$, 0.05%; K_2HPO_4, 0.025%; pH 6.8; autoclaved). Those organisms also grow, however, on much simpler media containing only KNO_3 as a nitrogen source and glucose as a carbon source in a mineral salts solution (e.g., CK1 and CK6 lm).

Casein peptones contain sufficient phosphate, so that extra phosphate need not be added. Thus, 0.5 mM phosphate was determined in a 0.2% casein peptone solution (38). In general, myxobacteria are rather sensitive to phosphate. Also it may have been realized that the media mentioned contain relatively high concentrations of $MgSO_4$; the optimum is indeed often at 5 to 10 mM. Calcium is normally present in adequate amounts or is not specifically required. In contrast, the cellulose degraders would not grow without an addition of $CaCl_2$ (41). Vitamins are usually not required, but an occasional strain may depend on vitamin B_{12}.

A peptone medium may be complemented with 0.2–1% of a carbohydrate, for example, glucose, sucrose, or starch. The latter is usually readily hydrolyzed. A carbohydrate is a must for most strains of *Sorangium*. Normally cultures of bacteriolytic myxobacteria do not grow faster in the presence of carbohydrate but rather achieve higher cell density. Also, the pH does not rise as fast and as high as in a pure peptone medium. The details of carbohydrate metabolism have not yet been studied for a wide variety of myxobacteria. Some appear not to utilize carbohydrates because they lack essential glycolytic enzymes (hexokinase and pyruvate kinase in *Myxococcus xanthus*; 42). Others utilize only polysaccharides, because they can only ingest tri- and oligosaccharides (*Corallococcus coralloides*; 3). In this case it was shown that the glucose produced within the cell is mainly utilized via the pentose phosphate pathway, probably only to produce ribose and deoxyribose for nucleic acid syntheses. Many bacteriolytic myxobacteria, however, metabolize also mono- and disaccharides under production of acid and radioactive CO_2, if labeled sugars are supplied (e.g., *Stigmatella aurantiaca*; 43). Nothing is known about the biochemistry of sugar metabolism in those organisms. The cellulose degraders utilize sugars very efficiently for energy and all kinds of syntheses, as is suggested by their growth in the minimal media just described. Fully synthetic, defined media have also been reported for several bacteriolytic myxobacteria. They contain various amino acids and can in fact be very simple. *Cystobacter fuscus* and *Cystobacter ferrugineus* strains grow, for example, in HP16 Im with (per liter) L-Gln·Na, 1 g; L-Ile, 40 mg; L-Phe, 40 mg; glucose, 5 g; $MgSO_4 \cdot 7H_2O$, 1 g; standard trace elements; in phosphate buffer, 0.5 mM, pH 6.5. Some strains become vitamin dependent on thiamine or biotin, when grown in this minimal medium, while in peptone media they are not. For most strains, defined media are, however, more complex, containing more amino acids and still other ingredients. Apparently the relative concentrations of amino acids are as important as their kind. Also, every strain may require a medium of its own. Essential amino acids often are the branched-chain and aromatic amino acids. In any case, growth in those defined media is always substantially slowed down, and cell yields are much reduced.

When an organism relies solely on amino acids for nitrogen, carbon and energy, elimination of NH_3/NH_4^+ becomes a problem. This problem is indeed a serious one with bacteriolytic myxobacteria. The intracellular ammonia pools may become very high under such circumstances: in *Myxococcus virescens* 80–140 mM has been measured (44). Although the pH shift by ammonia can easily be controlled in the bioreactor by titration and in shake flasks by buffering with HEPES or MOPS, for example, the regulatory effects of ammonium still may interfere substantially with growth and production of antibiotics. This was demonstrated by pumping the contents of a small bioreactor through a module with hollow fibers made of a hydrophobic membrane. The ammonia in the culture supernatant could thus be reduced from 35–42 mM to 3–7.5 mM. In consequence, the generation time fell from 4 to 2 h, the cell density more than doubled, and myxovirescin production rose from 8 to 115 mg/L (K. Gerth, personal communication). A technical solution of this problem is presently not available.

For large-scale fermentations to be cheaper, technical substrates may be desirable. A wide variety of such substrates have been tested with myxobacteria and several have been found useful: soybean flour and meal (must be defatted), single cell protein (Probion, Hoechst, no longer available), skim milk, maize gluten, corn steep powder, or suspensions of baker's yeast (45). Which substrate should be used in a specific case must be tested. Also, as is typical for such poorly defined materials, considerable differences are observed from batch to batch and from supplier to supplier. Production of secondary metabolites may vary substantially with the particular substrate used (39,45,46). An unexpected discovery was that soybean meal may be free of iron, so that the addition of $Na{\cdot}Fe^{III}$ EDTA (8 mg/L) becomes essential (47).

The temperature range for growth of myxobacteria is rather wide: they still grow in the refrigerator at 6 °C, and quite a few strains still grow at 38 or even 40 °C. The temperature curves are skewed as usual, and the optimum is close to the maximum by 1–3 °C. Useful temperatures for fermentations are much narrower, normally 28–32 °C. At least with respect to secondary metabolites, production often goes down or stops completely at higher temperatures even if growth still is satisfactory. Also, at higher temperatures the generation time may rise (47), and the cultures become more sensitive to unfavorable pH and oxygen conditions and quickly break down as soon as the stationary phase is reached. At temperatures below 28 °C, growth, production, and process performance slow down and become unfavorable.

The pH range of myxobacteria is narrow, as a rule 6.8 to 7.8. Cellulose degraders tolerate a slightly lower pH, down to about 6.2, but with ever more reduced growth rates. If a utilizable carbohydrate is present, the pH drops in unbuffered media but can be controlled by titration with a 10% KOH solution. Without carbohydrate or after carbohydrate is used up, the pH always rises and usually becomes decidedly alkaline (pH 8.0–8.5). This change can be prevented by adding 5% sulfuric acid or 30% acetic acid. In the latter case care must be taken because acetate concentrations exceeding 0.1% may soon become inhibitory for production and growth. In a process, pH can often be stabilized by feeding glucose whenever pH reaches a set limit.

Although myxobacteria are strict aerobes, their oxygen demand is moderate because of slow growth and modest biomass. This requirement may become a problem if the aeration rate cannot be lowered unrestrictedly in a bioreactor. In fermentations for secondary metabolites, the oxygen level may play a crucial but unpredictable role for production. There are examples of a high as well as a low requirement of oxygen for optimal biosynthesis. In Table 1, the aeration schedules of a selection of such fermentations are listed. It should be understood that in no case have strictly standardized and optimized fermentations been performed. Maximum total oxygen consumption of 1.8 g O_2/L during 22 h of fermentation on a single cell protein (Probion) medium has been reported for *Myxococcus fulvus* strain Mx f16 (45).

Special Problems with Secondary Metabolite Production

In principle, the situation with secondary metabolite-producing myxobacteria is not much different from that with other antibiotics-producing bacteria. Yields initially are usually, but not always, low, typically between 0.5 and 20 mg/L. However, wild strains with initial yields of 70 mg/L soraphen or 120 mg/L myxalamid (39,58) have also been isolated. In several cases, yields could be much improved, for example, to nearly 1 g/L with sorangicin or close to 2 g/L with soraphen. In other instances, yields remained low in spite of much effort, as with saframycin Mx (59).

The methods of yield improvement are the usual ones. The influence of medium components can be substantial, as already mentioned. Thus, in fermentations of *Stigmatella aurantiaca* yields varied by a factor of 3, between 3 and 11 mg/L stigmatellin and between 47 and 120 ml/L myxalamid, depending on whether corn steep powder or maize gluten (Zein) was used as the main medium ingredient (39). At the same time growth was rather poor on the Zein medium. An improvement of yield and production stability is almost always achieved if the strain is cloned and if low and nonproducing clones are eliminated. Unfortunately this is less trivial as it seems, because initially all strains grow in clumps when transferred to a liquid medium, and if homogeneous cell suspensions are available a suitable plating medium giving high numbers of single cell colonies must first be found. This can take weeks and months, because normally no colonies are formed on the usual culture media that allow excellent growth when massively inoculated. Also, every strain needs its own plating medium. In developing a plating medium, the kind and concentration of the medium components are crucial. Inclusion of autoclaved old liquid cultures may help (36). Development of single-cell colonies takes 8–12 days for most bacteriolytic myxobacteria and 14–21 days for *Sorangium* strains (30 °C).

As soon as single-cell colonies can be produced, a mutation program becomes feasible. Mutations can be induced in myxobacteria with high yields using UV irradiation or the mutagen NTG (*N*-methyl-*N'*-nitro-*N*-nitrosoguanidine, about 40 μg/mL) (60). When inducing mutations, photoreactivation has to be taken in account (61). The size of the inoculum should be 5–10% (v/v). Lower ratios, down to 1–2%, have been found possible in some cases, but this may be paid for with a longer lag phase and a lower biomass attained at the end of the fermentation. Also, a certain minimal cell density may be necessary to start solubilization of polymeric substrates, such as casein (62). Under these circumstances a substantial decrease of the mean doubling time was observed when the size of the inoculum was increased, for example, with two *Myxococcus xanthus* strains on a casein medium from 15 to 8 h and from 26 to 8.5 h, respectively, when initial cell densities were raised from 10^4 to 10^7 cells/mL (62).

A very useful strategy to improve yields is the addition to the cultures of a neutral adsorber resin such as Amberlite XAD-16 (formerly XAD-1180; Rohm & Haas). All myxobacteria appear to tolerate the resin in the culture without adverse effects on growth. So far, virtually all excreted myxobacterial metabolites have been adsorbed by the resin (46,47,49,52,55,58). Only strictly hydrophilic compounds would remain unadsorbed, but such substances appear not to be produced by the organisms or only

Table 1. Examples of Oxygen Demand during Myxobacterial Fermentations for Secondary Metabolites

Metabolite	Producer[a]	Main components of medium[b]	Volume (L)	Stirrer speed (rpm)	Aeration rate[c] (L L broth^{-1} h^{-1})	Oxygen saturation[d] (%)	Reference

[b]pep, casein peptone; yex, yeast extract; Prob, Probion (an experimental single-cell protein of the Hoechst Company); soy, soybean meal defatted; starch is often complemented with glucose.

[c]Stirrer speed is sometimes changed during fermentation to adjust dissolved oxygen.

[d]Dissolved oxygen is sometimes increased or held constant in the later stage of fermentation.

very rarely so. The advantages of the resin are obvious: by removing the metabolites from the supernatant, end product inhibitions are prevented, the adsorbed substances are stabilized and concentrated in a small volume, and harvest is much facilitated. If the strain grows as a homogeneous cell suspension, harvest can be done simply by collecting the resin on a sieve. The metabolites are recovered by eluting the washed resin with methanol or methanol–water mixtures. Sometimes a metabolite may crystallize from the eluate. The regulatory and protective effects of the resin are clearly demonstrated when fermentations are done without it. Almost always the yields decrease dramatically, and variants of the metabolite appear that have not been seen in cultures with resin. Normally an addition of 1–2% (v/v) is sufficient. If yields go up, and depending on the metabolite, higher amounts of resin may have to be added. Freshly bought resin is strongly alkaline and has to be washed until it becomes neutral. The resin is added to the culture medium and autoclaved together with it. Resin has also been used with excellent results in large-scale fermentations (47). There may be a loss of about 10% in the bioreactor from mechanical attrition, but the recovered resin can be regenerated by washing with NaOH solution after elution of the metabolites.

Most myxobacterial substances do not inhibit the producer. There are, however, exceptions. Myxovalargin, a peptide antibiotic that destroys the cell membranes (63), blocks growth of the producer, *Myxococcus fulvus* strain Mx f65, at 6 mg/L (64). Myxobacterial saframycin has a minimal inhibitory concentration of 15 mg/L for the producing strain, *Myxococcus xanthus* Mx x48 (58). In both cases mutants with somewhat increased resistance could be obtained, but removal of the inhibitor by adding adsorber resin to the cultures is an easy solution. As foaming is often a serious problem, an antifoam agent must always be added to myxobacterial fermentations. Silicon antifoams usually have been applied because they do not interfere with the chemical purification steps. For the organisms, however, other antifoam agents are also acceptable.

Feeding of precursors was successful only in a few fermentations. Thus, the addition of 0.3% sodium acetate stimulated production of myxalamid by *Myxococcus xanthus* strain Mx x12 (58). Normally, acetate is not a limiting factor, and its addition may even be inhibitory. This situation appears to be different with propionate. Added propionate is readily incorporated into polyketides containing propionate units and may indeed stimulate their production. Propionate is only tolerated in low concentrations, however, so that real yield improvements require repeated addition of small quantities. We have never observed a stimulation of secondary metabolite production by adding certain amino acids, probably because our peptone and protein media already contain an excess supply. It has been reported however that Ala, Ser, and Gly (0.9 mg/mL each) when given to *Myxococcus xanthus* strain TA result in higher yields of antibiotic TA (identical with myxovirescin). All three amino acids are indeed incorporated into the antibiotic, Ala and Ser serving as precursors for acetate, which seems to be not as readily taken up, while Gly is a building block of the molecule directly (65). The removal of inhibitory components may also be a prerequisite for production. The catechole iron chelator, myxochelin, is only produced when the iron content of the medium is about 10^{-7} M. Production is achieved by removing the iron in the medium by treatment with the chelating resin, Chelex 100 (Bio-Rad), and adding the optimal amount of $FeCl_3$ (66).

While feeding of specific precursors is problematical, fed-batch fermentations may be very useful (e.g., 47,67). Myxobacteria prefer moderate media concentrations: 1% peptone–protein and 0.5–1% carbohydrate are the upper limits allowing unrestricted growth, and optimal concentrations for production may be even lower. As mentioned, carbohydrate metabolism normally leads to acid production, so that feeding strategies can be developed using pH shifts or titration curves, respectively, as indicators. For, as soon as carbohydrate is used up, the metabolism switches to amino acids under ammonia production with a concomitant rise of pH. Sometimes production is directly connected to carbohydrate consumption, for example, that of tartrolon (55) and soraphen (47). Fed-batch fermentations often result in much higher yields; for example, in the case of disorazol a rise from 18 to 292 mg/L was achieved, with a production rate of 21 mg/L per day for 13 days (67). A fully standardized fed-batch process has still to be reported, however.

Often certain medium components have specific effects on production without much affecting growth. The type and concentration of peptone or protein is often critical (28,46,47,56,68). Individual sugars have differential effects on yields of myxalamid and stigmatellin even when produced biomass is comparable (46). Ripostatin synthesis is stimulated when 0.3% fructose and 0.01% pyruvic acid are added (53). *Sorangium cellulosum* strain So ce12 synthesizes concomitantly sorangicin, disorazol, chivosazol, and sorangiolid. In the presence of 0.1 mg/L sodium barbital the production rate of disorazol was reduced from 21 to about 2.5 mg/L per day irrespective of whether barbital was added in early or late log phase (67). Sorangicin production was not impeded.

As is well known for other producers, individual strains of myxobacteria may show a completely different production behavior for the same compound. A comparison of four wild strains producing soraphen revealed that all four synthesized the antifungal compound with reasonable yields at 30 °C in the presence of XAD resin (47). When the temperature was raised to 36 °C, however, one strain doubled soraphen yield while another one reduced it to 25%. When 0.2% casein peptone was added to the XAD culture at 30 °C, the yields of two strains dropped to near zero, while one strain increased its yield by more than 100%. In the absence of XAD the strains decreased their yields by 50% to 100%.

Efforts have been made to optimize myxovirescin production by *Myxococcus virescens* strain Mx v48 in a medium containing 1% casein peptone (69). The antibiotic is only synthesized under good oxygen supply. In normal batch cultures, antibiotic production started at the end of logarithmic growth at about 20 h after inoculation and continued until the stationary phase at about 50 h, that is, production took place in a typical idiophase. At the beginning of the production phase, the oxygen uptake and CO_2 production rates (both about 100 mg L^{-1} h^{-1}) slowed down, and the respiratory quotient, RQ, started to rise, up to 0.8 during the production phase. After 50 h, 3.1 g/L wet biomass was reached. The cell yield was 0.31 g dry biomass/g peptone, or 0.5 g dry biomass/g oxygen. Total oxygen consumption over 55 h was 6.25 g oxygen/L. Production of myxovirescin was very low, the final yield being 0.04 mg/L. By feeding peptone at different rates to a peptone-limited culture (0.16% peptone), it was demonstrated that the peptone consumption rate closely correlated with the myxovirescin production rate. In the batch culture, this rate reached a maximum of 0.4 g peptone g dry weight^{-1} h^{-1} after 8 h, but myxovirescin synthesis started only much later, after 26 h, when the peptone consumption rate was down at about 0.12 g peptone g dry weight^{-1} h^{-1}.

The feeding experiments revealed a very sharp optimum of the specific peptone uptake rate for maximal myxovirescin production. Under the chosen experimental conditions the optimal rate was about 1.8 g peptone g dry weight^{-1} h^{-1} and resulted in a specific myxovirescin production rate of about 0.05 mg myxovirescin g dry weight^{-1} h^{-1}. For optimal production, the specific peptone uptake rate had to be maintained between 0.15 and 0.2 g peptone g dry weight^{-1} h^{-1}. The final yield of myxovirescin still was very low, 2 mg/L. In another experiment under chemostat conditions, the myxovirescin production rate was raised from 0.12 to 0.55 mg L^{-1} h^{-1} under constant biomass by passing the culture supernatant through a vortex chamber containing XAD resin and thus removing myxovirescin continuously from the culture (70). Cell dry mass and antibiotic concentration reached a steady state after 170 h. The latter was reduced from 0.95 to 0.1 mg myxovirescin/L after the vortex chamber had been connected to the bioreactor. The effect on myxovirescin production of removal of NH_3 from the culture has already been mentioned. Incidently, in chemostat experiments myxobacteria turned out to respond very slowly to changed conditions, perhaps because they have a high homeostasis. For the same antibiotic, a scale-up procedure in a 0.5% Casitone (Difco) medium is also reported, although with a different producer, *Myxococcus xanthus* strain TA (71). The best titers were obtained at a relatively low oxygen absorption rate, which in fact was too low to be maintained in the largest bioreactor used. No direct correlation between growth and antibiotic production was seen. Final biomass yield was 3–4 g wet weight/L.

Several studies have reported immobilization of myxobacterial cells. The objectives were to retain a relatively high biomass, to perform chemostat experiments (not possible with a strain growing in flakes and nodules), and to investigate the influence of immobilization on the production rates of enzymes (72–74) and secondary metabolites (38,75). A more theoretical study considered the role of hydrophobic and electrostatic properties of bacterial cell surfaces on adsorbtion to porous SiO_2 (glass) and Al_2O_3 particles (76). This study included *Sorangium cellulosum*, which showed a relatively low zeta potential (-33 mV at pH 7 and in the presence of 1 mM NaCl) comparable to that of *E. coli*, but a very high hydrophobicity in the range typical for gram-positive rather than gram-negative bacteria. The contact angle, the measure of hydrophobicity, increased from 52° at the beginning of the growth curve to 75° at its end. Both values—low zeta potential and high contact angle—are contrary to good adsorption.

Immobilized cells of *Sorangium cellulosum* strain So ce12 were used to study the limitations of sorangicin synthesis (38). As immobilizing agent, calcium alginate (Pro-

tanal LF 20/60, Carroux) was found most suitable. Beads 1 mm in diameter containing 5% biomass (v/w) were prepared and used in a 1.6-L bioreactor with 1 L medium in continuous culture under chemostat conditions. Phosphate (0.23 mM) was used as the limiting factor preventing growing out of the enclosed cells. Higher phosphate concentrations also repressed sorangicin production. Consequently peptone from casein could only be added to such a concentration that its phosphate content did not exceed the optimal phosphate concentration; if that was the case, peptone stimulated sorangicin production. With the applied medium, the optimum dilution rate was 0.016/h, the optimum pH 7.8, and the optimum p_{O_2} 80% saturation (with free cells, 40% were optimal). For sorangicin production, the cells within the beads had to be maintained under growth conditions. Their generation time was 19 h (14 h with free cells). Productivity began to decline after 50 days and came to an end after 75 days when the cells within the beads degenerated. An increase of the biocatalyst wet weight beyond 60 g/L, or a liquid to catalyst ratio of 10:1 (v/v), resulted in a decrease of growth and production, partly because of oxygen limitation. Productivity could be stimulated by the addition of glycerol (9 mM) and pyruvate (5 mM), while the direct precursors, acetate and propionate, were inhibitory. A shift to enzyme activities of the pentose phosphate pathway in the immobilized cells compared with free cells was seen. The maximum volumetric productivity obtained with immobilized cells was 0.8 to 5 mg sorangicin $L^{-1}\,h^{-1}$ and the specific production rate was 0.25 mg sorangicin g biomass^{-1} h^{-1}, compared with 0.17 mg $L^{-1}\,h^{-1}$ and 0.12 mg g dry biomass^{-1} h^{-1}, respectively, with free cells.

In another project, cells of *Cystobacter* and *Corallococcus* strains were immobilized by either adsorbing them to nylon pads or by enclosing them in κ-carrageenan beads (75). The preparations were tested in shake flasks for production of chemically unknown antibiotics. Yields with adsorbed cells were 20–30% and those with enclosed cells 45–49% higher than with free cells which, however, also grew in small pellets. A substantial increase in the excretion of proteolytic enzymes has been reported for *Myxococcus xanthus* cells immobilized in calcium alginate beads (72,73,74). Yield improvements as high as eightfold have been found.

CONCLUSION

Myxobacteria may be at the threshold of biotechnological application as producers of secondary metabolites and of enzymes. No large-scale technical process has as yet been worked out for any one of them, but it already is obvious that they do not behave fundamentally different from other bacteria used in those fields. Solutions of problems met there may well be applicable or adaptable to myxobacteria.

ACKNOWLEDGMENT

I thank my secretary, Ms. Karin Rahn, for patiently and diligently typing the manuscript. I gratefully acknowledge financial support by the Fond der Chemischen Industrie.

OUTLINE

MANUFACTURE OF ACRYLAMIDE

Manufacture of acrylamide is the most important commercial application of nitrile hydratase. Acrylamide is used as a starting material for a variety of polymer products such as flocculant, paper-strength agent, coating materials, and EOR (enhanced oil recovery) polymers. Current world production of acrylamide exceeds 200,000 metric tons per annum (MTA). Nitto Chemical Industry Co., Ltd. (Japan) started commercial production of acrylamide in 1986 using a catalyst based on nitrile hydratase. This was one of the first commercial bioconversion processes that made a commodity chemical. The very first acrylamide process based on hydration of acrylonitrile with sulfuric acid (Fig. 1) was commercialized in 1950, which was replaced by the copper-catalyst process 20 years later. This copper-catalyzed process currently prevails in worldwide acrylamide production. Although the copper process gives an excellent efficiency in comparison with the acid hydration process, it still has some drawbacks, such as formation of impurities that are difficult to remove and adversely influence polymerization reactions. These impurities include ethylene cyanohydrin, β-hydroxypropionamide, and nitrilotrispropionamide, which may interfere with the chain reactions lowering the molecular weight of polymers and deteriorate the stability of the monomer product. Overcoming these limitations was one of the important motivations for the development of the enzymatic process using nitrile hydratase, which would minimize the side reactions caused by high specificity of enzymes and mild conditions under which they work.

Strain N-774

Because microorganisms capable of converting nitrile compounds to corresponding amides had been reported in the 1960s (1) many studies were conducted to find a microorganism with an activity high enough for industrial applications. *Rhodococcus* sp. N-774, discovered in 1980 (2), was the first strain that was put into commercial use to produce acrylamide from acrylonitrile. The nitrile hydratase enzyme is produced in this strain without an inducer. Thiamine is essential for the cell growth. Fe^{2+} and Fe^{3+} remarkably promote production of nitrile hydratase in the cell (3). Table 1 and Figure 2 show the effect of metal ions on the activity and the typical time course of the cell growth and the enzyme activity, respectively. The electron micrograph of the strain N-774 is shown in Figure 3.

Reaction Conditions

According to the semi-batchwise reaction test using immobilized cells of N-774 with a serial addition of acrylonitrile, a reaction temperature of 0 °C is optimum to obtain the product in high concentration, as shown in Figure 4 (4). Enzyme activity of this cell is light-inductive (5). Figure 5 shows the effect of light irradiation on the activity, which should be properly reflected on the reactor design.

Immobilization of the Cell

For mass production of biologically converted products, immobilized cells give wider options in selection and designing of the reactor. The bacteria cells entrapped in a polyacrylamide-based hydrogel are used in the production of acrylamide. To maintain the enzyme activity and improve the physical characteristics of the immobilized cells, the following techniques are used: (*1*) Swelling of the gel is controlled by copolymerization with cationic monomers (6); (*2*) Shearing force applied while mixing the cells with monomers or polymers is carefully controlled; (*3*) polymerization conditions are adjusted to minimize diffusion resistance within the gel, which not only reduces the apparent

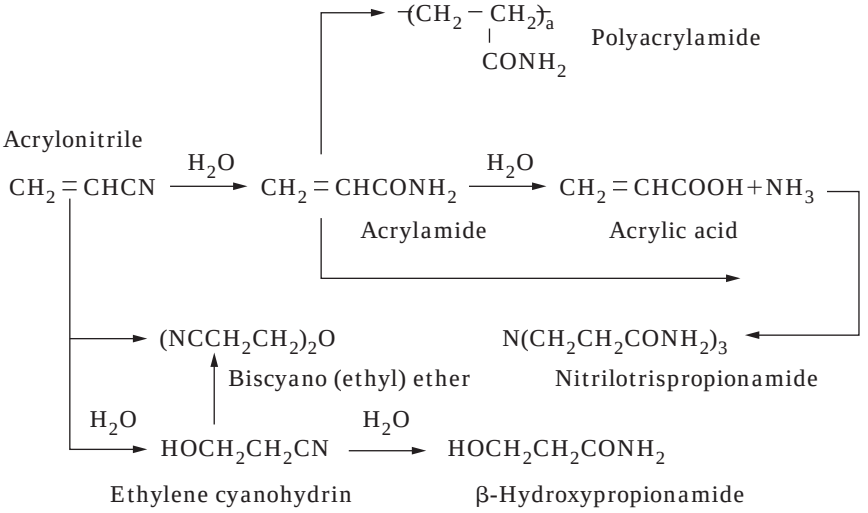

Figure 1. Products of acrylonitrile hydration.

Table 1. Effect of Metal Ions on Activity

Inorganic salts	(mg/L)	Call growth (g/L)	pH (−)	Specific activity (units/mg-dry cell)
$FeSO_4$ $7H_2O$	10	4.30	7.58	50.0
$MnSO_4$ $4H_2O$	10	4.75	6.94	0.70
$NiSO_4$ $6H_2O$	10	4.42	7.53	0.92
$CoSO_4$ $7H_2O$	10	4.34	7.37	1.27
$BaCl_2$ $2H_2O$	10	4.63	7.42	1.16
Na_2MoO_4 $2H_2O$	10	4.05	7.60	0.70
$CuSO_4$ $5H_2O$	2	4.54	7.30	1.24
$ZnSO_4$ $7H_2O$	2	4.38	7.45	0.96
None	—	4.42	7.47	1.05

Note: Basal medium: 10 g glucose, 3 g $(NH_4)_2SO_4$, 0.5 g KH_2PO_4, 0.5 g K_2HPO_4, 0.5 g $MgSO_4$ $7H_2O$, 0.1 g NaCl, 0.1 g $CaCl_2$ $2H_2O$, 5 g casamino acid and 0.002 g thiamine HCl in 1 L of distilled water, pH 7.5. Culture: at 30 °C for 55 hrs by shaking.

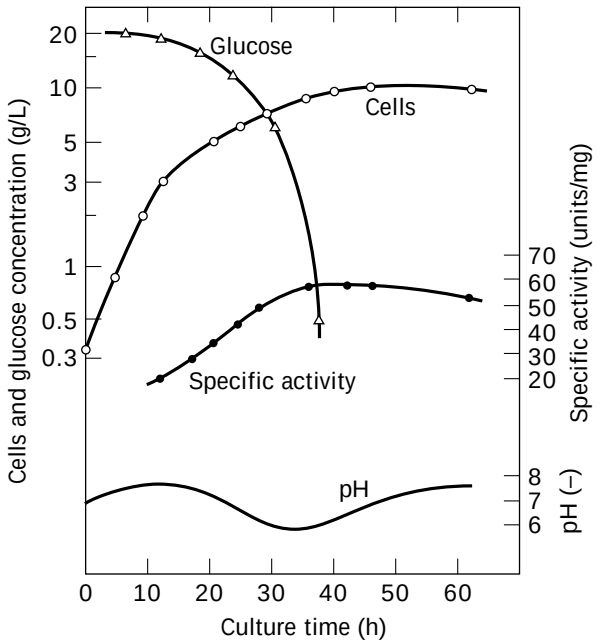

Figure 2. Time courses of cell growth and enzyme production. Culture conditions: medium consisting of 20 g glucose, 10 g peptone, 6 g yeast extract, and 6 g malt extract in 1 L of distilled water, pH, 7.2; aeration, 0.75 v/v/m; temperature, 30 °C; stirring, 350 rpm; culture volume, 13 L in a 20-L jar fermenter.

activity but also degenerates the activity by increasing the amide concentration near the active site (Figs. 6 and 7); and (*4*) Physical stability of the gel is improved by adjusting the polymer composition and polymerization conditions to prevent the cells from escaping the gel. An electron micrograph of the entrapped state of the cell is shown in Figure 8. The immobilization is carried out on a continuous basis at the commercial plant.

Bioreactor

Various types of the reactors—fixed bed, moving bed, fluidized bed, and stirred type—can be used (Membrane type does not seem suitable because of its flow-through resistance). The reactor is designed in consideration of (*1*) inhibition of polymerization; (*2*) replacement of degenerated catalyst; (*3*) control of reaction temperature; (*4*) control of substrate concentration; and (5) irradiation of light.

Comparison of the Processes

In comparison with the copper-catalyst process the biological acrylamide process features (*1*) 100% one-pass conversion; (*2*) no metal ions; (*3*) minimized organic impurities; (*4*) mild reaction conditions; and (*5*) a simplified process. The block diagram of the two processes is shown in Figure 9. Table 2 compares the typical product analysis.

Strain B-23

Pseudomonas chlororaphis B-23, discovered by Yamada et al. of Kyoto University (*7*) (Table 3), potentially gives higher activity than N-774. The tolerance to the product is also higher than that of N-774. Sucrose, glutamic acid, cystine, and proline are used as medium components to grow the enzyme with minimized catabolite repression (8).

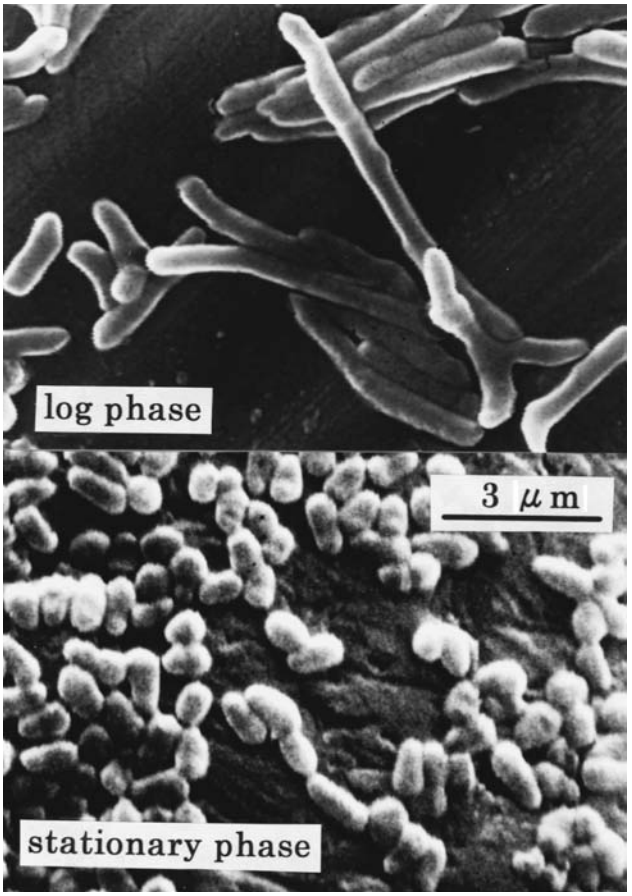

Figure 3. Electron micrograph of strain N-774.

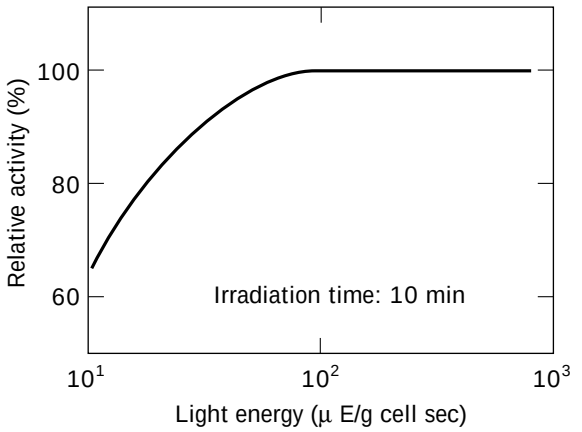

Figure 5. Activation of enzyme by light energy.

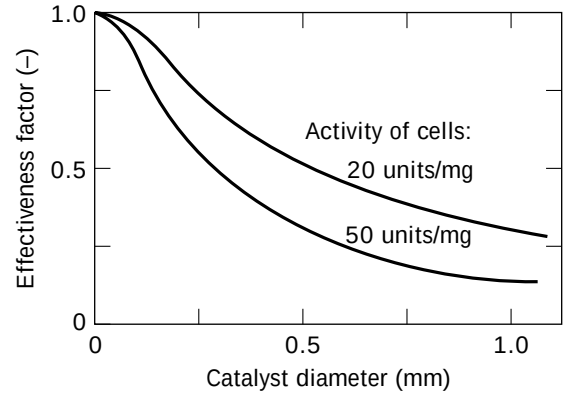

Figure 6. Catalyst particle size and effectiveness factor.

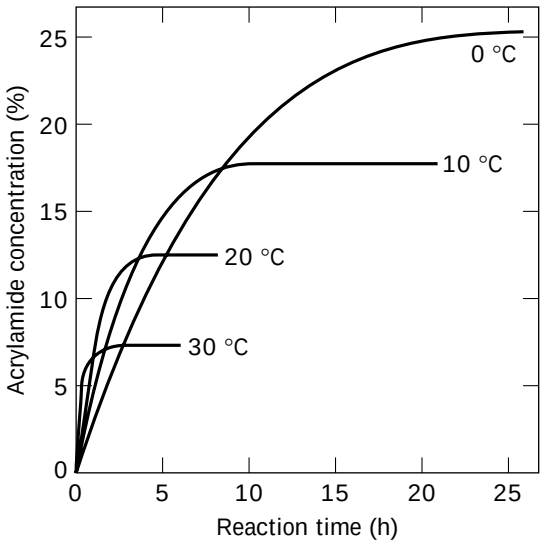

Figure 4. Effect of temperature on acrylamide production. The reaction was carried out in a semi-batchwise fashion in a stirred-tank reactor. Acrylonitrile was added consecutively. Reaction conditions: pH, 8.5; catalyst concentration, 0.5%; acrylonitrile concentration, 2.0%; temperature, as indicated in the figure.

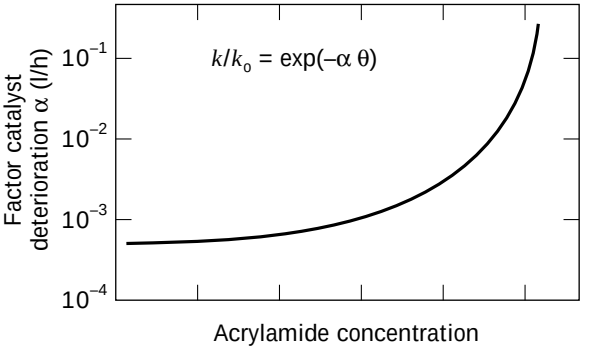

Figure 7. Catalyst deterioration by amide without reaction.

Methacrylamide works remarkably well as an enzyme inducer for this strain. The activity is improved by means of mutation using chemicals such as nitrosoguanidine. The mutant Am-324, shown in Figure 10, gives the activity 3,000 times as high as the original cell from nature. The catalyst based on this mutant, when used in the commercial acrylamide plant, increased the production capacity to 6,000 MTA from 4,000 MTA with the N-774 catalyst.

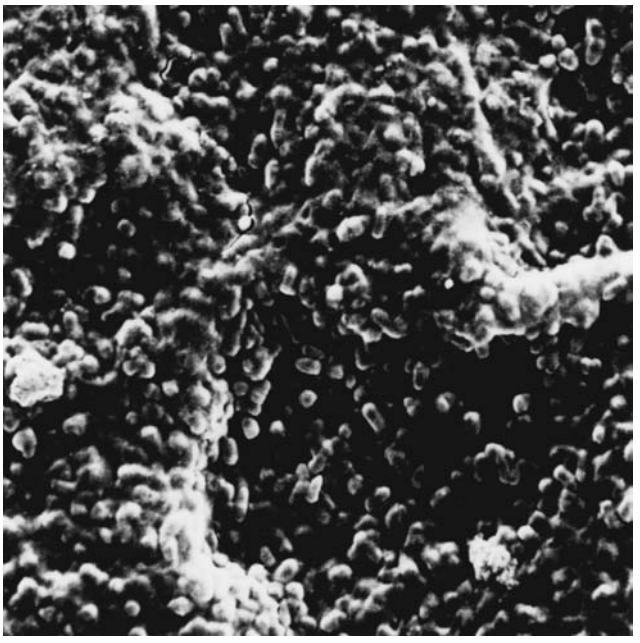

Figure 8. Electron micrograph of immobilized cells.

Table 2. Typical Product Analysis

Impurities	Acrylamide from enzymatic process	Acrylamide from copper-catalyzed process
Acrylonitrile	N.D. (<5)	100 ~ 200
Acrylic acid	<5.0	100 ~ 200
Ethylene cyanohydrin	N.D. (<10)	300 ~ 400
β-Hydroxypropionamide	N.D. (<10)	600 ~ 1000
Nitrilotrispropionamide	N.D. (<10)	~100
Propionamide	N.D. (<10)	20 ~ 50

Note: ppm in 50% aq. solution.

Strain J-1

The enzyme induction mechanism of *Rhodococcus rhodochrous* J-1 was also found by Yamada et al. (9). At the beginning of their discovery, J-1 produced two different kinds of nitrile-converting enzymes (nitrilase and nitrile hydratase), and the reaction activity of both enzymes was very low. They found addition of cobalt ions into the cell-cultured medium improved the nitrile hydratase activity, and further increase of the activity was affected by action of urea or its derivatives as an inducer in the presence of cobalt ions. This strain has very high tolerance to acrylamide. Table 4 shows properties of the nitrile hydratase from the strains N-774, B-23, and J-1. All three enzymes belong to the metalloenzyme group but are different in kind of the coordinated metals to their active sites (i.e., iron for N-774 and B-23 and cobalt for J-1). Nitrile hydratase enzymes having nickel as the coordinated metal have also been found. The protein chemistry of nitrile hydratase, including molecular weight and light inducibility, differs widely among different genuses and species. Reaction performance of the three strains, in laboratory tests and at the commercial plant, are compared in Figure 11 and

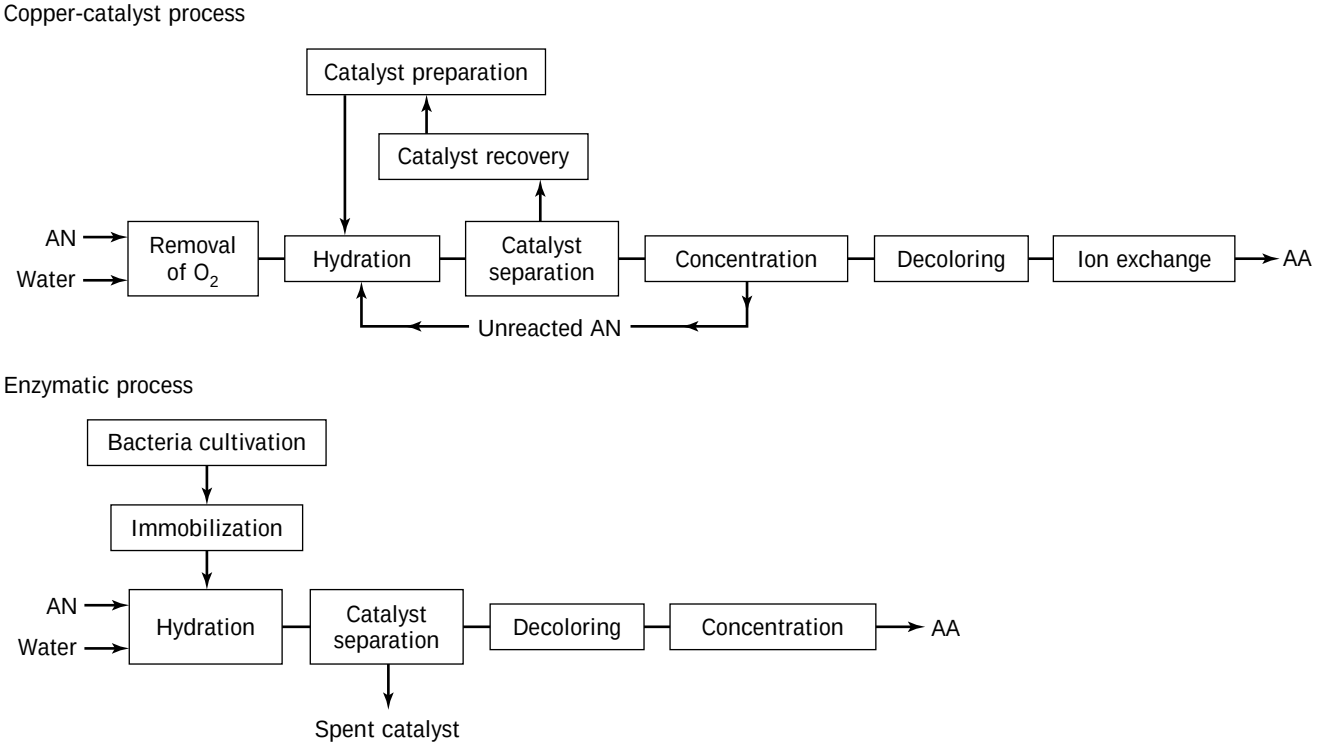

Figure 9. Comparison of enzymatic process with conventional process. AN = acrylonitrile; AA = Acrylamide (50% aqueous solution).

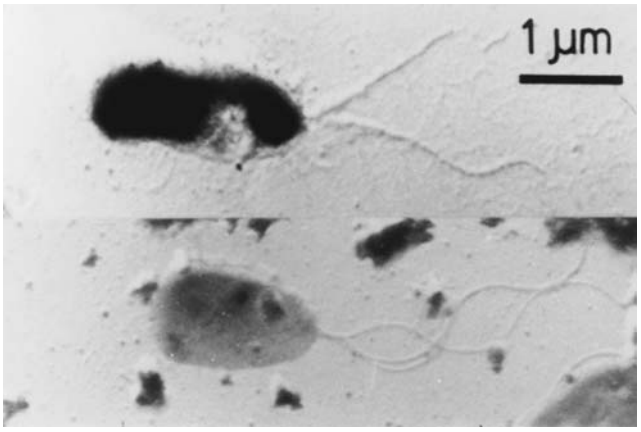

Figure 10. Electron micrograph of strain B-23.

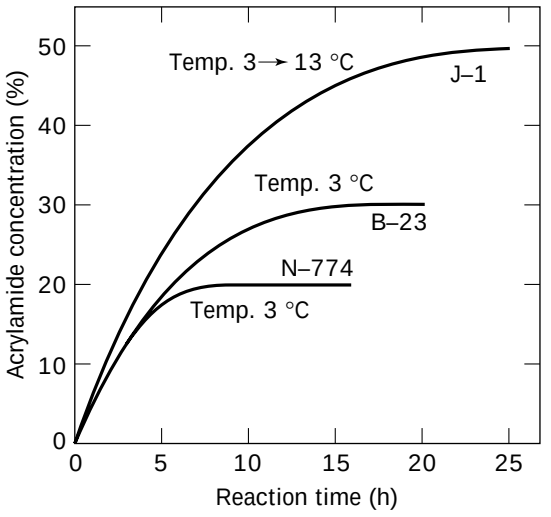

Figure 11. Comparison of reaction performance. The reaction was carried out in a semi-batchwise fashion in a stirred-tank reactor. Acrylonitrile was added consecutively. Reaction conditions: pH, 6.5 ~ 8.5; temperature, as indicated in the figure; acrylonitrile concentration, 2.0%.

Table 5. The optimized J-1 exhibits a magnitude of order higher productivity than the N-774. Production capacity of the acrylamide plant using the J-1 catalyst is by four to five times greater than that of the same plant with the N-774 catalyst.

APPLICATION TO OTHER AMIDES

Another important industrial application of nitrile hydratase is the production of nicotinamide, which is widely used as a vitamin supplement. At the end of 1997, Lonza Ltd. (China) was scheduled to manufacture 3,000 MTA of nicotinamide by the continuous biotransformation of 3-cyanopyridine using immobilized cells of *Rhodococcus rhodochrous*. Considerable quantity of nicotinic acid is inevitably formed as a by-product in alkaline hydrolysis of 3-cyanopyridine. Under the biological route, nicotinic acid and other contaminating by-products are not produced. This route is also competitive with the methylethylpyridine route.

NITRILASE

Nitrile hydratase is one of the two types of the enzymes that catalyze hydration or hydrolysis of nitrile compounds. The other one, nitrilase, converts nitriles to corresponding carboxylic acids. Some of the nitrilases are capable of hydrolyzing nitriles stereospecifically. Optical resolution of α-substituted nitriles using a nitrilase to obtain one of the corresponding acid enantiomers was reported (10). The yield of the proposed process, however, was limited to 50% with the other nitrile enantiomer remaining intact. The biotransformation process to produce *R*-mandelic acid using a *R*-specific nitrilase (equation 1) has been commercialized by Nitto Chemical (11). In this process, the unconverted *S*-nitrile enantiomer is racemized in one-pot equilibrium dissociation-association reactions (equation 2), which eventually gives nearly 100% conversion to *R*-acid enantiomer at an optical purity over 99%. Addition of sodium sulfate in the reaction mixture enhances the productivity sixfold by reversibly forming the benzaldehyde-sulfite complex to promote racemization of *S*-mandellonitrile (equation 3) (12).

$$\text{RS-}C_6H_5CH\ (OH)\ CN \rightarrow \text{S-}C_6H_5CH\ (OH)\ CN + \text{R-}C_6H_5CH\ (OH)\ COOH + NH_3 \quad (1)$$

$$C_6H_5CH\ (OH)\ CN \leftrightarrow C_6H_5CHO + HCN \quad (2)$$

$$C_6H_5CHO + Na_2SO_3 + H_2O \leftrightarrow C_6H_5CH\ (OH)\ SO_3Na + NaOH \quad (3)$$

Although R-specific nitrilase is found in a variety of bacteria, such as *Pseudomonas* sp., *Alcaligenes* sp., *Acineto-*

Table 3. The Development of B-23 Strain Am-324

Strain	Mutation	Medium	SA (U/mg)	BA (U/mL)	Property
Wild	—	M-A	0.72	0.4	Mucilaginous bacterium
↓	—	M-R	66	363	
Mutant I (Am-3)	NTG	M-R	65	465	Unmucilaginous
↓					
Mutant II (Am-324)	NTG	M-R	125	952	High activity
↓	—	Consecutive addition of inducer	141	1260	

Note: NTG = *N*-methyl-*N'*-nitro-*N*-nitrosoguanidine; SA = specific activity, BA = enzyme activity of culture broth.

Table 4. Properties of Nitrile Hydratase from N-774, B-23, and J-1

	Rhodococcus sp N-774	*Pseudomonas chlororaphis* B-23	*Rhodococcus rhodochrous* J-1
Molecular weight	70,000	100,000	520,000
Subunit molecular weight	α: 27,000	25,000	α: 26,000
	β: 27,500		β: 29,000
Metal	Fe	Fe	Co
Activation by light	Positive	Negative	Negative
Tolerance for acrylamide	High	Very high	Very high
Production of organic acid	Very low	Negligible	Low
Optimum temperature [°C]	35	20	
Heat stability	Unstable	Unstable	Stable
Optimum pH	7.7	7.5	
Stable pH	7.0 ~ 8.5	6.0 ~ 7.5	6.0 ~ 8.5
Enzyme formation	Constitutive	Inducible	Inducible

Table 5. Reaction Performance in Commercial Production

	Reaction conditions		Reaction performance	
	pH	7.5 ~ 8.5	Conversion of AN	99.9 %
N-774	Temperature	0 ~ 5 °C	Selectivity of AA	99.9 %
	AN concentration	1.5 ~ 2.0 %	AA concentration at outlet of reactor	20%
	pH	7.5 ~ 8.5	Conversion of AN	99.97 %
B-23	Temperature	0 ~ 5 °C	Selectivity of AA	99.98 %
	AN concentration	1.5 ~ 2.0 %	AA concentration at outlet of reactor	30 %
	pH	6.5 ~ 8.0	Conversion of AN	99.97 %
J-1	Temperature	0 ~ 15 °C;	Selectivity of AA	99.98 %
	AN concentration	1.5 ~ 2.0 %	AA concentration at outlet of reactor	50 %

Note: AN = acrylonitrile, AA = acrylamide.

bacter sp., *Caseobacter* sp., *Nocardia* sp., *Brevibacterium* sp., *Bacillus* sp., *Aureobacterium* sp., and *Rhodococcus* sp. (13), *S*-specific nitrilase has hardly been isolated.

OUTLINE

INTRODUCTION

As are microbial carbohydrates, microbial lipids are a diverse group of compounds with important biochemical functions. The exploitation of microbial oil (triacylglycerol) has been attempted since the 1980s. The term *single cell oil* is used for unique oils produced by microorganisms (1,2). It is probable that single cell oil could compete against plant seed oils or fish oils. Some yeasts and molds have long been known to accumulate very high levels of triacylglycerols. A lipid content in excess of 40% (w/w) is not exceptional, and values of 70% and even 80% have been reported (3). The oil produced by these oleaginous species not only has the same triacylglycerol structure as plant oils but also shows a similar distribution of fatty acids at the three positions: saturated fatty acids are almost totally excluded from the central (*sn*-2) carbon atom.

The fatty acyl groups themselves are the same as those found in plant seed oils or, in the highly polyunsaturated fatty acids, are the same as those found in fish oils or other animal products. Many attempts have been made to produce useful fatty acids or oils containing them by microbial processes. One example is the production of cocoa-butter-equivalent oil by a yeast that abundantly produces stearic acid (4,5). The most successful example occurs in the production of oils containing polyunsaturated fatty acids (PUFAs). Certain microorganisms may also produce prostaglandin precursors, or even prostaglandins themselves from PUFAs, as well as cerebroside lipids and other unusual lipids that are not normally regarded as being of microbial origin (6). Here, microbial PUFA production is discussed mainly as a typical example of a single cell oil.

OUTLINE OF MICROBIAL PUFA PRODUCTION

PUFAs are fatty acids having more than one double bond. Among these, 5(*Z*),8(*Z*),11(*Z*)-eicosatrienoic acid (20:3ω9; Mead acid), dihomo-γ-linolenic acid (20:3ω6; DGLA), arachidonic acid (20:4ω6; AA), and 5(*Z*),8(*Z*),11(*Z*),14(*Z*),17(*Z*)-eicosapentaenoic acid (20:5ω3; EPA) (see Fig. 1 for structures and biosynthetic pathways) are of interest because they are precursors for prostaglandins, thromboxanes, leukotrienes, prostacyclins, and so on (7–9), all of which have hormonelike activities. Possibly as a result of the physiological activities of these compounds, PUFAs exhibit several unique biological activities, such as lowering of plasma cholesterol level and prevention of thrombosis. The inclusion of EPA and 4(*Z*),7(*Z*),10(*Z*),13(*Z*),16(*Z*),19(*Z*)-docosahexaenoic acid (22:6ω3; DHA) as dietary supplements has been recommended for the prevention of heart diseases (10), and γ-linolenic acid (18:3ω6; GLA) has been recommended for the relief of eczema (11). Accordingly, PUFAs are highly important substances in the pharmaceutical, medical, and nutritional fields. Because food sources rich in these PUFAs are limited to a few seed oils that contain GLA and fish oil, which contains EPA and DHA, recent investigations have focused on microorganisms as alternative sources of oils containing these PUFAs.

Microorganisms are potentially very promising lipid sources because of their extremely high growth rates in simple media and the simplicity of their manipulation.

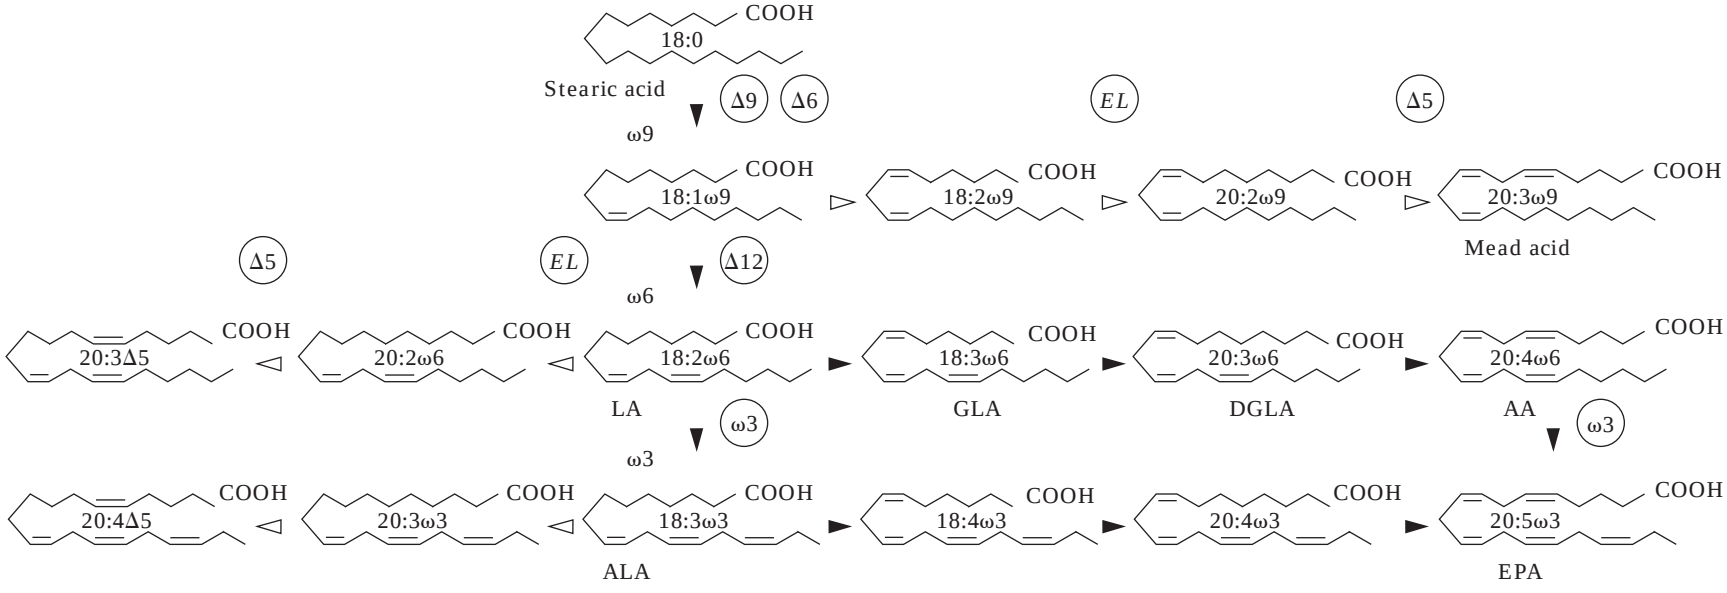

Figure 1. Proposed pathways for polyunsaturated fatty acid (PUFA) biosynthesis in *Mortierella alpina* 1S-4. *Open arrowheads* show bypaths through which *n*-9 fatty acids and nonmethylene-interrupted PUFAs are formed in Mut48 and Mut49, respectively. **Δ***n*, *Δ*n desaturation; *EL*, elongation.

Furthermore, microbial PUFA-containing oils are usually characterized by the absence of other PUFAs, making purification of individual fatty acids from microorganisms an easier task than it is from other sources. A variety of PUFAs have been detected in microorganisms including bacteria, fungi, algae, mosses, and protozoa (Table 1). Erwin and Bloch (12) suggested that lower classes of organisms including microorganisms can be classified into several groups based on their ability to produce PUFAs. Shaw (13) pointed out that some fungi belonging to the Mucorales can accumulate relatively large amounts of GLA in their mycelia. Based on these early observations, several groups have been screening for microorganisms capable of accumulating lipids containing PUFAs so as to obtain more suitable sources for large-scale preparation of important nutritional components.

Suzuki (14,15) found several potent producers of GLA through extensive screening of filamentous fungi. They reported that a strain of *Mortierella isabellina* accumulates about 3 g/L of GLA when grown in a medium containing glucose as the major carbon source. Based on this finding, commercial production of GLA with a *Mortierella* fungus recently commenced in Japan.

Shimizu et al. (16,17) found that several *Mortierella* fungi are potent producers for triacylglycerol containing AA, DGLA, or EPA. A soil isolate strain, *Mortierella alpina* 1S-4, produced AA on cultivation in a medium containing glucose and yeast extract. It also produced EPA when grown at low temperature (20 °C) or when grown in a medium supplemented with α-linolenic acid (18:3ω3; ALA). When grown in the presence of sesame seed oil, the same fungus accumulated DGLA in place of AA because of specific inhibition of Δ5 desaturase by sesamin and related lignan compounds present in the oil. Mutants that were considered to be defective (or to have low activity) in Δ5, Δ6, Δ12, Δ9, and ω3 desaturase were derived from *M. alpina* 1S-4 (Fig. 2) (18,19). Mutant Mut44 and S14 had low Δ5-desaturase activity and accumulated large amounts of DGLA. Mutant Mut48 was completely defective in Δ12 desaturase and produced three *n*-9 PUFAs: 6(*Z*),9(*Z*)-

octadecadienoic acid (18:2ω9), 8(*Z*),11(*Z*)-eicosadienoic acid (20:2ω9), and Mead acid. Two nonmethylene-interrupted PUFAs, that is, 5(*Z*),11(*Z*),14(*Z*)-eicosatrienoic acid (20:3Δ5) and 5(*Z*),11(*Z*),14(*Z*),17(*Z*)-eicosatetraenoic acid (20:4Δ5), and accumulation of linoleic acid (18:2ω6; LA) were found in the Δ6 desaturase-defective mutant Mut 49. Two other mutants, T4 and K1, were considered to have defects in Δ9 and ω3 desaturase, respectively. T4 accumulated a high level of stearic acid (18:0) and K1 did not produce *n*-3 fatty acids, which were usually produced by the parental strain at low temperature. Above all, *M. alpina* 1S-4 and its mutants are new and promising sources of C_{20} PUFAs. In addition, because of intensive investigations done worldwide, all PUFAs listed in Table 2 can now be obtained from a variety of microorganisms.

PRODUCTION OF C_{18} FATTY ACIDS

γ-Linolenic Acid

Suzuki (14,15) reported that several *Mortierella* strains belonging to the subgenus *Micromucor* produce lipids, mainly triacylglycerol rich in GLA, in their mycelia when grown in a liquid medium containing glucose or sugar cane molasses as the major carbon source. These strains grow rapidly in a medium containing a high concentration of glucose (200 g/L) under the conditions of 2 ppm dissolved oxygen, pH 4.0, and 30 °C, yielding a mycelial mass of 40–156 g/L. The lipid content of GLA was 18–41 mg/g dry mycelia, corresponding to a GLA yield of 1.2–3.4 g/L. The purified oil obtained from the mycelia contained myristic acid (0.7%, by weight), palmitic acid (27.2), palmitoleic acid (0.9), stearic acid (5.7), oleic acid (43.9), linoleic acid (12.0), GLA (8.3), arachidic acid (0.6), eicocenoic acid (0.4), behenic acid (0.1), and erucic acid (0.2). The GLA content of the oil was comparable to that of *Oenothera biennis* seed oil. The low linoleic acid content of the oil may be advantageous for obtaining a highly pure GLA preparation with a high recovery. Recently, *Mortierella ramanniana*, *Mucor rouxii*, and *Mucor ambiguus* were evaluated as to their productivities of GLA. *M. ambiguus* immobilized in porous support particles was shown to excrete lipids containing GLA into the culture broth or onto the surface of the cell wall in the presence of a nonionic surfactant.

Linoleic Acid

The mutant Mut49 derived from *M. alpina* 1S-4 was considered to be defective in Δ6 desaturase. This mutant accumulated high amounts of LA with low levels of GLA, DGLA, and AA in its mycelia (20) (Table 3).

Stearic Acid

Mutant T4 derived from *M. alpina* 1S-4 is considered to be defective in Δ9 desaturation (19). Its mycelial fatty acids included 38% stearic acid (18:0), the level being only 5% for the wild type (Table 3). When grown at 24–28 °C, its mycelial lipids included a markedly high level (up to 50 mol% of total mycelial lipids) of free fatty acids, of which about 90 mol% was stearic acid. However, the levels of free fatty acids were markedly decreased with a concomitant increase in the triacylglycerol level when the mutant was grown at 20 °C or lower. When mutant T4 was grown in a culture medium supplemented with LA or linseed oil that included about 60% ALA, decreased levels of free fatty acid and increased levels of triacylglycerol were also found, suggesting that PUFA is needed for the synthesis of triacylglycerol in this mutant.

PRODUCTION OF C_{20} FATTY ACIDS

Arachidonic Acid

Shimizu et al. have assayed the C_{20} PUFA productivity of a wide variety of microorganisms (16,17). Most C_{20} PUFA producers were found to be filamentous fungi belonging to the orders Mucorales and Entomophthorales. Mainly they produce C_{20} PUFAs of the *n*-6 family (i.e., AA and DGLA) together with C_{18} PUFAs of the same family (i.e., GLA). Most of the PUFA-producing isolates from natural sources were found to belong to the genus *Mortierella*. The genus *Mortierella* is subdivided into two subgenera, *Micromucor* and *Mortierella*. Interestingly, all the strains found as C_{20} PUFA producers belong to the subgenus *Mortierella*. Neither the stock cultures nor isolates belonging to the subgenus *Micromucor* showed any detectable accumulation of C_{20} PUFA, although they were good producers of GLA (51). As a result of this screening effort, a soil isolate was obtained that was taxonomically identified as *Mortierella alpina* 1S-4, as a potent producer of AA (16,17). The fungus effectively utilized not only glucose but glycerol, maltose, palmitate, stearate, oleate, *n*-hexadecane, and *n*-octadecane as carbon sources for AA production (Fig. 3).

Using a 10-m^3 fermentor, a mycelial mass of 20 kg/m^3 of medium (dry wt) containing 60% lipid, and 40% of AA in the total fatty acids, was produced by *M. alpina* 1S-4. This fermentation involved intermittent feeding of glucose and 7 days cultivation at 28 °C. The concentration of AA in the harvested mycelia increased to nearly 70% when allowed to stand at room temperature for a further 6 days. The lipids containing AA could be recovered as a triacylglycerol (80–90% recovery) from the mycelia using a seven-step process: *(1)* separation of the mycelia by filtration, *(2)* drying, *(3)* crushing by ball mill, *(4)* extraction of lipids with *n*-hexane, *(5)* removal of insoluble materials by centrifugation, *(6)* decolorization and deodorization with ac-

AA, arachidonic acid (20:4ω6); ALA, α-linolenic acid (18:3ω3); DGLA, dihomo-γ-linolenic acid (20:3ω6); DHA, 4(*Z*), 7(*Z*), 10(*Z*), 13(*Z*), 16(*Z*), 19(*Z*)-docosahexaenoic acid (22:6ω3); DPA(*n*-3), 7(*Z*), 10(*Z*), 13(*Z*), 16(*Z*, 19(*Z*)-docosapentaenoic acid (22:5ω3); DPA(*n*-6), 4(*Z*), 7(*Z*), 10(*Z*), 13(*Z*), 16(*Z*)-docosapentaenoic acid (22:5ω6); EPA, 5(*Z*), 8(*Z*), 11(*Z*), 14(*Z*), 17(*Z*)-eicosapentaenoic acid (20:5ω3); GLA, γ-linolenic acid (18:3ω6); LA, linoleic acid (18:2ω6); Mead acid, 5(*Z*), 8(*Z*), 11(*Z*)-eicosatrienoic acid (20:3ω9); *Mo., Mortierella; Mu., Mucor*.

tive charcoal, and *(7)* concentration (Fig. 4). If necessary, the AA in the purified oil could be isolated as the methyl or ethyl ester after successive transesterification, liquid–liquid partition chromatography, and high-performance liquid chromatography.

Dihomo-γ-Linolenic Acid

Most AA-producing fungi can accumulate small amounts of DGLA when they are cultivated under the conditions optimized for AA production (52). Because AA is derived from DGLA through the *n*-6 route, all AA-producing fungi potentially should produce large amounts of DGLA if one can block its conversion to AA (Δ5 desaturation).

The first approach to blocking the Δ5 desaturation began with screening for Δ5-desaturase inhibitors. Among various substances tested, sesame oil and peanut oil were found to cause a marked decrease in AA content (27,53) when added to the culture medium. On addition of 3% sesame seed oil to a glucose–yeast extract medium, the production of DGLA with *M. alpina* 1S-4 reached 1.7 g/L, whereas the production of AA was only 0.7 g/L. The effective factors responsible for this phenomenon were isolated from sesame seeds extracts or sesame oil and identified to be lignan compounds, that is, (+)-sesamin, (+)-episesamin, (+)-sesaminol, and (+)-episesaminol (Fig. 5) (54). The results obtained from experiments using either cell-free extracts of *M. alpina* 1S-4 or a rat liver microsomal fraction clearly demonstrated that these lignan compounds specifically inhibited Δ5 desaturase at low concentrations.

[a]—, undetectable.
[b]Both were found in all strains except for Mut48, in which GLA and DGLA were not detected. 20:0, arachidic acid; 22:0, behenic acid.
[c]ALA and 11(*Z*), 14(*Z*), 17(*Z*)-eicosatrienoic acid (20:3ω3) were found as an additional fatty acid on growth at 12 °C except for Mut48.

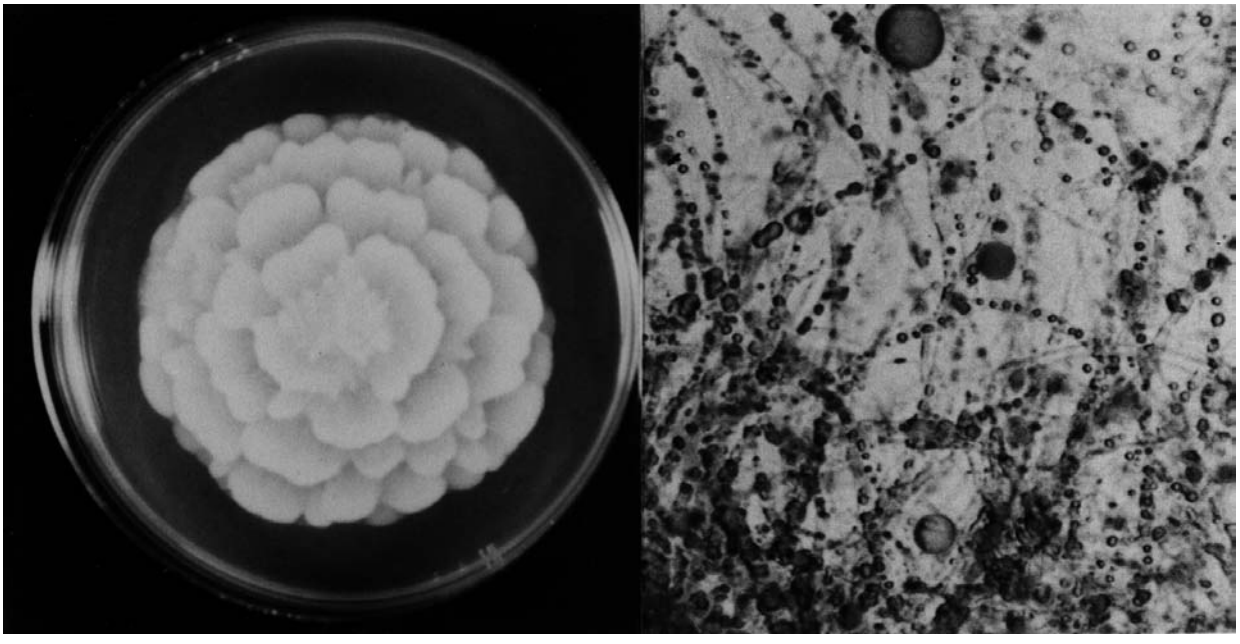

Figure 3. Photomicrographs of *M. alpina* 1S-4 colony grown on potato-dextrose agar (*left*) and oil droplets accumulated in mycelia (*right*).

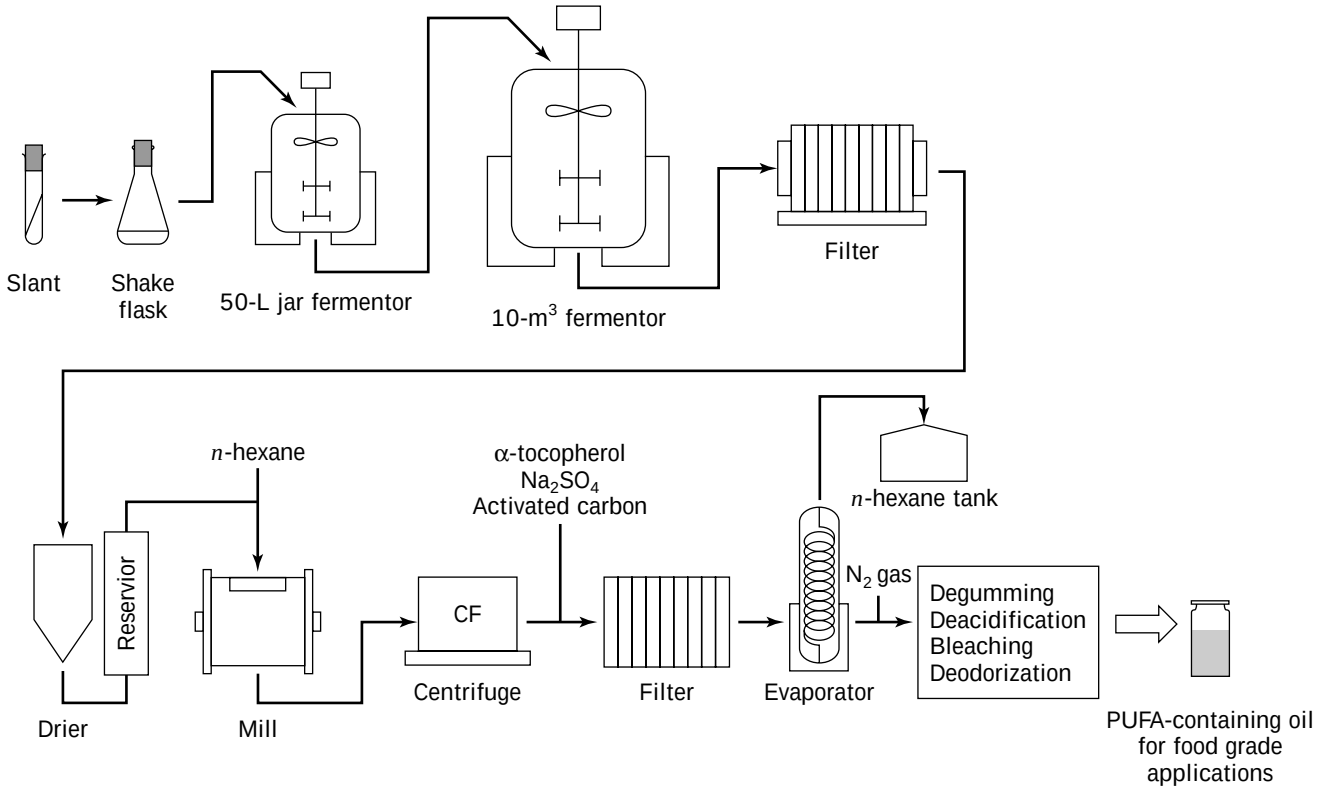

Figure 4. Flowchart for the production of a fungal single cell oil with a high PUFA content.

At these concentrations, none of the Δ6, Δ9, and Δ12 desaturases were inhibited by these lignan compounds. Kinetic analysis showed that sesamin is a noncompetitive inhibitor (K_i = 155 μM for rat liver Δ5 desaturase) (54). (−)-Asarinin and (−)-epiasarinin, the stereoisomers of (+)-episesamin and (+)-sesamin, respectively, which were isolated from a Chinese crude medicine "Saishin" (*Asiasari radix*), also showed specific noncompetitive inhibition of Δ5 desaturase (55). Another desaturase inhibitor, curcumin, was found in turmeric. Curcumin inhibited both Δ5 and Δ6 desaturase in vitro, but it was not as effective as sesamin in stimulation of DGLA production (56,57). Recently, an antioxidant, alkyl gallate (Fig. 5), and the Ca channel blockers nicardipine and nifedipine (Fig. 5) were also shown to inhibit both Δ5 and Δ6 desaturases (58). In a study on optimization of the culture conditions for the production of DGLA by *M. alpina* 1S-4, a medium containing glucose, yeast extract, and the non-oil fraction of sesame oil was found to be suitable. Under optimal conditions in a 50-L fermentor, the fungus produced DGLA at 2.2 g/L (107 mg/g dry mycelia) (Table 4). This value accounted for 23.1% of the total mycelial fatty acids.

The second approach to blocking the Δ5 desaturation began with screening for Δ5-desaturase-defective mutants. Several mutants of this type, which is characterized by a high DGLA level and a reduced AA level, were obtained, and two (Mut44 and S14) of them were studied in detail (28,29). The mycelial fatty acid composition of the two mutants is compared in Table 3. The mutant S14 has a higher DGLA level than Mut44; its AA level is about one-tenth that in Mut44. On cultivation for 6 days at 28 °C in a 10-L fermentor, Mut44 produced 3.2 g DGLA per liter of culture broth (123 mg/g dry mycelia), which accounted for 23.4% of the total mycelial fatty acids (28). The mycelial AA amounted to only 19 mg/g dry mycelia (0.5 g/L culture broth), which accounted for 3.7% of the total mycelial fatty acids (Table 4). The level of AA in Mut44 could be further decreased by growing the fungus in the presence of a mixture of Δ5-desaturase inhibitors, sesamin and episesamin. Using a culture medium supplemented with 0.075 g/L sesamin mixture, the production of DGLA was 2.1 g/L culture broth (16.1% of total fatty acids) and the AA production was 0.2 g/L (1.3%) (59). The DGLA production of S14 was 2.4 g/L culture broth (43.3% of total fatty acids) when grown at 28 °C for 7 days in a 5-L jar fermentor (29). The production of DGLA by using mutants was superior to the aforementioned method of using inhibitors because it did not require inhibitors and the concentration of DGLA in the mycelial oil was higher (Table 4).

By using mutant K1 derived from strain Mut44, which was considered to be defective in the conversion of *n*-6 to *n*-3 fatty acids (ω3 desaturation) (60), a DGLA-rich oil without *n*-3 fatty acids was obtained (Table 3). The mutant could not produce 8(*Z*),11(*Z*),14(*Z*), 17(*Z*)-eicosatetraenoic acid (20:4ω3) or any other *n*-3 fatty acids, of which about 10% was found in its parental strain on cultivation at 12 °C. The growth rate of the mutant was comparable to that of the parental strain when grown at 28 °C, but it became much slower when the mutant was grown at 12 °C, at

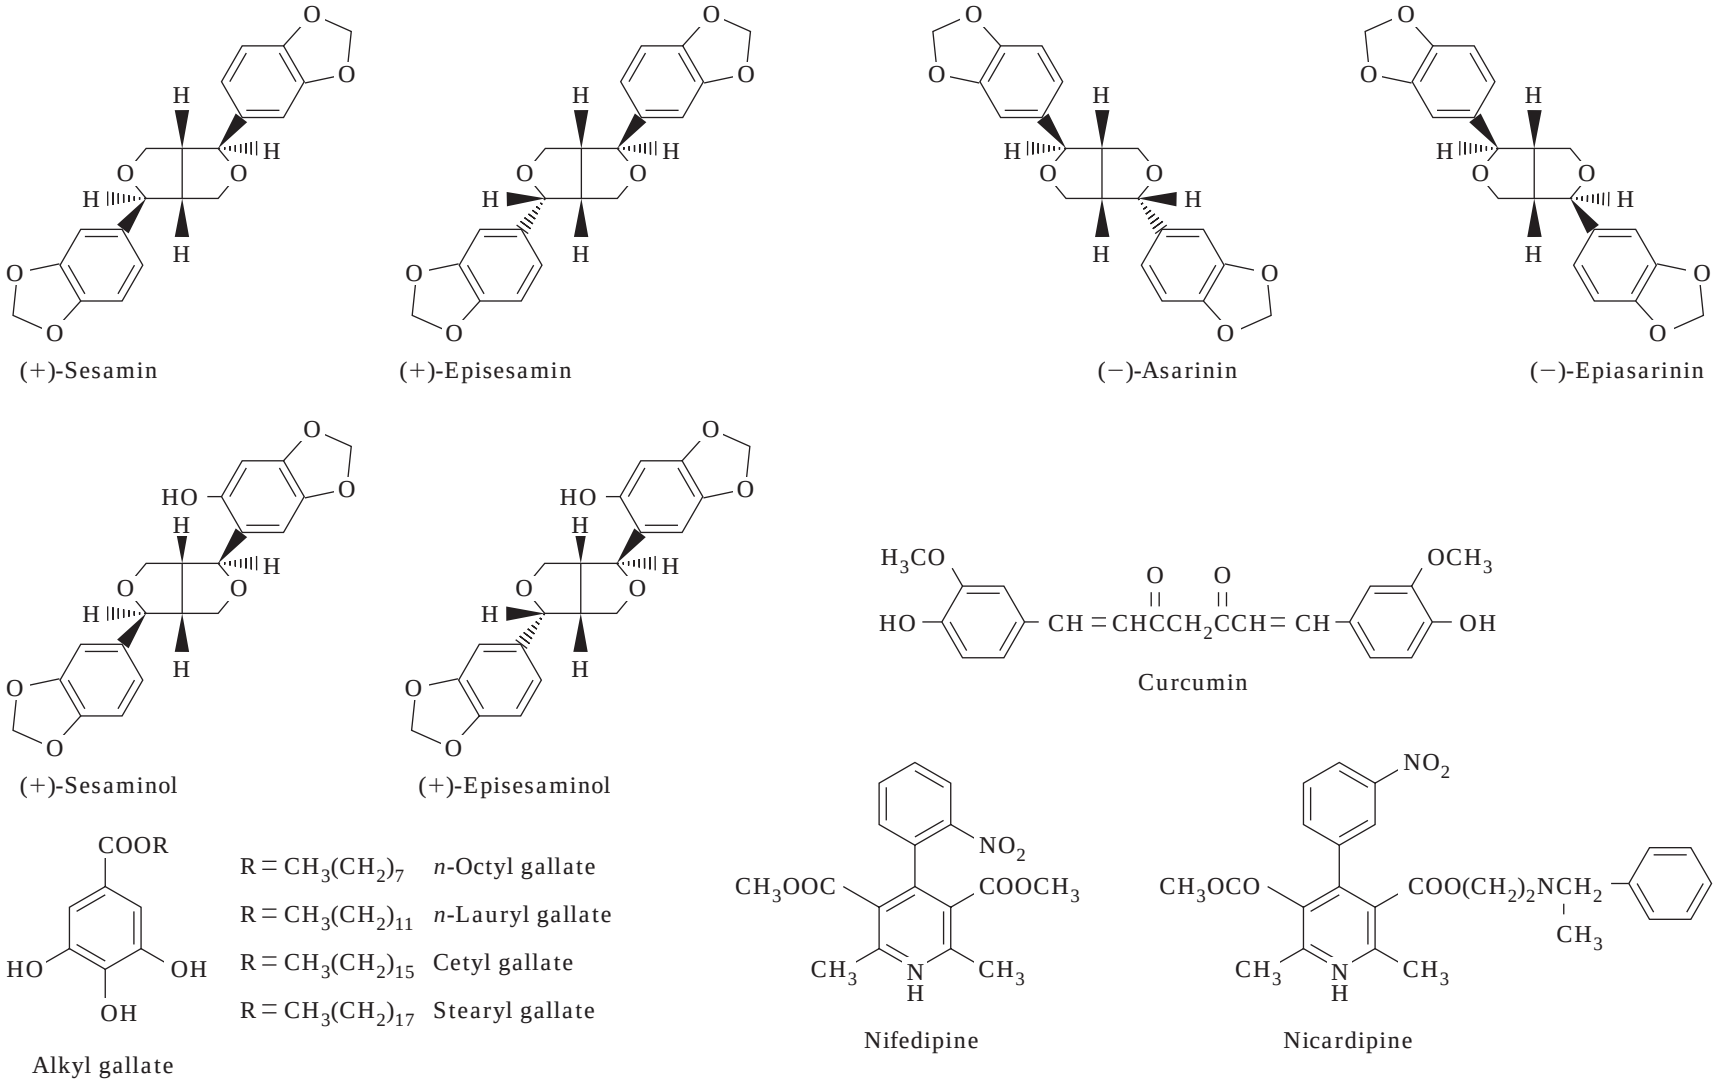

Figure 5. Sesamin and related compounds as desaturase inhibitor.

which point the lag phase for Mut44 was about 2 days but 5 days for the mutant.

Eicosapentaenoic Acid

Shimizu et al. (36,52) found that lowering the cultivation temperature caused the additional accumulation of EPA by all the AA producers tested. Most of these AA producers grew well at low temperature (6–16 °C) and produced enough mycelia in simple growth media. Experiments with cell-free extracts of *M. alpina* 1S-4 demonstrated that the enzyme that catalyzed the formation of EPA was produced even when the fungus was grown at high temperature, but that the reaction(s) yielding EPA did not take place at high temperature (52). The Δ17 (or ω3) desaturation of AA to EPA was observed in *Saprolegnia parasitica* by Gellerman and Schlenk (61). If this is also the case for *Mortierella* fungi, an enzyme or enzyme system catalyzing the methyl end-directed desaturation of AA (Δ17 (or ω3) desaturation) may be activated by cold treatment and the resultant EPA may be necessary for maintaining the proper membrane fluidity in a low-temperature environment. As shown in Table 5, *M. alpina* 1S-4 produced EPA at levels of more than 0.3 g/L at 12 °C.

It was further demonstrated that several AA-producing *Mortierella* strains accumulated detectable amounts of EPA in their mycelia when grown in media containing ALA (62). This observation suggests that the conversion of ALA to EPA through the *n*-3 route occurs in *Mortierella* fungi as well as in animals. This conversion is independent of the growth temperature, because EPA production takes place even at 28 °C. The ability of the *Mortierella* fungi to convert added ALA to EPA is very promising from a biotechnological point of view because various kinds of easily available natural oils contain ALA. The potential of such natural oils as precursors of EPA was examined. Linseed oil, in which ALA amounts to about 60% of the total fatty acids, was found to be the most suitable for EPA production. Under optimal culture conditions, *M. alpina* 1S-4 converted 3.8% of the ALA in the added linseed oil into EPA, and EPA production reached 0.99 g/L (41 mg/g dry mycelia). This value is 3.3-fold higher than that obtained under low-temperature growth conditions (Table 5). Another advantage of this conversion is that it can be carried out under normal growth temperature conditions (20–30 °C). Under such conditions, the fungal growth is rapid and dense, and the energy costs should be lower than those for low-temperature cultivation.

EPA production was further stimulated when AA-producing fungi were grown in a medium containing linseed oil at low temperature. This phenomenon was suggested to be mainly caused by the low temperature-dependent production of EPA from AA formed through the *n*-6 route, and the conversion of the 18:3ω3 in the added linseed oil to EPA through the n-3 route took place at the same time (63). Stimulation of the *n*-3 route itself at low temperature was also suggested to contribute to the increased EPA production. The amount of EPA accumulated reached 1.88 g/L (66.6 mg/g dry mycelia) on cultivation of *M. alpina* 1S-4 with 3% linseed oil at 12 °C (Table 5).

By using the Δ12 desaturase-defective mutant Mut48 derived from *M. alpina* 1S-4, an EPA-rich oil with a low level of AA was obtained. Like the wild-type strain, Mut48 converted exogenous ALA to EPA (39). On cultivation at 20 °C for 10 days in a 5-L fermentor containing medium supplemented with linseed oil, the production of EPA was about 1 g/L culture broth (64 mg/g dry mycelia), accounting for approximately 20% of the total mycelial fatty acids. The mycelial AA content was 26 mg/g dry mycelia (0.4 g/L), accounting for 7.8% of the total mycelial fatty acids. As shown in Table 5, the EPA concentrations were lower than AA concentrations in the oils produced by all strains, except for Mut48 in which the concentration of EPA was 2.5-fold that of AA because of the Δ12 desaturase defect.

Recently, *Saprolegnia* sp. 28YTF-1, isolated from a freshwater sample, was shown to be a potent producer of EPA. Accompanying production of AA and other *n*-6 PUFAs was markedly low in this organism (64).

8(*Z*),11(*Z*),14(*Z*),17(*Z*)-Eicosatetraenoic Acid

Δ5 Desaturase-defective mutants of *M. alpina* 1S-4 accumulate 8(*Z*),11(*Z*),14(*Z*),17(*Z*)-eicosatetraenoic acid (20:4ω3) when grown with linseed oil. One of the mutants,

Table 5. Comparison of EPA Productivities and Mycelial Fatty Acid Profiles of Some *Mortierella* Strains under Different Culture Conditions

Strain and conditions	Mycelial mass (g/L)	EPA content (mg/g dry mycelia)	EPA yield (g/L)	Mycelial fatty acid composition (wt%)

20 °C + linseed oil	15.1	64.0	0.97	0.3	20.3	0.8	7.8	19.5	51.3

AA, arachidonic acid (20:4ω6); ALA, α-linolenic acid (18:3ω3); DGLA, dihomo-γ-linolenic acid (20:3ω6); EPA, 5(*Z*), 8(*Z*), 11(*Z*), 14(*Z*), 17(*Z*)-eicosapentaenoic acid (20:5ω3); GLA, γ-linolenic acid (18:3ω6).

M. alpina S-14, produced about 1.7 g/L (66 mg/g dry mycelia; 11.6 wt% of total mycelial fatty acids) of this PUFA per liter of culture medium (35).

Mead Acid

A Δ12 desaturase-defective mutant, Mut48, derived from *M. alpina* 1S-4 is characterized by a high oleic acid (18:1ω9) level and the absence of *n*-6 PUFA in its mycelia. In contrast to the wild type, this mutant produces three *n*-9 PUFAs, that is, 6(*Z*),9(*Z*)-octadecadienoic acid (18:2ω9), 8(*Z*),11(*Z*)-eicosadienoic acid (20:2ω9), and Mead acid (44). Significantly high levels of these fatty acids were produced on growth of the mutant at low temperature (12–20 °C). On cultivation at 20 °C for 10 days in a 5-L fermentor, the production of Mead acid reached approximately 0.8 g/L (56 mg/g dry mycelia), accounting for 15 wt% of the total mycelial fatty acids. The other major fatty acids were palmitic acid (6%), stearic acid (11%), oleic acid (45%), 18:2ω9 (12%), and 20:2ω9 (3%). About 70 mol% of Mead acid was present in the triacylglycerol and the remainder in the phospholipid fraction, especially in phosphatidylcholine. The formation of Mead acid could occur through the same sequential reactions suggested by Fulco and Mead (65), that is, desaturation 18:1ω9 at the Δ6 position into 18:2ω9 followed by elongation and Δ5 desaturation to Mead acid (see Fig. 1).

Recently, enhanced production of Mead acid was reported by a mutant fungus, *M. alpina* M209-7, derived from Δ12 desaturase-defective Mut48 strain. The production of Mead acid by M209-7 strain was 1.3 times greater than in Mut48, thought to result from its enhanced Δ6 desaturation activity, which was 1.4 times higher than that of Mut48 (45).

8(*Z*),11(*Z*)-Eicosadienoic Acid

A mutant strain, *M. alpina* M226-9, was derived from the Δ12 desaturase-defective mutant *M. alpina* Mut48. In the M226-9 strain, Δ5 and Δ12 desaturases were completely defective and the microorganism could produce large amounts of 8(*Z*),11(*Z*)-eicosadienoic acid (20:2ω9) (1.68 g/L; 101 mg/g dry mycelia). No detectable Mead acid occurred in the resultant fungal oil. The major fatty acids other than 20:2ω9 (17.6%) were palmitic acid (6.1), stearic acid (7.0), oleic acid (44.0), and 6(*Z*),9(*Z*)-octadecadienoic acid (18:2ω9, 17.6). Addition of olive oil, in which oleic acid is abundantly present, to the growth medium enhanced the production of this unique fatty acid (S. Shimizu, unpublished observation, 1998).

Nonmethylene-Interrupted C_{20} PUFAs

The occurrence in plants of two nonmethylene-interrupted PUFAs, that is, 5(*Z*),11(*Z*),14(*Z*)-eicosatrienoic acid (20:3Δ5) and 5(*Z*),11(*Z*),14(*Z*),17(*Z*)-eicosatetraenoic acid (20:4Δ5), has been reported (40,41). Microorganisms could be a good source of nonmethylene-interrupted PUFAs. These nonmethylene-interrupted PUFAs were found in the Δ6 desaturase-defective mutant Mut49 (18). The amount of 20:3Δ5 was greatest (27 mg/g dry mycelia) on growth at 20 °C, and it accounted for about 7% of the total mycelial fatty acids. 20:4Δ5 was detected only when the mutant was grown at a temperature lower than 24 °C or in a culture medium supplemented with either ALA or 20:3ω3. 20:3Δ5 is believed to be derived from LA by two subsequent reactions without Δ6 desaturation, that is, elongation and Δ5 desaturation (see Fig. 1).

PRODUCTION OF C_{22} FATTY ACIDS

Docosahexanoic Acid

Nakahara et al. (66) have reported that a thraustochytrid isolated from the marine environment grew well in conventional seawater medium and accumulated DHA intra-

cellularly. The microorganism was thought to be a strain belonging to *Thraustochytrium / Shizochytrium*, because heterkont zoospores were observed in the early stage of growth in its life cycle. A dry cell weight of 40 g/L, lipid content of 2 g/L, and DHA content of about 35% were obtained in a stirred tank fermentor at 28 °C when grown in a medium that contained 90 g glucose, 10 g polypeptone, and 10 g corn steep liquor in 1 L diluted artificial seawater (one-half concentration of seawater) in 14 days. The lipids extracted were composed mostly of triacylglycerol (53.5% of total lipids). The main fatty acids in the total lipids were 16:0 (44.6%), DHA (34.0%), and 22:5 (8.5%); the EPA content was only 0.4%. The organisms may be an excellent source of DHA.

PRODUCTION OF NOVEL PUFAS

Odd-Numbered PUFAs

The occurrence of straight-chain odd-numbered PUFAs in the lipids of ruminants, fish, and several animals has been reported. Shimizu et al. found that *Mortierella* and several related filamentous fungi convert *n*-alkanes or fatty acids of 15 or 17 carbon atoms to unusual C_{19} PUFAs efficiently (Fig. 6) (46,47,67).

n-1 Fatty Acid

Mortierella alpina 1S-4 accumulates a novel 5(*Z*),8(*Z*),11(*Z*),-14(*Z*),19-eicosapentaenoic acid (20:5ω1) together with additional *n*-1 fatty acids, such as 15-hexadecenoic acid, 17-octadecenoic acid, and 8(*Z*),11(*Z*), 14(*Z*),19-eicosatetraenoic acid (20:4ω1) on growth with 1-hexadecene or 1-octadecene (Fig. 6) (48). Based on the hypothesis that a terminal double bond has no effect on PUFA biosynthesis, it is suggested that the 20:5ω1 is formed through the *n*-6 route. The ω methyl group, which is opposite the double bond end, may be first oxidized to a carboxyl group, and the resultant *n*-1 fatty acid may be introduced to the *n*-6 route.

PRODUCTION OF COCOA-BUTTER-EQUIVALENT YEAST OIL

Cocoa butter, the essential ingredient of chocolate, owes its unique physical properties to the fatty acyl groups on the three available positions of the glycerol moiety, these being palmitoyl, oleoyl, and stearoyl residues, respectively. Thus, an ideal oil substitute, or cocoa butter equivalent, should consist of two-thirds saturated fatty acid (palmitate and stearic acid) and one-third monounsaturated acid (oleic acid; 18:1ω9). When sterculic acid, a known inhibitor of the Δ9 desaturase, was added to growing yeast cultures, stearic acid accumulated to greater than 40% (w/w) of the total fatty acid in the yeast oil. The resulting oil was good for a cocoa butter equivalent (68). Based on this result, a number of oleic acid–requiring yeasts that had a functionally inactive Δ9 desaturase were screened and found to produce considerable amounts of stearic acid good for a cocoa butter equivalent (4). Decreasing the O_2 supply to culture of the yeasts could also increase the stearic acid content of the cell (69). As a result, the large-scale development of a yeast cocoa butter equivalent was established (5).

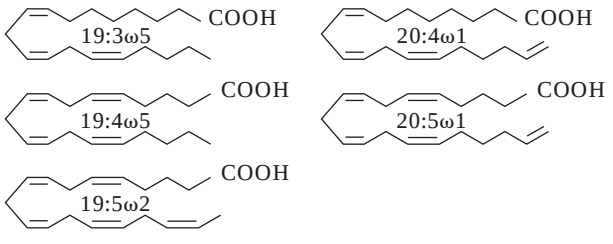

Figure 6. Novel PUFAs produced by *M. alpina* 1S-4 and related filamentous fungi.

CLOSING REMARKS

Filamentous fungi of the genus *Mortierella* are good producers of several useful single cell oils, especially those containing PUFAs such as AA, DGLA, and EPA. Furthermore, mutants of these fungi have expanded abilities for producing new oils and PUFAs or increased productivities for existing ones. A soil isolate, *M. alpina* 1S-4, and its mutants are useful not only as producers of some useful fatty acids and PUFAs such as AA, DGLA, and Mead acid, but they also provide useful information on PUFA biosynthesis. The enzymes, that is, desaturases and elongase, that are involved in the PUFA biosynthesis in this fungus seem to have a wide substrate specificity. For example, Δ5 desaturase can act on odd-numbered fatty acids (i.e., 19:3ω5), PUFA with an ω-terminal double bond (i.e., 20:4ω1), *n*-3 PUFA (i.e., 20:4ω3), *n*-6 PUFA (i.e., DGLA), *n*-9 PUFA (i.e., 20:2ω9), and PUFAs with no C-8 double bond (i.e., 11(*Z*),14(*Z*)-eicosadienoic acid and 11(*Z*),14(*Z*), 17(*Z*)-eicosatrienoic acid). However, the first double bond needs to be inserted at the C-9 position. These mutants may also be used as tools for cloning the desaturase genes that may be introduced into other organisms to produce either transgenic plants or animals that have more desirable fatty acid compositions.

Of longer-term interest is the prospect of using microorganisms to produce the end products of PUFA metabolism found in animals, the prostaglandins, leukotrienes, and thromboxanes, which are extraordinarily expensive to produce by chemical synthetic routes. Some microorganisms appear to have the ability to carry out a cascade of reactions, similar to those found in animals, leading to the formation of hydroxy-PUFAs and perhaps even to the prostaglandins (70). This concept would be a logical extension of the work already accomplished in the production of the PUFAs. The ability of microorganisms to catalyze the formation of products not found in plants, or that are difficult to extract from animals, is also promising. Microorganisms may be a source of these materials, and perhaps also some unusual lipids, ranging from the cerebrosides found in yeasts (6) to the ether lipids of archaebacteria, which approximate the platelet-activating factor found in animals (6).

Secondary amine dicarboxylic acid

OUTLINE

NATURALLY OCCURRING OPINES

Opines are unusual compounds found in crown gall tumor tissues in plants induced by an infection of *Agrobacterium tumefaciens* (1–6), and in muscle tissue of marine invertebrates (2,3,7–8). They can be categorized as secondary amine dicarboxylic acids (octopine and nopaline families), mannityl opines (agropine), and phosphorylated sugars (agrocinopine). Synthesis of opines in infected plants occurs when the infecting bacterium (i.e., *A. tumefaciens*) transfers a tumor-inciting (Ti) plasmid to the plant, causing tumorigenesis (9). A gene present in this plasmid induces opine synthesis in the plants, while a chromosomal gene encodes for the utilization of the synthesized opine. In the muscle of marine invertebrates, secondary amine dicarboxylic acids are the biochemical equivalent of lactate and represent the terminal products of the glycolytic pathway (10) due to an absence of lactate dehydrogenase (LDH) in their tissues.

SECONDARY AMINE DICARBOXYLIC ACIDS

Of the naturally occurring opines, secondary amine dicarboxylic acids (Fig. 1) are the most extensively studied. These compounds may be regarded as two amino acids linked via a common imino nitrogen, or as secondary amines. One group can be categorized as an octopine family (2,3,11), which has an N-substituted D-alanine moiety, and the other, representing N-substituted D-glutamate derivatives, is the nopaline family (2,3,12). The members of the former family are formed by the reductive condensation reaction between pyruvate and the α-NH_2 group of L-arginine, L-lysine, L-ornithine, L-histidine, and L-methionine, and the corresponding opines are named as octopine (13,14), lysinopine (4,15), octopinic acid (14,16), histopine (6), and methiopine (17), respectively. Octopine is also found in marine invertebrates, together with structurally related alanopine (18), strombine (19), β-alanopine (20), and tauropine (21), which have L-alanine, glycine, β-alanine, and taurine moieties, respectively. Opines of the nopaline family are derived from the condensation between α-ketoglutarate and the α-NH_2 group of L-arginine and L-ornithine, to give the corresponding opines nopaline (22) and nopalinic acid (23), respectively. Saccharopine, N^6-(1,3-L-dicarboxypropyl)-L-lysine, was isolated from brewer's yeast (24) and has the L,L-stereochemistry. In the amino acid pool of *Lactococcus lactis* subsp. lactis (2,3), Thompson et al. reported the existence of N^5-(1-L-carboxyethyl)-L-ornithine and N^5-(1-L-carboxyethyl)-L-lysine, the condensation products between alanine and the ω-NH_2 group of L-ornithine and L-lysine, respectively. Recently, Fushiya et al. (25) isolated four new opines, valinopine,

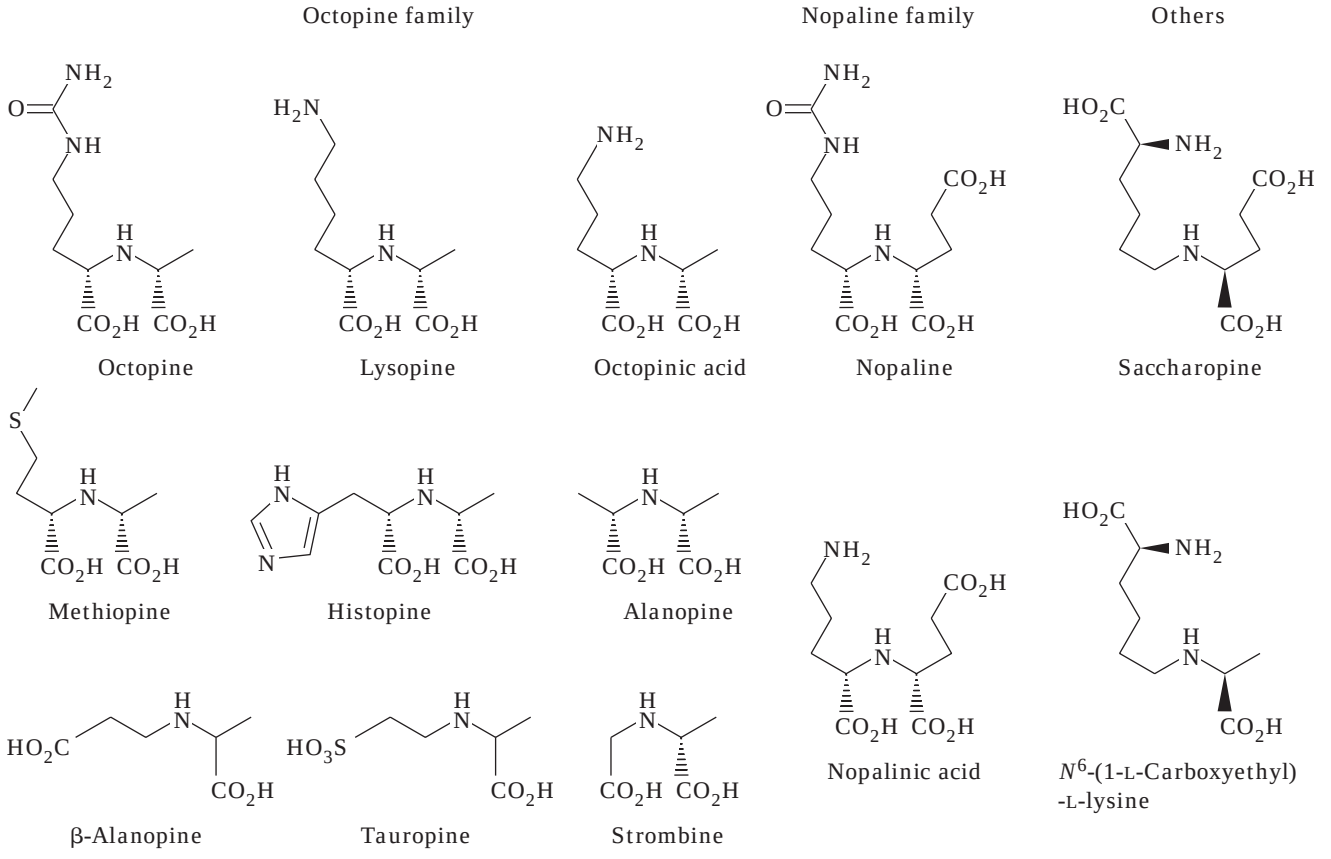

Figure 1. Naturally occurring secondary amine dicarboxylic acids.

epileucinopine, isoleucinopine, and phenylalanopine, which were derived from α-ketoglutarate and L-valine, L-leucine, L-isoleucine, and L-phenylalanine, respectively, from a poisonous mushroom, *Clitocybe acromelalga*.

ENZYMES ACTING ON SECONDARY AMINE DICARBOXYLIC ACIDS

Enzymes that can synthesize secondary amine dicarboxylic acids by the reductive condensation of an α-keto acid with the NH_2-group of an amino acid have been isolated from plants, marine invertebrates, and bacteria (2,3). These enzymes are all NAD(P)H-dependent oxidoreductases and appear to be responsible for the biosynthesis of opines.

Octopine dehydrogenase [N^2-(1-D-carboxyethyl)-L-arginine: $NAD(P)^+$ oxidoreductase, EC 1.5.1.1.1] has been purified from crown gall (26), *Pecten maximus*, and other marine invertebrates (27). The enzyme is a monomeric enzyme and has a molecular weight of 37,000–46,000. The enzyme from crown gall catalyzes the NAD(P)H-dependent condensation reaction between pyruvate and several amino acids such as basic and short-chain neutral amino acids (26), whereas that from *Pecten maximus* exhibits a marked preference for pyruvate, L-arginine, and NADH. The gene encoding the enzyme (*ocs*) has been cloned and sequenced from *A. tumefaciens* (28,29).

Lysopine dehydrogenase [N^2-(1-D-carboxyethyl)-L-lysine: $NADP^+$ oxidoreductase, EC 1.5.1.16] has been purified from crown gall tumor tissues (30). The enzyme catalyzes pyruvate-dependent synthesis of secondary amine dicarboxylic acids of L-lysine, L-arginine, L-ornithine, L-histidine, L-methionine, L-glutamine, and L-citrulline. The enzyme is a monomeric enzyme with a molecular weight of 35,000 and prefers NADP(H) to NAD(H) as the cofactor. This makes it different from the analogous enzyme, octopine dehydrogenase, which utilizes both NAD(H) and NADP(H).

Nopaline dehydrogenase [N^2-(1,3-D-dicarboxypropyl)-L-arginine: $NADP^+$ oxidoreductase, EC 1.5.1.19] catalyzes the α-ketoglutarate-dependent condensation reaction with L-arginine and L-ornithine, producing nopaline and nopalinic acid (ornaline), respectively. The enzyme has been purified from tumor tissue of *Nicotiania tabacum* (31) and sunflower crown gall (32). The enzyme is a tetrameric protein with a subunit molecular weight of 40,000 and requires NADP(H) as a specific cofactor. L-Lysine and L-histidine, good substrates for octopine and lysopine dehydrogenases, do not act as substrates for the enzyme. The nopaline dehydrogenase gene (*nos*) from *A. tumefaciens* has been cloned and sequenced, and the enzyme was expressed in *Escherichia coli* (33,34).

Alanopine dehydrogenase [*meso*-*N*-(1-carboxyethyl)-alanine: NAD^+ oxidoreductase, EC 1.5.1.17] has been purified to homogeneity from adductor muscle of oyster (35)

and partially from the lungworm (36) and the foot muscle of the mussel (37). The monomeric enzyme with a molecular weight of 38,500–46,000 requires NADH as a cofactor and catalyzes the reversible condensation reaction between hydrophilic α-keto acids, such as pyruvate, glyoxylate, α-ketoglutarate, and hydroxypyruvate, and amino acids, such as L-alanine, glycine, L-cysteine, L-serine, and L-threonine.

Strombine dehydrogenase [*N*-(1-carboxymethyl)-D-alanine: NAD^+ oxidoreductase, EC 1.5.1.22] has been purified from *Mytilus edulis* (37). The enzyme (M_r = 38,000) catalyzes the NAD(H)-dependent reversible condensation reaction between glycine and pyruvate. Although the enzyme and alanopine dehydrogenase exhibit similar substrate specificities with respect to glycine and alanine, the enzyme prefers glycine as its amino donor.

Tauropine dehydrogenase [*N*-(2-sulfonylethyl)-D-alanine: NAD^+ oxidoreductase, EC 1.5.1.-] has been purified from *Arabella iricolor* (Polychaeta: Errantia) (38). The monomeric enzyme (M_r = 43,500) catalyzes the NAD(H)-dependent reversible condensation reaction between taurine and hypotaurine, and hydrophilic α-keto acids, such as pyruvate, oxalacetate, α-ketobutyrate, hydroxypyruvate, and glyoxylate.

These $NAD(P)^+$-dependent dehydrogenases appear to share a similar reaction mechanism with the $NAD(P)^+$-dependent amino acid dehydrogenases. It is peculiar that the $NAD(P)^+$-dependent secondary amino acid dehydrogenases will form a D-configuration from α-keto acid in the reductive amine-forming reaction because no $NAD(P)^+$-dependent amino acid dehydrogenase forms a D-amino acid from the ketoanalog in the reductive amination reaction, with $NADP^+$-dependent *meso*-α, ε-diaminopimelate D-dehydrogenase as an exception (39).

Saccharopine dehydrogenase, isolated from yeasts and fungi (2,3), catalyze the reversible oxidoreduction reaction of N^6-(1,3-L-dicarboxypropyl)-L-lysine, and the enzyme gene from *Yarrowia lipolytica* has been cloned and sequenced (40). Thompson purified an NADPH-dependent oxidoreductase responsible for the biosynthesis of both N^5-(L-1-carboxyethyl)-L-ornithine and N^6-(L-1-carboxyethyl)-L-lysine from *Lactococcus lactis* subsp. lactis (2,3). This enzyme, N^5-(L-1-carboxyethyl)-L-ornithine: $NADP^+$ oxidoreductase (EC 1.5.1.24), is a tetramer composed of identical subunits (M_r = 35,000) and mediates the reductive condensation reaction between pyruvate and the ω-NH_2 group of L-ornithine and L-lysine, but not an oxidation reaction of the secondary amine dicarboxylic acids. Recently, the gene encoding for the enzyme was cloned and sequenced, and the enzyme was expressed in *E. coli*. (41). Both enzymes are different from the already-mentioned dehydrogenases because opines synthesized by the enzymes arise via alkylation of the ω-NH_2 group of amino acids, and the stereochemistry of the newly formed asymmetric center is of L-configuration.

OPINE DEHYDROGENASE FROM *ARTHROBACTER* SP. STRAIN 1C

Asano et al. have purified phenylalanine dehydrogenases in crystalline forms or to homogeneity and characterized those from *Sporosarcina ureae* SCRC-R04 (42), *Bacillus sphaericus* SCRC-R79a (42), and *B. badius* IAM 11059 (43). The *pdh* genes have been cloned into plasmids and expressed in *E. coli*, and the *pdh* gene has been sequenced (44,45). They have used phenylalanine dehydrogenase and other amino acid dehydrogenases to synthesize optically pure, natural and unnatural amino acids from their corresponding α-keto acids (46,47). Much attention has been paid to a new amino acid dehydrogenase acting on secondary amine dicarboxylic acid. Comparison of the primary structure of the dehydrogenase with that of the known amino acid dehydrogenases would give a valuable information on the structure and function of this class of enzymes. Furthermore, the reversible nature of the enzyme-catalyzed reaction will make it possible to synthesize new chiral opine derivatives, the chemical synthesis of which is rather laborious.

Isolation of (1-D-Carboxyethyl)-L-Phenylalanine-Assimilating Bacteria

Several opine degraders, such as *A. tumefaciens*, *Pseudomonas* sp., and *Arthrobacter* sp., were isolated from soil and crown gall tumors (48,49). Degradation of opines (i.e., lysopine by *A. tumefaciens*) has been attributed by Jubier (50) to a membrane-bound enzyme complex that is responsible for the oxidation of lysopine, forming lysine and pyruvate.

In an attempt to utilize an NAD^+-dependent dehydrogenase for the stereospecific in vitro enzymatic synthesis of a wide variety of opines, Asano et al. (51,52) attempted to isolate several microorganisms that can grow on chemically synthesized opines. They isolated the bacterial strain YEO8, which utilizes *N*-(1-D-carboxy-2-phenylethyl)-D-phenylalanine as its carbon source from soil and is identified as a glucose-nonfermenting Gram-negative bacteria under CDC group IVc-2 (52). The cell-free extract of the strain contained enzymes that catalyzed the oxidation of the opine into phenylpyruvate and D-phenylalanine, with DCPIP but not NAD(P) as its hydrogen acceptor. They isolated a novel NAD^+-dependent secondary amine dicarboxylic acid dehydrogenase producer, strain 1C, from soil with *N*-(1-D,L-carboxyethyl)-L-phenylalanine as a substrate (51). The taxonomical studies of the strain 1C indicate that it belongs to the genus *Arthrobacter* because it is nonmotile and never fermentative, occurs in rod-coccus shape, its peptidoglycan contains lysine as the diamino acid, and no mycelium formation is observed. *Arthrobacter* strains in the type culture collections did not grow on a medium containing *N*-(1-D-carboxyethyl)-L-phenylalanine as the sole source of carbon.

Purification of Opine Dehydrogenase from Arthrobacter sp. Strain 1C

The enzyme activity found in *Arthrobacter* sp. strain 1C was inducible in the presence of *N*-(1-D,L-carboxyethyl)-L-phenylalanine; only one tenth of total enzyme activity per culture was obtained in the absence of the substrate. The enzyme was purified about 57-fold, with a 36% yield from the cell-free extract of the strain by a procedure involving ammonium sulfate fractionation, and DEAE-Toyopearl,

butyl-Toyopearl, and Sephadex G-200 column chromatographies (53). The enzyme has a molecular weight of about 70,000 and consists of two identical subunits with an M_r of 36,000. Typical properties of the enzyme are shown in Table 1. The enzyme catalyzes a reversible oxidation–reduction reaction of opine-type secondary amine dicarboxylic acids. The enzyme is unique because the only similar microbial enzyme thus far reported (2,3) is N^5-(L-1-carboxyethyl)-L-ornithine: $NADP^+$ oxidoreductase from *L. lactis* subsp. lactis, which catalyzes only the reductive secondary amine forming reaction with NADPH, not the oxidative degradation reaction. The velocity of opine dehydrogenase for the secondary amine–forming reaction is about six times greater than that for the oxidative reaction. In the oxidative deamination reaction, the enzyme is active toward synthetic opines such as *N*-(1-D-carboxyethyl)-L-methionine and *N*-(1-D-carboxyethyl)-L-phenylalanine, and its K_m values for them are 9.0 and 14 mM, respectively. On the other hand, the enzyme does not act on naturally occurring opines, such as saccharopine, D-octopine, and L-allooctopine, or stereoisomers of *N*-(1-D-carboxyethyl)-L-phenylalanine, such as *N*-(1-L-carboxyethyl)-L-phenylalanine, *N*-(1-L-carboxyethyl)-D-phenylalanine, and *N*-(1-D-carboxyethyl)-D-phenylalanine. In the reaction that forms secondary amines using pyruvate as a fixed amino acceptor, the enzyme is active toward short-chain aliphatic L-amino acids and those substituted with acyloxy, phosphonooxy, and halogen groups, as shown in Table 2. Hydrophilic α-keto acids, such as pyruvate, oxaloacetate, glyoxylate, and α-ketobutyrate, are accepted as amino acceptors (Table 3). Based on its results of substrate specificity, the enzyme is tentatively named *N*-(1-D-carboxyethyl)-L-norvaline: NAD^+ oxidoreductase (L-norvaline-forming: EC 1.5.1.-, opine dehydrogenase [ODH]). Other substrates for the enzyme are 3-aminobutyric acid and L-phenylalaninol.

The $NADP^+$-dependent D-lysopine dehydrogenase (31,32) and D-nopaline dehydrogenase (30) catalyze a reversible oxidation–reduction reaction similar to the reaction catalyzed by ODH. However, it is a monomeric protein and the substrate and coenzyme specificities are totally different from those of ODH. In the reductive secondary amine–forming reactions with NADPH and NADH (20% the velocity with NADPH) as cofactors, the enzyme does not accept L-phenylalanine, L-alanine, and L-isoleucine, and so on, which are good substrates for ODH.

Table 1. Properties of Opine Dehydrogenase from *Arthrobacter* sp. Strain 1C

Molecular weight	
SDS	36,000
Gene sequencing	37,935
Molecular structure	Dimer
Maximum absorption wavelength	280 nm
Absorption coefficient	ε_{280} = 75.87 mM^{-1} cm^{-1}
Specific activity[a]	140 U/mg
Optimum pH	8.0 (reduction) 10.0 (oxidation)
Optimum temperature	55 °C
pH stability[b]	pH 5.0 ~ 9.5
Temperature stability[c]	~50 °C
K_m for NAD^+	0.76 mM
Inhibitors	Sulfuhydryl reagents
	Heavy metals

[a]Measured by an oxidation of 10 mM of *N*-(1-D-carboxyethyl)-L-phenylalanine at pH 9.5.
[b]The enzyme activity was measured after incubation at various temperatures and pH 8.0 for 10 min.
[c]The enzyme activity was measured after incubation at 30 °C for 1 h with buffers at various pHs.

Table 2. Substrate Specificity of Opine Dehydrogenase in the Reductive Secondary Amine–Forming Reaction with Pyruvate as a Fixed Substrate

Amino donor[a]	Relative activity (%)[b]	K_m (mM^{-1})
L-Norvaline	100	2.17
L-α-Aminobutyric acid	83.7	20.0
L-Norleucine	72.5	3.72
β-Chloro-L-alanine	53.1	3.19
O-Acetyl-L-serine	35.8	5.94
L-Methionine	23.9	4.10
L-Isoleucine	22.3	6.20

α-Ketobutyrate	11	28
Hydroxypyruvate	6.1	N.D.[c]
α-Ketocaproate	2.1	N.D.[c]

Note: Assayed with fixed concentrations of L-methionine and NADH at 10 and 0.1 mM, respectively.
[a]α-Keto-γ-phenylbutyrate, glyoxal, α-ketoglutarate, phenylpyruvate, and acetone were inert as a substrate.
[b]The enzyme activity for pyruvate was taken as 100%.
[c]Not determined.

Cloning, Nucleotide Sequencing, and Expression of Opine Dehydrogenase

The gene coding for ODH was cloned into plasmid p-Bluescript KS(−), and the nucleotide sequence of the 1,077-bp open reading frame consisting of 359 codons was identified as the *odh* gene coding for the enzyme (54). About 6.6-fold total activity per liter of culture was detected with a feeding of 1 mM IPTG, as compared with the wild-type strain *Arthrobacter* sp. 1C (51). The enzyme was purified and crystallized from the cell-free extracts of the recombinant strain (Fig. 2). The chemical and physical properties of the purified enzyme showed a complete agreement with those of the wild type.

The enzyme (359 amino acids) is similar to the sequence of the 40-kDa protein (27.4% identity among 359 amino acids) of the Ti plasmid of *A. tumefaciens* (55), D-lysopine dehydrogenase (24.6% identity among 358 amino acids) (28) and D-nopaline dehydrogenase (20.8% identity among 168 amino acids) (34) of *A. tumefaciens*, D-nopaline dehydrogenase (21.8% identity among 371 amino acids) of *A. vitis* (56), and phenylalanine dehydrogenases of *B. sphaericus* (21.8% identity among 78 amino acids) (44) and of *B. badius* (25.6% identity among 60 amino acids) (45). There is no apparent homology between ODH and saccharopine dehydrogenase (21) or N^5-(L-1-carboxyethyl)-L-ornithine: $NADP^+$ oxidoreductase (41). The common similarities between the 40-kDa protein, D-lysopine dehydrogenase, and the N-terminal region of ODH and the phenylalanine dehydrogenase (PheDH) are in the glycine-rich nucleotide-binding domain G-X-G-X-X-(G or A), connecting the β-strand with the α-helix in the region of adenine dinucleotide phosphate (ADP)–binding $\beta\alpha\beta$ folds, which is strongly conserved among $NAD(P)^+$-dependent dehydrogenases and FAD-containing oxidoreductases (57).

It can be suggested that ^{34}D of ODH corresponds to ^{214}D of the NAD^+-dependent *B. sphaericus* phenylalanine dehydrogenase, the position of which is considered to be important for the NADH binding discriminating NADPH among $NAD(P)^+$-dependent dehydrogenases (57). The equivalent positions with ^{34}D of the enzyme in the 40-kDa protein and D-lysopine dehydrogenase (which utilizes both $NADP^+$ and NAD^+) are neutral ^{30}S and ^{32}A, respectively, which are found in $NADP^+$-dependent dehydrogenases. There is also a similarity among these enzymes in the conserved ^{238}D-X-X-^{241}R residue, which is thought to be important for the proton-relay mechanism (3). The nucleotide-binding domain, as can be seen in typical lactate dehydrogenases, is located at the N-terminal region of these secondary amine dicarboxylic acid dehydrogenases, whereas other amino acid dehydrogenases have one more domain in the N-terminus important for accommodating the amino acid substrate (58). Octopine and nopaline dehydrogenases show 26% amino acid identity (3), but no similarity was seen with saccharopine dehydrogenase and N^5-(L-1-carboxyethyl)-L-ornithine: $NADP^+$ oxidoreductase. The former enzymes synthesize opines having D,L-configuration and are linked via the α-NH_2 group of amino acids, but the latter ones produce opines with L,L-configuration and are linked via the α- and ε-NH_2 group of amino acids. These differences in substrate specificities reflect the amino acid sequence similarity between these enzymes.

Although N^5-(L-1-carboxyethyl)-L-ornithine: $NADP^+$ oxidoreductase (41) has a similarity with lactate and alanine dehydrogenases (59) at pyruvate-binding sites, including active arginine (which is a catalytically relevant residue), ODH might have a different binding site with pyruvate because the enzyme had no similarity with these enzymes.

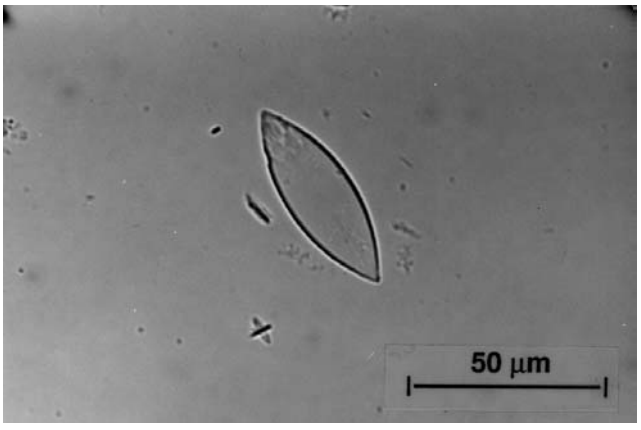

Figure 2. Photomicrograph of crystalline opine dehydrogenase.

Stereoselective Synthesis of Opine-Type Secondary Amine Carboxylic Acids by Opine Dehydrogenase

Opine-type secondary amine dicarboxylic acids are useful chiral intermediates of angiotensin-converting enzyme (ACE) inhibitors such as enalapril and lysinopril (60). They have been chemically synthesized by reductive condensation reactions of α-keto acids or their esters and amino acid derivatives (61,62) or SN_2 reactions of optically active 2-halo- and 2-trifluoromethanesulfonyloxy esters with amino acid derivatives (63,64). However, these methods generally require protection of the functional groups, and the stereoselectivity is not always high. Kato et al. (53) constructed a new system for the synthesis of secondary amine dicarboxylic acids by ODH coupled with NADH regeneration by formate dehydrogenase (FDH) from *Moraxella* sp. C-1 (65), without protection of the substrates (Fig. 3).

As shown in Table 4, several secondary amine dicarboxylic acids have been synthesized from amino acids and their analogues, such as L-methionine, L-isoleucine, L-leucine, L-valine, L-phenylalanine, L-alanine, L-threonine, and L-serine, and α-keto acids, such as glyoxylate, pyruvate, and 2-ketobutyrate, using ODH. A diastereo and enantiomerically pure secondary amine carboxylic acid from (*S*)-phenylalaninol and pyruvate was also quantitatively synthesized. The absolute configuration of the nascent asymmetric center of the opines was of the D-stereochemistry with $> 99.9\%$ ee. This method seems to be the simplest for stereoselectively synthesizing opines without protection of the substrates, because chemical processes generally require five to eight steps.

On the other hand, one-pot synthesis of *N*-[1-D-(carboxyl)ethyl]-L-phenylalanine from phenylpyruvate

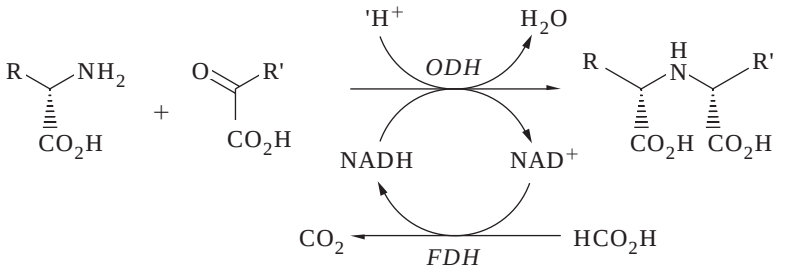

Figure 3. Synthesis of secondary amine dicarboxylic acids from L-amino acids and α-keto acids by opine dehydrogenase with regeneration of NADH by formate dehydrogenase. ODH, opine dehydrogenase from *Arthrobacter* sp. 1C; FDH, formate dehydrogenase from *Moraxella* sp. C-1.

and pyruvate by using ODH, FDH, and PheDH from *B. sphaericus* (43,46) is also described, as shown in Figure 4. This reaction can be carried out well because of the substrate specificities of the enzymes thus used; ODH acts on pyruvate but not on phenylpyruvate (51), whereas PheDH acts on phenylpyruvate but not on pyruvate (43). The opine compound was obtained in a yield of 87.5% with high (>99.9%) enantio- and diastereomeric excess.

CONCLUSION

Both secondary amine dicarboxylic acid and amino acid dehydrogenases use NAD(P)H, α-keto acids, and amino donors as substrates and have a common consensus motif in their primary structures. The structural and catalytic similarities of these enzymes suggest that these genes have evolved from a common progenitor. On the other hand, differences have been found in the substrate specificities: *(1)* secondary amine dicarboxylic acid dehydrogenases utilize the α- or ε-amino group of amino acids, but amino acid dehydrogenases use ammonia as amino donors; and *(2)* the asymmetric center newly formed by secondary amine dicarboxylic acid dehydrogenases is of D-stereochemistry, except saccharopine dehydrogenase and N^5-(L-1-carboxyethyl)-L-ornithine: $NADP^+$ oxidoreductase, but that by formed amino acid dehydrogenases is exclusively of L-

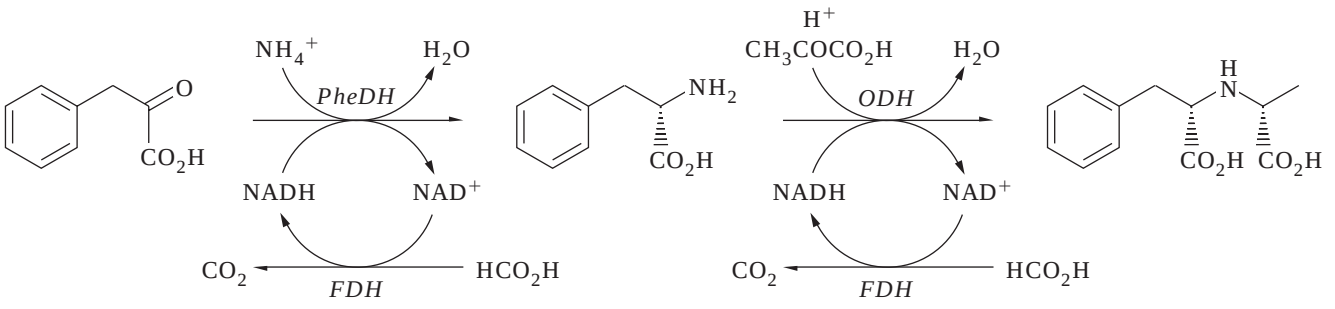

Figure 4. One-pot synthesis of *N*-(1-D-carboxyethyl)-L-phenylalanine from phenylpyruvate and pyruvate by phenylalanine and opine dehydrogenases with NADH regeneration by formate dehydrogenase. stereochemistry. Among secondary amine dicarboxylic acid dehydrogenases, some differences found in the substrate specificity include octopine, lysopine, and nopaline dehydrogenases characteristically promoting reductive alkylation at the α-NH_2 of basic amino acids; ODH, alanopine, and strombine dehydrogenases acting on that of neutral amino acids; and saccharopine dehydrogenase and N^5-(L-1-carboxyethyl)-L-ornithine: $NADP^+$ oxidoreductase accommodating the ε-NH_2 of basic amino acids. Octopine, lysopine, alanopine, and strombine dehydrogenases, N^5-(L-1-carboxyethyl)-L-ornithine: $NADP^+$ oxidoreductase, and ODH accept pyruvate as an amino acceptor, whereas nopaline and saccharopine dehydrogenases act on α-ketoglutarate. A comparison of the structure of ODH with other amino acid dehydrogenases would provide insight to the catalytic, structural, and evolutionary relationships among them. To determine the high-dimensional structural elucidation of ODH, X-ray crystallographic studies are in progress (66,67) and should provide details of the structure of the catalytic domains of ODH. The findings might help in understanding the mechanism and evolutionary relationship among the amino acid dehydrogenases.

OUTLINE

INTRODUCTION

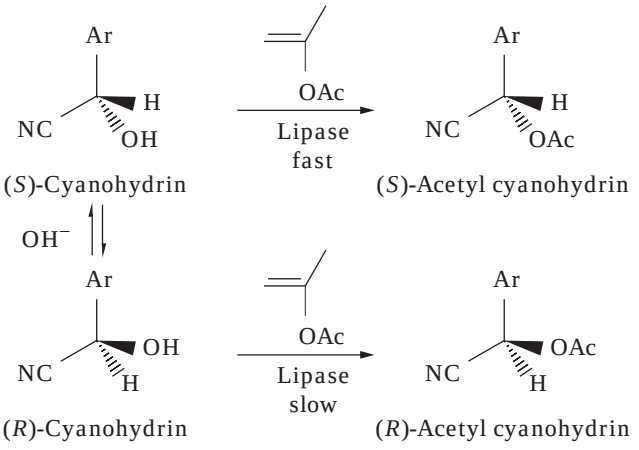
Enzyme proteins are produced by living organisms as biochemical catalysts. A typical feature of biocatalysts is the ability to catalyze stereo- and regiospecific reactions under mild conditions (e.g., neutral pH, normal temperature, and pressure).

Increasingly, enzymes are used in organic synthesis, especially for optical resolution of racemic organic compounds. This article provides an overview of some of the newer optical resolution reactions that use enzymes and microbial cells.

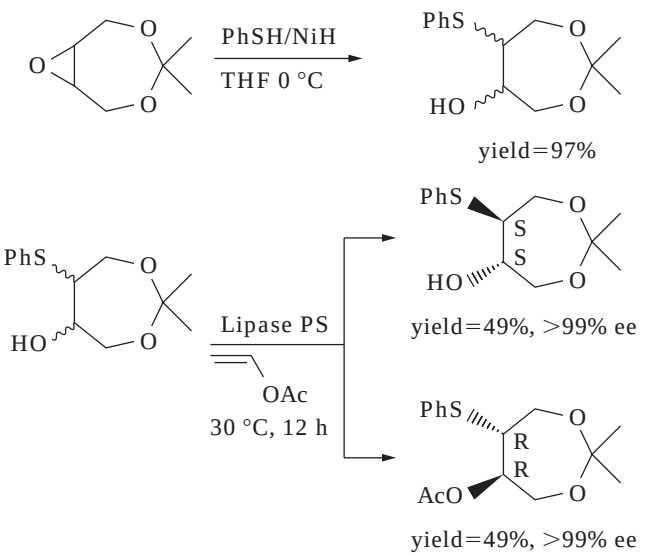
OPTICAL RESOLUTION WITH LIPASE-CATALYZED TRANSESTERIFICATION

Transesterifications catalyzed by lipases in organic solvent are most widely applied for optical resolution of racemic alcohols. Various kinds of racemic alcohols have been successfully resolved by lipase-catalyzed enantioselective transesterification reactions (1,2). Ward reported several examples of optical resolution accompanying the epimerization or racemization of starting materials at high conversion rates (3). Ward further introduced the enzyme-catalyzed acylating reaction of a racemic cyanohydrin under racemization of the residual enantiomer by a basic anion with extremely high conversion rates (Scheme 1).

A method of kinetic resolution of *cis*-1-diethylphosphomethyl-2-hydroxymethyl cyclohexane **1** by lipase has been developed (Scheme 2 and Table 1). The transesterification of (±)-**1** with vinyl acetate in the presence of lipase AK without solvent resulted in (+)-**1** with 99% ee and 41% yield and the corresponding acetate with 93% ee and 35% yield (the E value as reported by Sih was 152) (4).



Scheme 1. Lipase-catalyzed asymmetric acylation of racemic cyanohydrin.



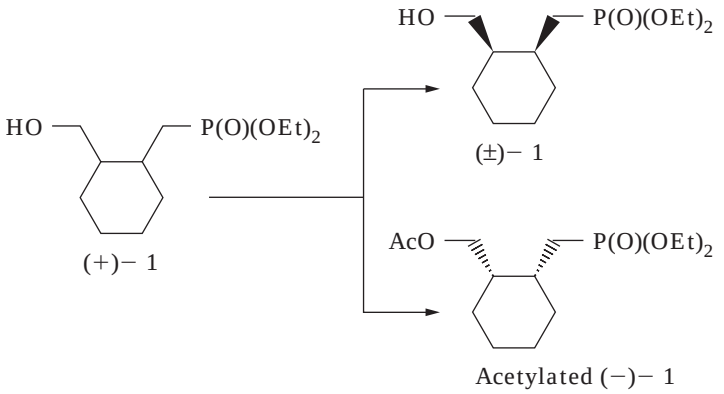
Scheme 3. *meso*-Mediated preparation of optically pure four-carbon triols with transesterification by lipase PS.

Enantioselective synthesis of both enantiomers of 1-arylethanols with a condensed aromatic ring has been achieved through acetylation of the racemic alcohols with vinyl acetate in the presence of lipase from *Pseudomonas aeruginosa* (Toyobo, LIP). The lipase catalyzed the reaction of (±)-(3-phenanthrenyl)ethanol with vinyl acetate at high enantioselectivity (99% ee and conversion; 49% of (±)-substrate). The remaining alcohol had a high optical purity (94% ee). The E value was 100 as determined by Sih's method (5).

Yamada et al. (6) reported an expedient route to optically pure four-carbon diols and triols using a *meso*-symmetric four-carbon precursor and lipase-mediated kinetic resolution as a key step in the transesterification reaction with vinyl acetate in an organic solvent (Scheme 3).

Tanaka et al. (7) reported a facilitated route to optically pure 3-*endo*-hydroxy dicyclopentadiene via lipase-mediated kinetic resolution in a transesterification reaction with vinyl acetate in an organic solvent (Scheme 4).

Chromobacterium viscosum lipase (CVL) catalyzes selectively the acylation of the C-5 hydroxyl of the three stereoisomeric vitamin D A-ring precursors **1a**, **2a**, and **2b** (Fig. 1). It stereoselectively acylated the hydroxyl group at the carbon of the 3-position of the fourth stereoisomer, **1b**,

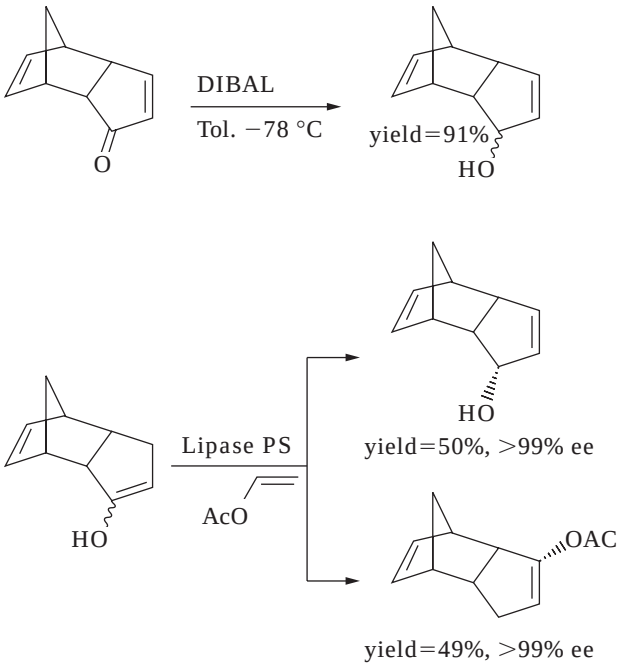


Scheme 2. Transesterification of phosphono alcohol 1 catalyzed lipases.

Table 1. Transesterification of (+)-1 Catalyzed Lipases

	Condition		Alcohol (+)1		Acetyl-(−)1		
Lipase mg/100 mg of 1	solv.	time (h)	Yield (%)	ee (%)	Yield (%)	ee (%)	E value
PS (200)	THF	15	38	60	55	36	3.7
PS (100)	THF	15	60	62	35	97	62
PS (100)	*t*-BuOMe	12	38	14	25	14	1.3
PS (50)	None	52	42	98	54	64	20
AK (50)	None	6.5	41	>99	35	93	152

Note: All reactions were carried out at 37 °C. PS = *Pseudomonas cepacia*, Amano; AK = *Pseudomonas fluoresence*, Amano.



Scheme 4. Preparation route to optically pure 3-*endo*-hydroxydicyclopentadiene.

with vinyl acetate under the same conditions in organic solvent (95% isolated yield, 90% ee) (8).

Izumi et al. (9) reported that *trans*-2,3-dihydro-3-hydroxy-2-phenyl-4H-1-benzopyran-4-one (*trans*-flavanon-3-ol) was resolved to acetate of (2*S*,3*S*)-(−)-*trans*-flavanon-3-ol with 96% ee and (2*R*,3*R*)-(−)-*trans*-flavanon-3-ol by an enzymatic transesterification with vinyl acetate in the presence of *P. capacia* lipase (Scheme 5).

Lundth et al. (10) proposed that enzyme-catalyzed transesterification of racemic alcohol with vinyl acetate by lipase from *P. fluorescens* (PFL) was a reversible process, although it is commonly referred to as irreversible. When racemic *β*-methyl-(2-thiophene)propanol **1** was resolved via a transesterification reaction catalyzed by lipase from

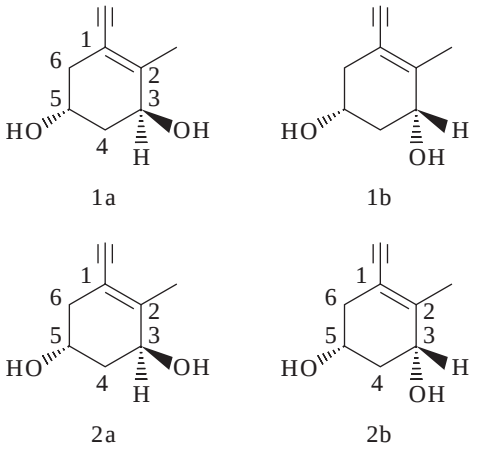


Figure 1. Structure of precursors of vitamin D A-ring.

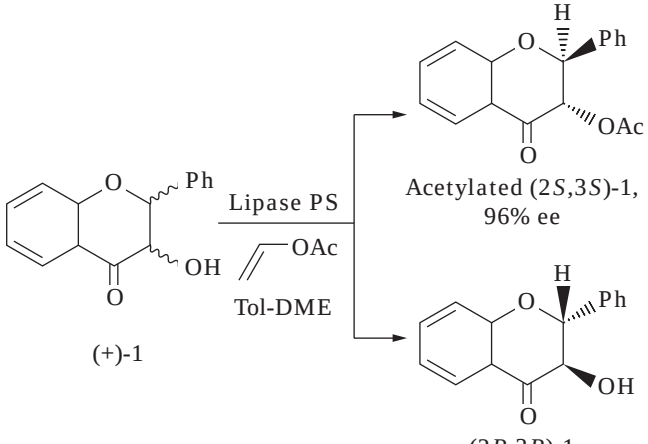
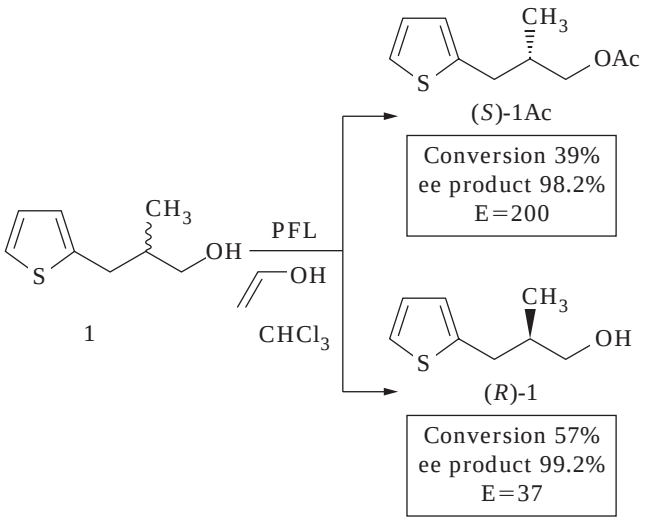
PFL using an excess vinyl acetate in chloroform, the enantioselectivity was a high E = 200 (conversion, 39%), as calculated from enantioexcess (ee) of (*S*)-ester, (*S*)-**1Ac**. However, based on the ee of the remaining (*R*)-alcohol (*R*)-**1**, assuming irreversibility, and when measured at a conversion rate of 57%, the value E = 37 was obtained. Similarly, when the 5-(1-ethoxyethoxy)-3-pentyn-2-ol **2** was resolved using immobilized lipase B from *Candida antarctica* (Novozym SP435) under similar conditions, the (*R*)-ester product (*R*)-**2Ac** was obtained at 22% conversion with E = 140, compared with 65% conversion and E = 15 for the remaining alcohol (*S*)-**2**. These results were interpreted as the consequence of a reversible process occurring in transesterifications of this type, which were referred as irreversible (Schemes 6 and 7).

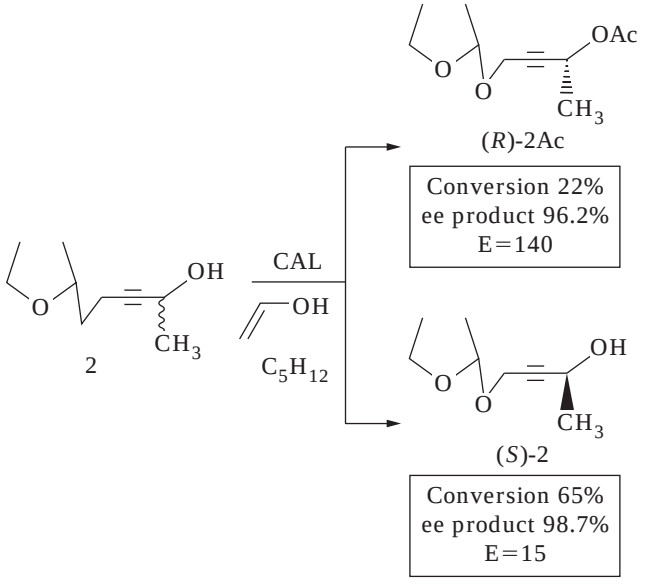
In the total synthesis of *endo*-brevicomin **1**, a pheromone of bark beetles such as *Dendrocutonus frontalis* and *Dryocoetes aoutograghus*, Kim et al. (11) examined *anti*-trityloxy-3,4-diol **2** as a substrate with lipase PS (LPS) from *P. capacia* in transesterification. They found that it was optically resolved by LPS with high enantioselectivity, thus allowing preparation of each enantiomer in optically pure form (>98% ee). The synthesis of optically pure (+)-



Scheme 5. Enzymatic resolution of *trans*-flavanon-3-ol by lipase.



Scheme 6. Transesterification of 2-methyl-3-(2′-thienyl)-1-propanol.



Scheme 7. Transesterification of 5-(1-ethoxyethoxy)-3-pentyn-2-ol by lipase.

endo-brevicomin **1** was achieved from the resolved (−)-2 by transesterification with vinyl acetate using LPS (Scheme 8).

Yamane (12) reported the total synthesis of optically pure (+)-Mitsugashiwa lactone by lipase-catalyzed transesterification under the presence of vinyl acetate in organic solvents (Scheme 9).

OPTICAL RESOLUTION WITH LIPASE-CATALYZING HYDROLYSIS

The stereoselective hydrolysis of 2-(3′-methylphenoxy)propionyl and 2-(2,3-dimethylphenoxy)propionyl esters by carboxy esterase NP was estimated under different experimental conditions to verify whether their optical resolution could be performed using this procedure. The reaction was performed on methyl, ethyl, isopropyl, isobutyl, and benzyl esters of 2-(3-methylphenoxy)propionic and 2-(2,3-dimethylphenoxy)propionic acids in aqueous media. The best substrate for the biocatalytic resolution was the *S* enantiomer for the monomethyl-substituted compounds and the *R* enantiomer for the dimethyl derivative. The extent of 2-(3-methylphenoxy) propionic ester hydrolysis was greater than the 2-(2,3-dimethyl phenoxy) propionic esters. The hydrolysis of isobutyl and benzyl derivatives suffered from poor enantioselectivity and long reaction time; this may be attributable to steric hindrance (caused by the acidic moiety) of the substrates' interaction with the active sites of the enzymes. Changes in pH, temperature, and substrate/enzyme ratio were investigated.

Optimum conditions for these biocatalytic resolutions were obtained when methyl 2-(3-methylphenoxy)-propionate and isopropyl 2-(2,3-dimethyl phenoxy)propionate were hydrolyzed at pH 7.2, 23 °C, and substrate/enzyme ratio 50. The scaling-up to preparative amounts of the enzymatic hydrolysis of these compounds succeeded in producing satisfactory quantities of the corresponding acids and residual esters with a good-enough optical yield (13). An enzymatic method for preparation of the enantiomers of chiral diols **1** and their monoacetate **2** with 100% enantiomeric purity was established using lipase-catalyzed esterification and/or hydrolysis.

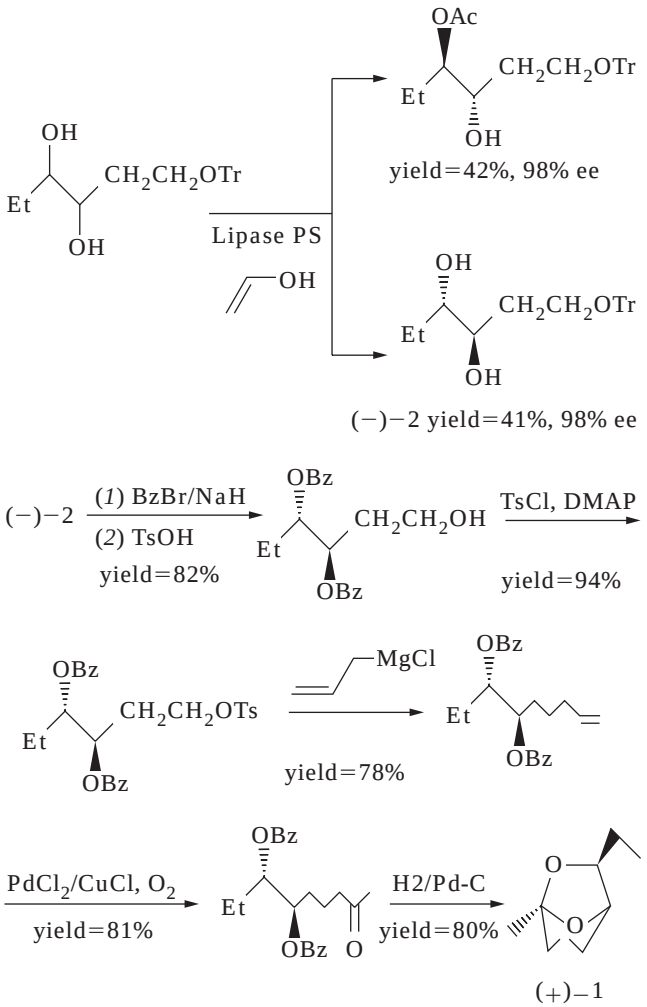
The (*R*)-enantiomers were more susceptible in both acetylation of (±)-**1** and hydrolysis of (±)-**2** catalyzed by lipase OF from *Candida cylindracea* (14) (Scheme 10).

Tan et al. (15) envisioned that thioesters of certain carboxylic acids having the chiral center at the α-carbon might be susceptible to sufficiently acidic deprotonation, resulting in racemization under conditions of enzymatic resolution. Although thioesters have been used as substrates in enzymatic resolution, their α-proton acidity has apparently never been exploited for resolution coupled with substrate racemization. To demonstrate that thioester could be used for racemization coupled with enzymatic resolution, ethyl thioester of α-(phenylthio)propionate **1** was used (Scheme 11).

The corresponding (*R*)-acid **2** was subjected to diastereoselective oxidation for conversion to sulfoxide in the synthesis of a chiral vinyl sulfoxide. Because of the insolubility in water of **1** and most other substrates of interest, it was decided to use a lipase as catalyst in a biphasic system (water and water-immiscible organic solvent) while inducing racemization of the substrate in the organic phase.

A novel enzymatic process for the optical resolution of racemic pantolactone through the stereospecific hydrolysis of D-pantolactone by lactonohydrolase of *Fusarium oxysporum* was reported (16). *F. oxysporum* cells were found to catalyze the stereoselective hydrolysis of the D-enantiomer of racemic pantolactone. With 135g/L of DL-pantolactone as the substrate, 41% of the substrate was hydrolyzed to produce pantoic acid with optical purity of 90% enantiomer excess (for D-pantoic acid) (Scheme 12).

Bommarius et al. (17) reported the synthesis of enantiometrically pure *tert*-leucine, which was prepared using



Scheme 8. Total synthesis of (+)-*endo*-brevicomin via transesterification reaction by lipase PS.

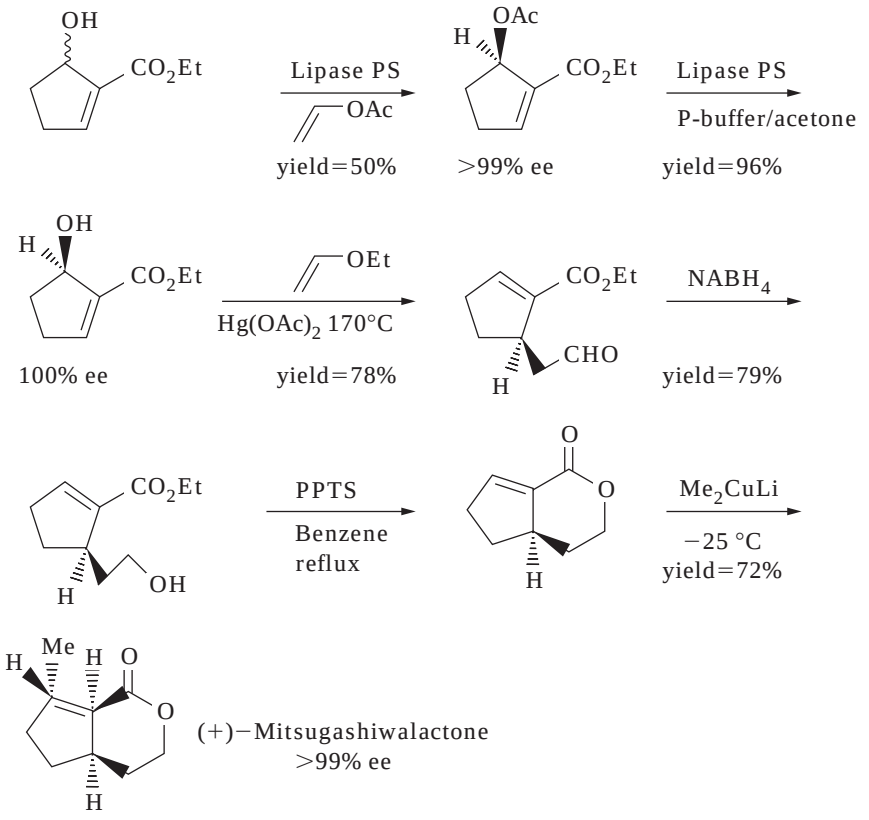
various methods using penicillin-G acylase, hydantoinase, and dehydrogenase.

Owing to its bulky, inflexible, and hydrophobic *tert*-butyl side chain, the use of *tert*-leucine has increased in templates and catalysts in asymmetric synthesis as well as in medicinal peptide compounds. (*S*)-*tert*-Leucine, available through a large-scale enzymatic reductive amination process, has been incorporated into a variety of anti-AIDS and anticancer compounds.

Optically pure inden-1-ol **1** has potential utility as a key starting material for the preparation of HIV-1 protease inhibitors such as L-735,524 and L-754,394. Synthesis of optically active inden-1-ol **1**, however, has been little studied, and only one enantiotopical preparation has been reported so far. Takahashi et al. (18) first examined the kinetic acetylation of racemic inden-1-ol, (±)-**1** with vinyl acetate in organic solvent in the presence of a lipase. However, no practically satisfactory conditions could be established, although partial optical resolution was observed using lipase PS-on-Celite (*Pseudomonas* sp., Amano) (22% ee). They next examined the kinetic deacetylation of racemic 1-acetoxyinden (±)-**2** in a phosphate buffer-acetone solution in the presence of lipases. Of the enzymes tested, lipase PS (*Pseudomonas* sp., Amano) gave the best result. From 10 mg/mmol of the racemic acetate (±)-**2**, 94% ee of (*R*)-inden-1-ol (*R*)-**1** was obtained in 46% yield with recovery of optically pure (*S*)-1-acetoxyinden (*S*)-**2** in 45% yield after 48 h (Scheme 13).

Ibuprofen is a nonsteroidal anti-inflammatory drug with annual sales of about $100 million (U.S.) in 1994. Sales are expected to reach $600 million by the year 2000. The physiological performance of the *S* form of ibuprofen is 28-fold higher than that of the *R* form. The price of the *S* form is three times that of its racemic mixture. Therefore, pharmaceutical companies have devoted much effort to developing production of the *S* form. Ibuprofen can be optically resolved by chemical and enzymatic methods and asymmetric synthesis. Many enzymatic resolutions are reported with lipase-catalyzed hydrolysis or transesterifications. Tai et al. (19) reported that enzymatic hydrolysis of ibuprofen esters produced 99% optically pure (*S*)-(+)-ibuprofen by immobilized lipase MY entrapped in chitosan-*N*-(3-dimethyl aminopropyl)-*N′*-ethylcarbodiimide-glutaraldehyde.

Sulfoxides are valuable chiral auxiliaries as precursors because they carry out carbon–carbon bond formation. As a route to enantiomerically pure sulfoxides, Serreqi et al. (20) examined hydrolase-catalyzed kinetic resolution by



Scheme 9. Total synthesis of Mitsugashiwalactone via lipase catalyzing transesterification with vinyl acetate.

hydrolysis of a pendant acetoxy group. Screening of hydrolases for enantioselective hydrolysis of the acetate in 2-(methylsulfinyl) phenyl acetate (**1**) identified cholesterol esterase (CE) as the most enantioselective enzyme. The enantiomeric ratio, E, ranged from 10 to 25, favoring the (*R*)-configuration at sulfur. Competing chemical hydrolysis of **1** caused a large range in measured E values. A small-scale resolution of (±)-**1** yielded (*S*)-**1** with 99% ee (11% yield) after recrystallization. Changing the methyl substituent to phenyl or *n*-butyl did not significantly change enantioselectivity (E = 10 and 15, respectively), but changing it to a chloromethyl substituent did lower enantioselectivity slightly (E = 5). Changing the phenyl acetate to a naphthyl acetate (2-(phenylsufinyl) acetate versus 1-(phenylsulfinyl)-2-naphthyl acetate) increased the enantioselectivity from 10 to 19 (E value). In all cases, CE favored the (*R*)-sulfoxide. To aid the design of new resolutions with CE, Serreqi et al. proposed an empirical rule that accounts for the observed enantiopreference of CE toward these five compounds of sulfoxides and 15 compounds of other chiral aryl acetates. This empirical rule uses both the size of the substituents and their conformational preferences to predict which enantiomer reacts faster (Fig. 2).

(±)-1-(2-Thienyl)propyl acetate (±)-**1** was optically resolved by *P. capacia* lipase (PCL)–catalyzed hydrolysis to afford (*S*)-(−)-1-(2-thienyl)propyl acetate (*S*)-**1** with >99% ee (21). (*S*)-(−)-1-(2-Thienyl)propyl acetate (*S*)-**1** thus obtained was transformed to (*S*)-(+)-3-octanol (*S*)-**4**, the alarm pheromone of ants, *Crematoster castanea* and *C. liengmei* (Scheme 14).

4-Aryl-1,4-dihydropyridines are novel and potent calcium antagonists; their derivatives have been widely investigated from pharmacological points of view, and some of them have already been used therapeutically as antihypertensive drugs. These agents are known to exhibit their vasodilative activities through affinity with voltage-dependent calcium channels. Different substituents in their compounds lead to chiral derivatives possessing an asymmetric carbon at the 4-position, and the enantiomers have been reported to show different biological activities.

Ebiike et al. (22) synthesized a homochiral 4-aryl-1,4-dihydropyridine-5-phosphate (NZ105) from racemic materials. Enantioselective hydrolysis by lipase AH (*Pseudomonas* sp.) catalyst proceeded smoothly with use of propionyloxymethyl (PROM) ester derivative in organic solvents. They succeeded in converting an optically active carboxylic acid into an optically active calcium antagonist medicine (Scheme 15).

The hydrolysis of methyl D,L-3,3-difluorophenyl alanate **1a** and methyl D,L-3,3-difluoro-2-aminobutanoate **1b** and their *N*-acetyl derivatives **2a** and **2b** by subtilisin (protease) has been studied (23). All derivatives examined were enzymatically resolved to separable mixtures of the corresponding 3,3-difluoro-L-amino acids (**3a** and **3b**) or *N*-acetyl amino acids (**5a** and **5b**) and the unchanged 3,3-difluoro-D-amino acid (**4a** and **4b**) or *N*-acetyl amino acid (**6a** and **6b**). Acidic hydrolysis of methyl 3,3-difluoro-D-phenyl alanate (**4a**) or its *N*-acetyl derivative (**6a**) led to 3,3-difluoro-D-phenyl alanine (**8a**).

In the same manner, L- and D-2-amino-3,3-difluorobutanoic acids (**7b**) and (**8b**) were prepared starting from (**5b**)

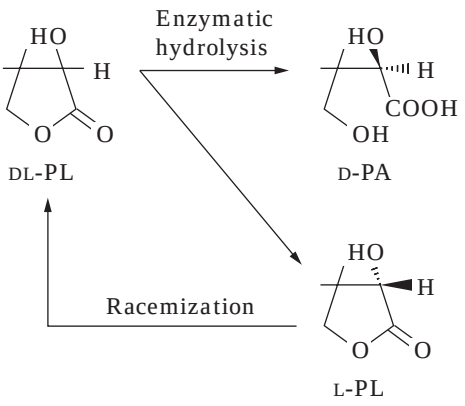
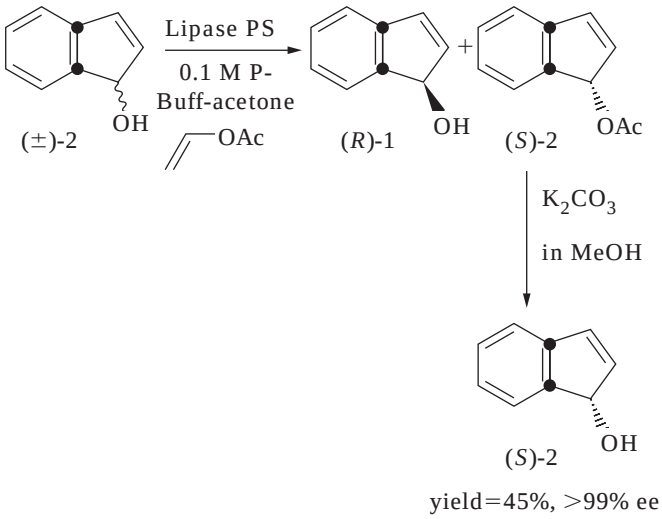


Scheme 12. Schematic presentation of the enzymatic resolution of DL-pantolactone.

and (**6b**). With these methods, unchanged methyl 3-3-difluoro-D-amino ester derivatives showed an ee of >90%, and L-amino acids were estimated to have an ee of >95% (Scheme 16).

Kinetic resolution of 2,2-disubstituted epoxides was accomplished with epoxide hydrolases from bacterial and fungal origin by using lyophilized whole microbial cells (24). In all cases investigated, biocatalytic hydrolysis was shown to occur with retention of configuration at the stereogenic center, leading to 1,2-diols and other results leading to epoxides. The selectivity of the reaction was depen-



Scheme 13. Lipase-mediated resolution of inden-1-ol.

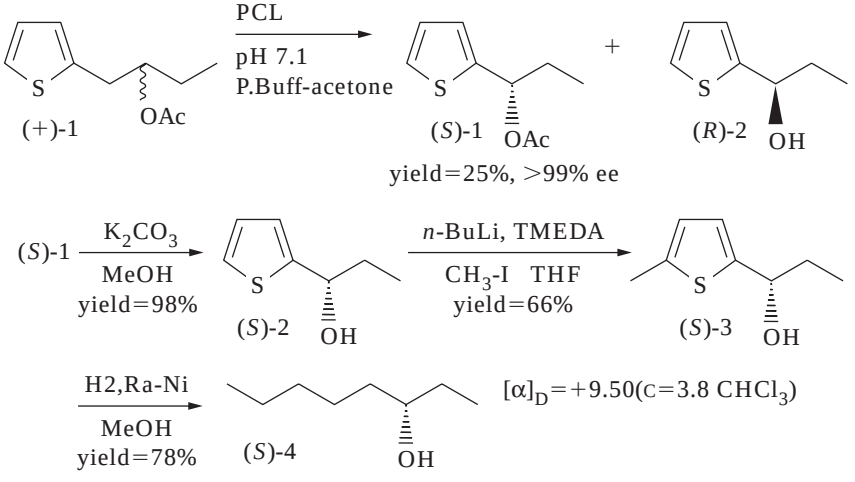
dent on the substrate structure and the strain used. Specifically, in the case of 2,2-disubstituted oxyrane (2-methyl-2-nonyl-1,2-oxyrane), (*S*)-(2-methyl)undecan-1,2-diol was obtained by lyophilized *Rhodococcus* sp. with high stereoselectivity (E >200) (Scheme 17).

Akita et al. (25) reported a highly stereoselective synthesis of a versatile chiral synthon possessing two stereogenic centers (2*S*,3*S*)-**1** (>99% ee) and successful synthesis of Nikkomycin B. (Scheme 18).

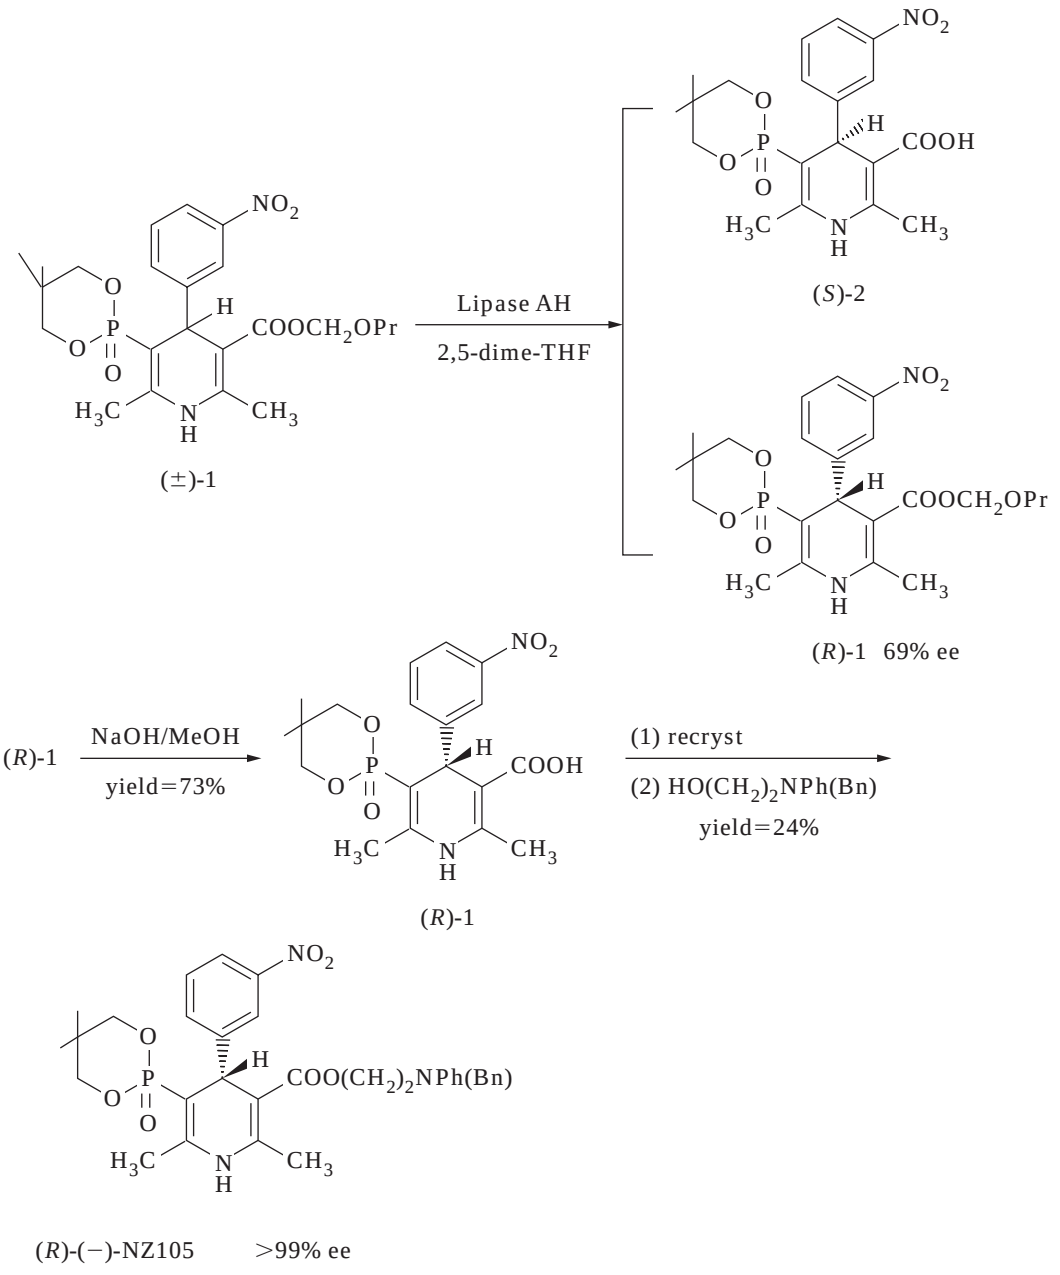
OPTICAL RESOLUTION BY LIPASE-CATALYZING ESTERIFICATION

The reaction for the resolution of (*R*,*S*)-ibuprofen was scaled-up to yield gram quantities of (*S*)-ibuprofen, which was accomplished through a two-stage enantioselective reaction, each stage catalyzed by Novozym 435 (26). In the first reaction, starting from 300 g of racemic ibuprofen, 88.9 g of enantio-enriched (*S*)-ibuprofen with 85% ee was produced. In the subsequent reaction, 76 g of the 85% ee materials were used to produce 38.4 g of (*S*)-ibuprofen with 97.5% ee (Scheme 19).

Synthesis of both enantiomers of fluorophoracantholide **1**, (9*S*)-10-fluorodecan-9-olide (9*S*)-(−)-**1** and (9*S*)-10-fluorodecan-9-olide (9*R*)-(+)-**1**, has been achieved through lipase-catalyzed enantioselective acetylation of methyl 10-fluoro-9-hydroxy decanoate (**2a**) with acetic anhydride in the presence of lipase amano PS (*P. capacia*) (27). The higher homologue, methyl 11-fluoro-10-hydroxyundecanoate (**2b**), has also been optically resolved. These enzymatic resolutions by acetylation of ω-fluorohydroxyalka-



Scheme 14. Chemicoenzymatic synthesis of alarm pheromone of ants, *Crematoster* sp.



Scheme 15. Lipase-catalyzed enantiosynthesis of a calcium antagonist for medication.

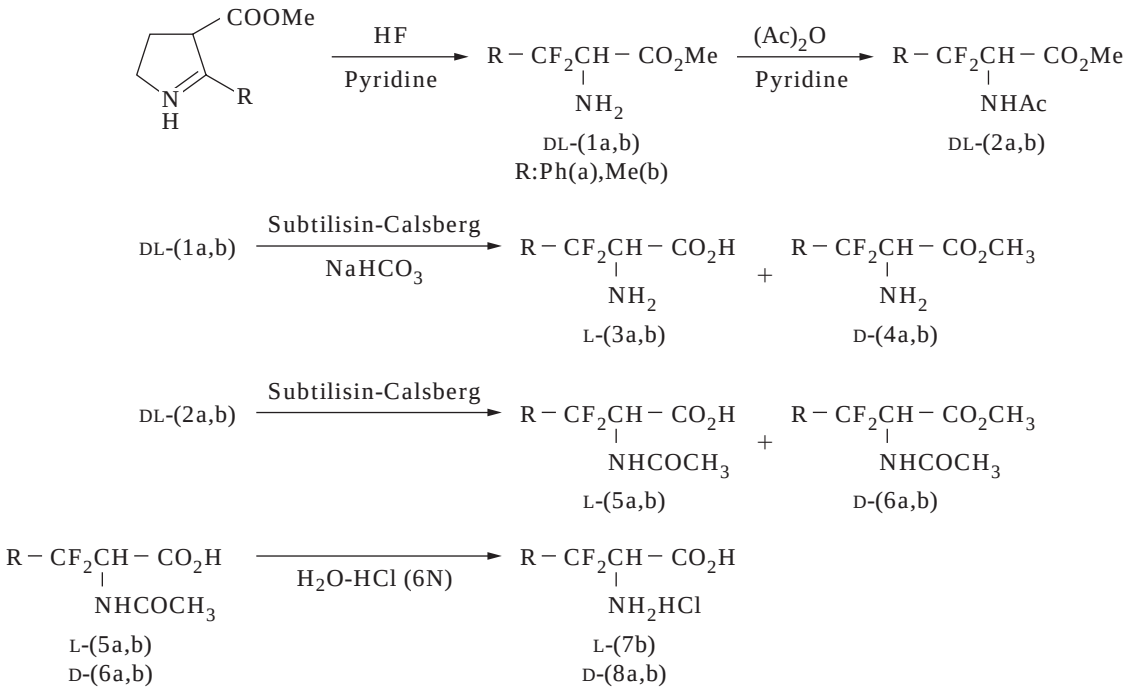
noic acid esters of long-chain fatty acids represent the first lipase-catalyzed enantioselective esterification of *β*-fluoroalcohol (Scheme 20).

Many adrenergic drugs are 2-amino-1-arylethanols possessing a stereogenic center with a secondary alcohol function. It is well known that the two enantiomers of a chiral drug often display different biological activities. Consequently, the enantiomeric purity of such compounds is very important. The drugs of (*R*)-enantiomers of amino ethanol and (*S*)-enantiomers of amino-2-propanol are generally associated with agonist or *β*-blocking activity because of their structural similarity to natural catecholamines.

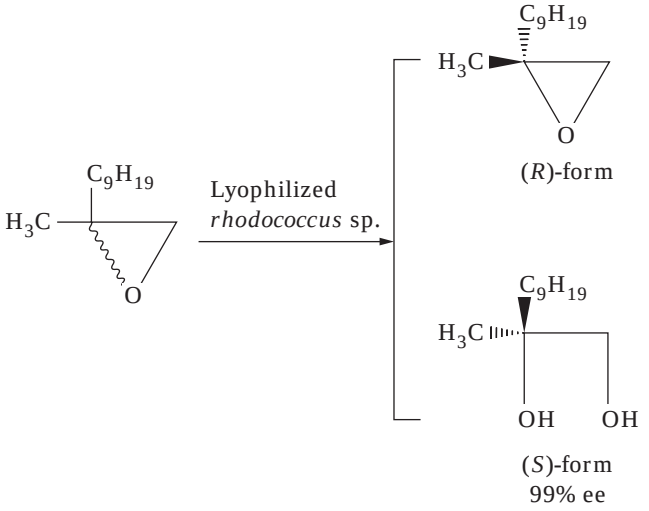
The enantiomers of 2-amino-1-(4-methoxy)phenylethanol were obtained at enantiomeric purity (99% ee) at 50% conversion by *P. capacia* lipase-catalyzed O-acylation of the corresponding amino alcohol (28) (Scheme 21).

The kinetic lactonization of *γ*-hydroxyesters by porcine pancreatic lipase (PPL) has been demonstrated by Sugai et al. (29). The reaction has been used in the synthesis of Japanese beetle pheromone with 78% ee in 29% conversion. Clearly, this chemistry has tremendous potential because of the importance of lactones in biologically active compounds. However, it is restricted to very low yields if high enantiomeric purity is desired.

Taylor et al. prepared the enantio-enriched *γ*-hydroxyesters from corresponding *γ*-ketoesters using Baker's yeast reduction (30). They attempted Baker's yeast reduction of **1** and obtained the corresponding *γ*-hydroxyesters **2** in a



Scheme 16. Enzymatic resolution of fluoro amino acids by subtilisin.



Scheme 17. Resolution of 2,2-disubstituted oxyrane using *Rhodococcus* sp. NCIMB 11216.

yield of 46% with 95% ee. This product **2** (predominantly (*S*)-**2**) was obtained by treating with PPL with 99.7% ee in 61% conversion (Scheme 22).

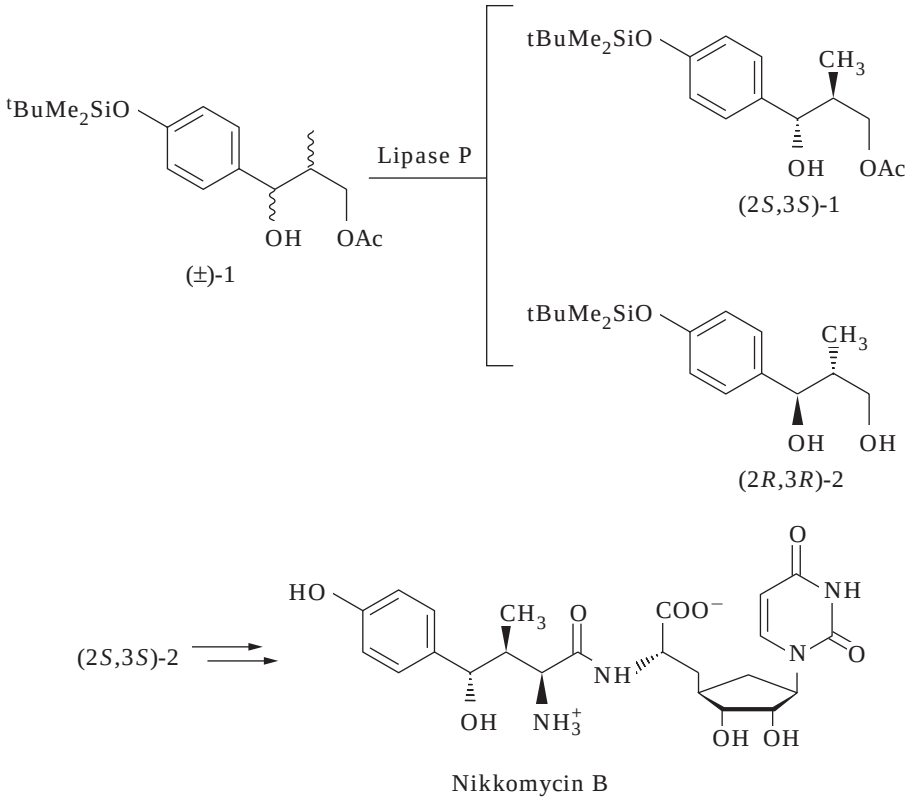
Taylor et al. also reported the high optical purity preparation of another two important lactones, key intermediates used in the synthesis of Japanese beetle pheromone and anti-AIDS drugs, using a complementary, two-stage enantioselective strategy. In this approach, an enzymatic kinetic resolution is performed to enrich the faster-reacting enantiomer in a starting material obtained by an earlier enantioselective step. The results show that conversions, yields, and ee can be dramatically increased by this complementary approach. The authors illustrate how modestly enantio-selective techniques can be combined with kinetic resolution procedures to yield optically pure compounds. The utility of many modestly enantio-selective techniques can be enhanced thereby.

OPTICAL RESOLUTION BY HYDANTOINASE-CATALYZING HYDROLYSIS

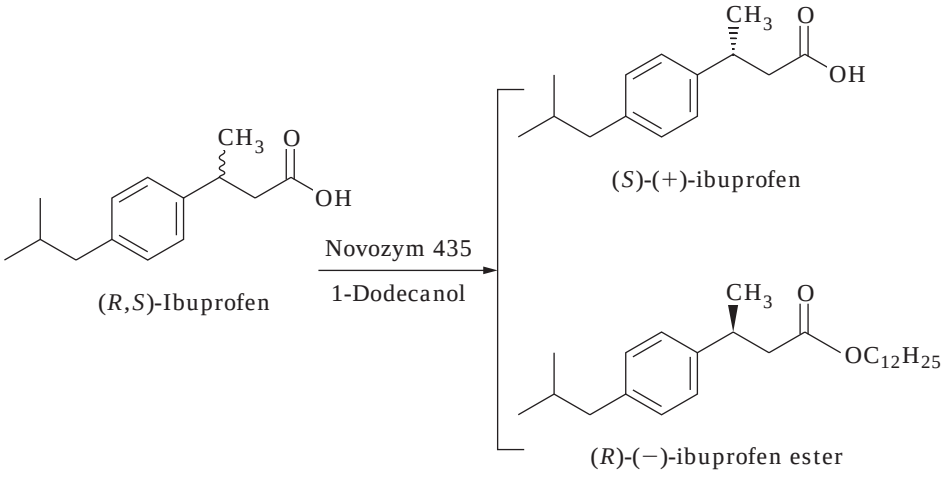
Racemic amino acid hydantoins can be converted into D-amino acids using a system consisting of a D-hydantoinase and a carbamoylase. D-Citrulline can be obtained from corresponding racemic hydantoin with 92% ee in 79% yield (31) (Scheme 23).

Agrobacterium tumefaciens strain 47C expresses an inducible D-hydantoinase that catalyzes the formation of optically pure *N*-carbamoyl D-amino acids from racemic hydantoin precursors. The D-hydantoinase was shown to be active and stable at higher temperature and higher pH values, thus affording favorable bioreaction conditions that result in racemization of DL-hydantoins to D-isomer. The optimal performance (reaction kinetics) was demonstrated at pH 10 and 70 °C. The enzyme exhibited a distinctive substrate specificity and was not activated further by any metal ions. *A. tumefaciens* hidantoinase was most active on 5,6-dihydro uracil and DL-5-methyl hydantoin but only slightly active on DL-benzyl hydantoin (32).

Kim and Kim (33) reported that D-hydantoinase and N-carbamoylase of the bacterium *Agrobacterium* sp I-671 were partially purified to about 90% purity on sodium dodecyl sulfate–polyacrylamide gel electrophoresis and that biochemical properties of the enzymes were characterized.



Scheme 18. A total synthesis of Nikkomycin B based on enzymatic resolution of a primary alcohol.



Scheme 19. The enantioselective reaction for the enzymatic resolution of (*R*,*S*)-ibuprofen.

The *N*-carbamoylase was found to be severely inhibited by ammonium ions coproduced with D-*p*-hydroxyphenylglycine (D-HPG). The conversion yield of D-HPG significantly increased on addition of specific adsorbents for ammonium ions. To determine the ratio of D-hydantoinase to *N*-carbamoylase, which best minimizes the accumulation of intermediate (*N*-carbamoyl-D-HPG) in the direct enzymatic production of D-HPG, a sequential reaction was numerically simulated. Simulation results coincided well with experimental data, and the optimal ratio of D-hydantoinase to *N*-carbamoylase was found to be about 1:3 by weight.

OPTICAL RESOLUTION BY OXIDOREDUCTASE-CATALYZING OXIDATION AND REDUCTION

Lipase-catalyzed kinetic resolution of secondary alcohols via hydrolysis, esterification, and transesterification has been widely used to obtain optical active compounds as described in this article.

Fantin et al. (34) succeeded in achieving the kinetic resolution of heteroaryl ethanols via oxidation both with baker's yeast and *Bacillus stearothermophilus*. These organisms were also used in the kinetic resolution of bicyclic octenol and heptenol with excellent results (35). Although

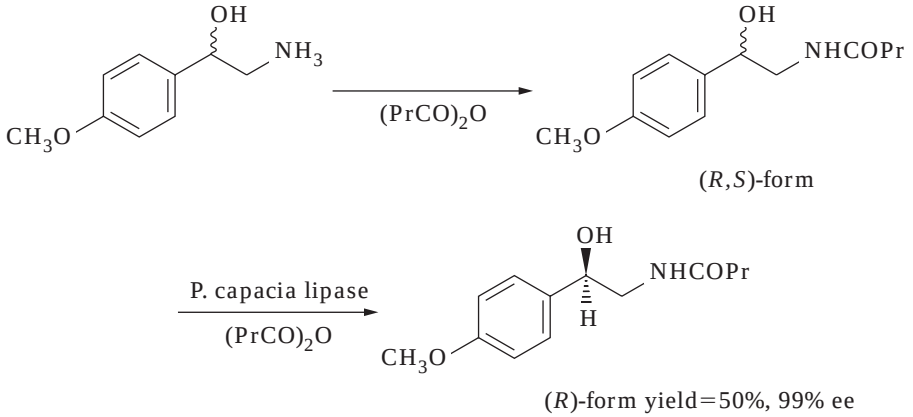
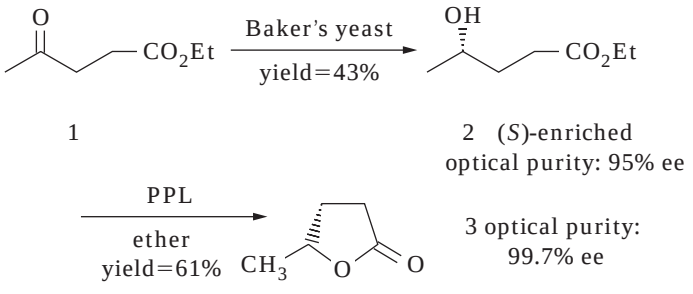


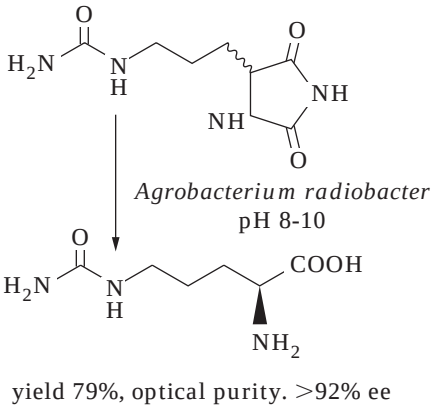
Scheme 21. Synthesis of optically pure precursor of adrenergic drugs by lipase-catalyzed acylation.

hydrolytic enzymes such as lipases and hydrolases are known to retain their activity in organic solvents, dehydrogenase and oxidoreductase are different because their catalytic reactions require the assistance of a stoichiometric amount of coenzymes, which has to be reproduced in order to elaborate the substrates catalytically in the cells. However, the organic solvents often cause serious damage on the hydrophobic cell membranes of the microbe, resulting in a leakage of the contents of the cell. To avoid this problem, the organic solvents were used with immobilized microorganisms because immobilization enhances their stability against denaturation by organic solvents.

Fantin et al. (36) reported that racemic 6-*endo*-bicyclo[3.2.0]hept-2-en-6-ol **1** was oxidized and kinetically resolved in heptane to give (1*S*,5*R*)-bicycloheptenone **3** in 49% conversion with 100% ee. Parallel experiments in water and with immobilized cells in heptane gave lower yields (41%) but equally high enantiomeric excess (99 to 100%



Scheme 22. The kinetic lactonization of *r*-hydroxyesters by porcine pancreatic lipase.



Scheme 23. D-Citrulline preparation by hydantoinase.

ee). Similar results were obtained in the oxidation of the racemic 2-*endo*-bicyclo[3.3.0]oct-7-en-2-ol **2**, but the reaction rate was higher. In fact, after only 4 h in heptane, (1*S*,5*S*)-bicyclo-octenone **4** was obtained in 48% yield and with 98% ee. In water, the yield was lower (37%). Oxidation with *B. stearothermophilus* in heptane is the first example of a reaction with bacteria carried out in organic solvents, and it is as efficient as water. The advantages of this methodology are that the procedure is simpler because the filtration of the cells and concentration of the solvents afford the crude reaction mixture. On the other hand, oxidation with the immobilized cells is very promising for use on a preparative scale (Scheme 24).

The fungus *Rhizopus arrhizus* has been used for reduction of acetophenone and its *o*-, *m*-, and *p*-methoxy derivatives **1a** to **1d** to the corresponding (*S*)-(−)-alcohols (37). To optimize the reaction time for microbial cell-catalyzed reduction, experiments were carried out with **1a** for different periods of time. Fermentation for 7 days was found to yield the best results. The 1-phenylalkanones **1a** to **1d** were therefore incubated with *R. arrhizus* in modified Czepak Dox medium for 7 days. At the end of fermentation, the transformation products 2a–d were isolated and characterized. All these alcohols were found to have negative specific rotations (Scheme 25).

The (1*R*,2*S*)- and (1*S*,2*R*)-2-methyl-2,3-epoxy-1-phenylpropanols were prepared from α-methylcinnamyl chloride by use of baker's yeast and lipase PS. Takeshita et al. (38) reported the synthesis of (1*R*,2*S*)-2-methyl-2,3-epoxy-1-phenylpropanol **3a** and (1*S*,2*R*)-2-methyl-2,3-epoxy-1-phenylpropanol **3b** starting from α-methylcinnamyl chloride **1** by use of baker's yeast and lipase PS (*Pseudomonas* sp., Amano). At first, when α-methylcinnamyl chloride **1** was fermented with baker's yeast for 36 h at 28 °C, rearrangement occurred to give 2-methyl-1-phenylallyl alcohol **2** in 68% yield. Two pairs of racemic epoxy alcohols, (**3a**, **3b**) and (**3c**, **3d**) (2:1), were separated by silica gel column chromatography (total yield 73%) after epoxidation of **2** with *m*-chloroperbenzoic acid. Enzymatic treatment of epoxy alcohols (**3a**, **3b**) with vinyl acetate in *t*-butyl methyl ether in the presence of lipase PS for 17 h or 24 h at 30 °C gave the optically active acetate **4** and alcohol **3b** in chemical yields of 31 and 46%, respectively. However, the same reaction for racemic epoxy alcohols (**3c**, **3d**) was very sluggish (under the above conditions, esterification proceeded only in 27% chemical yield in 3 weeks, and the optical yield was very low, 56% ee) (Scheme 26).

Fantin et al. (39) reported a new method for preparing optically pure secondary alcohols by combining microbial oxidation and reduction. The chiral secondary alcohols were obtained by microbial or enzymatic reductions of the

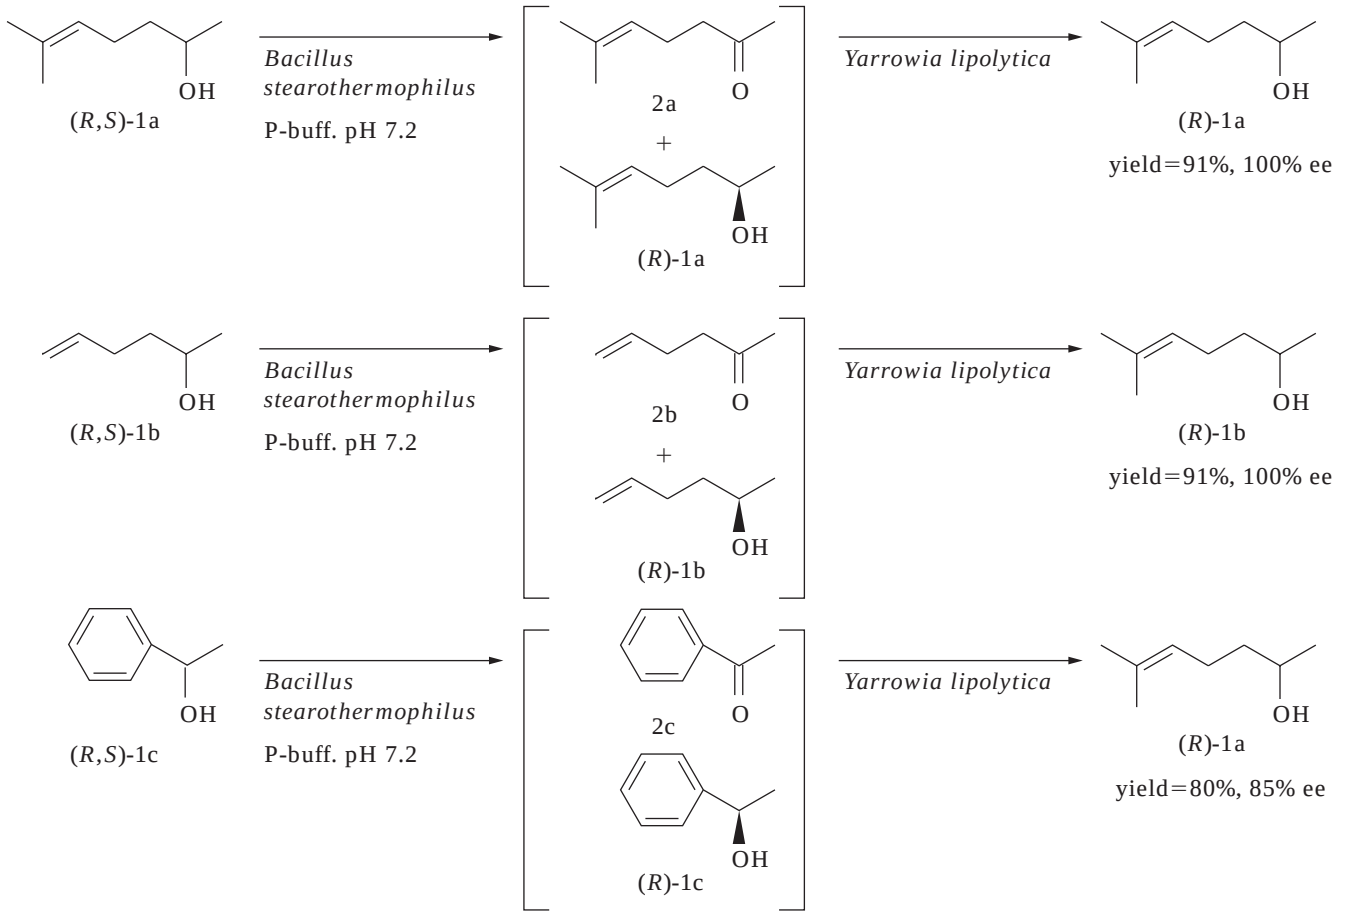
corresponding ketones followed by kinetic resolution of the racemic alcohols via esterification or hydrolysis of the corresponding ester with lipases. Various ketones were reduced using baker's yeast or purified alcohol dehydrogenases. The reaction with baker's yeast yielded almost exclusively the (*S*)-alcohol, whereas the enzyme produced the hydride either from the *si*-side (i.e., *Lactobacillus kefir* alcohol dehydrogenase) or the *re*-side (i.e., *Thermoanaerobium brockii* alcohol dehydrogenase) of the ketone to give (*R*)- or (*S*)-alcohols, respectively. For most cases, the stereochemical course of the reaction, which mainly depended on the steric requirements of the substrate, could be predicted from the simple model that is generally referred to as Prelog's rule. A majority of the dehydrogenases used for the stereospecific reduction of ketones and a majority of microorganisms follow Prelog's rule, giving (*S*)-alcohols. However, the enzymatic resolution of racemic alcohols with lipases, in which a high enantioselectivity is exhibited, stops at the 50% conversion stage. The authors (39) succeeded in establishing an alternative method for kinetic resolution of secondary alcohols via oxidation with baker's yeast and *B. stearothermophilus*, affording (*R*)-enantiomer in high enantiomeric excess. Moreover, they also reported an anti-Prelog behavior (formation of the (*R*)-alcohol) in microbial reductions of various carbonyl compounds with *Yarrowa lipolytica* strains, a new yeast species. They described a new approach to the high-yield synthesis of homochiral secondary (*R*)-alcohols starting from the corre-



Scheme 27. Optical resolution of the racemic alcohols by a combination of microorganism-catalyzed oxydation and reduction.

sponding racemates. The approach consisted of (*1*) kinetic resolution via oxidation with *B. stearothermophilus* and (*2*) reduction of the obtained oxidation mixture with *Yarrowia lipolytica* (Scheme 27).

The asymmetric microbial degradation of (*S*)-(+)-mandelic acid was investigated in order to develop a practical process for (*R*)-(−)-mandelic acid production from racemic mandelic acid, which is commercially produced on a large scale at low cost using chemical synthesis. Among the 790 culture strains tested, microorganisms belonging to the *Brevibacterium*, *Pseudomonas*, *Rhodococcus*, *Rhodotorula*, *Rhodosporidium*, *Sporobolomyces*, and *Gibberela* genera exhibited high (*S*)-(+)-mandelic acid–degrading activity. *P. polycolor* IFO 3918 was determined to be the best strain and used as a biocatalyst for eliminating the (*S*)-(+)-isomer (40). The maximum rate of (*S*)-(+)-isomer degradation was obtained at 30 °C and pH 7.0. Under these optimal conditions, the (*S*)-(+)-isomer in a racemic mandelic acid 45 g/L mixture was completely degraded within 24 h, with 20 g of (*R*)-(−)-mandelic acid per liter remaining in the reaction mixture. Crystalline (*R*)-(−)-mandelic acid with a chemical purity greater than 99% and optical purity with 99.9% ee was obtained in 35% yield by acidification of the reaction mixture, extraction with ethyl acetate, and subsequent concentration.

CONCLUSION

Optical resolution by enzymes and microorganisms facilitates enantio-selective synthesis of the bioactive chiral compounds and precursors of natural compounds. Combination of organic synthesis with biotransformation should afford efficient optical-selective and regioselective preparation processes for bioactive natural products such as antibiotics, hormones, pheromones, natural fragrances, and various kinds of natural drugs.

OUTLINE

INTRODUCTION

Many industries such as chemicals, pharmaceuticals, and food require a means of monitoring their production processes. For example, during fermentation, pH, oxygen, carbon dioxide, amino acids, and product concentrations are only a handful of the many parameters that should be monitored to maximize the utilization of reactants and maximize product formation. Most significantly, the lack of suitable sensors in the biotechnology industry is the major obstacle to improve yields through real-time process control. Similarly, monitoring a multitude of analytes during the experimental research and development phase, such as in shaker flasks or microtiter plates, would significantly enhance the ability of biochemical engineers to optimize a process. This article presents the development and application of fiberoptic chemical sensors for bioprocess monitoring.

BIOPROCESS MONITORING

Important Analytes in Bioprocesses

The most common industrial biochemical process is batch aerobic fermentation. Most fermentation processes require control of physical, chemical, biochemical, and biomass parameters. Physical variables such as temperature, pressure, agitation speed, and feed rates are presently measured on-line with conventional sensors that are generally well-developed and reliable. The common chemical measurements of interest in all fermentation broths, from brewing beer to the most modern biotechnological process, include pH, dissolved oxygen, dissolved carbon dioxide, and redox potential. Oxygen and carbon dioxide are also monitored in the reactor vent gases using either infrared or mass spectroscopic analyzers. Next in importance are the biochemical components in the medium essential for harvest decisions, reaction optimization, and model building. These species include those of general interest in all bioreactions, such as glucose, lactate, ammonia, and phosphate, and those of specific interest, such as tetracycline, penicillin, amino acids, and ethanol. Presently these variables are analyzed off-line by removing filtered samples using sterile sampling techniques.

Requirements of Analytical Measurement Systems for Bioprocess Monitoring (1)

Chemical sensors for monitoring can be divided into four broad categories: electrochemical, optical, mass, and thermal. Bioengineers are perhaps most familiar with electrochemical sensors in the guise of pH electrodes. These sensors have been used for decades in the fermentation industry and have many of the attributes of an ideal sensor. They can be sterilized-in-place; they maintain calibration (to a reasonable degree) during the fermentation process; they are robust and can be used multiple times; and they can be interfaced to a controller that automatically adjusts the pH. The pH electrode is almost an ideal sensor from the bioengineer's perspective. Because the sensor is in direct contact with the fermentation broth, it avoids the need to acquire samples, which limits the number of samples that can be measured per unit time, and avoids errors introduced by separating, preparing, handling, transporting, and storing the samples. In addition, there is no time delay in the feedback control loop. The time-delay problem is particularly significant when intervention or corrective action is required to adjust the parameter being measured to a desired level.

By contrast, chemical sensor technology allows a device to dwell in the sampling environment. By responding rapidly and continuously to concentration changes, sensors can generate a vast amount of data. Microprocessors can store and evaluate as much data as the sensors can produce. Sensors avoid all the problems associated with sample acquisition and handling and allow for timely intervention to make appropriate adjustments.

PRINCIPLES OF CHEMICAL SENSORS AND THEIR APPLICATION TO BIOPROCESS MONITORING

In this section, a brief overview of chemical sensors, their construction, and types are given. The reader is referred to other texts (2,3) that treat the subject of chemical sensor technology in greater depth, including design, mathematical treatments, examples, and limitations.

Definition of a Chemical Sensor

A chemical sensor (4) is a device that incorporates a sensing reagent integrated with a signal transducer to afford a system that can measure a target analyte(s) (Fig. 1). The interaction of the target analyte with the sensing reagents generates a signal (electrochemical, thermal, optical) proportional to the concentration of the analyte in the bulk medium. Binding can occur by molecular recognition, such as host–guest, antibody–antigen, or protein-ligand binding, or can involve chemical reactions such as acid–base, redox, or ion exchange.

An ideal chemical sensor must possess certain characteristics for it to be a useful analytical tool in bioprocess monitoring (5). First, the sensor must be specific to the target analyte. This specificity depends on the immobilized

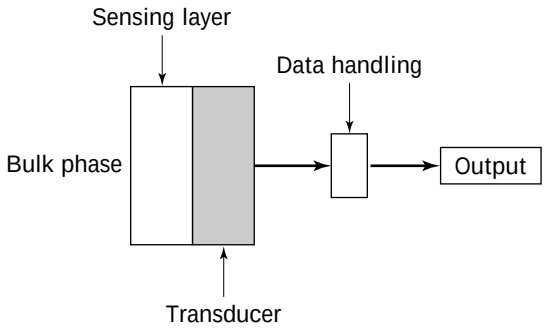

Figure 1. Components of a chemical sensor.

reagents. Biologically derived materials such as enzymes, receptor proteins, and antibodies are extremely valuable in this regard because nature has generated many analyte specific compounds. Second, the signal changes on interaction with the target analyte must be large and be sensitive in the concentration range of interest. If the latter is not possible, then sample pretreatment is required, which leads to uncertainty in the final measurement. Third, the sensor must have a response time consistent with timely intervention. For bioprocesses, response times on the order of a few seconds are sufficient. Finally, the sensor must be stable for the duration of the fermentation process; recalibration is difficult when the sensor is being used on-line or in situ.

Other important factors must be considered for application to bioprocess monitoring, such as the ability of the sensors to withstand autoclaving in situ and to avoid losing sensitivity or calibration during the process. In situ calibration is difficult and seldom practiced.

Types of Chemical Sensors

The interaction of the target analyte with the sensing layer produces a signal when it is interrogated by a suitable transducer. The transducer is usually one of four types: electrochemical, mass, thermal, or optical.

Electrochemical Sensors (6). Many chemical interactions at the sensing layer involve ionic equilibrium or electron transfer. These interactions can be interrogated using an electrochemical transducer such as a metal electrode. There are three main types of electrochemical sensors: potentiometric (symmetric), potentiometric (asymmetric), and amperometric.

Symmetric potentiometric sensors are commonly known as ion-selective electrodes (ISEs) (7) and typically consist of two electrolytes separated by a selective membrane. The potential difference between the internal reference solution and the bulk sample solution is measured with respect to a reference electrode (e.g., Ag/AgCl or saturated calomel electrode).

The classical example of an ISE is the pH electrode. First reported by Cremer (8), it is the best developed sensor and has been commercially available since the 1920s. Symmetric potentiometric devices are also available for many other single and divalent cations (e.g., Na^+, NH_4^+, Ca^{2+}). The pH electrode has been used to prepare CO_2 sensors and other potentiometric biosensors.

Asymmetric potentiometric sensors are different from ISEs in that they do not contain an internal electrolyte solution. In these devices, sometimes referred to as solid-state devices, the sensing membrane is in contact with only one electrolyte (9). This approach has led to the development of ion-selective field effect transistors (ISFETs) (10) and consists of an ion-selective membrane in contact with semiconductor surfaces. The stability of these devices has been limited and matches that of ISEs. Potentiometric sensors are equilibrium devices, and the output is governed by the Nernst equation. The potential is proportional to the log of the activity of the target analyte (11).

In amperometric devices (12), the current at an electrode is measured at a fixed electrode potential. The current generated is proportional to the concentration of the target analyte. The first report of this type of sensor was the Clark oxygen electrode (13). In this device, a layer of buffer solution is trapped on the surface of a platinum electrode by a gas permeable membrane, typically PTFE or silicone rubber. The electrode is polarized to -750 mV versus Ag/AgCl reference electrode. At this potential, any oxygen arriving at the electrode surface is reduced; thus, the magnitude of the resulting current is directly proportional to the external oxygen concentration when mass transport through the membrane is rate limiting.

Mass Sensors (14). The interaction of a target analyte with a sensing layer results in an overall increase in mass at the sensing site. Microbalances can be used to prepare chemical sensors based on the mass increases. Piezoelectric materials (e.g., quartz) are ideal for use in preparing microbalances or piezoelectric sensors. In these devices, the piezoelectric material is used to create and conduct acoustic waves. The crystals are configured into resonant structures that transmit acoustic signals in a frequency-dependent manner. A change in mass of the material on the piezoelectric crystal will cause the resonant frequency to change, which is proportional to the concentration of the analyte. A detailed mathematical treatment of the principles of this work is given elsewhere. Piezoelectric mass detectors have been used to prepare humidity gauges, thin film sensors, and gas detectors. Liquid-phase systems have also been reported for a variety of analytes.

Thermal Sensors (15). Many chemical interactions result in the evolution or absorption of heat. The change in temperature brought about by the interaction can be used to make analytical measurements. The sensing tip is usually a thermocouple or any other temperature probe such as a thermistor. The sensing layer is usually an enzyme that generates heat via catalysis of substrate to product.

Optical Sensors (16). Spectroscopic techniques are well established and are routinely used in analytical laboratories. These techniques interrogate the optical properties of molecules that vary depending on the nature of their environment or change as a consequence of a chemical interaction. Fiberoptic chemical sensors (FOCSs) consist of an indicator molecule immobilized on the distal end or along

the length of an optical fiber. The fiber is used primarily for carrying light information to and from the controlling instrument. A full treatment of FOCSs is given later.

Biosensors (17). Biosensors are devices that incorporate a biological catalyst connected or integrated with a transducer. The biocatalyst catalyzes a chemical reaction, and the transducer converts the biochemical activity into an electrical, optical, or thermal signal. The biological element can be an enzyme, antibody, receptor, tissue, organism, or whole cells.

The first biosensor reported was developed for the measurement of glucose (18). The device consists of a Clark oxygen electrode with the enzyme glucose oxidase immobilized on the external side of the gas-permeable membrane. The device operates by measuring the depletion of oxygen brought about by the oxidation of glucose by glucose oxidase.

The amperometric determination of glucose has been commercialized in the form of test strips for blood glucose measurements by Medisense Inc. In their device, the oxygen dependency of the Clark device is removed by the introduction of an Fe^{2+}/Fe^{3+} redox transport system.

The literature is replete with articles on biosensors, and there are several journals dedicated to this subject.

Sampling Methods (19)

There are two main strategies for on-line fermentation analysis: either the sensor is located outside the reactor and the sample is transported to the sensor (ex situ) or it is placed directly in the fermenter (in situ).

In Situ Monitoring (20). A chemical sensor that meets all the requirements for applications monitoring can be used on-line or in situ. Several assemblies that have been developed to undertake in situ monitoring are shown in Figure 2. In situ monitoring with chemical sensors is rare and generally limited to gas sensing where the transducer surface is protected by a gas-permeable membrane. Sensors that use semipermeable membranes are subject to rapid fouling and poisoning of the sensor surface.

Ex Situ Monitoring (21). The problems associated with in situ monitoring have resulted in the development of ex situ (Fig. 3) systems. In ex situ monitoring, the sample is drawn continuously to a remote site where the analysis is carried out. The procedure removes the need for sensor sterilization, and on-line calibration is easily achieved. In many cases, sample pretreatments are required before analysis, such as filtering, adjustment of the sample pH, temperature, and dilution. The main drawbacks to ex situ monitoring are the need for the use of pumping systems, the possibility of back-contamination at the sampling port, and the effect on the analyte after sample pretreatment.

Application of Chemical Sensors to Bioprocess Monitoring (22)

In the previous section, the requirements of chemical sensors and other analytical systems to bioprocess monitoring were discussed. There are inherent problems with using sensors for bioprocesses. Some of the main difficulties that have to be overcome include the needs to provide aseptic sensors; to prevent microbial fouling, poisoning, and disruptive effects of chemical and biochemical constituents on the sensors; to avoid biochemical and chemical interferences in complex analyte mixtures; to preclude analyte chelation, binding, and buffering effects; and to perform sensor calibration, all while operating under a wide variety of aqueous physiochemical conditions.

Despite the large number of papers, books, and reviews on chemical sensors in the public domain, only a tiny fraction are dedicated to bioprocess monitoring, and very few results have been presented on the successful application of these devices to bioprocess monitoring.

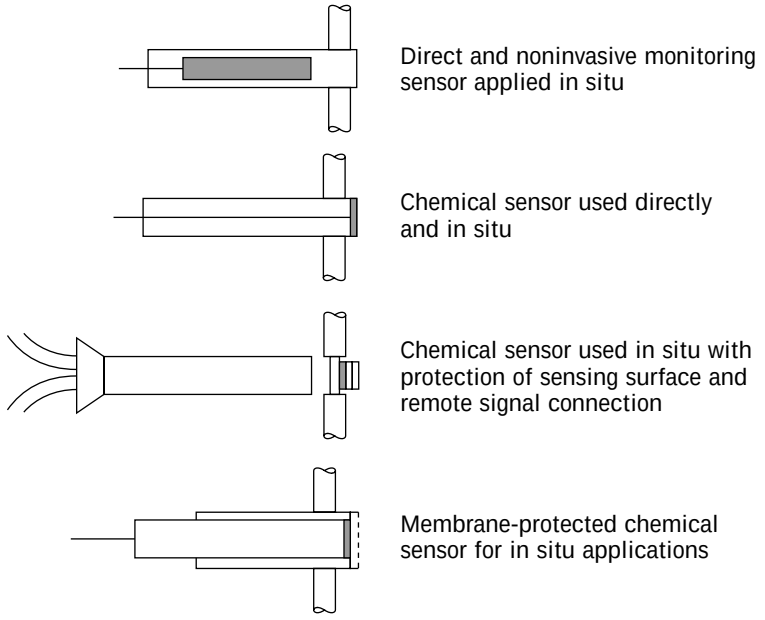

Figure 2. In situ sampling assemblies used for chemical sensors in fermentation monitoring. The sensor is in direct contact with the fermentation sample. Sample pretreatment is not possible with these configurations.

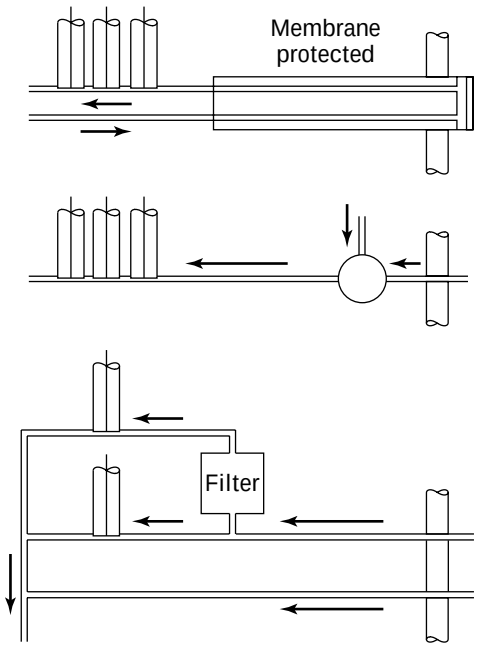

Continuous flow dilution cell and multiprobe used ex situ

Continuous flow-line sampling of untreated or filtered culture

Figure 3. Ex situ sampling assemblies for using chemical sensors on-line. The sample is drawn from the fermentation vessel to the sensor(s). Sample pretreatment is possible with these configurations.

The first electrochemical sensor developed was the potentiometric pH glass electrode, and it has been modified and implemented for in-line or in situ bioprocess monitoring (23). It is by far the most widely used and the most successful chemical sensor to date. The pH sensor can be autoclaved and is generally considered biocompatible. The sensor is calibrated both before and after the fermentation, and these data are used to correct the measured pH values.

Carbon dioxide sensors based on pH measurements have also been used for in situ bioprocess monitoring (24). Carbon dioxide is measured indirectly by measuring the pH of a bicarbonate buffer solution in equilibrium with carbon dioxide. These types of sensors are based on original work by Severinghaus and Bradley (25).

The Clark oxygen sensor has also been adapted for bioprocess monitoring (26). Steam sterilizable glucose sensors based on oxygen measurements have been reported with lifetimes sufficient to last the course of the fermentation (27).

Commercial Chemical Sensor Systems for Bioprocess Monitoring

The measurement of key analytes in bioprocesses has led to the commercialization of several chemical sensors. The market is dominated by sensors for the most important analytes: pH and dissolved O_2. Table 1 summarizes a few of the commercially available sensors. Sensors for CO_2 are available but used primarily for off-line gas analysis. Most CO_2 gas analysis is performed using nondispersive FT-IR measurements. Optical sensors are not currently available commercially for bioprocess monitoring.

Table 1. Commercial Sensors for Bioprocess Monitoring

Manufacturer	Analyte	Transducer

	Dissolved O_2	Amperometric

FIBEROPTIC CHEMICAL SENSORS

Optical Fibers

Optical fibers (28), also called fiberoptics, are used extensively in the telecommunications industry as a means for conducting information over long distances. Optical fibers are strands of glass or plastic consisting of a core, clad, and protective outer sheath. Generally, optical fibers range in diameter from 50 μm to 1 mm. The transmission of optical signals through an optical fiber is based on the phenomenon of total internal reflection. Figure 4 shows a typical optical fiber made of a core material of refractive index n_1 surrounded by a cladding material with a lower refractive index n_2. Because the index of refraction changes abruptly from the core to the clad, this type of arrangement is described as a step-index fiber. When the incident light entering the fiber strikes the core–clad interface, part of the light will be transmitted and some reflected. If light strikes the interface at an angle greater than the critical angle C as defined by equation 1,

$$\sin C = n_2/n_1 \tag{1}$$

then only light within a characteristic acceptance cone will be introduced into and carried within the fiber, as described by equation 2,

$$\sin\alpha = [(n_1^2 - n_2^2)^{1/2}]/n_0 \tag{2}$$

where sinC is the acceptance cone half angle and n_0 is the

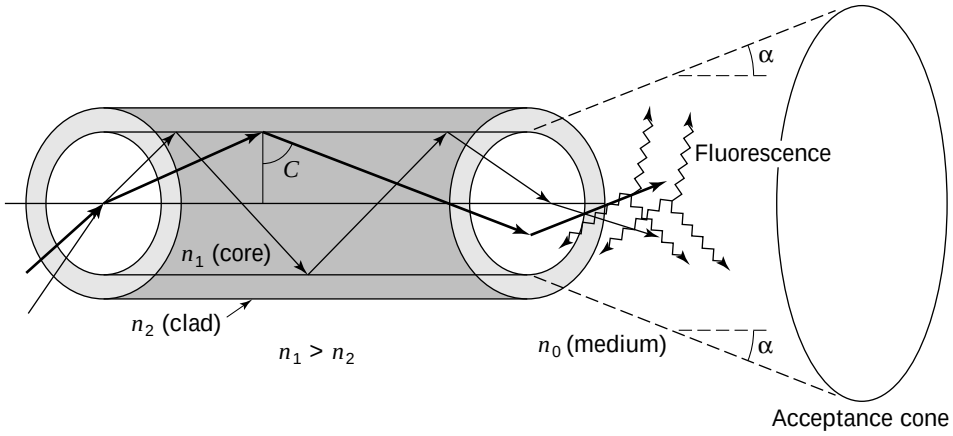

Figure 4. Cross-section of an optical fiber showing core, clad, and optical pathways.

index of refraction of the medium. By convention, collection efficiency is described by the numerical aperture (NA) or f number. As defined by equations 1 and 2, the greater the difference in refractive indices between the core and clad, the larger the acceptance half angle and therefore the more efficient the light collection of the fiber.

Preparation of FOCSs

The preparation of FOCSs requires immobilizing the indicator onto the optical fiber. The indicator is immobilized onto the core of the fiber either on the distal end or along the length of the fiber. The latter approach is used for the preparation of evanescent wave devices (16). In this article, only distal-end FOCSs will be considered because these are dominant and more useful in bioprocess monitoring.

Immobilization Techniques (29). One of the most critical aspects of optical sensors is the method of coupling the various indicating species to the optical fiber, a process known as immobilization. Immobilization techniques vary and are used according to the type of sensor being developed.

Single-Analyte Sensors. Several ways of immobilizing indicating species are shown in Figure 5. Figure 5**a** shows the most rudimentary form of an optical sensor. In this design, the optical fiber is used simply to conduct light to and from an indicator solution that is affixed to the distal end via a semipermeable membrane. Analyte diffuses across the semipermeable membrane and reacts with the indicator. Under ideal circumstances, the indicator is reversible, so that when the concentration of analyte is reduced, it dissociates from the indicator and leaves the solution in contact with the optical fiber. Many different forms of this design exist. Such designs can be extremely robust. This approach suffers from the need to assemble them by hand. Furthermore, they are not reproducible and generally possess long response times.

Figure 5**b** shows a sensor in which the sensing layer is coupled directly to the optical fiber surface. In this approach, a polymer layer containing immobilized indicator is in direct contact with the fiber. This approach is technically more demanding because it requires significant

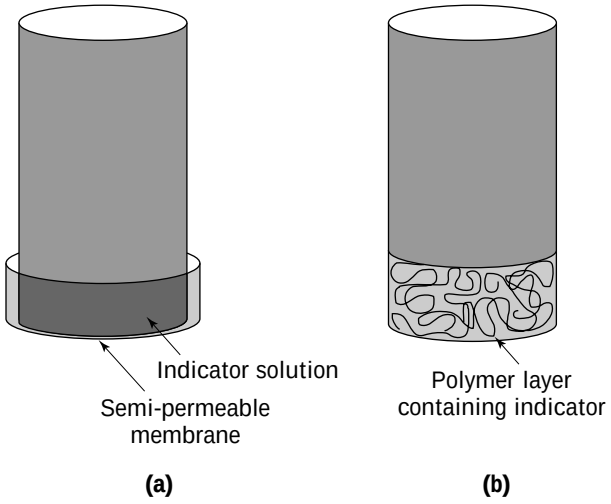

Figure 5. Immobilization methods for the preparation of FOCSs.

surface and polymer chemistry for implementation. First, the optical fiber surface is modified to possess reactive functional groups. Next, a prepolymer solution containing a modified indicator is applied to the optical fiber surface. Polymerization is initiated using either a thermal or photochemical approach. Surface reactive groups on the fiber engage in reaction with the prepolymer and functionalized indicator. In this manner, the indicator is covalently linked to the fibers' distal tip, creating a robust, resilient polymer layer to which the indicator is attached.

Multianalyte Sensors (30). In a typical measurement scenario, a multitude of analytes is often measured. Using conventional single-core optical fibers, it is necessary to use a separate optical sensor for each analyte. With additional sensors, the complexity of the readout instrumentation increases. An alternative approach uses imaging optical fibers (31). These fibers are arrays of coherent fused bundles containing thousands of individual optical fibers, each with its own clad and core, that are capable of transmitting images from one end of the array to the other. Such a transmitted image is shown in Figure 6.

As can be seen in Figure 6, the image is built up pixel by pixel similar to the way the compound eyes of insects

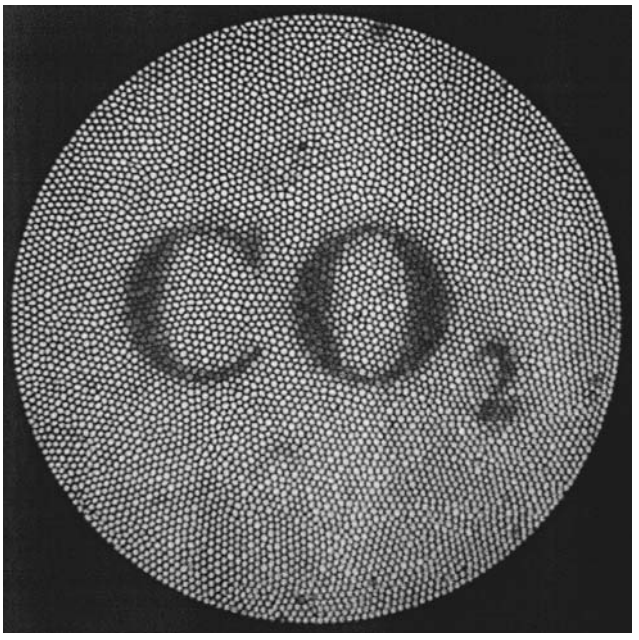

Figure 6. Imaging fiber is comprised of thousands of coherent individual fibers and is able to transmit an image.

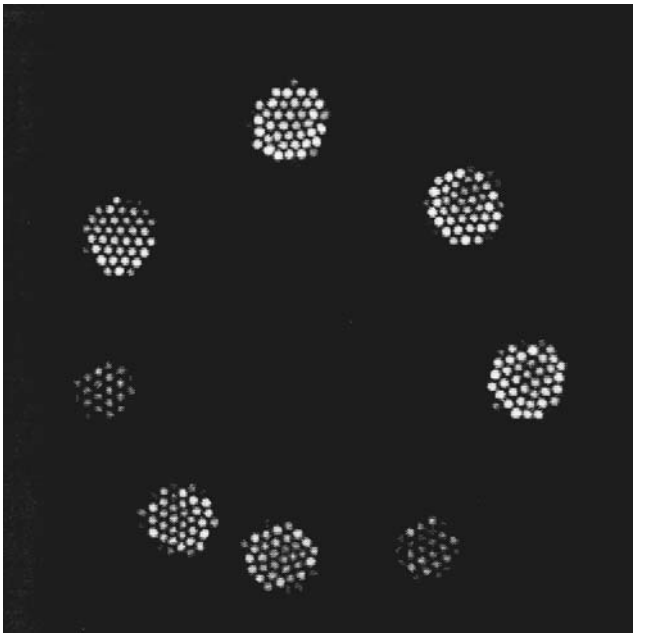

Figure 7. Collected fluoroscence image from a multianalyte imaging sensor shows sensor regions are polymerized over multiple fibers.

operate. This array architecture can be used to create a multianalyte optical sensor (32). In this approach, individual sensors are polymerized in discrete locations on the distal tip of the imaging fiber array using a photodeposition process. Each sensor element conveys an optical signal only through the optical fibers in contact with it. All sensors in the array can be addressed simultaneously. An array detector, such as a CCD camera, can be used to measure the signals from each sensor region. A example of a collected image from a multianalyte sensor array is shown in the Figure 7.

Transduction

There are a myriad of ways in which an optical fiber can be converted into a chemical sensor. In general, one must attach some type of chemical-indicating species to the optical fiber. The chemical-indicating species must provide an optical response that can be measured by the optical fiber.

Absorbance (33). In absorbance-based measurements, the presence of a particular chemical entity is detected by a change in the intensity or color of an indicator or reagent. The indicator is attached to the distal end of the optical fiber. In the presence of analyte, the absorbance increases or decreases in accordance with Beer's law:

$$A = \varepsilon bc \tag{3}$$

where ε is the extinction coefficient, b is the path length, and c is the sample concentration.

Fluorescence (34). An alternative method of detection uses fluorescence. Fluorescence sensors use fluorescent indicators that are more sensitive than absorbance-based sensors. Fluorescent indicators absorb light of one wavelength and emit light at a different wavelength. The advantage of such indicators is that they provide a black-background method because the emission signal arises from a zero background.

Theory of FOCSs

Fluorescence measurements can be made by using either the intensity of fluorescence or the fluorescence lifetime. With intensity measurements, the presence of the analyte correlates directly with the fluorescence intensity signal:

$$I_0/I = 1 + K_s[A] \tag{4}$$

where $K_s = [FA]/[F][A]$ is the binding constant, F is the fluorescence indicator, A is the analyte concentration, I_o is the fluorescence intensity in absence of analyte, and I is the fluorescence intensity in presence of analyte.

Upon binding analyte, the indicator can either increase or decrease its fluorescence intensity. An alternative intensity-based fluorescence measurement results from dynamic fluorescence quenching. This process involves collisional quenching in which the excited state indicating species collides with the analyte during the excited state lifetime. This process can be described by the Stern-Volmer equation:

$$I_0/I = 1 + K_{sv}[A] \tag{5}$$

where K_{sv} is the Stern-Volmer constant and $[A]$ is the analyte concentration.

Fluorescence Lifetime Measurements (35). A second measurement technique involves fluorescence lifetime. A variety of techniques are available for making fluorescence lifetime measurements. For most sensor applications, indicators are still used. The most common technique involves measuring the fluorescence lifetime directly. In this approach, the fluorescent indicator's lifetime is affected by analyte binding. By measuring the fluorescence decay as a function of time, the indicator lifetime can be calculated and correlated to analyte concentration. A significant advantage of this approach is that the background fluorescence does not interfere. Typical background fluorescence decays very rapidly, but most fluorescent indicators have longer lifetimes in the millisecond to nanosecond range. By watching the signal decay, one collects only signals emanating from the indicator. An increasingly popular method for performing fluorescence lifetime measurements is to use a frequency-modulated or phase-angle approach. This approach is based essentially on interferometry in which the delay between the excitation source and the emission signal is measured. The advantage of this technique is it does not require the sophisticated instrumentation necessary to measure fluorescence lifetimes. Fluorescence methods have the advantage of greater sensitivity relative to absorbance-based measurements, with fluorescence lifetime measurements requiring more sophisticated and somewhat more expensive instrumentation.

Ratiometric Measurements (36). With absorbance- or fluorescence-based measurements, it is advantageous to use ratiometric indicators. Ratiometric indicators possess either two excitation or two emission wavelengths that can be measured separately. A hypothetical example of a ratiometric indicator is shown in Figure 8. In this example, the fluorescent indicator has two distinct emission wavelengths. As the analyte concentration increases, the spectral contribution from one of the emission wavelengths increases while the other emission wavelength decreases. Replotting the data in Figure 8 shows that by plotting the ratio versus analyte concentration, the measurement becomes insensitive to the fluorescence intensity of a single peak. Furthermore, the ratiometric measurement is insensitive to changes in light intensity of the excitation source and/or the detector sensitivity. In addition, the measurement is independent of the absolute amount of dye present; dye leaching or photobleaching does not affect the measurement.

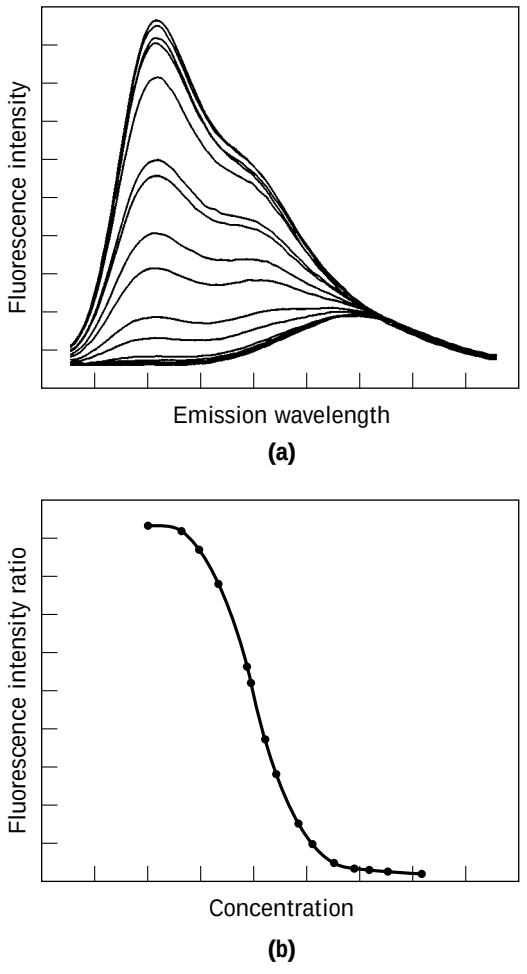

Figure 8. Ratiometric dye with two emission maxima (**a**). Replot of ratio versus analyte concentration is insensitive to instrumental variables (**b**).

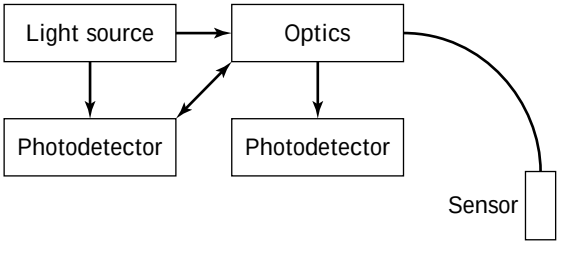

Figure 9. Typical instrumentation design for operating FOCSs.

Instrumentation (37)

The elements required to operate FOCS are shown in Figure 9. Typically, the instrument consists of a light source, optics, photodetector, and controller. The second photodetector is a reference detector that is sometimes necessary when ratiometric and lifetime measurements are not possible.

Light Source. Light sources can be either lasers or lamps, and their choice is dependent on the mode of operation. For example, for fluorescence lifetime measurements, lasers are used because they are good at producing nanosecond excitation light pulses. Table 2 provides a summary of some lasers that are used for optical sensing. In applications where a continuous light source is sufficient, then an arc lamp is often the choice. Lamps generally have relatively broad spectral emission and are much cheaper to purchase and operate than lasers. Figure 10 summarizes the available lamp types.

Optics. The optical components are responsible for focusing, splitting, directing, and selecting light from the

light source to the sensor and back to the detector. Figure 11 shows two possible configurations for operating FOCSs. Figure 11a is suitable for operating a single fluorescence-based sensor, and Figure 11b is suitable for absorbance-based systems.

Refracting, reflecting, and focusing light is achieved using lenses. Refractive optics include spherical, aspheric, and gradient index lenses, and reflection is accomplished using elliptical, spherical, and parabolic mirrors. Light splitting is achieved using optical couplers, beam splitters, or dichroic filters. Optical wavelength selection is necessary for (*1*) isolating an excitation spectral band, (*2*) selecting an optical signal from stray light, and (*3*) separating the excitation from the emission light. Even with the monochromatic light from a laser, a notch filter is required to avoid scattered or reflected laser light from reaching the detector. Wavelength selection is carried out using optical filters such as absorption and interference filters. It can also be achieved using diffraction gratings.

Photodetectors. The photodetector collects the photons emerging from the optical fiber that carries the information relating to the analytical measurement. There are three types of photodetectors: thermal, photoemissive, and quantum. The most popular types are the photoemissive or photomultiplier tubes (PMTs), which are based on the emission of electrons from a photocathode in a vacuum chamber. When photons of sufficient energy strike the photocathode, it emits an electron from the surface—the photoelectric effect. The electrons are accelerated by a voltage drop across a gap to a secondary emitting electron surface where its numbers are multiplied. The electrons are collected at the anode where they can readily be detected. Available photodetectors are summarized in Figure 12.

FIBEROPTIC SENSORS FOR BIOPROCESS MONITORING

The successful application of FOCSs to bioprocess monitoring has had limited success. The reasons for this lack of success will be discussed later. In this section, optical sensors that have been successfully used in fermentation analysis will be described.

pH Sensors

Measurement of pH. The measurement of pH in bioprocess is routinely carried out and is a good indicator of the state of the process. The spectroscopic determination of pH can be achieved using a variety of absorbance or fluorescent indicators. The particular indicator used depends on

the pH range of interest because most indicators are only sensitive to ±2 pH units around their pK_a. Generally, indicators are selected with a pK_a close to 7 because most fermentations are carried out between pH 5 and 9.

Theory of Spectroscopic pH Measurement (38). The spectroscopic determination solution pH is accomplished by measuring the concentration ratio of the dissociated (In^-) and undissociated (HIn) forms of the indicator. The overall equilibrium can be written $HIn \rightleftharpoons H^+ + In^-$. The acid dissociation constant, K_a, is given by $K_a = [H^+][In^-]/[HIn]$. Provided the total concentration of the indicator remains constant, then

$$pH = pK_a + \log([In]/[HIn]) \quad (6)$$

One form of the indicator (either associated or dissociated) must absorb or fluoresce. In the case where the absorbance of the undissociated indicator is negligible,

$$pH = pK_a + \log\{A/(A_0 - A)\} \quad (7)$$

where A is the absorbance of the dissociated indicator and A_0 is the absorbance when the indicator is completely dissociated. In the case of fluorescence,

$$pH = pK_a + \log\{I/(I_0 - I)\} \quad (8)$$

where I is the fluorescence intensity and I_0 is the intensity when the indicator is completely dissociated. A more optimal situation occurs when both forms of the indicator absorb or fluoresce. In this case, the ratio of the two indicator forms is characteristic of pH (see earlier text).

Bioprocess pH Sensors. The first measurement of fermentation pH using fiberoptics was achieved by dosing the fermentation media with a pH indicator. The optical fiber was placed in situ as a means of delivering and collecting light in order to measure the pH (39). This approach is not optimal because the introduction of a foreign species in a chemically sensitive environment can be detrimental to the outcome of the overall process.

The first example of a FOCS for fermentation pH was described by Agayn and Walt (40), and, to date, it is the only successful report of this type of sensor. The sensor consists of a fluorescein-derivatized hydroxyethyl methacrylate (HEMA) polymer covalently attached to the distal end of an optical fiber. The polymer thickness is approximately 10 μm, and the response time for a step change in pH is less than 5 s. The sensor operates in the ratiometric mode to account for system instability. The sensor can be steam sterilized in situ without any effect on the response characteristics and can be used for at least 2 months with no special storage requirements. The effects of temperature, stirring, and aeration had no significant effect on the sensor response for application to typical fermentation processes. Practical use of the device was demonstrated in the continuous measurement of pH during an *Escherichia coli* fermentation. The ability of this sensor to operate in fermentation media is attributed to the use of the ratiometric method and the use of an acrylate-based hydrogel polymer for the indicator immobilization. Acrylate polymers have been found to be compatible with fermentation and physiological media (41).

CO_2 Sensors

Measurement of CO_2. Cell activity in bioprocesses usually involves the production or uptake of CO_2. The continuous monitoring of both dissolved and off-gas CO_2 are good indicators of fermentation efficiency. Off-gas CO_2 analysis can be achieved using FT-IR analyzers (42) or mass meters, but direct measurement of dissolved CO_2 is not well established. The only chemical sensor developed for CO_2 measurements is the Severinghaus P_{CO2} electrode, as described in "Application of Chemical Sensors to Bioprocess Monitoring." This sensor has not been widely accepted because of extensive drift.

Theory of Spectroscopic CO_2 Measurement (43). The fiberoptic chemical sensor for CO_2 is the optical equivalent of the Severinghaus electrochemical sensor. In this case, the pH electrode is simply replaced by a pH-sensitive optical sensor. The CO_2 sensor consists of a pH sensor covered by a CO_2-sensitive bicarbonate solution. The solution is trapped within the fiber by a gas-permeable membrane, normally PTFE or silicone rubber, which excludes H^+ ions from the solution. The sensor measures the pH of the internal bicarbonate solution in equilibrium with the external CO_2 outside the membrane:

$$CO_{2(ext)} \rightleftharpoons CO_{2(mem)} \rightleftharpoons CO_{2(int)} + H_2O \rightleftharpoons H^+ HCO_3^- \rightleftharpoons 2H^+ + CO_3^{2-}$$

The relationship between the total CO_2 and H^+ is given by

$$[H^+]^3 + N[H^+]^2 - (K_1[CO_2] + K_w)[H^+] - 2K_1K_2[CO_2] = 0 \quad (9)$$

where N is the concentration of sodium bicarbonate in the solution, and K_1 and K_2 are the first and second acid dissociation constants for carbonic acid. CO_2 sensors operate in the pH and CO_2 range where the first and third terms are negligible. K_w is ignored because it is much greater than $K_1[CO_2]$. With these consideration the above equation reduces to

$$[H^+] = K_1[CO_2]/N \quad (10)$$

making the CO_2 concentration directly proportional to the H^+ concentration. A direct consequence of this analysis shows that as the bicarbonate concentration is reduced, the sensor's sensitivity is increased. Unfortunately, this increase in sensitivity is at the expense of a reduced dynamic range.

Bioprocess CO_2 Sensors. The successful measurement of dissolved CO_2 in fermentation media using a FOCS was first reported by Uttamlal and Walt (44). The sensor is based on the Severinghaus P_{CO2} electrode as described earlier. The pH indicator used in the sensor was a dual exci-

tation fluorescent dye, hydroxypyrenetrisulfonic acid (HPTS), and allows the sensor to be operated in the ratiometric mode. The sensor has a reversible dissolved CO_2 dynamic range of 0 to 0.25 atm. The sensor can be autoclaved without affecting calibration. The response time to varying CO_2 step changes is in the range 1 to 13 minutes, in good agreement with studies carried out with the Severinghaus electrode. The temperature effect is negligible in the range 5 to 35 °C. Calibrations performed in fermentation media and clean solutions were alike, making it possible to carry out ex situ calibration. The practical suitability was tested in the monitoring of CO_2 production during the early stages of a beer fermentation.

A second system, reported by Sipior et al. (45), has been developed for off-gas CO_2 analysis and again is based on pH measurement. The sensor operates on changes in fluorescence lifetime in the frequency domain of a pH fluorophore sulforhodamine 101 (SR101) induced by an absorbance-based pH indicator, *m*-cresol purple (MCP). As the pH of the internal solution changes, the absorbance spectrum of MCP changes and alters the degree of interaction with SR101. The change in spectral overlap causes a change in the lifetime of SR101. The sensor calibration is obtained by correlating the phase change as a function of CO_2 concentration. The dynamic working range is 0 to 0.1 atm, and the response time to step changes in CO_2 is a few seconds. The sensor was used to take off-gas CO_2 measurements in an *E. coli* fermentation over a period of 10 h successfully. The lifetime of the sensor is on the order of 2 weeks.

O_2 Sensors

Measurement of O_2. The measurement of dissolved oxygen is important and, like pH and dissolved CO_2, is also an indicator of fermentation efficiency. For example, in beer fermentation, oxygen is required in the early stages for yeast to generate the lipids and sterols in the cell membrane essential for growth. The rate of oxygen uptake has also been shown to be an indicator of yeast vitality (46). Therefore, the importance of dissolved oxygen measurements in beer fermentation is twofold: as a tool to ensure the initial oxygen content is sufficient and to obtain an early indication of fermentation performance.

Theory for Spectroscopic O_2 Measurement (47). The vast majority of fiberoptic oxygen sensors are based on fluorescence quenching of the indicator. The best systems consist of a fluorescent indicator immobilized in a hydrophobic environment (e.g., siloxane). The fluorescence quantum yield is reduced by either static quenching (i.e., the indicator and oxygen associate in the ground state to give a nonfluorescent molecule), or dynamic quenching (i.e., an indicator collides with oxygen, leading to radiation-less deactivation of the excited state). The relationship between the fluorescence intensity (I), the unquenched intensity (I_o), and oxygen concentration is given by

$$I_0/I = 1 + K_{SV}[O_2] \qquad (11)$$

The relationship in equation 11 is known as the Stern-Volmer equation, and it is applicable for both quenching models. If the sensor is operated using lifetime measurements, then I_o/I is replaced by τ_o/τ, where τ_o and τ are the unquenched and quenched lifetimes, respectively.

Bioprocess O_2 Sensors. The successful application of FOCS for O_2 to on-line or in situ bioprocess monitoring has not been demonstrated. However, several systems have been described where the sensors can be steam sterilized and hence are suitable for in situ applications (48,49).

Multianalyte Sensors

The measurement of a single analyte is important, but it reveals only limited information on the state of the fermentation process. A more informed analysis requires the simultaneous measurement of several analytes. Using imaging fiber bundles, Ferguson et al. (50) reported a sensor capable of simultaneously measuring O_2, CO_2, and pH in a beer fermentation.

Figure 13 shows a SEM of the individual sensors that comprise the multianalyte sensor. The working dynamic range of the individual sensors are 0 to 1 atm dissolved O_2 and 0 to 0.1 atm for dissolved CO_2; the pH range is 5.5 to 7.5.

Figure 14 shows the results obtained with the sensor during a beer fermentation. Upon pitching the yeast, O_2 in the wort decreases, pH decreases, and CO_2 increases. These results are as one would predict for such a fermentation and can be used to assess yeast vitality at very early stages of the process.

Optical Biosensors

Carbon and nitrogen sources provide fuel for cell metabolism in fermentation processes. Carbon sources generally consist of glucose and other related sugars, and nitrogen sources include a variety of amino acids. The monitoring of key carbon and nitrogen compounds indicate the state of the fermentation process. The measurement of individ-

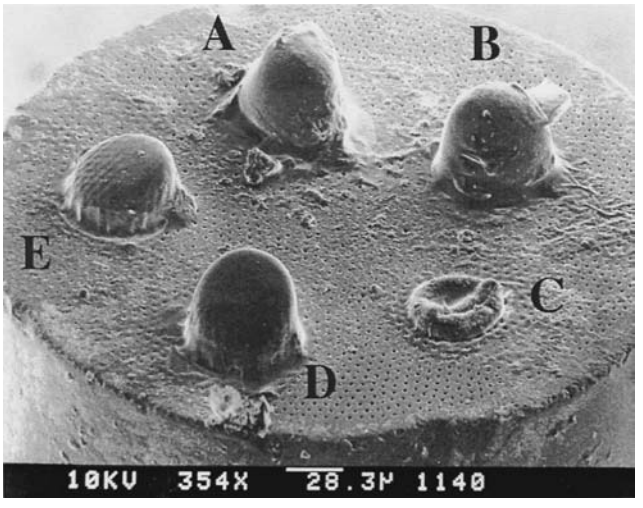

Figure 13. Multianalyte fiberoptic imaging sensor for pH, O_2, and CO_2. Sites *A* and *B* measure CO_2; *C*, pH; and *D* and *E*, O_2.

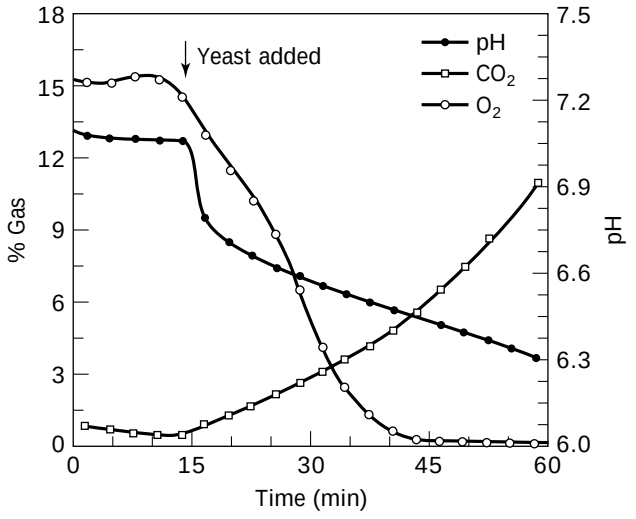

Figure 14. pH, O_2, and CO_2 profile in a beer fermentation using an imaging fiber sensor.

ual sugars and amino acids can be achieved using optical biosensors (51).

Theory of Optical Biosensors. The use of biological species in general and enzymes in particular for analysis is well established, and their incorporation into biosensors was first achieved in the 1950s by Clark and Lyons (18). In optical biosensors, the enzyme is immobilized onto the optical fiber in a suitable matrix. In most biosensors, the reaction of the biological component with the analyte is designed to generate a change in pH, O_2, or CO_2 near the sensor. The measurement of pH, O_2, and CO_2 has been described earlier. To illustrate this principle, glucose analysis can be performed using the enzyme glucose oxidase (GO/FAD):

$$\text{glucose} + \text{GO/FAD} \rightarrow \text{gluconic acid} + \text{GO/FADH}_2 \rightarrow \text{gluconate} + \text{H}^+$$

$$\text{GO/FADH}_2 + \text{O}_2 \rightarrow \text{GO/FAD} + \text{H}_2\text{O}_2$$

By either measuring the production of acid or the depletion of O_2 at the sensor, the glucose concentration can be inferred. It is also possible to measure H_2O_2 production using the indicator luminol; however, this is an irreversible measurement.

Bioprocess Biosensors. Biosensors are very difficult to use in on-line or in situ monitoring because the biological component cannot withstand autoclaving. Therefore, the use of optical biosensors is primarily for ex situ analysis. If in situ measurements are required, alternative sterilization protocols are possible, such as treating the sensor with radiation, ethanol, or antibiotics. After such treatment, the sensor can be inserted aseptically into the fermenter. There are only a few reports of optical biosensors that have been used in fermentation analysis. Short descriptions of three are given next.

Glucose. Glucose and fructose are the main carbon energy sources for cell activity in bioprocesses. Other carbohydrates such as sucrose and maltose are also used as energy sources, but they are broken down first to glucose and fructose by enzymes in the cell (52).

The development of FOCS glucose sensors using the enzyme GO/FAD has been achieved based on O_2 (53), pH (54), and H_2O_2 (55) measurements. These sensors have fast response times and have the dynamic range suitable for fermentation analysis (i.e., 0 to 50 mmol dm^{-3}); however, use in on-line bioprocess monitoring has not yet been achieved.

Amino Acids. Many bioprocesses require a nitrogen source for cell growth (52). Free amino acids, ammonium salts, urea, and gaseous nitrogen are typical of nitrogen-containing compounds used. Pure nitrogen-containing compounds are expensive, so alternatives such as corn steep liquor, yeast extract, peptones, and soy meal are commonly used. These liquors and extracts also contain a carbon source.

The measurement of nitrogen-containing compounds is therefore important in order to achieve a better understanding of the processes taking place and the state of the fermentation, with the particular nitrogen compound depending on the fermentation. An important nitrogen source are amino acids. It is possible to make optical sensors for L-amino acids using L-amino acid oxidase with transduction via the ammonia, ammonium ion, or H_2O_2 produced during biocatalysis:

$$\text{R—CH(NH}_3^+\text{)—CO}_2^- + \text{H}_2\text{O} + \text{O}_2 \xrightarrow{\text{L-Amino acid oxidase}} \text{R—C(=O)—CO}_2^- + \text{NH}_4^+ + \text{H}_2\text{O}_2$$

The sensor responds to many amino acids, and the output corresponds to an aggregate amino acid concentration. Electrochemical devices based on this enzyme have been developed and used in bioprocess monitoring (56).

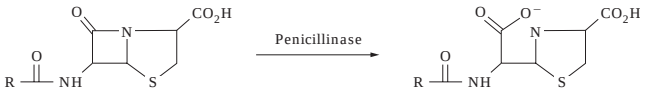
Another example that has been reported is the measurement of urea using the enzyme urease (57):

$$\text{Urea} \xrightarrow{\text{Urease}} 2\text{NH}_4^+ + \text{HCO}_3^-$$

The reaction generates a pH change that can be monitored using a pH sensor.

Penicillins. The discovery of penicillin by Fleming was a major breakthrough in the treatment of infectious diseases. The full-scale production was developed after World War II, and today penicillin and penicillin derivatives are produced in huge quantities (58).

Penicillin production has been monitored using both electrochemical and fiberoptic sensors. Most devices are based on the measurement of pH changes brought about by the hydrolysis of the β-lactam ring by the enzyme penicillinase (59):



The major drawback to this method is that an independent measurement of pH must be made because the solution pH varies during the course of the fermentation. This measurement is not difficult, and pH is generally monitored anyway. A multianalyte FOCS that measures both pH and penicillin has been reported (60). The sensor was used offline to measure penicillin production during a *Penicillium chrysogenum* fermentation (61), and results obtained from the sensor were in close agreement using a standard kit system.

DISCUSSION

The need to measure key analytes in bioprocesses is important for two reasons. First, monitoring will ensure that the process is operating correctly, and second, the information obtained will allow a better understanding of the process that regulates production. To achieve this, new methods of analysis have to be developed. FOCSs, because of their advantages over other analytical systems, are ideally suited for this type of monitoring; however, there are a number of issues that need to be solved before sensors can be implemented in bioprocess monitoring: fouling, drift, in situ calibration, and sterilization are a few of the more important ones.

Fouling

Biofouling occurs when surfaces come into contact with cells and media. When surfaces such as glass, plastic, or metal come into contact with a biological medium, protein adsorption occurs. After protein adsorption, adherent cells can attach to the protein layer. Cell and protein adhesion often result in a relatively thick layer called a biofilm that covers the end of the sensor. Such coverage compromises the measurement capability of the sensor and, in the worst cases, isolates the sensor from the medium. To avoid biofilm formation, it may be necessary to include an antifoulent, such as an antibiotic, that can be placed on the end of the sensor. This material must not interfere with the sensing capabilities of the sensor. Alternatively, it may be possible to place the sensor in a high-shear environment so that cells cannot readily adhere to the sensor surface.

Drift

In cases where internal calibration cannot be used, it may be necessary to account for sensor drift. Drift can be accounted for in several ways. If the properties of the sensor are measured for extended periods of time, it may be possible to observe a consistent change in sensor response as a function of time. For example, if dye photobleaching is a problem, one can measure the photobleaching rate as a function of time and obtain a photobleaching rate constant. This constant can then be used to correct for photobleaching effects during the fermentation process. A second method to account for sensor drift is to perform an in situ calibration in which a sample is taken from the fermentation vessel and the parameter of interest is measured using a conventional chemical analysis. The sensor is then reset to the measured value.

In situ calibration

In situ calibration for sensors being used in situ is difficult to achieve. Doping the fermentation medium with a known amount of analyte can be used, but the implications to the process can be severe. This approach can be a source of contamination, and in addition to other disadvantages, it means that in situ calibration is very rarely undertaken in nonexperimental fermentations.

For sensors that are being used ex situ, the problem is more easily solved. A pumping mechanism with valves can be used to switch between sample and a calibration solution. Sensor lifetime and reliability are increased using this method, but it is not always possible to make measurements in this way.

Sterilization

One of the most vexing issues with respect to sensor implementation is that of sterilization. The most common sterilization protocol in bioprocessing is steam sterilization. Unfortunately, many sensing chemistries are extremely sensitive to the high temperatures required during autoclaving. This problem is of particular concern when dealing with biosensors in which the active enzyme or antibody is denatured during the sterilization process. The only way to obviate this problem is to sterilize the sensor outside the fermentation vessel using a chemical approach, such as soaking the sensor in ethanol or a high concentration of antibiotic and then inserting it aseptically through the appropriate port on the fermentation vessel.

Sensor Lifetime

Another limitation of sensors, particularly biosensors, is their limited lifetime. During the long fermentation runs (e.g., months) of some mammalian cell cultures, sensors and biosensors may lose their activity or sensitivity. In this case, it may be necessary to replace a sensor during the culture. For particularly sensitive cultures in which it would be dangerous or inadvisable to replace a sensor, it may be possible to prolong the lifetime of a sensor by simply decreasing the duty cycle. For example, if photobleaching is a serious problem, one can simply calculate the sensor's total allowable light exposure and then determine how often a reading can be obtained during the fermentation run without compromising the photobleaching sensitivity.

SENSING BIOPROCESSES IN THE FUTURE

The successful monitoring and eventual control of bioprocesses in the future using optical sensors will depend on overcoming the problems discussed earlier and then on developing new molecules and chemical methodologies to undertake the analyses. The following examples of work in

the early stages of development will, we hope, mature to produce ideal optical sensors for bioprocess monitoring.

Multianalyte Sensing

As sensors become more sophisticated, there will be an increasing demand to measure an ever-increasing number of analytes. In addition to the consensus analytes discussed earlier, there are a number of other species that, if monitored, would provide additional information as to the status of a particular fermentation. These analytes include trace minerals such as metal ions, complex or exotic carbon and nitrogen sources, growth regulators, enzymes or other proteins, and a wide variety of products and by-products. As information is gleaned from the Human Genome Initiative, there may be even more need to monitor additional regulators, peptides, and small organic molecules. Furthermore, there will be tremendous value placed on being able to detect specific gene sequences or, more importantly, the expression levels of messenger RNA. In principle, such gene-expression monitoring combined with the conventional and expanded set of analytes discussed above may result in the need to monitor hundreds, if not thousands, of distinct species simultaneously. Although this may seem like a daunting task, tremendous advances are being made presently in the areas of high detection sensitivity, miniaturization, and high-density arrays. Advances in all of these areas may one day lead to the ability to continuously monitor the multitude of analytes necessary to give a complete picture of the conditions and state of a particular fermentation process.

Electronic Noses

All the sensors discussed earlier are based on the conventional one-sensor–one-analyte paradigm in which a selective sensor is designed to respond to a single analyte. As the number of analytes increases, the size and complexity of the sensing system increases proportionately. A recent trend is to construct a sensing system that mimics the olfactory system. The olfactory system relies on a multitude of cross-reactive receptor cells that respond broadly to a wide variety of odorous substances (62). The complex pattern generated by the cells when an odor is presented is relayed to the olfactory bulb and then further transmitted to the higher-order cortical regions of the brain where it is recognized as a particular odor. In a similar vein, electronic noses (63,64) are based on cross-reactive arrays of sensors that differentially respond when exposed to a particular vapor. The generated response pattern is used to train a computational network that then recognizes the particular pattern upon a subsequent vapor exposure. Such a system presents a significant advantage in terms of sensor construction because additional sensors are not required to detect additional analytes; it is sufficient simply to train the network on an additional pattern. Existing manifestations of these systems are expensive and require significant sample preconditioning before sample introduction (65). A limited amount of work has been conducted on the off gases from particular fermentation processes (66). All such systems have only been demonstrated for vapor-phase measurements. The application of such an approach to liquid measurements has not been demonstrated to date. These systems can be trained in a manner more sophisticated than simply detecting the presence or absence of a particular analyte. Such a system can be trained to look at the overall quality or character of the volatile materials in the head space. In principle, such a system may allow the biochemical engineer to train for a desired outcome without necessarily knowing the specific chemical composition of the fermentation broth. For example, it may be possible to train the system on such qualities as maximum product concentration, minimum by-product concentration, off odors, and so on, without specifically training on those particular characteristics. In other words, the sensor may be able to key on surrogate components that are indicative of the desired outcome. This approach has the potential to be a very powerful tool for the biotechnologist and challenges our conventional thinking with regard to chemical monitoring.

Thermostable Enzymes

Thermostable enzymes are isolated from thermophilic microorganisms that exist at elevated temperatures in hot springs and deep ocean vents. Thermostable versions of useful enzymes are presently used in glucose sensors and as reagents for the polymerase chain reaction used in molecular biology. The ability to incorporate thermostable enzymes into biosensors may ultimately enable such sensors to be steam sterilized. Attempts to accomplish such heat stability have met with failure because existing thermostable enzymes still exhibit appreciable denaturation at elevated temperatures.

By isolating and determining the structures of thermostable proteins, researchers are beginning to understand the structural features that lead to enhanced stability. Eventually it may be possible for molecular biologists to engineer enzymes, antibodies, and receptor proteins with extremely high thermal stabilities.

Designed Receptors

An area of significant relevance to sensors is that of molecular recognition. Organic chemists are making great strides in understanding the principles governing how molecules and ions are recognized. For sensors, recognition is only half the story; it is critical that recognition be coupled to signal transaction. Rational molecular design is one approach to developing such receptors. An alternative and increasingly popular approach relies on combinatorial chemistry. In this approach, libraries of large numbers of distinct molecules are created and screened for function. Although most of the focus of combinatorial chemistry has been directed toward drug discovery (67), some recent work has used the approach to search for structures that combine binding with signal transduction (68).

SUMMARY

There are presently a limited number of analytes that can be monitored continuously during a fermentation or cell culture. The bioprocess monitoring scene is changing as

new sensors become available. Optical sensors offer significant advantages because of their small size, internal calibration capability, freedom from electromagnetic interference, and multiplexing ability. As new sensing materials and sensing paradigms become available from the fields of molecular recognition and combinatorial chemistry, thermostable enzymes, microfabrication, electronic noses, and advanced sensors with powerful analytical capabilities will become available. Ultimately, such sensing systems will provide the biotechnologist and bioengineer with timely information regarding the status and composition of a particular fermentation process.

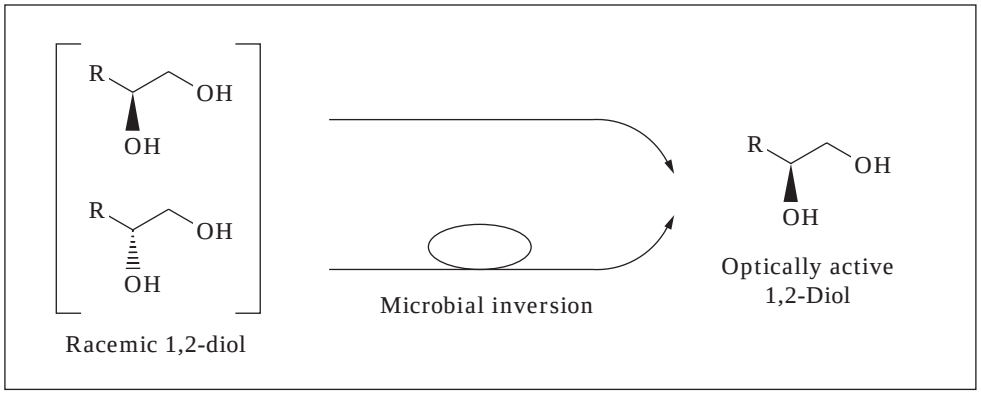
OUTLINE

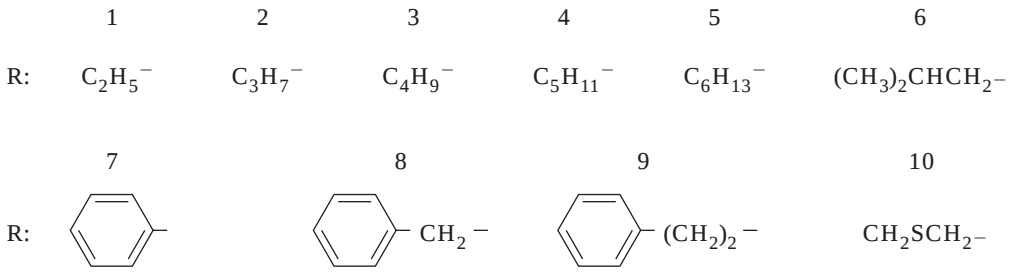
INTRODUCTION

Optically active 1,2-diols are a versatile group as chiral starting materials for the syntheses of pharmaceuticals, agrochemicals, pheromones, liquid crystals, and so on. Several routes of preparation for optically active 1,2-diols have been reported.

1. Microbial reduction of 1-hydroxy-2-ketones (1–5)
2. Chemical reduction of optically active 2-hydroxy acids prepared from 2-keto acids by enzymatic reduction of amino acids (6–11)
3. Optical resolution of racemic 1,2-diols by lipase-catalyzed transesterification in organic media (12)
4. Chemical preparation from naturally occurring products, such as (*S*)-malic acid (2), D-mannitol (2,13,14) or (+)-pulegone (15).

We developed two efficient methods for producing various optically active (*S*)-1,2-diols with high optical purities. One is the organic synthetic method using the Grignard reaction starting from (*R*)-3-chloro-1,2-propanediol as a starting material can be produced easily from the racemate by microbial optical resolution using *Serratia marcescens* (17). The other is the microbial stereoinversion method using racemate as a substrate (18). In the course of the studies on the microbial optical resolution of racemic 1,2-pentanediol, we found a unique microbial stereoinversion consisting of two successive reactions. It is a known fact that in all enzymatic or chemical optical resolution processes, the theoretical yield of one part of enantiomer is maximally 50%. However, (*S*)-enantiomer of 1,2-pentanediol was found higher than the theoretical yield when the racemate was incubated in the culture broth of *Lodderomyces elongisporus* IFO 1676. This result indicated that this microorganism could invert (*R*)-1,2-pentanediol in the racemate to (*S*)-enantiomer. This finding led us to rescreen the microorganisms that could invert (*R*)-1,2-pentanediol to the (*S*)-enantiomer, and we found that a number of microorganisms had this ability, similar to *L. elongisporus* IFO 1676. We applied this microbial stereoinversion to various 1,2-diols by use of *Candida parapsilosis* IFO 0708, and we confirmed that nine kinds of (*S*)-1,2-diols (**1** to **9**) and (*R*)-3-methylthio-1,2-pentanediol (**10**) with high optical purities could be obtained in high yields (Scheme 1).





Scheme 1.

EXPERIMENTAL

Chemicals

Racemic 1,2-heptanediol (**4**), 4-methyl-1,2-pentanediol (**6**), 3-phenyl-1,2-propanediol (**8**), and 4-phenyl-1,2-butanediol (**9**) were prepared from the corresponding 1-alkenes by a method similar to that of Blau et al. (19). Other 1,2-diols used were purchased from Aldrich Chemicals Company. 1-Hydroxy-2-pentanone was prepared from 1,2-pentanediol by microbial oxidation using *Saccharomycopisis lipolytica* IFO 1551; (bp 62 °C, 6 to 7 mmHg), NMR $\delta_H(CDCl_3)$: 0.95 (3H, t, J = 7.5 Hz, CH_3), 1.68 (2H, m, J = 7.3 Hz, -C**H**$_2$-CH_3), 2.44 (2H, t, J = 7.5 Hz, -C**H**$_2$-(C=O)-), 3.43 (1H, broad, OH), 4.29 (2H, s, -C**H**$_2$-OH), MS m/z: 102 (M^+), 71 (M^+ -CH_3O).

Microorganisms and Cultivation

All microorganisms used were stock cultures kept in our laboratory. The medium used contained 4% glucose, 0.3% yeast extract, and 10% (v/v) mineral solution, pH 7.0. The mineral solution consisted of 13% $(NH_4)_2HPO_4$, 7% KH_2PO_4, 0.8% $MgSO_4$ $7H_2O$, 0.1% NaCl, 600 ppm $ZnSO_4$ $7H_2O$, 900 ppm $FeSO_4$ $7H_2O$, 50 ppm $CuSO_4$ $5H_2O$, and 100 ppm $MnSO_4$ $4H_2O$. Microorganisms were cultured in a 500-mL Sakaguchi flask containing 50 mL of the medium at 30 °C for 1 to 2 days with shaking. When the cell grew maximally, the cells were harvested by centrifugation and were used for the reaction.

Screening of Microorganisms Producing (*S*)-1,2-Pentanediol by Stereoinversion

Cells were suspended in 50 mL of 0.1 M potassium phosphate buffer (pH 6.5) containing 250 to 500 mg of racemic 1,2-pentanediol. The reaction was conducted in 500 mL-Sakaguchi flasks that were incubated at 30 °C for 24 to 96 h with shaking. Two milliliters of the reaction mixture was used for GLC analysis of 1,2-pentanediol. The remainder was centrifuged to remove the cells, and the supernatant was concentrated to 3 to 4 mL. 1,2-Pentanediol was recovered by extraction with ethyl acetate (100 mL) and used for measurement of enantiomeric excess by HPLC.

Preparation of Cell-Free Extract and Enzyme Assay

Cells of *C. parapsilosis* IFO 0708, which grew for 24 h under the conditions described earlier, were collected and washed with 10 mM tris-HCl buffer (pH 7.0). Thirty-three grams of washed cells were suspended in 40 mL of the same buffer containing 1 mM EDTA and 0.2 mM phenylmethylsulfonylfluoride, a serine-protease inhibitor, and disrupted with a Braun homogenizer. Cell debris was removed by centrifugation (15,000 rpm × 30 min), and the supernatant was filtered through a millipore membrane (0.22 μm) and dialyzed against 10 mM tris-HCl buffer overnight. The cell-free extract was used for assay of the enzyme activities. The enzyme activities for (*R*) and (*S*)-1,2-pentanediol oxidation were assayed by measuring the increase of optical absorbances at 370 nm caused by the reduction of NAD^+ or $NADP^+$, respectively. The assay mixture in a final volume of 3.0 mL contained 3.0 μmol of $NAD(P)^+$, 0.3 mmol of (*S*) or (*R*)-1,2-pentanediol, 0.3 mmol of sodium carbonate buffer (pH 10), and a suitable amount of the cell-free extract. Incubation was performed at 25 °C in a cuvette of 1-cm light path length. The reduction of 1-hydroxy-2-pentanone was monitored by measuring the decrease of optical absorbency at 340 nm caused by the oxi-

dation of NADH or NADPH. The assay mixture in a final volume of 3.0 mL contained 1.0 μmol of NAD(P)H, 0.3 mmol of 1-hydroxy-2-pentanone, 0.3 mmol of tris-maleate buffer (pH 6.0), and a suitable amount of the cell-free extract. The incubation was carried out under the same conditions as the method for oxidation of 1,2-pentanediol.

Preparative-Scale Reaction and Isolation of Optically Active 1,2-Diols

C. parapsilosis IFO 0708 was cultured in a 5-L jar fermenter containing 3 L of the medium at 30 °C for 23 h (aeration 0.5 vvm, agitation 450 rpm, inoculum size 1.6%). After the cultivation, racemic 1,2-diol (9 to 30g) was added to the culture broth. During the reaction, the pH of the reaction mixture was controlled at 6.5 with 4 N NaOH, and 30 g of glucose was added once a day. After the reaction, cells were removed by centrifugation, and the supernatant was concentrated to about 150 mL under reduced pressure. 1,2-Diols were extracted with 500 mL of ethyl acetate three times. The solvent was removed by evaporation, and the 1,2-diols were purified by distillation or silica gel chromatography (Wako gel G-200, solvent: *n*-hexane/ethyl acetate).

Analytical Methods

1,2-Diols were assayed by GLC using a Hitachi 163 gas chromatograph with a hydrogen flame ionization detector. Two different types of liquid phases were used. The glass column (0.3 × 100 cm) packed with Silicone OV-17 on Chromosorb WAW DMCS (Gasukuro Kogyo, Japan) was used to assay **7,8** and **9**. Flow rate of nitrogen gas was 20 mL/min, and column temperature was 220 °C. The other glass column (0.3 × 100 cm) packed with FAL-M 6%/TENAX GC (Wako Pure Chemical, Japan) was used to assay the other 1,2-diols and 1-hydroxy-2-ketones. Flow rate of nitrogen gas was 35 mL/min, and the column temperature was 175 °C. The samples for GLC analyses were prepared as follows: 2 mL of the reaction mixture was saturated with ammonium sulfate, 1,2-diol was extracted with 4 mL of ethyl acetate, and the organic layer was used for GLC analysis.

The enantiomeric excess of 1,2-diol was measured by HPLC analysis of the corresponding 1-tosylated derivatives except for 1-phenyl-1,2-ethanediol. Preparation and purification of 1-tosylated derivatives were done by the procedures reported (5,20). The columns and the other conditions used are shown in Table 1.

NMR and mass spectra were recorded on a Varian EM-90 spectrometer and Shimadzu QP-1000 GC-Mass spectrometer, respectively. Optical rotation was measured with a Horiba polarimeter SEPA-200. Melting points were measured using a Büchi melting point apparatus.

[e]Two columns were connected and used.

RESULTS

Screening of Microorganisms Producing (*S*)-1,2-Pentanediol by Stereoinversion

At the start of this study, we had planned the production of (*S*)-1,2-diols from racemates by stereoselective degradation of (*R*)-1,2-diols using microorganisms. We screened for suitable microorganisms for this purpose from the stock culture collection in our laboratory and found that many microorganisms degraded (*R*)-1,2-pentanediol more easily than (*S*)-enantiomer. *Lodderomyces elongisporus* IFO 1676 was selected among them and used for large-scale preparation of (*S*)-1,2-pentanediol. In this experiment, we found that the optical purity of residual 1,2-pentanediol reached approximately 100% ee as (*S*)-enantiomer when only 22% of racemic 1,2-pentanediol added in the reaction mixture was degraded. This result suggested that this microorganism could convert (*R*)-1,2-pentanediol to the (*S*)-enantiomer. This observation led us to rescreen the microorganisms that had the ability to produce (*S*)-1,2-pentanediol having high optical purity from the racemate by stereoinversion, and we found that various microorganisms had the similar ability as *L. elongisporus*. They belonged to the genera *Candida*, *Debaryomyces*, *Pichia*, *Stephanoascus*, *Endomyces*, *Fusarium*, *Giberella*, *Gongronella*, and others. Among them, the microorganisms that produced (*S*)-1,2-pentanediol excess of 70% molar yield from the racemate are listed in Table 2. *C. parapsilosis* IFO 0708 was used for further experiments.

Production of (*S*)-1,2-Pentanediol by *C. parapsilosis* IFO 0708

C. parapsilosis IFO 0708 was cultured in a 5-L jar fermenter containing 3 L of medium for 23 h under the conditions described earlier. After then, 75 g of racemic 1,2-pentanediol and 25 g of glucose were added to 2.5 L of the culture broth in a 5-L jar fermenter, and the pH of the reaction mixture was adjusted to 6.5 with 4 N NaOH. The reaction-accompanied cultivation was conducted for 26 h under the same conditions. Figure 1 shows the course of the reaction. Racemic 1,2-pentanediol was converted to (*S*)-1,2-pentanediol with a molar yield of 93% after incubation for 24 h. It was noteworthy that 1-hydroxy-2-pentanone was de-

Gongronella butleri IFO 8080	96	84	71 (*S*)	72

[a]At the start of reaction, 10 mg/mL of racemic 1,2-pentanediol (1,2-PDO) was added except for *G. butleri* (5 mg/mL).
[b](*S*)-Isomer yield (C) = Net yield of (*S*)-isomer from the racemate = A × [1 − (100 − B)/200].

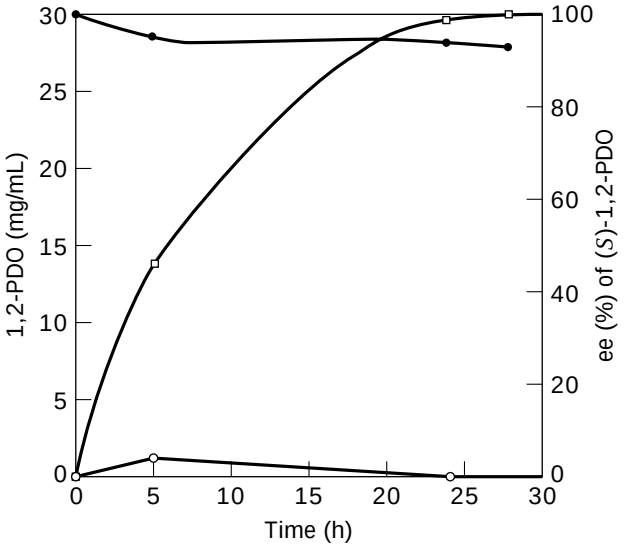

Figure 1. Production of (*S*)-1,2-pentanediol by *C. parapsilosis* IFO 0708. ● = 1,2-pentanediol; ○ = 1-hydroxy-2-pentanone; □ = enantiomeric excess of (*S*)-1,2-pentanediol.

tected in the reaction mixture. After the reaction, the cells were removed by centrifugation, and the supernatant was concentrated to 375 mL under reduced pressure. (*S*)-1,2-Pentanediol was extracted with 750 mL of ethyl acetate. The solvent was dried up by evaporation, and 66 g of yellowish oil was obtained. (*S*)-1,2-Pentanediol was purified by distillation (76 to 77 °C [3 mmHg]), and 60 g of (*S*)-1,2-pentanediol was obtained (yield 80%). GLC purity 99.9%, $[\alpha]_D^{20}$ −17.3° (c = 1, MeOH), −23.2°(c = 1, EtOH), 100% ee, (lit.(14), $[\alpha]_D^{25}$ −16.1°(c = 3, EtOH)), NMR δ_H($CDCl_3$): 0.92 (3H, t, CH_3), 1.13 to 1.83 (4H, m, -$(CH_2)_2$-), 3.27 to 3.92 (3H, m, -C**H**(OH)-C**H**$_2$OH), 4.12 (2H, broad, OH), MS *m*/*z*: 87 (M^+-OH), 73 (M^+-CH_3O), 61 ($C_2H_5O_2^+$).

Mechanism of Stereoinversion of 1,2-Pentanediol in *C. parapsilosis* IFO 0708

To obtain the information on the stereoinversion mechanism, we used the cell-free extract of *C. parapsilosis*. Usually, alcohol dehydrogenase requires NAD^+ or $NADP^+$ as a coenzyme to catalyze the oxidation of alcohols. As the first experiment, we investigated the requirement of coenzyme for the oxidoreduction between (*R*)/(*S*)-1,2-pentanediol and 1-hydroxy-2-pentanone in this microorganism. As shown in Table 3, both NADH and NADPH served as a coenzyme to reduce 1-hydroxy-2-pentanone to 1,2-pentanediol in the cell-free extract. In the reverse reaction, NAD^+ mainly played the coenzyme role in oxidation of (*R*)-1,2-pentanediol, and the reaction rate of the oxidation of (*R*) and (*S*)-1,2-pentanediol using $NADP^+$ as a coenzyme was very slow. This NAD^+-linked (*R*)-specific 1,2-pentanediol dehydrogenase resembles the glycerol dehydrogenase isolated from *Cellulomonas* sp. (5,21) in its stereospecificity and NAD^+ requirement. Sugiura et al. reported that NAD^+-linked glycerol dehydrogenase from *Erwinia aroideae* (22) was inhibited by $CuSO_4$ and $ZnSO_4$. The effects of these metals and *p*-chloromercuribenzoate on both NADH-linked and NADPH-linked 1-hydroxy-2-pentanone reductase activities were tested. It was found that 1 mM $CuSO_4$ and 0.17 mM *p*-chloromercuribenzoate inhibited NADH-linked 1-hydroxy-2-pentanone reductase very strongly. In order to know the stereospecificity of NADPH-linked 1-hydroxy-2-pentanone reductase, 3 mM of $CuSO_4$ was added into the reaction mixture (10 mL) containing 0.50 mmol NADPH, 0.24 mmol of 1-hydroxy-2-pentanone, and the cell-free extract (2 mL). The reduction was carried out for 16 h at 25 °C. The steric configuration of 1,2-pentanediol produced under the above conditions was the

Table 3. Oxidoreduction between 1,2-Pentanediol and 1-Hydroxy-2-Pentanone by the Cell-Free Extract of *C. parapsilosis*[a]

Reaction and substrate	OD at 340 nm[a]	
Reduction (pH 6.0)	NADH	NADPH
1-Hydroxy-2-pentanone	−0.667	−0.232
Oxidation (pH 10.0)	NAD^+	$NADP^+$[b]
(*R*)-1,2-Pentanediol	0.722	0.014
(*S*)-1,2-Pentanediol	0.005	0.018

Note: The conditions of oxidation and reduction were described in the text.
[a]The change of optical density at 340 nm during the first 1 min of the reaction is listed.
[b]In the case of oxidation using $NADP^+$, the reactions were carried out at pH 8.0 using 0.1 M tris-HCl buffer instead of 0.1M sodium carbonate buffer (pH 10.0), because the reduction of $NADP^+$ was not observed at all under these conditions.

(*S*)-form, and its optical purity was very high (Table 4). The activities of NAD^+-linked and $NADP^+$-linked 1,2-pentanediol dehydrogenases at various pHs are shown in Figure 2. Oxidoreduction between 1,2-pentanediol and 1-hydroxy-2-pentanone by NAD^+-linked dehydrogenase is reversible, but reduction of 1-hydroxy-2-pentanone to (*S*)-1,2-pentanediol is practically less reversible. From these observations, the mechanism of the stereoinversion of 1,2-diol in *C. parapsilosis* may be explained as follows. Only (*R*)-1,2-pentanediol in the racemate is oxidized to 1-hydroxy-1,2-pentanone by NAD^+-linked (*R*)-specific dehydrogenase. Then, 1-hydroxy-2-pentanone is reduced to (*S*)-1,2-pentanediol by NADPH-linked (*S*)-specific reductase (Scheme 2).

	3	31	98 (*S*)

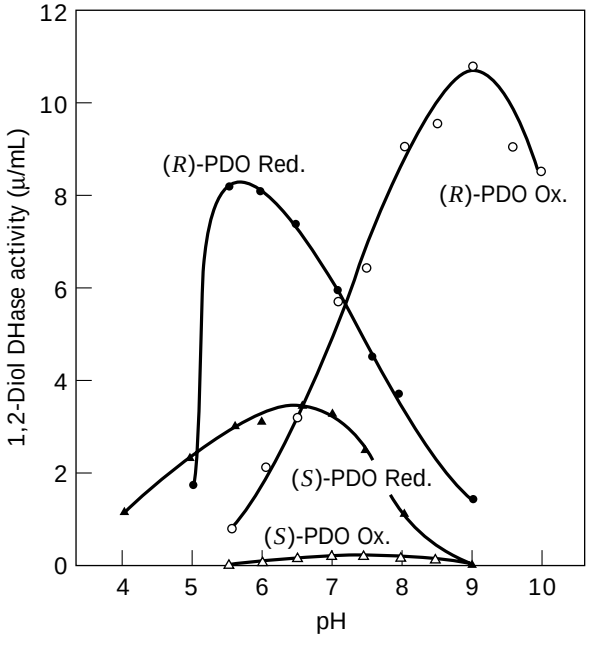

Figure 2. Effect of pH on 1,2-pentanediol oxidoreductase activities. The basic composition of the reaction mixtures was described in the text, and the following buffers were used to maintain the respective pHs: pH 4.0 to 5.5 acetate buffer, pH 5.5 to 6.5 tris-maleate buffer, pH 6.5 to 7.5 phosphate buffer, pH 7.5 to 9.0 tris-HCl buffer, pH 9.0 to 11.0 sodium carbonate buffer. ○ = NAD^+, (*R*)-1,2-pentanediol oxidation; ● = NADH, 1-hydroxy-2-pentanone reduction; △ = $NADP^+$, (*S*)-1,2-pentanediol oxidation; ▲ = NADPH, 1-hydroxy-2-pentanone reduction; (1 unit = 1 μmol of $NAD(P)^+$ reduction or NAD(P)H oxidation per min).

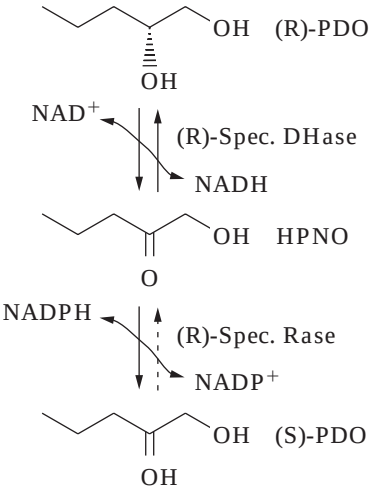

Scheme 2.

Production of Various Optically Active 1,2-Diols by Stereoinversion Using *C. parapsilosis* IFO 0708

It was very beneficial for us to apply this unique microbial reaction to production of various optically active 1,2-diols. Fourteen kinds of racemic 1,2-diols were tested: 1,2-propanediol, 1,2-butanediol (**1**), 1,2-pentanediol (**2**), 1,2-hexanediol (**3**), 1,2-heptanediol (**4**), 1,2-octanediol (**5**), 4-methyl-1,2-pentanediol (**6**), 1-phenyl-1,2-ethanediol (**7**), 3-phenyl-1,2-propanediol (**8**), 4-phenyl-1,2-butanediol (**9**), 3-methylthio-1,2-propanediol (**10**), 3-chloro-1,2-propanediol, 3-methoxy-1,2-propanediol, and 3-phenoxy-1,2-propanediol. Among them, the microbial stereoinversion was observed on 10 kinds of 1,2-diols listed in Table 5. These 1,2-diols had the same absolute configuration on the secondary alcohol. The yields and properties of optically active 1,2-diols obtained were as follows.

(*S*)-1,2-Butanediol (1). (*S*)-Isomer yield 56%, bp 65 °C (3 mmHg), (lit.(6), bp 94 to 96 °C (9 mmHg)), GLC purity 99.9%, $[\alpha]_D^{20}$ −8.57° (c = 1, MeOH), −31.9° (c = 1, EtOH), 79% ee, (lit.(6), $[\alpha]_D^{25}$ −15.35° (c = 2.6, EtOH)). NMR δ $_H(CDCl_3)$: 0.92 (3H, t, CH_3), 1.45 (2H, m, -C**H**$_2$-CH_3), 3.23 ~ 3.83 (3H, m, -C**H**(OH)-C**H**$_2$OH), 4.03 (2H, broad, OH), MS *m*/*z*: 61 ($C_2H_5O_2^+$), 59 (M^+-CH_3O).

(*S*)-1,2-Hexanediol (3). (*S*)-Isomer yield 95%, bp 86 °C (3 mmHg), (lit.(1), bp 110 to 113 °C (6 mmHg)), GLC purity 99.7%, $[\alpha]_D^{20}$ −16.4° (c = 1, MeOH), −22.1° (c = 1, EtOH), 100% ee, (lit.(1), (*R*)-isomer $[\alpha]_D^{22}$ + 15.2° (c = 14, EtOH)), NMR δ $_H(CDCl_3)$: 0.92 (3H, t, CH_3), 1.13 to 1.83 (6H, m, -$(CH_2)_3$-), 3.23 to 4.23 (3H, m, -C**H**(OH)-C**H**$_2$OH), 3.73 (2H, broad, OH), MS *m*/*z*: 87 (M^+-CH_3O), 61 ($C_2H_5O_2^+$).

(*S*)-1,2-Heptanediol (4). (*S*)-Isomer yield 97%, bp 101 °C (4 mmHg), (lit.(2), 67 to 70 °C (0.04 mmHg)), GLC purity 99.6%, $[\alpha]_D^{20}$ − 15.4° (c = 1, MeOH), −20.6° (c = 1, EtOH), 98% ee, (lit.(2), $[\alpha]_D^{22}$ − 16.6° (c = 11.9, EtOH)), NMR δ $_H(CDCl_3)$: 0.87 (3H, t, CH_3), 1.10 to 1.87 (8H, m, -$(CH_2)_4$-), 3.22 to 4.13 (3H, m, -C**H**(OH)-C**H**$_2$OH), 3.75 (2H, broad, OH), MS *m*/*z*: 101 (M^+-CH_3O), 61 ($C_2H_5O_2^+$).

(*R*)-Isomer yield 65%, bp 101 °C (3 mmHg), GLC purity 99.7%, $[\alpha]_D^{20}$ −12.9° (c = 1, MeOH), −11.9° (c = 1, EtOH), 98% ee, MNR δ_H($CDCl_3$): 2.13 (3H, s, CH_3-), 2.60 (2H, d, *J* = 6.0Hz, -S-CH_2-), 3.18 ∼ 4.32 (3H, m, -C**H**(OH)-C**H**$_2$OH), 3.83 (2H, broad, OH), MS *m*/*z*: 122 (M^+), 104 (M^+-H_20), 61 (CH_3-S-CH_2^+, $C_2H_5O_2^+$).

We tried this microbial stereoinversion for production of optically active 1,2-propanediol, 3-phenoxy-1,2-propanediol, 3-methoxy-1,2-propanediol, and 3-chloro-1,2-propanediol, but these 1,2-diols were not good substrates. In cases of 1,2-propanediol and 3-phenoxy-1,2-propanediol, their (*S*)-isomers were isolated from the reaction mixtures, but the yields and the optical purities of both (*S*)-1,2-diols were not over 50%. With the other 1,2-diols, their racemates were recovered from the reaction mixtures.

In this study, we presented a novel method for production of optically active 1,2-diols using a microbial stereoinversion. This unique bioinversion consisted of two successive reactions via 1-hydroxy-2-ketone, namely the oxidation of (*R*)-1,2-diol to 1-hydroxy-2-ketone by NAD^+-linked (*R*)-specific alcohol dehydrogenase, followed by the reduction of 1-hydroxy-2-ketone to (*S*)-1,2-diol by an NADPH-linked (*S*)-specific reductase. To the best of our knowledge, this is the most convenient procedure for producing optically active 1,2-diols among the reported methods.

OUTLINE

INTRODUCTION

Cellulose is the most plentiful of all of the naturally occurring organic compounds. It is a high molecular weight linear polysaccharide composed of two residues (β-1,4-linked glucose, known as cellobiose) in repeated units. Complete hydrolysis of cellulose using strong mineral acids yields glucose. The basic building blocks of cellulose are chemically reactive, making it susceptible to chemical modifications. Cellulose has great economical importance; it is processed to produce papers, fibers, and chemical derivatives to yield substances used in the manufacturing of such items as plastics, photographic films, rayon, and so on. Other cellulose derivatives are used as adhesives, explosives, and thickening agents for foods. Figure 1 shows some common uses of cellulose.

Cellulose exists in nature in two principal types: the pectocelluloses such as flax, hemp, and ramie that contain more than 80% cellulose; the lignocelluloses composed mostly of cellulose, hemicellulose, and lignin. As a basic component of plant cell walls, cellulose comprises at least 30% of all plant matters (90% of cotton and up to 50% of wood are cellulose). Table 1 shows the approximate composition of the selected lignocellulosic materials.

Because lignocellulosic materials are renewable and abundant, extensive research in recent years has been undertaken to convert cellulose, particularly agricultural residues, forest by-products, and waste cellulose, into food, chemicals, and fuels. In this article, the emphasis will be on the production of ethanol from lignocellulosic materials. Other products such as solvents (acetone and butanol) (7), 2,3-butanediol (8), and single-cell proteins (9) have been reviewed.

Relationship between Structural Features of the Cell Wall and Cellulolytic Enzymes

Native lignocellulosic materials are heterogeneous, containing cellulose, hemicellulose, lignin, ash, protein, and a

wide array of minor extractives. The most important structural feature in a plant cell wall is the capillary area, whose dimensions and shapes control the accessibility of lignocelluloses by hydrolytic enzymes. The lumen (Fig. 2) is the largest capillary in a plant cell, followed by pit apertures and pores in the pit-membrane, ranging from 200 Å to 10 or more μm in diameter. Most of these capillaries are filled with hemicellulose, pectic materials, and lignin, which form a protective sheath around the cellulose (10,11). Therefore, any treatment of lignocellulosic materials that solubilizes and/or removes lignin and hemicelluloses from the cell wall can enlarge the capillaries. As a result, the accessibility of cellulose to cellulase can be increased.

Molecules of cellulolytic enzymes of various microorganisms are water-soluble proteins of high molecular weight that are 13 $\times$ 79 Å in width and 42 $\times$ 252 Å in length. The relatively large enzyme molecules cannot be diffused into plant cell walls unless pretreatment is conducted to increase the size of the cell wall capillaries.

CELLULOSE PRETREATMENT

Many factors have been identified as influencing the reactivity and digestibility of the cellulose fraction of lignocellulose materials. These factors include lignin and hemicellulose contents, crystallinity of the cellulose, and the porosity of the biomass. Pretreatment of lignocellulosic materials prior to utilization is a necessary element in the biomass-to-ethanol conversion processes. The objective of the pretreatment is to render biomass materials more accessible to either chemical or enzymatic hydrolysis for efficient product generation. There are several goals of the pretreatment.

- Disrupt and remove the lignin sheath
- Remove and separate hemicellulose from cellulose
- Decrease the crystallinity of the cellulose
- Increase the accessible surface area
- Increase the pore size to facilitate the penetration of hydrolysis agents

There have been many processes developed for the treatment of various biomass. In general, agricultural residues are more easily treated than hardwood materials. The most difficult biomass to treat is that derived from softwood because it has a relatively high lignin content. Most processes exploit a variety of mechanisms to render

the carbohydrate components of lignocellulosic materials more susceptible to enzymatic hydrolysis and microbial conversion (for detail see refs. 10 and 12).

The majority of the pretreatment methods involve a combination of mechanical size reduction, alkali swelling, acid hydrolysis, steam and other fiber explosion techniques, or exposure to supercritical fluids. The processes involving irradiation, strong mineral acids, cellulose solvents, and concentrated alkali chemicals are not suitable methods for the pretreatment of lignocellulosic materials because of their high cost. Biological methods, such as those applying "white rot" fungi to remove lignin from cellulose-hemicellulose, are also unsuitable due to the length of time they take, unless the lignocellulosic material is intended for single-cell protein (e.g., mushrooms) production (13). Therefore, the chosen pretreatment process must be efficient, cost effective, and environmental friendly.

Many different pretreatment approaches have been designed and tested, and some processes have also been tried in pilot scale. Ideally, the most desirable method of treatment is the dissolution of the solid materials into aqueous substrate. Many cellulose solvents at high enough concentrations can penetrate into the cellulose crystalline structure, causing the dissolution of solid cellulose. The resulting materials can be readily hydrolyzed to glucose by cellulase either in situ, or after the dissolved cellulose has been reprecipitated (14). Although cellulose solvents are powerful-solubilization agents, they are toxic, corrosive, and hazardous, and recovery costs are high. For these reasons, cellulose solvents are generally considered inappropriate for large-scale pretreatment processes.

Alkaline Treatment

Alkaline treatment causes lignocellulosic materials to swell; increased swelling leads to higher susceptibility of cellulose to saccharification. In the presence of alkaline chemicals (e.g., NaOH or NH_3), cellulose, hemicellulose, and lignin bonds can be disrupted, which permits cellulose to swell beyond normal water-swollen stages. Consequently, the pore size, intraparticle porosity, and capillary size are increased. There is also a phase change in the cellulose crystalline structure (15).

Sodium hydroxide is the most commonly used chemical in the treatment of lignocellulose to enhance digestibility for animals. It is a strong swelling agent for cellulose and may also be responsible for changing cellulose crystalline structure from cellulose I to cellulose III (decrystallization). The amount of NaOH used for treatment ranges from 2 to 20%, and the temperature for the treatment ranges from ambient to 120 °C. Under mild conditions (low concentration and low temperature) substrate components remain unchanged. Under harsher conditions, most of the lignin and hemicellulose are solubilized. Consequently, the cellulose fraction is exposed to hydrolysis agents.

Similar to NaOH, ammonia is useful in increasing the in vitro digestibility of lignocellulosic materials. It is also effective in the preparation of substrates for single-cell protein production. Ammonia is one of the most heavily used industrial chemicals. On a weight basis, aqueous ammonia is about one-third the cost of NaOH. In addition, ammonia is easily recoverable from an aqueous mixture because of its high volatility; it is also far less corrosive than mineral acids at high temperature. Increasingly, ammonia has been used in combination with other methods to treat lignocellulosic materials.

Ammonia-Recycled Percolation Process. The ammonia-recycled percolation (APR) process (16) uses ammonia as

the treatment agent. In one example, the reactor was a packed-bed flow-through type (percolation reactor) and was used in a recirculation mode (Fig. 3). The intended biomass material was packed in a pressure vessel with preheated liquid ammonia passing through the substrate. The reaction temperature was 150 °C, and pressures were up to 325 psi. As the name of the process indicates, ammonia was recycled for further treatment of cellulosic materials. The scanning electron microscope examination of treated samples showed an increase in pore size and porosity. The amount of lignin removed was in the range of 23–63%, and hemicellulose removed was in the range of 20–36%.

Alkaline Peroxide Process. Chopped wheat straw was steeped in an aqueous alkaline solution (pH = 11.5) of H_2O_2 at a ratio of 0.25 g/g substrate at 25 °C. Lignin removal was 50%, and hemicellulose solubilized was almost 100%. The results of *Trichoderma* cellulase hydrolysis of cellulose indicated that glucose yield was approaching 100% with a substrate solid content of 5% (17).

Ammonia Freeze Explosion. The ammonia freeze explosion (AFEX) process is the pretreatment method that utilizes steam explosion techniques with ammonia as the chemical reagent (6,18). The intended biomass material is placed in a pressure vessel with liquid ammonia (1:1) and treated similarly as in the steam explosion process but with much lower temperatures (up to 80 °C) and pressures (up to 15 psi). Using this process, ammonia was recovered. Exposure to ammonia in the AFEX process causes swelling and partial decrystallization of the cellulose. It also caused the partial solubilization of lignin and hemicellulose resulting in the exposure of cellulose. This pretreatment method is more effective with agricultural residues (e.g., corn stover and straws) than with woody materials.

Steam Treatment with or without SO_2

Steam explosion of biomass materials has been studied by many investigators (see Ref. 19 for review). Biomass material (woodchips or wheat straw) was placed in a high-pressure stainless steel tube and was exposed to steam under pressures ranging from 250 to 650 psi at 200–240 °C for up to 20 min. The sudden pressure release caused an explosion of biomass material, thereby disrupting the lignin and hemicellulose bonding toward cellulose. The addition of SO_2 enhanced the pretreatment effect and also increased the recovery of cellulose (20–22).

Dilute Acid Pretreatment

The use of dilute acid hydrolysis pretreatment has been studied extensively (4,23). The overall goal of dilute acid pretreatment is to attain a high yield while minimizing the breakdown of hemicellulose sugars into decomposition products. The pretreatment usually involves mineral acids (e.g., HCl and H_2SO_4) at a concentration from 0.3 to 2% (w/w). The temperature for treatment ranged from 120 to 180 °C, and the length of treatment ranged from less than 1 min to 2 h or longer. The objective in dilute acid treatment is to separate hemicellulose from lignin and cellulose. It is effective in hydrolyzing hemicellulose, but a portion of lignin was also solubilized, resulting in the complication of utilization of hemicellulose carbohydrates. Depending on hydrolysis conditions, carbohydrate degradation products also formed, which interfered with microbial activities.

Because the hemicellulose fraction of biomass materials can be separated from lignin and cellulose by dilute acid treatment, cellulose becomes more reactive toward cellulase. Hemicellulose hydrolysis rates vary with acid concentration, temperature, and solid-to-liquid ratio. With most lignocellulosic materials, complete hemicellulose hydrolysis can be achieved in 5–10 min at 160 °C, or 30–60 min at 140 °C. Dilute acid hydrolysis forms the basis of many pretreatment processes; autohydrolysis and steam explosion are two examples that are based on high-temperature-dilute-acid-catalyzed hydrolysis of biomass.

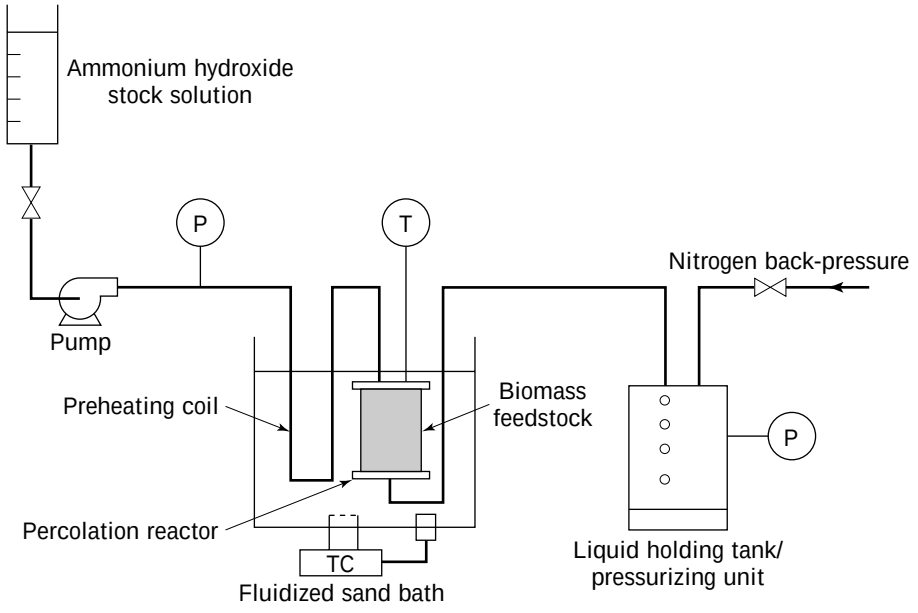

Figure 3. Schematic diagram of the ammonia-recycled percolation process. *Source*: From Ref. 16.

CELLULASE

Unlike chemical hydrolysis, enzymatic hydrolysis of cellulose has the advantage of producing only sugar as product and no sugar degradation byproducts. However, enzymatic hydrolysis of cellulose is a slow process with low yield and a long reaction time. The slow reaction is further complicated by the complex features of biomass materials. Factors affecting the rate of enzymatic hydrolysis of lignocelluloses are the following: the presence of a lignin-hemicellulose shield surrounding cellulose fibers in plant cell walls; the crystallinity of the cellulose; and the relatively small pore sizes in biomass materials that impose mass transfer limitations on the penetration of both microorganisms and the hydrolytic enzymes. Enzyme activity is also subjected to hydrolysis product feedback inhibition. Consequently, some form of pretreatment is needed to expose the cellulose matrix and increase the diffusion of cellulases into the matrix of the substrate.

There are many different microorganisms, including fungi, bacteria, and protozoa, that are capable of producing cellulase enzymes. *Trichoderma reesei* (formerly *T. viride*) is the best-known cellulase-producing microbe; it produces a highly active cellulase complex toward insoluble cellulose. A large number of fungi isolated from rotten cellulosic materials were identified, and their ability to produce cellulase was examined by Reese and Levinson (24).

The extensive research by Reese et al. resulted in the development of the multiple enzymes (C_1 and Cx) concept that could involve in the degradation of crystalline cellulose (25). It also resulted in the use of *Trichoderma reesei* as a source of most investigated active cellulase for the hydrolysis of insoluble cellulose. *Trichoderma* cellulase preparations are available in several different forms from various commercial entities.

Mode of Action of *T. reesei* Cellulase Components

It is widely recognized that true cellulolytic microorganisms produce three basic cellulase components, namely, endocellulase, exocellulase, and cellobiase. The three enzyme components act in concert to hydrolyze crystalline cellulose to its end product, glucose. The components of cellulase enzymes have been studied extensively, and the modes of action of cellulase components have been elucidated (see Refs. 26 and 27 for review). Table 2 summarizes the three major *Trichoderma* cellulase components, the substrates for measurement of enzyme activities, and the mode of action of enzymes.

Crude cellulase activity can be approximated by analyzing the soluble color intensity released from commercially available remazol brilliant blue acid-swollen cellulose (cellulose-azure, Sigma). The standard method (Procedure No. 009) for measurement of overall cellulase activity in terms of filter paper units (FPU) has been provided by National Renewable Energy Laboratory (NREL) (28).

Production of Cellulase

The basic medium for cellulase production from *T. reesei* was developed by Mandels and Reese (29). The composition of the medium is given in the following section. There have been variations in medium composition, especially in the nitrogen source and in the addition of surfactants, such as Tween 80, to reduce the cost of the medium as well as to increase the yields of cellulases. The most common substrates for cellulase production are commercially available materials such as filter paper and Solka-Floc.

Medium. The basic medium has the following composition: $(NH_4)_2SO_4$, 1.4 g/L; KH_2PO_4, 2.0 g/L; urea, 0.3 g/L; $CaCl_2$, 0.3 g/L; $MgSO_4$, 0.3 g/L; trace elements, $FeSO_4 \cdot 7H_2O$, 5.0 mg/L; $MnSO_4 \cdot H_2O$, 1.6 g/L; $ZnSO_4 \cdot 7H_2O$, 1.4 g/L; $CoCl_2$, 2.0 g/L; cellulose, 0.75–1%; protease peptone, 0.075–0.1%; Triton X-100, 0.1–0.2%; initial pH = 5.0–6.0. Rapidly metabolizable carbon sources, such as glycerol or glucose, repress cellulase formation until these carbon sources are depleted by the organism, that is, unless the hypercellulase-producing mutant Rut-C30 is used (30). The Rut-C30 produces cellulase even in the presence of glucose. The addition of small amounts (0.1%) of a readily metabolizable carbon source, such as glycerol, with peptone and cellulose reduces the lag phase for the growth of the organism, consequently increasing cellulase production. The representative cellulase production profile is presented in Figure 4 (31,32).

Supplementation of Cellulases

Commercial cellulase preparations are derived mostly from the *Trichoderma* species (*T. reesei*, and *T. koningii*). *Trichoderma* enzyme preparations are deficient in cellobiase. To enhance the saccharification of cellulose during SSF process, cellobiase derived from *Aspergillus* species is often added. The amounts of cellobiase supplementation are often at 1 unit per FPU cellulase (33).

SIMULTANEOUS SACCHARIFICATION AND FERMENTATION

In general, conversion of cellulosic materials to ethanol involves two stages: *(1)* conversion of cellulose to glucose by either chemical or enzymatic processes, and *(2)* microbial conversion of the resulting glucose to ethanol. In nature, the microbes that are rich in cellulolytic enzymes are usually those with relatively slow growth, such as wood-rotting fungi. The natural selection process has resulted in cellulolytic enzymes that are often highly regulated by the reaction end products. Cellulase activity is subjected to product feedback inhibition (34). When there is a significant concentration of glucose, the enzymatic activity of cellobiase will be affected, which results in the accumulation of cellobiose. The accumulation of cellobiose in turn inhibits its cellulase activities (for details see Ref. 27). To overcome the problems caused by the glucose feedback inhibition, a process known as simultaneous saccharification and fermentation (SSF) was developed.

SSF is a process in which production of ethanol from cellulosic materials is achieved by utilizing cellulose, cellulase, ethanol producing microbes, and nutrients in the same reactor. This process is attractive because the continuous removal of sugars by fermentative organisms allevi-

Table 2. Common Names and Mode of Action of Three Cellulase Components

General category	Other Names	Substrate	Mode of action
β-1,4-Glucan glucanohydrolase (EC.3.2.1.4)	Cx Endoglucanase Endo-β-glucanase CMCase	Acid-swolen cellulose Bacterial cellulose Cellodextrins CMC	Hydrolyze cellulose in random fashion into smaller chains; create reactive site for exocellulase

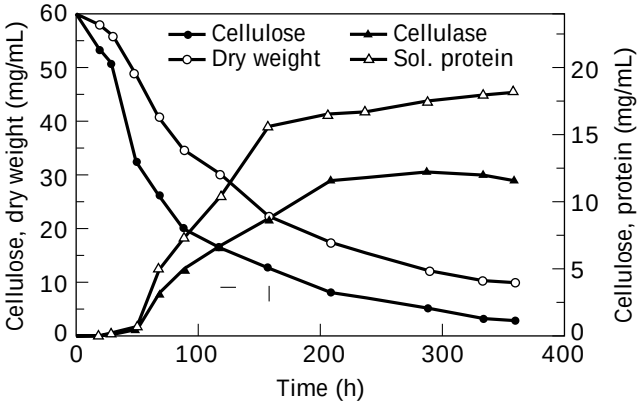

Figure 4. Typical *Trichoderma* cellulase production profile. *Source*: From Ref. 32.

ates the end-product inhibition of saccharification. The process is also simplified because only one reactor is used for SSF. The SSF process for ethanol production from cellulosic materials was reported by Blotkamp et al. (35) and was later tested in the pilot scale (for details see Ref. 36).

The advantages of SSF over the separate saccharification and fermentation of cellulose include the following:

- Reduction of contamination risk
- Lower enzyme loading requirements
- Faster hydrolysis reaction rate
- Higher product yield
- Lower operational expenses

For these reasons, SSF is the preferred process for the bioconversion of the cellulose fraction of lignocellulosic materials to ethanol and other chemicals at the present time. The SSF process involving lignocellulosic material has been reviewed in Ref. 36. There are several factors that are important for an efficient SSF process:

- The physical state of the substrate (particle size and crystallinity of the cellulose)
- Characteristics of the cellulase and cellulase concentration
- Effect of fermentation product on enzyme activity
- Compatibility of saccharification and fermentation temperature
- Characteristics of the yeast strains and yeast concentration
- Maintaining a low level of saccharification products

The nature of the cellulosic substrate is important because the degree of saccharification in the SSF system is often rate limiting with respect to ethanol production. Temperature also determines the economics of ethanol production from cellulose. In most studies, cell densities and enzyme concentration exerted little effect on the amounts of ethanol produced from cellulose under typical SSF conditions (37). In designing an efficient SSF system for the conversion of cellulose to ethanol, the fermentation temperatures should be compatible with operation temperatures, which are generally between 45 and 55 °C. The optimal temperature for the most commonly available cellulase is about 50 °C. Therefore, the use of high-temperature-tolerant microbes is desirable for the application of the SSF process for ethanol production. For the industrial production of ethanol from biomass materials, the use of yeast cultures is preferred over bacteria because the bacterial phage problem can be avoided. In addition, by-product credit can be obtained by marketing spent yeast cells as single-cell protein.

Typical industrial ethanol-producing yeast strains are mesophilic, with an optimal fermentation temperature of 30–37 °C. No true thermophilic yeast species has been reported, and only a few yeast strains that are thermotolerant as well as good ethanol fermentors have been described.

Supraoptimal Temperature Fermentation

In 1986, Anderson et al. (38) studied several thermotolerant yeast strains isolated from sugarcane factories in Australia. Most of the good ethanol-producing yeast strains belong to *Kluyeromyces marxianus* var. maxianus. Some are capable of producing over 6% ethanol (w/v) from glucose at an incubation temperature up to 43 °C after 14 h of fermentation. Over 80% of yeast cells remained viable at the end of fermentation.

Ballesteros et al. (39) studied the high-temperature SSF fermentation of pure cellulose at 42 and 45 °C at cellulase loading of 15 FPU/g substrate. The best results were achieved at 42 °C with a strain of *K. maxianus* and a strain of *K. fragilis*. Both yeast strains produced close to 38 g/L ethanol in 78 h. The results also confirmed the importance of using thermotolerant yeast in SSF processes in order to improve hydrolysis rates and achieve higher ethanol production. There are several possible benefits of using thermotolerant yeast to carry out ethanol fermentation at a supraoptimal temperature:

- Faster rate of saccharification
- Higher rates of sugar production and product (ethanol) formation
- Reduction of contamination by mesophilic yeast and bacteria
- Facilitation of product recovery
- Simplification of cooling during industrial-scale fermentation

However, yeast activities are more sensitive to inhibitory effects of ethanol with increasing temperature.

Improvement of the SSF Process

Typically, the SSF process is carried out in a continuous stirred-tank reactor (CSTR) in batch mode. Under this reaction condition, the fermentation product, ethanol, exerted its effect not only on microbes but also on cellulose hydrolysis activity. To overcome this problem and to improve the efficiency of ethanol production from cellulose, the continuous removal of end product during ethanol production should be beneficial. With this type of process application, the SSF process can be operated in a fed-batch mode. Fed-batch operation is similar to continuous operation except the fermentation broth is retained in the fermentor at all times, whereas the solid substrate is continuously fed into the fermentor.

Different methods of in situ removal of ethanol while it was being formed have been investigated (for review see Ref. 40). The processes include gas stripping, vacuum fermentation, solvent extraction, and the use of membrane bioreactors. Of these alternatives, gas stripping offers advantages in terms of its effectiveness and ease of operation. Ethanol can be recovered from the carrier gas stream by adsorbing onto activated carbon (41), or by condensation from the gas carrier (42). The experiments involving the gas (CO_2) stripping of ethanol during fermentation have been conducted in conventional stirred-tank bioreactors (41,43). Due to poor gas distribution in the stirred tanks, energy consumption for gas input into the fermentor is high. With an airlift fermentor, this drawback can be overcome. The airlift fermentor is the reactor that has a simple structure and provides better gas distribution and uniform air bubble size. The airlift fermentor is also about one-third less energy intensive than stirred tanks (44) because mechanical agitation is replaced by gas upflow to provide the required mixing. Recently, Tsao et al. (45) developed a novel airlift fermentor with a side arm (ALSA). This modified airlift fermentor improves liquid circulation velocities and minimizes the need for antifoaming agents. An ALSA fermentor coupled with gas stripping was used for the removal of ethanol from the fermentation broth during the fermentation of a substrate that contained a high glucose concentration. The ethanol concentration in the broth was maintained at under 4% (w/v) at all times due to the continuous removal of ethanol. The configuration of an ALSA fermentor integrated with a CO_2 stripping system is shown in Figure 5.

The application of this type of integrated fermentation system for high-solid SSF fermentation of biomass materials at an elevated temperature has the potential to overcome ethanol inhibition and temperature incompatibility.

XYLOSE FERMENTATION

Upon the hydrolysis of hemicellulose, xylose becomes the major monosaccharide component in the hemicellulose hydrolysate. Also, in the hydrolysates of lignocellulosic materials, mixtures of glucose and xylose will be expected. Usually, glucose in the hydrolysate can be completely fermented to ethanol within a few hours. However, the complete conversion of xylose to ethanol will take 48–72 h or longer. The nonmatching fermentation rates between glucose and xylose cause difficult design problems. The development of the SSF process has made it possible to convert lignocellulosics to ethanol with cellulase and fermenting microbes in the reactor at the same time. Again, the conversion of cellulose to glucose and finally to ethanol can be completed quickly. Nevertheless, the batch lasts a long time, until the xylose fermentation is completed.

Xylose can be metabolized by bacteria, fungi, or yeast. In bacteria, the initial step of xylose metabolism involves inducible enzymes (xylose transport enzymes, xylose isomerase, and xylulokinase). The direct isomerization of xylose to xylulose is the first step in xylose utilization by bacteria. They produce a variety of end products, including ethanol, from xylose (46). Recently, through advances in genetic engineering, a few bacterial strains have been genetically constructed to efficiently produce ethanol as the major product from xylose (47,48).

In yeast and mycelial fungi, xylose is metabolized via the coupled oxidation–reduction reactions. Xylose reductase is the enzyme involved in the reduction of xylose to xylitol, the sequential enzymatic events through the oxidation of xylitol to xylulose that lead to the utilization of xylose. Many yeast species utilize xylose readily, but ethanol production capability is very limited. Only a few yeast species such as *Pachysolen tannophilus*, *Candida shihatae*, and *Pichia stipitis* are relatively good ethanol producers when xylose is the substrate (49). The production of ethanol from xylose by those three yeast strains has been studied extensively in recent years. Recently, genetically engineered yeast strains have been constructed for more effective conversion of xylose to ethanol (50).

Xylose fermentation by yeast strains is subjected to regulation by dissolved oxygen (51) and by the presence of extraneous materials in the substrate (52). It is also affected by the presence of the fermentation end product,

ethanol. Ethanol, at about 45 g/L, will become inhibitory toward the ability of either naturally occurring or genetically modified xylose-fermenting microbes. To overcome the end-product inhibition by ethanol, Tsao et al. (45) used a modified airlift fermentor (ALSA) coupled with a gas-stripping system to remove ethanol continuously from the fermentation broth. Their results (Fig. 6) showed that xylose can be converted into ethanol without the feedback inhibition by ethanol that was encountered under typical stirred-tank fermentation conditions.

Inhibitors

In addition to producing monomer sugar residues, thermochemical processing of biomass is known to produce substances that are inhibitory to microbial growth and ethanol production. For example, furfural derived from pentose sugars, hydroxymethylfurfural, and levulinic acid from hexose sugars are known inhibitors (53). In addition, soluble phenolic compounds derived from lignin degradation and alkaline extractives are also inhibitory toward yeast in low concentration (Table 3). Another potential inhibitor is acetic acid, which can be present in relatively high concentrations (6–15 g/L); it exists as an integral part of hemicellulose. Various procedures have been investigated to minimize the inhibitory effect of the processing by-products. The methods include careful control of the pretreatment process to minimize sugar degradation, using ion exchange resins and activated charcoal to remove

Table 3. The Effects of Potential Inhibitors on Growth and Ethanol Production from Xylose

Compound	Concentration (g/L)	Inhibition (% growth)	Inhibition (% EtOH)
Furfural	2	90	90
HMF[b]	5	92	96
Acetate	10	16	38

the inhibitors, or the soaking of materials in an alkaline solution prior to hydrolysis.

BIOMASS FRACTIONATION

The rationale behind the fractionation of lignocellulose into lignin, hemicellulose, and cellulose components prior to utilization is as follows:

- Alkaline extractives, soluble lignin, and lignin-derived soluble products are inhibitory to microbial fermentation.
- Hemicellulose is much more susceptible to acid hydrolysis than cellulose.
- Cellulose carbohydrate can be fermented to ethanol much faster than can hemicellulose-derived carbohydrates (e.g., xylose).

	Lignin	25.0	7.11	6.97	7.41	0.85	0.91

Source: From Ref. 55.

The biomass fractionation options and their economical benefits were recently reviewed and discussed by Elander and Hsu (54). The objective of the fractionation is to separate different biomass components and subsequently convert the cellulose and the hemicellulose into separate products. To achieve this objective, mild treatment conditions such as low temperature, low concentration of reagents (or easily recoverable reagents), and low pressures are necessary. Under this biomass component fractionation scheme, cellulose sugar (glucose) and hemicellulose carbohydrates (mostly xylose) can be converted in different reactors to produce different products, if so desired.

Cao et al. (55,56) examined a fractionation option that used corn cobs and aspen woodchips as the substrates. In this biomass fractionation scheme (Fig. 7), the majority of lignin, alkaline extractives, and acetate were solubilized and separated from cellulose and hemicellulose fractions by alkaline treatment. Hemicellulose was thereafter hydrolyzed to its sugar constituents by dilute acids. Hemicellulose carbohydrates were then fermented to ethanol, 2,3-butanediol, or xylitol by xylose-fermenting microbes. The cellulose fraction, after separation from lignin and hemicellulose, was used as the substrate in the SSF process for ethanol production with a thermotolerant yeast strain as the biocatalyst, or it can be bioconverted into other products. Table 4 shows the changes of biomass components after ammonia and dilute acid treatments.

OUTLINE

INTRODUCTION

Silicon, which is the second most abundant element in the Earth's crust, belongs to the same group as carbon, which is one of the most fundamental elements for organisms, but is different from carbon in its characteristics (1). Silicon is less electronegative and has a bigger covalent radius than carbon (Table 1). A bond between silicon and oxygen is stronger than the corresponding bond between carbon and oxygen, whereas its bonds with carbon and hydrogen are weak.

Silicon plays an important role in the biosphere and is present mainly in living organisms, especially at a lower stage of evolutionary development. Silicate bacteria, the simplest algae, and spore plants, in fact, contain very large amounts of silicon (2,3). Recent research has indicated that silicon is also important for higher plants, animals, and humans (4), although its actual biochemical function is at present not fully defined. It seems, however, that natural biochemical processes mainly involve silicon bound to oxygen, whereas organosilicon compounds containing Si–C bonds have not been detected (1–3). Therefore, the effects of organosilicon compounds on organisms and/or enzymes are very interesting.

The explosive growth of organosilicon chemistry has created a growing awareness of its considerable utility to organic chemists and has shown that a wide spectrum of organosilicon compounds often exhibit interesting biological properties (2,3). Recently, pharmaceutical applications of organosilicon chemistry have also been gaining attention (2,3,5–7). Therefore, the production of organosilicon compounds with desired chemical and physical properties by the use of effective biocatalysts is of great importance. Several examples of bioconversion of organosilicon compounds have been summarized by Ryabov (8) and Tanaka and Kawamoto (9).

MICROBIAL REDUCTION OF ORGANOSILICON COMPOUNDS

Stereoselective microbial reduction of organosilicon compounds was first demonstrated by Tacke et al. (10). Analogous to the microbial reduction of alkyl acetoacetates to optically active 3-(*S*)-hydroxybutyrates, the sila analogues **1a** and **1b** could be transformed stereoselectively into the corresponding reduction products (*S*)-**2a** and (*S*)-**2b** by using growing cells of the yeast *Kloeckera corticis* (Fig. 1). This stereoselective reduction could be performed on a preparative scale with good yields. The optical purities obtained were about 80% ee for (*S*)-**2a** and (*S*)-**2b**.

In this case, the carbonyl groups attacked by the microorganism are relatively far away from the silicon atom. However, it was also shown that compounds containing a carbonyl group bound directly to the silicon atom can also be reduced stereoselectively by microorganisms. For example, achiral acetyldimethylphenylsilane (**3**) was transformed stereoselectively into the optically active reduction product (*R*)-**4** (86% ee) by growing and resting cells of the yeast *Trigonopsis variabilis* DSM 70714 (Fig. 2) in a yield of 70% (11). Furthermore, a wide range of microorganisms

Table 1. Physical Properties of the Silicon Atom and the Carbon Atom

Atom	Electronegativity	Bond	Bond length (nm)	Bond dissociation energy (kJ mol^{-1})
C	2.55	C—C	0.153	334
Si	1.90	C—Si	0.189	318

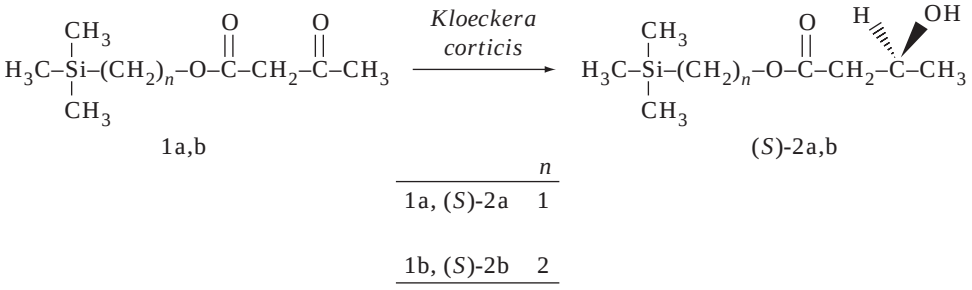

Figure 1. Stereoselective microbial reduction of sila-analogues of alkyl acetoacetates.

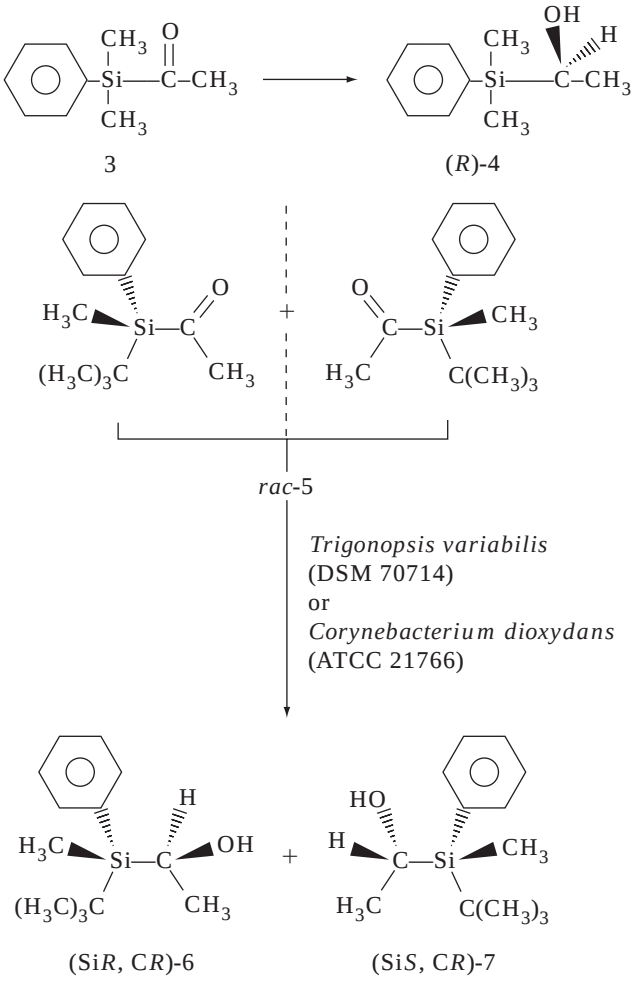

Figure 2. Microbial reduction of organosilicon compounds having a carbonyl group bound directly to the silicon atom.

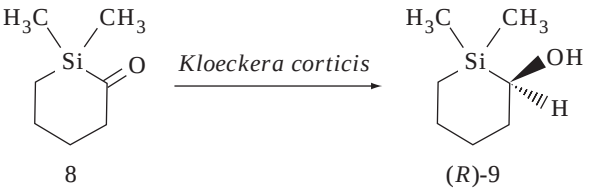
such as bacteria, yeasts, fungi, and green algae showed the ability to accept **3** as a substrate for stereoselective reduction (12). Among 30 strains of microorganisms tested as resting cells, *T. variabilis* DSM 70714 was found to exhibit the highest specific activity (1.5 mg product g wet $mass^{-1}$ min^{-1}), whereas the highest stereoselectivity (95% ee) was observed with the bacteria *Acinetobacter calcoaceticus* ATCC 31012 and *Corynebacterium dioxydans* ATCC 21766. The same bioconversion could be performed by resting cells of *Saccharomyces cerevisiae* DHW S-3 at a rate of 44–45 μmol L^{-1} min^{-1} with a yield of 40% and optical purity of more than 99% after purification (13). Plant cell suspension cultures of *Synphytum officinale* L. and *Ruta graveolens* L. served as the biocatalysts for the conversion of **3** to (*R*)-**4**, although the yields and optical purities were not satisfactory (*S. officinale*: 81% ee, yield 15%; *R. graveolens*: 60% ee, yield 9%) (14).

It is noteworthy that a carbonyl group bound to the silicon atom can be transformed by various microorganisms, as in the case of conventional ketones, although there are big differences in physical and chemical properties between these compounds. Another example of microbial reduction of organosilicon compounds is the transformation of racemic acetyl(*tert*-butyl)methylphenylsilane (*rac*-**5**) with resting cells of *T. variabilis* DSM 70714 (15) and *C. dioxydans* ATCC 21766 (16). In these cases, enantioselective reduction of both enantiomers of the racemic compounds was observed, resulting in the formation of the diastereomeric optically active silanes (Si*R*,C*R*)-**6** (*T. variabilis*: 97% ee, yield 74%; *C. dioxydans*: 99% ee, yield 20%) and (Si*S*,C*R*)-**7** (*T. variabilis*: 96% ee, yield 70%; *C. dioxydans*: 99% ee, yield 20%). Growing cells of *K. corticis* catalyzed the stereoselective reduction of 1,1-dimethyl-1-silacyclohexan-2-one (**8**) to (*R*)-1,1-dimethyl-1-silacyclohexan-2-ol ((*R*)-**9**) (92% ee, yield 60%) (Fig. 3) (17). Reduction of (+)-(benzyloxymethyl)(*tert*-butyl)methylsilyl methyl ketone ((+)-**10**) to (Si*R*,1*R*)-(+)-1-[(benzyloxymethyl)(*tert*-butyl)methylsilyl]ethanol ((+)-**11**) and its



8 (*R*)-9

Figure 3. Microbial reduction of 1-silacyclohexan-2-one.

(Si*S*,1*R*)-enantiomer ((+)-**12**) was performed by resting free and immobilized cells of *T. variabilis* (>96% ee, yield 67–99%) (Fig. 4) to prepare (*R*)-(−)-**10** and (*S*)-(+)-**10**, the former being the intermediate in the synthesis of (*R*)-(+)-1-phenylethanol (18).

These studies clearly demonstrate that organosilicon compounds could be transformed by microorganisms and that the microbial transformation is useful for the preparation of optically active organosilicon compounds.

OXIDOREDUCTION OF ORGANOSILICON COMPOUNDS BY ALCOHOL DEHYDROGENASES

Bioconversion of organosilicon compounds by alcohol dehydrogenases (ADHs) is very attractive because of the importance of asymmetric alcohol/carbonyl oxidoreduction in organic chemistry. Although several papers are available on the reduction of organosilicon compounds by microorganisms as mentioned earlier, it is not clear whether ADH can actually catalyze the oxidoreduction of organosilicon compounds in these organisms, and it has not been possible to discuss the effect of the silicon atom on enzymatic reactions with ADH.

It was shown for the first time by Zong et al. (19) that ADH from horse liver (HLADH) could catalyze the dehydrogenation of organosilicon compounds and that the silicon atom in the substrates had unique effects on enzymatic reactions due to specific characteristics of the silicon atom. The bioconversion of three organosilicon compounds with different chain lengths between the silicon atom and the hydroxyl group ($Me_3Si(CH_2)nOH$, n = 1–3) by HLADH was systematically studied in comparison with the corresponding carbon compounds ($Me_3C(CH_2)nOH$, n = 1–2). HLADH, but not yeast alcohol dehydrogenase, catalyzed the dehydrogenation of 2-trimethylsilylethanol (n = 2) **(14a)** and 3-trimethylsilylpropanol (n = 3) **(15a)**. **14a** was a better substrate than both its carbon analogue, 3,3-dimethylbutanol **(14b)** and ethanol. The improved activity of HLADH on **14a** could be accounted for by a lower activation energy of the reaction by HLADH than that with the carbon analogue. In contrast, HLADH showed no activity on trimethylsilylmethanol (n = 1) **(13a)**, whereas it catalyzed the dehydrogenation of the carbon analogue, 2,2-dimethylpropanol **(13b)**. This phenomenon was explained by the β-effect of the silicon atom, that is, stabilization of a negative charge at the α-position and a positive charge at the β-position of the carbon atom from the silicon atom (1). As the silicon atom stabilizes the positive charge of the β-carbon atom, the H^- anion could be removed more easily from the β-carbon atom of **14a**, which is the first step of the dehydrogenation of alcohol catalyzed by ADH. As a result, the activation energy of the dehydrogenation of **14a** by HLADH probably became lower than that of **14b**, and thus **14a** is a better substrate than the carbon counterpart (Fig. 5). Conversely, it is more difficult for the H^- anion to be removed from the α-carbon atom of **13a** because the electron density around the α-carbon of **13a** is higher than that of **13b** owing to a lower electronegativity of the silicon atom (Fig. 5). Sonomoto et al. (20) also confirmed the same phenomena.

It was also demonstrated that HLADH could catalyze the enantioselective dehydrogenation of racemic trimethylsilylpropanols, 1-trimethylsilyl-2-propanol **(16a)** and 2-trimethylsilyl-1-propanol **(18a)** (Fig. 6) in a water–organic solvent two-layer system with coenzyme regeneration by a glutamate dehydrogenase-2-oxoglutarate system (21). Especially, the enantiomeric excess of **16a** remaining at 51% conversion was as high as 99%. In this case, 1-trimethylsilyl-1-propanol **(17a)** did not serve as a substrate. A comparative study with their carbon counterparts (**16b** and **18b**) showed results similar to those of the hydrolases to be described later, that is, substitution of the silicon atom for the carbon atom improved the enantioselectivity of HLADH.

Tsuji et al. (22) found that enantioselective dehydrogenation of primary alcohol β-hydroxyalkylsilane, 2-trimethylsilyl-1-propanol **(18a)**, could be carried out with only a catalytic amount of NAD^+ and HLADH in an aqueous system containing 5% tetrahydrofuran. When **18a** (5

$\times$ 10 μmol) was applied to the HLADH-catalyzed dehydrogenation with a small amount of NAD^+ (5×10^{-1} μmol) in the aqueous system, NAD^+ could be regenerated in situ through reduction of 1-propanal **(20)** formed by spontaneous degradation of the dehydrogenation product, 2-trimethylsilyl-1-propanal **(19)**, in the presence of water (Fig. 7). In this case, conversion ratio reached 75% after 14 h of reaction; the turnover number of NAD^+ was calculated to be about 75, where the optical purity of remaining **18a** was 90% ee. If the amount of NAD^+ was reduced to 5×10^{-2} or 5×10^{-4} μmol (**18a**, 5×10 μmol), the turnover number of NAD^+ reached 640 or 7,200, respectively. This novel reaction system is simple and advantageous because it does not require any other enzyme and substrate for regeneration of NAD^+, and there is no product inhibition due to the spontaneous degradation of the dehydrogenation product. On the other hand, dehydrogenation of the corresponding carbon analogue **(18b)** did not proceed under this condition because the aldehyde formed by dehydrogenation of **18b** with HLADH did not undergo the degradation to provide a substrate for NAD^+ regeneration. These results indicate that application of organosilicon compounds makes it possible to construct an efficient and unique conversion system, which is impossible in the case of conventional carbon compounds. Other primary β-hydroxysilanes having different substituents on the silicon atom or on the stereogenic carbon atom, 2-trimethylsilyl-1-butanol, 2-trimethylsilyl-1-hexanol, and 2-dimethylphenylsilyl-1-butanol, were also found to serve as substrates in enantioselective dehydrogenation by HLADH with this novel NAD^+ regeneration system. In contrast, dehydrogenation of the secondary β-hydroxysilane, 1-trimethylsilyl-2-propanol **(16a)**, was negligible under the same conditions, although HLADH could convert **16a** with conventional coenzyme regeneration (21). The dehydrogenated product of **16a**, 1-trimethylsilyl-2-propanone, was supposed to be degraded by the addition of water into trimethylsilanol and acetone also in this case, but regeneration of NAD^+ did not occur because acetone was not recognized as the substrate by HLADH and so the dehydrogenation reaction did not proceed over the catalytic amount of NAD^+.

Recently, Wong et al. (23) have reported that NADPH-requiring *Lactobacillus kefir* ADH could catalyze the enantioselective carbonyl reduction of ketones having a large variety of side chains, including trimethylsilyl-protected terminal alkyne ketones, and NADPH regeneration in the presence of 2-propanol.

BIOCONVERSION OF ORGANOSILICON COMPOUNDS BY HYDROLASES

Hydrolases such as lipases, esterases, and proteases are the easiest enzymes to handle because hydrolases do not require coenzymes and are readily available in a large quantities. Therefore, they have been extensively used as catalysts in regio- or enantioselective conversion.

Therisod and Klibanov (24) mentioned additionally, in the regioselective acylation of secondary hydroxyl groups of C-6 protected glucose, that modification of the C-6 hydroxyl group of D-glucose with a more bulky *tert*-butyldiphenylsilyl group increased the regioselectivity of *Candida cylindracea* lipase toward the C-2 position, compared with 6-*O*-butylylglucose. It was, however, not clear how reactive the compound modified with the *tert*-butyldiphenylsilyl group was in the lipase-catalyzed acylation. Luyten et al. (25) reported in the study on enantioselective hydrolysis of several functionalized dimethyl malonates **(21a–f)** by pig liver esterase (PLE) (Fig. 8) that a *tert*-butyldimethylsilyl derivative of dimethyl 2-(hydroxymethyl)-2-methylmalo-

nate **(21c)** gave a high enantioselectivity (95 % ee) but a sluggish reaction. As a result, the yield of the optically pure product ((*R*)-**22c**) was very low (49%). In this study, a (*tert*-butoxy)methyl derivative **(21e)** showed the best results, namely, a high enantioselectivity (96% ee) and a high yield (90%). Mori and Takeuchi (26) prepared enantiomerically pure (1*S*, 4*R*)-4-*tert*-butyldimethylsilyloxy-3-chloro-2-cyclopenten-1-ol **(24)** (ca. 100% ee), which is a key chiral building block for synthesis of punaglandin 4, a chlorinated marine prostanoid, through the asymmetric hydrolysis of the mixture of 3-acetoxy-5-*tert*-butyldimethylsilyloxy-1-chlorocyclopentenes **(23)** with pig pancreatic lipase (PPL) (Fig. 9) in 25% yield.

In the case of the organosilicon compounds already mentioned, functional groups attacked by hydrolases were far away from the silicon atom. Therefore, the effect of the silicon atom itself on enzymatic reactions seems very weak. It is interesting to study the bioconversion of organosilicon compounds whose silicon atom more strongly affects the functional groups to be attacked by biocatalysts. Interesting attempts were made by Therisod (27). He tried to use trimethylsilyl ethers instead of alcohols as novel nucleophiles in hydrolase-catalyzed transesterification (Fig. 10), but failed.

Kawamoto et al. (28) attempted a comparative study by using organosilicon compounds having a different chain length between the hydroxyl group and the silicon atom ($Me_3Si(CH_2)nOH$, n = 0, 1, 2, and 3) and the corresponding carbon compounds ($Me_3C(CH_2)nOH$, n = 0, 1, and 2) as an acyl acceptor in the enantioselective esterification of 2-(4-chlorophenoxy)propanoic acid **(25)**, whose *R*-enantiomer is useful as an herbicide, with lipase OF 360 of *C. cylindracea* (Fig. 11) and discussed the effects of the silicon atom on the enzymatic reaction in connection with the distance between the hydroxyl group and the silicon atom. Trimethylsilylmethanol (n = 1) **(13a)** was found to be a particularly superior substrate, that is, the reaction rate was much higher than that with the corresponding carbon compound **(13b)**, and the enantiomeric excess of the acid remaining was above 95% at about 50% conversion. In the case of conventional substrates such as the carbon analogue and linear-chain alcohols, a high reaction rate was not consistent with a high enantioselectivity. These results indicate that organosilicon compounds may solve the unavoidable and probably inherent problems of enantioselective reactions with conventional substrates. On the other hand, no difference was observed between 2-trimethylsilylethanol (n = 2) **(14a)** and its carbon analogue, 3,3-dimethylbutanol **(14b)**, with respect to enzymatic activity and enantioselectivity. Thus, the silicon atom mimicked the carbon atom for lipase in the case of **14a** but was different from the carbon atom in enhancing the reactivity of **13a**. The phenomena were explained on the basis of the properties of the silicon atom, such as its low electronegativity and big atomic radius compared with those of the carbon atom. A lower electronegativity of the silicon atom results in a higher nucleophilicity of the oxygen atom of **13a** compared with that of the corresponding carbon analogue **(13b)**, and the hydroxyl group of **13a** is less sterically hindered due to the longer bond between Si and C than between C and C in **13b** (Fig. 12). **13a** is, therefore, more easily accessible to the acyl-enzyme intermediate and reacts as an acyl acceptor much faster than the carbon analogue. In the case of **14a**, the favorable effect of the silicon atom mentioned earlier was negligible owing to the presence of a long ethylene group between the silicon atom and the hydroxyl group. **14a**, and probably 3-trimethylsilylpropanol (n = 3) **(15a)**, were consequently regarded as similar substrates to the corresponding carbon compounds by lipase. In spite of the favorable characteristics of the silicon atom, trimethylsilanol (n = 0) did not serve as a substrate similarly to the corresponding tertiary alcohol.

To our knowledge, this work is the first study in which the effects of the silicon atom in substrates on enzymatic reaction were discussed systematically. Furthermore, this study showed for the first time the ability of organosilicon compounds to break the limit of conventional substrates, owing to their unique characteristics. According to this explanation, trimethylsilylmethylamine ($Me_3SiCH_2NH_2$) can also be expected to be a better acyl acceptor than the cor-

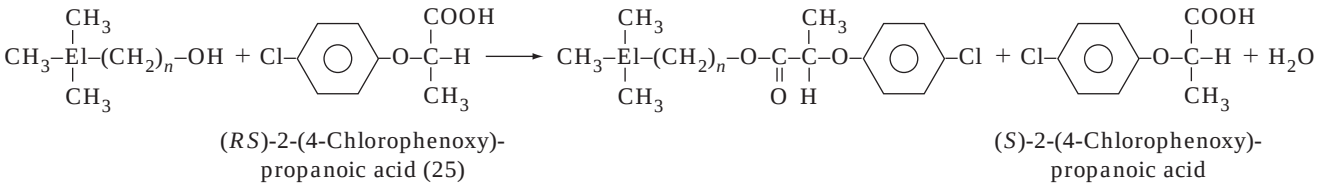

Figure 11. Lipase-catalyzed enantioselective esterification of 2-(4-chlorophenoxy)propanoic acid with silicon-containing alcohols and the corresponding carbon analogues. El, Si or C.

responding carbon compound, 2,2-dimethylpropylamine ($Me_3CCH_2NH_2$), in hydrolase-catalyzed amide bond formation. In fact, trimethylsilylmethylamine was a better substrate for hydrolases such as lipase OF 360 (*C. cylindracea*), lipase KLIP-100 (*Pseudomonas* sp.), lipoprotein lipase Type A (*Pseudomonas* sp.), and cholesterol esterase Type A (*Pseudomonas* sp.) than the corresponding carbon compound in amide bond formation with octanoic acid (R.S. So, Y. Masuda, T. Kawamoto, and A. Tanaka, unpublished results).

In contrast to our results, Tsai and Wei (29) reported that both **13a** and **14a** were effectively applied to the enantioselective esterification of racemic naproxen (2-(6-methoxy-2-naphthyl)propionic acid), a nonsteroidal anti-inflammatory drug, by *C. cylindracea* lipase. However, these alcohols were not good substrates for *Mucor javanicus* lipase. They have developed this esterification reaction system with **13a** (30,31).

Optical resolution of organosilicon compounds having a functional group attached to the carbon atom at the α-position from the silicon atom was also studied, and the enantioselective hydrolysis of racemic 2-acetoxy-1,1-dimethyl-1-silacyclohexane (*rac*-**26**) in an aqueous solution and enantioselective esterification of racemic 1,1-dimethyl-1-silacyclohexan-2-ol (*rac*-**27**) with triacetin in isooctane were successfully carried out by the use of a crude lipase preparation of *C. cylindracea*, leading to (*S*)-**27** (yield 71%, 95% ee) and (*S*)-**26** (yield 92%, 95% ee), respectively (Fig. 13) (32).

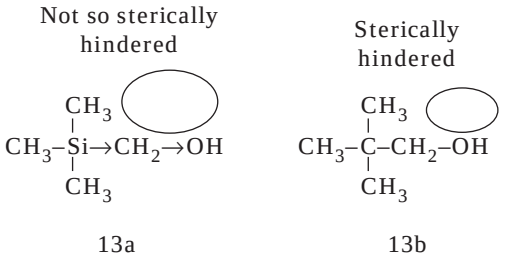

Figure 12. Effect of the silicon atom in trimethylsilylmethanol on esterification.

In general, it is difficult to perform the highly enantioselective conversion of primary alcohols. However, the efficient optical resolution of a primary alcohol, 2-trimethylsilyl-1-propanol **(18a)**, was achieved with 95% ee at 50% conversion by the enantioselective esterification with lipase Saiken 100 from *Rhizopus japonicus* in water-saturated isooctane (33). In the study on the enantioselective esterification of three isomers of trimethylsilylpropanols, 1-trimethylsilyl-2-propanol **(16a)**, 1-trimethylsilyl-1-propanol **(17a)**, and **18a**, and the corresponding carbon analogues (**16b, 17b**, and **18b**) (Fig. 6) with 5-phenylpentanoic acid by hydrolases in water-saturated isooctane, it was indicated that the silicon atom in the substrates generally enhanced the enzyme enantioselectivity. It is also worth noting that the β-hydroxyalkyl-

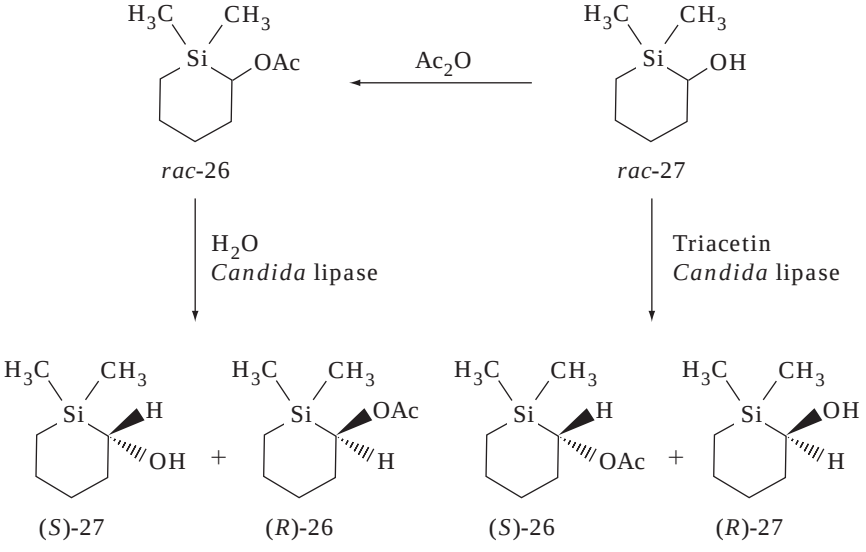

Figure 13. Lipase-catalyzed enantioselective hydrolysis and transesterification of organosilicon compounds whose functional group is attached to the carbon atom at the α-position from the silicon atom.

silanes, **16a** and **18a**, were effectively esterified by hydrolases, but they were easily converted to alkenes via *β*-elimination under both acidic and basic conditions (Peterson olefination) (1), and consequently, it is not possible to esterify them by chemical catalysts such as acids. Several enzymes could convert such unstable compounds with enantioselectivity. This fact is a good example showing the effectiveness of introduction of biochemical methods into organosilicon chemistry.

Optical resolution of organosilicon compounds, which have a stereogenic silicon atom, is also an important target for the application of enzymes. Furthermore, it is interesting to find out whether enzymes can recognize the chirality on the silicon atom, and such chiral silanes are expected to be new materials, synthetic reagents (34), or biologically active compounds (2). When PhSi(Me)(Et)CH_2OH **(28)** was esterified with 5-phenylpentanoic acid, various types of hydrolases exhibited a good esterification activity but low enantioselectivity. Of the enzymes examined, a commercial preparation of crude papain gave the best results, that is, a moderate reaction rate and a high enantioselectivity (35). Consequently, the enantioselective esterification of several primary alcohols, hydroxyakylsilanes, having a stereogenic silicon atom **(28–36)** was attempted (Fig. 14) with 5-phenylpentanoic acid by crude papain in water-saturated isooctane to study the effects of chain length between the silicon atom and the hydroxyl group **(28–30)** and the substitution groups on the silicon atom **(28,31–36)** (35). A short methylene chain between the silicon atom and the hydroxyl group and a phenyl substitution on the silicon atom were found to be essential for the high activity and the high enantioselectivity in the crude papain-catalyzed kinetic resolution of these organosilicon compounds. The optical purities of (+)-PhSi(Me)(Et)CH_2OH **(28)**, (+)-PhSi(Me)(Pr)CH_2OH **(31)**, (+)-*p*-Me-PhSi(Me)(Et)CH_2OH **(33)**, and (+)-*p*-F-PhSi(Me)(Et)CH_2OH **(34)**, obtained were 92 (yield 42% from the racemic substrate), 93 (yield 42%), 96 (yield 41%), and 99% ee (yield 41%), respectively.

Figure 15. Asymmetrization of prochiral organosilicon compounds by lipases. LCC, lipase from *Candida cylindracea*; LCV, lipase from *Chromobacterium viscosum*.

Djerourou and Blanco (36) demonstrated the preparation of silyl-chiral optically active compounds by the asymmetrization of prochiral organosilicon compounds with hydrolases. The prochiral 2-sila-1,3-propanediol derivatives **(37a,b)** were asymmetrized through transesterification with oxime ester or methylisobutyrate by lipase from *C. cylindracea* (LCC) and lipase from *Chromobacterium viscosum* (LCV) (Fig. 15), although the enantiomeric excess of the resulting esters did not exceed 70–76%.

The enantioselective hydrolysis of amide was also useful for the preparation of optically active organosilicon compounds. Optically active (*R*)-(1-aminoethyl)dimethylphenylsilane ((*R*)-**39**) was obtained in 40% yield with an enantiomeric purity of 92% ee by enantioselective hydrolysis of racemic dimethylphenyl[1-(phenylacetamido)-ethyl]silane **(38)** using immobilized penicillin G acylase from *Escherichia coli* 5K pHM 12 (Fig. 16) (37).

PREPARATION OF SILICON-CONTAINING AMINO ACIDS

Optically active nonnatural amino acids are very interesting and useful as the precursors of pharmaceuticals, agricultural chemicals, food ingredients, and so forth. Furthermore, they are also used as chiral auxiliaries for organic synthesis. Therefore, it will be very important to prepare novel nonnatural amino acids, such as silicon-containing ones. These amino acids can be expected to exhibit improved biological activities or new functions because of the characteristics of the silicon atom.

An efficient system has been developed to prepare optically active 3-trimethylsilylalanine (TMS-Ala) **(41)** by kinetic resolution with acylase I from porcine kidney from chemically synthesized *N*-acetyl-D,L-TMS-Ala **(40)** (Fig. 17) (38). Although both acylase I from porcine kidney and that from *Aspergillus melleus* showed activity on this substrate, the porcine enzyme was found to have much higher activity. The optimum pH of the reaction was 7.5, and the addition of 0.5 mM Co^{2+} accelerated the reaction. Optically pure L-**41** (>99% ee) was obtained in 72% yield. Furthermore, highly optically pure D-**41** (96% ee) could also be obtained in 76% yield by chemically hydrolyzing the residual substrate. **41** may be used as an analogue of leucine in the synthesis of bioactive peptides.

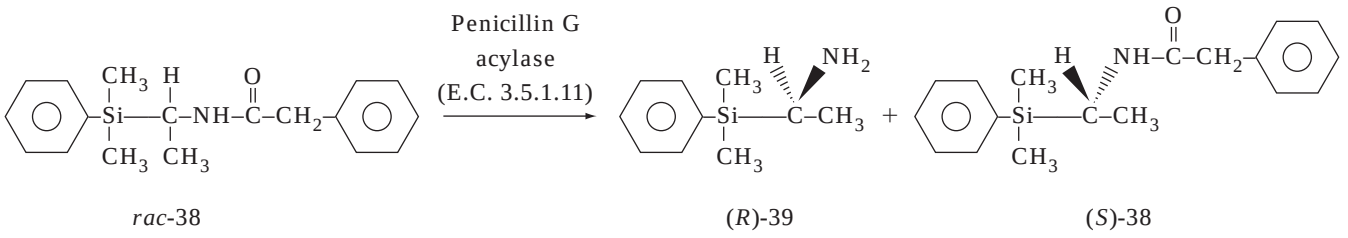

Figure 16. Enantioselective hydrolysis of a silicon-containing amide by penicillin G acylase.

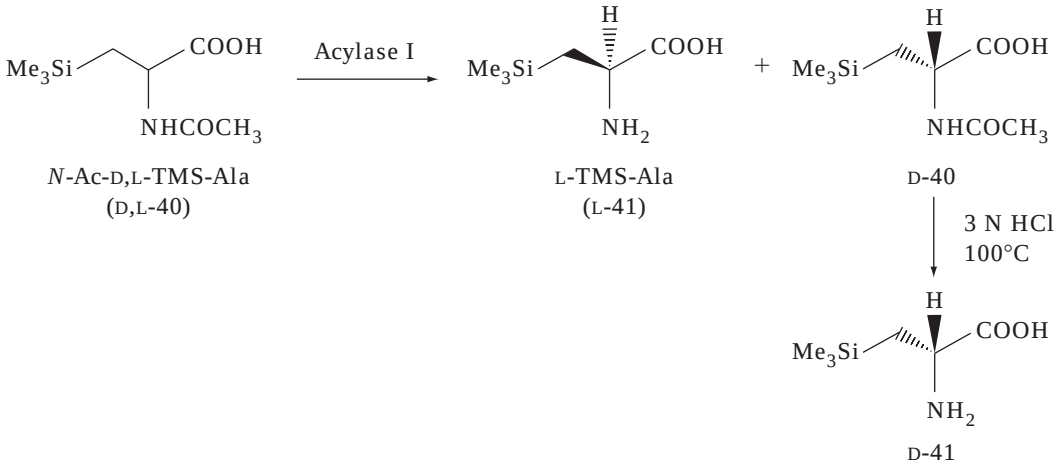

Figure 17. Preparation of optically active trimethylsilylalanine. TMS, trimethylsilyl.

As a homologue of phenylglycine and its analogues, which can be applied as side chains of penicillins and cephalosporins, optically active *p*-trimethylsilylphenylalanine **(44)** was prepared enzymatically. First, an attempt was made to obtain D-**44** from chemically synthesized D,L-5-(*p*-trimethylsilylphenylmethyl)hydantoin **(42)** via *N*-carbamoyl-D-*p*-trimethylsilylphenylalanine **(43)** through hydantoinase reaction, but none microbial strains tested exhibited the satisfactory activity to hydrolyze **42** to **43**. However, several strains, especially *Blastobacter* sp. A17p-4, showed good activity in the hydrolysis of **43** to yield **44**. Therefore, D,L-**43** prepared chemically from D,L-**42** was subjected to enantioselective hydrolysis to obtain optically active **44**. When D,L-**43** was hydrolyzed with cells or cell-free extract of *Blastobacter* sp., optical purity of D-**44** obtained was low because the cells contained not only *N*-carbamoyl-D-amino acid amidohydrolase (DCase) but also *N*-carbamoyl-L-amino acid amidohydrolase (LCase). DCase and LCase in the cell-free extract could be separated by DEAE-Sephacel-column chromatography. The optimum pH for the hydrolysis of D,L-**43** by partially purified DCase was 8.0, and addition of 2.5% *N*,*N*-dimethylformamide was effective to increase the substrate concentration without inactivation of the enzyme. Under the optimized conditions, highly optically pure (98% ee) D-**44** was obtained (39).

This process has been further improved by using the cell-free extract of *Blastobacter* sp. as the source of both DCase and LCase. As DCase of *Blastobacter* sp. had been known to be thermostable, the cell-free extract of this bacterium was treated at 50 °C and pH 7.0 for 40 min to inactivate LCase. After hydrolysis of D,L-**43** with the heat-treated cell-free extract, the product, D-**44**, and the residual substrate, L-**43**, were separated by silica-gel-column chromatography. L-**43** was further subjected to hydrolysis with nontreated cell-free extract as the LCase source after optimization of the reaction conditions (Fig. 18). Thus, optically pure D-**44** (99% ee) and L-**44** (99% ee) were obtained in yields of 80% and 89%, respectively, after purification (40).

CONCLUSION

This article outlines the bioconversion of various organosilicon compounds. In spite of the remarkable development of biotechnology, there have so far been only limited studies on bioconversion of organosilicon compounds. It has, however, been found that biocatalysts such as microorganisms, various types of hydrolases, and alcohol dehydrogenases are able to accept organosilicon compounds as substrates for transformation. Other types of enzymes will also be active on organosilicon compounds, although no experimental results are available at present. Introduction of biochemical methods into organosilicon chemistry has great potential because of the superior properties of biocatalysts, such as reaction selectivity, regioselectivity, enantioselectivity, stereoselectivity, and mild reaction condi-

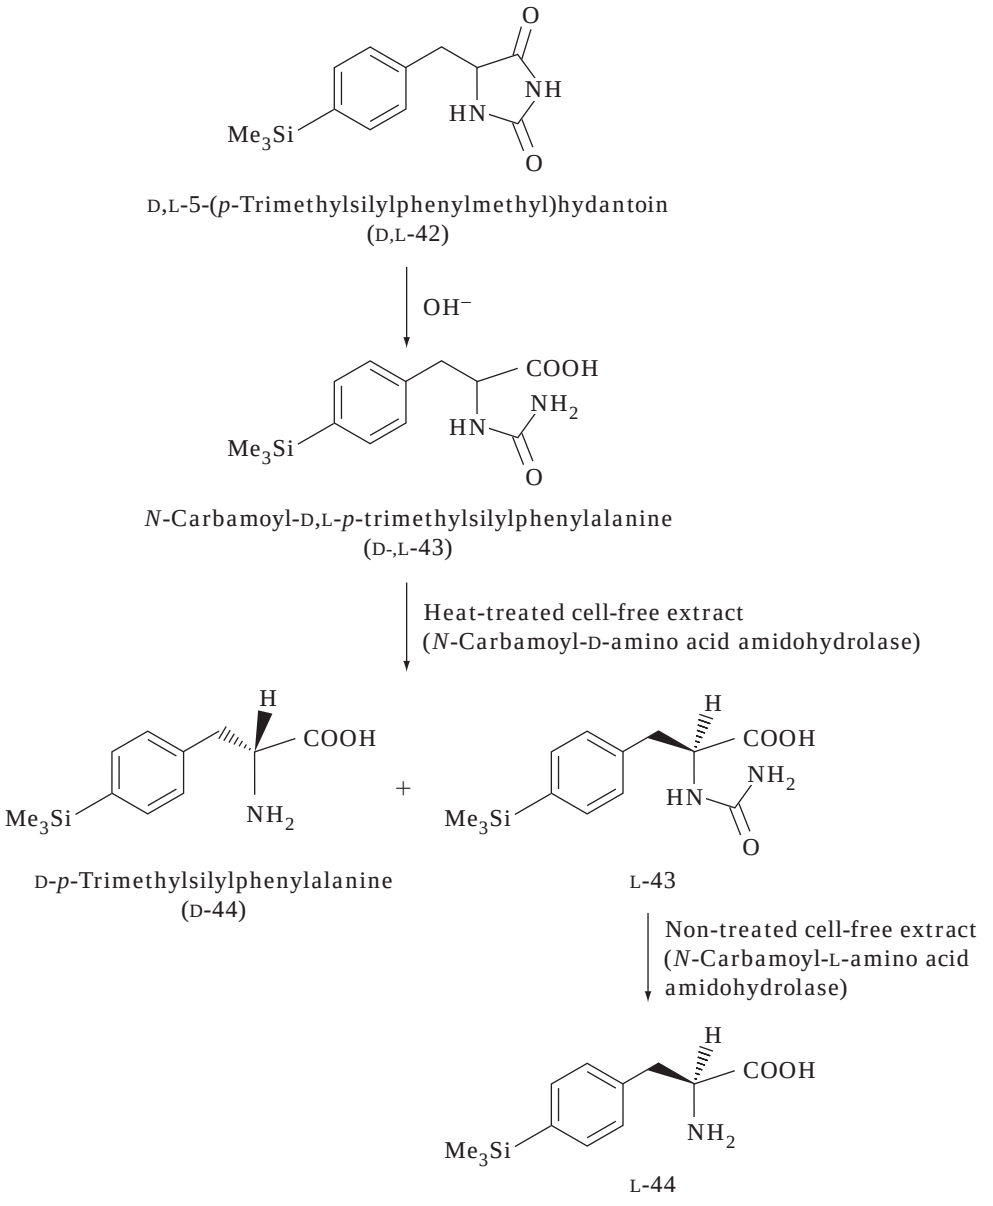

Figure 18. Preparation of optically active *p*-trimethylsilylphenylalanine.

tions. Furthermore, the application of the differences between organosilicon compounds and the corresponding carbon compounds to biochemical processes might make it possible to explore latent abilities of biocatalysts, giving fundamental information about biochemical and biological events. The field of organosilicon biochemistry, a fusion of biochemistry and organosilicon chemistry, will provide great possibilities to biotechnology in the future.

OUTLINE

INTRODUCTION

Osmolality is one of the most important physical properties of culture media. Osmolality is a measure of concentration and is defined as the molality of particles in a solution. Most cell culture media are designed to have an osmolality of 280 to 320 mOsm/kg through balancing the concentration of nutrients and osmolytes (1).

When cells are bathed in a solution of the same osmolality as the cytoplasm, they neither shrink nor swell. Osmotic pressure results when concentrations of dissolved solutes on the inside and on the outside of a cell are different. The effects of osmotic pressure on cells in culture are too complex to be discussed in detail in this article. Here, we focus on the effect of osmotic pressure on hybridoma cells in regard to cell growth and antibody secretion rates. In an effort to improve antibody productivity of hybridoma cells, the effect of osmotic pressure on hybridoma cells has been extensively studied. As a result, the following observations have been made.

1. The response of hybridoma cells to osmotic pressure varies among cell lines (2,3).
2. For most hybridomas, hyperosmotic pressure induced by either sugar or ionized salts suppresses cell growth, but it increases the specific antibody secretion rate (q_{Ab})(2–8).

3. The enhanced q_{Ab} resulting from hyperosmotic pressure is not transient and is maintained in successive passages (9).
4. Hypo-osmotic pressure also suppresses cell growth, but it does not enhance q_{Ab} (10).

Hyperosmotic pressure, which can be induced by addition of cheap salts to media, has been suggested as being an economical solution to increase q_{Ab} in hybridoma cell cultures. Despite the potential of commercial strategies based on hyperosmotic pressure, the use of hyperosmolar medium has not been popular mainly because cell growth is depressed at elevated osmolality. Hence, the enhanced q_{Ab} in a batch culture does not result in a substantial increase in the final antibody concentration (2,4–6). To overcome this drawback, several strategies, such as adaptation of cells to hyperosmotic pressure (5,8), use of osmoprotectants in media (6,7,11), and two-stage culture (12), have been applied for improved antibody production. This article deals with the responses of hybridoma cells to osmotic pressure and its application to hybridoma cell cultures for improved antibody production.

OSMOLALITY

Osmolality is a measure of concentration and is often expressed in units of osmoles. The most commonly used abbreviation, based on milliosmoles per kilogram, is mOsm/kg. One osmole of a substance is equal to 1 g mol divided by the number of particles formed by the dissociation of the molecules. If a solution is composed of a nondissociable solute, the osmolality is simply equal to the molality. For a solution of a dissociable salt, 1 mol solution is n osmole, where n is the number of ions produced per molecule.

In the literature, the terms osmolarity and osmolality are frequently used interchangeably. Osmolality is related to osmolarity in the same manner as molality is related to molarity. Thus, osmolality is a more accurate description of concentration because it is a mass per unit mass measurement and is independent of temperature.

Osmolality values of media cannot be easily calculated because media contain a wide range of compounds as well as degrees of ionization. The osmolality of the media is determined more easily by using either vapor pressure elevation or freezing-point depression. The osmometers operate based on the principle that changes in osmolalities of a solution result in changes in certain properties such as vapor pressure and freezing point. Osmolality values measured by osmometers give reliable and reproducible results with a standard deviation of less than 5%.

MEDIUM OSMOLALITY

Medium osmolality is one of the important factors that is frequently overlooked in cultivating mammalian cells. Cell culture medium is designed to have osmolality in the range of 280 to 320 mOsm/kg, basically to mimic the osmolality of serum at 290 mOsm/kg (1). The major component in maintaining osmotic pressure in cell culture media is NaCl. Other inorganic ions (K^+, Mg^{2+}, Ca^{2+}) and glucose also contribute significantly. On the other hand, larger molecules like proteins play a lesser role, and changes in their concentrations do not affect osmolality significantly.

The measurement of osmolality is a useful control step if one makes up media. It is particularly important to check osmolality if alterations are made in the constitution of the medium. During batch culture, nutrients are consumed and metabolites such as lactate and ammonia are accumulated in the media. However, medium osmolality does not change significantly (9). The osmolality of culture media can change drastically as a result of evaporation when small-scale cultures such as Petri-dish or open-plate cultures are incubated in nonhumidified incubators. In this case, a slightly hypotonic medium may be better to compensate for evaporation during incubation. Osmolality should be also carefully monitored in fed-batch culture where medium concentrates are repeatedly fed to the culture. Addition of medium concentrates results in a substantial increase in medium osmolality, although they do not contain major salts. Thus, the culture longevity, which is important for the design of high-yield processes, is often limited by elevated osmolality caused by repeated nutrient feedings (13,14).

EFFECT OF OSMOTIC PRESSURE ON HYBRIDOMA CELL GROWTH AND ANTIBODY PRODUCTION

Medium osmolality in the range of 280 to 320 mOsm/kg is known to be quite acceptable for most cells; therefore, most commercially available media are designed to have an osmolality of this range (1,15). As the osmolality goes far from this standard range, some obvious changes in cell size, cell shape, nutrient transport, cellular synthesis, specific growth rate (μ), and q_{Ab} occur. Among these changes, the most important changes for cell culturists are probably those in μ and q_{Ab}. The common osmolyte used for altering the medium osmolality is NaCl. As summarized in Table 1, elevated osmolality suppresses cell growth and increases q_{Ab}. The q_{Ab} increased up to 3.2-fold for cells grown above 300 mOsm/kg and up to 435 mOsm/kg. However, because of the depressed cell growth at higher osmolalities, similar final antibody titers were obtained in most cases.

Regardless of serum concentrations, cultivation methods (static and suspension cultures), and basal media (IMDM, DMEM, and RPMI 1640), hyperosmotic pressure substantially enhanced q_{Ab} of S3H5/γ2bA2 hybridoma in batch culture by depressing cell growth, although the degree of enhancement in q_{Ab} was influenced (2,9,10).

Ozturk and Palsson (4) altered the osmolality of the medium by addition of both ionic (NaCl- and phosphate-buffered saline) and nonionic substances (sucrose). Similar data were obtained regardless of the osmolytes used. Thus, the changes in cells in hyperosmolar media described earlier appear to be caused only by medium osmolality.

If the enhanced q_{Ab} at elevated osmolality is not transient, it can be used to maximize antibody productivity in perfusion culture systems where cell growth and production are separated. As shown in Figure 1, the enhanced q_{Ab} of hybridoma at elevated osmolality decreased while the cells were adapting to hyperosmotic pressure in long-term,

Table 1. Effect of Osmolality on Antibody Production in Batch Culture

Cell line	Osmolality (mOsm/kg)	Media	Relative q_{Ab}	Relative antibody titer	References
Hybridoma (S3H5/γ2bA2)	281	IMDM	1.0	1.00	9,15
	390	IMDM	2.5	0.86	
Hybridoma (DB9G8)	281	IMDM	1.0	1.0	2,9,15
	390	IMDM	1.1	0.9

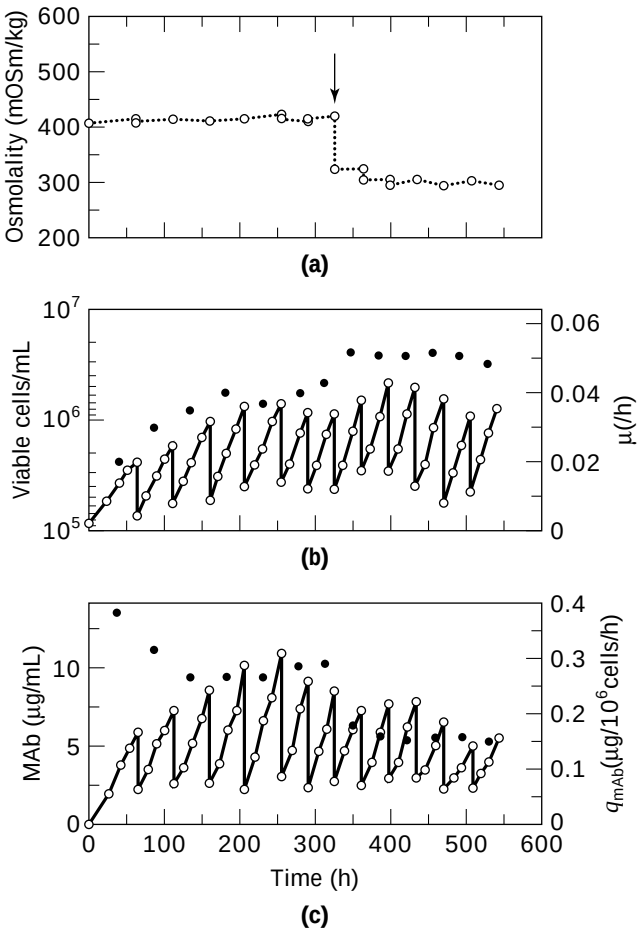

Figure 1. Repeated-fed batch culture in a spinner flask. (**a**) Osmolality, (**b**) viable cell concentration (○) and μ (●); (**c-**) antibody concentration (○) and q_{Ab} (●). The *arrow* indicates the time of switching hyperosmolar medium to standard medium.

repeated-fed-batch culture (9). However, the cells even after adaptation could still maintained the significantly enhanced q_{Ab} when compared with the q_{Ab} of cells obtained from standard medium in the batch culture, indicating the potential of using hyperosmolar medium for improved antibody production in a perfusion culture. In addition, when the hyperosmolar medium switched back to a standard medium, the physiological changes of the cells resulting from hyperosmotic pressure rapidly disappeared. Accordingly, the q_{Ab} and μ in perfusion systems may be controlled simply by changing the osmolality of medium. However, it should be noted that all the hybridomas do not display enhanced q_{Ab} at elevated osmolality. Cell-line specificity will be discussed in a later section.

Although much work has been performed on the response of hybridomas to hyperosmotic pressure, there are, to date, few reported studies on the response of hybridomas to hypoosmotic pressure.

Ryu and Lee reported the response of hybridomas (S3H5/γ2bA2 and DB9G8) to hypo-osmotic pressure resulting from NaCl subtraction (10). As shown in Figures 2 and 3, both hybridomas showed similar responses to hyperosmotic pressure in regard to cell growth and antibody production. The cell growth and antibody production at 276 mOsm/kg were comparable to those at 329 mOsm/kg (standard DMEM). Both cells grew well at 219 mOsm/kg, although their growth and antibody production were slightly decreased. When the osmolality was further decreased to 168 mOsm/kg, the cell growth did not occur. When subjected to hyperosmotic stress, both cells displayed significantly enhanced q_{Ab}. However, the cells subjected to hypoosmotic pressure did not display enhanced q_{Ab}.

Taken together, medium osmolality is one of the important factors that can be easily manipulated by addition or subtraction of inorganic salts or sugars. When subjected to hyperosmotic pressure, most hybridomas display enhanced q_{Ab} by suppressing cell growth. Hypo-osmotic pressure also suppresses cell growth but does not enhance q_{Ab}.

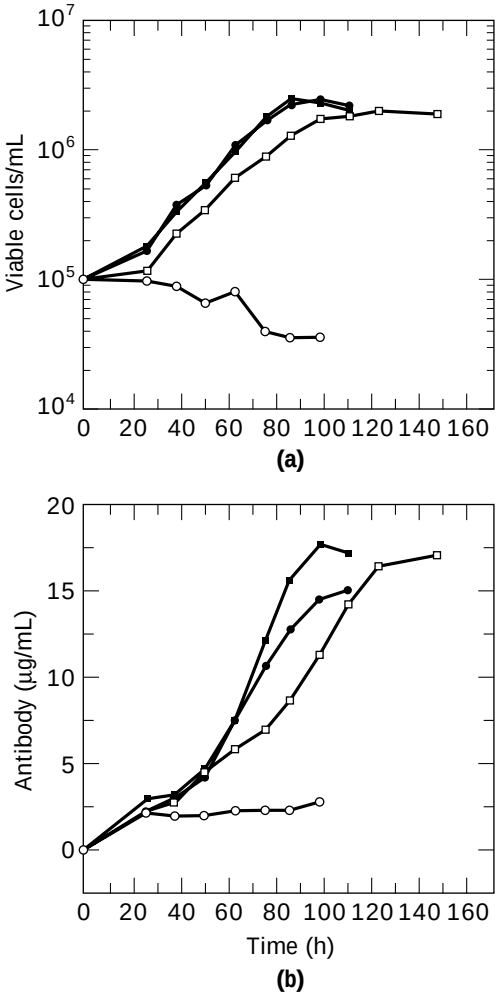

Figure 2. Cell growth (**a**) and antibody production (**b**) during a batch culture of S3H5/γ2bA2 hybridoma cells in hyperosmolar media. Data points: ○, 168; □, 219; ●, 276; ■, 329 mOsm/kg.

ENHANCED SPECIFIC ANTIBODY SECRETION RATE OF HYBRIDOMAS RESULTING FROM HYPEROSMOTIC PRESSURE IS CELL-LINE SPECIFIC

As mentioned earlier, some hybridomas do not display enhanced q_{Ab} at elevated osmolality.

Reddy and Miller reported the effects of osmotic pressure on antibody production in hybridoma cells that differed in production kinetics (3). AB2-143.2 cells exhibit non-growth-associated antibody production, whereas IND1 cells exhibit growth-associated production. Both hybridomas displayed enhanced q_{Ab} after abrupt batch osmotic stress. AB2-143.2 cells also increased q_{Ab} in response to gradual osmotic stress in continuous culture. In contrast, IND1 cells decreased q_{Ab} during gradual osmotic stress. It was hypothesized that this difference between cell lines in response to gradual osmotic stress in continuous culture might be related to the fact that antibody production is growth-associated in IND1, but not in AB2-143.2 cells.

Lee and Park (2) reported that two murine hybridomas exhibiting non-growth-associated antibody production (S3H5/γ2bA2 and DB9G8) showed different responses to hypersomotic pressure regarding q_{Ab}, although they showed similar depression of cell growth in hyperosmolar media. The q_{Ab} of S3H5/γ2bA2 hybridoma in a hyperosmolar medium (396 mOsm/kg) was enhanced by approximately 180% when compared with that in a standard medium (283 mOsm/kg), whereas q_{Ab} of DB9G8 hybridoma in the same hyperosmolar medium was enhanced by only 10%. Accordingly, regardless of antibody production kinetics of the cell lines, enhanced q_{Ab} of hybridomas resulting from hyperosmotic pressure appears to be cell-line specific. Thus, the strategy of using hyperosmolar media for improved antibody production cannot be applied for all cell lines.

EXPLANATION FOR ENHANCED Q_{AB} AT ELEVATED OSMOLALITY

Although the detailed mechanism of enhanced q_{Ab} is not clearly understood at the basic cellular level, several explanations based on noticeable changes induced by hyperosmotic pressure can be proposed for possible influences of NaCl on cellular functions and antibody production.

1. The increase in osmotic pressure may enhance the transport of nutrients, in particular, amino acids into the cells (5,8,11). Amino acid transport regulations in animal cells are controlled by both Na^+ ion-dependent and Na^+ ion-independent transport systems (16). Excess Na^+ ions on the outer membrane would increase the transmembrane electrochemical gradient, facilitating the simultaneous flow of ions and amino acids into the cells. Thus, the feeding of excess nutrients into the cell could increase cytoplasmic protein production, especially antibody productivity in hybridomas. The release of additional energy and precursors as a result of increased metabolism is not diverted to growth but to the synthesis and secretion of antibody (5). For hypersomotically stressed hybridomas, amino acid uptake by Na^+-dependent system A increases, whereas the activity of other Na^+-independent systems remains relatively unchanged (8). Proline, alanine, and glutamine, which are transported by this Na^+-dependent system A under hyperosmotic condition, are known to act as osmoprotective agents to compensate for osmotic imbalance of the environment (7,17). This observation would support a model for cell volume swelling and increased q_{Ab} at elevated osmolality. However, this postulate will have to be investigated further because it does not explain the workings of other osmolytes like sucrose or KCl (4,6,8). Table 2 shows that the enhancement of q_{Ab} of hybridomas subjected to hyperosmotic stress is not influenced significantly by the sources of osmotic stress.

2. The increase in osmotic pressure may induce transcriptional activation because of the change of chromatin structure, as is observed in the case of butyrate treatment (8,18–22). Acetylation of histone residue is thought to act as a transcription-stimulating event in many organisms. Unbinding of the histones from DNA results in the disper-

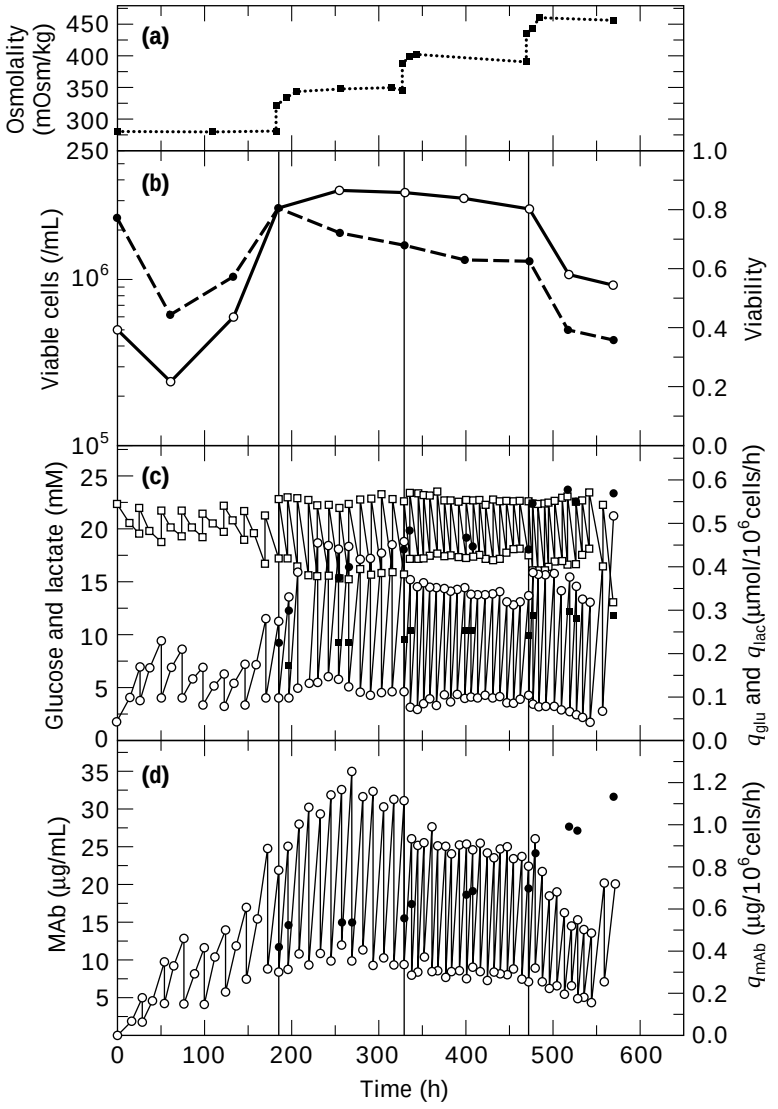

Figure 5. Immobilized cell culture with gradual hyperosmotic stress: (**a**) osmolality; (**b**) viable cell concentration of immobilized cells (○) and viability (●); (**c**) glucose (□) and lactate concentrations (○), q_{glu} (■), and q_{lac} (●); (**d**) antibody concentration (○) and q_{Ab} (●). The *vertical lines* indicate the time of elevating the osmolality of medium.

sal of the chromatin structure, which may expose segments of the chromatin, making them more accessible to RNA polymerase for mRNA transcription (21). In fact, elevated mRNA expression of certain proteins has been reported after treatment of butyrate (18,22–24).

3. The increase in osmotic pressure may stimulate the expression of chaperone-like proteins in the endoplasmic reticulum (ER) such as protein disulfide isomerase (PDI) or glucose-regulating proteins (GRPs) that are involved in protein processing and secretion (25,26).

All these postulates, however, should be confirmed by concrete experimental data, and solid, detailed mechanisms or sequential events that explain increased q_{Ab} will have to be discovered.

APPLICATION OF HYPEROSMOTIC PRESSURE TO ANTIBODY PRODUCTION PROCESSES

Hyperosmotic stress resulting from NaCl addition has been suggested as being an economical solution to increase the q_{Ab} in hybridoma cultures. However, the use of hyperosmolar medium has not been popular probably because of the following reasons. Because the enhanced q_{Ab} of hybridomas resulting from hyperosmotic stress is cell-line specific (2,3), the hyperosmolar medium cannot be used for all cell lines. Furthermore, cell growth is depressed at elevated osmolality. Hence, the enhanced q_{Ab} in batch culture does not result in a substantial increase in the final antibody titer (2,4–6). To overcome these drawbacks, the following strategies have been applied for improved antibody production.

1. Hybridoma cells are first adapted to higher osmolality media to elevate antibody levels (5,8). Before adaptation, 2HG11 hybridoma cells placed in higher osmotic pressures (350 and 400 mOsm/kg) were severely suppressed in growth down to 25% of the control (300 mOsm/kg), although total antibody titers achieved were similar to the control. After 1 week of adaptation to 350 and 400 mOsm/kg media, cell growth was not as drastically suppressed. As a result, considerably higher antibody levels were obtained at these elevated osmolalities (Table 3).

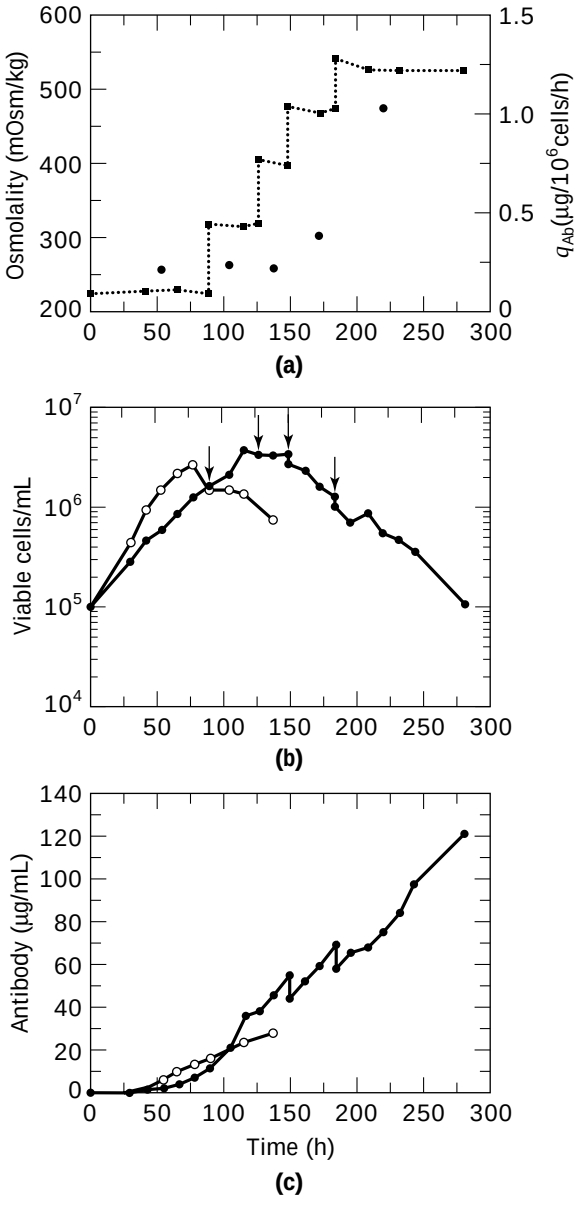

Figure 6. Fed-batch culture using a hypo-osmolar medium as an initial basal medium. (**a**) Changes in medium osmolality (■) and q_{Ab} (●). (**b**) Cell growth in batch (○) and fed-batch (●) cultures. The *arrows* indicate the addition of medium concentrates. (**c**) Antibody production in batch (○) and fed-batch (●) cultures.

2. Osmoprotective compounds, especially glycine betaine, are included in hyperosmolar media (6,7,11). Osmoprotective agents are known to exert osmoprotective effects by being accumulated inside cells to compensate for osmotic imbalance between in and out of the cells. Glycine betaine, sarcosine, proline, and glycine have all been shown to be strong osmoprotective compounds for 6H11 hybridoma cells under various hyperosmotic stress, with glycine betaine being the most effective of the four (6). When glycine betaine was included in the hyperosmolar media, q_{Ab} was increased up to 2.6-fold and maximum antibody titer up to twofold over that obtained in the control culture, as shown in Figure 4. A similar pattern of response was observed when other osmoprotective compounds (sarcosine, proline, glycine) were included in the hyperosmolar media. The improvement of cell growth by use of osmoprotective compounds did not cost increased q_{Ab} obtained under hyperosmotic condition, suggesting that medium osmolality, rather than growth rate, will determine the q_{Ab} by 6H11 hybridoma cells growing in hyperosmolar media. The use of osmoprotective compounds does not influence hyperosmotically enhanced specific metabolic rates. Accordingly, the simultaneous use of hyperosmotic stress and osmoprotective compounds can be a means to increase both q_{Ab} and maximum antibody titer in hybridoma cell culture.

3. The enhanced q_{Ab} resulting from hyperosmotic stress can be used for a higher volumetric antibody productivity in perfusion systems where cell growth and antibody production are separated. In perfusion systems such as hydrogel beads or hollow fibers, the cells maintain minimal growth rates after the cell concentrations are saturated. Thus, after achieving high cell concentration in perfusion systems, the switch of standard medium to hyperosmolar medium may significantly improve the volumetric productivity. A feasibility of using hyperosmolar medium resulting from NaCl addition for improved antibody production in a perfusion system was demonstrated by using calcium-alginate-immobilized S3H5/γ2bA2 hybridoma cells (12). First, immobilized cells were grown in the medium supplemented with 10% serum to achieve high cell concentration rapidly. Second, after the cell concentration reached more than 2×10^6 cells/mL, the medium was switched to the hyperosmolar medium supplemented with 1% serum for economical antibody production. An abrupt increase in osmolality, however, inhibited cell growth, resulting in no increase in volumetric antibody productivity. On the other hand, gradual increase in osmolality allowed further cell growth while maintaining the enhanced q_{Ab} of immobilized cells, as shown in Figure 5. Accordingly, the volumetric antibody productivity was increased by about 40% when compared with that in the control immobilized cell culture. This enhancement of volumetric antibody productivity of immobilized hybridoma cells by applying hyperosmolar stress suggests the potential of using hyperosmolar medium in other perfusion systems for improved antibody production.

APPLICATION OF HYPO-OSMOTIC PRESSURE TO ANTIBODY PRODUCTION PROCESSES

Cell culture longevity in fed-batch culture of hybridomas is often limited by elevated medium osmolality caused by repeated nutrient feedings (13,14). Shotwise feeding of 10× DMEM concentrates elevated the osmolality of medium up to 540 mOsm/kg at the end of fed-batch culture of S3H5/γ2bA2 hybridoma, which is known to be lethal to most hybridomas. S3H5/γ2bA2 hybridoma has been shown to grow without significant growth depression at 219 mOsm/kg in DMEM supplemented with 10% fetal bovine serum. In order to improve culture longevity in fed-batch culture of S3H5/γ2bA2 hybridoma, a hypo-osmolar medium (223 mOsm/kg) was used as an initial basal medium

(27). As shown in Figure 6, the use of hypo-osmolar medium delayed the onset of severe cell death resulting from elevated osmolality and allowed one more addition of 10× DMEM concentrates to the culture. As a result, a final antibody concentration obtained was 121.5 μg/mL, which is approximately 1.5-fold higher compared to fed-batch culture using a standard medium (335 mOsm/kg). When compared to batch culture, a 5.2-fold increase in the final antibody titer was achieved. Taken together, the use of hypo-osmolar medium as an initial medium in fed-batch culture improved culture longevity of S3H5/γ2bA2 hybridoma, resulting in substantial increase in the final antibody titer.

In conclusion, hyperosmotic pressure, which can be induced by addition of cheap salts to media, has been suggested as being an economical solution to increase q_{Ab} in hybridoma cell cultures. The utilization of osmotic pressure for improved antibody production in hybridoma cell cultures will be substantiated in future.

OUTLINE

INTRODUCTION

Pantothenic acid (*R*- or D-(+)-*N*-(2,4-dihydroxy-3,3-dimethyl-1-oxobutyl)-*β*-alanine; for chemical formula, see Table 1) was first isolated in the 1930s from liver and found to be an essential growth factor for yeasts (15). During this period it was also identified independently with the chick antidermatitis factor, the filtrate factor, the chick antipellagra factor, and an essential growth factor for lactic acid bacteria. Later these activities were shown to be identical with those of pantothenic acid. Because the factor could be obtained from a variety of plants and animal tissues, Williams named it pantothenic acid, meaning "from everywhere." The compound is also referred to as vitamin B_5. It was independently synthesized by two groups in 1940.

Pantothenic acid occurs in living organisms of all types, both in a free form and in conjugated forms such as coenzyme A, pantetheine (*Lactobacillus bulgaricus* factor), and 4′-phosphopantetheine (*Acetobacter suboxydans* factor) (see Table 1). The coenzyme form of the vitamin, coenzyme A, was discovered as an essential cofactor for the acetylation of sulfonamide in the liver and the acetylation of choline in the brain by Lipmann and coworkers (16). It has been since identified with "active acetate" and has been found to be essential for a variety of biochemical transacylation reactions. 4′-Phosphopantetheine is also a coenzyme form of pantothenic acid that functions as a prosthetic group of the acyl carrier protein of fatty acid synthetase, citrate-cleaving enzyme, and enzymes involved in the synthesis of peptide antibiotics. These early studies have been reviewed by several authors (15–20).

CHEMISTRY

Pantothenic acid can be obtained as a colorless, viscous oil by drying under high vacuum in P_2O_5. It is an acid and has a marked tendency to absorb water from the air. Under alkaline hydrolysis, it breaks down into *β*-alanine and pantoic acid. The latter readily forms a lactone, D-(−)-pantolactone, in acid solution or on heating. Acid hydrolysis of pantothenic acid gives *β*-alanine and pantolactone. Pantothenic acid is soluble in water, ethyl acetate, dioxane, acetic acid, ether, and amyl alcohol but is insoluble in benzene and chloroform.

The structure of pantothenic acid contains a single asymmetric center, so that it is optically active; only the natural D-(+)-isomer has vitamin activity. The absolute configuration of the vitamin has been defined as *R* (21). The conformation of the vitamin has also been reported (22).

The calcium salt of pantothenic acid, which can be obtained as needle crystals from methanol, is moderately hygroscopic and is rather more stable to heat, air, and light than is the free acid. It is soluble in water and glycerol and slightly soluble in alcohol and acetone. Reviews by Baddiley (23) and Wagner and Folkers (17) summarized early studies on the chemistry of pantothenic acid.

The naturally occurring derivatives of pantothenic acid (see Table 1) can be grouped into three types on the basis of their chemical structures: simple pantothenate derivatives, pantetheine derivatives in which cysteamine (or its analogs) attaches by an amide linkage, and coenzyme A derivatives in which the pantetheine is adenosylylated (Fig. 1).

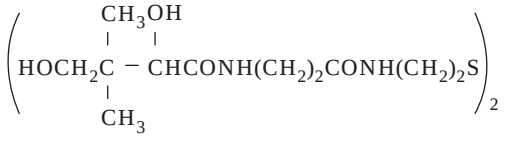
Pantothenyl alcohol, an alcohol analog of pantothenic acid, is also a pharmaceutically important unnatural derivative. Unnatural analogs of pantothenic acid and coenzyme A have been reviewed by Shimizu (10).

Table 1. Panthothenic Acid and Its Naturally Occurring Derivatives

D-Pantothenic acid  $C_9H_{17}NO_5$ MW: 219·23	Unstable, viscous oil. Extremely hydroscopic, easily decomposed by acids, bases, heat. Soluble in water, ethyl acetate, dioxane, glacial acetic acid; moderately soluble in ether, amyl alcohol; insoluble in benzene, chloroform. Solutions are stable between pH 5 and 7. $[\alpha]_D^{25}$ + 37.5°. (From Stiller et al. [1].)
Calcium D-pantothenate  $C_{16}H_{32}CaN_2O_{10}$ MW: 476·53	White needles. Moderately hygroscopic. Soluble in water, glycerol; slightly soluble in alcohol, acetone; insoluble in ether, benzene, chloroform. Decomposed by bases. Solutions are stable between pH 5 and 7. mp 195–196° (dec); $[\alpha]_D^{25}$ + 28.2 °C (c = 5).
Sodium D-pantothenate  $C_9H_{16}NaNO_5$ MW: 241·21	White, hygroscopic crystals. Decomposed by acids and bases. Solutions are stable between pH 5 and 7. mp 122–124° $[\alpha]_D^{25}$ + 27.1° (c = 2). For solubility, see calcium pantothenate.
4′-Phosphopantothenic acid (Ba salt)  $C_9H_{16}NO_8P$ MW: 313·27	Soluble in water; insoluble in ethanol. Unstable to bases. Free acid is unstable. $[\alpha]_D^{24}$ + 9.0° (c = 3.3) (From King and Strong [2] and Okada et al. [3].)
Pantothenoyl-L-cysteine (Ba salt)  $C_{12}H_{22}N_2O_6S$ MW: 322·38	Soluble in water, methanol; moderately soluble in ethanol; insoluble in ether. Unstable to acids and bases. $[\alpha]_D$ −14° (c = 2). (From Ohta et al. [4].)
4′-Phosphopantothenoyl-L-cysteine (Ba salt)  $C_{12}H_{23}N_2O_4PS$ MW: 416·42	Soluble in water; slightly soluble in alcohol. Unstable to acids and bases. Easily oxidized in air. $[\alpha]_D^{20}$ 0° (c = 2). (From Baddiley and Mathias [5] and Nagase [6].)
Pantetheine  $C_{11}H_{22}N_2O_4S$ MW: 278·37	Syrup or glass. Soluble in water; slightly soluble in alcohol; insoluble in ether, benzene, chloroform, ethyl acetate. Unstable to acids and bases. Easily oxidized in air. $[\alpha]_D^{23}$ + 12.2° (c = 3.45). *Lactobacillus bulgaricus* factor. (From Shimizu et al. [7].)

Table 1. Panthothenic Acid and Its Naturally Occurring Derivatives (*continued*)

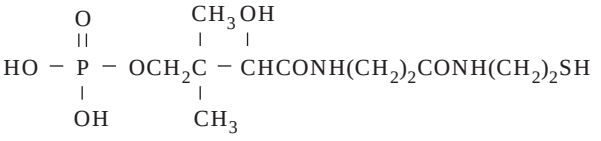
Pantetheine



$C_{22}H_{42}N_4O_5S_2$ MW: 554·72

Disulfide form of pantetheine. Glassy, colorless to light yellow substance. Unstable to acids. $[\alpha]_D^{23}$ + 17.1° (c = 3.2). For solubility and references, see pantetheine.

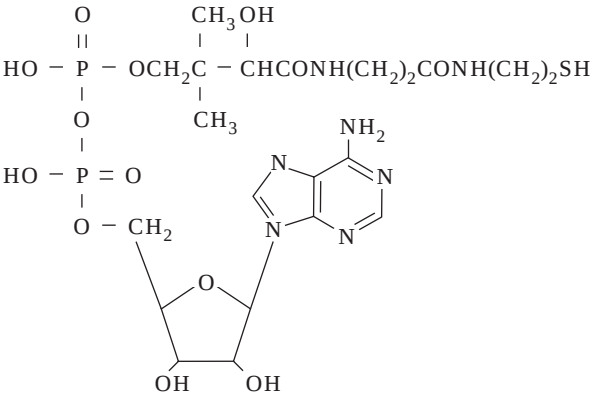
4′-Phosphopantetheine (Ba salt)



$C_{11}H_{23}N_2O_7PS$ MW: 358·35

Soluble in water; slightly soluble in ethanol; insoluble in ether. Unstable to acids and bases. Easily oxidized in air. $[\alpha]_D^{23}$ + 13.3° (c = 2.25). Oxidized form, $[\alpha]_D^{23}$ + 12.2°. *Acetobacter suboxidans* factor. (From Baddiley and Thain [8], Moffatt and Khorana [9], and Nagase [6].)

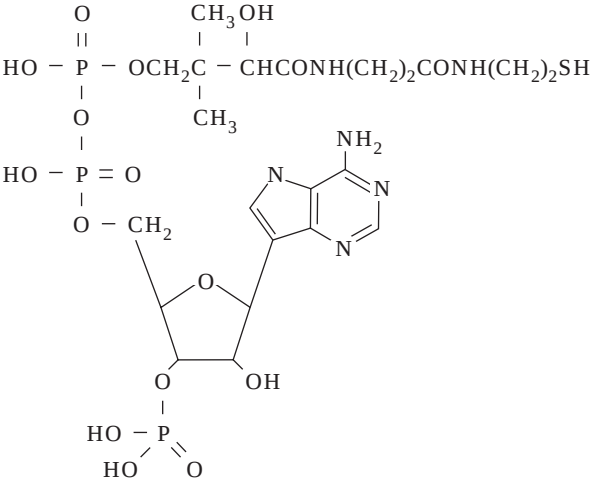
Dephospho-coenzyme A (Li salt)



$C_{21}H_{35}N_7O_{12}P_2S$ MW: 687·56

Soluble in water, methanol; insoluble in acetone. Unstable to acids and bases. For references, see coenzyme A.

Coenzyme A



$C_{21}H_{36}N_7O_{16}P_3S$ MW: 767·55

Soluble in water; insoluble in ethanol, ether, acetone. Decomposed to pantetheine-2′,4′-cyclic phosphate and 3′,5′-ADP in 1 N NaOH (100°, 2 min). Decomposed to pantetheine-4′-phosphate and adenine in 1 N HCl (100°, 5 min). Easily oxidized in air. (From Moffatt and Khorana [9], Shimizu [10], and Shimizu et al. [11].)

Table 1. Panthothenic Acid and Its Naturally Occurring Derivatives (*continued*)

4′-Phosphopantetheine-*S*-sulfonate (Ca salt)  $C_{11}H_{23}O_{10}N_2S_2P$ MW: 438·41	Soluble in water. $[\alpha]_D^{22}$ + 7.2° (c = 1.95). *Bifidus* factor. (From Yoshioka and Tamura [12].)
4′-*O*-(*β*-glucopyranosyl)-D-pantothenic acid  $C_{44}H_{25}O_{14}N$ MW: 791·68	Soluble in water. $[\alpha]_D^{23}$ −18.2° (c = 1.0). Growth factor of *Leuconostoc*. (From Amachi et al. [13].)
OA-6129A (Na salt)  $C_{20}H_{31}N_3O_7S$ MW: 457·54	Unstable to acids and bases. $[\alpha]_D^{24}$ + 11.6° (c = 1.0). Antibiotic produced by *Streptomyces* sp. OA-6129. (From Yoshioka et al. [14].)

BIOSYNTHESIS

Although pantothenic acid cannot be synthesized by animals, microorganisms and plants are generally able to produce it from the precursors pantoic acid and *β*-alanine through catalysis of the enzyme pantothenate synthetase (EC 6.3.2.1). Animals, plants, and microorganisms can convert pantothenic acid to 4′-phosphopantetheine and coenzyme A, the metabolically active forms of the vitamin. The pathway for the biosynthesis of pantothenic acid and coenzyme A has been elucidated by several workers since the early 1950s and has been reviewed (24–27). The pathway

leading to the vitamin and the coenzymes from common precursors can be summarized as shown in Figures 2 and 3.

β-Alanine

Three routes to β-alanine have been reported. Several microorganisms have been reported to form β-alanine by α-decarboxylation of L-aspartic acid (Fig. 2; reaction 1). Confirmatory evidence for this conversion was provided by Williamson and Brown (28), who purified (to apparent homogeneity), from extracts of *Escherichia coli*, an enzyme that catalyzes the α-decarboxylation of L-aspartic acid to yield β-alanine and CO_2. These investigators also reported that the enzyme is missing in a mutant of *E. coli* that requires either β-alanine or pantothenate as a nutritional factor, but is present in the wild-type strain and in a revertant strain of the mutant. It has also been suggested, on the basis of the observation that mutants of *Salmonella typhimurium* lacking the ability to degrade uracil require *N*-carbamoyl-β-alanine, β-alanine, or pantothenate, as a nutritional factor, that β-alanine is produced by decarboxylation of *N*-carbamoyl-β-alanine formed from uracil (Fig. 2; reactions 2–4) (29). β-Alanine may also be produced by transamination of malonylsemialdehyde produced from propionic acid (Fig. 2; reaction 5 or 6), because enzyme activity catalyzing this conversion has been detected in several microorganisms. However, there have been no further studies concerning this reaction.

Pantoic Acid

The route to pantoic acid from pyruvate (as shown in Fig. 2) has been elucidated mainly in *E. coli* and *Neurospora crassa*. Two enzymes catalyzing the conversion of pyruvate to α-ketoisovalerate (Fig. 2; reactions 7 and 8) in this route are shared by the route for the biosynthesis of the branched chain amino acids. In *E. coli*, two enzyme activities have been detected for the conversion of α-ketoisovalerate to ketopantoic acid (Fig. 2; reaction 9): one is dependent on tetrahydrofolate and the other is not. The physiological significance of tetrahydrofolate-independent activity seemed to be questionable because of its high K_m values for formaldehyde (10 mM) and α-ketoisovalerate (100 mM). Because a mutant lacking tetrahydrofolate-dependent activity requires pantothenate for growth although the same amount of tetrahydrofolate-independent activity is found in the same mutant, concrete evidence is provided to support the theory that the tetrahydrofolate-dependent enzyme is responsible for the ketopantoate needed for the biosynthesis of pantothenate. The tetrahydrofolate-dependent enzyme (i.e., ketopantoate hydroxymethyltransferase, EC 2.1.2.11) has been purified and characterized in some detail. The observation that pantoate, pantothenate, and coenzyme A are all allosteric inhibitors of this enzyme also supports this conclusion (30,31).

The reduction of ketopantoic acid to D-pantoic acid (Fig. 2; reaction 10) is catalyzed by an NADPH-dependent enzyme, ketopantoic acid reductase (EC 1.1.1.169). This enzyme activity has been detected in *Saccharomyces cerevisiae* and *E. coli*. The same reduction is also catalyzed by α-acetohydroxy acid isomeroreductase (EC 1.1.1.1.86), which is the enzyme responsible for the conversion of α-acetolactate to α-ketoisovalerate (Fig. 2; reaction 8) (32). Recently, Shimizu et al. (33) isolated ketopantoic acid reductase in a crystalline form from *Pseudomonas maltophilia* and characterized it in some detail. They also demonstrated that this reductase is the enzyme for D-pantoic acid formation, necessary for the biosynthesis of pantothenic acid, because mutants lacking this enzyme require either D-pantoic acid or pantothenate for growth and the revertants regain this activity.

Coenzyme A

The pathway for the biosynthesis of coenzyme A from pantothenic acid, L-cysteine, and ATP (Fig. 3) was first demonstrated by Brown (34,35) on the basis of his studies with *Proteus morganii* and early observations in the 1950s with pig liver and other organisms. Later, the validity of this pathway was confirmed by Abiko and coworkers, who separated and characterized the enzymes involved in this pathway in rat liver (26).

The first step in this pathway is the phosphorylation of pantothenic acid (Fig. 3; reaction 1) by pantothenate kinase (EC 2.7.1.33). The enzyme has been purified and characterized from rat liver (36) and *Brevibacterium ammoniagenes* (37). Both enzymes undergo allosteric inhibition by coenzyme A, the end product of the pathway. Because such feedback inhibition by coenzyme A is observed only at this step and no other regulation mechanism is known, this inhibition seems to be the most important mechanism for controlling the cellular level of coenzyme A. Pantetheine is also phosphorylated by the same enzyme to yield 4′-phosphopantetheine (Fig. 3; reaction 7), which can be converted to coenzyme A.

The condensation of 4′-phosphopantothenic acid with L-cysteine to yield 4′-phosphopantothenoyl-L-cysteine (Fig. 3; reaction 2) is catalyzed by 4′-phosphopantothenoyl-L-cysteine synthetase (EC 6.3.2.5). The mammalian enzyme requires ATP as energy for the condensation, whereas the bacterial enzyme preferably utilizes CTP (34). 4′-Phosphopantothenoyl-L-cysteine is then decarboxylated to yield 4′-phosphopantetheine (Fig. 3; reaction 3) by 4′-phosphopantothenoyl-L-cysteine decarboxylase (EC 4.1.1.36). The enzyme has been shown to be independent of pyridoxal 5′-phosphate. This step is the only one that does not require ATP among the five steps in the biosynthesis of this coenzyme.

The pyrophosphate linkage formation between 4′-phosphopantetheine and ATP to yield 3′-dephosphocoenzyme A (Fig. 3; reaction 4), and its phosphorylation (Fig. 3; reaction 5) are catalyzed, by dephosphocoenzyme A pyrophosphorylase (EC 2.7.7.3) and dephospho-coenzyme A kinase (EC 2.7.1.24), respectively. In rat liver, both enzymes are present as a complex or a bifunctional enzyme (38). The reversibility of the former reaction may be important for controlling cellular levels of coenzyme A and 4′-phosphopantetheine.

The presence of an alternate route to yield 4′-phosphopantetheine via pantetheine (Fig. 3; reactions 6 and 7) has been suggested in *Acetobacter suboxydans*, *Lactobacillus*

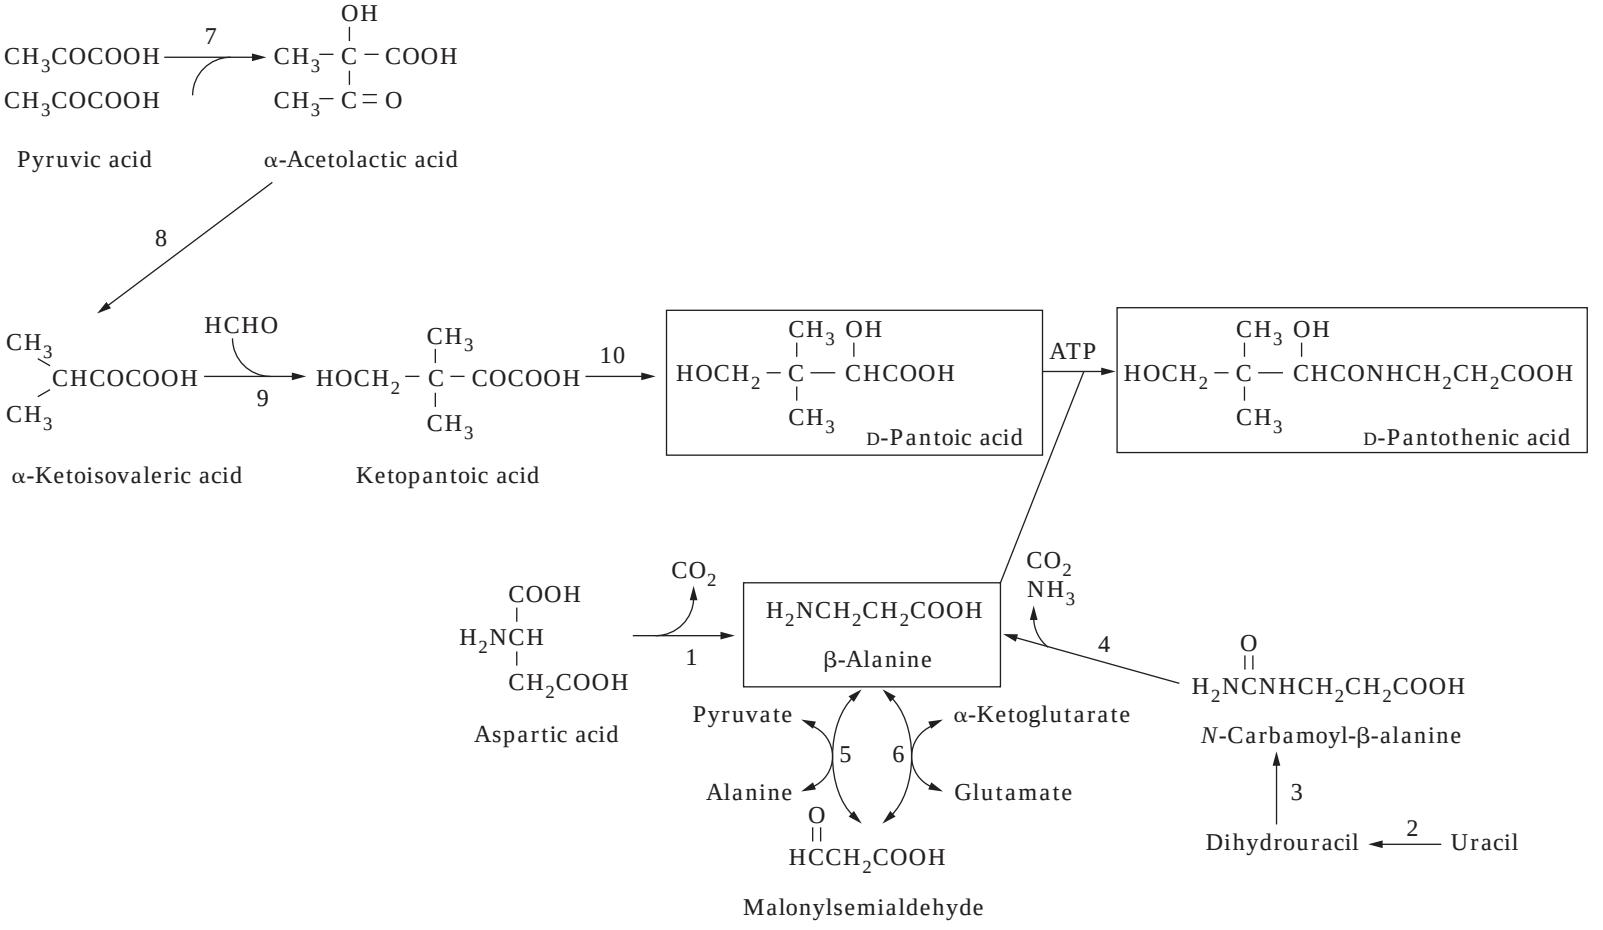

Figure 2. The pathway for the biosynthesis of pantothenic acid.

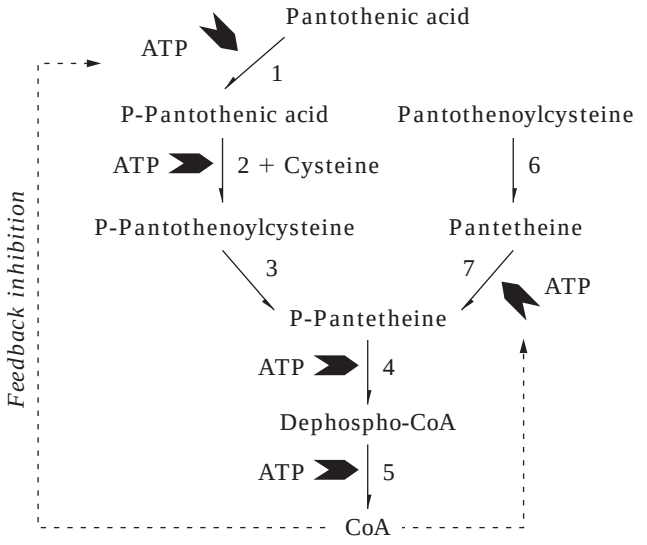

Figure 3. The pathway for the biosynthesis of coenzyme A from pantothenic acid, L-cysteine, and ATP. For chemical structures of each compound, see Table 1. CoA, coenzyme A.

helveticus, and other microorganisms (35), but confirmatory evidence is not available.

Control Mechanisms for the Biosynthesis

The allosteric inhibition of ketopantoic acid hydroxymethyltransferase of *E. coli* by D-pantoic acid, pantothenic acid, or coenzyme A may be involved as a control mechanism in pantothenate biosynthesis (30). On the other hand, such inhibition was not observed in the case of ketopantoic acid reductase of *Pseudomonas maltophilia* (33).

In the pathway to coenzyme A from pantothenic acid, the involvement of the feedback inhibition of pantothenate kinase by coenzyme A and 4′-phosphopantetheine as a control mechanism in the biosynthesis has been demonstrated (36,37,39). Because this inhibition was generally observed regardless of species and the other four steps following this reaction are not significantly inhibited by coenzyme A or 4′-phosphopantetheine, this may be one of the most important mechanisms in the control of cellular levels of coenzyme A. No other mechanism, such as repression, has been observed in either pantothenate or coenzyme A biosynthesis.

Pantetheinase, which specifically degrades pantetheine to pantothenic acid and cysteamine, may also be an important enzyme because coenzyme A can be degraded to pantetheine enzymatically and pantetheine can be reused as a precursor of coenzyme A after phosphorylation by pantothenate kinase. Cellular coenzyme A levels may be influenced by competition between pantetheinase and pantothenate kinase toward their substrate, pantetheine (40).

CHEMICAL AND MICROBIAL PRODUCTION METHODS

Pantothenic Acid

At present, commercial production of pantothenate depends exclusively on chemical synthesis. As outlined in Figure 4, the conventional chemical process involves reactions yielding racemic pantolactone from isobutyraldehyde, formaldehyde, and cyanide, optical resolution of the racemic pantolactone to D-(−)-pantolactone with quinine, quinidine, cinchonidine, brucine, and so on, and condensation of D-(−)-pantolactone with *β*-alanine. This is followed by isolation as the calcium salt and drying to obtain the final product. A problem associated with this chemical process apart from the use of poisonous cyanide is the troublesome resolution of the racemic pantolactone and the racemization of the remaining L-(+)-isomer. Therefore, most of the recent studies in this area have concentrated on development of an efficient method to obtain D-(−)-pantolactone.

Enzymatic resolution of racemic pantolactone can be carried out by specific fungal lactonohydrolases. Shimizu et al. found that many mold strains belonging to the genera *Fusarium*, *Gibberella*, and *Cylindrocarpon* stereospecifically hydrolyze D-(−)-pantolactone to D-(−)-pantoic acid (41,42). If racemic pantolactone is used as a substrate for the hydrolysis reaction by the microbial lactonohydrolase, only the D-(−)-pantolactone might be converted to D-(−)-pantoate and the L-(+)-enantiomer might remain intact. Consequently, the racemic mixture could resolved into D-(−)-pantoate and L-(+)-pantolactone as shown in Figure 5 (42,43). After the removal of L-(+)-pantolactone from the reaction mixture by solvent extraction, etc., remaining D-(−)-pantoate could be easily converted to D-(−)-pantolactone by heating under acidic conditions. The reverse reaction, that is, lactonization of D-(−)-pantoate, might also be possible for the resolution. In this case, D-(−)-pantoate in a racemic mixture of pantoate is specifically lactonized into D-(−)-pantolactone (see Fig. 5) (44). When *Fusarium oxysporum* mycelia were incubated in 700 g/L aqueous solution of racemic pantolactone for 24 h at 30 °C with automatic pH control (pH 6.8–7.2), about 90% of the D-(−)-isomer was hydrolyzed. The resultant D-(−)-pantoic acid in the reaction mixture showed a high optical purity (96% ee), and the coexisting L-(+)-isomer remained without any modification.

Practical hydrolysis of the D-(−)-isomer in a racemic mixture is carried out using immobilized mycelia of *F. oxysporum* as the catalyst. Stable catalyst with high hydrolytic activity can be prepared by entrapping the fungal mycelia in calcium alginate gels. When the immobilized mycelia were incubated in a reaction mixture containing 350 g/L racemic pantolactone for 21 h at 30 °C under automatic pH control (pH 6.8–7.2), 90–95% of the D-(−)-isomer was hydrolyzed (optical purity, 90–97% ee). After reactions repeated 180 times (i.e., for 180 days), the immobilized mycelia retained more than 90% of their initial activity (Fig. 6).

The overall process for the present enzymatic resolution is compared with the conventional chemical process in Figure 7. The enzymatic process allows skipping several tedious steps that are necessary in chemical resolution and is highly advantageous for practical purposes.

Coenzyme A

The production methods for coenzyme A roughly fall into chemical and microbial categories. The chemical methods,

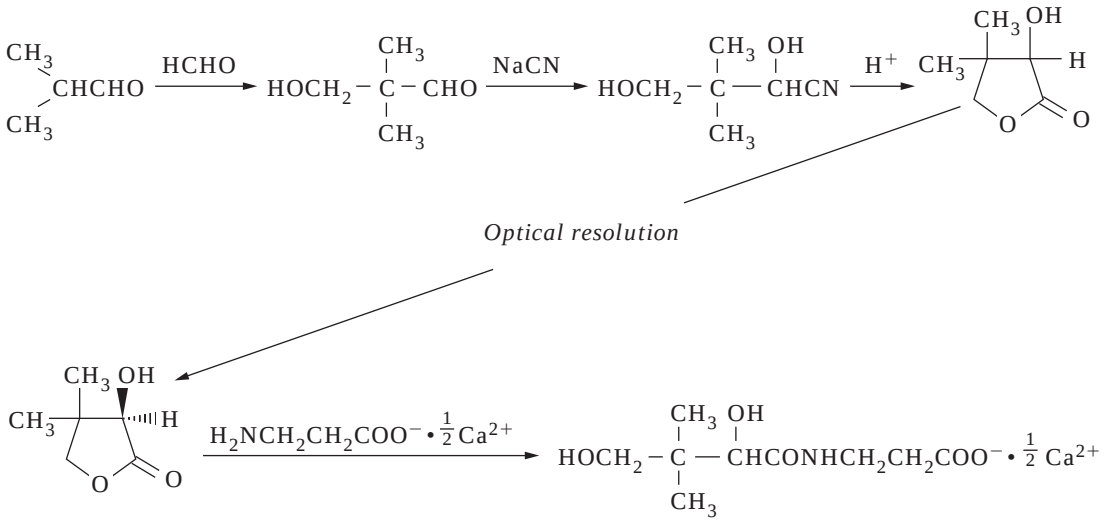

Figure 4. Outline of the chemical synthesis of D-pantothenic acid.

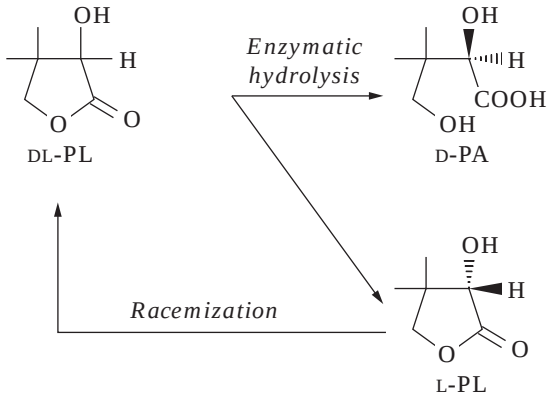

Figure 5. Schematic representation of the enzymatic resolution of racemic pantolactone. PL, pantolactone; PA, pantoate.

which have been reviewed by Shimizu (10) and Mautner (45), are too complex to be practical. Therefore, commercial production is carried out by microbiological methods. Extraction of coenzyme A from yeast cells has been performed since the early 1950s. Cells of baker's or brewer's yeasts, which are relatively rich in coenzyme A, were usually used as the source. Later, an efficient enzymatic method using *Brevibacterium ammoniagenes* cells as the catalyst was developed. These microbial methods have been reviewed by Shimizu and Yamada (46).

A successful enzymatic method using the biosynthetic route of coenzyme A from pantothenic acid, L-cysteine, and ATP was first reported by Ogata et al. (47), who found that *B. ammoniagenes* has all five enzymes necessary for the biosynthesis of coenzyme A in high activities. These three substrates, when added to a reaction mixture containing the bacterial cells, were converted to coenzyme A with a satisfactory yield (2–3 g/L). Ogata et al. also found that the same organism can accumulate coenzyme A directly in the culture medium on addition of pantothenic acid, L-cysteine, and AMP, adenosine, or adenine in the presence of a surfactant, cetylpyridinium chloride, and high levels of glucose (usually 10%), K_2HPO_4, and $MgSO_4 \cdot 7H_2O$. Under optimal conditions, the amount obtained was 5.5 g/L. Most coenzyme A in the medium was present in the disulfide form because of the vigorous shaking during the reaction. After treatment of the culture filtrate with Duolite S-30, charcoal, and Dowex 1 (Cl^-), and reduction of the disulfide, the very pure thiol form was obtained in high yield. The mechanism of this coenzyme A production has been suggested to be that shown in Figure 8 (for details, see Refs. 11 and 48).

To improve product yield further, the mechanism for regulation of biosynthesis was investigated. As described in the preceding section, the biosynthesis of coenzyme A in *B. ammoniagenes* is controlled mainly by the feedback inhibition of pantothenate kinase by coenzyme A. This was the main problem in the practical production, because the overproduced coenzyme A itself stopped the biosynthesis. Two methods to abolish this feedback inhibition have been reported.

A synthetic scheme was investigated in which the reaction is initiated by the condensation of 4′-phosphopantothenic acid and L-cysteine or the transadenosylylation of 4′-phosphopantetheine, because these routes do not involve phosphorylation of pantothenic acid or pantetheine by pantothenate kinase. Replacement of the enzymatic phosphorylation of pantothenate or pantetheine with chemical phosphorylation followed by the enzymatic reaction increased the yield of coenzyme A 10- to 20-fold. Yields from 4′-phosphopantothenic acid and 4′-phosphopantetheine were 33 g/L (molar yield based on ATP; 64.5%) and 115 g/L (100%), respectively (49). This method is applicable to coenzyme A production under ATP-generating conditions (see Fig. 8). 4′-Phosphopantothenic acid (25 g/L), L-cysteine (15 g/L), and AMP (33 g/L), when added to the culture broth of *B. ammoniagenes*, were converted to coenzyme A with a yield of 23 g/L (50).

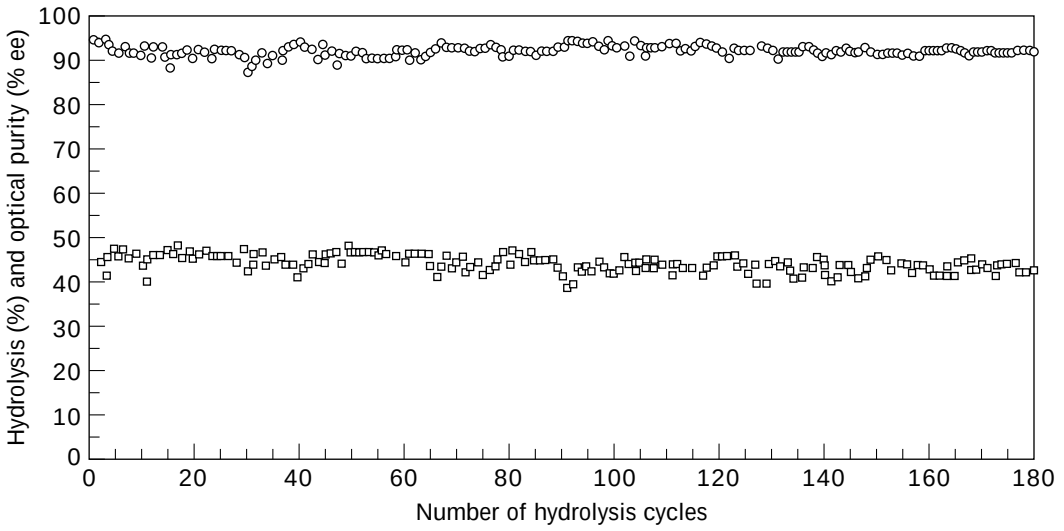

Figure 6. Stereospecific hydrolysis of pantolactone by *Fusarium oxysporum* mycelia entrapped in calcium alginate gels: 280 L immobilized mycelia (containing 15.2 kg wet cells) was incubated with 350 L aqueous racemic pantolactone solution (350 g/L) at 30 °C for 21 h. The pH of the mixture was automatically controlled at 6.8–7.2 with 15 M NH_4OH. All the immobilized mycelia filtrated from the reaction mixture were used for the subsequent reactions. The hydrolysis reactions were carried out 180 times. ○, optical purity for D-(−)-pantoate; □, hydrolysis rate.

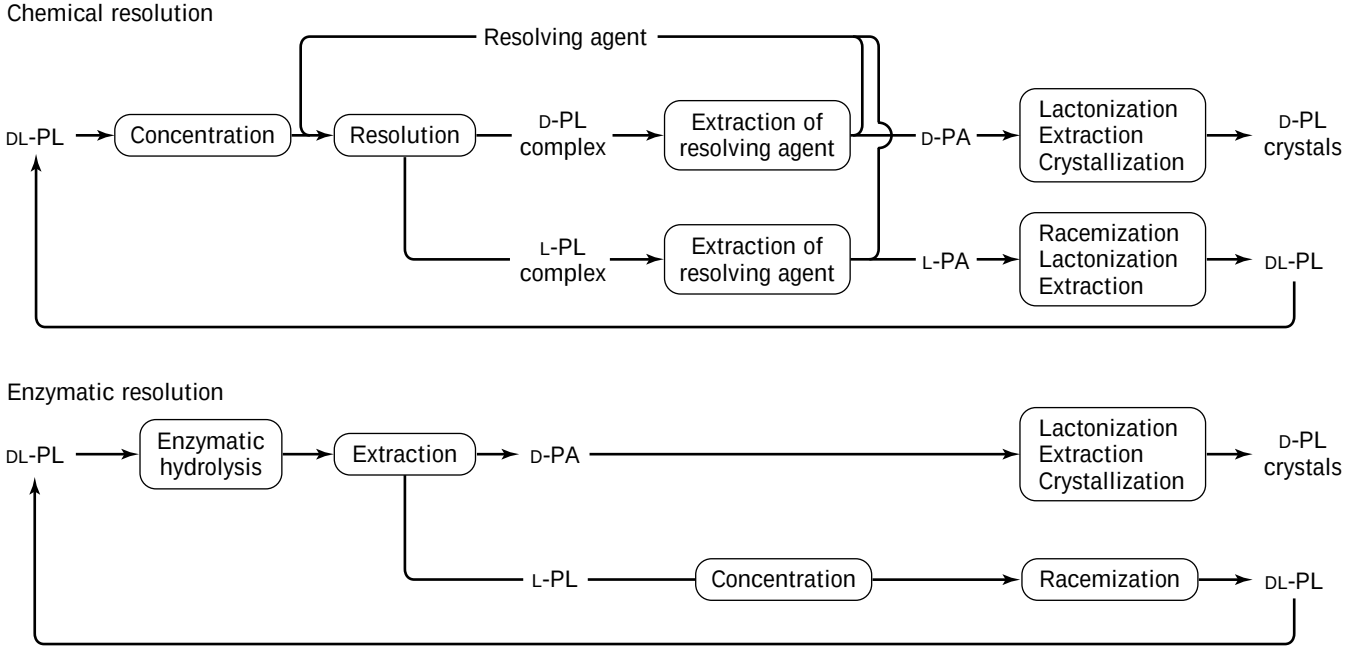

Figure 7. Comparison of enzymatic and conventional chemical resolution processes for racemic pantolactone.

Another way to improve the yield is to use mutants derepressed for the feedback inhibition or those showing elevated pantothenate kinase activity. A mutant of *B. ammoniagenes* that is resistant to oxypantetheine (the corresponding oxygen analog of pantetheine) was found to have an elevated activity of pantothenate kinase. Under ATP-generating conditions, the yields of coenzyme A from pantothenic acid (3.6 g/L), L-cysteine (1.8 g/L), and AMP (6 g/L) or from pantetheine (5 g/L) and AMP (6 g/L) were 9.3 or 11.5 g/L, respectively. These values were about threefold higher than those obtained with the parent strain, and 70–100% of the added AMP was converted to coenzyme A (51) (Fig. 9).

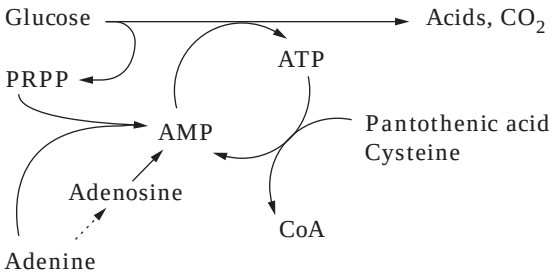

Figure 8. Reaction sequences of coenzyme A production with *Brevibacterium ammoniagenes* under ATP-generating conditions. PRPP, 5-phosphoribosyl-1-pyrophosphate; CoA, coenzyme A.

Continuous production of coenzyme A through five enzymatic steps using gel-entrapped cells of *B. ammoniagenes* has also been reported (48,52).

4′-Phosphopantetheine and Other Intermediates in Coenzyme A Biosynthesis

4′-Phosphopantetheine together with other intermediates in coenzyme A biosynthesis can be effectively synthesized by using *B. ammoniagenes* cells as the catalyst and by modifying the reaction conditions (11) as follows: 4′-phosphopantothenic acid on omission of L-cysteine from the reaction mixture, 4′-phosphopantetheine on addition of CTP or CTP and GTP in place of ATP (because pantothenic acid is phosphorylated in the presence of CTP or GTP as well as ATP and the condensation of 4′-phospho-

4′-Phosphopantetheine	Pantetheine	GMP	7		4–5	
3′-Dephosphocoenzyme A	Pantothenic acid and L-cysteine	ATP	1–5	1–2		

Note: For details, see Shimizu et al. (11,48).

[a]Numbers correspond to those given in Figure 3.

[b]In this case, the nucleoside monophosphates added are presumed to be converted to the corresponding nucleoside triphosphates and used for the reactions in a manner similar to that shown in Figure 8.

pantetheine with nucleoside triphosphate is specific for ATP), and 3′-dephosphocoenzyme A on treatment of the reaction mixture containing coenzyme A with 3′-nucleotidase. The amounts of these intermediates obtained by this method are summarized in Table 2.

ASSAY METHODS

Test microorganisms normally used for the microbiological assay of pantothenic acid are *Lactobacillus plantarum* (ATCC 8014; *L. arabinosus* 17-5), *L. casei* (ATCC 7469), and *Saccharomyces uvarum* (ATCC 9080; *S. carlsbergensis*). *Lactobacillus plantarum* is suitable for determining unconjugated pantothenate in samples. It should be noted that pantetheine, when simultaneously present in a molar ratio to pantothenate of more than 0.5, gives positive errors in the determination. *Saccharomyces uvarum* also shows almost specific growth response to free pantothenate, but *β*-alanine stimulates its growth. Hence, an assay procedure employing this organism is also the one chosen for determining the pantothenic acid that occurs in natural products together with other pantothenate forms. *Lactobacillus casei* responds not only to pantothenate but also several conjugated forms of pantothenate. *Lactobacillus helveticus* (ATCC 12046) and *L. bulgaricus* B1 are recommended for determination of pantetheine (or pantethine) because both these organisms require more than 100 times as much pantothenic acid as pantethine to give the same response. Treatment of samples and details of assay procedures have been described (53).

A sensitive enzymatic assay method using pantothenase has been reported (54), but the enzyme is not commercially available. Chemical and physical methods have also been reported. These are often used in determining pantothenic acid in pharmaceutical products but are not suitable for determination of natural samples because of their low sensitivity.

USE AND ECONOMIC ASPECTS

The current world capacity of calcium pantothenate production and its demand are presumed to be about 4,000 and 3,600–4,000 tons per year, respectively. It is mainly used as an additive to animal feed (about 3,000 tons per year) and as a pharmaceutical product (about 600 tons per year). Pantothenyl alcohol is used as a source of pantothenate activity for pharmaceutical vitamin products. Pantothenyl alcohol itself has no pantothenate activity; in fact, it is a competitive growth inhibitor of several pantothenate-requiring lactic acid bacteria. However, it has been demonstrated to be quantitatively converted to pantothenic acid in the animal body and to be equivalent to pantothenic acid in man.

Pantethine, the disulfide of pantetheine, and coenzyme A are also used as pharmaceutical products in several countries. They have been suggested to be effective in reducing cholesterol level, curing fatty liver, and treating related diseases.

Some sulfonate derivatives of pantetheine or coenzyme A (*Bifidus* factors), such as 4′-phosphopantetheine-*S*-sulfonate, that were originally isolated from carrot roots have been shown to be growth factors of *Bifidobacterium* (12). Addition of the *bifidus* factors to dried milk for infants has been suggested to be useful in improving the quality of the milk. A carbapenem antibiotic, OA-6129A (see Table 1) produced by *Streptomyces* sp. OA-6129, may be an interesting example suggesting a new use of the vitamin as a building block for its synthesis (14).

OUTLINE

INTRODUCTION

Peptides may be structurally defined as amino acid–derived compounds containing at least one amide (peptide) bond. Conventionally, a size limit is imposed for polypeptides of defined sequence above the range of 50 to 100 amino acids, which are termed proteins. Peptide classifications so far use either structural features, biological properties, or biosynthetic considerations (1,2). The major group of peptide antibiotics comprises structurally diverse types such as linear, cyclic and multicyclic peptides, peptidolactones, depsipeptides, and peptides modified with diverse nonpeptides moieties including acyl and aryl groups, polyketide or terpenoid-derived building blocks, or carbohydrate decorations (3). In addition, the biological properties of many compounds termed antibiotics have been shown to be diverse, thus extending the classical definition, which implies the inhibition or elimination of a certain type of organism (Table 1) (4).

From the point of view of peptide production, the bio-

Table 1. Selected Peptides of Current Interest

Compound	Structural type	Source	Properties/applications
Aspartame	Dipeptide	Synthetic	Sweetener
Glutathione	Tripeptide	Various	Detoxification and antioxidant compound
TRH	Modified tripeptide	*Homo sapiens* (hypothalamus)	Thyrotropin-releasing hormone, also stimulates prolactin release
Penicillin	Modified tripeptide	*Penicillium chrysogenum*	Antibacterial drug
Cephalosporin	Modified tripeptide	*Acremonium chrysogenum*	Antibacterial drug
Ergotpeptides	Modified tripeptide	*Claviceps* sp.	Uterine relaxant, treatment of parkinsonism, acromegaly, breast cancer
HC-toxin	Cyclotetrapeptide	*Helmintosporium carbonum*	Plant pathogenic (corn)
Enkephalins	Pentapeptides	*Homo sapiens* (brain)	Opioid activity
Actinomycin	Chromophore-attached pentapeptidolactone	*Streptomyces antibioticus*	Anticancer drug
Destruxin	Hexapeptidolactone	*Metarrhizium anisopliae*	Insecticidal peptide
Enniatin	Cyclohexadepsipeptide	*Fusarium* sp.	Antibacterial, antiviral, antihelminthic
Ferrichrome	Cyclohexapeptide	Various fungi	Siderophore
L-365,209	Cyclohexapeptide	Synthetic	Oxytocin antagonist, uterine relaxant
Vancomycins, ristocetins	Modified heptapeptides	Various Actinomycetes	Antibacterial drugs, antiviral compounds
Microcystins	Cycloheptapeptide	*Microcystis* sp. cyanobacteria	Hepatotoxic water contaminant
Lophyrotomin	Aryloctapeptide	*Lophyrotoma interrupta* (sawfly and other insects)	Hepatotoxin
Amanitins	Modified cyclooctapeptides	*Amanita phalloides*	Toxin
Surfactin	Octapeptidolactone	*Bacillus subtilis*	Surfactant, antifungal, antiviral, and antimycoplasma drug
Sandostatin	Modified octapeptide (disulfide)	Synthetic	Somatostatin agonist, treatment of acromegaly and carcinoid syndrome
PF-1022	Cyclooctadepsipeptide	*Mycelia sterilia*	Antihelminthic
Oxytocin	Nonapeptide (disulfide)	*Homo sapiens*	Smooth muscle contraction, principle birth hormone
Vasopressin	Nonapeptide amide(3 disulfides)	*Homo sapiens*	Control of diabetes insipidus
Desmopressin	Nonapeptide amide (disulfide)	Synthetic	Vasopressin analog, treatment of diabetes insipidus
Aureobasidin	Nonapeptidolactone	*Aureobasidium pullulans*	Antifungal drug
Gonadotropin-releasing hormone	Modified decapeptide Amide	*Homo sapiens* (hypothalamus)	Causes release of luteinizing hormone and follicle-stimulating hormone
Buserelin	Modified decapeptide	Synthetic	GnRH analog, treatment of prostate cancer
Tyrocidine	Cyclodecapeptide	*Bacillus brevis*	Topical antibacterial
Gramicidin S	Cyclodecapeptide	*Bacillus brevis*	Topical antibacterial, antihelminthic
Polymyxins	Heptacyclodecapeptide	*Bacillus polymyxa*	Antibacterial drug
Cyclosporin	Cycloundecapeptide	*Tolypocladium niveum*	Immunosuppressant, antifungal
Bacitracin	Modified heptacyclododecapeptide	*Bacillus licheniformis*	Antibacterial drug, proteinase inhibitor
Somatostatin	14-peptide (2 disulfides)	*Homo sapiens* (hypothalamus, gastrointestinal, tract, etc.)	Various gastrointestinal functions (antacid)
Gramicidin (linear)	Pentadecapeptide	*Bacillus brevis*	Antibacterial, ion-channel-forming
Tachyplesins	17- to 18-peptide	*Tachypleus* sp. (horseshoe crab) and related species	Antimicrobial compounds
Alamethicins	Modified nonadecapeptides	*Trichoderma viride*	Antibiotic, ion-channel-forming
Ranalexin	Modified 20-peptide (1 disulfide)	*Rana catesbeiana* (bullfrog, skin)	Antibacterial
Aborycin	Modified 21-peptide (3 disulfides)	*Streptomyces griseoflavus*	Antiviral (HIV-1)
Magainins	21- to 27-peptide	*Xenopus laevis* (skin)	Antimicrobial drugs
Melittin	26-peptide amide	Bee (venom)	Hemolytic compound
Ac-AMP	29-peptide (3 disulfides)	*Amaranthus canditus* (seeds)	Antimicrobial compound

Table 1. Selected Peptides of Current Interest (*continued*)

Compound	Structural type	Source	Properties/applications
Defensins	29- to 32-peptide	Mammalian (various sources)	Antimicrobial compounds
Human neutrophil peptide (HNP-1)	30-peptide	*Homo sapiens* (neutrophils)	Antibacterial, antifungal, cytotoxic
Cecropins	31-peptide	*Sus scrofa* (pig, small intestine)	Antibacterial (Gram negative)
Calcitonin	33-peptide amide	*Homo sapiens*	Treatment of hypercalcemia, osteoporosis
Subtilin	Modified 32-peptide	*Bacillus subtilis*	Antibacterial food preservative
Subtilosin	Modified 33-peptide	*Bacillus subtilis*	Antibacterial
Nisin	Modified 34-peptide	*Streptococcus lactis*	Antimicrobial food preservative
Mj-AMP	36-peptide	*Mirabilis jalapa* (seeds)	Antimicrobial compound
Cecropins (insect)	37- to 41-peptide amides	Various insects	Antibacterial compounds
Corticotropin (ACTH)	39-peptide	*Homo sapiens* (anterior pituitary gland)	Antibacterial compounds Control of glucocorticoid release
Thionins	34- to 47-peptide (3 or 4 disulfides)	Various plant sources	Antibacterial, antifungal
Defensins (plant)	45- to 51-peptide (4 disulfides)	Various plant sources	Antimicrobial compounds
AgaIVC	48-peptide	*Agelopsis aperta* (spider)	Venom, contains a D-Ser in position 48
Insulin	51 amino acids (2 chains, 3 disulfides)	Mammalian	Treatment of type I diabetes
Trefoil peptides	51–56 amino acids	Mammalian	Tissue repair and cell proliferation
Hirudin	65-peptide	Leeches (buccal gland)	Protease inhibitor, anticoagulant, antithrombotic agent

Note: See Ref. 11 for more extensive coverage.

synthetic origin is of primary importance. Although the ribosomal peptide biosynthetic system is an essential constituent of all self-replicating organisms, nonribosomal peptide forming systems, with few exceptions (bacterial cell wall peptides, glutathione), are not essential and are themselves gene products. So ribosomally derived peptides are directly encoded by gene transcripts, whereas nonribosmally derived compounds are the products of biocatalysts or multienzyme systems. To propagate each type of peptide in a cellular environment requires exceedingly different approaches. A decapeptide gene may be defined by a 30-bp reading frame and additional features permitting efficient transcriptional and translational processing. A biocatalyst forming a decapeptide requires approximately 40,000 bp of genetic information, and thus a considerably more complex genetic background (5,6).

Genome sequencing efforts have revealed the absence of such complex biosynthetic systems in most organisms investigated so far. These systems are especially prominent in microbial sources such as Actinomycetes, Bacilli, cyanobacteria, and filamentous fungi and are already being exploited for useful metabolites. Peptides of human origin, acting as hormones, neurotransmitters, growth factors, cytokines, and so forth are involved in the regulation of a variety of functions, including the central nervous system and cardiovascular, gastrointestinal, immunological, reproductive, and growth activities (7–10). Peptide therapeutics have been and are being developed for various treatments (Table 1).

STRUCTURAL FEATURES

The peptides compiled in Table 1 are products of different biosynthetic systems. In most cases, the current state of knowledge permits the prediction of each biosynthetic path from the structural features involved. This information permits the respective biotechnological (fermentation of microbial producers or hosts, cell culture), in vitro enzymatic, or chemical production. The new emerging approaches of combinatorial biosynthesis or synthetic peptide libraries are especially linked to biosynthetic considerations.

Biosynthesis

Peptides of biological origin differ in various structural features (Table 2) but also share the template-mediated assembly from carboxyl-activated amino acid precursors into linear precursor molecules, growing in the carboxy-terminal direction. Depending on the biosynthetic origin, the template is either nucleic acid (ribosomal) or protein (nonribosomal) (5).

Ribosomal Peptide Formation. Ribosomally formed peptides are directly gene encoded, and their mRNA template utilizes the available codons for linear assembly guided by the ribosomal architecture. Each amino acid is activated as aminoacyl-tRNA by a specific aminoacyl-tRNA synthetase; this process includes proofreading steps for structurally related compounds and achieves an accuracy of about 10^{-4} (12). Genes and their respective mRNAs encode polypeptides and proteins up to about 27,000 amino acids (titin), but the average size of translation products is about 300 amino acids.

Amino Acids. The translation process is restricted to the 20 protein amino acids and selenocysteine (13,14). Organisms may differ in their codon usage, and rare codons are thought to function in the control of both the transla-

Table 2. Structural Features of Peptides of Ribosomal and Nonribosomal Origin

	Ribosomal path	Nonribosomal path//multienzymes
Size (amino acids)	No size limitation, 2–20 residues Peptides, 20–50 residues Polypeptides, more than 50 residues Proteins, largest structures up to 30,000 residues	2 to about 50, 4 to 10 dominating; polymers up to about 1,000 residues
Amino acid constituents	21 protein amino acids (including selenocysteine) and modified amino acids	Various types of amino acids including 2-, 3- and 4-amino compounds (more than 300 known)
D-Amino acids	Not more than one, epimerized posttranslationally; in lantibiotics epimerization of several residues by dehydration and thioether formation	Often several, either incorporated directly, or epimerized during synthesis
Non–amino acid constituents in the peptide chain	Acyl residues, amines originating from decarboxylation	Various acyl residues, including aromatic acids, hydroxy acids
Cyclic structures	Rare, frequent disulfide cycles, often with several disulfide linkages; thioether cycles in lantibiotics (lanthionine)	More frequent than linear structures, various peptide bond cyclizations, but also lactones
Side-chain modifications	Hydroxylation, dehydration (Ser, Thr), side-chain cyclization (Cys to thiazoles, Thr to oxazoles, Glu to pyroGlu), frequently glycosylation	N-Methylation, hydroxylation, side-chain cyclization (Cys to thiazole), glycosylation, side-chain cross-linking (aromatic rings), glycosylation
Unusual constituents	Not known	Urea type of peptide bond, phosphoamino acids, amino-modified fatty acids–derived components (lipopeptides), mixed polyketide structures, terpenoid-derived groups
Biosynthesis	Gene can be identified; consider splicing, processing, and posttranslational modification; often prepropeptides detected	Nonribosomal enzyme systems present; peptide families are frequent in the same or related organisms; biosynthesis of rare precursors needed
Sources	Various animals and plants, sometimes bacteria	Mainly bacteria and lower fungi, occasionally plants and insects

tion rates and the folding of the primary intermediates (15,16). Heterologous expression sometimes needs codon adjustment for the intended host. Exploitation of this process to adapt synthetic nonprotein amino acids has been achieved in vitro by making use of nonutilized codons and their respective tRNAs (17). More than 100 mostly nonnatural amino acids have been introduced into peptides by biocatalytic procedures (18,19). Such procedures permit, for example, the direct incorporation of photofunctional amino acids (20). Current work focuses on the introduction of an engineered tRNA/aminoacyl-tRNA synthetase pair into *Escherichia coli*, delivering unnatural amino acids (21). D-Amino acids in ribosomally encoded peptides originate from the respective L-epimers, which are epimerized in chain by specific racemases first isolated from the spider *Agelopsis aperta* (22,23)

Peptide Processing. These primary translation products may undergo a variety of modification reactions. Besides hydrolytic removal of the initiating formyl-methionine residue (24), regions of the pre- or protranslation products may be involved in targeting and transport events, acting as signals recognized by the various proteins or nucleic acid species. Signal sequences may be removed by signal peptidases, and proteolytic processing may even continue; this is well known among hormones. Thus proopiomelanocortin gives rise to different peptides in different tissues, including ACTH, α-MSH, different forms of LPH, and β-endorphin. A rare event, now firmly established, is the joining of peptide fragments, which in analogy to the exon–intron structures of genes have been termed exteins and inteins (25). Cyclization of peptides by peptide bonds is likewise rare (26).

Side-Chain Alterations. Most common alterations besides N-terminal acylation (24) include hydroxylations of proline and lysine residues and the formation of regional specific disulfide bonds. Such processes may involve not only disulfide isomerases (27) but chaperones as well. Multiple disulfide bridges are found in peptides with up to four positionally conserved links. Such conformationally stabilized structures show antimicrobial (defensins, ranalexin, cecropins), antiviral (aborycin), and cytotoxic properties (human neutrophil peptides, HVP), or as the trefoil factor rITF from rat intestine, act as a covalently linked dimer in tissue repair and cell proliferation.

Side-chain modification of cysteine and serine residues to thiazole and oxazole derivatives are found in the gyrase inhibitor microcin and the rhizobial peptide trifolitoxin. A respective transforming enzyme complex has been characterized from the microcin B17 biosynthetic gene cluster (28). Stable thioether links between cysteine and serine or threonine side chains are prominent structural features of the lantibiotics (29–31). The name points to the unusual amino acids lanthionine and methyllanthionine formed upon hydrolysis. The respective biosynthetic clusters contain genes for enzymes catalyzing dehydration of serine or threonine to dehydroalanine and dehydrobutyrate, respec-

tively, which undergo addition with thiols from adjacent cysteines, leading to inversion of the configuration.

In Vitro Applications of the Ribosomal System. Ribosomal peptide synthesis as a complex process involving about 150 proteins and ribonucleic acids and is being studied in detail (32). Functional in vitro systems are available from several organisms including *E. coli*, yeast, wheat germ, and rabbit reticulocytes (33). Such systems are especially useful for the production of antibacterial and cytotoxic peptides, which are not accessable by fermentation (34). Technology for mRNA production or the use of coupled transcription–translation systems introducing plasmids as informational molecules have been worked out (35). So far, peptide synthesis has been restricted to the laboratory scale, but yields up to the milligram per milliliter range have been reported. Efficiencies of such systems can be improved by cofactor regeneration (e.g., ATP). Synthesis of reporter molecules such as photoproteins permit the functional monitoring and the direct detection of, for example, translational inhibitors (36).

Nonribosomal Peptide Formation. Two basic types of peptide-forming systems account for most of the nonribosomal peptide formation structures known so far: single-step and multistep systems (Table 3). Single-step systems add amino acids to activated precursor amino acids or peptides; thus the precursors are directly activated, generally as phosphates by cleavage of ATP to ADP, and the amino acid to be added is in the free soluble state. The limit of performance appears to be the size of the substrates in relation to the enzymes involved. Covalently acting multistep systems add activated precursors to an activated amino acid, thus maintaining the activated state. In analogy to the ribosomal system, these multienzyme systems have no free intermediates, and product release involves catalysis as well (6).

Single-Step Systems. Prominent products of single-step systems are glutathione, coenzyme A, and peptides of the murein sacculus, including the uridin-diphosphomuramyl-N-acetyl precursor and various interpeptide bridges. Some steps involve aminoacyl-tRNA and are thus nucleic acid dependent (37). Enzymes involved can be identified at the gene level by characteristic motifs (38), but the class is heterogenous.

Single-step enzyme systems are obviously suited for the production of repeated sequences and polymers. Such examples include glutathion-related peptides involved in sequenstering metal ions. These have been termed phytochelatins and are induced in yeast or plant cells upon exposure to Cd^{2+}, Cu^{2+}, or Zn^{2+} (39). The compositions vary from (γGlu-Cys)*n*Gly, (γGlu-Cys)*n*Glu, to (γGlu-Cys)*n*, with *n* ranging from 2 to 11 (40,41), and imply dipeptide condensations as a biosynthetic principle. Likewise, cyanophycin, a cyanobacterial storage polypeptide, is composed of the dipeptide units L-Arg-L-Asp. Synthetase and depolymerase have been identified in *Synechocystis* sp. and *Anabaena variabilis*, and the export of the polymerizing activity into *E. coli* has been demonstrated (42). Examples of amino acid polymers include γ-linked glutamate tails of folate (ranging in length from 1 to 11), β-lysine tails of nucleoside antibiotics such as nourseothricin, lysine polymers up to 25 residues in Streptomycetes, and γ-D-glutamyl capsular polymers in *Bacillus anthracis* and other spore-forming Bacilli. The molecular mechanisms of control of peptide and polypeptide chain length are unknown.

Multistep Systems. The covalent catalysis principle found in the multienzyme system closely resembles the ribosomal elongation principle. Equivalents to aminoacyl-tRNA and peptidyl-tRNA are aminoacyl and peptidyl carrier proteins. However, the protein system depends largely on fusing functional domains, which leads to multifunctional structures of impressive sizes. Grouping enzymes according to size, peptide- and polyketide-forming enzymes will occupy all top positions. On the other hand these synthetases will be at the bottom of the list if overall rates are compared. The largest known enzyme, cyclosporin synthetase, contains 41 functional domains fused into a 1.7-MDa protein. It integrates all 40 reactions, leading to a cycloundecapeptide with seven methylated peptide bonds (43). Peptide-forming systems currently under study have been compiled in Table 4.

Activation of Amino Acids and Other Carboxyls. Differing from polyketide systems, activation of amino acid carboxyl groups is an integrated function in peptide synthetases. The activation function is a preselection step in the events controlling fidelity of the peptide chain. Adenylate-forming domains share extensive homologies with acyl-CoA synthetases and the homologous insect luciferases, which likewise form acyl adenylates followed by transfer to the thiol group of CoA. Amino acid selection is controlled with varying selectivity: sometimes there is discrimination of leucine against valine or isoleucine, but occasionally all branched-chain types are accepted. Likewise phenylalanine might be discriminated against in favor of tyrosine and tryptophan, whereas some activation sites are known to accept various aromatic amino acids. Stereoselective discrimination of L- and D-residues is common, and both epimers may be direct precursors. In some cases both epimers are substrate, but the subsequent condensation reaction is stereocontrolled. Adenylates are thought to be stabilized by the interaction of the two subdomains of the adenylate domain. With low efficiency they may be subject

Table 3. Peptide-Forming Enzyme Systems

	Single-step systems	Multistep systems
Types of peptide made	Linear peptides, branched peptides	Linear and cyclic peptides, peptidolactones and depsipeptides; polymers?
Length of peptide made	2 to 5, or polymers	2 to 48 (?)
Activation of carboxyl groups	Phosphate or adenylate	Adenylate
Intermediates	Free intermediates (not clear for polymers)	Intermediates remain enzyme bound

Table 4. Nonribosomal Peptide Synthetase Systems

Peptide	Organism	Structural type	Gene(s) cloned	Enzymology
		Linear		
Bacilysin	*Bacillus subtilis*	P-2-M	(+)	(+)
Anguibactin	*Vibrio anguillarum*	R-P-2-M	+	−
ACV	*Streptomyces clavuligerus*	P-3	+	+
	Nocardia lactamdurans		+	+
	Lysobacter lactamgenus		+	+
	Aspergillus nidulans		+	+
	Penicillium chrysogenum		+	+
	Acremonium chrysogenum			
Bialaphos	*Streptomyces hygroscopicus*	P-3	+	+
Yersiniabactin	*Yersinia enterocolitica*	R-P-3-M	+	+
Phaseolotoxin	*Pseudomonas syringae* pv. ph.	P-4-M	(+)	−
Ardacin	*Kibdelosporangium aridum*	P-7-M	(+)	−
Chloroeremomycin	*Amycolatopsis orientalis*	P-7-M	+	−
Pyoverdin	*Pseudomonas aeruginosa*	R-P-8-M	+	−
Bleomycin	*Streptomyces verticillius*	P-8-M	+	−
Alamethicin	*Trichoderma viride*	R-P-19-M	−	+

Lysobactin	*Lysobacter* sp.	P-11-L-9	(+)	+
A21798A	*Streptomyces roseosporus*	R-P-13-L-10	(+)	+
A54145	*Streptomyces fradiae*	R-P-13-L-10	−	+
Tolaasin	*Pseudomonas tolaasii*	R-P-18-L-5	(+)	−

Note: Abbreviations: P, peptide; C, cyclopeptide; L, lactone; E, ester; R, acyl; M, modified. The structural types are defined by the number of amino, imino, or hydroxy acids in the precursor chain. The ring sizes of cyclic structures are indicated in the number following C, L, or E, defining the type of ring closure.

to aminolysis, leading to dipeptide formation without stereoselectivity (44).

Acyl and Peptidyl Carrier Domains. Adjacent to each adenylate domain is the carrier domain, homologous to the well-known acyl carrier protein of fatty acid biosynthesis. Carrier domains are posttranslationally modified with 4′-phosphopantetheine. This modification is catalyzed by specific CoA-4′-phosphopantetheine-protein transferases (45,46). The terminal cysteamine thiol of the cofactor is the acceptor of the aminoacyl moiety of the adenylate, with release of AMP. Thiol-bound intermediates can be isolated and characterized. This system property has led to the name thiotemplate mechanism.

Condensation Domains. The directed condensation of either two aminoacyl intermediates (initiation) or a peptidyl and an aminoacyl intermediate (elongation) is thought to take place at a condensation domain, interacting with the two adjacent carrier domains. This reaction is strictly stereospecific. If both epimers are present as intermediates because of the action of a reversible epimerase in the multienzyme, only the respective D-isomer is processed. The condensation domains are highly similar in structure to epimerization domains, catalyzing the conversion of thioester-attached aminoacyl or peptidylcarboxyl groups. Special types of condensation domains have been identified in systems forming thiazolidine-containing peptides such as bacitracin or yersiniabactin (47). These perform the cysteine side-chain modifications as well.

Termination Reactions. Termination of synthesis may proceed by hydrolysis (thioesterase required) or various modes of cyclization, leading to cyclic or branched cyclic peptides, peptidolactones, or cyclodepsipeptides. Flexibility of the process permits the processing of hydroxy acids as well, leading to depsipeptides, or the repeated use of templates, leading to dimers, trimers, or tetramers. Known processes are the dimerization of two pentapeptides in gramicidin S formation, the trimerization of dihydroxybenzoylseryl- or hydroxyisovaleryl-N-methylvalyl intermediates in enterobactin or enniatin synthesis, respectively, or the suspected tetramerization in the cases of bassianolide and PF1022. As in polyketide biosynthesis, repositioning of a terminating thioesterase domain may promote the release of intermediates (48). Both integrated and and associated thioesterase-like proteins are suspected to function in termination reactions (49).

Side Reactions. Two types of side reactions have been observed so far: the aminolysis of aminoacyladenylates as reactive mixed anhydrides, leading to dipeptides (44), or reactions of thioester intermediates. As in solid-phase peptide synthesis, certain steric conditions favor abortive cyclization reactions, especially of proline-containing or N-methylated dipeptides and ornithyl side chains. Less expected have been out-of-sequence dipeptide formations in ACV syntetase, actinomycin synthetase II (50), and cyclosporin synthetase. Such side reactions are promoted when lack of substrates prevents the completion of the entire catalytic cycle.

Reprogramming of Peptide Synthetases. The modular arrangement of most polycondensation pathways implies reprogramming by modular exchange. In the peptide field, functional hybrid synthetases have been constructed by module exchange between the gramicidin S synthetase system, ACV synthetase, and the surfactin synthetase system (51,52). At present the often low catalytic efficiencies of the constructs present a problem difficult to approach without the knowledge of the detailed spatial structures involved.

In Vitro Applications of Peptide Synthetases (53). The in vitro studies of peptide synthetases permitted an understanding of the catalytic principles involved. Small amounts of peptides have been produced in a variety systems (Table 3). Applying cyclosporin synthetase for preparative work, more than 100 cycosporin analogs have been prepared (43). Generally no more than two structural alterations have been found to be tolerated. Peptide synthetases obviously do not match the performance of chemical methods with regard to structural analog utilization because additional constraints are involved, including substrate selection and protein stability. However, peptide synthetases combine a number of advantages, including stereoselectivity and efficient cyclization. Another feature of special significance is the target-oriented product profile, which provides essential clues in structure–function work.

PEPTIDE PRODUCTION

Sources and Screening

Healing experiences and later ecological considerations have led to the concept of microbial warfare and eventually to the isolation of the first peptide antibiotics penicillin, tyrothricin (a mixture of linear gramicidin and tyrocidine), and gramicidin S. Although investigations of this type are continuing with the still-large reservoir of rare and difficult-to-cultivate microorganisms, new fields have been emerging that consider the defensive compounds from higher organisms. Pioneered in the fields of amphibian and insect defense strategies (54–57), antimicrobial peptides keep being discovered in mammalian and plant sources (58–61). In the field of secondary metabolites, microbial sources are generally exploited by fermentational procedures. Products of plants and animals have been investigated largely from chemical synthesis, but production can be achieved by recombinant DNA approaches (62,63).

Besides functional and chemical screening of extracts, genetic screening is now emerging as a tool to identify sources of presumably active natural products. The increasing knowledge of biosynthetic enzyme systems permits the probing of DNA isolates for the presence of peptide synthetase genes (64) or related modifying enzymes.

Fermentation. Submersed fermentation accounts for the majority of peptides produced from bacteria and filamentous fungi. Research has shifted from engineering approaches to detailed studies of the molecular mechanisms involved. Thus the productivity of cultures is increased by empirical media optimization, tight parameter control of the growth and production processes (O_2, CO_2, redox potential, cell morphology), and random and defined mutagenesis operations. The complexity of metabolite production is far from being understood.

The fermentation of β-lactam antibiotics represents the best-studied system (65). Penicillin biosynthesis is catalyzed by three enzymes: δ-(L-α-aminoadipyl)-l-cysteinyl-D-valine synthetase (ACVS), isopenicillin-N-synthase (IPNS), and acyltransferase (AAT). The respective genes are are combined in a biosynthetic cluster, which has been found to be amplified in production strains (66). Thus the gene copy number appears to be a major factor of productivity. However, production strains with a single copy of the cluster have also been selected as efficient producers. The regulation of expression is being currently studied, which affords the detailed understanding of the complex promoters involved (67). In this respect the utilization of autoregulators to induce the biosynthesis of specific metabolites is a fascinating tool already applied in peptide fermentation in Actinomycetes (68).

In addition, subcellular localization plays a significant role. Although IPNS is soluble and located in the cytosol, ACVS seems only partially soluble, and AAT is located in a peroxisome-like compartment, termed the microbody. The substrate transfer between ACVS and IPNS may involve complex formation and channeling, but the transfer of isopenicillin-N into the microbody, and the export of penicillins out of the microbody and through the cellular envelope, have not been studied so far. The role of molecular transport processes involved in biosynthetic processes is largely unknown. Export processes of bioactive compounds, especially peptides, seem also to be essential for self-protection, and thus critical for an intended overproduction. Peptide export proteins have been detected, and compounds such as cyclosporin are known to affect export systems including multi-drug-resistance proteins. Production processes utilize both product excretion and retainment in the microbial cells. Gramicidin S can accumulate up to 20% peptide within the cellular dry mass of the producer *Bacillus brevis*. Fermentation techniques to avoid feedback problems utilize solid-state approaches (69), microfiltration (70), or aqueous two-phase systems (71).

Finally, efficient substrate concentrations play a significant role in peptide fermentation. In special cases direct feeding of amino acid precursors may shift the product profile to a certain analog (72). Considering however, that the price of the penicillin precursor amino acid cystein exceeds that of the product, improvement focuses on the precursor biosynthetic systems, including uptake of basic nutrients such as glucose, ammonium, and sulfate.

Recombinant DNA Approaches in Peptide Production

The introduction of rDNA techniques permits the efficient production of various peptides independent of organ or animal sources, and thus free of viral contaminants. Current limits are related to certain posttranslational modification events, if relevant, which still have to be evaluated. An amidating enzyme system has been established (73), whereas specific glycosylation systems are still unavailable. So current production routes employ, for example, yeast or insect cell cultures that often contain similar modification systems. Prominent examples of peptides currently produced include insulin (74) and hirudin, but the vast majority of products are proteins.

Enzymatic Procedures in Peptide Production

Introduced more than 50 years ago, the reversal of proteinase reactions has been widely used in peptide synthesis (75). Strategies exist for regio- and stereospecific synthesis of peptide bonds (76,77), and new trends consider heterogeneous media (78) or even frozen aqueous solutions (79). Generally all procedures permit the construction of a single, specified peptide bond, but fragment condensations and protein modifications have been established in peptide production as well. Substrates to be converted generally need protection groups to avoid side reactions.

OUTLINE

INTRODUCTION

The amino acid phenylalanine is currently manufactured worldwide at an annual scale exceeding 12,000 metric tons. The vast majority of this material is L-phenylalanine, synthesized specifically for incorporation into the dipeptide sweetener aspartame. Production of L-phenylalanine grew rapidly during the 1980s in parallel with the demand for aspartame and has grown steadily in recent years. L-Phenylalanine is also used in additional food and medical applications and is in increasing demand in pharmaceutical development as a chiral intermediate or as a precursor of chiral auxiliaries such as benzyloxazolidinone. In contrast, only a few metric tons of D-phenylalanine are used annually, also in pharmaceutical drug development, although this application is increasing. During the past two decades, a number of manufacturers have developed chemoenzymatic and purely biological routes for L-phenylalanine manufacture, as shown in Table 1. Chemoenzymatic syntheses have relied on resolution technology, applied to chemically prepared racemic phenylalanine derivatives or DL-5-monosubstituted hydantoins and biotransformation routes from chemically prepared achiral precursors of L-phenylalanine. Purely biological routes have concentrated on direct synthesis of L-phenylalanine through microbial fermentative means. Today, the largest and most commercially successful synthetic routes to L-phenylalanine production use large-scale fermentation of bacterial strains that overproduce L-phenylalanine. Such microorganisms have been isolated through a combination of classical mutagenesis selection procedures and molecular genetic manipulation, the latter deriving from a detailed understanding of the molecular biology of the pathways involved in bacterial L-phenylalanine biosynthesis. Conversely, the present commercial production of D-phenylalanine relies solely on chemoenzymatic resolution.

L-PHENYLALANINE-OVERPRODUCING MICROORGANISMS

Common Aromatic and L-Phenylalanine Biosynthetic Pathways

Efforts to develop L-phenylalanine-overproducing organisms have been vigorously pursued by Nutrasweet Company, Ajinomoto, Kyowa Hakko Kogyo, and others. The focus has centered on bacterial strains that have previously demonstrated the ability to overproduce other amino acids. Such organisms include principally the coryneform bacteria, *Brevibacterium flavum* (1,2) and *Corynebacterium glutamicum* (3,4) used in L-glutamic acid production. In addition, *Escherichia coli* (5) has been extensively studied in L-phenylalanine manufacture because of the detailed characterization of the molecular genetics and biochemistry of

Table 1. Commercial Processes for L-Phenylalanine Synthesis

Manufacturer	L-Phenylalanine processes developed
Ajinomoto	Microbial fermentation
Biotechnica	Microbial fermentation
Degussa/Rexim	Enzymatic resolution (aminoacylase)
DSM	Enzymatic resolution (amino acid amidase)
Genex	Biotransformation (phenylalanine ammonia lyase)
Kyowa Hakko	Microbial fermentation

Tanabe Seiyaku	Enzymatic resolution, biotransformation (aminoacylase, aminotransferase)

its aromatic amino acid pathways and its amenability to recombinant DNA methodology. The biochemical pathway that results in the synthesis of L-phenylalanine from chorismate is identical in each of these organisms (Fig. 1**b**); the common aromatic pathway to chorismate is shown in Figure 1**a**. In each case, the L-phenylalanine biosynthetic pathway comprises three enzymatic steps from chorismic acid, the product of the common aromatic pathway. The precursors of the common aromatic pathway, phosphoenolpyruvate (PEP) and erythrose-4-phosphate, derive from the glycolytic and pentose phosphate pathways of sugar metabolism, respectively. Although the intermediate compounds in both pathways are identical in each of the organisms, there are differences in the organization and regulation of the genes and enzymes involved (2,6,7). Nevertheless, the principal points of pathway regulation are very similar in each of the three bacteria (4,6,8). Conversely, tyrosine biosynthesis, which is also carried out in three biosynthetic steps from chorismate, proceeds through different intermediates in *E. coli* than the coryneform organisms (6,8).

Regulation of phenylalanine biosynthesis occurs both in the common aromatic pathway and in the terminal phenylalanine pathway, and the vast majority of efforts to deregulate phenylalanine biosynthesis have focused on two specific rate-limiting enzymatic steps. These are the steps of the aromatic and the phenylalanine pathways carried out, respectively, by the enzymes 3-deoxy-D-arabino-heptulosonate-7-phosphate (DAHP) synthase and prephenate dehydratase. Classical mutagenesis approaches using toxic amino acid analogues and the molecular cloning of the genes encoding these enzymes have led to very significant increases in the capability of host strains to overproduce L-phenylalanine. This has resulted from the elimination of the regulatory mechanisms controlling enzyme synthesis and specific activity. The cellular mechanisms that govern the activity of these particular enzymes are complex and illustrate many of the sophisticated means by which bacteria control gene expression and enzyme activity. Chorismate mutase, the first step in the phenylalanine-specific pathway, and the shikimate kinase activity of the common aromatic pathway are subject to a lesser degree of regulation and have also been characterized in detail (9,10).

Classical Mutagenesis and Selection

Classical methods of strain improvement have been widely applied in the development of phenylalanine overproducing organisms (5,11,12,13). Tyrosine auxotrophs have frequently been used in efforts to increase phenylalanine production through mutagenesis. These strains often already overproduce phenylalanine because of the overlapping nature of tyrosine and phenylalanine biosynthetic regulation (3,14,15). Limiting tyrosine availability leads to partial genetic and allosteric deregulation of common biosynthetic steps (16). Such strains have been subjected to a variety of mutagenesis procedures to further increase the overall titer and the efficiency of phenylalanine production. In general, this has involved the identification of mutants that display resistance to toxic analogues of phenylalanine or tyrosine, such as β-2-thienyl-DL-alanine and *p*-fluoro-DL-phenylalanine (3,5,17). Such mutants can be readily identified on selective plates in which the analogue is present in the growth medium. The mutations responsible for the phenylalanine overproduction have frequently been located in the genes encoding the enzymatic activities of DAHP synthase, chorismate mutase, and prephenate dehydratase. In turn, this has prompted molecular genetic approaches to further increase phenylalanine production through the isolation and in vitro manipulation of these genes, as described next.

Deregulation of DAHP Synthase Activity

The activity of DAHP synthase commits carbon from intermediary metabolism to the common aromatic pathway converting equimolar amounts of PEP and E4P to DAHP (18). In *E. coli* there are three isoenzymes of DAHP synthase of comparable catalytic activity encoded by the genes *aroF*, *aroG*, and *aroH* (19). Enzyme activity is regulated by the aromatic amino acids tyrosine, phenylalanine, and tryptophan, respectively (16,20–23). In each case, regulation is mediated both by repression of gene transcription and by allosteric feedback inhibition of the enzyme, though to different degrees.

The *aroF* gene lies in an operon with *tyrA*, which encodes the bifunctional protein chorismate mutase–prephenate dehydrogenase (CMPO). Both genes are regulated by the TyrR repressor protein complexed with tyrosine. The *aroF* gene product accounts for 80% of the total DAHP synthase activity in wild-type *E. coli* cells. The *aroG* gene is repressed by the TyrR repressor protein complexed with phenylalanine and tryptophan. Repression of *aroH* is mediated by tryptophan and the TrpR repressor protein (20). The gene products of *aroF* and *aroG* are almost completely feedback inhibited respectively by low concentrations of tyrosine or phenylalanine (24), whereas the *aroH* gene product is subject to maximally 40% feedback inhibition by tryptophan (24). In *B. flavum*, DAHP synthase forms a bifunctional enzyme complex with chorismate mutase and is feedback inhibited by tyrosine and phenylalanine synergistically but not by tryptophan (25,26). Similarly, in *C. glutamicum*, DAHP synthase is inhibited most significantly by phenylalanine and tyrosine acting in concert (27), but unlike *B. flavum* reportedly does not show tyrosine-mediated repression of transcription (25,28).

Many examples of analogue-resistant mutants of these organisms display reduced sensitivity of DAHP synthase to feedback inhibition (3,5,7,25,29,30). In *E. coli*, the genes encoding the DAHP synthase isoenzymes have been characterized and sequenced (6,31,32). The mechanism of feedback inhibition of the *aroF*, *aroG*, and *aroH* isoenzymes has been studied in considerable detail (32), and variants of the *aroF* gene on plasmid vectors have been used to increase phenylalanine overproduction. Simple replacement of transcriptional control sequences with powerful constitutive or inducible promoter regions and the use of high copy number plasmids has readily enabled overproduction of the enzyme (33,35), and reduction of tyrosine-mediated feedback inhibition has been described using resistance to the aromatic amino acid analogues β-2-thienyl-DL-alanine and *p*-fluoro-DL-phenylalanine (33,35).

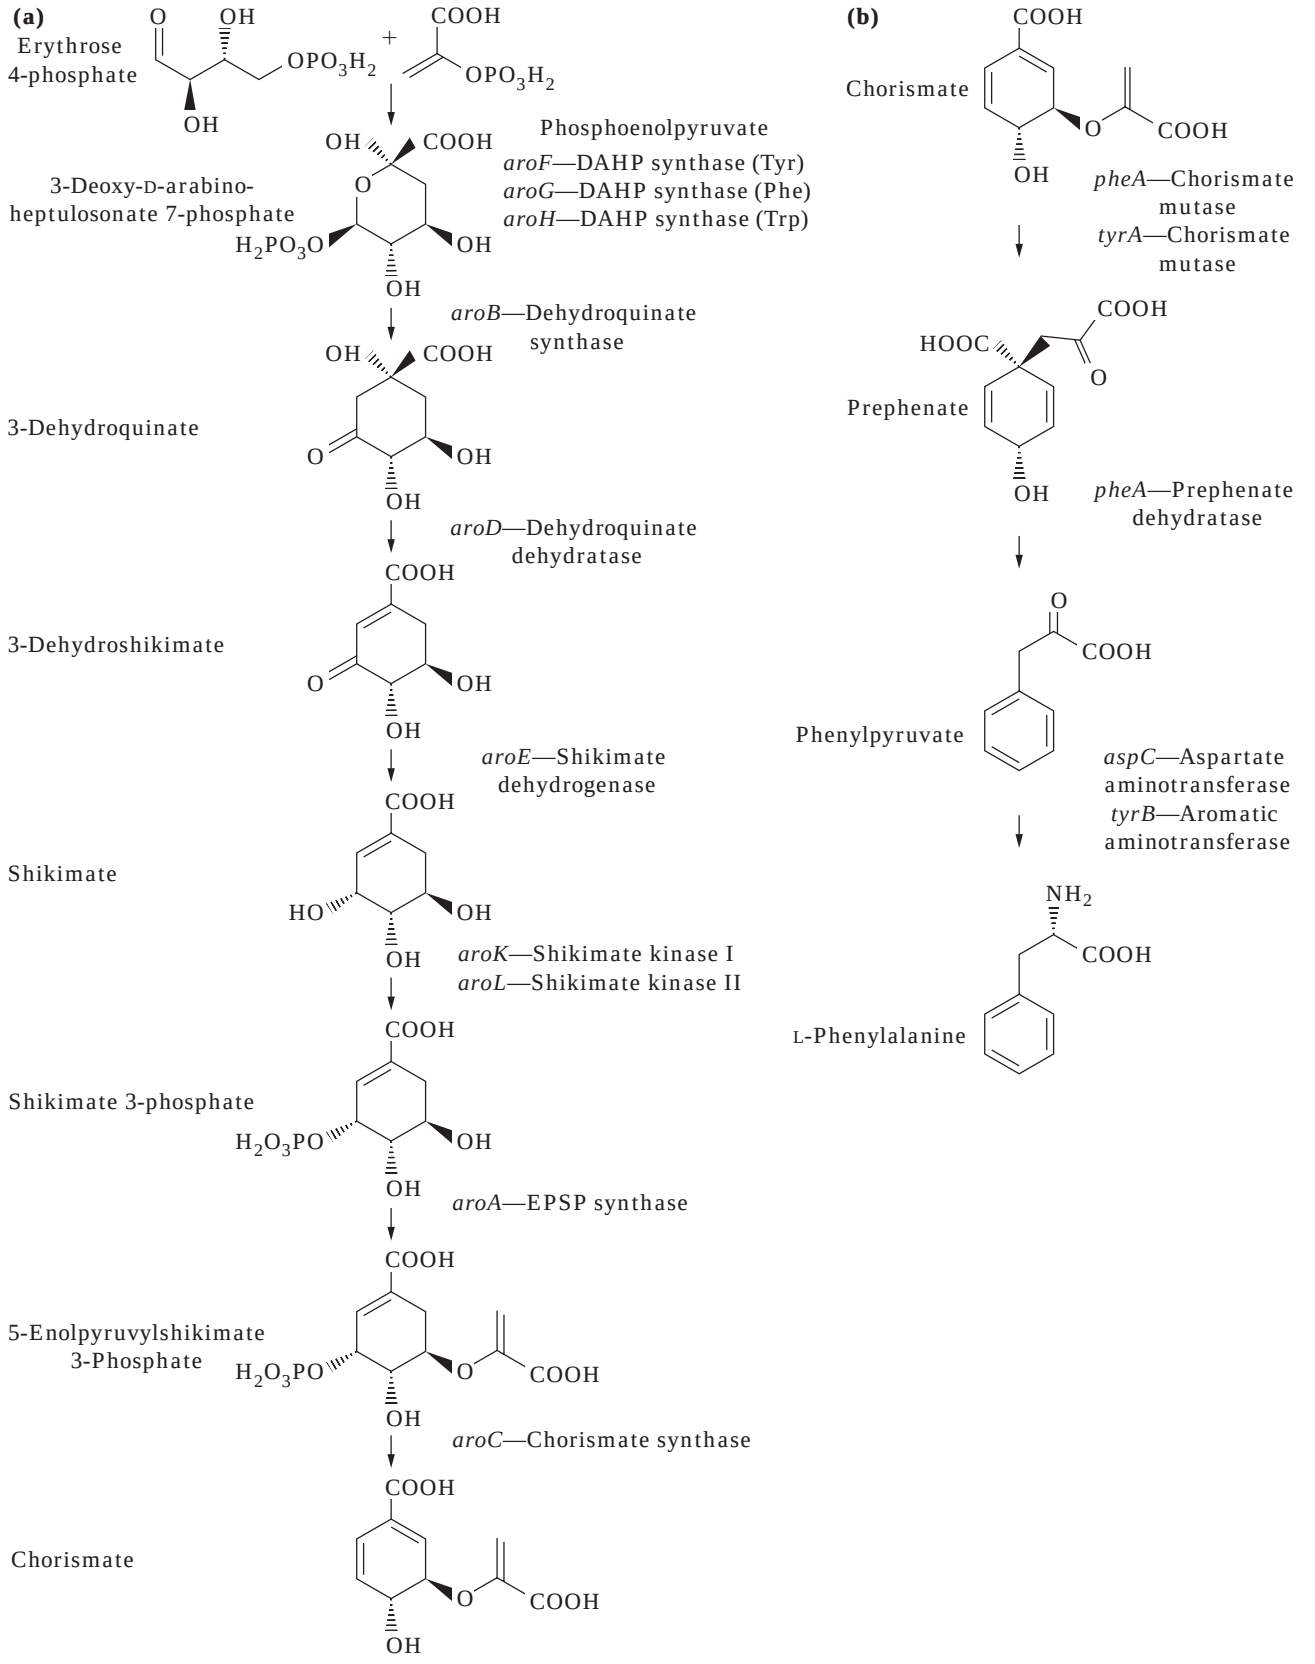

Figure 1. (**a**) The common aromatic pathway to chorismate in *Escherichia coli* K12. The enzymes responsible for each step are indicated to the right preceded by the encoding gene mnemonic. (**b**) The L-phenylalanine biosynthetic pathway from chorismate to L-phenylalanine in *Escherichia coli* K12.

Deregulation of CMPD

The three enzymatic steps by which chorismate is converted to phenylalanine appear to be identical among *C. glutamicum*, *B. flavum*, and *E. coli*, although only in *E. coli* have detailed reports appeared upon the characterization of the genes involved. In each case, the principal regulatory step is that catalyzed by prephenate dehydratase. In *E. coli*, chorismate is converted first to prephenate and then to phenyl pyruvate by the action of a bifunctional enzyme, CMPD, encoded by the pheA gene (6). The final step, in which phenyl pyruvate is converted to L-phenylalanine, is carried out predominantly by the aromatic aminotransferase encoded by *tyrB* (36). However, both the aspartate aminotransferae, encoded by *aspC* and the branched-chain aminotransferase encoded by *ilvE*, can efficiently catalyse this reaction (37). Phenylalanine biosynthesis is regulated by control of CMPD through phenylalanine-mediated attenuation of *pheA* transcription (6) and by feedback inhibition of the prephenate dehydratase and chorismate mutase activities of the enzyme. Inhibition is most pronounced upon the prephenate dehydratase activity, with almost total inhibition observed at micromolar phenylalanine concentrations (38,39). Chorismate mutase activity in contrast is maximally inhibited by only 40% (39). In *B. flavum*, prephenate dehydratase and chorismate mutase are encoded by distinct genes. Prephenate dehydratase is again the principal point of regulation, with the enzyme subject to feedback inhibition, but not transcriptional repression, by phenylalanine (40,41). Chorismate mutase, which in this organism forms a bifunctional complex with DAHP synthase, is maximally inhibited by phenylalanine and tyrosine to 65%, but this is significantly diminished by the presence of very low levels of tryptophan (42). Expression of chorismate mutase is repressed by tyrosine (29,43). The final step is carried out by at least one transaminase (44). Similarly, in *C. glutamicum*, the activities are encoded in distinct genes, with prephenate dehydratase again being more strongly feedback-inhibited by phenylalanine (45–47). The only transcriptional repression reported is that of chorismate mutase by phenylalanine. The *C. glutamicum* genes encoding prephenate dehydratase and chorismate mutase have been isolated and cloned from analogue-resistant mutants of *C. glutamicum* (8,48) and used along with the cloned DAHP synthase gene to augment L-phenylalanine biosynthesis in overproducing strains of *C. glutamicum* (48).

Many publications and patents have described successful efforts to reduce and eliminate regulation of prephenate dehydratase activity in phenylalanine overproducing organisms (5,9,34,35). As with DAHP synthase, the majority of the reported efforts have focused on the *E. coli* enzyme encoded by the *pheA* gene that is transcribed convergently with the tyrosine operon on the *E. coli* chromosome (6). The detailed characterization of the *pheA* regulatory region has facilitated expression of the gene in a variety of transcriptional configurations, leading to elevated expression of CMPD, and a number of mutations in *pheA* that affect phenylalanine-mediated feedback inhibition have been described (9,33,49). Increased expression of the gene is readily achieved by cloning *pheA* onto multicopy plasmid vectors and deletion of the nucleotide sequences comprising the transcription attenuator (Fig. 2**a**). Most mutations that affect the allosteric regulation of the enzyme by phenylalanine have been identified through resistance to phenylalanine analogues such as β-2-thienylalanine, but there are examples of feedback-resistant mutations arising through insertional mutagenesis and gene truncation (33,49). Two regions of the enzyme in particular have been shown to reduce feedback inhibition to different degrees. Mutations at position Trp338 in the peptide sequence desensitize the enzyme to levels of phenylalanine in the 2 to 5 mM range but are insufficient to confer resistance to higher concentrations of L-phenylalanine (33,49). Mutations in the region of residues 304 to 310 confer almost total resistance to feedback inhibition at L-phenylalanine concentrations of at least 200 mM (9). Feedback inhibition profiles of four such variants (JN305–JN308) are shown in Figure 2**b**, in comparison to the profile of wild-type enzyme (JN302). It is not clear if the mechanism of resistance is similar in either case, but the difference is significant to commercial application because overproducing organisms readily achieve extracellular concentrations of L-phenylalanine over 200 mM.

Precursor Supply

Rate-limiting steps in the common aromatic and phenylalanine biosynthetic pathways are obvious targets in the development of phenylalanine overproducing organisms. However, the detailed biochemical and genetic characterization of *E. coli* has enabled additional areas of its metabolic function to be specifically manipulated to determine their effect on aromatic pathway throughput. Besides efforts to eliminate additional lesser points of aromatic pathway regulation, attempts have been made to enhance phenylalanine production by increasing the supply of aromatic pathway precursors and by facilitating exodus of L-phenylalanine from the cell. The precursors of the common aromatic pathway D-erythrose 4-phosphate and PEP are the respective products of the pentose phosphate and glycolytic pathways. Precursor supply in aromatic amino acid biosynthesis has been reviewed very recently (50,51). Theoretical analyses of the pathway and the cellular roles of these metabolites suggest that the production of aromatic compounds is likely to be limited by PEP availability (52,53) because PEP is involved in a number of cellular processes, including the generation of metabolic energy through the citric acid cycle (54) and the transport of glucose into the cell by the phosphotransferase system (55). Strategies to reduce the drain of PEP by these processes have included mutation of sugar transport systems to reduce PEP-dependent glucose transport (56) and modulation of the activities of pyruvate kinase, PEP synthase, and PEP carboxylase, which regulate PEP flux to pyruvate, oxaloacetate, and the citric acid cycle (50,54,57). Similarly, the availability of E4P has been increased by altering the levels of transketolase, the enzyme responsible for E4P biosynthesis (58). In general, these efforts have been successful in directing additional flux of PEP of E4P into the aromatic pathway, although their effect has not proved to be as predictable as the deregulation of rate-limiting

pathway steps, and their overall impact on L-phenylalanine overproduction has not been well characterized.

Secretion of Phenylalanine from the Cell

Exodus of phenylalanine is of manifest importance in the large-scale production of phenylalanine because the amino acid is typically recovered only from the extracellular medium and washed cells. Lysis of cells to recover additional phenylalanine is not generally practical, and so L-phenylalanine remaining within the cells after washing is usually lost. Because cell biomass is extremely high in large-scale fermentations, this can represent up to 5% of total phenylalanine produced. Additionally, because L-phenylalanine is known to regulate its own biosynthesis at multiple points through feedback inhibition, attenuation, and TyrR-mediated repression, methods to reduce intracellular concentrations of phenylalanine through reduced uptake or increased exodus throughout the fermentation have been sought. Studies have addressed the means by which L-phenylalanine is both taken up and excreted by bacterial cells and whether this can be altered to increase efflux. In overproducing strains, it is likely that most phenylalanine leaves the cell by passive diffusion but specific uptake and exodus pathways also exist. In *E. coli*, L-phenylalanine is taken up by at least two permeases (59), one specific for phenylalanine encoded by *pheP* and the other encoded by *aroP* a general aromatic amino acid permease responsible for the transport of tyrosine and tryptophan in addition to phenylalanine. The genes encoding the permeases have been cloned and sequenced, and *E. coli* mutants deficient in either system have been characterized (60,61). The effect of an *aroP* mutation has been evaluated in L-phenylalanine overproduction (5). In addition, specific export systems have been identified that although not completely characterized have been successfully used to increase exodus of L-phenylalanine from strains of *E. coli* (62,63). In one such system, the Cin invertase of bacteriophage P1 has been shown to induce a metastable phenylalanine hypersecreting phenotype upon a wild-type strain of *E. coli*. The phenotype can be stabilized by transient introduction of the invertase on a temperature-sensitive plasmid replicon and is sufficient to establish L-phenylalanine overproduction in the absence of any alterations to the normal biosynthetic regulation (63).

Summary

The incremental gains made from the various levels at which phenylalanine biosynthesis has been addressed has led to the high-efficiency production strains currently in use today. Almost all large-scale L-phenylalanine manufacturing processes in present operation are fermentations using bacterial strains such as those described in this article in which classical strain development or molecular genetics have been extensively applied to bring about phenylalanine overproduction. The low substrate costs and the economics of scale associated with this approach have resulted in significant economic advantages. However, a number of alternate biotransformation and chemoenzymatic resolution strategies have been extensively developed that have also demonstrated commercially viable levels of L-phenylalanine synthesis.

BIOTRANSFORMATION ROUTES TO L-PHENYLALANINE

L-Phenylalanine Ammonia Lyase Process

The use of L-phenylalanine ammonia lyase (PAL) in various overproducing strains of the yeast *Rhodoturula* was developed by Tanabe Seiyaku Co. and by Genex Corporation in the 1980s to produce phenylalanine in the reaction shown in Figure 3. In this process, fermented cells of yeast strains *R. glutinis, R. rubra* or *R. graminis* (64–67) were recovered and washed before bioreaction under batch or immobilized conditions with *trans*-cinnamic acid and ammonia. The elevated pH and high concentration of ammonia used under the process conditions enabled the normally catabolic PAL reaction (68,69) to favor formation of L-phenylalanine. Significant development work was carried out to determine the appropriate conditions for optimal growth and maximal induction of the PAL enzyme (70) and the appropriate process conditions for retention of PAL activity (71). The principal drawbacks of the PAL process lay in substrate inhibition of the enzyme, low enzyme-specific activity, and enzyme instability. Screening regimes carried out to address these limitations resulted in the identification of an *R. graminis* strain that displayed greater enzyme specific activity and stability than the *R. rubra* and *R. glutinis* strains used previously (64). Subsequent mutagenesis and selection procedures carried out on this strain using the cinnamic acid analogue phenylpropiolic acid led to a further increase in PAL activity through a significant elevation in PAL gene expression (64). Such strain and process development strategies enabled the Genex process to achieve yields of L-phenylalanine in excess of 50 g/L, with close to 90% conversion of substrate to product (67). Nevertheless, the biotransformation could not favorably compete with the economics of fermentative production, and it is not presently used in L-phenylalanine production.

Aspartate or Aromatic Aminotransferase Process

A number of reports from PEI, Nutrasweet, and Allelix, among others, have described the use of aminotransferases (transaminases) to produce L-phenylalanine in the reaction shown in Figure 4. The reaction proceeds by a ping-pong (72,73) mechanism whereby the amino group of a donor amino acid, typically aspartic acid, is exchanged with the keto group of phenylpyruvic acid, yielding L-phenylalanine and the by-product oxaloacetate. Aminotransferases are ubiquitous in nature, and microorganisms typically possess multiple aminotransferases that are involved in the biosynthesis of a number of amino acids, often catalyzing the terminal step from the keto acid precursor (73–75). The enzymes use pyridoxal 5′-phosphate as cofactor and typically possess high catalytic rates and stereoselectivity with broad substrate specificities (76).

This is exemplified by the multiple transaminases in *E. coli* that can each catalyze the synthesis of L-tyrosine, L-aspartate, and L-valine and L-leucine in addition to L-

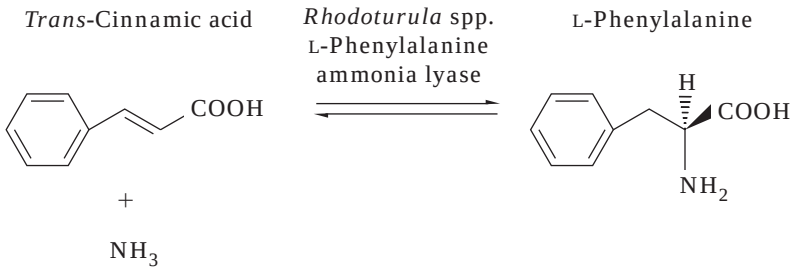

Figure 3. L-Phenylalanine-ammonia-lyase-catalyzed synthesis of L-phenylalanine from *trans*-cinnamic acid.

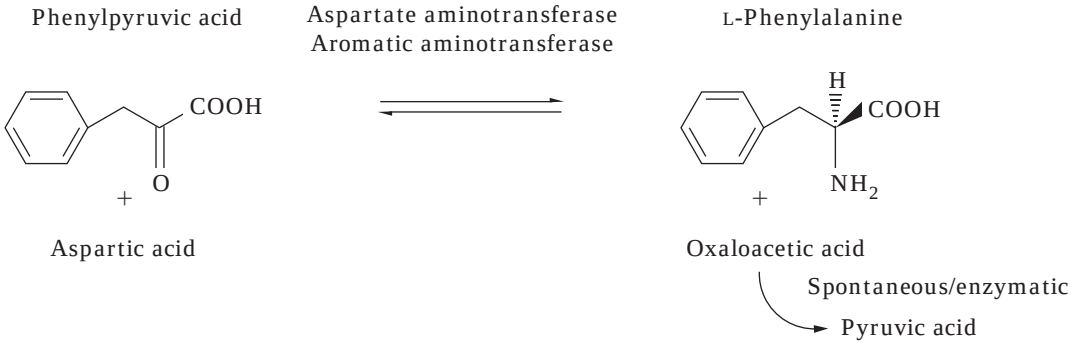

Figure 4. Aminotransferase-catalyzed synthesis of L-phenylalanine from phenylpyruvic acid using aspartic acid as the amino donor. Decarboxylation of oxaloacetic acid drives the reaction toward completion.

phenylalanine (37). Many aminotransferase encoding genes have been cloned and used to overproduce the enzymes (37,77,78). Significant sequence homology often exists among the aminotransferases of individual strains as well as between the corresponding enzymes of microbial and mammalian origin (37). In addition, the tertiary structures of a number of aminotransferases have been determined, furthering the mechanistic understanding of the enzyme and prompting mutagenesis approaches to altering enzyme properties (79). Aminotransferases from many microorganisms have been applied in L-phenylalanine biosynthesis (80–82). In the case of *E. coli*, the highly homologous aspartate and aromatic aminotransferases encoded respectively by the *aspC* and *tyrB* genes have both been developed and applied in this bioconversion (83–85). The aspartate aminotransferase has been generally preferred, having shown greater throughput and increased stability over the *tyrB* gene product (85,86). A number of L-phenylalanine biosynthetic processes involving aminotransferases have been described using either isolated enzyme or whole cells in batched or immobilized systems (82,85,87,88). In the mid 1980s, one such immobilized process was commercialized by PEI using the *E. coli* aspartate aminotransferase (85). In this case, the PPA substrate was economically derived from chemically synthesized 5-benzilidene hydantoin. The highest yields in the transaminase synthesis are generally obtained from batch processes at the expense of the greater catalyst stability of the continuous systems. The cost of catalyst regeneration in batch systems is a drawback of the aminotransferase approach, as is the need for two primary metabolites as substrates. The principal drawback, however, lies in the reaction equilibrium, which being close to 1 limits the yield of the reaction to 50% unless the keto acid by-product can be eliminated from further reaction. To overcome this limitation, commercial transamination approaches have almost invariably used aspartate as the amino donor, which upon transamination to the relatively unstable oxaloacetate will spontaneously decarboxylate to yield pyruvate. Because pyruvate is frequently not a substrate for these transaminases, this enables the reaction to proceed to a yield often exceeding 90%. The decarboxylation of oxaloacetate is more rapid at elevated temperature and has prompted the development of transaminase bioconversions carried out in excess of 50 °C (86). Aminotransferases from thermophiles have been explored in this respect as well as chemical and enzymatic steps to accelerate oxaloacetate decarboxylation and thereby optimize product yield and substrate conversion (89).

Phenylalanine Dehydrogenase Process

A similar process using the phenyl pyruvate precursor has also been developed using the enzyme phenylalanine dehydrogenase. Unlike the aminotransferases, phenylalanine dehydrogenase uses ammonia as a substrate in the reductive amination of phenyl pyruvate, thereby realizing a cost advantage. In addition, the reaction equilibrium lies heavily in favor of phenylalanine synthesis. These advantages in the reaction mechanism are diminished by the dependence of the dehydrogenase on an NADH cofactor that in turn requires enzymatic regeneration. This has been ad-

dressed through the use of a coupled enzyme system (90) in which formate dehydrogenase is used along with phenylalanine dehydrogenase in the reaction scheme shown in Figure 5. The reaction proceeds quantitatively because of the evolution of CO_2 generated in the oxidation of formate. Using partially purified enzymes in membrane reactors, this reaction has achieved phenylalanine titers and substrate conversions comparable to the aminotransferase based systems (90,91). Despite the high efficiencies (92) obtained in this bioconversion, commercial production of L-phenylalanine using this method has not been economically competitive with fermentative processes, mainly because of the costs of phenylpyruvic acid preparation. Nevertheless, in a similar process operated by Degussa using leucine dehydrogenase, this approach has been successfully applied to the synthesis of compounds of higher intrinsic value such as the unnatural amino acid tertiary leucine (93).

RESOLUTION-BASED L-PHENYLALANINE SYNTHESIS

Amino Acid Amide Resolution

In contrast to the various fermentation and bioconversion approaches that have used enzyme stereoselectivity to synthesize L-phenylalanine as a single isomer, additional methods have been developed that rely on the same stereoselectivity to resolve chemically synthesized amino acid DL-racemic mixtures. One such general approach that has been successfully commercialized in L-phenylalanine production relies on cleavage of the L-isomer of a DL-α-amino acid amide mixture by a highly enantiospecific amidase enzyme. The general procedure operated by DSM and shown in Figure 6 uses an amidase containing strain of *Pseudomonas putida* to specifically hydrolyze the L-isomer of the DL-amino acid amide mixture. The racemic amino acid mixture is prepared inexpensively from an aldehyde precursor (94,95) via the Strecker reaction, with alkaline hydrolysis of the resulting aminonitrile. Treatment with benzaldehyde after selective hydrolysis of the L-amino acid amide yields an insoluble Schiff base that forms between benzaldehyde and the residual D-amino acid amide. In this way, the residual D-amino acid amide may be readily separated (96) from the resulting L-amino acid and can then be

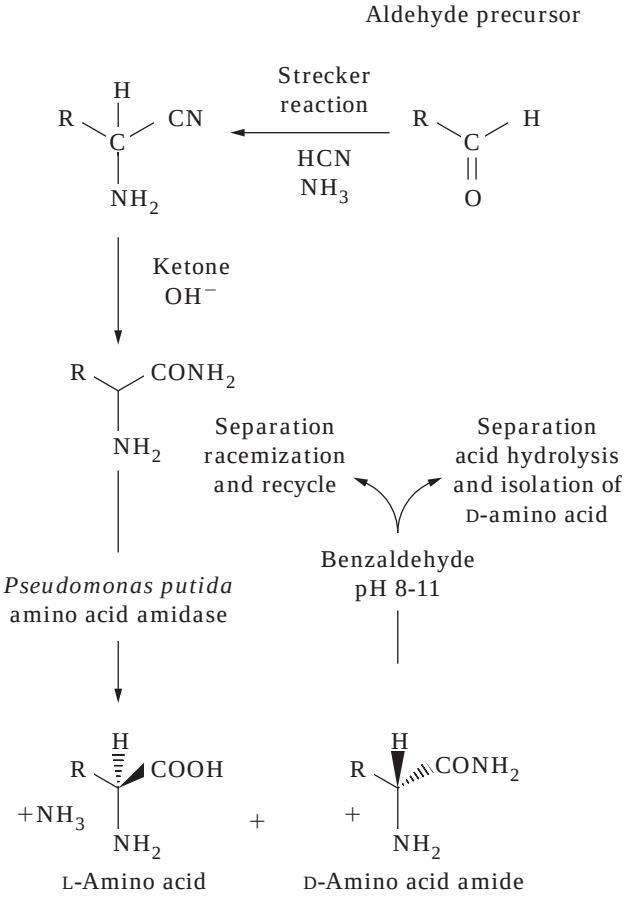

Figure 6. The DSM process for the manufacture of L- and D-α-amino acids.

chemically hydrolyzed and purified or racemized and recycled (97). The advantages of this process include general applicability to the preparation of a range of amino acids (95,98) and the opportunity to recover the D-amino acid if desired from the reaction in addition to the L-amino acid. Conversely, in the preparation of only the L-amino acid by this approach, the need to recycle the unreacted substrate is considered a drawback of the process, necessitating ad-

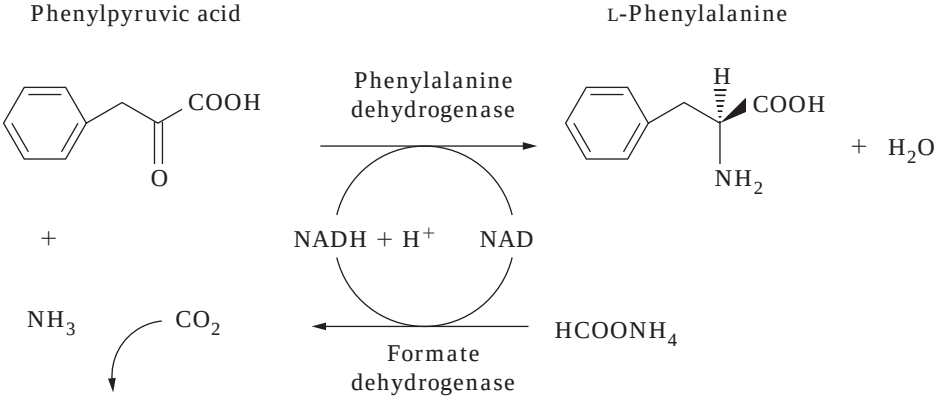

Figure 5. Reductive amination of phenylpyruvic acid to L-phenylalanine using L-phenylalanine dehydrogenase with cofactor regeneration by coupled formate dehydrogenase.

ditional complexity and cost. This aspect has been considered in a further development of this process by DSM in which *P. putida* strains possessing D- or L-amino acid amidase as well as amino acid racemase activity have been identified. The in situ coupling of either amidase with the racemase activity avoids the recycling requirement of the process and facilitates direct conversion of the DL-amino acid amide mix into the desired isomer (99).

Acylase Process

An earlier strategy involving stereoselective enzyme hydrolysis of chemically prepared racemic precursors has been operated successfully for many years by Tanabe Seiyaku. In this process, illustrated in Figure 7, a DEAE-Sephadex immobilized L-specific aminoacylase selectively hydrolyzes *N*-acetyl-L-amino acids from an *N*-acetyl-DL-amino acid mixture (100,101). After hydrolysis, the L-amino acid is isolated by selective crystallization and the remaining *N*-acetyl-D-amino acid is racemized either chemically or enzymatically (102) and recycled. The preferred aminoacylase for this reaction was obtained from the mold *Aspergillus oryzae* and is readily isolated and immobilized in the bioreactor (100). The enzyme has broad substrate specificity and has been used by Tanabe in the production of L-methionine and L-valine and addition to L-phenylalanine. More recently, this process has been further developed by Degussa/Rexim (103) to prepare bulk quantities of L-phenylalanine and a large number of L-amino acids. In addition, Tanabe has reported on the further development of the aminoacylase process through the coupling of acetamidocinnamate aminohydrolase and aminotransferase activity. In this process, L-phenylalanine is produced in two steps from acetamidocinnamic acid through a phenylpyruvic acid intermediate using immobilized cells of two independent bacterial strains (87).

DL-5-Monosubstituted Hydantoin-Based Strategies

The recycling aspect of resolution-based amino acid syntheses such as the amidase and aminoacylase processes is again considered and largely overcome in an alternative strategy using DL-5-monosubstituted hydantoins. Inexpensive chemical routes such as the Bucherer-Bergs synthesis or the condensation of aldehydes with hydantoin (104–107) are used to prepare the racemic hydantoin derivatives that are then resolved using either L- or D-enantiospecific hydantoinase and *N*-carbamoyl amino acid amidohydrolase enzymes to yield the desired amino acid isomer. The process is shown in Figure 8. In the case of phenylalanine, both L- and D-phenylalanine can be prepared from racemic DL-5-benzylhydantoin. The advantage of the hydantoinase process is that in many cases a dynamic resolution can be established whereby the unreacted isomer can be racemized in situ either chemically (108) or in the presence of a racemase (109) enzyme to enable the process to approach 100% yield. Enzymes with L- and D-specific hydantoinase activity have been described in a number of microbial species, with the D-specific activity having been identified much more frequently, often attributable to dihydropyrimidinases involved in pyrimidine catabolism (110–114). Substrate specificities vary significantly between enzyme isolates and contribute to the broad applicability of this approach (113–116). Molecular cloning has been applied in at least one case to isolate a D-hydantoinase encoding gene from a thermophilic bacillus and to subsequently overproduce the enzyme (117). The D- and L-specific *N*-carbamoyl amino acid amidohydrolases have also been shown to be widely distributed in microorganisms (113,114,116,118). The bioconversion steps are typically carried out using whole cells in immobilized systems (110,118) with racemization of the unreacted hydantoin occurring under the normal alkaline conditions of the reaction (108). In some cases, microbial racemases have been used to optimize the racemization step (109,119). The hydantoinase process offers the advantage of relatively inexpensive precursors and high conversion rates through the in situ racemization of the substrate. In addition, through the broad substrate range of hydantoinase and carbamoylase enzymes, the process is broadly applicable in L- and D-amino acid biosynthesis. However, it is in D-amino acid production that large-scale commercial application of the hydantoinase process has been more significantly applied, most notably by Recordati and Kanegafuchi in the manufacture of D-phenyl glycine and D-*p*-hydroxyphenyl glycine as components of semisynthetic penicillins and cephalosporins (120–122) but also by Degussa and Ajinomoto in the production of additional D-amino acids, including D-phenylalanine (122–124).

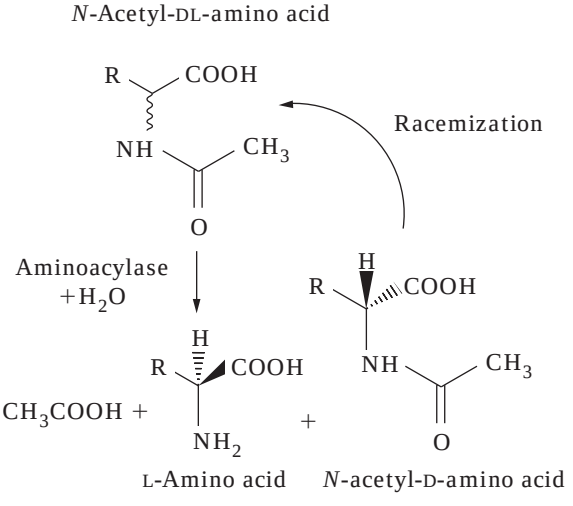

Figure 7. Resolution of *N*-acetyl-DL-amino acids using aminopeptidases yielding L-amino acid and recycling of residual *N*-acyl-D-amino acid.

CONCLUSIONS AND FUTURE PROSPECTS

Numerous commercial processes have been developed for the large-scale commercial production of L-phenylalanine since the early 1980s, fueled by the enormous increase in L-phenylalanine demand for the dipeptide sweetener aspartame. The most successful processes use microbial enzymes at some stage, either in an enantioselective hydrolysis or biotransformation step using chemically derived precursors or in whole cell fermentations using microorganisms engineered through classical and recombinant

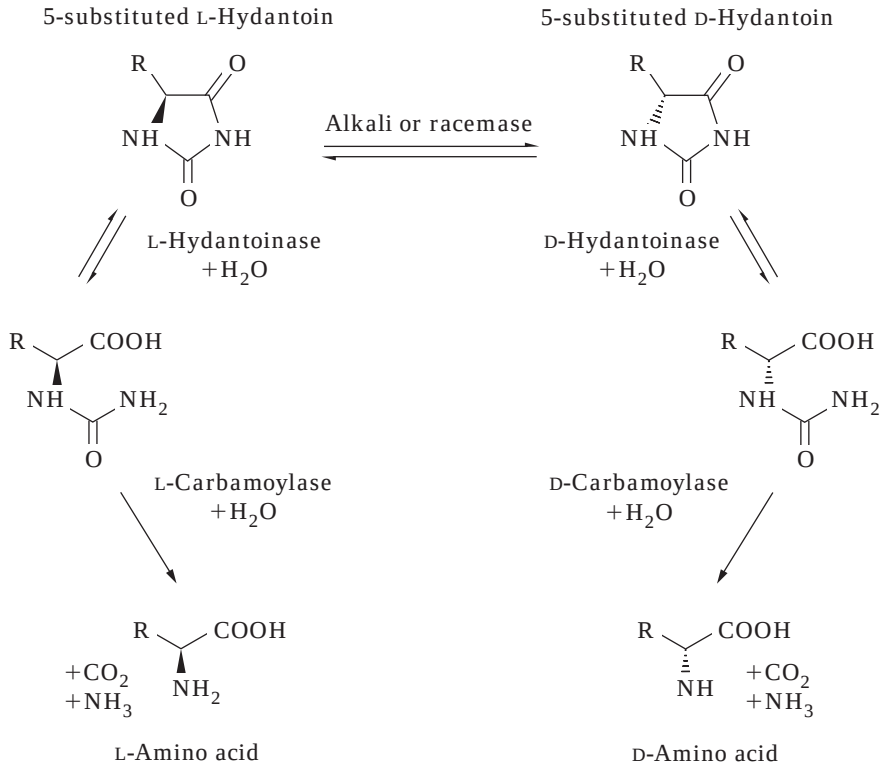

Figure 8. Hydantoinase/carbamoylase-based dynamic resolution of DL-5-monosubstituted hydantoins to either D- or L-amino acids.

strain improvement methodology. In general, the most economically competitive processes have resulted from large-scale fermentation approaches. This is mainly because of the incremental savings achieved in such processes through increased understanding of the physiology and molecular genetic regulation of L-phenylalanine biosynthesis in microbes and the low raw material costs attained through media and process development. In these processes, the concentration of L-phenylalanine can often exceed 50 g/L in crude fermentation broth with the overall incorporation of carbon into phenylalanine from a source such as glucose, equaling or exceeding the theoretical maximum calculated at around 25 to 30% (125). With this level of efficiency, it is unlikely that most major manufacturers of L-phenylalanine will continue to invest significantly in the development of fermentation processes as the return on investment is diminished.

Several elegant biotransformation approaches such as the PAL and dehydrogenase processes have been optimized through molecular genetic strategies but have been impacted by the drawbacks of greater precursor cost and in some cases limited biocatalyst stability. As a result, none of these approaches are currently used to produce L-phenylalanine. Nevertheless, a number of manufacturers, including DSM, Degussa/Rexim, and Tanabe, successfully produce L-phenylalanine through chemoenzymatic routes that are generally more versatile and are often part of more broadly applicable processes in natural and unnatural amino acid manufacture. This is apparent in the manufacture of D-phenylalanine where, in contrast to the preponderance of fermentative routes to L-phenylalanine, the synthesis is currently carried out using the hydantoinase and amidase resolution strategies mentioned earlier. Ultimately, through a greater understanding of microbial pathway engineering and the increasing availability of novel enzymatic activities, it is quite possible that the favorable economics of large-scale fermentation may also become more applicable to D-phenylalanine biosynthesis (126,127).

OUTLINE

INTRODUCTION

NAD^+-dependent phenylalanine dehydrogenase (PheDH, phenylalanine: NAD^+ oxidoreductase, deaminating (EC 1.4.1.20)) was found to occur in *Brevibacterium* sp. by Hummel et al. in 1984 (1). Asano et al. first described the enzymological properties of PheDHs with crystalline enzymes from *Soprosarcina ureae* and *Bacillus sphaericus* (2,3). Similar enzymes that catalyze a reversible oxidation-reduction of amino acids (acting on -CH-$NH_{(2)}$) with NAD^+ or $NADP^+$ as an electron acceptor are classified in EC 1.4.1., which includes glutamate dehydrogenase (GluDH, EC 1.4.1.2-4) (4), alanine dehydrogenase (AlaDH, EC 1.4.1.1), leucine dehydrogenase (LeuDH, EC 1.4.1.9), and other oxidoreductases acting on several amino acids (5).

Since its discovery (1,2,3), much attention has been paid to PheDH because it appeared to be a useful catalyst in the enantioselective synthesis of Phe and related L-amino acids from their keto analogs (6). Some microbial PheDH producers have been isolated from nature, and the enzymes have been characterized. Since 1992, PheDH has been used as a reagent in the colorimetric microdetermination of Phe to detect phenylketonuria (PKU) in the blood of neonates in Japan (7,8).

Here we deal with the occurrence, properties, and structures of bacterial PheDHs, and their applications to the synthesis and determination of amino acids.

DISCOVERY, ENZYMATIC PROPERTIES, AND FUNCTIONS OF PheDH

Hummel et al. screened for a PheDH-producing strain of bacteria from soil and isolated a *Brevibacterium* sp. by an enrichment culture technique (1). Culture conditions for PheDH formation and some reaction conditions to synthesize Phe and Tyr with the crude enzyme were optimized. Asano et al. noted PheDH production in the gram-positive spore-forming bacteria *S. ureae* SCRC-R04 (2,3), *B. sphaericus* SCRC-R79a (3), and *B. badius* IAM 11059 (7) and described its purification, crystallization, and characterization; no activity was found in yeasts. Following these studies, PheDH was given a new entry number: EC 1.4.1.20 (5). Later, *Rhodococcus maris* (9), *Nocardia* sp. (10), *Thermoactinomyces intermedius* (11), *Rhodococcus* sp. (12), *Bacillus cereus* (13), and *Microbacterium* sp. (14,15) were found to produce the enzyme. The occurrence of PheDH appears to be limited in some groups of gram-positive spore-forming bacteria and thermophilic Actinomycetes (11). The distribution of PheDH seems similar to that of LeuDH (16), although the distribution of the former is much more limited than that of the latter, which may be implicated in microbial sporulation, which shuffles carbon and nitrogen metabolism of amino acids by their reversible nature. Because PheDH is specifically distributed in *B. sphaericus* and *B. badius*, which are characterized to be poor in sugar oxidation among the genus *Bacillus* (17), PheDH seems involved in the catabolism of Phe and other amino acids in the medium.

Hummel et al. suggested that PheDH is responsible for the degradation of Phe, not its synthesis (1); however, in *S. ureae* (3), L-phenylalanine aminotransferase activity with oxaloacetic acid as an amino acceptor was detected during growth on a medium containing Phe at a range between 0.001 and 0.006 units/mg, while PheDH was highly induced (0.033 units/mg, measured in the oxidative deamination reaction). The formation of PheDH was growth associated, indicating that the enzyme is responsible for the catabolism of Phe. On the other hand, when the strain was grown in M9 medium supplemented with 0.1% yeast extract, the PheDH activity was detected only in the exponential phase at a level as high as 0.059 units/mg, which is much higher than L-phenylalanine aminotransferase activity (less than 0.001 units/mg). Because the equilibrium of PheDH favors the synthesis of the amino acid, the enzyme probably also functions in the anabolism of Phe, depending on the environment.

Enzymatic Properties

The enzymatic properties of PheDH are summarized in Table 1. The molecular weight of the PheDH subunits are in the range of 36,000 to 42,000. The higher structures vary; PheDHs from *Sporosarcina* (2,3), *Bacillus* (3), and *Microbacterium* (15) are octameric enzymes, whereas PheDH from *Rhodococcus* sp. (12) is tetrameric, that from *Rhodococcus maris* (9) is dimeric, and that from *Nocardia* (10) is monomeric. The molecular weight of PheDH ranges from 42,000 (the monomeric *Nocardia* enzyme) to 331,480 (the octameric *B. sphaericus* enzyme). The optimum pH for the reversible oxidative deamination and reductive amination varies by about 1 pH unit; the former reaction varies in the range of pH 10.4 to 11.3, whereas the latter is in the range of pH 9 to 10.3. The velocity toward the reductive amination to synthesize Phe generally is several times faster than that for the reverse reaction at optimum pH; the V_{max} values for the oxidative deamination reaction of Phe catalyzed by *Sporosarcina* and *B. sphaericus* PheDH are both 114, whereas those for the reductive amination reaction for phenylpyruvate are 598 and 416, respectively (3). The K_m values toward the preferred substrates of L-amino acids and keto acids are in the range of 0.1 to 1 mM, though much higher K_m values of around 100 mM were observed toward ammonia.

Substrate Specificity and Kinetic Properties

In the oxidative deamination reaction, Phe and L-norleucine were active as substrates for the *Sporosarcina* enzyme. The from enzymes *B. badius* and *S. ureae* show narrower substrate specificity than that from *B. sphaericus*, which has almost equal affinity toward Tyr and its keto analog (Table 2), thus *B. sphaericus* PheDH may be called *tyrosine dehydrogenase*. On the other hand, the enzymes showed wider substrate specificities in the reductive amination reaction than observed in the oxidative deamination reaction. The substrate specificity of PheDH has been extensively characterized with the *B. sphaericus* enzyme by using chemically synthesized substrates and substrate analogs (3,6). The relative rates of the reductive amination of α-keto acids and their analogs catalyzed by PheDH from *S. ureae* and *B. sphaericus* are shown in Table 3. The substrate specificity of *B. sphaericus* was examined in detail with various synthetic compounds as shown in Table 4. The enzyme was found to accommodate α-keto acids with large substituents, including compounds substituted at the β-position of pyruvic acid with a longer or bulkier group, although the relative velocity of the reductive amination reaction was low. Phenylpyruvate analogs substituted at the phenyl ring were relatively good substrates, whereas the substitution at the β-position of phenylpyruvate with a bulkier group, such as a hexyl group, greatly lowered the reaction velocity. On the other hand, pyruvate, α-ketoglutarate, α-hydroxypyruvate, benzoylformate, α-keto esters such as ethyl phenylpyruvate and ethyl α-keto-γ-phenylbutyrate, β-keto esters such as ethyl β-keto-γ-phenylbutyrate, β-keto acids such as β-keto-γ-phenylbutyrate, and α-ketoalcohols such as α-keto-β-phenylpropanol were inactive as substrates. Thus, it was shown that the enzyme acts solely on α-keto acids, and a free carboxylic acid moiety is required for a compound to be recognized as a substrate. It was also revealed that the enzyme does not differentiate the configuration of the substituent at the β-position of pyruvic acid; for example, a diastereomeric mixture of L-α-amino-β-DL-methyl-β-phenylpropionate was synthesized from α-keto-β-DL-methyl-β-phenylpropionate. Gln, Asp, methylamine, dimethylamine, trimethylamine and ethylamine (each at 200 mM) did not replace the ammonium ion in the reductive amination reaction. Thus, PheDH from *B. sphaericus* showed wide substrate specificity toward substituted pyruvic acids. The finding that the enzyme utilized α-keto-γ-phenylbutyrate and α-keto-ε-phenylvalerate, but not β-keto-γ-phenylbutyrate, shows it has a definite requirement for a distance between the carbonyl carbon and the carboxyl group of the substrates. For the *Sporosarcina* enzyme, phenylpyruvate, α-ketocaproate, α-keto-γ-methylthiobutyrate, *p*-hydroxyphenylpyruvate, and α-ketoisocaproate were active as substrates. NAD^+ was active as a cofactor for both enzymes, whereas $NADP^+$ was not. The mean value of the apparent equilibrium constant (K_{eq} = [phenylpyruvate][NADH][NH_4^+][H^+]/[Phe][NAD^+][H_2O]) was determined using the *Sporosarcina* enzyme to be 1.4×10^{-15} at the pH range of 7.0 to 11.5 and 25 °C, assuming the conventional concentration of water ([H_2O] = 1 M) (3). For the *B. sphaericus* enzyme, it was calculated to be 2.0×10^{-15} at pH 8.40 to 10.38 (6). The substrate specificities of PheDH from *B. badius* (7) and *R. maris* (9) are similar to that of *S. ureae* (3), which shows more limited activities than the *B. sphaericus* enzyme, although *R. maris* PheDH has a slightly higher affinity toward Tyr than *S. ureae* PheDH. It is notable that the PheDH of *Nocardia* sp. is 0.54 and 2.4 times more active toward indolepyruvate and α-ketoisocaproate, respectively, than toward phenylpyruvate (10), and *T. intermedius* PheDH is inactive toward Tyr and its keto analog (11).

STRUCTURE OF PheDH

The *pdh* genes have been cloned and sequenced, and overproduction of the *Bacillus* enzymes has been achieved (7,18,19). *Escherichia coli* JM 109/pBPDH1-DBL expresses about 120-fold higher activity of PheDH (7,200 units/L) than the wild type *B. sphaericus*. The nucleotide sequences for the *pdh* genes from *B. sphaericus* (19), *B. badius* (20), *S. ureae* (21), *T. intermedius* (22), and *Rhodococcus* sp. (12) have been reported.

Computer assessment of the data showed that the deduced primary structure of *B. badius* PheDH (20) is similar to PheDH of *B. sphaericus* (67.9% identical over 377 amino acids) (19) and *T. intermedius* (56.6% identical over 346 amino acids) (22), LeuDH from *B. stearothermophilus* (23) (49.9% identical over 353 amino acids), $NADP^+$-dependent valine dehydrogenase from *Streptomyces coelicolor* (24) (46.6% identical over 352 amino acids), PheDH from *Rhodococcus* sp. (34.7% identical over 334 amino acids) (12), and GluDH from *Clostridium symbiosum* (25.9% identical over 185 amino acids) (25). Similarities between these proteins are seen in the catalytic domains of amino acid dehydrogenases, G-G-(G or A)-K (26), and the glycine-rich

Table 1. Comparison of Properties of PheDHs

nucleotide-binding domain G-X-G-X-X-(G or A), connecting β-strand with α-helix in the region of adenine dinucleotide phosphate (ADP)-binding $\beta\alpha\beta$ folds, which is strongly conserved among $NAD(P)^+$-dependent dehydrogenases and FAD-containing oxidoreductases (27).

Reaction Mechanism

Speculation concerning the reaction mechanism of PheDH is based on the findings with respect to the substrate specificity already described, and on other experiments with GluDH and LeuDH. The formation of 2-iminoglutarate, catalyzed by GluDH, has been proved (28). The *pro-S* hydrogen at position 4 of the reduced pyridine ring of NADH is incorporated into the product Phe in the reductive amination reaction of PheDH (B-stereospecific) (3). Studies on the steady-state kinetics of the PheDH reaction revealed that the reaction proceeds sequentially (3); that is, after all three substrates (phenylpyruvate, ammonia, and NADH) bind to the enzyme, the product Phe is released. In a homology search of the deduced primary structure of PheDH, a sequence similar to the active site of GluDH, which also resembles LeuDH, has been found (29). The reaction catalyzed by PheDH would be analogous to that of GluDH from *Clostridium symbiosum* discussed on the basis of X-ray crystallographic studies by Rice et al.

(25,26,29–32) and to that of *B. stearothermophilus* LeuDH estimated by the kinetic studies done with wild-type and mutant enzymes by Tanizawa et al. (33). The first step would be initiated by the deprotonation of the α-amino group of Phe by an acidic residue (^{126}Asp in *B. sphaericus* PheDH, which corresponds to ^{165}Asp in GluDH) acting as a general base. Subsequently, a hydride transfer from the hydrogen attached to the α-carbon to the *Si* face of NAD^+ (a hydride transfer between the *pro-S* hydrogen of NADH and the *Re* face of the imino acid) occurs (3). Next, the iminophenylpyruvate produced is hydrated by the action of a general base (^{90}Lys in PheDH, which corresponds to ^{125}Lys in GluDH and ^{80}Lys in LeuDH) in the consensus sequence (G-G-X-K, X = G or A or S). The iminophenylpyruvate breaks into phenylpyruvate, ammonia, and a proton. The orientation of phenylpyruvate is fixed, with the phenyl group accommodated in the hydrophobic pocket and the carboxyl group as an anchor, as evidenced by the finding that the enzyme does not catalyze the reductive amination of neutral α-keto-β-phenylpropanol and the α-keto esters (6). Tanizawa et al. (33) generated LeuDH mutants of *B. stearothermophilus* in which ^{80}Lys was changed to Ala, Arg, or Gln and found that the mutants showed reduced activities, but their K_m values for substrate and coenzyme did not change significantly. They analyzed the pH dependence of the reaction and observed a solvent isotope effect, suggesting that ^{80}Lys participates in catalysis as a general base and assists a nucleophilic attack of water to the substrate α-carbon atom in the oxidative deamination reaction.

PheDH of *T. intermedius* acts preferentially on Phe and Tyr (11), whereas LeuDH of *B. stearothermophilus* acts almost exclusively on Leu and some other branched-chain L-amino acids (34). The two enzymes share a similar sequence (47%). The inherent hexapeptide segment (^{124}FVHAAR) in the substrate-binding domain of a mutant PheDH of *T. intermedius* was replaced by the corresponding part of LeuDH (MDIIYQ) (35). The catalytic efficiencies (K_{cat}/K_m) of the mutant enzyme with aliphatic amino acids and aliphatic keto acids as substrates were 0.5 to 2% of those of the wild-type enzyme. However, the efficiencies for Phe and phenylpyruvate were greatly reduced to 0.008 and 0.035% of those of the wild-type enzyme, respectively. Soda et al. (36) constructed a chimeric enzyme consisting of an N-terminal domain of PheDH containing the substrate-binding region and a C-terminal domain of LeuDH containing the NAD^+-binding region. The chimeric enzyme showed 6% of that of the parental PheDH activity on Phe and had broader substrate specificity in the oxidative deamination. The substrate specificity of the chimeric enzyme in the reductive amination was an admixture of PheDH and LeuDH. The chimeric enzyme has a Gly corresponding to position 124 of PheDH and a Val corresponding to position 307.

Engel et al. showed the same effect by changing only two sites. ^{124}Gly and ^{307}Leu of PheDH from *B. sphaericus* were altered by site-specific mutagenesis to the corresponding residues in LeuDH, Ala and Val, respectively (19,37). These two residues have previously been implicated (by molecular modeling based on the X-ray crystallographic analysis of *C. symbiosum* GluDH [25,26,28–32]), as important residues in determining the degree of substrate discrimination. Of the single mutants L307V and G124A, and the double mutant G124, L307V displayed lower activities toward Phe and enhanced activity toward almost all aliphatic amino acid substrates tested compared to the wild-type; thus an amino acid dehydrogenase that shows closer resemblance to LeuDH was made from PheDH by changing only two residues.

APPLICATION OF THE ENZYME

Application of thermostable AlaDH and LeuDH is reviewed by Ohsima and Soda (34). A review on regeneration of NADH for organic synthesis was published by Chenault and Whitesides (38). By carefully choosing the differences in the substrate specificities of PheDHs, *B. sphaericus* enzyme was applied to the synthesis of various L-amino acids (6). PheDH from *B. badius* was shown be narrower in substrate specificity (7) and, therefore, was applicable to the microdetermination of Phe and phenylpyruvate in blood (8).

Synthesis of L-Amino Acids from Their α-Keto Analogs

The production of Phe as a starting material for the artificial sweetener aspartame has been a target of industrial development (39). Several enzymatic processes of Phe synthesis have been reported: L-specific hydrolysis of benzylhydantoin (40), amination of *trans*-cinnamic acid (41), transamination from an amino donor to phenylpyruvate (42), and two-step conversion starting from acetamidocinnamic acid *via* phenylpyruvate (43,44). Because the α-keto acids are generally more expensive than the L-amino acids, it has been impractical to use the α-keto acids as starting materials for the synthesis of L-amino acids. With the development of an efficient method of phenylpyruvic acid synthesis by double carbonylation of benzylchloride in the

presence of a cobalt catalyst, a new enzymatic method for the synthesis of Phe from phenylpyruvate was sought (45). Previously, the enzymatic synthesis of Phe from phenylpyruvate was accomplished with the transamination reaction. However, this process requires an L-amino acid, such as Asp, as an amino donor, and after the reaction, a by-product such as oxaloacatate or its degradation product, pyruvic acid, are formed. With PheDH, ammonia can be used as a ammonium source.

The discovery of PheDH made it possible to devise a reaction scheme for the synthesis of Phe from phenylpyruvate with NADH as a reducing agent. The enzyme from *B. sphaericus* was chosen to study the application of the enzyme to the synthesis of various L-amino acids because it is very stable and shows broader substrate specificity than other PheDHs, acting on Tyr as well as Phe. Using PheDH from *B. sphaericus* and formate dehydrogenase (FDH) from *Candida* (Fig. 1), with a catalytic amount of NAD^+, Phe was synthesized in a good yield (120 g/L) (6,46).

In the study on substrate specificity of the enzyme in the reductive amination of α-keto acids, various optically pure L-amino acids were quantitatively synthesized using PheDH and FDH. Table 5 shows the yield of L-amino acids thus synthesized (6). The products from α-keto-β-DL-methylbutyrate and α-keto-β-DL-methyl-β-phenylpyruvate were identified as diastereomeric mixtures of Ile and L-*allo*-isoleucine, and L-α-amino-β-DL-methyl-β-phenylpropionic acid, respectively. L-α-Amino-γ-phenylbutyric acid (L-homophenylalanine) and other unnatural L-amino acids could be efficiently synthesized. L-Homophenylalanine is a building block of some of the angiotensin-converting-enzyme inhibitors (47). The solubility of these Phe homologs, such as Tyr, L-α-amino-γ-phenylbutyric acid, L-α-amino-ϵ-phenylvaleric acid, and so on, is so low that they are easily separated in crystalline forms from the reaction mixture by filtration. The filtered enzyme solution can be used for further repeated synthesis.

L-β-Chloroalanine is a useful intermediate for the synthesis of several L-amino acids. Conditions for the synthesis of optically pure L-β-chloroalanine from β-chloropyruvate using AlaDH, LeuDH, and PheDHs from *B. badius*, *S. ureae*, and *T. intermedius* with a regeneration of NADH by FDH were investigated (48). The enzymatic reaction was carried out at neutral pH because of the chemical instability of β-chloropyruvate under alkaline conditions. AlaDH from *B. stearothermophilus* IFO 12550 showed the highest activity for the production of L-β-chloroalanine at pH 7.5. L-β-Chloroalanine was produced with high chemical (>90%) and optical yields (100% enantiomeric excess) and at a high concentration (43 g/L).

Immobilized *Nocardia opaca* cells were used to synthesize Phe from phenylpyruvate and ammonia under hydrogen pressure, although no enzymological study was done (49). Thermostable L-amino acid dehydrogenases such as PheDH and formate dehydrogenase were simultaneously expressed in *E. coli*, which was utilized for the synthesis of L-amino acids from their keto analogs (50).

Continuous Synthesis of Phe

Membranes are efficiently used in the enzyme-catalyzed syntheses of optically active compounds on laboratory and industrial scales (51–53). This technique can be applied for the repeated use of the enzyme in the synthesis, especially if smaller amounts of enzyme are available. Small amounts of PheDH from *B. sphaericus* and FDH were placed in a dialysis tube to check their durability and ef-

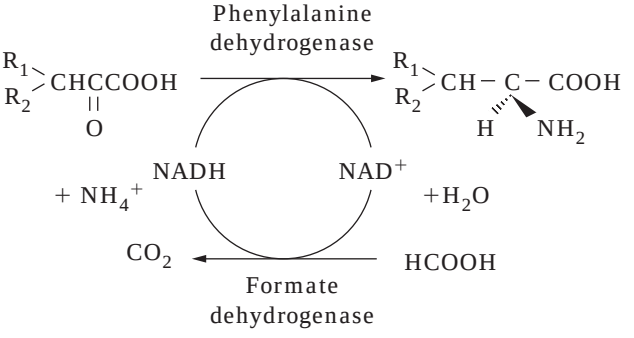

Figure 1. Synthesis of L-amino acids from their β-keto analogs by PheDH with a regeneration of NADH by formate dehydrogenase.

Table 5. Synthesis of L-Amino Acids from α-Keto Acids by Using *B. sphaericus* PheDH and FDH (6)

Substrate	Product	Yield (%)
Phenylpyruvate	L-Phe	>99
4-Hydroxyphenylpyruvate	L-Tyr	>99
4-Fluorophenylpyruvate	L-4-Fluorophenylalanine	>99
α-Keto-γ-phenylbutyrate	L-α-Amino-γ-phenylbutyric acid	99
α-Keto-ϵ-phenylvalerate	L-α-Amino-ϵ-phenylvaleric acid	98
α-Keto-β-methyl-β-phenylpropionate	L-α-Amino-β-DL-methyl-β-phenylpropionate	98
α-Ketononanoate	L-α-Aminononanoic acid	99

Note: To prevent substrate inhibition, α-keto acids have been divided into portions and added to the reaction mixture, not to exceed 50 mM.

ficiency in the continuous synthesis of Phe. The *B. sphaericus* PheDH proved to be very stable in the synthesis, with high efficiency. PheDH maintained its activity for up to 28 changes. During the 34-day operation, 10.74 g (6.51×10^{-2} mol) of Phe was synthesized, using 45 μg (5 units, 1.35×10^{-10} mol) of PheDH, ca. 7.5 mg (15 units) of FDH, and ca. 35 mg of $NAD^+ \cdot Na$ (5×10^{-5} mol). Thus, 1 mol of PheDH catalyzed the synthesis of 4.8×10^8 mol of Phe, which is 2.4×10^5 times the weight of the enzyme (6). Continuous synthesis of Phe by the use of membrane reactors has been demonstrated with PheDHs from *Brevibacterium* sp. (54) and *Rhodococcus* sp. (55,56).

To avoid the multistep purification procedure, the use of enzymes in whole cells is preferable. Acetone-dried cells of *B. sphaericus* and *C. boidinii* were also effective for Phe synthesis, providing a simple microbial method of synthesis. In a typical course of the reductive amination reaction of phenylpyruvate using the mixture of acetone-dried cells as catalysts, the concentration of Phe reached 61.5 mg/mL with a yield of more than 99% (6).

Tyr and Phe labeled with a positron-emitting radionuclide would be useful for positron emission tomography (PET) studies of tissues and neoplasms, such as measuring protein synthesis in tumor and brain tissue. ^{13}N-Labeled Phe, Tyr, and L-dopa were synthesized for PET (57). PheDH catalyzes the reductive ^{13}N amination of either phenylpyruvate or *p*-hydroxyphenylpyruvate to form [^{13}N]Phe or [^{13}N]Tyr, respectively, with NADH as a reducing agent. After short incubation of ^{13}N ammonia and either phenylpyruvate or *p*-hydroxyphenylpyruvate with the enzyme immobilized on the CNBr-activated Sepharose column, 83% of the ^{13}N ammonia was converted to [^{13}N]Phe, and 38% of the ^{13}N was converted to [^{13}N]Tyr, respectively. The labeled amino acids were >30 mCi. L-Dopa was labeled by the exchange reaction between L-dopa and ^{13}N ammonia in the presence of NAD^+ and PheDH; 9% of the label was transferred to L-dopa. In a separate experiment involving the exchange reaction between Phe and ^{13}N ammonia, transfer of label from ^{13}N ammonia to Phe was 50% (Scheme 1). Thus, utilizing *B. sphaericus* PheDH is useful for preparing [^{13}N]Tyr and [^{13}N]Phe.

Microdetermination by Cycling Assay

Quantitative determination of Phe in the plasma is important in diagnosing PKU. Several groups have been investigating the use of PheDH for the microdetermination of Phe and phenylpyruvate in blood samples (58–70). *B. badius* PheDH was found to be structurally closely related to that from *B. sphaericus*, although the former has a narrower substrate specificity suitable for the microdetermination, whereas the latter is more stable and shows a wider specificity suitable for the synthesis of various L-amino acids.

$$^{13}NH_3 + \text{L-dopa} \xrightarrow[NADH+H^+]{PheDH} NH_3 + \text{L-[}^{13}\text{N]dopa}$$

Scheme 1. Enzymatic synthesis of L-[^{13}N]-dopa by an exchange reaction.

Utilizing *B. sphaericus* PheDH, enzymatic cycling assay for the determination of Phe and phenylpyruvate in deproteinized tissue extracts was devised by Cooper et al. (61). Assay 1 couples glutamine transaminase K with PheDH (Scheme 2). Assay 2 combines PheDH, L-amino acid oxidase, and catalase (Scheme 3). In both assays, Tyr and some other amino acids (or their α-keto acid analogs) can replace Phe (or phenylpyruvate) to a small extent. Thus, when measuring Phe, a correction must be made for the nonspecificity of the reaction. By removing Phe on a cation exchange column, it was possible to measure phenylpyruvate in tissue extracts. Concentrations of phenylpyruvate (μmol/kg) in normal rat liver, kidney, and brain were 2.1 $\pm$ 1.1 (n = 8), 1.8 $\pm$ 0.4 (n = 4), and 3.3 $\pm$ 0.6 (n = 4), respectively.

A spectrophotometric recycling assay for the quantitation of Phe (and phenylpyruvate) involves the coupling of PheDH with rat kidney cytosolic glutamine transaminase K (68). The latter enzyme possesses high affinity for phenylpyruvate. Recycling results in a 50-fold increase in sensitivity over that of a conventional spectrophotometric end-point analysis procedure. The spectrophotometric recycling procedure has now been adapted to the measurement of Phe in microliter quantities of human blood. The procedure is 10 times more sensitive than the end-point assay for the spectrophotometric measurement of Phe in

human blood. The findings suggest that the recycling procedure adapted for fluorometry will be even more sensitive.

Microdetermination by End-Point Assay

Naruse et al. have introduced a sensitive enzymatic microplate method using PheDH from *B. badius* for the mass screening of PKU among neonates (7,8) as an alternative method for the Guthrie test (71). The principle of this system involves two steps. First, Phe is oxidized by PheDH to phenylpyruvate, reducing NAD^+ to NADH, which then serves as the electron donor in a colorimetric reaction as follows. In the presence of NADH and the electron carrier l-methoxy-5-methylphenazium methylsulfate (l-MPMS), Co^{3+} is reduced to Co^{2+}, which produces a colored chelate with the metal indicator 2-(5-bromo-2-pyridyazo)-5-(*N*-propyl-*n*-sulfopropyl-amino)phenol (5-BrPAPS) (Scheme 4). This assay system detected Phe in filter paper blood in the concentration range of 0.02–1.50 mM. This method uses a simple TCA extraction method and a PheDH reaction with high substrate specificity that produces very sensitive colorimetric quantitation. The absorbance at 585 nm of this chelate can be measured by a colorimetric microplate reader. This highly specific and sensitive method has been used to screen neonates for PKU in Japan since 1992.

CONCLUSION

Since the recent discovery of PheDH in 1984, several microbial producers of the enzyme have been isolated and their enzymological properties and primary structures have been studied. Indeed, PheDH has been used to detect PKU in the blood of neonates in Japan since 1992. However, PheDH has many further applications to be studied. If the structure and function of the amino acid dehydrogenases are thoroughly understood, it might be possible to create a new amino acid dehydrogenase with a wider scope of application.

OUTLINE

INTRODUCTION

D-Phenylglycines is a general name of a representative group of industrially useful D-α-amino acids. They consist of 2-phenyl and substituted phenylglycine, which have D-form stereo configuration, that is, the opposite stereo configuration of L-amino acids.

D-Amino acids are often called "unnatural" amino acids, and they are not as commonly used as L-amino acids. However, they are widely distributed in various living metabolites and play important roles as physiologically active components.

In recent years, D-amino acids have become increasingly important in the pharmaceutical field as intermediates or chiral synthons for the preparation of β-lactam antibiotics, peptide hormone mimics, pyrethroids, and other compounds. Some D-phenylglycines (D-PGs) are important intermediates for well-known semisynthetic penicillins and cephalosporins, such as ampicillin or amoxicillin, as their side chains.

Among the various D-PGs, D-phenylglycine (D-PG) and D-*P*-hydroxyphenylglycine (D-HPG) are the most important intermediates and are produced and used in large amounts (several thousand metric tons per year) throughout the world. Although they had been produced by classical optical resolution methods until the 1980s, economical and efficient unique synthetic methods have been established that employ asymmetric inversions accomplished chemically (dynamic optical resolution) or enzymatically (hydantoinase process).

STRUCTURE AND NOMENCLATURE

D-PGs are substituted at the second-position proton in glycine (2-amino acetic acid) by phenyl or substituted phenyl radicals to form the D-stereo configuration, as shown in Figure 1. The absolute stereo configuration of the structure is (*R*)-form. D-PGs are enantiomers of L-phenylglycines (L-PGs), which have the reverse stereo configuration.

Representatives of D-PGs include D-phenylglycine (all X = H) and D-*p*-hydroxyphenylglycine (X = *p*-OH), which are also called D-2-amino-2-phenylacetic acid and D-2-amino-2-(4-hydroxyphenyl)acetic acid, respectively.

DERIVATIVES AND USAGE

The practical usage of D-PG and D-HPG is essentially limited to the creation of side chains for various semisynthetic penicillins (SSPs) and semisynthetic cephalosporins (SSCs), as shown Tables 1–3. Among of them, D-PG is used mainly for the side chain of ampicillin and cephalexin, and D-HPG is used mainly for the side chain of amoxicillin and cefatrizine, as shown in Figure 2.

When D-PGs are used for the production of these penicillins and cephalosporins, it is usually as active derivatives such as DANE-salt or acid chloride, which are reacted with 6-aminopenicillanic acid (6-APA, etc.) or 7-amino cephalospollins (7-ACA, 7-ADCA, etc.), as schematically shown in Figure 3.

The DANE-salts of D-PGs are prepared by the reaction of alkali metal salts (Na, K) of D-PGs with methyl acetoacetate (MAA). The acid chlorides of D-PG and D-HPG are prepared by the reaction of D-PGs with chlorinating reagents such as phosphorous pentachloride (PCl_5) or phosgene ($COCl_2$), followed by hydrogen chloride treatment, respectively.

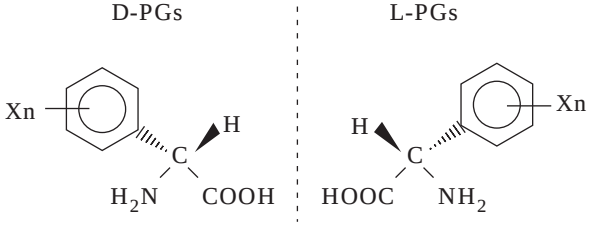

Figure 1. Stereo configurations of D-phenylglycines.

PRODUCTION METHODS

Industrially, D-PGs have been produced by resolving the racemic DL-PGs obtained by chemical syntheses. Typical optical resolution methods are resolution by fractional crystallization of the corresponding diastereomer salt, and by predominant crystallization of the corresponding aromatic sulfuric acid salt. However, these conventional methods are disadvantageous. The former method requires many reaction steps as well as an expensive resolving agent, and the optical purity of the product is not high. The yield obtained in one cycle of the latter method is very low. Furthermore, each method requires a complicated step for racemizing the residual useless L-PGs, and a step for recyclization of the optical resolution in order to increase the overall yield of D-PGs.

To overcome these difficulties, efficient synthetic methods have recently been established by employing unique

asymmetric transformations that are based on in situ racemization, also called deracemization, of the substrate. These new processes have none of the disadvantages of the optical resolution (conventional) method and are technically and economically advantageous. The overall result of these methods is an asymmetric transformation in which, in principle, 100% yield and 100% ee can be obtained.

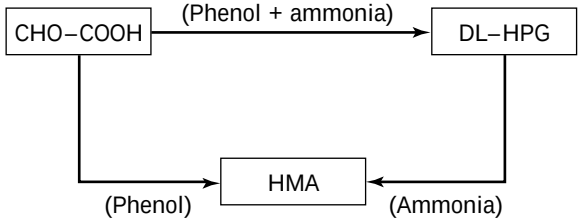
One typical method is based on the dynamic resolution process; the other is the hydantoinase process. These methods are used for the economical production of D-PGs, including D-PG and D-HPG, with good efficiency.

Dynamic Resolution Process

In the conventional optical resolution process, the maximum yield of one cycle is not higher than 50%. However, in the dynamic resolution process, the theoretical resolution yield of D-PGs from DL-PGs can be 100% because in situ racemization of L-PGs occurs through Schiff base tautomerism with the precipitation of the diastereomer salt of the D-PGs plus the resolving agent concomitantly. The mechanism of racemization through Schiff base tautomerism is shown in Figure 4. Some aldehydes or ketones are required as a racemization catalyst to form the Schiff base of the amino acid or its derivatives in an acidic solvent such as acetic acid.

D-PG Production. The dynamic resolution process for D-PG uses DL-phenylglycin amide as the substrare, mandelic acid (MA) as the resolving agent, and benzaldehyde as the racimezation calalyst, followed by acid hydrolysis (1,2). This process is shown schematically in Figure 5.

D-HPG Production. The starting material, DL-HPG, is basically produced from glyoxylic acid, phenol, and ammonia. In DL-HPG preparation, there are two processes: the "one-pot" process and the via-HMA process. In the one-pot process, glyoxylic acid, phenol, and ammonia are reacted at the same time. But the yield is not high (not more than 40%) because of the complex formation of DL-HPG produced with glyoxylic acid under the reaction conditions. So usually, DL-HPG is produced via the reaction of 4-hydroxymandelic acid (HMA), which is produced from glyoxylic acid and phenol, with ammonia or its salts, in good yield (60 to 70%).



DL-HPG can be efficiently resolved into D-HPG by two dynamic resolution processes: (*1*) a dynamic preferential resolution process using arylsulfonic acid (Ar · SO_3H) to precipitate D-HPG · arylsulfonate salt preferentially by the salt seeding (3,4), and (*2*) a dynamic diastereomer resolution process using D-bromocamphorsulfonic acid (BCSA) as the resolving agent (5), as shown in Figure 6. Because of the high reproducibility and high yield, the later process is generally used for commercial D-HPG production. The yield of D-HPG is approximately 90%, and there is almost 100% ee.

Hydantoinase Process

The hydantoinase process, which is an attractive chemicoenzymatic process from both the economical and technical standpoints, was initially developed for the production of various D-amino acids by employing microbial hydantoinase (6). In the process, racemic DL-hydantoins,

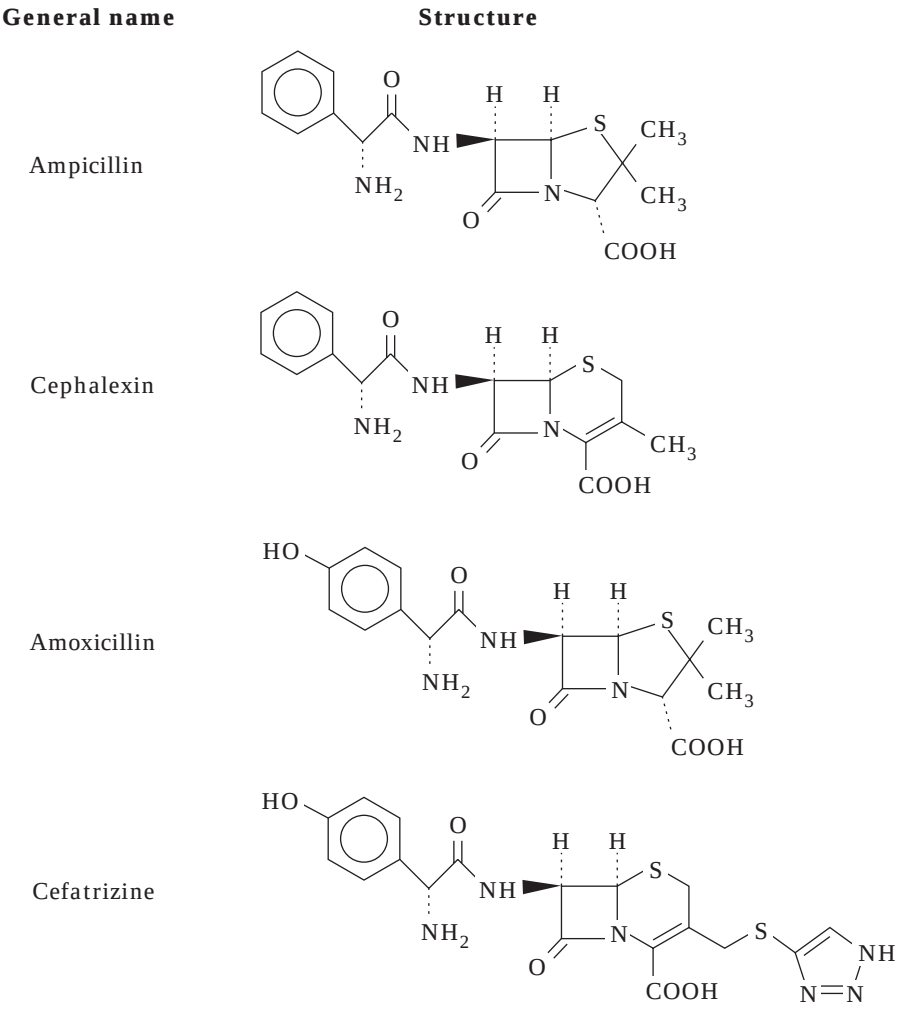


Figure 2. The representative semisynthetic penicillins and semisynthetic cephalosporins.

prepared by a Bucherer-Berg reaction from aldehyde, can be completely transformed into the corresponding optically active *N*-carbamoyl-D-amino acids, because in situ racemization of L-hydantoins occur mainly through keto–enole tautomerism of the hydantoins under the enzymatic reaction conditions. The *N*-carbamoyl-D-amino acids thus obtained can be readily transformed into D-amino acids in good yield by two methods: the chemical method using nitrous acid, or the enzymatic method using *N*-carbamoyl-D-amino acid amidehydrolase.

D-PG can be efficiently produced by the hydantoinase process from benzaldehyde, but the chemical resolution method is usually used for this purpose owing to its easy racemization of the unuseful L-PG.

After the establishment of a new synthetic method for DL-5-(4-hydroxyphenyl)hydantoin (p-HPH), the substrate for D-HPG production, the hydantoinase process was developed mainly for D-HPG production; a practical hydantoinase process was established and began to be used commercially. At present, most commercial D-HPG is produced by this process.

Hydantoinase and D-amino Acid Production. Despite many attempts at L-amino acid production from DL-hydantoins, D-amino acid production from hydantoins was not achieved until the end of the 1970s.

Dudley et al., in the course of studies on the metabolic fate of the anticonvulsants ethotoin and dilantin, found that only the D-form of 5-phenylhydantoin was hydrolyzed into *N*-carbamoyl-D-phenylglycine under the catalysis of animal dihydropyrimidinase (E.C.3,5,2,2), which catalyzed the hydrolysis of dihydropyrimidines to *N*-carbamoyl-*β*-amino acids (7). On the basis of these findings, Cecere et al., studied the specificities of the enzyme and showed that the D-form of several 5-substituted hydantoins were hydrolyzed to provide the corresponding *N*-carbamoyl-D-amino acids (8).

The distribution of hydantoin-hydrolyzing activity in microorganisms was investigated by Yamada and Takahashi (9), and high activity was found in various bacteria belonging to the genera *Pseudomonas*, *Aerobacter*, *Agrobacterium*, *Bacillus*, *Corynebacterium*, and *Actinomycetes*. A hydantoin-hydrolyzing enzyme (hydantoinase) was purified and crystallized from the cell extract of *Pseudomonas striata*, and its properties were established in some detail (10). The bacterial enzyme showed its highest activity and affinity toward dihydrouracil, suggesting its identity with dihydropyrimidinase. The enzyme also catalyzed the

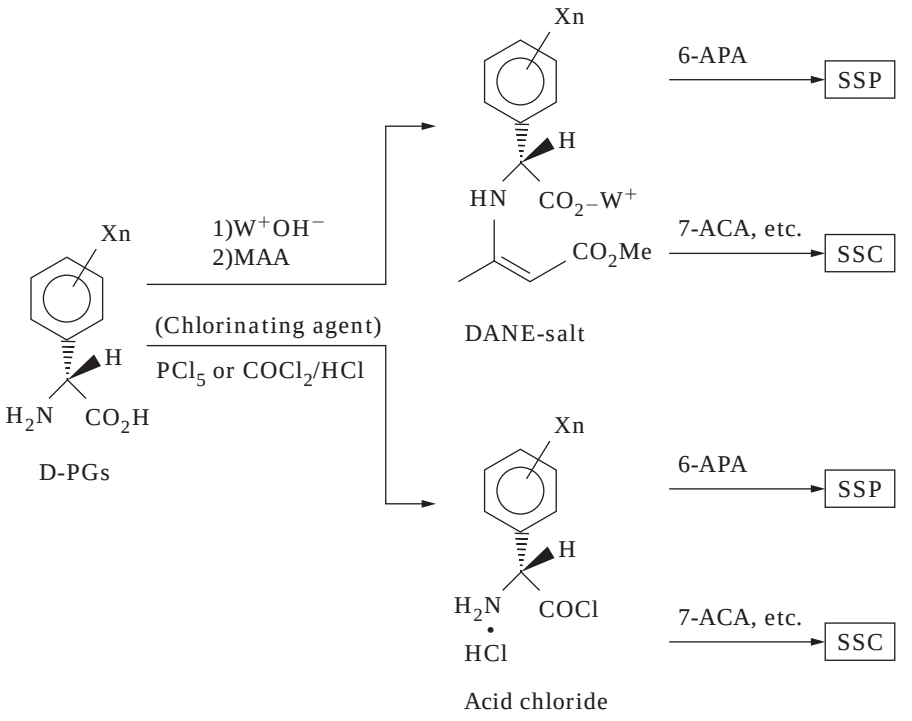

Figure 3. Derivatization of D-PGs and the synthesis of semisynthetic penicillins (SSP) and semisynthetic cephalosporins (SSC).

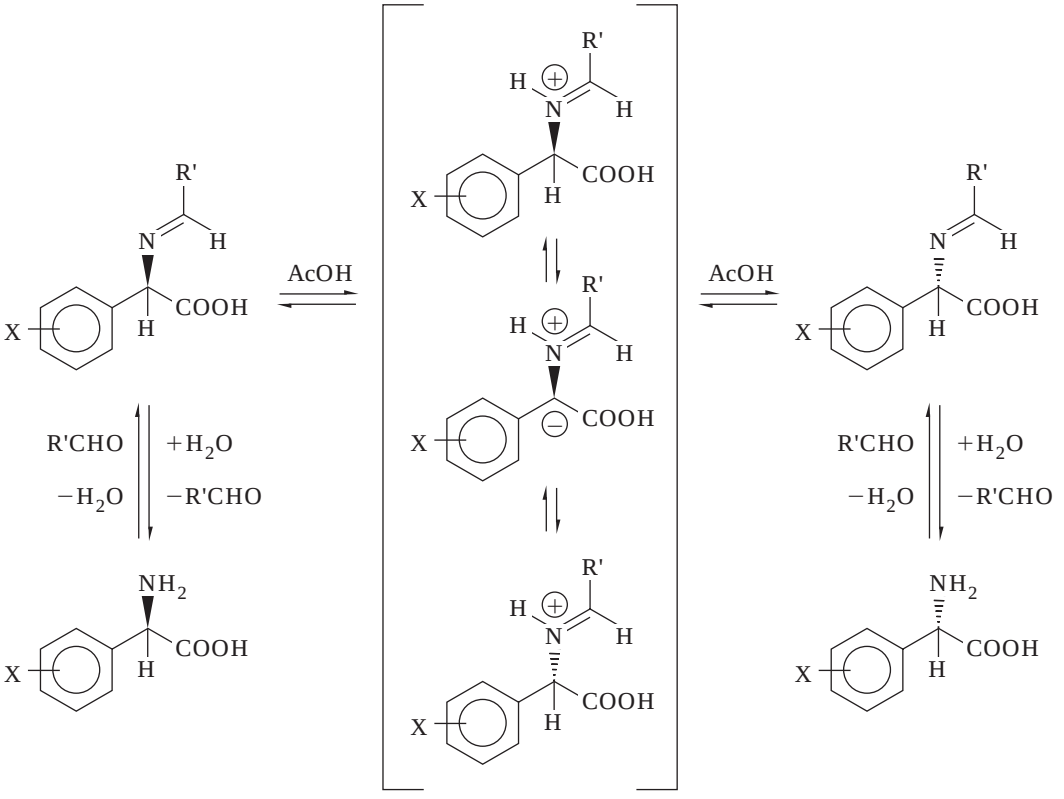

Figure 4. Racemization mechanism.

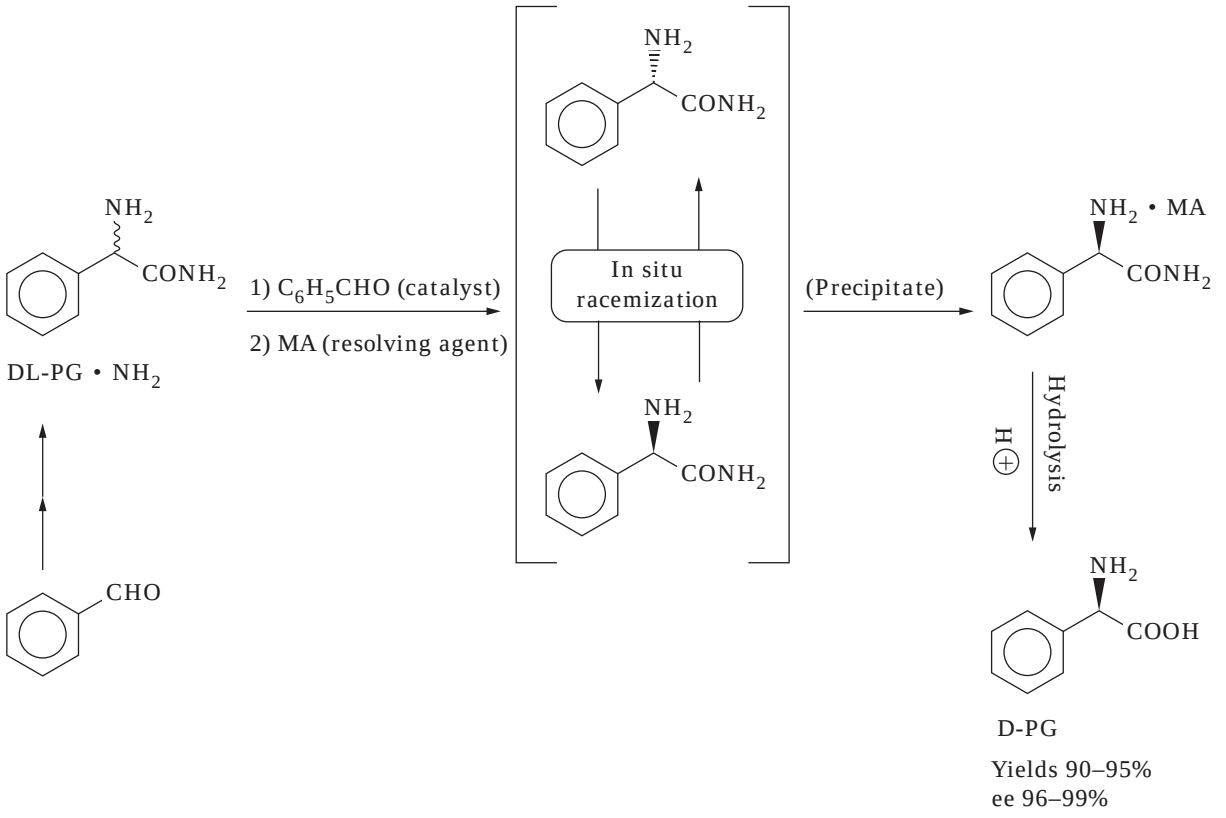

Figure 5. D-PG production.

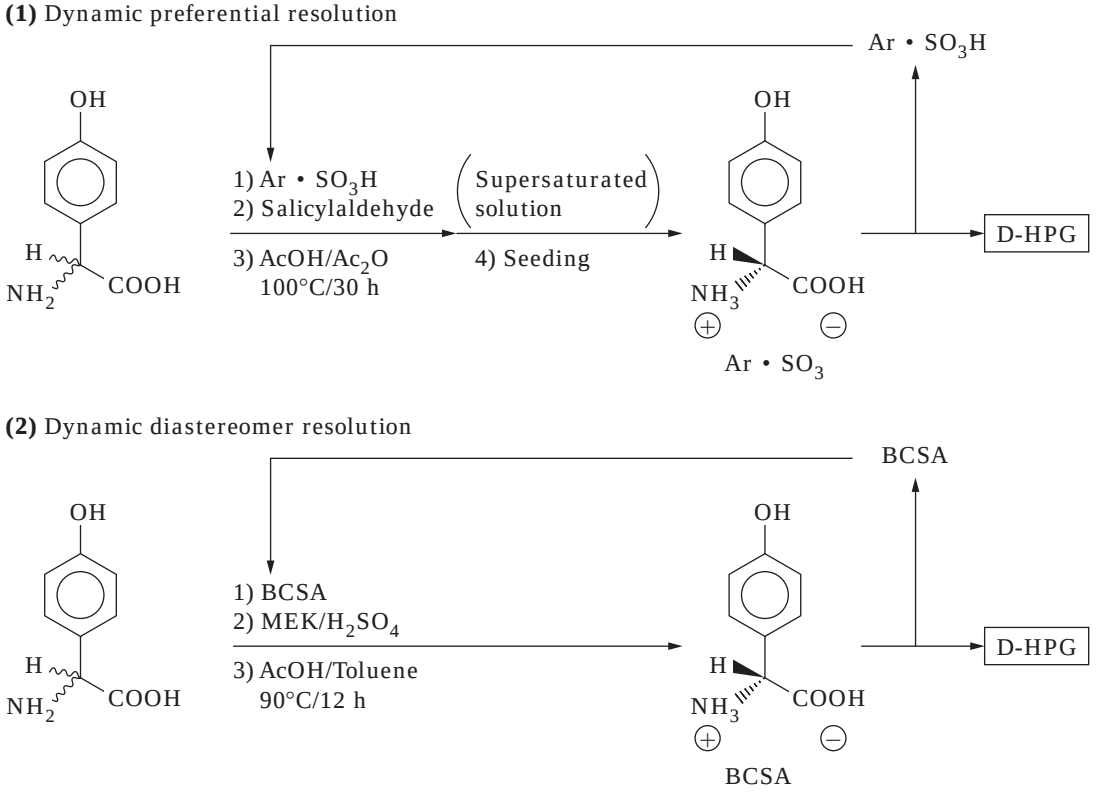

Figure 6. Resolution of DL-HPG into D-HPG.

hydrolysis of a variety of 5-substituted-D-hydantoins, as shown in Table 3. The D-form of 5-aliphatic and aromatic hydantoin such as 6-phenyl, 5-(4-hydroxyphenyl), and 5-thienylhydantoin were hydrolyzed easily to the corresponding *N*-carbamoyl-D-amino acids. However, other hydantoins having a charged group in the amino acid moieties were generally resistant to hydrolysis.

The *N*-carbamoyl-D-amino acids thus obtained were quantitatively transformed to D-amino acids by treating them with nitrous acid under acidic conditions. These results suggested that the combination of the D-stereoselective hydantoinase reaction and the decarbamoylation by nitrous acid was useful as a simple method of D-amino acid production (6).

This chemicoenzymatic process consists of two chemical steps (steps 1 and 3) and one enzymatic step (step 2), as follows:

1. Hydantoin synthesis (generally according to Bucherer–Berg synthesis)
2. Transformation of hydantoin to *N*-carbamoyl-D-amino acid (microbial hydantoinase)
3. Decarbamoylation of *N*-carbamoyl-D-amino acid (nitrous acid treatment)

D-HPG Production. The hydantoinase process for D-HPG production consists of three steps (11), as follows:

1. Hydantoin (5-(4-hydroxyphenyl)hydantoin:p-HPH) synthesis from glyoxylic acid (GOA)
2. Transformation of the hydantoin into carbamoyl-D-HPG using hydantoinase
3. Decarbamoylation of carbamoyl-D-HPG into D-HPG

However, three sub-types are differentiated in the step 3 decarbamoylation:

1. Chemical decarbamoylation using sodium nitrite
2. Enzymatic decarbamoylation using immobilized *N*-carbamoyl-D-amino acid amidehydrolase
3. Enzymatic decarbamoylation using bacterial cells that contain hydantoinase and *N*-carbamoyl-D-amino acid amidohydrolase

A summary is shown in Figure 7.

Synthesis of p-HPH. p-HPH is an important intermediate in the hydantoinase process for D-HPG production. It is known that p-HPH can be synthesized by the reaction of 4-hydroxybenzaldehyde, ammonium carbonate, and sodium cyanide, according to Bucherer–Berg's method. However, this method requires the use of dangerous sodium cyanide and expensive aldehyde. Furthermore the crude hydantoin obtained is contaminated by impurities caused by the oxidative side reaction of the phenol nucleus in an alkaline condition, or it may take on a brownish color.

A novel and unique method for preparing p-HPH involving amidoalkylation of phenol with glyoxylic acid derivatives was established (12). According to this method, p-HPH can be readily prepared in high purity and good yield from relatively inexpensive raw materials such as phenol, glyoxylic acid, and urea.

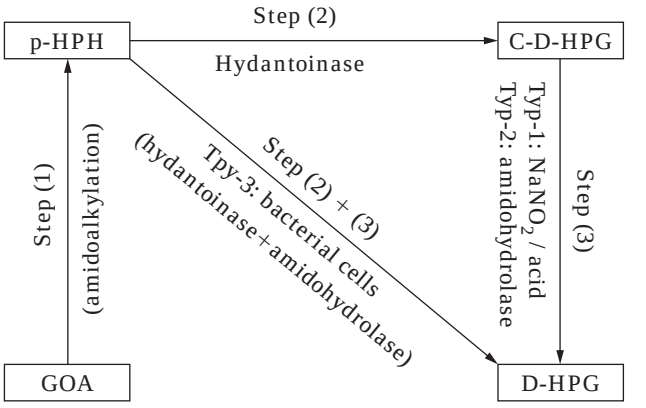

Figure 7. Hydantoinase process of HPG production.

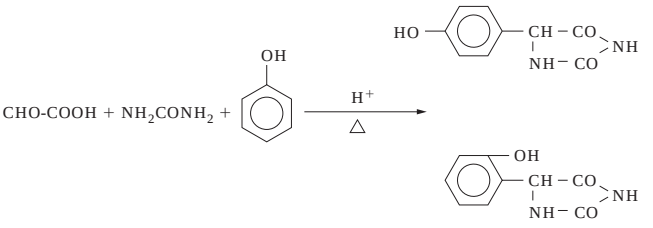

The main product of this reaction is p-HPH, but its isomer, 5-(2-hydroxyphenyl)hydantoin (o-HPH), is produced concomitantly. For the efficient synthesis of p-HPH, the ratio of p-HPH to o-HPH and total HPH yield should be increased concurrently. However, practically speaking, because o-HPH is hard to crystallize and more soluble, p-HPH can be easily obtained in a high state of purity by merely precipitating and separating it from the reaction mixture.

More recently, various methods for p-HPH synthesis have been investigated using glyoxilic acid derivatives. Among them, the method via *p*-hydroxymandelic acid, which is prepared from glyoxylic acid and phenol, seems promising because by-product o-HPH preparation can be minimized.

Transformation of p-HPH into N-Carbamoyl-D-HPG. *Enzyme (hydantoinase) preparation.* Hydantoinase-producing microorganisms can be found in a wide range of genera; high activity is found particularly in bacteria. The stable hydantoinase from thermophilic microorganisms is useful for high productivity.

Cells with high hydantoinase activity can be obtained by culturing the microorganism in a medium supplemented by pyrimidine base or a metabolite such as uracil, thymine, or *β*-alanine as the inducer. The accumulation of hydantoinase in the cells is further increased when a metal ion such as manganese is added to the medium together with the inducer.

Recently, to drastically increase hydantoinase levels, genetic engineering methods were attempted and resulted in reports of 4- to 40-fold higher enzyme activity with an

overexpression plasmid vector. Hydantoinase from thermophilic microorganisms such as thermophilic *Bacillus* seem to be very useful because their stability is rather higher than that of mesophilic microorganisms.

Asymmetric hydrosis of p-HPH. In the asymmetric hydrosis of p-HPH, racemic p-HPH can be completely transformed into *N*-carbamoyl-D-HPH by the action of hydantoinase. Technically and economically, this is a great advantage for the industrial production of D-HPG. The mechanism of this interesting reaction seems to be as follows.

It is well known that hydantoins are readily racemized in dilute alkaline solution through base-catalyzed tautomerism. In practice, p-HPH undergoes spontaneous racemization very easily under mild conditions such as those of the enzymatic reaction. In the reaction system for the asymmetric hydrolysis of p-HPH, only the D-form of p-HPH is susceptible to enzymatic hydrolysis. Unreactive L-p-HPH undergoes rapid spontaneous racemization in the same system. However, the *N*-carbamoyl-D-HPG formed is never racemized under these conditions. Consequently, in this system the enzymatic hydrosis of the hydantoin ring and chemical racemization of the substrate proceed simultaneously, so that DL-p-HPH can be completely transformed into the D-form of *N*-carbamoyl-HPG (Figure 8).

Hydantoinase is employed via intact whole cells or immobilized enzyme resin. In the immobilized form, the stable hydantoinase from a thermophilic microorganism such as thermophilic *Bacillus* is very useful for good performance even after repetitive use.

The concentration of the substrate DL-p-HPH that is available to the reaction depends on the enzyme activity used. A large portion of p-HPH is present in suspended form because the solubility of p-HPH in water is very low (ca. 50 mM). However, this is not an obstacle to the reaction, because the substrate is successively dissolved during the progress of the reaction in alkaline pH (ca. pH9). It is preferable to maintain the pH by adding alkaline solution successively, because the pH lowers in the course of hydrolysis; a drop in pH will result in a lowered reaction rate. It is also effective to cover the reaction mixture with an inert gas such as nitrogen to avoid the oxidative side reaction of the phenol nucleus. Under these optimum conditions, the yield of *N*-carbamoyl-D-HPG formed is almost quantitative.

Decarbamoylation of N-Carbamoyl-D-HPG *N*-Carbamoyl-D-HPG produced by enzymatic hydrolysis can be readily converted into D-HPG by decarbamoylation with nitrous acid under acidic conditions. The principle of this oxidative reaction is based on the Van Slyke determination, and the reaction seems to be a consecutive reaction. With respect to the stereochemistry of the reaction, the retention of the configuration is achieved completely. Therefore, optically pure D-HPG can be readily obtained in good yield. The decarbamoylation is preferably carried out by reacting *N*-carbamoyl-D-HPG with approximately equimolar nitrous acid in an aqueous medium in the presence of a strong mineral acid such as sulfuric or hydrochloric acid. It is convenient to employ a water-soluble salt of nitrous acid such as sodium nitrite or potassium nitrite. Because this decarbamoylation is an exothermic reaction and generates large quantities of gas (N_2 and CO_2), an aqueous solution of nitrous acid is added gradually to the reaction medium with agitation to facilitate a smooth reaction. The reaction temperature is usually kept below 20

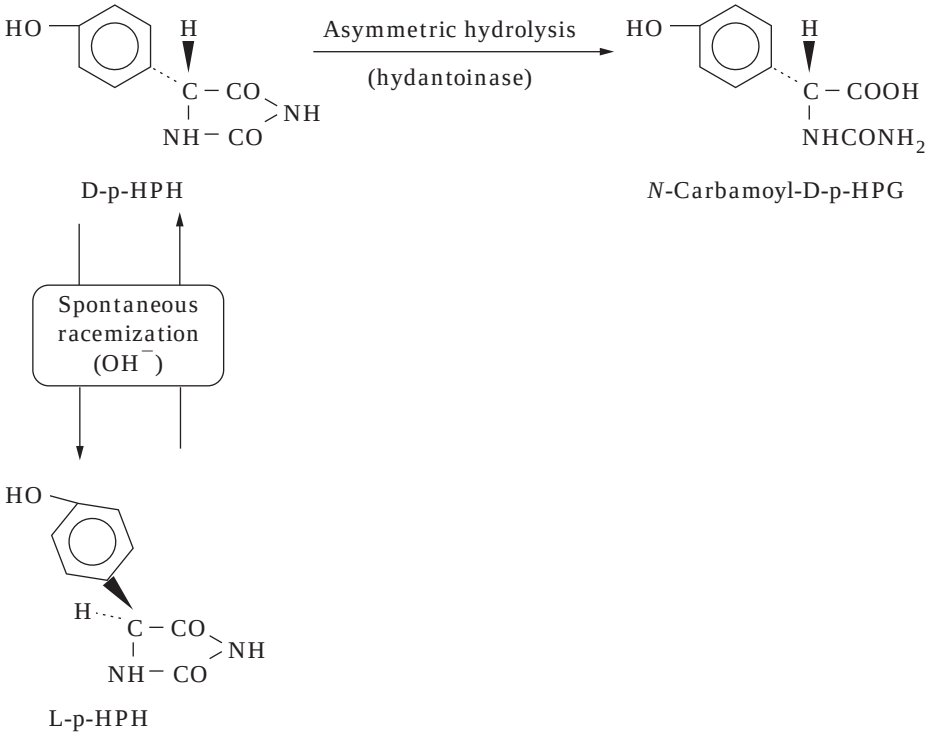

Figure 8. The mechanism of asymmetric hydrolysis of DL-p-HPH.

°C to avoid a side reaction such as the further degradation of D-HPG into 4-hydroxymandelic acid and other compounds. Under these optimum conditions, the yield of D-HPG from *N*-carbamoyl-D-HPG is almost quantitative.

OUTLINE

INTRODUCTION

Since the advent of the recombinant DNA technology, a wide variety of expression systems for protein production have become available. These include systems based on bacteria, lower eukaryotes (yeast and fungi), invertebrates (cells or larvae), vertebrates (cells or whole animal), and plants (cells or whole plant). Of these, only the yeast and fungal expression systems have many of the attributes of both the bacterial and higher eucaryotic expression systems. Yeasts have the robust growth characteristics and ease of manipulation of a bacterial system and at the same time perform many posttranslational modifications found in higher eukaryotes. The purpose of this article is to highlight the strategies one can apply to optimize protein expression in the *Pichia* yeast expression system.

BACKGROUND

Pichia pastoris is a methylotrophic yeast. It is able to use methanol for energy as well as for growth. It possesses a highly regulated pathway for the utilization of methanol (Fig. 1). Synthesis of the enzymes of methanol metabolism increase rapidly once the cells are placed in the methanol medium. The most dramatic effect is seen for methanol oxidase, which accounts for 35% of the cellular protein in cells adapted to grow on methanol. An extensive proliferation of the peroxisomes, known to sequester methanol oxidase and dihydroxy acetone synthase, is also observed in methanol grown cells (1).

Pichia was initially investigated at Phillips Petroleum Company as a potential source of single cell protein. Thus, a very efficient fermentation process (cell density $>$ 130 g dry cell weight per L and biomass productivity $>$ 10 g/L-h) was developed (2). Though impressive, this process could not compete with the economics of production of soy protein. After this setback, Phillips Petroleum Company directed its efforts in developing *Pichia* as an expression system for the production of recombinant proteins. This has turned out to be a worthwhile endeavor.

STRATEGIES FOR OPTIMIZATION OF PROTEIN EXPRESSION

Typical *Pichia* expression vectors (Fig. 2), for example, pHIL-A1 (3), pHIL-D2 (4), pHIL-D7 (5) and pPIC9 (6) are based on the strong methanol oxidase gene (*AOX1*) promoter (7). A wide variety of proteins have been produced in this system (Table 1). The final yield of a protein expressed in *Pichia* is largely influenced by its inherent properties. Nevertheless, the production yield of a protein can be significantly enhanced by using a strategy that takes into account the multiple factors that influence protein expression.

Cellular State of the Expression Cassette

The expression cassette can be introduced into *Pichia* cells by way of chromosomal integration or autonomous replication. However, the integrative approach is preferable because it has the following advantages: (*1*) expression cassette stability; (*2*) ability to generate clones that contain multiple copies of the expression cassette (see section on gene dosage); (*3*) control over the sites of integration (*HIS4* or *AOX1* loci); and (*4*) ability to engineer different modes of integration (with or without the eviction of the *AOX1* coding sequences) (see section on methanol utilization phenotype).

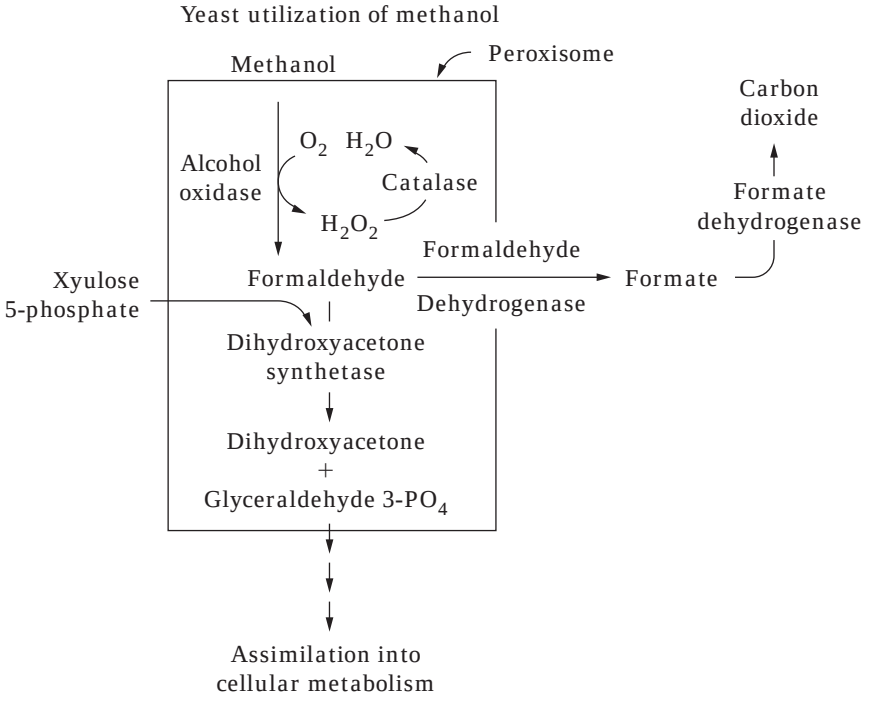

Figure 1. Methanol utilization pathway in methylotrophic yeasts.

Plasmids based on autonomous vectors such as pHIL-A1 (Fig. 2) are maintained in *Pichia* cells at low copies and are rapidly lost from the population of dividing cells. In a small number of cells, autonomous plasmids do eventually integrate. Thus, to arrive at a stable clone, a secondary selection screen should be implemented. This makes autonomous plasmids less attractive for protein expression. However, owing to their ability to transform *P. pastoris* spheroplasts at a very high frequency, the autonomous plasmids are useful for cloning genes in *Pichia* by functional complementation.

Site of Integration of the Expression Cassette

Both *AOX1* and *HIS4* sites have been used successfully for expression. Occasional loss of the expression cassette at the *HIS4* locus because of intrachromosomal crossover between mutant *his4* and the good *HIS4* has been observed. Thus, the *AOX1* locus is the preferred site for stable expression.

Methanol Utilization Phenotype, Mut^+ or Mut^- of the Host

Transformation of a *P. pastoris his4* strain using linear DNA with the ends bearing homology to the 5′ and 3′ regions of the *AOX1* chromosomal locus (e.g., *Bgl*II digested pHIL-D7, or pPIC9 or *Not*I-digested pHIL-D2 [Fig. 2]) results in the site-specific eviction of the *AOX1* structural gene, as illustrated in Figure 3. The eviction of the *AOX1* occurs at a frequency of 1 to 5 per 20 His^+ transformants. *AOX1*-deleted clones show a slower growth phenotype (Mut^-) on minimal methanol medium, as compared to *AOX1* intact clones, which have phenotypically normal growth characteristics (Mut^+) on minimal methanol medium. The Mut^+ transformants arise presumably because of circularization of the linear DNA inside the yeast cell and subsequent integration into one or more of the *AOX1* or *HIS4* chromosomal loci. Thus, in a single transformation experiment, both Mut^+ and Mut^- transformants can be obtained.

For intracellular expression, it is preferable to use Mut^- cells because they will have a lower level of alcohol oxidase protein and the expressed protein can be more readily purified. For secretion, either one of Mut^+ or Mut^- constructs can be used. There is no significant difference between these two types of host cells in the secretion of human serum albumin (74,75).

Gene Dosage: Exploiting the Clonal Variation of Expression

In many instances of *Pichia* expression of heterologous proteins, namely, expression of LACZ (8), hepatitis B surface antigen (9), invertase (33), and human serum albumin (HSA) (4), a single copy of the expression cassette was sufficient for optimal production. Deliberately increasing the copy number had no significant effect on production in these instances. Yet, in other cases, multiple copies of the expression cassette (> 10) are a must for high-level expression. A dramatic effect of copy number on protein production in *P. pastoris* is seen in the production of human tumor necrosis factor (TNF), tetanus toxin fragment C, *Bordetella pertussus* pertactin P69, and mouse epidermal growth factor (EGF) (6,13,14,74,76). In some rare instances, an increase in copy number has a negative effect on the production level (16).

Because the effect of gene copy number on expression is unpredictable, it is necessary to examine the production level as a function of gene dosage. The spheroplast method of transformation of *P. pastoris* results in transformants with a wide range of copy numbers (14,74,76). Analysis of as few as 100 individual clones for protein production is generally adequate to arrive at a good producer. If other methods of transformation (e.g., LiCl method or electroporation) that do not give rise to multicopy transformants at a high frequency are used, then more efficient screens can be used, such as colony hybridization (or dot blot analysis) with DNA probes or selection for multicopy integrants based on increased level of resistance to antibiotic G418 (77) or Zeocin (Invitrogen, San Diego, Calif.).

Alternatively, multicopy constructs of the expression cassette can be obtained by transformation with DNA concatamers or by using multicopy construction vectors such as pAO815 (3,16). This is not a method of choice because it permits production analysis over only a narrow range of gene dosage.

Translational Optimization: 5′ Untranslated Region

The nucleotide (nt) sequence and the length of the 5′ untranslated region (5′ UTR) can be detrimental to optimal protein translation. The leader length of the highly expressed *AOX1* mRNA is 114 nt long, and the sequence is A + U rich (7). For optimal synthesis of heterologous proteins, it is essential that the 5′ UTR of the expression cassette should closely resemble that of the *AOX1* mRNA. Ideally, it is preferable to make it identical to that of the *AOX1* mRNA. The expression level of HSA is increased more than 50-fold by adjusting the 5′ UTR to be closer to that of the *AOX1* mRNA. Expression plasmid such as pHIL-D7 can be used to readily make 5′ exact constructs.

Translational Optimization: Initiation Codon AUG Context

The translation initiation codon AUG should be avoided in the 5′ UTR to ensure efficient translation of mRNA from the actual translation start site. The mRNA secondary structure around the initiator AUG may be adjusted, so that AUG is relatively free of secondary structure (74). This can be accomplished by redesigning the initial portion of the coding sequences with alternate codons (3,74).

Transcriptional Optimization

Genes with high A + T nucleotide clusters are inefficiently transcribed because of premature termination. One such sequence, ATTATTTTATAAA, present in HIV-gp120 has been identified to block transcription in *P. pastoris*, and when this stretch is altered to TTTCTTCTACAAG, the premature termination is abolished (17). Because there are many yet unidentified AT-rich stretches that act as transcriptional terminators, a general strategy would be to redesign the genes using *P. pastoris* preferred codons (3,74) so as to have an A + T content in the range of 30 to 55%. By using this approach, it has been possible to con-

Product Secretion

If a protein can be secreted, it is the desired mode of protein production because of the ease of product recovery. Furthermore, certain normally secreted proteins, such as HSA and growth hormones, remain insoluble when expressed intracellularly. For a protein that is not normally secreted, it may be difficult to cause secretion. However, there are some encouraging results with respect to yeast secretion of cytochrome P-450 (78) and rat liver elongation factor (55) that suggest that at least in some instances it may be possible to secrete a normally intracellular protein.

The choice of secretion signal is rather arbitrary (Table 1). In several cases, (HSA, invertase, bovine lysozyme, etc.), the native signal sequence is adequate. We have found that the native secretion signals present in matrix metalloproteinases 1,2,3,9 (MMP-1,2,3,9) and tissue inhibitor of matrix metalloproteinases 1 (TIMP-1) are functional in the *P. pastoris* system. If a native secretion signal sequence is not available, then a signal sequence based on the *S. cerevisiae* invertase (Suc2p), the *S. cerevisisae* α-mating factor (αMF), or the *P. pastoris* acid phosphatase (Pho1p) can be used.

The pre-pro αMF signal works very efficiently, especially for the secretion of a large variety of proteins, including the smaller-sized products such as aprotinin, EGF, thrombomodulin fragment, blood factor XII, a fragment of amyloid β-protein, antibody single-chain Fv fragment, and ghilanten (Table 1). In making protein fusions to the αMF signal, it is prudent to retain the Glu-Ala spacers adjacent to the Kex2-like protease cleavage site: (. . . V-S-S-L-E-Lys-Arg-^{vKex2p}Glu-Ala-^{vDapp}Glu-Ala-^{vDapp}fused protein). The presence of the Glu-Ala spacers help to alleviate the steric interference by the fused protein, resulting in an efficient cleavage of the pro sequence by the *P. pastoris* Kex2-like protease (16). The Glu-Ala spacer sequence is subsequently cleared by a diamino peptidase (Dapp) to yield the protein of interest free of additional N-terminal amino acid residues. In spite of taking this precaution, we have noticed that the pro sequence is not cleaved when the αMF signal is fused with human brain-derived neurotrophic factor (BDNF) (mol. wt. $\sim$ 14 kDa). In this situation, BDNF is secreted into medium as a 26 to 30 kDa product, which is the expected result if the pro portion of the αMF signal is not cleaved and is heterogeneously glycosylated at the multiple glycosylation sites present in the αMF pro peptide (5).

Acid phosphatase (Pho1p) secretion signal sequence, invertase secretion signal, and a hybrid sequence consisting of Pho1p secretion signal containing a Kex2 protease recognition sequence has also been used successfully for high level (>g/L) secretion of certain proteins (Table 1).

Choice of the Secretion Signal

In most of the examples listed in Table 1, the relative efficacies of the different secretion signals for a given product have not been examined. Only in a limited number of cases has a rough comparison been made between native signal versus pre-pro αMF. For example, in the case of invertase secretion, both the extent of glycosylation and secretion kinetics are enhanced when the invertase signal sequence

Figure 2. Typical *Pichia* expression vectors. (**a**) pHIL-D1(3) is an *E. coli–P. pastoris* shuttle vector, with sequences required for selection in each host. The left half of the plasmid is a portion of pBR322, from *Cla*I (at position 7676 in the map) to *Pvu*II site (modified to *Bgl*II [at nt 5319 in the map]). This segment of pBR322 contains the ampicillin-resistance encoding gene (Ap^R) and the origin of replication (ColE1 *ori*). The *Eco*RI site in this segment has been eliminated. The DNA elements comprising the rest of the plasmid are derived from the genome of *P. pastoris*, except for short regions of pBR322 used to link the *Pichia* sequences. The *P. pastoris* elements in the plasmid are as follows: (*1*) 5′ *AOX1*, approximately a 1,000 bp of the alcohol oxidase promoter. The *AOX1* sequences following the nt A of the ATG start codon have been removed by BAL 31 treatment and the synthetic linker 5′-GGAATTC added to generate a unique *Eco*RI cloning site. (*2*) AO-t, approximately a 300 bp of the *AOX1* terminating sequence. (*3*) *P. pastoris* histidinol dehydrogenase gene, *HIS4*, contained on a 2,800-bp fragment to complement the defective *his4* gene in the *P. pastoris* strains such as GS115, SMD1168, etc. (*4*) Region of 3′*AOX1* DNA approximately 650 bp, which together with the 5′*AOX1* region is necessary for the site-directed displacement of *AOX1* coding sequences (see Fig. 3). The unique *Sac*I (at nt 209 in the map) and *Sal*I (at nt 2875 in the map) sites present in the plasmid can be used for site-directed integration of the entire plasmid into the *AOX1* and *HIS4* loci of *P. pastoris*, respectively. (**b**) Plasmid pHIL-A1 is an *E. coli–P. pastoris* shuttle vector, with sequences required for selection and autonomous replication in each host. The left half of the plasmid is a modified portion of pBR322 containing the Ap^R gene and the ColE1 *ori*. The DNA elements comprising the rest of the plasmid are derived from the genome of *P. pastoris*, except for short segments of pBR322 used to link the yeast sequences. The various *P. pastoris* sequences are as follows: (*1*) 5′*AOX1*, approximately 750-bp portion of the *AOX1* promoter with the *Eco*RI (at position 337 in the map) engineered as previously described (Fig. 1). (*2*) AO-t and *HIS4* are same as in Figure 1. (*3*) *PARS1*, approximately 190-bp segment of a *P. pastoris* autonomous replication sequence. The unique *Sal*I (at nt 2885 in the map) site can be used to direct the integration of pHIL-A1 into the *HIS4* loci of *P. pastoris*. (*c*) pHIL-D2 (4) has a 458-bp DNA containing the f_1-*ori* inserted between the original *Dra*I sites of pBR322. The *Not*I sites at nt 8 and 5337 are used for site-directed displacement of *AOX1* coding sequences. The other details are the same as described for pHIL-D1 (**a**). (**d**) pHIL-D7 is a shuttle plasmid containing the kanamycin-resistance-encoding gene (Km^R) and is useful for selection of multicopy transformants based on increased level of resistance to G418. Unlike the commonly used vectors such as pHIL-D1 and pHIL-D2, we have designed pHIL-D7 so that it has a unique *Asu*II site at nt position 934 (the second *Asu*II site present in the 3′*AOX1* has been eliminated). Therefore, the sequence TTCGAAACG can be added immediately upstream of the start codon (ATG) of the gene of interest, and an *Eco*RI site can be added downstream of the stop codon. The modified gene can then be inserted between the *Asu*II (at nt 934 in the map) and *Eco*RI (at nt 944 in the map) region TTCGAAACGAGGAATTC of pHIL-D7. Thus, the modified gene will have identical 5′ UTR to that present in *AOX1*. The other details are same as described for pHIL-D1 (**a**). (**e**) pPIC9 (6), a secretion vector with αMF secretion signal and multicloning sites. The other details are same as for pHIL-D1 (**a**).

Table 1. Partial List of Heterologous Proteins Expressed in *P. pastoris*

Intracellular expression

E. coli β-galactosidase (LACZ) (8)
Hepatitis B surface antigen (HBsAg) (9)
Human tumor necrosis factor-α (TNF-α) (10)
Human TNF-α analogues (11)
Salmon growth hormone (SGH) (K. Sreekrishna and K. A. Parker, unpublished observations, 1987)
Streptokinase (12)
Tetanus toxin fragment C (13)
Bordetella pertussus pertactin P69 (14)
Human inteleukin 2 (W. R. McCombie, personal communication, 1988)
B. sphaericus mosquitocidal components, BSP1, BSP2, and BSP1 + BSP2 (15)
Superoxide dismutase (SOD) (16)
Human serum albumin (HSA) (4)
HIV gp120 (17)
Porcine leukocyte lipoxygenase (18)
$p110^{RB}$ retinoblastoma tumor suppressor protein 919
Hamster prion protein (20)
Spinach phosphoribulokinase (21)
Spinach cytochrome C oxidase (22)
Spinach glycolate oxidase (23)
Dogfish shark cytochrome P450c17 (hydroxylase and lyase activities) (24)
Algal phytochrome (25)
Green fluorescent protein (GFP) (26)
Arabidopsis chaperone protein ATJ2 (27)
Corn cytochrome *b* and cytochrome *c* reductases (28)
Mouse thioether methyltransferase (29)
Polyomavirus large T antigen (30)
Rat liver mitochondrial carnitine palmitoyltransferase I and II (31)
Mouse $5HT_{5A}$ serotonin receptor (32)

Secretion using native secretion signal sequence

S. cerevisiae invertase (*SUC2*) (33)
Human serum albumin (HSA) (4)
Bovine lysozyme (34)
Matrix metalloproteinases MMP-1,2,3, and 9 (5)
Tissue inhibitor of matrix metalloproteinases-1 (TIMP-1) (5)
MMP-1,2,3, or 9 coexpressed with TIMP-1 (5)
Barley α-amylases 1 and 2 (35)
Cathepsin E (36)
D-alanine carboxypeptidase (dacA) of *Bacillus stearothermophilus* (37)
Pectate lyase pel B from *Fusarium solani f.* sp. *pisi* (38)
IgE receptor (α subunit) (39)

Secretion using pre–pro α *mating factor (*α*MF) secretion signal sequence*

Aprotinin (16)
S. cerevisiae invertase (*SUC2*) (16)
Human epidermal growth factor (EGF) (16)
Mouse epidermal growth factor (EGF) (6)
Insulin-like growth factor-1 (IGF-1) (40)
Kunitz protease inhibitor (nexin-2) (41)
Human vascular endothelial factor (VEGEF) (42)
κ-Bungaratoxin (43)
Cathepsin L pro-peptide (44)
Human fibroblast collagenase, matrix metalloproteinase-1 (MMP-1) (45)
N-Lobe of human serum transferin (46)

Table 1. Partial List of Heterologous Proteins Expressed in *P. pastoris* (*continued*)

C. albican hyphal surface protein HWP1 (47)
Coffee bean α-galactosidase (48)
Major histocompatibility (MHC) class II human leukocyte antigens DRα-Fos and DRβ-Jun (49)
Human immunodeficiency virus envelope glycoprotein gp120 (17)
Ghilanten (50)
Human factor XII (51)
Cellulose binding domain (CBD)–factor X variant fusion protein (52)
Cellulose binding domain (CBD)–steel factor fusion protein (1996 Invitrogen) (52)
Human gelatinase B (matrix metalloporiteinase-9, MMP-9) fragment (53)
Measles viral glycoprotein (54)
Rat liver elongation factor-2 (eEF-2) (55)
Human growth hormone (56)
Drosophila notch protein EGF-like domains (57)
Type II fish antifreeze protein (58)
Follicle stimulating hormone, FSH α and β chains (59)

Secretion using acid phosphate secretion signal sequence

Human vascular endothelial factor (VEGEF) (60)
Pectate lyase pelC from *Fusarium solani* f. sp. *pisi* (61)
Catalytic domain of 92-kDa gelatinase (matrix metalloproteinase-9, MMP-9) (62)
Angiotensin-converting enzyme (ACE) and its mutants (63)
Rabbit plasma cholesteryl ester transfer protein (CETP) (64)
β-Cryptogein elicitor protein secreted by *Phytophthora cryptogea* (65)
Candida albicans aspartic proteinases (66)
Angiostatin (an integral fragment of plasminogen) (67)
Rabbit reticulocyte 15-lipoxygenase (68)
A single chain antibody (69)
Human monocyte chemotactic protein-3 (MCP-3) (70)

Secretion using a hybrid of acid phosphatase signal sequence with a synthetic pro sequence and a KEX2 protease cleavage site

Tick anticoagulant peptide (TAP) (71)

Secretion using invertase (SUC2) secretion signal sequence

A single-chain antibody (P. Mezes, personal communication, 1992)
Porcine tumor necrosis factor-α (TNF-α) (72)
Boophilus microplus Bm 86 antigen (73)

Note: As of November 1998, the number of proteins expressed in the *Pichia* system is 172.

is substituted with the pre-pro αMF sequence (secretion $t_{1/2}$ of 10 min for pre-pro αMF signal, compared to 90 min for the native invertase signal) (16). Thus, in this case, one would avoid using αMF signal if hyperglycosylation is not desired. However, if higher productivity (product yield per liter per hour) is desired, then it is preferable to use the pre-pro αMF signal. The secretion kinetics can also impact on the recovery of the intact protein, if the expressed protein is susceptible to proteolysis in the *Pichia* broth. For example, the yield of full length MMP-1 from the culture medium is significantly improved by using the αMF signal instead of the native signal (5,45,47).

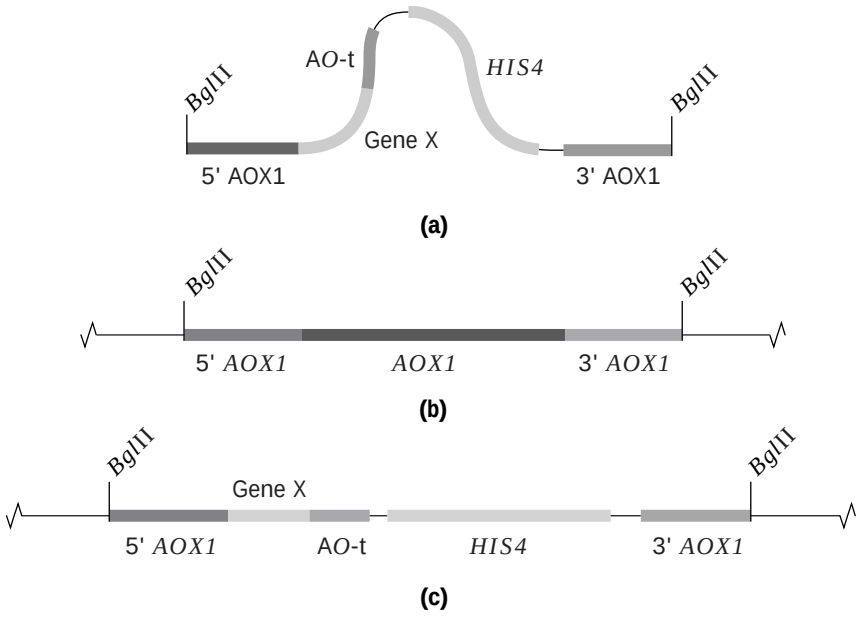

Figure 3. Site-specific eviction of *AOX1* by gene replacement. (**a**) *Bgl*II-digested DNA derived from pHIL-D1 expression plasmid used for transformation. Gene X is the gene of interest cloned at the *Eco*RI site of pHIL-D1. (**b**) *P. pastoris* chromosomal *AOX1* locus. (**c**) Chromosomal structure resulting from the replacement of the entire *AOX1* locus by the transforming DNA (shown in **a**).

Product Stabilization by Media Manipulations

In some instances, a secreted protein is rapidly degraded in the *Pichia* broth. The stability of a protein in the *Pichia* broth can be improved by manipulating the pH of the induction medium. The recommended pH range for experimentation is between 2.8 to 8.0. The pH control is best maintained in a fermenter, although it is possible to have a reasonable pH control even in shake flask cultures with the use of appropriate buffers (phosphate buffer for pH 5.7 to 8.0; alanine-HCl buffer for pH 2.5 to 3.6; citrate buffer for pH 3.0 to 6.0). The product stability is further enhanced by addition of casamino acids (1 to 4%) or yeast extract (1%) plus peptone (2%) to the medium (6,16,40,74,75). For example, secretion of HSA was significantly improved by raising the pH of the medium from 5.2 to 6.0, and the yield was further enhanced by the addition of yeast extract and peptone (4,74). Production of mouse EGF was favored at pH 3.0 in the presence of casamino acids (6). Casamino acids are preferable to yeast extract plus peptone, because the peptide components of peptone (such as bovine collagen fragments) can interfere in product analysis and recovery (5). Addition of 5 mM EDTA to the medium also improves product stability. It should be noted that media manipulation can significantly alter the profile of protein components, so that previously unnoticed proteins can become evident (5). The susceptibility of a protein to proteolysis in the *Pichia* culture medium can be determined beforehand if sufficient quantity of protein is available and proper adjustments can be made to the culture medium.

Protease-Deficient Strains

In addition to the media optimizations described in the previous section, the product yield can be further improved by using a protease-deficient *Pichia* strain. Two generally applicable techniques have been used to generate protease deficient strains. In one approach, a specific *Pichia* protease is knocked out by site-specific gene disruption, and in the other approach, a *Pichia* strain is engineered to express a specific protease inhibitor. Both types of protease-deficient strains have been found to be superior for expression of certain products. Even while using the protease deficient strains, it is essential to optimize the culture medium as discussed in the previous section.

By using the gene disruption approach, three protease-deficient strains, SMD1168 (*his4, pep4*), SMD1165 (*his4, prb1*), and SMD1163 (*his4, pep4, prb1*), that are defective in one or more of protease A (PEP4) or protease B (PRB1) have been constructed. Because a functional PEP4p is necessary for the maturation of PRB1p, the use of the single knockout strain SMD1168 alone should be adequate. The production yield of insulin-like growth factor-1 (40) and ghilanten (50) are improved twofold to threefold by using SMD1168 as compared to the strain GS115, which has intact PEP4p.

Co-expression of MMP-9 along with its inhibitor, TIMP-1, significantly improves the expression level of MMP-9 (5). Furthermore, TIMP-1 expression results in overall stabilization of several *Pichia* secreted proteins. Thus, strains engineered to express protease inhibitors such as aprotinin (16) and TIMP-1 (5) should be useful for high-level expression of proteins that are susceptible to rapid degradation.

Strategies for Coexpression of Proteins

In many instances it is required or desirable to express two or more heterologous proteins at the same time. The fact that *Pichia* can stably integrate multiple copies of an expression cassette implies that it should be possible, at least in principle, to express numerous heterologous proteins at the same time in *Pichia*. The first example of simultaneous expression of two proteins is that of the construction of *Pichia* strains expressing high levels of BSP1 (43 kDa) and BSP2 (52 kDa) components of *Bacillus sphaericus* mosquitocidal toxin (15). Since then, there have been few other

reports in literature for coexpression of two proteins in *Pichia* (5,49,51).

Two generally applicable approaches have been used for coexpression. In one approach, *Pichia* is cotransformed with two expression cassettes, the resulting His^+ transformants are screened for the presence of both the expression cassettes by PCR and subsequently examined for expression (49). In another approach, a *Pichia* expression plasmid is engineered with two expression cassettes (Fig. 4) so that the DNA used for transformation has both the expression cassettes present on the same fragment. In this situation, every His^+ transformant is expected to contain both the expression cassettes. Plasmids such as pAO815 or pAO856 (3,16) can also be used to readily construct expression plasmids for simultaneous expression of two or more products.

One can also use sequential transformation to construct *Pichia* strains that coexpress two or more different proteins, because numerous transformation markers, namely His^+, Arg^+, Suc^+, $G418^R$, and $Zeocin^R$ markers are available for *Pichia*.

Leucine Zipper Dimerization Motif Mediated Protein Assembly

Several membrane receptors, such as major histocompatibility complex (MHC) class I molecules, MHC class II molecules, T-cell receptors, are multiprotein complexes. These receptors are comprised of α- and β-chains, each of which have a large NH_2-terminal extracellular portion, a transmembrane region, and a short C-terminal cytoplasmic tail. Efforts to express soluble $\alpha\beta$-heterodimers of MHC class II molecules by coexpressing just the extracellular portions of α and β chains have proved impossible. The reason for this is that the transmembrane region of MHC class II α- and β-chains facilitate the proper assembly of $\alpha\beta$ heterodimer, and in their absence, assembly is hampered. Interestingly, this problem has been overcome (49) by substituting the transmembrane regions of α- and β-chains with the leucine zipper dimerization motifs from the transcription factors Fos and Jun, which are known to assemble as stable, soluble heterodimers. The leucine zippers are characterized by five leucines that are spaced periodically at every seventh residue (heptad repeat); each heptad repeat contributes two turns of the α-helix (3.5 residues/turn). The leucine residues play a special role in dimerization, and they form the interface between the two α-helices in the coiled coil. The Fos-Jun dimer is soluble because of the charged amino acid residues on the outer surface of the coiled coil. The Fos/Jun leucine zipper dimerization domains (Table 2) may have general applicability in the expression of extracellular domains of multiprotein membrane receptors.

Product Toxicity

In some instances, the product being expressed may be toxic to *Pichia*. In such cases, a stepwise induction is suggested. First, the cell mass is built up using glucose as sole carbon source, taking care to see that glucose is not limiting. Under these conditions, very little product is made because of strong repression of the *AOX1* promoter by glucose. Subsequent to this, the product production phase is initiated with methanol feed. Whether a particular product is toxic to *P. pastoris* can be evaluated by comparing the growth of transformants in 1% sorbitol (or 100 mM alanine) media to that on sorbitol plus methanol or alanine plus methanol media. If the expressed protein is toxic, then the growth in the presence of methanol will be drastically impaired.

Strategies for Induction of Protein Expression

Expression vectors for heterologous expression in *P. pastoris* are typically derived from *AOX1* regulatory sequences (7). One or more of the following induction strategies can be used for optimal protein expression. Refer to the "Fermentation Process" section for induction of expression in the fermenter. Refer to the "Media Composition" section for details of media composition.

Continuous Induction for Intracellular Expression. The *AOX1* promoter can be maximally activated (derepression or induction) by growing cells on methanol as the sole source of carbon and energy in shake flasks, shake tubes, or plates at 30 °C. The doubling time on methanol is $\simeq$6 h as compared to $<$2 h on glucose or glycerol medium. Even the cells in which the *AOX1* gene has been evicted (Mut^-) can grow on methanol. However, the growth rate is slow (doubling time, 18 to 24 h) because it is solely dependent on a secondary alcohol oxidase, *AOX2*, which is expressed only at low levels (79). In such cases the growth rate can be enhanced by supplementing the minimal methanol medium with 1% sorbitol or 100 mM alanine. The advantage of using sorbitol or alanine lies in the fact that these compounds do not interfere with the induction of *AOX1* promoter. Induction of expression on plates is carried out by streaking or plating cells on a methanol medium (MM) plate.

Stepwise Induction for Intracellular Expression. For liquid cultures, cells are initially grown to an OD_{600nm} of 2 to 10 on a nonactivating carbon source such as glycerol or glucose (minimal glycerol yeast extract medium [MGY] or minimal dextrose medium [MD]) in shake flasks or tubes at 30 °C. The cells are then harvested by centrifugation and shifted to MM and incubated with shaking at 30 °C for 1 to 4 days. Induction of expression on plates is carried out by streaking or plating cells on a nitrocellulose or cellulose acetate membrane placed on an MD or MGY plate. Once colonies appear, the filter is lifted and placed on an MM plate.

Efficient Secretion of Proteins. The conditions described thus far work well for the intracellular accumulation of heterologous proteins, but are rather inadequate for secreted proteins. The following protocols work well for secreted proteins for both Mut^+ and Mut^- cells (3,75).

Shake Tube Cultures. First cells are grown to saturation in 10 mL buffered minimal glycerol yeast extract medium (BMGY) placed in a 50 mL tube (2 to 3 days). The OD_{600nm} of culture will be in the range of 10 to 20. The cells are harvested by centrifugation, and the cell pellet is

resuspended with 2 mL of buffered minimal methanol–yeast extract medium (BMMY). The tube is covered with a sterile gauze (four layers of cheesecloth; USP type VII gauze, 20 × 12 mesh from Ultimed International Inc., Glendale Heights, Ill.) and incubated in the shaker for 4 days. Aliquots of supernatant can be analyzed for product secretion at desired time intervals. Fresh media should be added to account for loss of media caused by evaporation.

Shake Flask Cultures. Cells are grown in 1 L of BMGY in a 2-L flask. Cells are harvested and resuspended in 50 mL of BMMY in a 300- to 400-mL low baffle flask, covered with four layers of cheesecloth as described in the previous section, and incubated in a 30 °C shaker for 2 to 4 days. The media supernatant is analyzed for product at different time intervals. Fresh BMMY media is added as necessary to prevent loss of liquid caused by evaporation.

Plates. Cells are patched or plated on nitrocellulose filter (sterile), placed on a square or circular BMGY plate, and incubated at 30 °C for 2 to 3 days. Once colonies have grown to ≃2 mm in size, the filter is removed and placed over a BMMY plate. The filter containing colonies is covered with a sterile nitrocellulose filter. If desired, a cellulose acetate filter can be interfaced between the two nitrocellulose filters and incubated at 30 °C for 2 to 3 days. The secreted protein on the nitrocellulose filter can be analyzed by ELISA or another suitable procedure.

FERMENTATION PROCESS

The general methods for production of biomass as well as for the production of heterologous proteins using Mut^+ and Mut^- cells in both continuous and batch modes of fermentation are described here. The process can be scaled up (>1,000 L) or scaled down (0.2 L) as desired. Fermentation can be conducted over a wide pH range (3.0 to 6.5) at 30 °C. (see "Media Composition" section for details of media.) For example, HSA secretion yield is improved more than threefold by using pH 5.85 compared to the generally used pH of 5.0 (4). In the case of secretion of the V1 domain of CD4 (amino acid residues number 1 to number 106 of mature CD4), intact product was seen only at acidic pH (2.5 to 3.5) (R.G. Buckholz, personal communication, 1990). As high as a twofold to fourfold increase in secreted yields of human EGF and human insulin-like growth factor-1 are observed at pH 3.0 (40).

Fermentation Equipment

A typical benchtop fermenter has a 2- to 20-L capacity, a 1- to 10-L operation volume, and monitors and controls for pH, dissolved oxygen (DO), agitator speed, temperature, air flow, pressure, foam, and weight.

Fermenters can be custom built or purchased from one of the numerous commercial sources such as B. Braun Biotech Inc., Allentown, Penn.; Biolaffitte, SA, France; New

Brunswick Scientific, Edison, N.J.; Porton Instruments Inc., Hayward, Calif.; Infors, UK Ltd., Crewe, Cheshire, Great Britain; Caltec Scientific Ltd., Edmonton, Alberta, Canada; Hotpack Corp., Philadelphia, Penn.; J & H Berge Inc., S. Plainfield, N.J.; Setec Inc., Livermore, Calif.; Techne, Inc., Princeton, N.J.; and VWR Scientific Products, W. Chester, Penn.

Sixfors, offered by Infors, UK Ltd., can bridge the gap between shake flasks and fermenters. They can be used for small-scale (typically 0.3 L) continuous, batch, or cascade processes where the growth from one vessel is passed into another.

Methods for Monitoring the Fermentation Process

Bio-Rad's portable fermentation monitoring analyzer can be used on the spot to provide fast HPLC analysis of the concentration of methanol, glycerol, ethanol, glucose, acetic acid, lactic acid, fructose, maltotriose, and maltose. The equipment is compatible with automatic sampling and computerized data analysis. Analysis takes only 10 min. The conditions used are as follows:

1. *Instrument*: Bio-Rad's fermentation monitoring analyzer
2. *Column*: Fermentation monitoring column (150 × 7.8 mm)
3. *Sample*: Extracellular broth, prefiltered through a 0.22-μm syringe filter; sample volume: 10 to 20 μL
4. *Injector*: Rheodyne injector valve with a 10-μL injection loop
5. *Solvent*: 0.002 N H_2SO_4 in water at a flow rate of 0.8 mL/min (isocratic, so only one pump is required)
6. *Temperature*: 65 °C
7. *Detector*: Refractive index detector

To determine the wet cell weight of the culture, 1 mL of the fermenter broth is centrifuged in a microfuge, and the cell pellet is weighed after carefully decanting the cell-free supernantant. To determine the washed dry cell weight of the culture, cells are harvested by centrifugation (3000 × *g* for 10 min at room temperature) from a known volume of the fermenter culture (typically 10 to 50 mL). The cell pellet is washed twice with water (10 to 50 mL), dried overnight at 100 °C, and weighed. Alternatively, the dry cell weight can be readily determined in less than 10 min with the use of a moisture balance such as the Mettler LP16 Infrared Dryer (Mettler Instrument Corporation, Hightstown, N.J.).

Mass transfer is determined by measuring the air flow to the fermenter and the composition of both the inlet and outlet air with a Perkin-Elmer gas analyzer. The O_2 transfer rate (OTR) is calculated as follows:

$$\text{OTR} = f(C_{\text{in}} - C_{\text{out}})/V$$

where f is flow rate L/h, C_{in} and C_{out} are the concentration in mmol of O_2 in the inlet and outlet gases, and V is the ungassed broth volume. OTR can also be established from yields using the equation

$$\text{OTR} = \mu X/Y \times O_2$$

where μ is the specific growth rate or dilution rate (h^{-1}), X is the cell density (g/L), and $Y \times O_2$ is the yield on O_2 (g cells/mmol O_2).

Heat transfer rate and heat load can be determined by measuring the temperature of the circulating water in and out of the fermenter heat exchanger.

Productivity (P) for the continuous culture is determined using $P = DX$, where D is the dilution rate (h^{-1}), and X is the cell density. An increase in D and/or X will result in higher productivity. Because D also equals the specific growth rate μ, the dilution rate is limited by the microorganism's intrinsic characteristics. Once $\mu_{\max}$ or $D_{\max}$ is reached, P can only be increased by increasing the cell density. A set of parameters determined for the high-productivity process for *P. pastoris* on methanol in a 1,500-L fermenter are given in Table 3.

Extracellular protein concentration (for secreted proteins) can be estimated by using a Lowry-type protein analysis on TCA-precipitated material and analyzed for specific product by SDS-PAGE and immunological methods. Aliquots of cells are lysed to prepare cell extracts for protein analysis.

Continuous Culture of Mut$^+$ and Mut$^-$ *Pichia* on Methanol

Fermentation is carried out in two steps, first in the batch mode on glycerol as the carbon source, followed by continuous mode on methanol-containing medium.

Inoculum for the fermenter is prepared by growing cells in 1 L of MMD, YMPD, YMPGy, MGyB, MMGY, or YPD grown to an OD_{600nm} of 2 to 10 in a 2-L shake flask. This volume of inoculum is used for inoculating a 20-L fermenter containing 9 L of basal salt FM21 medium containing 5% glycerol (higher levels may be toxic to the cells) or 5 to 10% glucose and pH adjusted to 5.0 (by using 50% NH_4OH solution or NH_3 gas). Biotin stock (4 mL) and PTM1 trace mineral mix (11 mL) are also added. Fermentation is conducted until the glycerol or glucose (carbon source) is exhausted. During the run, dissolved O_2 is maintained at >20%, with the agitator speed set between 500 to 1,500 rpm and a vessel pressure of 2 to 3 psi. Foaming is con-

Table 3. Parameters Determined for a High Cell-Density Process in a 1,500-L Fermenter

Substrate	Methanol
Substrate concentration (g/L)	263
Dilution rate (h^{-1})	0.11
pH	3.5
Temperature (°C)	30
Cell mass (g of cells/L)	105
Productivity (g/L h)	11.6
Yield (g of cells/g of methanol)	0.4
OTR (mmol O_2/L h)	880
Oxygen consumption (g O_2/g cells)	2.42
Heat release	
kcal/L h	109
kcal/mol O_2	123.9

trolled through the addition of a 5% Struktol J673 (Struktol Company of America, Stow, Ohio) or Mazu DF 37C (Mazer Chemicals, Inc., Gurnee, Ill.). The cell yield expected for the batch phase on 5% glycerol under these conditions is 20 to 25 g of washed dry cell weight per liter.

Continuous fermentation is established by feeding FM21-methanol (15% v/v) for Mut^+ cells or FM21-methanol (1% v/v) plus 15% glycerol, sorbitol, or alanine for Mut^- cells. The feed for continuous culture is also supplemented with PTM1 (1.1 mL of stock solution per liter) and biotin (0.4 mL of the stock solution per liter). Feed sterilization is carried out by filtration (Pall Ultipor disposable filter assembly DFA 4001 AR, 0.2 μm). Feed addition is achieved with a Milton-Roy positive-displacement metering pump (Model 2396 Duplex). Continuous culture is performed as a chemostat under steady-state conditions where the dilution rate (D) is equal to the growth rate of the population. The growth rate of cells can be controlled by adjusting the flow rate of fresh medium into the fermenter. Typical D values range from 0.056 h to 0.11 h. Dissolved oxygen is held in the 45 to 75% air saturation range by varying air flow, vessel pressure, or agitator speed. The maximum cell mass achievable under these conditions is around 80 g of washed dry cell weight per liter with a cell productivity of approximately 10 g/L h. If a higher cell mass is desired, the amount of carbon source in the feed can be raised (e.g., 25% methanol for Mut^+ and 1% methanol plus 25% glycerol, sorbitol, or alanine for Mut). This would also necessitate a proportional increase in the amount of minerals, trace elements, and biotin. As high as 110 g/L washed dry cell weight with 11.6 g/L h. productivity are achievable in this process. Highest induction of the *AOX1* promoter occurs using methanol (Mut^+ cells) or methanol plus sorbitol or alanine (Mut^-) as the carbon source in the feed. Intermediate levels of induction are seen with methanol plus glycerol feed.

Fed-Batch Fermentation of Mut^+ and Mut^- *Pichia* on Methanol

Fermentation is carried out in three steps: glycerol batch phase, glycerol fed-batch phase, and methanol-fed batch phase.

One liter of inoculum (prepared as previously described for the continuous fermentation protocol) is used for inoculating a 20-L fermenter containing 5 L of basal salt BSM medium with 5% v/v glycerol (higher levels may be toxic to the cells) or 5 to 10% glucose as carbon source; the pH of which is adjusted to 5.0 by using 50% NH_4OH solution or NH_3 gas. Biotin stock (40 mL) and PTM1 trace mineral mix (40 mL) are also added. Fermentation is conducted as previously described until all the carbon source (glucose or glycerol) is completely consumed. This phase should take 18 to 24 h. After this, a fed-batch phase on glycerol is initiated with a 50% w/v glycerol feed (500 mL of 100% glycerol + 480 mL water + 10 mL each of PTM1 and biotin stock solution) at a feed rate of 18 mL/h/L initial fermentation volume with the aid of a peristalic pump. Glycerol feeding is carried out for 4 h. The cell yield at this point will be in the range of 180 to 220 g/L of wet cells (equivalent to approximately 30 to 55 g washed dry cell weight per liter). This phase can be manipulated by varying the concentration of glycerol or the duration of fermentation to achieve optimal heterologous protein production in the methanol-fed batch phase. Some suggested cell yield ranges that should be tested for are listed in Table 4.

The fed-batch phase on methanol is initiated with a methanol feed (980 mL of 100% methanol + 10 mL of PTM1 + 10 mL of biotin stock solution) at a rate of 1 to 4 mL/L/h of the initial culture volume. The methanol-feed flow rate is adjusted such that with Mut^- strains, the methanol concentration in the fermenter is maintained in the 0.2 to 0.5% v/v level, whereas with the Mut^+ strains, methanol levels in the fermenter approach zero and the fermenter is run in a methanol-limited fashion. Dissolved oxygen in both cases is maintained at the 20 to 70% range. If dissolved oxygen falls below 20%, the methanol feed is stopped, and nothing should be done to increase oxygen rates until an upward spike in the dissolved oxygen level is seen. At this point, adjustments (rpm, aeration, vessel pressure, oxygen feed) can be made. Maintaining the dissolved oxygen above 20% may be difficult depending on the OTR of the fermenter. With stainless steel vessels, the system can be pressurized up to 15 to 30 psi to increase OTR. Also, the oxygen feed (air plus oxygen mixture) at 0.1 to 0.3 vvm can be used to maintain adequate levels of dissolved oxygen. The methanol fed-batch phase generally lasts for 70 h. However, it may prolong to more than 200 h if the feed rate is slowed down because of the fall in dissolved oxygen levels. Another factor that may also influence the fermentation time is the secretion rate of the heterologous protein. Longer times may be necessary to allow for accumulation of high levels of a slowly secreted protein in the broth. Depending on the product being produced, adjustments in the media (addition of casamino acids) and pH will have to be made to increase product yield. One technique that can be used to lower the pH is by setting the pH to the desired lower value (e.g., pH 3.0) and then letting the culture pH to decrease to the new set point of pH 3.0 as a result of cellular metabolism (40).

Strategies for Multicycle Fermentation

Considerable time is expounded on setting up a fermentation run. It would make sense to reap as many cycles of product production as possible for each start-up. Continuous fermentation on methanol, which works well for biomass production (1,2,80), is largely not applicable for recombinant protein production, especially with Mut^- strains, because they grow poorly on methanol. Use of methanol plus glycerol mixed feed restores the cell productivity, with considerable level of protein expression; optimal level is not achievable because of partial repression of the *AOX1* promoter by glycerol (11). This problem can be overcome by using a sorbitol plus methanol mixed feed, because sorbitol is a nonrepressing carbon source. However, sorbitol is a poorer carbon source than glycerol and also needs supplementation with 1% each of malt extract, peptone, and yeast extract for improved growth. Nevertheless, this strategy has been used successfully to accomplish several cycles of MMP-2 production in a Biostat-B (Braun) benchtop fermenter (5). In this approach, after recovery of 90% of the fermenter sample from the first fermentation

Table 4. Cell Yield Ranges

Mut^- intracellular expression	50–100 g/L dry cell weight or 200–400 g/L wet cell weight
Mut^+ intracellular expression	30–80 g/L dry cell weight or 140–320 g/L wet cell weight
Mut^- secretion	20–40 g/L dry cell weigth or 80–160 g/L wet cell weight
Mut^+ secretion	12–80 g/L dry cell weight or 50–300 g/L wet cell weight

Note: It is obvious from the suggested ranges for cell density that in several instances the glycerol fed-batch phase is not even necessary.

cycle, the fermenter is rebooted with an appropriate volume of fermenter growth media containing sorbitol as carbon source and supplemented with 0.1% yeast extract and 0.2% peptone. After growth for 16 to 20 h, a fed-batch fermentation with sorbitol plus methanol nutrient feed is continued for another 72 h for MMP-2 production. The whole process of product recovery and rebooting the fermenter can be repeated as many times as one desires. By this approach, using a 4-L fermenter with one start-up, we were able to generate 25 L of MMP-2 broth in less than 4 weeks. This approach is also useful for Mut^+ cells; it reduces overall methanol consumption because most of the growth is supported by sorbitol. Methanol can be added to the sorbitol feed at any desired point, to initiate induction of expression.

CONCLUSIONS AND FUTURE PERSPECTIVES

Problems generally encountered in protein expression may be overcome in most instances by taking due consideration of the factors that influence protein expression. Nearly every expression project has given new insight into the intricacies of the *Pichia* system. In spite of due consideration and careful planning, certain proteins are difficult to express in this system. Now that the expression system is readily available from Invitrogen (San Diego, Calif.), hundreds of investigators around the world are currently exploring the system, and their results will undoubtedly provide new insights as well as expand our knowledge base about the utility and limitations of the system.

Within the near future, it is anticipated that *Pichia*-produced HSA will reach the market. It will make one think of what to do with the tens of thousands of tons of *Pichia* yeast that would become available as a by-product of HSA production plants. It is tempting to speculate that the *Pichia* HSA strain would also be engineered to produce an intracellular insecticidal toxin, and thus the *Pichia* cells resulting from the HSA production can be used as a biopesticide.

Several modifications have recently been made to the *P. pastoris* expression vectors by Invitrogen (San Diego, Calif.). These newer vectors (pPICZ A,B,C series, and pPICZα A,B,C series) are smaller in size and have $Zeocin^R$ marker. Furthermore, they allow in-frame fusion to *myc* epitope and His_6 tags. It has been previously noticed that the addition of eight amino acid carboxy terminal tags to TNF rendered the tagged proteins completely insoluble under nondenaturing conditions, whereas the untagged TNF was completely soluble (11). Thus, a tag enthusiast should bear in mind that in some instances, a tag can bring about an undesirable change in the property of a protein.

Overexpression of ubiquitin (Ubi) seems to enhance the secretion of a human leukocyte protease inhibitor in *S. cerevisiae* (81). Ubi is recognized to be a normal secreted component of *P. pastoris* (5). Thus, it is presumable that the overexpression of Ubi in *P. pastoris* may also enhance heterologous protein secretion. A *P. pastoris* host strain that overexpresses Ubi can be engineered using one of the available Ubi cDNAs. Also, a Ubi expression plasmid can be introduced into any *P. pastoris* strain by using one of the dominant selection markers for transformation, such as invertase, *SUC2* (82), $G418^R$ (77,83) or $Zeocin^R$ (available from Invitrogen, San Diego, Calif.). Thus, the effect of Ubi overexpression on product secretion can be tested in any of the existing production strains. A note of concern may be warranted while using $zeocin^R$ for selecting *P. pastoris* transformants. $Zeocin^R$ is a strong mutagen, and thus cells challenged with Zeocin*R* on a complex medium may acquire some undesirable change that may interfere with growth and thus reduce the overall productivity under the growth conditions in a fermenter.

A major concern for large-scale use of *Pichia* in the production of biologicals has been the substrate methanol, which is toxic, inflammable, and volatile. With the existing technology in a typical production plant, one will have to use several tons of methanol for the production phase of the operation. It will certainly be an added advantage if the amount of methanol required can be reduced or even eliminated. Two recent developments in this direction have been made. In one case, a mutant strain of *Pichia* that is able to turn on the *AOX1* promoter in the absence of methanol has been generated (A.A. Sibirny, personal communication, 1992). This mutant still responds to repression by glucose and ethanol. In another instance, a *Pichia* strain in which both the alcohol oxidase structural genes *AOX1* and *AOX2* have been deleted has been constructed and shown to express heterologous protein LACZ in response to methanol induction (V. Chiruvolu, personal communication, 1995). This novel alcohol oxidase null strain (*aox1, aox2*) uses considerably lower amounts of methanol for production of hetrologous protein.

Another development that one can speculate is that *Pichia* will be engineered to express human post-translational modification enzymes (e.g., glycosyl transferases, amidating enzyme, vitamin K-γ carboxylase, etc.), so as to obtain *Pichia* strains that can be used to produce more authentic human proteins.

MEDIA COMPOSITIONS

Stock Solutions

Note: For filter sterilization of various solutions and liquids, filter wares (disposable or reusable types) equipped

with cellulose acetate or cellulose nitrate membranes (pore size 0.2 to 0.22 μm) from one of the several manufacturers (Nalgene Company, Rochester, N.Y.; Costar Corporation, Cambridge, Mass.; Corning Glass Works, Corning, N.Y.) can be used. For filter sterilization of methanol and methanol-containing media, only cellulose acetate membranes (0.2 to 0.22 μm) are suitable, because methanol does not filter through cellulose nitrate membranes of pore size 0.2 μm.

10× YNB. Dissolve 13.4 g of yeast nitrogen base without amino acids (YNB, Difco Labs., Detroit, Mich.) in 100 mL of water (heat if necessary) and filter sterilize. This solution can be stored for over a year at 4 °C.

500× B. Dissolve 20 mg of D-biotin (Sigma Chemicals, St. Louis, Mo.) in 100 mL of water and filter sterilize.

100× H. Dissolve 400 mg L-histidine in 100 mL of water (heat if necessary) and filter sterilize.

10× D. Dissolve 20 g of D-glucose in 100 mL water. Autoclave for 15 min or filter sterilize. Stores well for years at room temperature.

10× GY. Mix 100 mL of glycerol with 90 mL of water. Filter sterilize. Stores well for years at room temperature.

10× M. Mix 5 mL of methanol (100%) with 95 mL of water. Filter sterilize and store at 4 °C.

100% methanol. Filter sterilize pure methanol (100%). Store at room temperature in a fireproof cabinet.

Minimal Media Compositions

MD. Mix 100 mL of 10× YNB, 2 mL of 500× B, and 100 mL of 10× D with 800 mL of autoclaved water (include 15 g bacto agar for plates).

MM. Mix 100 mL of 10× YNB, 2 mL of 500× B, and 100 mL of 10× M with 800 mL of autoclaved water (include 15 g bacto agar for plates).

MGY. Mix 100 mL of 10× YNB, 2 mL of 500× B, and 100 mL of 10× GY with 800 mL autoclaved water (include 15 g bacto agar for plates).

All these liquid media and plates store well for several weeks at 4 °C.

Minimal media with other carbon sources (such as D-sorbitol, D,L-alanine) are prepared by using the desired carbon source at 10 g/L in place of glucose in MD. Minimal media containing a mixture of carbon sources can also be prepared by combining two or more desired substrates in the growth medium.

Supplemental Minimal Media Compositions

Minimal media are supplemented with necessary supplemental nutrients such as amino acids depending on the specific requirement of a given strain. For example, *P. pastoris* strains GS115 and KM71, commonly used in molecular genetic manipulations, are auxotrophic for histidine. Such strains will grow in minimal media only in the presence of supplemental histidine. However, once transformed with *HIS4* (histidinol dehydrogenase gene) they readily grow in the absence of histidine.

The composition of supplemental minimal histidine media (suitable for histidine auxotrophic strains such as GS115) is as follows. Other supplemental media can be prepared depending on the need of a particular strain in use.

MDH. Mix 100 mL of 10× YNB, 2 mL of 500× B, 100 mL of 10× D, and 10 mL of 100× H with 790 mL of autoclaved water (include 15 g agar for plates).

MMH. Mix 100 mL of 10× YNB, 2 mL of 500× B, 100 mL of 10× M, and 10 mL of 100× H with 790 mL of autoclaved water (include 15 g agar for plates).

MGyH. Mix 100 mL of 10× YNB, 2 mL of 500× B, 100 mL of 10× GY, 10 mL of 100× H with 790 mL of autoclaved water (include 15 g agar for plates).

MGyB. Dissolve 11.5 g KH_2PO_4, 2.66 g K_2HPO_4, 6.7 g YNB, pH 6.0, and 20 mL glycerol in 1 L water and autoclave.

All these liquid media and plates will store well for several weeks at 4 °C.

Supplemental minimal histidine media with other carbon sources is prepared by adding a similar amount of histidine as above to the minimal media with the desired carbon source.

Complex Media Composition

YPD. Dissolve 10 g of bacto yeast extract, 20 g of peptone, and 20 g of glucose in 1,000 mL of water (also include 15 g bacto agar for slants and plates) and autoclave for 20 min.

YMPD. Dissolve 3 g of yeast extract, 3 g of malt extract, 5 g of peptone, and 10 g of glucose in 1 L of water and autoclave.

YMPGy. Same as YMPD with the exception that 10 mL of 100% glycerol is used instead of 10 g of glucose.

Secretion Media Composition

BMGY. Mix 100 mL of 1 M potassium phosphate buffer, pH 6.0, 100 mL of 10x YNB, 2 mL of 500x biotin (refer to growth and storage section for composition of stock solutions), and 10 mL of glycerol. Filter sterilize and add to an autoclaved solution of 10 g yeast extract and 20 g peptone in 788 mL water (15 g bacto agar is included for plates).

BMMY. Same as BMGY, with the exception that 5 mL of methanol is added in the place of 10 mL glycerol.

Note: Yeast extract and peptone in the above media can be replaced by 1% casamino acids. The pH 6 suggested here may not be optimal for every secreted product. Experimentation with pH values in the range 2.5 to 8 (by using appropriate buffers) is suggested to determine the optimal pH for a particular product. Some suggested buffers are as follows:

Phosphate buffer for pH range 5.7 to 8.0
Alanine-HCl buffer for pH range 2.5 to 3.6
Aconitic acid-NaOH buffer for pH range 2.5 to 5.7
Citrate buffer for pH range 3.0 to 6.2

Avoid buffers such as succinate buffer, because succinate can serve as a carbon source and will repress activation of the *AOX1* promoter.

Fermentation Media Composition

FM21 basal salt media

Composition is for 1 L final volume in water:

Phosphoric acid, H_3PO_4 (85%)	3.5 mL
Calcium sulfate, $CaSO_4 \cdot 2H_2O$	0.15 g
Potassium sulfate, K_2SO_4	2.4 g
Magnesium sulfate, $MgSO_4 \cdot 7H_2O$	1.95 g
Potassium hydroxide, KOH	0.65 g

Biotin stock solution

Biotin	0.2 g/L

PTM1 trace salts

Composition is for 1 L final volume in water:

Cupric sulfate ($CuSO_4 \cdot 5H_2O$)	6.0 g
Manganese sulfate ($MnSO_4 \cdot H_2O$)	3.0 g
Ferrous sulfate ($FeSO_4 \cdot 7H_2O$)	65.0 g
Zinc sulfate ($ZnSO_4 \cdot 7H_2O$)	20.0 g
Silfuric acid (H_2SO_4)	5.0 mL
Cobalt chloride ($CoCl_2 \cdot 6H_2O$)	0.5 g
Boric acid (H_3BO_3)	0.02 g
Sodium molybdate ($NaMoO_4 \cdot 2H_2O$)	0.2 g
Potassium iodide (KI)	0.1 g

BSM medium composition

Composition is for 1 L final volume in water:

Phosphoric acid, H_3PO_4 (85%)	26.0 mL
Calcium sulfate, $CaSO_4 \cdot 2H_2O$	0.9 g
Potassium sulfate, K_2SO_4	18.0 g
Magnesium sulfate, $MgSO_4 \cdot 7H_2O$	14.0 g
Potassium hydroxide, KOH	4.0 g

GLOSSARY OF *P. pastoris* VECTORS

pHIL-A1	Autonomously replicating vector (3)
pHIL-D1	Integration vector with or without deletion of AOX1 structural gene (3)
pPIC3	pHILD1 type vector with multiple cloning sites (3)
pAO815	pHILD1 type vectors for making multicopy expression units (3)
pAO856	pAO815 with a unique *Bg1*II site (3)
pHIL-D2	Modified pHILD1 with *Not*I site and fl ori (3)
PHIL-D3	Derived from pHIL-D2 for making constructs with exact 5′-UTR (3)
pHIL-D4	pHILD1 with kanamycin-resistance marker (3)
pPIC3K	pPIC3 with kanamycin-resistance gene (3)
pHIL-D5	pHILD2 with kanamycin-resistance gene (3)
pHIL-D7	pHILD4 with a unique *Csp45*I (*Asu*II) site for making exact 5′-UTR constructs (75)
pHIL-S1	Secretion vector with *P. pastoris* acid phosphatase secretion signal (3)
pPIC9	Secretion vector with *S. cerevisiae* αMF pre-pro signal (6)
pPIC9K	pPIC9 with kanamycin-resistance gene (77)
pPICZ A, B and C	Zeocin^R marker and *myc* epitope–His_6 tag (Invitrogen Inc.)
pPICZα A, B, and C	Zeocin^R marker, *myc* epitope–His_6 tag, and αMF secretion sequence (Invitrogen Inc.)

GLOSSARY OF *P. pastoris* STRAINS

NRRL Y-11430-SC5 (wild type) (3)

GS115 (*his4*)—this strain is also known as GTS115 (3)

KM71 (*his4*, *aox1*::*ARG4*) (3)

PPF1 (*his4*, *arg4*) (3)

Mc100-3 (*aox1*::*ARG4*, *aox2*::*his4*, *his4*, *arg4*) (79)

Protease deficient strains (derived by protease A (*PEP4*) and/or protease B (*PRB*) gene disruption (3):

- SMD1163 (*his4*, *pep4*, *prB1*)
- SMD1165 (*his4*, *prB1*)
- SMD1168 (*his4*, *pep4*)

KEY WORDS

Biopharmaceutical
Bioprocessing
Pilot plant
Process development
Scale-up

OUTLINE

INTRODUCTION

Several diverse roles, objectives, and purposes are associated with a bioprocessing, biochemical, or biopharmaceutical pilot plant. These include, but are not limited to, manufacture of clinical supplies, process development for new products in the company pipeline, process improvement including technical support for existing products on the market, and production of biologically produced materials (which are not intended for the clinic) to support basic research efforts such as screening, assays, and disease mechanism elucidation. Unlike chemical pilot plants, pharmaceutical pilot plants are used not only to scale up laboratory processes but also to produce developmental quantities of chemicals (and biological substances) for safety, toxicological, and clinical studies (1). Thus, balancing the demands for scale-up and development research with those for clinical production is a key dilemma for pilot plant operation (2). The timing of clinical production is critical because expensive and time-consuming clinical programs can be delayed, thus postponing product application filings, approvals, and launches (2). Although traditionally pilot plants have not manufactured material for sale, accelerated launch dates, deferred manufacturing facility capital commitments, and other areas of project uncertainty have prompted consideration and use of pilot plants for manufacturing in recent years.

The types of products manufactured using biologically based methodologies include primary metabolites, secondary metabolites (ranging from pharmaceuticals to biopolymers), constitutive proteins, recombinant proteins, intracellular or extracellular enzymes and biocatalysts, antigens, viruses, polysaccharides, and DNA itself. These products are made using a wide range of cell cultivation and isolation techniques suitable for bacteria, yeast, fungi, actinomycetes, suspension animal cells, anchorage-dependent animal cells, insect cells, and plant cells. Processing equipment varies considerably among these diverse systems.

Designing for extensive processing flexibility can be expensive, potentially in excess of $100 million dollars, depending on the specific process requirements, size, and intended use of the pilot plant. Processing requirements can change dramatically as products are deemphasized and reemphasized in development. These decisions on priorities are likely not to result from the robustness of the process but rather from the state of the clinical data or potential market share. The ability to process multiple products in an acceptable manner typically is desirable to maximize facility use. Although designers may need to predict future types of processes and products, they should be cautious about overdesigning the facility in terms of containment and flexibility (3).

The general areas required in a pilot plant might include support labs for bench-scale development and quality control, production suites for scale-up, utility areas, and personnel offices, as well as ample storage areas for raw materials, supplies, product, samples, and documentation (2). There should be a clear division between controlled and noncontrolled areas, by utilizing signs at a minimum and perhaps by physically restricting access. General design criteria might focus on modularity, simplicity, future growth provisions, redundancy, construction costs, operating costs, and air and water waste containment (4). Future operating costs are an important consideration for pilot plants because ample funds are necessary for raw materials, staffing, maintenance, and additional capital modifications to permit improvements.

OPERATIONAL CONCEPTS AND DESIGN REQUIREMENTS

Several operational concepts influencing design requirements need to be resolved before initiation of design activities. Agreement should be sought among end users, operations staff, compliance auditors, environmental consultants, and safety officers as well as from appropriate levels of management directly or indirectly influencing and controlling capital expenditures. A written document summarizing consensus on these issues may then become the basis for conceptual design activities.

Major decisions influencing pilot plant capabilities include whether the facility will produce bulk drugs (thus falling under the regulation of Center for Drug Evaluation and Research (CDER) and following guidelines from 21CFR 210/211) or biologics (thus falling under the regulation of Center for Biologics Evaluation and Research (CBER) and following guidelines from 21 CFR 210/211 and 600) (5). The level of validation and the validation philosophy are directly related to the end use of the resulting pilot plant products, specifically whether they are used for process development, clinical supplies (presafety/basic research, safety, phase I, phase IIa, IIB, phase III), or material for sale. Validation strategies, as well as other operational and design issues, are also influenced by whether the pilot plant is administratively located within the manufacturing or research division. Individual company preferences and guidelines for similarity between manufacturing and pilot plant areas need to be identified and evaluated for their impact on the proposed pilot plant facility. Typical areas targeted for standardization within a company are vessel designs, computer systems and interfaces, equipment vendors, and construction specifications.

Design requirements center around the desired initial and end product stages of processing, specifically the forms of the pilot plant inputs and outputs. Example stages include master/working seed preparation, fermentation broth, initial captured product (e.g., microfiltration retentate, ultrafiltration concentrate, cell paste), crude product (e.g., rich ion exchange fraction), finished isolated or sterile bulk, and filled vials. Ambient, refrigerated, and frozen storage requirements based on these inputs and outputs then need to be addressed in the areas of seed, raw materials, intermediates, clinical supplies, and process samples.

The scale of the pilot plant relative to current or proposed manufacturing scale and relative to laboratory scale needs to be established. Generally, a 1:5 or 1:10 scale-up is common, but smaller ratios can be advantageous in terms of minimizing risk during factory start-up. The appropriate level of biosafety also must be considered, with good large scale practice (GLSP) being sufficient for most recombinant work. Some pilot plant areas may require biosafety level 1–large scale (BL1-LS) and/or biosafety level 2-large scale (BL2-LS), and careful consideration of multiple-use/decontamination issues for BL1- and BL2-containing facilities is necessary. Solvent use areas need to be identified and minimized if possible because cost implications for explosion-proof design can be substantial.

Primary motivations to design a multiuse pilot plant are the conservation of capital and improved response time for clinical manufacturing needs for new development products. The strategy for multiuse should be identified and considered throughout the design process. Common strategies (6) include using totally dedicated equipment and limiting production to one product at one particular production stage, using campaigned equipment in which multiple products are sequentially processed in the same equipment "campaign style," with documented product changeover procedures completed to minimize cross-contamination potential, and conducting concurrent manufacturing in dedicated equipment in which several products are simultaneously produced in segregated areas with segregation achieved via physical separation or closed systems. These strategies result in minimization of cross-contamination potential through engineering controls, standard operating procedures (SOPs), or temporal segregation (7). Typical pilot plants combine the second and third strategies by providing segregated and dedicated ar-

eas for certain types of processing (e.g., virus and nonvirus areas, GLSP versus BL1/BL2 areas, beta-lactam antibiotic processing, heat-resistant spore-former cultivation) (8). Example layouts for product-specific and common areas depending on the strategy selected have been described (9).

Guidelines for the use of open versus closed systems for various processing stages need to be devised and justified based on available and cost-effective technologies as well as quality requirements. In a closed system, the product is not exposed to the immediate environment. The quality of materials entering a closed system (such as water, steam, or air entering a bioreactor) is controlled by its quality as well as the manner in which these materials are entering the closed system (such as filter sterilization, autoclaving, or steam sterilization of system connections) (6). In an open system, the product is exposed directly to the surrounding environment, thus necessitating the creation of a controlled or sometimes even a closed system around the open system. One example of this strategy is the transfer of seed vial contents in a biosafety cabinet. Other examples might include the supply of higher-quality filtered air to areas for the cooldown of autoclaved materials and assembly of clean equipment. Thus, levels of containment can be constructed until all open systems are contained within controlled or closed systems to meet quality requirements for the specific processing stage.

The specific issue of potential exposure of product to spore-forming organisms has been debated extensively. The closed system concept appears to minimize the concern for airborne spores typically found in the environment. Cultivation guidelines for spore-forming organisms within a multiuse facility appear to have been redefined to evaluate the robustness of the spore type formed. Careful consideration of segregation has been given when cultivating organisms such as *Bacillus* that form difficult-to-kill spores. A separate, self-contained area with no shared equipment, air systems, or entrances minimizes exposure concerns for other products. The relatively heat-sensitive, substantially larger, fungal spores have not been highlighted as a substantial cross-contamination concern. Thus, segregation for these types of processes is not as critical, although it still might be implemented due to company preferences for separate bulk drug and biologics processing areas.

DESIGN

The initial generation of flow charts for a bioprocessing, fermentation, or isolation pilot plant is best conducted based on model processes that are developed and critiqued by several end users of the equipment and facility. These model processes should be carefully selected as to give adequate and appropriate representation to current and reasonable future needs of the pilot plant. As they form a preliminary but sound basis for equipment and utility sizing, they should include unit operations as well as expected cycle times. In some cases, simulation (10–12) or actual laboratory- or pilot-scale testing (13) of critical equipment under typical processing conditions or with expected process streams may be warranted to further define design specifications. Example model processes have been published for vaccines (14) and intracellular and extracellular products (15–18). Resulting flow charts can focus on raw materials for fermentation or isolation, seed development, fermentation, recovery, crude product isolation, final product isolation, product finishing, buffers, utilities, and waste (including chemical waste, biological waste, and any necessary offgas treatment) (15).

The requirements for these model processes, coupled with an estimate of the required facility output, can be used to construct a preliminary architectural layout that divides the facility into sections (termed modules, cubes, or suites). These sections are surrounded by controlled corridors and accessed via airlocks (3). Based on this initial layout, flow patterns are developed to permit the logical, usually unidirectional, flow of personnel, raw materials, product, waste, and clean or used equipment throughout the facility. Flows are designed primarily to minimize cross-contamination from multiple products and from clean and used equipment while maintaining access and flexibility (3). This separation often is accomplished by using clean and return corridors located on either side of the processing area as well as by temporal segregation using appropriate SOPs. Evaluation of these flow patterns should be conducted carefully and should incorporate end users as well as quality auditors. In some cases, companies may solicit outside good manufacturing practice (GMP) reviews of the project at this time from external consultants, a second design firm, or even FDA representatives. Gathering and organizing up-to-date accurate information and comments about the impact on model process needs are critical factors in forming a successful basis of design (19).

Example layouts for process flows for biotech facilities have been published (6,20,21). An extensive reference (including (piping and instrument diagrams (P&IDs), layouts, and flow diagrams) for the design of biopharmaceutical plant equipment, utilities, heating, ventilation, and air-conditioning (HVAC), and waste treatment also has been published (22). Although it was based on acceptable practices in 1991, the strategies and concepts for design presented are still quite relevant. Adequate space around the equipment needs to be reserved for operations and maintenance access as well as for related portable equipment. The movement, segregation, storage, and cleaning of portable equipment such as vessels, skids, hoses, and carts should be fully examined.

Various reports of successful and problematic aspects of project design, construction, start-up, and validation have been published. Cost control issues and the benefits of formulating a master schedule (23) need to be reviewed in terms of their potential validation impact. Construction concerns and "lessons learned" from multiple biotech installations also have been summarized (24). One case study of a laboratory facility highlights the need for teamwork among client, design firm, and construction manager (25). This trio can be extended to include the validation contractor in an effort to minimize "finger pointing" and "blame storming" when unforeseen problems are uncovered. Regardless of who may actually be perceived as being "at fault," the company owning the facility ultimately is adversely affected by substantial start-up and validation

delays. A comprehensive overview of biochemical pilot plant design and operational guidelines appeared in the mid-1980s (26).

Process Equipment

The major decision regarding process equipment is that of similarity versus diversity as it applies to specific process steps as well as multiple products. The extent of commonality required in equipment specifications is an important operational factor to be considered because equipment specifications are based on inputs from model processes. For a pilot plant to accept a manufacturing interface role, at least a portion of the equipment design and selection should match that of the factory which the pilot plant is intended to support. For example, if the factory intends to use continuously sterilized medium for large-scale fermentation, then there should be provisions in the pilot plant to perform continuous sterilization as products get closer to the transfer to production. Alternatively, depending on individual company preferences for the pilot plant role, later clinical batches (phase II and beyond) might be manufactured in the factory to facilitate eventual process transfer and ensure consistency of equipment.

Skid-mounted equipment has been often selected in recent installations because it puts the design burden entirely on one vendor, who specifies the appropriate quality, supply rate, and pressure of the required utilities. Skid-mounted equipment can be fixed or portable, which permits different types of processing in the same space as necessary. Consistency in skid designs with respect to components and spare parts may be a drawback as vendors might not be willing to build skids to individual company specifications without added costs. This situation can be particularly problematic if the skid manufacturer has arranged a low-cost deal with a vendor (e.g., diaphragm valves) or programmed software on a programmable logic controller (PLC) that may not be the vendor of choice for the rest of the plant. There also may be incompatibilities in piping, utility requirements, or software when the skid is connected (27) if miscommunications occurred between the skid vendor and the facility designer.

The traditional alternative to skid-mounted designs is to purchase the equipment components separately and request the facility designer to develop the system. One advantage to this approach is that total flexibility in equipment selection now rests with the pilot plant designers, who may be quite confident in their ability to design the equipment based on their extensive prior experience. Drawbacks of this approach include placement of the design burden on the facility as well as added design costs for one-of-a-kind systems. Specific references are available for flow charts and detailed designs for fermentation and harvest equipment (28–31) as well as for filtration units (32), chromatographic equipment (20,33,34), and centrifuges (35,36). A list of typical process, utility, and support equipment that might be required in a bioprocessing pilot plant has been compiled (Table 1).

For a bioprocessing facility, certain aspects of equipment and piping specifications should be uniform throughout the installation where possible. These specifications might include requirements for orbital welding of lines, documented weld inspections, passivation, pressure testing, self-draining (sloped) piping, minimal lengths for dead legs and pockets, restricted use of flanged connections, level of polish on product contact surfaces, stainless steel quality (typically 316L for product contact surfaces), and use of FDA-approved polymers in specific applications (gasket, o-rings, valve seats, distribution piping). Proper storage of fabricated piping awaiting installation as well as prominent identification of valves and lines also must be considered. Valve specifications can be important to determine early in the design estimation phase. Valve capital cost contribution is high because large numbers are required and any installed valves (either diaphragm or ball) need subsequent maintenance. Consideration should be given as to whether live steam, set up as a steam block, should be used to continually purge the back side of product contact valves and whether live steam should be used for tracing in between double o-rings on a port or manway (28). While such designs traditionally have increased sterility assurance for lengthy secondary metabolite fermentations, they may create detrimental localized hot spots during animal cell cultivation. Neither the equipment itself nor its disposable or replaceable parts should release any extractable substances (after the initial postinstallation rinsing and cleaning steps) into the product (28). An overview of sanitary piping design, installation, and validation concerns is available (37).

Transfer piping strategy is another major design decision. One common strategy is for several transfer lines to meet at a transfer panel or process manifold, typically located at a high point between two or more areas, and be connected using spool or “jumper” pieces to move material in the desired fashion (3). Steam entry is at the high point and condensate drainage at the low point for steam-in-place (SIP) during sterile transfers. Clean-in-place (CIP) solutions are passed along the direction of the transfer. Advantages to this approach include reduced piping distribution costs and space requirements, which can multiply rapidly when multiple tanks and multiple types of process transfers are required. Disadvantages center on operational restrictions concerning the elapsed time between successive transfers through a common manifold system as well as cross-contamination associated with transfers of nonsterile media/buffer, sterile media/buffer, inoculum, harvested broth, CIP solutions, and water through common lines. A listing of product and nonproduct transfer line/utility piping that might be required in a bioprocessing facility has been compiled in Table 2.

Both sterilization and cleaning sequences need to be defined and documented during the equipment and transfer piping specifications because retrofits after installation can be time consuming and expensive. P&IDs should be traced through these sequences before approval by both operational and validation personnel. Requirements for validation testing and in-use monitoring of equipment operation also need to be identified during the equipment specification phase. Examples include sizing condensate lines to permit adequate drainage of condensate when spore strips are present, specification of additional validation ports for thermocouples on vessels and condensate

Table 1. Types of Processing Equipment and Utilities Possibly Required for a Bioprocessing Pilot Plant

Fermentation and harvest	Isolation	Utilities	Support
Culture storage freezer	Low-pressure chromatography columns	Clean steam generator	Sterilizing autoclave
Incubator/shaker	High-pressure chromatography columns	USP purified water system	Decontamination autoclave
Biosafety cabinet	Solvent blending and delivery system	WFI system	Depyrogenation ovens
Laminar flow hood	Sterile filtration assembly	Deionized water	Laminar flow hoods for cooldown and equipment assembly
Seed fermentor(s)	Laminar flow hood	Process (city) water	Glasswasher(s) (glassware, vials, stoppers)
Production fermentor(s)	Liquid transfer pumps	Compressed clean air	Buffer preparation tanks
Nutrient feed tank(s)	Dispensing machines	Compressed instrument air	Media preparation tanks
Harvest tank(s)	Chemical fume hood	Compressed plant air	In-line mixer
Microfiltration skid	Portable tanks	Compressed gases (O_2, N_2, CO_2, NH_3)	In-process sample refrigerator/freezer
Ultrafiltration skid	Laboratory-scale centrifuge	Electricity	Raw material, cold/frozen storage
Pilot-scale centrifuge	Ultracentrifuge	Chilled water	Floor and bench scales
Homogenizer	In-process refrigerator/cold room/freezer	Cooling tower water	Process and equipment monitoring/alarm systems
Continuous sterilizer	Product refrigerator/freezer	Plant steam	Uninterrupted power source (UPS)
Filter integrity tester	Syringe/vial filling equipment	Glycol	Offgas analyzer (mass spectrometer)
Sterile tubing welder	Lyophilizer	HVAC and building automation system	Bar-code system
		CIP skid(s)	
		Biowaste inactivation system	
		Environmentally potent chemical destruction system	
		Dust collection system	

Table 2. Transfer Lines and Utility Piping Possibly Required in a Bioprocessing Pilot Plant

Product contact	Nonproduct contact
Utilities	Utilities
Clean water	Chilled/cooling water and/or glycol
Clean air	Instrument/plant air
Clean steam	Plant steam
CIP solutions	Contained sewer
Other compressed gasses (CO_2, O_2, N_2, NH_3)	Chemical (noncontained sewer)
Process	Sanitary water
Sterilized medium or buffer	Vacuum system
Sterilized nutrient/acid/base/antifoam feeding	Natural gas
Nonsterilized medium or buffer	
Inoculum	
Harvest	

lines, installation of product contact utility sampling stations (especially at worst-case locations), and installation of temperature sensors on critical lines to monitor sterilization and proper trap operation.

Utilities

Product contact utilities might include water, clean steam, compressed air and other gases, and CIP systems. Nonproduct contact utilities generally include chilled water, instrument air, plant steam, and plant air, although in some cases plant steam may be appropriate for product contact (Table 3). A listing of product and nonproduct contact utilities is compiled in Table 2. Multiple utility use points are located within and among suites for both product and nonproduct utilities; these are organized into utility stations for each equipment skid. To minimize piping, it might seem convenient to use product contact utilities in nonproduct contact applications such as compressed clean air on a vessel jacket, relying on a check valve for backflow prevention. This approach can risk disaster because the operation and quality of utilities can affect processing throughout the entire facility. Cross-contamination for product contact utilities among suites is rare because of positive pressures of utilities piping into each module.

Peak utility loads should be based on carefully investigated assumptions that are transferred from design directly to validation testing. Although it may be possible to run several large fermentors simultaneously, each at maximum airflow rate, it may be less likely that several large fermentors are cooled simultaneously after completion of sterilization. Thus, air compressors might be sized assuming maximum load while process chillers might be sized on the basis of an operationally realistic fractional load. Assumptions about processing cycle times and tank volumes are important particularly when sizing CIP systems and

Table 3. Example Plant Steam and Clean Steam Achievable Quality Comparisons

Quality attribute	Clean steam	Plant steam
Bioburden	<0.1 cfu/mL	<0.1 cfu/mL
Total organic carbon	<0.5 ppm	<2.0 ppm
Endotoxin	<0.25 EU/mL	<0.5 EU/mL
pH	5–7	5–8
Conductivity	Meets USP 23 Suppl. 5 standards	N/A

liquid waste decon systems. Shorter (20-h) *Escherichia coli* fermentations might require a smaller tank volume [1,000 L] but are run more frequently, compared with longer (400-h) fungal fermentations, which might require a larger tank volume (20,000 L) but are run less often.

Product Contact. The most critical product contact utility is often water because of the sheer volume needed during typical processing steps. It is well known that the quality of water needs to be appropriate for the intended application, but water system design decisions often are conservative. In many installations, purified water is used for upstream processes while WFI is reserved for downstream isolation and for cultures sensitive to endotoxin such as animal cells (38). A brief overview of various methods to produce pure water is available (39).

Water-for-injection (WFI) is often favored for the entire facility for uniformity. Specifications are set for parameters such as bioburden (typically 0.1 cfu/mL) and endotoxin (typically 0.25 enzyme units, EU/mL) as well as USP chemical tests that include conductivity, pH, and total organic carbon (TOC). WFI systems containing stills generally are designed as a hot 80 °C loop with point-of-use coolers that can provide water at a user-selected temperature. These coolers can form deadlegs and thus require substantial flushing before use. It is also possible to design a cold or ambient WFI loop with periodic (typically daily) heating to 80 °C or ozonization for sanitization purposes. In some applications, reverse osmosis (RO) systems are used, but care of the membranes is critical to consistent operation.

USP purified water is an attractive alternative to WFI for various upstream applications. Specifications include bioburden (typically 100 cfu/mL) and USP chemical tests. Although such systems can be operated hot or cold, recent success with ambient systems sanitized with ozone and ambient systems sanitized chemically (40) has been reported. Other noncompendial grades of water may be required. In these cases, quality attributes typically are established by the facility to address the needs of specific processing steps (Table 4). Examples might be deionized water with bioburden (typically <500 cfu/mL) and resistivity (>1 Mohm) specifications or process water (municipal water passing through a break tank).

General design elements for water systems include the desired flow rate at each use point and the desired number of simultaneous use points in operation. Use-point positioning should consider the height of the take-off valve, automation of take-off valves, and sink or sewer location for flushing, as well as cleaning, sanitization, and acceptable noncoiled storage for associated use-point hoses. These values are combined to obtain the total "take-off" flow rate; the system and piping are then sized such that velocity of the remaining flow rate is sufficient to minimize bioburden and biofilm growth. Suggested methods for obtaining this residual velocity have been outlined (41). In addition, water systems should be designed with specific sanitization procedures identified at the outset. Steam, ozone, or chemical sanitization methods are most common, although steam sanitization generally has not been recommended for plastic loop systems because of concerns about distribution pipe sagging. Plastic systems utilizing polyvinylidene fluoride (PVDF) instead of stainless steel are becoming more common and effective at achieving even WFI conditions. A direct comparison of plastic piping with stainless steel with respect to ion leaching, smoothness, and cfu counts has been made (42).

Clean steam can be generated from a purified water feed using plant steam for supplying heat of vaporization. Increased heat exchanger fouling may occur if a controlled feed water supply is not used. Clean steam distribution piping is designed with regulators to reduce the pressure from 5 atm down to about 2–2.5 atm as needed for typical SIP operations. Sanitary pressure gauges, placed near or on equipment skids, can assist in determining dynamic pressures during SIP cycles. Steam sampling stations generally take the form of a removable sanitary trap to which a sample cooling device (typically a heat exchanger) is attached. Consequently, a source of cooling water is necessary, either piped from local lines or transported by gravity via a portable holding tank about 20 L in volume. Traps should be placed in header branches and equipment supply lines such that condensate buildup does not occur when skid equipment is isolated for repair. Periodic cleaning of the clean steam system assists in cleaning fouled heat exchange surfaces and in minimization of rouging.

Compressed air in product contact generally is used for fermentation sparger air supply and pressurized transfers. Oil-free compressors are favored, with intakes positioned away from other building effluents. Heating up to and holding at 200 °F (93 °C), typically accomplished by design of the compression ratio and residence time in a receiver, is desirable to minimize airborne biological contaminants such as bacteriophage, although there is some evidence that submicrometer (0.1 μm) filtration also can be effective. Humidity can then be reduced from the compressed air using refrigeration and desiccant dryers. Moisture removal is desirable to a dew point of -40 °C. Air is then microfiltered (0.2 μm) at the point of use to remove microbes and particulates. Compressed air may be sampled for any or all of the following depending on the application: identity, hydrocarbon level, microbial content, and particulates. Other gases may be required for the facility such as oxygen enrichment for microbial cells, carbon dioxide for pH control of bicarbonate-buffered media, nitrogen and oxygen supplementation for animal or insect cells, and appropriate gas blending and control systems. Planning should consider storage of bottled gas cylinders outside the facility or in segregated maintenance areas to minimize the transport of unclean cylinders in controlled locations.

Table 4. Comparison of Example USP Purified Water, Deionized Water, and Process Water Achievable Quality Attributes

Quality attribute	USP purified water	Deionized water	Process (city) water
Bioburden	<100 cfu/mL	<500 cfu/mL	<500 cfu/mL
Coliforms	Absent	Absent	Absent
Total organic carbon	<0.5 ppm	<2.5 ppm	<5 ppm
Endotoxin	<0.25 EU/mL (for information only)	N/A	N/A
pH	5–7	5–8	5–8
Conductivity/resistivity	Meets USP 23 Suppl. 5 standards	>1 Mohm	N/A

CIP skids can be portable and moved into place in the suite at a designated utility location or one or more fixed main skids can be located permanently in the utility area. CIP systems are composed of supply and return pumps, one or more cleaning agent dilution tanks, provisions for heating cleaning agents, and a PLC for sequence control and associated data acquisition. Because multiple tankage and pumps are required (20), these skids often are located in utility areas where acid- or caustic-based cleaning agents arriving in drums can be suitably diluted. More than one CIP skid may be necessary to provide product segregation and minimize cross-contamination. Multiple skid requirements depend on design decisions concerning the level of containment and product segregation (3) as well as capacity.

Nonproduct Contact. The type of cooling/heating system desired, while not in product contact, has widespread design implications. Recirculating temperature control loops containing high surface area/unit volume heating and cooling heat exchangers, an expansion tank, and a circulation pump are common. These systems rely on indirectly heating or cooling of jacket fluid so their response can be slow, particularly if heat exchangers were not sized according to user expectations. The involvement of heat exchangers means that practical application may be limited to vessels a few thousand liters in size. Jacket fluids can be water, glycol, or novel fluids with wide temperature ranges. Operation of the circulation pump and internal (as well as external) integrity of the heat exchangers are also critical. Cooling heat exchangers can use either chilled water or glycol, whereas heating heat exchangers generally use plant steam. Dual parallel filter housings, containing 10 to 50-μm elements, are advantageous to reduce heat exchanger fouling. Sediment buildup on filters can be monitored using measured pressure differentials across the filters, and the assembly can be designed so that one filter may be replaced while maintaining flow to the second filter.

Direct application of heating or cooling fluids to process jackets is the traditional alternative. Consecutive application of chilled water and steam on the jacket is acceptable if the design evacuates the jacket using higher-pressure compressed air such that banging is minimized. Use of glycol and steam on the same jacket can have environmental implications from glycol losses. Regardless of the indirect or direct mode of application, jacket design can greatly affect heat transfer effectiveness. Dimpled or straight jackets are preferred for smaller vessels, with external half-pipe cooling coils used in larger vessels. The largest manufacturing scale vessels utilize internal cooling coils but these present additional internals for cleaning and increased sterility risks, particularly at welds, because cooling water can be at a higher pressure than the fermentor contents.

Filtered dried instrument air, typically at a pressure near 100 psi, is required for solenoids. Pressure specifications for control valve operation vary considerably among vendors. Plastic hosing, although convenient and cost effective, should be evaluated carefully for instrument air lines, especially on hot equipment where heat-induced leaks can develop and in solenoid cabinets where crimping can slice the tubing. A backup instrument air compressor can minimize operational consequences from supply pressure dips. A separate compressed air source, at a higher pressure than chilled/cooling water and jacket steam, is desirable for evacuation of vessel jackets to minimize risk of backflow into the instrument air system.

Natural gas usage, if required, might best be addressed using bottled gas for safety reasons, which discourage distribution piping throughout the facility. Favored for flaming of openings in many microbiological procedures, the use of Bunsen burners in a biosafety cabinet or laminar flow hood should be examined carefully with company safety department representatives. Care should be taken to minimize the potential for reaching the lower explosive limit near the motor of the cabinet or hood. Compatibility of plastic laboratory ware with flames also should be ensured.

HVAC. HVAC is a key and costly component of the facility. Its design and operation needs to be understood by operating, maintenance, and quality assurance personnel. Requirements for air cleanliness, as well as the ability to achieve them, are determined by HEPA filtration, airflow volume, and pressurization room design as well as the type of operation being conducted (Table 5) (3). HEPA filters are often used for inlet air but are only used for exit air when required by biosafety containment. The specific classification of processing areas depends on processing step quality concerns. Classification level, representing the maximum number of particles permitted per cubic foot of air sampled, of an area increases from fermentation (class 10,000–100,000; 20–40 room changes per hour) to purification (class 1,000–10,000; up to 100 room changes per hour) (3). Within a room there are cleaner areas surrounding open transfers (e.g., biosafety cabinets or laminar flow hoods) that are class 100 (540 changes per hour) (43). For viable particles, the range is from class 100,000, which permits 2.5 cfu/ft^3, down to class 100, which permits 0.1 cfu/ft^3 with

Table 5. Example Controlled and Noncontrolled Area Achievable Quality Comparisons Based on Room Design

Type of area	Pressurization	Airflow changes (#/h)	Inlet filtration	Nonviable (#/ft)	Viable (cfu/ft^3)
Bulk fermentation processing	None	60	Coarse	<250,000	<25
Laboratory	Positive	60	Coarse	<100,000	<2.5
Laboratory	Positive	10	HEPA	<100,000	<2.5
Laboratory, clean construction	Positive	25	HEPA	<100,000	<2.5
Laboratory, clean construction	Positive	20	HEPA	<10,000	<0.5
Laboratory, contains autoclave	Positive	100	HEPA	<100,000	<2.5
Laboratory, contains glasswasher	Negative	50	HEPA	<100,000	<2.5

intervening levels generally determined by individual application (43). Sufficient air velocities also are necessary to dilute particulate contaminants. In some cases, separate air handlers are considered for critical sterile areas, inoculum preparation areas, high particle or dust areas, and segregated product areas. In other instances, airflow is designed in a once-through pathway, which may increase heating and cooling utility costs substantially.

Inlet air enters from the top of the room, flows downward, and exits from ducts near the floor. Any recirculation, which may be desirable to minimize capital costs for heating and cooling equipment as well as operational costs, should be only from the room where the air originated, limited to areas that do not generate substantial amounts of particles, and pass through inlet HEPA filters again. This strategy is beneficial to the life span of the HEPA filters and the ease of maintaining constant temperature and humidity (3). Exit ducts should be placed near equipment within a processing area that generates the most particulates or aerosols so as not to spread them throughout the area. Specific examples include autoclaves, glass washers, and cell-disrupting homogenizers.

Room pressurizations should be higher for cleaner areas and lower for areas that generate particles (3). Higher pressurization levels should be assigned to airlocks between adjacent areas for which it is desired to minimize cross-contamination. Relative pressurizations between rooms sharing a common wall should be considered to supplement or minimize reliance on completely sealing rooms during their construction. The use of door sweeps and gasketted ceiling tiles to achieve and maintain pressurization should be evaluated relative to floor cleanability and ceiling maintenance access, respectively. Pressure differentials might be as high as 0.03 in of water between classified areas and as high as 0.05 in between classified and nonclassified areas. Lower pressure differentials might be acceptable depending on the specific product so long as the direction of airflow remains consistent. Interlocks, control, monitoring, and alarm building automation systems may be designed to reduce pressure losses when doors are opened and to alert users to unsatisfactory conditions.

Facility temperature is generally maintained on the cool side because gowning tends to make workers warm. Inaccurate assumptions concerning the impact of radiant heating may cause temperatures to be higher than desired on certain days of operation. Humidity should be comfortable to avoid drying of workers' respiratory membranes during extended hours. Care should be taken to specify tolerance limits that have quality implications relevant to the processing steps expected to be conducted in that area to avoid unnecessary facility costs. While specific example guidelines are 23 ± 3 °C for temperature and 40–60% relative humidity (44), substantially larger ranges may be acceptable for many processing applications. An extensive P&ID design of HVAC for clean spaces is available as a published reference (43). In addition, consideration should be given to Federal Standard 209E, Airborne Particulate Cleanliness Classes in Clean Rooms and Clean Zones, as well as European Economic Community (EEC) regulations that establish parallel categories of Grade D (100,000), Grade C (10,000), and Grades A + B (different designs of class 100) (43).

Containment

Similar issues exist for product, environmental, and personnel protection. Often the resulting design specifications overlap with those items necessary for sterile or sanitary operation. This concept is addressed in the literature (45) in which solutions to prevent microbial transport for the purposes of containment were compared with those to maintain sterility for fermentors. A unified approach is recommended with the goal of minimizing unnecessarily stringent specifications that can substantially augment capital and operating costs. Environmental and personnel protection issues should be evaluated for each new process undertaken by the facility, along with product protection quality concerns. Samples of broth, and other product, intermediate, and waste streams, should be submitted for aquatic and human toxicity testing in advance of processing in the pilot plant when appropriate. Preliminary laboratory data then might be available to evaluate potential hazards in conjunction with published documentation concerning the relationships of the questionable compounds, raw materials, or organism with known hazards.

Product Protection. The major concept for product protection is the closed system in which all material entering or leaving the process must be controlled in a specified and documented manner. This requirement extends to product contact utilities such as purified water, clean steam, compressed air, and controlled/monitored room air so that when equipment is opened for cleaning the quality of the surrounding environment is consistently at a known and documented level. The equipment is cleaned to an acceptable quality level. After sterilization, material enters the closed system via a sterilizing filter, steamed connection to an autoclaved bottle assembly, or sterilized transfer line.

Offgas passes through a 0.2 μm steam-sterilized vent filter, often contained in a low-pressure steam-jacketed housing preceded by a coalescing filter, condenser, or vent heater to avoid pluggage from moisture. Double mechanical seals are utilized with a barrier fluid of a controlled quality (typically condensed clean steam) at a higher pressure than the vessel. A closed system also can be used to surround an open operation such as the use of isolator technology (i.e., glove box) as an alternative to clean rooms or biosafety cabinets (46,47).

Environmental Protection. Environmental protection concerns focus on emissions in air, liquid, and solid waste. State air permits typically are required for new vessels and need to be altered if additional air treatment devices such as vent filters, incinerators, or scrubbers are added. Hydrophobic vent filters can provide emergency foam control and prevent external product release. These filters can be monitored for pluggage over cultivation time using pressure differentials with plugged filters able to be replaced during a run only if a bypass line has been installed. Liquid emissions include accidental spills/sewerings, which can be minimized by locking vessel bottom valves, blocking open sewer connections, collecting sample line flush waste, and providing clear written instructions to personnel regarding batch disposition using batch sheets and appropriate signs. Dikes, troughs, and vaults can be used to contain large spills or divert inadvertently sewered material. Sample waste can be minimized using low-volume sampling devices. Thermal or chemical (less common) batch or continuous kill tanks need to be considered for biological hazards. For chemical hazards, other appropriate waste destruction and minimization systems may include hot caustic hydrolysis, reverse osmosis, and evaporative condensers. Batch leakage into cooling water utility systems can be minimized by pressurizing utility systems higher than the batch, but this might introduce contamination if jacket cooling coils develop leaks. Alternatively, the utility system return headers can be isolated from general use until their contents are treated and/or tested. This solution might be attractive for cooling water as well as condensate, especially when it is returned to river sources. Care must be taken to avoid sequestering large quantities of potential waste for long periods of time. Solid waste can be controlled procedurally using clearly labeled containers.

Personnel Protection. Personnel protection is not as great a concern now that most recombinant organisms can be grown under typical operating conditions of GLSP. For other pilot plant processes requiring personnel protection, either the culture is rated at or above BL1-LS or a compound produced by the culture adversely affects human heath (e.g., a genotoxin, mutagen, teratogen, or carcinogen). Environmental monitoring of the operating area is necessary for the compound or culture of interest using air or swab sampling techniques. For optimal recovery, swabs should be soaked in a solvent known to dissolve the compound of interest. Screening and monitoring of personnel potentially in contact with the process (operator, mechanics, janitors, engineers, visitors) must be arranged and notification given to those personnel at unacceptable levels of risk relative to their individual health histories. A key element of personnel protection is personnel protective equipment (PPE). This equipment can include gowns, uniforms, safety glasses, lab coats, and gloves at a minimum but can be extended to include face shields and respirators as required. Spill response equipment, procedures, and training are also necessary.

Reduction to practice techniques are presented in the literature for general biocontainment issues (48) and biocontainment regulations and requirements (49). Specific examples are available for the design of waste inactivation systems (50,51), contained facility design and operation (52,53), design details for cleanliness and containment for floors, walls, ceilings, and penetrations (54), and contained sampling systems (55).

Instrumentation

The main purpose of a pilot plant is to collect data in as many ways as possible. Thus, a large fraction of the pilot plant capital allocation might be devoted to instrumentation. Traditional instruments for on-line monitoring, particularly for fermentation, include pH (56), dissolved oxygen (DO) (57–59), temperature, agitator speed, agitator power draw, backpressure, foam detection, batch level or weight, airflow rate, and vent gas analysis via mass spectrometry (60). Redundant instrumentation is desired for critical parameters such as pH and DO. Instrumentation for isolation monitoring includes monitoring of conductivity, pH, ultraviolet wavelength intensity, and refractive index detection. Useful utility instrumentation includes on-line total organic carbon (TOC) and resistivity/conductivity meters. Local readouts of transmitter values can be useful, particularly for pressure and possibly temperature, although the potential for differences between field and control room values may have to be addressed.

Many novel sensors have been developed including dissolved carbon dioxide probes (56,61), redox sensors (56), glucose sensors (62), near-infrared detectors (63,64), fiber optic biosensors (65), fluorometry of intracellular NADPH (66), and cell density probes (67–69). Another novel measurement device example incorporates fermentor side streams to measure viscosity on-line (70). A description of useful sensors may be found in the literature (71). Characteristics of on-line and in situ devices include cleanability, minimal drift, minimal interferences, versatility, sterilizability, ease of calibration, and several other factors. Utilization of any sensor should be evaluated for its effect on bioreactor sterility as well as product quality.

Automation and Control

The need for flexibility and change within the pilot plant (as compared with production) needs to be apparent in control schemes, event sequencing, data collection and presentation, and alarming (72). Increased amounts of automation restrict abilities of the end user to implement changes, but do reduce the number of manual operations and thus possibly headcount. Specifically the control system needs to readily permit set-point and alarm changes. Control systems can be distributed or centralized, with distributed control systems (DCS) favored because there are

individual controllers/computers for each unit, often connected to a central computer via a high-speed network. Thus, the loss of one centralized computer is not catastrophic (72).

While there can be "islands of automation" within a facility, connectivity in a centralized location for data monitoring, set-point/alarm changes, and data archiving might be desirable. Substantial advantages exist for localized controls on skids when many field-based inputs are required based on an operator's evaluation of field conditions. A local readout of monitoring data versus a centralized "control room" monitoring area (or even both) is dependent on the degree of operator supervision versus intervention required for the processing. This decision is related directly to the flexibility of operators to go in and out of the field in terms of gowning procedures and ease of access. The ability to remotely input set-point or alarm changes can be useful when containment or product protection levels are high. Multiple areas for setting parameter values need to be considered carefully from the aspect of operational control to avoid duplication of desired changes and to minimize batch record log omissions. Verbal communications between the field and the control room using radios or intercoms also need to be considered.

Distributed control systems are favored for process management. System architecture requirements vary depending on the processing requirements but examples for a non-PC based system have been published (73). Distributed control systems also can be PC-based using commercial PC control/data acquisition software (74). In either case, some type of process-level controller is required such as a PLC, loop controller (LC), personal computer–based controller) (PCBC) (32). The ability for those without computer expertise to easily modify and understand control sequences using newly developed commercial control software is attractive but requires effective change control and documentation procedures. The ability to readily configure the data acquisition system to download and archive data is a consideration important for later operation and process development.

There are several types of computer inputs and outputs (72), which include *(1)* digital inputs in the form of an on–off signal used for foam probe, pressure, flow, or temperature switches; *(2)* digital outputs in the form of an on–off signal used for the flow of antifoam, open–close valves, or pump/motor start/stops; *(3)* analog inputs in the form of an amplified output in the range of 4–20 mA used for temperature, pressure, pH, dissolved oxygen, flow, and power draw; and *(4)* analog outputs in the form of a proportional signal that controls the valve opening via an I/P conversion, typically used for back pressure, cooling, and airflow valves or for signals such as motor speed.

The type of control most frequently utilized is the proportional integral differential (PID) control loop. It is tuned using three parameters to minimize oscillations, which can change depending on the specific process (e.g., for dissolved oxygen cascade control of a fermentor cultivating faster-growing *E. coli* versus slower-growing yeast cells) or over the course of the same process (e.g., for glucose and ethanol consumption phases of a baker's yeast fermentation) (75). These three parameters are the size of the error relative to the proportional band with smaller bands resulting in more sensitive systems, integral of the error over time with longer error durations resulting in greater corrections, and rate of error change with time with larger increases in correction with time calculated the faster the error is growing with time (71). Typically the third parameter is at a minimal value near zero for the optimally tuned loop.

A conscious decision needs to be made concerning the desired level of automation for CIP, SIP, and vessel-to-vessel transfers. Higher levels of automation may ensure reproducibility of operation, reduce reliance on operational staff, and simplify SOPs. Raising the level of automation increases capital, validation, and maintenance costs while reducing flexibility. Operating personnel who routinely observe automated processing steps may be less familiar with the details of automated versus manual equipment operational sequences. A domino effect may exist in that automation of one valve may lead to automation of several related valves, severely increasing design complexity and cost. Limit switches often are installed that confirm to the control system that the desired automatic valve has opened or shut as requested. Automatic pulsed diaphragm valves have been successful for nutrient feeding as well as for sterilization of transfer lines in automatic plants (76). One prominent example of a highly automated but apparently reliable fermentation facility is operated for the manufacture of cephamycins as well as for pilot use (77). Typical diagrams for monitoring and control of a fermentor (20,72) and for monitoring and control of an ultrafiltration unit (32) have been published.

Data Acquisition and Archiving

The collection and management of data during pilot plant operations are critical, with the collection interval dependent on the nature of the processing step. For fermentations, intervals might be every 15–20 min during secondary metabolite or animal cell cultivations but might shrink to 5–10 min for faster-growing bacterial or yeast cultures, especially when a key process addition or change is planned to be made on the basis of offgas or dissolved oxygen data. Typically, 5- to 10-min intervals are appropriate for microfiltration or centrifugation operations. Smaller data collection intervals may create substantial data archiving demands that may be alleviated by only saving those data substantially different from previous values, based on some user-defined value. Continuous data collection in the form of chromatograms is typically required for chromatographic operations.

In-process trending of data is attractive to permit timely evaluation of process status and troubleshooting of processing problems. Automatic recording of alarms and changes to the control system, preferably sorted according to the equipment and/or batch on which they occurred, also can help trace back processing problems and actions taken. On-line data might be archived on a common server by some unique batch delimiter, according to the established facility SOP for archiving data. One formidable challenge is to incorporate off-line data in the same or a closely related reference database; this off-line data can get fragmented among the notebooks and files of individual re-

searchers. Novel customized systems for bar-coding samples taken from the field and creating a database for results can be helpful and can also create possibilities for the use of robotic systems for sample analysis. Remote access is an attractive option for monitoring processes from off-site locations. Remote alarming can be triggered to a satellite pager, thus removing the necessity for round-the-clock coverage. Remote control of operations can be administratively challenging to regulate and document as well as a potential safety issue. Security issues must always be considered for any established remote capability.

Warehousing

Warehousing needs for the facility need to be determined based on expected production capacity. Common items that might be stored include ambient, cold, or frozen solid or liquid hazardous and nonhazardous raw materials (controlled temperature and/or relative humidity storage), disposables, equipment, and spare parts as well as sample and product storage. Computerized inventory systems, organized by process or equipment, can be useful for most of these items with reminders to reorder when supplies decline to a critical level. Marker equipment also might be purchased for long-lead replacement parts for which redundancy was not desired during the original facility design. Sizing of these storage areas should consider typical lot volumes of prepared culture media and solids to minimize repetitive release testing for multiple lots. For a pilot plant, in which several diverse processes may be run, additional process-specific storage often is required. The relative amount of storage necessary in the building should be compared with other on-site and off-site options. Vendor manufacturing schedules often require purchasing larger quantities of rare raw materials to avoid future shortages. In this instance, if on-site storage is not available, vendor storage or a third-party warehouse alternative may be required. Warehouse access may need to be restricted depending upon the nature of its contents. There should be segregation for released, unreleased, and quarantined materials either by physical separation or by designated labels.

While the entire facility should have a comprehensive pest monitoring program, as well as an SOP, there may be a need to directly address pest control, particularly for flours and meals used in certain secondary metabolite fermentations. These food ingredients when purchased for pilot-scale fermentation purposes may not pass through fumigation unless specifically requested on the purchase order. Typically, larger customers in the food industry have invested capital for on-site fumigators, but commercial nutrient vendors may not have this type of equipment because of their high rate of inventory turnover.

Staging areas should be available for collecting raw materials and supplies for a specific batch. Some method of inventory assessment and control should be available; one convenient method is to use computerized bar-coding to check inventory as well as to confirm use of specified materials when charging occurs. In addition, controlled sampling areas (to provide raw material protection, environmental, and/or personnel protection) for sampling raw materials may be necessary.

Backup Systems and Redundancy

A critical design decision centers on the level of backup or redundancy required in the pilot plant. While typically none of the material created in the pilot plant is "for sale," mechanical problems can delay processing and clinical material production, which may interrupt clinical supplies and compromise the success of ongoing studies. Even if no clinical material is at risk, process development efforts are hampered when experiments are frequently interrupted for mechanical support-type equipment failures (4). Scenarios that might be protected against include loss of clean steam lubrication to agitator seals, loss of positive air pressure on a sterile tank, and loss of electrical power to a controller. Corresponding equipment needs might include redundant clean air compressors, clean steam generators, and purified or WFI water generation systems, with the peak plant capacity needs split between two systems rather than relying on a single system sized for peak usage. Such redundancy usually is achievable because utility costs are low compared to equipment costs (4). An uninterrupted power source (UPS) system sized to include the most critical equipment (typically controllers and data acquisition devices) might also be installed. Backup power for large electrical loads such as motors might not be economical; however, consideration might be given to installing connections for a gas-powered generator if future evaluations altered the economics.

Future Expansion and Modification

Because future processing needs may change, the pilot plant must adapt to maintain its usefulness to the company. Large initially underutilized spaces might be outfitted with utility headers to minimize processing disruption during future installation. Oversizing of utilities for anticipated future loads (4) as well as unforeseen procedural modifications warranted on the basis of validation testing results such as additional rinsing cycles assures subsequent flexibility. Selection of portable equipment permits exchanges for new processes, provided there are procedures developed for storage and start-up of this equipment.

One aggressive approach to increase versatility is the availability of a modular mobile validated pilot plant (78), composed of a system of interconnected and integrated modules. Modules are selected according to processing needs and can be assembled rapidly to form a processing plant capable of undergoing validation. Production modules include fermentation, recovery, and purification; the utility module includes clean water and clean steam; the personnel support module includes lockers and changing areas; and the HVAC module houses the air handling and filtration equipment. Additional modules can then be added or deleted as required.

OPERATION

Each pilot plant facility must decide for itself whether it is required to operate in a continuous mode of GMP compliance or whether it can selectively apply GMP practices to certain batches [but not to other concurrently run batches]

or during certain specific processing periods. A conservative solution might be to operate continually in GMP compliance, thus insuring facility readiness and preventing omission of a required procedure for an actual batch destined for the clinic. Dual GMP and non-GMP operation serves to create two standards and may cause confusion among operating and maintenance staff. If dual operating modes are considered, then a clear distinction between GMP and non-GMP operation must be established, documented, and maintained.

Maintenance

Preventative. Preventive maintenance (PM), performed during an annual facility shutdown, is probably the most important factor influencing smooth operation throughout the upcoming year. The scheduling of an annual facility shutdown is desirable for several reasons including the ease of lockout and tagging of hazardous energy sources, the time economies of concentrating several maintenance workers in a single area, and the ability to collect and document completion of a large fraction of maintenance work at one time. This yearly PM binder can then serve as the model for maintenance personnel for the following year's shutdown. Individual PM work orders, spread over the course of a year, result in substantial time and effort expended in scheduling, preparing, and documenting the work done. Interspersing of annual PM work among batch processing inevitably results in PM delays due to equipment and/or manpower unavailability. Guidelines for planning and executing an annual plant shutdown are available (79).

All PM work orders should be listed on a single spreadsheet to be reviewed before the facility shutdown and augmented with any modifications or one-time replacement work orders that are requested. As PM work is completed, documentation might be signed by the tradesperson as applicable and reviewed by mechanical and operational staff for completeness. Problems identified with equipment or instrumentation should be highlighted as they occur and then entered into change control work order systems so that they can be tracked for their potential effect on validation.

Before the annual shutdown, transfer line manifolds and utility supply lines, which typically cannot be shut down entirely for maintenance throughout the year, might be leak tested to identify faulty valves in need of replacement. After the annual shutdown, equipment start-up procedures should be documented, preferably through the use of equipment start-up batch sheets. These procedures might include equipment cleaning, testing of instrument calibrations such as level, temperature, and pressure (80), and vessel integrity testing for leaky valves. Instrument calibration accuracy should be evaluated for random or systematic errors, with random error within accepted tolerances being the expected outcome.

Some general PM procedures have been outlined that can apply to several areas in a pilot plant, both product and nonproduct contact. Sanitary fittings, which tend to loosen during repeated heating and cooling cycles, should be checked, with gaskets replaced and clamps tightened as required. Any flanges in product contact should be tightened to a specified torque. PM inspections of vessel internals should be conducted with lock washers on nuts that may loosen due from repeated heating and cooling. A PM should be developed for inspection of vessel cooling coil leaks that can result in inadvertent cooling water contact with product (81). For agitated systems, there should be a regular examination of foot bearings, motor/drive vibration, oil analysis, and shaft runout. Double mechanical seals, the failure of which can lead to condensate buildup or batch contamination, should be tested regularly and replaced preventatively based on a minimum life expectancy (82). An outline of specific PM procedures for laboratory fermentors can be applied to larger-scale fermentors (83). An example of documentation for the maintenance of horizontal laminar flow hoods also is available (84) that can be readily adapted to other HEPA filter units. PMs should be conducted on all utility systems, which may include rebuild of air compressor heads, descaling of heat exchange surfaces, and replacing of air dryer desiccant, among other items recommended by the equipment manufacturer. Finally, novel predictive maintenance evaluation techniques should be explored and implemented as appropriate to identify imminent equipment failures (85).

It is most appropriate to perform any annual validation work (e.g., fermenter SIP, autoclave load pattern, controlled temperature unit) at the conclusion of the annual PM shutdown. In this manner, proper equipment operation can be documented and the effectiveness of PM procedures can be evaluated. Often inadvertent mistakes or omissions during maintenance can be identified before they have an adverse, and possibly widespread, quality impact.

Ongoing. A system of tracking outstanding maintenance by equipment or by process should be designed. Each piece of equipment should have a clearly distinguished tag name. Work orders need to be initiated, evaluated for their effect on validation, marked as complete when mechanical work is done, and finalized when process personnel have checked the job. A computerized database can readily track maintenance and identify repetitive maintenance problems. Such a system permits easy review of outstanding work orders for each piece of equipment by the operation group before it is readied for service. All maintenance work orders need to be tracked within one system; care should be taken not to bypass the operations area when maintenance needs are identified by those directly controlling the mechanical staff.

Interim maintenance work, such as calibrations and subannual PM work, should be documented and filed in a manner equivalent to the yearly PM results. PM schedules should be reviewed based on the frequency and results of interim maintenance work. Unusually common equipment failures can be identified through maintenance database searches so that appropriate longer-term repair efforts or replacement can be justified and undertaken.

Calibrations. Additional concerns are associated with calibrations because important processing decisions may be based on the accuracy of the instrument readings. In

some cases, specific instruments are designated as "critical" for a processing step; in other cases, desired specification ranges for the processing step are targeted based on certain identified instruments. These two methods provide assurance that product quality is not compromised if any of the other instruments fail in the equipment being used.

Although some facilities distinguish between calibration procedures for critical and noncritical instrumentation, it may be prudent for a pilot plant to calibrate all instruments in a reliable and documented manner because their accuracy may be important for useful process development data. Calibrations should be performed using National Institute of Standards and Technology (NIST) traceable instruments and should include full loop calibration to the process monitor as appropriate. A specific calibration and maintenance SOP for the instrument is most desirable, but a general SOP referencing vendor manual might also be acceptable, particularly in the interim period while instrument calibration SOPs are being developed. The as-found and as-left conditions should be documented along with the serial number of the standard used. Establishment of an acceptable tolerance for each instrument ensures consistency. When an instrument is found to be outside the tolerance specified, the impact of this calibration error on previously executed batches may need to be evaluated. Thus, a confirmation of the error might be warranted before correcting the calibration. Records should be evaluated for the amount of instrument drift, which may indicate the need to either recalibrate on a more frequent basis or else replace or upgrade aging equipment. An example calibration sheet is available (86).

Modifications and Change Control. Any validated facility needs to devise procedures for tracking changes on equipment as well as on processes and computers. Incomplete documentation of changes can obviate extensive time and money spent on validation testing. Although the exact contents may change, such a procedure starts during the initial design phase as equipment specifications are altered, continues through the facility start-up and qualification phases, then moves directly into the facility operational phase. Adherence to change control procedures may be difficult during facility start-up as many unexpected items are discovered to be incorrect and management pressure to have the facility operational may mount. Depending on the philosophy of the individual facility, the scope of this change control procedure may include product and nonproduct contact equipment to varying degrees. The procedure identifies the individual or individuals that need to approve changes and determine before or in concert with the change implementation what additional validation testing is required. Often, processing personnel, being most familiar with the equipment being modified and the reason for its modification, can provide valuable leadership in this area and initiate contact with quality and validation personnel as required for input.

Generally replacements in kind are accepted without additional testing unless the item being replaced was specifically tested or calibrated during the initial validation effort. Example items and associated testing might include a replacement or rebuilt motor or associated drive (measure motor amperage draw at various agitator speed settings) or replacement instrumentation (calibrate transmitter). Replacement items in this category need to be tagged appropriately in the field with the same tag number as the original item and serial numbers updated in any centralized maintenance data bank as well as recorded on installation documentation.

Modifications or obvious changes in equipment or instrumentation need to be evaluated for their potential impact on the validated state of the equipment. This impact is particularly important for SIP and CIP cycles. Such modifications may be minor, such as a change in gasket or o-ring material of construction, or major, such as a change in piping. An example procedure is available that can ensure proposed changes are reviewed by operations, maintenance, and quality for their potential impact (87). Specific attention should be given to alterations needed in P&IDs, SOPs, PMs, batch sheets, or training programs. Equipment modifications, necessary to accommodate a new process, need to be identified early and their impact evaluated (2). It is critical to recognize the need to balance the request for change with an evaluation of its validation impact; changes cannot be discouraged in a multipurpose pilot plant but need to be controlled and managed in a logical manner.

Staffing

Personnel needs are best defined based on the production process (88), but in a pilot plant setting production processes change rapidly. A decision needs to be made early in the design process concerning the level of off-shift activity reasonably expected in the facility because this can severely impact items such as utility capacity and operation. Round-the-clock coverage, while demanding for personnel involved, may be necessary a large fraction of the days to ensure success and timeliness of production. The use of unionized personnel, technicians, or process development staff should be incorporated into the educational and manual workload expectations for the operating staff. A core operations group, responsible for the facility, can ensure continuity in areas such as SOP updates, maintenance work order tracking, batch sheet content, and equipment operation. Such a group might be supervised by an area manager responsible for coordination and scheduling who might interface with those involved directly in process development. Processing groups might then rotate through the pilot plant as their projects demanded, accompanied by a member of the operations group. Alternatively, a dedicated pilot production process development staff might be instituted, responsible for translation of laboratory processes into GMP batches. A shift report or log should be established and continually updated as to the mechanical and operational status of individual pieces of equipment and utilities.

Laboratory Support

To provide adequate and accurate sample analyses, laboratory support needs should be identified and addressed through either on-site or contract laboratories. Targets for testing might include final product, in-process samples,

raw materials, sterility, culture purity, environmental quality of controlled environments, and utility quality (Table 6). While the goal of these laboratories might be to work toward using validated methods and approved SOPs for all assays, this goal might not be attainable for project-specific assays until the later stages of a successful development project. Initially, in the early project stages, only notebook procedures might be available to guide laboratory testing. Information directly impacting quality should be communicated directly to operating personnel and appropriate investigations conducted both in the field and in the laboratory for failing results.

A microbiological laboratory is critical for fermentation-based operations to prepare seed cultures and to test new culture seed vials for culture purity and productivity in lab-scale processes. An examination of up-to-date sterility/culture purity results before vessel-to-vessel transfers should be undertaken as close to possible to the time of transfer to minimize adverse impacts of contaminated cultures. In a pilot plant setting, tension may exist between the time required to adequately test new cultures and the development pressure to use the latest mutant or transformant in a pilot-scale cultivation to evaluate its capabilities. Reasonable procedures need to be established in advance for the introduction of new processes or new cultures into the pilot plant. Laboratory-prepared nutrients, trace ingredients, and sterilized additions need to be evaluated for their quality impact, and the procedures used for their preparation should be documented where possible.

Standard Operating Procedures

SOPs are essential for the planning and standardization of various procedures conducted by operational staff and maintenance personnel that need to be completed before, during, and after pilot plant batches (2). Typical categories include SOPs for equipment operation, facility and equipment cleaning, sampling, sterilization/sanitization, maintenance, and documentation procedures for tasks such as product changeover, change control, and batch sheets (Table 7). When referencing SOPs as part of the batch record, working versions of SOPs can be helpful to track progress in the field. An SOP on the requirements for writing, issuing, and inactivating an SOP is also useful. SOPs focus operation, guide operations staff, document the order and scope of activities, standardize approaches, define regulatory needs and constraints, and increase the speed of new personnel training (2). They should be written by a person familiar with the facility or equipment operation that is the subject of the SOP, reviewed by another person who might be asked to follow the SOP, and approved by a quality group. Each SOP should have an effective date of issue, be available to those who need it, and be archived when a future revision is created.

The need for structure and consistency within an SOP must be balanced by the need for flexibility in a pilot plant when unexpected process requirements arise. Procedures must be defined for what to do when an SOP is altered intentionally to accommodate a new process or a surprise development in an existing process. Consideration to SOPs should be given during the equipment design phase so that tasks can be performed in a logical clockwise or counterclockwise fashion (88). SOPs should be clear so that the expected outcome is assured. Specific examples of details often omitted include statements regarding settings for pressure switches and acceptable calibration error tolerances, insertion diagrams, part numbers, and manual ref-

Table 6. Types of Testing (Sampling and Analysis) Possibly Required by On-Site or Off-Site Support Laboratories for a Bioprocessing Pilot Plant

Facility and Utility monitoring	Sterilization cycle validation	Cleaning cycle validation	Process monitoring
Total organic carbon	Indicator spore strip incubation	Total organic carbon (swab and rinse water)	Spectrophotometer
pH	Indicator water spore suspension incubation	pH	pH meter
Conductivity	Indicator media spore suspension incubation	Conductivity	HPLC for organic acids, amino acids, sugars
Endotoxin (LAL)	Sterility	Endotoxin (LAL)	HPLC for product/impurity analysis
Bioburden and coliforms	Culture purity (bacterial and fungal)	Bioburden (swab and rinse water)	LC-mass spectrometry
Airborne viable particles	Filter integrity testing	Ultraviolet light absorbance	Protein gel analysis
Airborne total particles	Microbial identification	Visible light absorbance	Osmometer
Surface, viable particles	Gram stains	Filtered solids	Microscope
Compressed gas, viable particles		Dissolved solids	Coulter counter
Compressed gas, nonviable particles			Conductivity
Compressed gas, identity			Metabolite analyzer
Noncondensable gases in steam condensate			Plate readers
			Blood gas analyzer
			Laboratory-scale control/ troubleshooting experiments

Table 7. Example Types of Procedures Possibly Required in a Bioprocessing Pilot Plant

Administrative	Process equipment	Laboratory equipment	Maintenance	Operations
Processing abnormality	Sterilization-in-place	Autoclave operation: sterilization and decontamination	Instrument calibration	Gowning
Investigation of contamination	Cleaning-in-place	Autoclave load patterns	Equipment preventative maintenance	Water system flushing/ sampling
Product changeover	Sanitization	Glasswasher, operation	Utility preventative maintenance	Steam system sampling
Writing of an SOP	Vessel setup and operation	Glasswasher, load patterns	HVAC preventative maintenance	Spill containment
Personnel training on equipment/operations	Transfer line/panel operations	Working in biosafety cabinet	Equipment change control	Facility housekeeping and cleaning
Personnel training on assays	Batch harvest (noncontained)	Working in laminar flow hood	Equipment start-up after processing hiatus	Facility start-up after processing hiatus
Personnel training on computers	Batch harvest (contained)	Incubator/shaker operation	Equipment start-up after major mechanical work	Daily utility checkout
Issuing and review of batch sheets	Equipment integrity test	Freezer	Equipment storage during processing hiatus	In-process sampling and analysis
Raw material release and storage	Utility systems operation	Refrigerator/cold room	Computer system change control	Data archiving
Investigation of monitoring excursions	HVAC systems operation	Tubing welder use and cleaning	Computer system failure recovery	Computer system operation
Forklift certification	Media/buffer preparation	Manual washing	Shutdown/interim maintenance documentation	Monitoring-controlled environments
Pest control	Specific equipment SOPs	Usage of scales and checkweights	Equipment isolation for maintenance	Tracking of process/ equipment status
Ongoing validation testing		Calibration of pH meter	Issuing and tracking of work orders	
Ongoing facility monitoring		Facility monitoring assays		
Introduction of new products/processes		In-process monitoring assays		
		Fume hood use		
		Seed preparation		

erences to aid in following the procedure, and reliance solely on valve numbers, not valve purposes, to describe the procedure. While SOPs should be reviewed periodically every few years to determine if they need clarification, care should be taken to minimize the number of similar versions of the same SOP issued to the field. Operational clarification memos, issued to all operational staff and signed off when read, might be used to provide additional SOP clarification without reissuing the SOP during the interim period between SOP reviews. All major SOP changes should be documented, evaluated for their effect on validation, and communicated to staff in a documented manner.

Safety

Because concerns regarding product exposure to personnel are similar to concerns for personnel exposure to product, GMP guidelines overlap with safety regulations in many respects such as training, SOPs, preventative maintenance including calibrations, and validation/change control (2). Safety captions can be required for certain raw materials based on review of material safety data sheet (MSDS) documentation. Broths, as well as isolated compounds, might be submitted for toxicity testing as soon as they are cultivated at a larger scale. Safety is a component of installation qualification as pressure vessel documentation and utility connections are reviewed. Hazard operability (HAZOP) reviews for pressure vessels (e.g., fermentors, autoclaves) and utilities (e.g., clean steam generators) often are required by company policy and summaries included within equipment qualification reports. HAZOP action items need to be addressed promptly and modifications to equipment or procedure made to minimize risk. Equipment design needs to be reviewed for the ease of lockout and removal of hazardous energy sources (e.g., bleed valves for the evacuation of process and utility lines, field-mounted pressure gauges to confirm depressurization) as well as the individual isolation of skids/units for maintenance. In addition, specific SOPs for preparing equipment for maintenance might be required.

Regular safety inspections with documented action item lists communicated to all affected personnel (i.e., operating staff, technicians, engineers, management) can identify and correct nonoptimal working conditions and cluttered processing areas. Exposure of personnel to excessive sound, heat, or dust should also be considered during facility design as well as monitored during facility operation. Although personal protective equipment such as ear plugs, heat-resistant gloves, and respirators is available, when

possible engineering controls such as sound dampeners, insulation, and dust collectors may be better solutions. Safety during validation testing should always be considered, particularly when groups outside of operations are involved in setting up or operating equipment and when sources of hazardous energy are involved. Whether during validation testing or operational use, fittings of any sort should be tightly secured and should not be tightened when equipment is under pressure or hot, specifically during SIP and CIP procedures. Summaries of generally accepted laboratory and pilot plant safety procedures to consider are available (89).

According to ASME code, overpressurization protection using relief devices is required for vessels more than 6 in in diameter. The background for this regulation as well as details of pressure relief valves and rupture disks is available (90). Sanitary rupture disks are most desirable for product contact; once blown, processing must stop until they are replaced. Sometimes a rupture disk is installed, followed by a pop safety valve rated at a slightly higher pressure with a pressure gauge between to indicate rupture of the disk (48). If this arrangement is used, then the cleanliness of the area between the rupture disk and pop safety valve must be demonstrated for the batch to not be adversely impacted if the disk ruptures but the pop safety valve does not release. Removal of the entire rupture disk assembly (not the removal of the disk from the assembly) for cleaning should be checked with company policy but may be acceptable in most cases.

Another often-overlooked matter is that the outlets of safety relief devices (which might be unexpectedly spewing steam, hot water, or broth after relief) should be oriented such that personnel safety is considered for those who may be standing near them. One method is to pipe outlets to outside containment troughs, but it may not be desirable to have a potential connection to the outside. A second alternative is to create a designated area within the pilot plant processing area. While outlets to the floor beside the equipment should be minimized, if they are found to be necessary they should be carefully situated outside the normal path of personnel.

Training

Initial and ongoing training programs need to be developed and documented for each individual associated with the facility, based on the facility needs. A training SOP should be developed, which might include a training manual containing useful items such as key SOPs, facility layouts, equipment diagrams, and policies. Initial training might include items from vendor-supplied training sessions to validated load pattern arrangements. Often this training falls at a peak workload period during the facility start-up and validation when attention can be diverted into seemingly more urgent areas. In other cases, more individuals require training than can reasonably be accommodated in the area surrounding the equipment. When permitted, such training might be recorded for later review by the staff when they have fully assumed responsibility for operation. Another alternative is for those just trained to provide training to others, which may be suitable for certain operations. For best results, training should occur with written documentation available to those being trained for reference.

Ongoing training should be done on a regular basis; once every 1 or 2 months seems most appropriate for an active pilot plant facility. Training should include supervisors, operators, engineers, and maintenance personnel as well as validation and GMP staff. Training might include a process review that highlights critical steps and equipment, SOP reviews, identification of personnel safety and environmental containment issues, and review of PM and ongoing maintenance needs, as well as what operational personnel should look for with respect to proper equipment function (88). Training sessions are one method to communicate recent SOP changes as well as to explain why certain procedures are necessary. These might also be used for periodic SOP reviews to obtain feedback from those using the SOP frequently. Attendance should be required and sessions recorded when possible; those new to the facility should review prior training sessions for the past few years as applicable.

Validation

The recent guideline issued by the FDA (91) makes pilot plants eligible for product licensure should company needs require a product launch from a pilot plant facility. When manufacturing clinical materials, pilot plants are evaluated under the guidelines for investigational new drug products, among other regulations which clearly state that GMPs apply for drug products approved for clinical trials in humans and animals (92). Individual company philosophies vary on the suitability or desirability of their pilot plants for this task because using a pilot facility for manufacturing reduces its availability for the production of clinical material. The level of validation effort required is best considered during the initial facility design. Validation can be done retrospectively, although the collection of the required documentation may be more challenging and modifications necessary for testing may be costly.

The major steps for validation ensure that installed equipment and utilities operate in a manner acceptable for the process to be run in that equipment. Because multiple processes, many of which are not necessarily identified at the time of validation, may be conducted in a pilot plant, operational ranges need to be set to accommodate a wide range of reasonably expected processes. For example, an incubator might be validated for temperatures between 25 and 37 °C to accommodate common bacterial, yeast, and fungal cultures, but not necessarily at 45 °C to accommodate thermophiles. The selection of worst-case scenarios can be difficult for a pilot plant if the associated worst-case conditions are unduly burdensome for normal operation. Specifically, the cleaning procedures required after a 3-week fungal production cultivation are significantly more complex than those required after a 2-day fungal seed cultivation of the same culture. Similarly, the sterilization cycle hold time for a concentrated sugar solution is substantially longer than that required for a heat-sensitive waterlike growth medium. Approaches to resolving these multiproduct validation issues can be complicated by desires to follow manufacturing validation guidelines, which most likely were established based on a single product.

Often validation, qualification, verification, commissioning, and start-up are used with specific definitions in mind for individual facilities and organizations. Generally, validation implies the highest rigor of direct reproducible testing of a specific procedure. Qualification encompasses a wider range of documentation collection and testing of capabilities. Verification might imply a single test against an identified standard. Commissioning can refer to documented troubleshooting of newly installed equipment, whereas start-up might refer to initial equipment checkouts directly after installation. The major validation phases are divided to focus on qualification followed by validation. Installation qualification (IQ) focuses of the verification of proper installation, appropriate utility connections, and adherence to manufacturer and purchase order specifications (93). Operational qualification (OQ) includes testing of equipment function and an acceptance criteria for performance (93). Performance qualification (PQ) centers on process-specific testing for SIP, CIP, and autoclave sterilizing and decontamination load patterns. For computers, a system life cycle methodology incorporating specifications, program design, coding, testing, start-up, operation, and maintenance has been adopted (93).

Process validation centers on the reproducibility of the process in the manufacturing area. Parameters influencing this reproducibility might be best studied in the pilot plant to obtain acceptable operating ranges for those processing parameters, such as cultivation temperature, pH, and dissolved oxygen, found to influence product quality. The set of criteria for proceeding to the next processing step, specifically volumetric or specific productivity, yield, and purity, must be validated in a documented fashion. The critical processing steps important to process quality should be identified and validated (93). Other noncritical process steps may be studied for their impact on manufacturing productivity. Process validation may require multiple identical pieces of equipment, such as fermentors, at the laboratory and process scale to define acceptable processing ranges in a parallel rather than sequential manner.

Batch and Facility Records

Documentation associated with a new facility can be extensive initially and can increase substantially during the time that the facility operates. While centralizing all documentation in a single area can be attractive, duplicate copies of some items often are needed in other locations as well as for archival backup purposes. For example, equipment manuals and facility drawings may be needed near the actual location of the equipment, in the maintenance area, and in the centralized documentation area. Validation documentation, consisting of IQ, OQ, PQ, and load pattern and SIP/CIP reports, is generated both during the initial validation as well as during annual retesting and ongoing environmental monitoring programs. Storage of change control documentation might be accomplished through notebooks and file folders for individual pieces of equipment or by individual suites. SOPs might be archived in a centralized location but also posted near equipment for ready reference. Access and sign-out procedures for the control of documentation need to be developed.

A robust system for batch records needs to be created, based on individual batch sheets for processing steps or for individual pieces of equipment or some appropriate combination of the two approaches. Issued batch sheets should be tracked by a unique sequential number with the product, processing step, and/or equipment number clearly identified. There is a need to track the use of equipment by product and batch, particularly for multipurpose facilities. While this might be done through individual equipment use logs, it is also necessary to include such tracking within the batch record itself.

Newly authored or completed batch sheets should be reviewed by the operations area and may be required to be approved by a quality group before execution. Batch sheets should have clear written instructions as well as a signature, date, and time, as required, for each step. Handwritten instructions, likely to be added during the processing of pilot-scale batches, may need to be reviewed by representatives from operation or quality groups. Brief justifications for alterations in batch sheet instructions also should be considered. An written explanation documenting that the material from the current step is acceptable for continued processing in a subsequent step is recommended. Care should be taken to use common templates wherever possible to simplify successive batch sheet differences and minimize the review effort. Executed batch sheets should be reviewed for completeness by the operations area, by those in charge of the batch, and by a quality group as required. A tracking system should be instituted to monitor the review of completed batch sheets as well as to ensure that all issued batch numbers are accounted for in the batch record filing cabinets. Photocopying, microfilming, or scanning of completed batch sheets serves to provide a backup in case of loss or damage. Paperless batch records, as well as electronic signatures, have also been considered to minimize documentation volume, and guidelines for implementation and validation have been published (94).

OUTLINE

INTRODUCTION

Plasmids are extrachromosomal replicons found in Gram-negative and Gram-positive bacteria as well as in some lower eukaryote organisms. They are present in bacterial cells replicating at a specific number of copies per cell. Their size varies from a few to several hundred kilobase pairs, and bacterial cells can harbor more than one plasmid species (1).

The term *plasmid* originally was used by Lederberg to describe all extrachromosomal hereditary determinants. Currently, the term is restricted to the autonomously replicating extrachromosomal DNA of bacteria. Although plasmids replicate autonomously, they generally rely on some host-encoded factors for their replication. Although not essential for the survival of bacteria, plasmids may encode a wide variety of genetic determinants that permit their bacterial hosts to survive better in an adverse environment or to compete better with other microorganisms occupying the same ecological niche. Plasmids are found in a wide variety of microorganisms, and it is as difficult to generalize about plasmids as it is to generalize about the microorganisms that harbor them. Plasmid DNA is mostly isolated as covalently closed, circular double-stranded DNA molecules, although recently linear plasmids have been described in certain bacterial species (2). Furthermore, single-stranded DNA plasmids were identified as intermediates during the process of replication in certain Gram-positive bacteria (3). Plasmids also include the replicative forms of filamentous coliphages and the prophage state of phages such as P1 (4).

The medical importance of plasmids that encode for antibiotic resistance (R plasmids) and those that contribute directly to microbial pathogenicity, such as for instance iron transport in several pathogens or the presence of adhesions, invasins, or antiphagocytic proteins, is well documented, as is the role played by plasmids in bacteria of importance in agriculture and industry (5–8). Some plasmid genes encoding antibiotic resistances and other traits are frequently located in transposable elements or integrons (9–11). This produces great variation and flexibility in the constitution of plasmids. These extrachromosomal elements are of equal importance, however, for the study of the structure and function of DNA. Plasmids have taken on paramount importance in recombinant DNA technology (12). In this section we describe the mechanisms of the control of plasmid DNA replication and examine the replication of plasmids ColE1 and R6K, found in Gram-negative organisms, and pT181, found in Gram-positive bacteria. In addition, we also discuss linear plasmids. For the replication mechanisms of other plasmids we refer the reader to other reviews (13–23).

ColE1-TYPE PLASMIDS

The ColE1-type family encompasses both a large number of naturally occurring plasmids and many of the most commonly used cloning vehicles (16,18,24–30). The mechanism controlling initiation of replication of these plasmids is among the best understood, perhaps reflecting the importance of this family of plasmids in recombinant DNA applications (11,16–18,31–36).

Replication of plasmids containing the ColE1 origin is initiated at a unique startsite *(ori)* (37,38) (Fig. 1). Unlike in other plasmid families, initiation of replication of ColE1 is not mediated by a plasmid-encoded protein; instead ColE1 requires the host DNA polymerase I (Pol I) (39). In addition, initiation of replication of ColE1 requires the presence of a host-encoded RNA polymerase and ribonuclease H (RNase H) (39–41). Replication of the plasmid is initiated by the synthesis of an RNA molecule by the host RNA polymerase 555 bases upstream of *ori* (Fig. 1, panel a). This RNA species, called RNA II, extends about 700 nucleotides from its initiation (Fig. 1, panels b and c) (40,42). The 3′ of this RNA molecule subsequently forms a duplex with the DNA of the plasmid at a region close to the origin of replication, which is located at nucleotide 555 of RNA II (Fig. 1, panel c) (40). The formation of the duplex structure (known as coupling) begins following the synthesis of a portion of the RNA II molecule. The coupling event is strongly dependent on the formation of a specific secondary structure at the 5′ end of the RNA II molecule that results in an interaction between the RNA portion on the *ori* and an upstream region of this molecule with the template DNA (Fig. 1, panel c) (43–46). The appropriate conformation of RNA II necessary to form the hybrid with DNA is shown in Figure 2 (46,47). The duplex RNA II–DNA structure acts as a substrate for the subsequent action of RNase H, which cuts the RNA at the replication origin, leaving a 3′-hydroxyl group that serves as the primer for DNA synthesis catalyzed by Pol I (Fig. 1, panels c and d) (40). It has been shown that certain point mutations in RNA II prevent RNA II from adopting the right conformation, which affects hybridization with the template DNA (44,45,47). Once Pol I begins the addition of deoxynucleotides, the remaining RNA hybridized to the DNA strand is digested by RNase H at other sites on the molecule and by the 5′-3′ exonuclease activity of Pol I. RNase H also functions to remove the RNA primer from the growing DNA strand (Fig. 1, panel d) (48). Replication of ColE1 then proceeds unidirectionally with the initiation of the lagging strand synthesis at specific ColE1 sites.

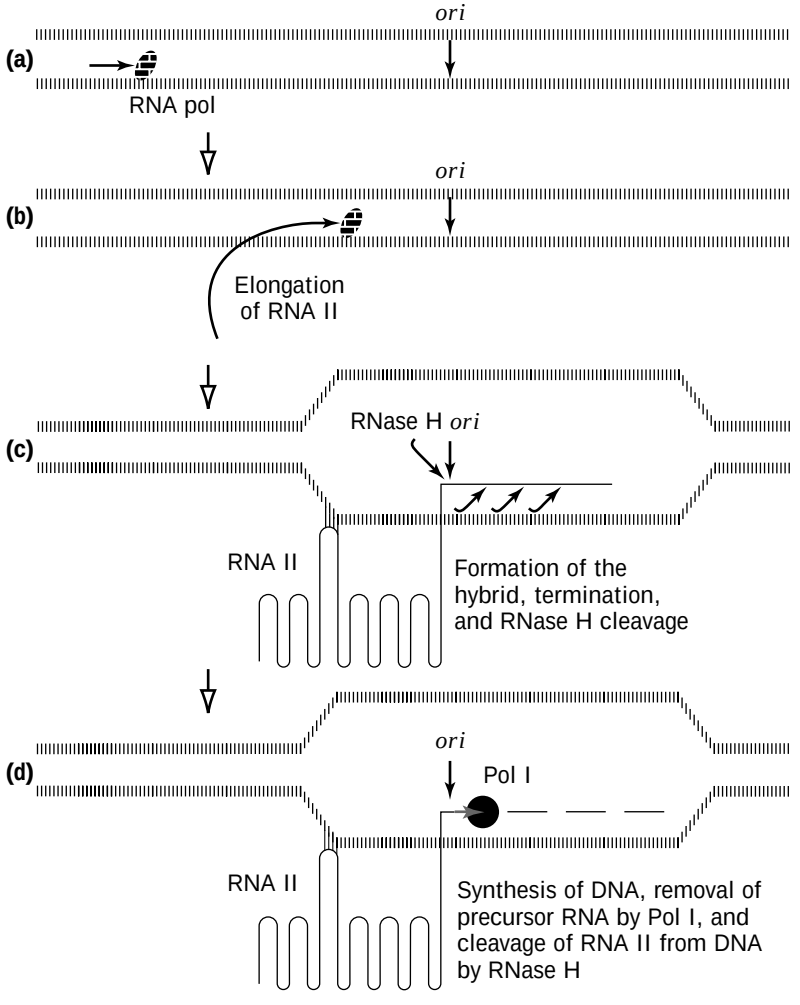

Figure 1. Mechanism of initiation of ColE1 replication in wild-type *E. coli*. The horizontal black arrow in (**a**) indicates the transcription start site (555 nucleotides upstream of *ori*) of RNA II. The origin of replication is indicated by a vertical arrow. ↖, indicates sites of action of RNase H; ||||||, DNA; ■, RNA; ⇶, RNA polymerase I. See the text for details.

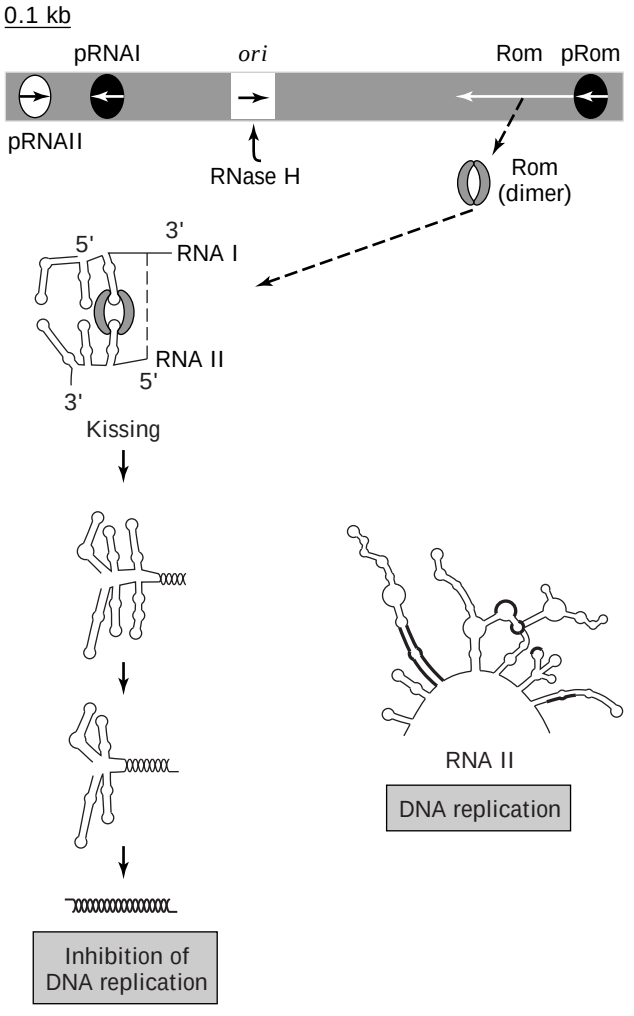

Figure 2. Proposed mechanism of the succession of events involved in the regulation of the initiation of replication of ColE1 by RNA I and Rom. The upper portion shows a genetic map of the origin of replication of ColE1. |||||| represents ColE1 DNA, with the promoters indicated by arrows inside circles. The open arrow indicates the *rom* gene. In the left panel, a schematic of the mechanism of RNA I and RNA II interaction that leads to the inhibition of DNA synthesis is shown. The first interaction between RNA I and RNA II (kissing) is reversible and stabilized by the Rom protein. The dimeric form of Rom is shown both below its gene and in the interaction with RNA I and RNA II. The right panel of the figure indicates the secondary structure that leads to DNA replication. For this to occur, an RNA II molecule that is not coupled with RNA I binds to DNA and acts as a primer after RNase H digestion. The structures reported by Fitzwater et al. as well as Masukata and Tomizawa are almost identical (46,47). A more detailed scheme of the possible interactions between the RNA and Rom species has been reported elsewhere (18). *Source*: Adapted from Ref. 18.

It has been further shown that replication of plasmids containing the ColE1 origin of replication can proceed using two alternative modes of replication that allow for replication in the absence of either RNase H alone or RNase H and Pol I (49–51) (Fig. 3). These two mechanisms appear to not be utilized in wild-type cells, however, and probably represent adaptations to specific host mutations (49,51–53). One of these mechanisms is independent of the presence of Pol I and involves the elongation of RNA II coupled to the template DNA. The lack of RNase H allows the formation of a single-stranded DNA region that can extend to a length that is adequate for assembly of a replisome and initiation of synthesis on the opposite DNA strand (lagging strand) (Fig. 3, panel a) (18,50).

Another initiation mechanism has been demonstrated in RNase H–deficient mutants that is dependent of Pol I. In this case, the extended RNA II species can be recognized by Pol I and used as a primer (Fig. 3, panel b) (49). However, this mechanism of initiation has proved to be inefficient in in vitro experiments (40). Regardless of the replication mode, however, RNA II must be produced in the correct structural configuration to act as the primer for DNA replication (49,51,54).

Control of initiation of replication of ColE1 is mediated by the interaction of RNA II with a 108-nucleotide antisense RNA transcript, called RNA I, that is encoded in a region that overlaps the coding region for RNA II (Fig. 2) (40,55). RNA I binds to nascent RNA II by complementary base pairing, triggering a conformational change in RNA II that prevents coupling with DNA, thereby inhibiting replication initiation (42,44,55–57). Within the secondary structures of both RNA species there are several stem-loops (Fig. 2). Interaction between both RNA species starts at complementary loops in a reversible process known as "kissing," which results in the generation of an unstable initial complex (Fig. 2) (58–62). After this initial contact takes place, an irreversible process leads to the formation of an RNA duplex between RNA I and RNA II (Fig. 2) (56,60,62,63). RNA I achieves its inhibitory effect only if it is present during a short, specific interval in the synthesis of RNA II (56,64). This situation occurs most frequently because RNA I transcription occurs as much as five times more often than transcription of RNA II. This results in the formation of a productive primer only in about 1 out of every 20 RNA II molecules that are started (65). The available amount of RNA I in the cell is influenced by polyadenylation (66,67) and the bacterial RNase E, which cleaves the 5′ end of RNA I, rendering it inactive (68).

A second factor involved in the control of initiation of replication of ColE1 is the plasmid-encoded 63–amino acid protein Rom (RNA one modulator), also known as Rop (Repressor of primer) (Fig. 2) (56,60,62,69,70). The gene encoding Rom is located downstream of *ori* (Fig. 2). In the early stages of plasmid replication, Rom binds to the stem-loop portions of the unstable initial complex (58,59), reducing the dissociation constant of the complex, thus creating a pathway for stable binding of RNA I and RNA II (Fig. 2) (60,71). As a consequence, ColE1 deletion derivatives that lack *rom* present a higher copy number than plasmids that have the complete ColE1 replication region (62,72). The presence of Rom, however, is not needed for viability of the plasmid, and in some RNA-regulated replicons is not present (16).

Incompatibility is the failure of two plasmids to be stably inherited in the same cell line. This phenomenon is a consequence of sharing elements of plasmid inheritance functions such as replication or partition (1,17,73). RNA I

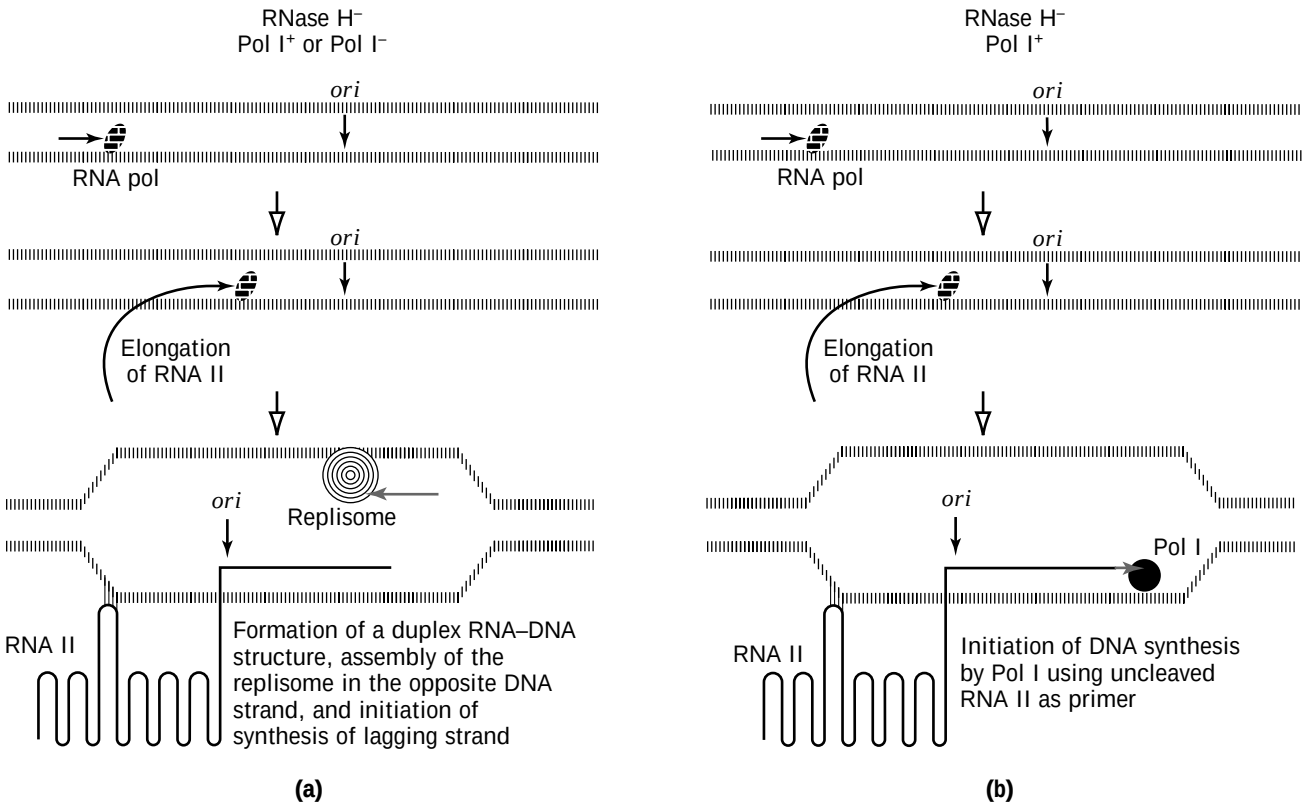

Figure 3. Alternative mechanisms of initiation of replication of ColE1 in RNase H–deficient mutants. (**a**) Proposed mechanism of initiation in RNase H–deficient *(rnh)* and Pol I positive (*polA*$^+$) or negative (*polA*) mutants (52). is the main incompatibility determinant in ColE1-type plasmids. Two plasmids that depend on the same RNA I species for regulation of initiation of replication can not coexist in the same cell (1,17,73). It has been shown that even single nucleotide changes can have profound effects in the incompatibility properties of ColE1-type plasmids (55,57).

THE R6K PLASMID

R6K is a naturally occurring conjugative plasmid that encodes resistance to the antibiotics ampicillin and streptomycin (74). This plasmid is an example of an extrachromosomal element of intermediate size and copy number because it is about 38 kb in size and has a copy number of 13 to 40 per cell (75). These features, together with a unique mode of replication, make R6K an attractive system to study the genetic and molecular mechanisms involved in plasmid DNA replication. In addition, this plasmid and its replication components were among the first used to generate gene fusions, transcription enhancement, protein tagging, and site-specific proteolysis (76–79); it is currently utilized for high expression and rapid isolation by affinity chromatography of a large variety of proteins. Furthermore, R6K derivatives were instrumental in designing a series of suicide vectors successfully used to generate mutants by allelic exchange or transposition mutagenesis in Gram-positive bacteria (80,81).

Plasmid R6K is a member of a growing group of replicons encoding an initiator protein that binds to nucleotide sequence repeats, called iterons, located within *ori*. This group of iteron replicons includes the *Escherichia coli oriC* (82) and the plasmids F (83), pSC101 (84), P1 (85), PMJ101 (86), Rts1 (87), the REPI replicon of pColV-K30 (88), and the RK2- and RP4-related plasmids (89). R6K has three origins of replication, named *ori*α, *ori*β, and *ori*γ (90,91), all clustered within a 4-kb DNA fragment (Fig. 4). In addition, the *pir* and *bis* genes encoding the π and Bis replication proteins, respectively, were found within this replication region. Near this region is located the replication termination site containing the τ sequence that binds the host-encoded ter protein and arrests the movement of the replication fork (90,92,93). The main active origins in vivo are α and β, while *ori*γ tends to remain inactive (90,91) due to the synthesis of a silencer RNA encoded immediately downstream from the *ori*γ sequence (94). The silencing activity of this RNA was explained by the formation of a silencer RNA-activator RNA hybrid, driven to completion of the R6K-encoded replication protein, that leads to the in-

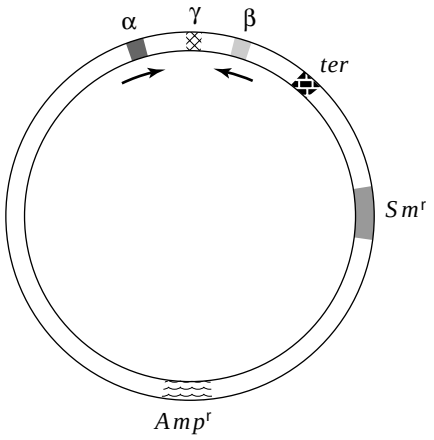

Figure 4. Diagram of R6K showing the 4-kb replication region containing the α-, β-, and γ-origins. The location of the termination site (*ter*) and the genes encoding resistance to streptomycin *(Sm)* and ampicillin *(Amp)* are also indicated. The arrows mark the in vivo direction of the initial replication from the α- and β-origins.

activation of *ori*γ (95,96). However, *ori*γ can replicate autonomously when the other two origins are deleted and the *pir* gene is provided in *cis* or in *trans* (97–101). Thus, *ori*γ has served as the simplest model system derived from R6K to study the replication of an iteron-containing DNA molecule.

The γ origin is the major initiator binding site and is required in cis for initiation of plasmid replication from the other two sites (102–104). Therefore, the γ origin behaves as a prokaryotic enhancer-type element in the sense that DNA–protein interactions at this site induce significant changes in DNA structure that facilitate initiation of DNA replication from distantly located origins (105). Figure 5a shows a diagram of the complete *ori*γ replication region. The molecular organization of this origin is similar to other plasmid origins, although it contains two functionally distinct segments (104,106). The 277-bp core segment, common to all three origins, is essential for replication, and consists of three distinct regions: (*1*) the AT-rich region, bound by π and the integration host factor (IHF) protein, (*2*) seven 22-bp repeats bound by π, and (*3*) a multiprotein-binding region interacting with DnaA, IHF, and RNA polymerase. Immediately to the left of the core lies the 106-bp origin enhancer, which includes a DnaA box and a small segment containing the *stb* locus (107). Even though the enhancer is not absolutely required for replication at low level of wild-type π-protein, it was found that the enhancer region is required for stable maintenance of γ-origin-containing plasmids. Although the *stb* locus has some similarities with the *par* locus of pSC101, the partition systems of these two plasmids differ from each other in several aspects (107). It has been proposed recently by Wu et al. (107) that a host-encoded protein may be binding to the *stb* repeats. The finding that R6K derivatives carrying the intact three origins can bind in vitro to both inner and outer membrane fractions of *E. coli* (108) appears to support this hypothesis. An alternative explanation is that *stb* mediates plasmid partition by altering the structure of γ-origin-containing plasmids (107). The host-encoded protein Fis also binds to 10 sites in the γ-origin that overlap all the previously identified binding sites for the R6K-encoded π-protein and the host-encoded DNA binding proteins DnaA, IHF, and RNA polymerase (109). However, it appears that the Fis protein is required for plasmid replication only when π-copy-up variants and the penicillin-resistant marker are simultaneously used, suggesting that plasmid sequences such as those encoding antibiotic resistance play a role in plasmid DNA replication.

The analysis of the functional α-replicon revealed that it is composed of two elements that must be present in *cis* and oriented as in the intact R6K: (*1*) a 580-bp fragment containing the α-origin, and (*2*) the 277-bp core segment located within the γ-origin (110) (Fig. 5b). These two elements are separated by approximately 3 kbp, which are not required for the α-origin activity. The 580-bp fragment contains a long 98-bp palindrome, and it was suggested that this sequence serves as the recognition signal for initiation of DNA replication in the α-origin. DNA homology analysis also revealed the presence of a 23-bp sequence that resembles the seven 22-bp iterons found in the core segment (110) and plays a role in the π-protein-mediated looping between the γ- and α-sequences (105). In addition, this fragment contains a DnaG binding site that can serve as DnaB loading site by DnaB–DnaG interaction (111).

The minimal β-replicon was defined as a 2-kbp fragment that encompasses the following elements: (*1*) the γ-core region, (*2*) the *pir* gene encoding the π-initiator protein, (*3*) the *bis* gene encoding the 17.2-kDa Bis protein, and (*4*) the β-origin (102,112–114) (Fig. 5c). The Bis protein is required only by the β-origin, and its synthesis is coupled in cis to the expression of π-protein from an unaltered *pir* gene (113). The β-origin also contains a half 22-bp iteron and a 98-bp palindrome that has 96% homology with the α-origin hairpin (110). The presence of these pallindromic sequences at the *ori*α and *ori*β regions was previously assessed by electron microscopy. The half iteron and the long palindromic sequence are required for the π-mediated looping between the γ- and β-sequences (105) and the initiation of DNA replication at the *ori*β, respectively.

The π-initiator protein is essential for replication from each R6K origin and, although it can be provided in cis or trans to regulate the activity of the γ- and α-origins, it is required in cis for activation of the β-origin (97,102, 110,114,115). This protein is a homodimer with a 36-kDa molecular weight for the monomeric form, which is lysine rich and weakly basic (98). In its native dimeric form (116), or as a hybrid with β-galactosidase (78,117) or collagen (77), it has been shown to bind to the seven iterons in the γ-origin as well as to an eighth iteron and a smaller inverted pair of repeats located in the operator-promoter region of the *pir* gene (78,116–118). In addition, this initiator protein interacts with the iterons located in the α- and β-iterons; however, these contacts are weak and require the enhancing effect of π already bound to the seven γ-iterons (105,119).

The π-protein has both positive and negative roles in the replication of R6K (120). The positive role of π is displayed by its ability to enhance replication of *ori*α and *ori*β. This activity is mediated by the promotion of conforma-

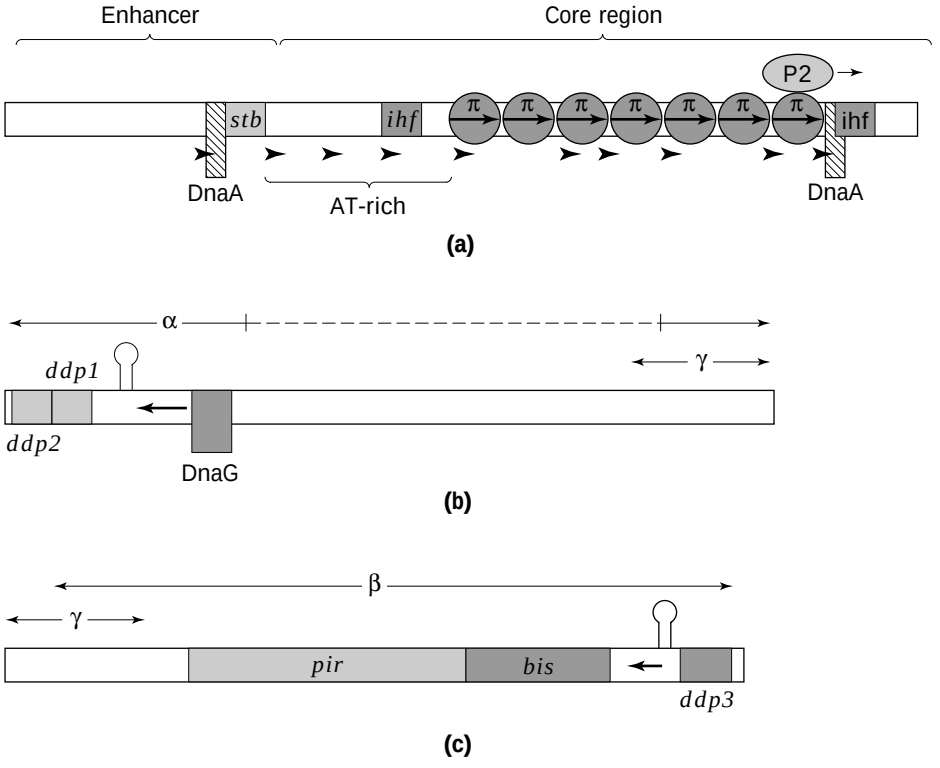

Figure 5. Diagram of the three R6K origins of DNA replication. (**A**) Components of the enhancer and core regions of the γ-origin. The long rectangle represents the DNA region containing binding sites for the host-encoded proteins DnaA (tall rectangles), IHF (short rectangles), and RNA polymerase (oval). P2 and the open arrow represent the promoter site and the direction of transcription of the *pir* gene, respectively. The thick arrows represent the seven iterons that bind the π-replication protein (circles). *stb* represents the locus involved in plasmid maintenance. The 10 arrowheads represent the location of the Fis binding sites. (**B**) Components of the active α-origin. The double-headed arrows indicate the DNA fragment containing the α-origin and the γ-core region required in cis for active replication. The dashed line represents the intervening sequences not involved in DNA replication. The hairpin marks the location of the long inverted repeat located in the α-origin, followed by the genes encoding the DDP1 and DDP2 proteins (small rectangles). The thick arrow and the large rectangle indicate the position of an iteron and a DnaG binding site, respectively. (**C**) Components of the active β-origin. The double-headed arrows indicate the DNA fragment containing the γ-core region and β-origin required in cis for active replication. The β-origin includes the *pir* and *bis* genes (long rectangles), a half iteron (half thick arrow), the *ori*β long inverted repeat (hairpin), and the gene encoding the DDP3 protein (short rectangle).

tional changes, such as DNA unwinding and bending, in the replication region that cause activation of these two origins by looping out intervening sequences located between the *ori*γ core region and the α- and β-origins (119,121). Site-directed mutagenesis showed that π-protein is necessary but not sufficient for activation of *ori*β and probably *ori*α (105). This observation suggested that the DNA looping process must also be required for the transfer of a multiprotein complex capable of initiating DNA replication. Supporting this hypothesis, it was recently reported that π specifically interacts with the host-encoded helicase DnaB replication protein (111). This result indicates that DnaB is initially recruited by π, already bound to the γ-origin, and then delivered to the two other origins by the DNA looping induced by the R6K-encoded replicator protein.

The π-protein has been shown to possess two negative activities on the replication of R6K. One of them is as an autorepressor at the level of transcription and involves its binding to iteron sequences located within the operator-promoter site of the *pir* gene. These interactions act by either preventing the binding of the RNA polymerase to the promoter or displacing the RNA polymerase from promoter–enzyme complexes (99,118,122). The other negative role of the π-protein is its negative control of R6K replication. Biochemical and genetic experiments showed that increased intracellular levels of initiator protein will either lower the plasmid copy number or completely prevent its replication (120). The copy-up phenotype of some of these mutants correlates with base changes within a 100-bp fragment of the *pir* gene and can be suppressed by the presence of the wild-type initiator protein at concentrations lower than that of the mutant protein (123). This negative regulatory activity of π was explained by molecular models involving either direct π–DNA interactions or association of π with either other π molecules or with host-

encoded proteins (120,124). One of these models, termed *handcuffing*, is based on the observation that π has the ability to associate two DNA molecules containing γ-origin sequences and to enhance the DNA ligase–catalyzed multimerization of a single DNA fragment carrying this R6K origin of replication (124). In addition, it was shown that the negative domain of π is located in the N-terminal region of this protein and that the π-mediated inhibition of R6K replication does not require direct binding to DNA (125). Consequently, the origins located within these DNA–protein complexes are unable to initiate replication, most likely because π-induced DNA structure alterations in the origins or potential π–host protein interactions are prevented. In summary, all these observations suggest that the dual activity of π and the regulation of R6K replication is the result of a competition between positive γ–α and γ–β interactions and the inhibitory aggregation of γ-containing molecules, all mediated by the π-replication protein.

Recently, three novel R6K-encoded proteins, designated DDP1, DDP2, and DDP3, were identified (126). DDP1 and DDP2 are encoded by two tandem genes located at the 5′ end of the long inverted repeat of the α-origin, while the gene encoding DDP3 was mapped at the 3′ end of the β-origin long inverted repeat. These three proteins are required for the distortion of the DNA structure of the two R6K active origins. Although the distortions caused by these proteins are potentially linked to R6K replication, they are not equivalent to those described in other replication regions previously characterized (82). It was also suggested (126) that this distortion system serves to synchronize the initiation of replication and establishes the direction of replication from the α- and β-origins by generating a "locked" preinitiation protein–DNA complex.

PT181-TYPE PLASMIDS

The rolling circle type of replication is most often utilized by a number of small, high-copy-number plasmids from Gram-positive bacteria (13,15,21,127). However, plasmids that replicate using this mechanism have recently been identified in a number of Gram-negative bacteria (128–132).

Gram-positive plasmids that replicate using rolling circle mechanisms are classified into five families based on sequence comparisons and genetic organization of the replication regions (13,16,21,133). All plasmids in these families replicate by an asymmetric rolling circle pathway that resembles that of the single-stranded filamentous bacteriophages (16,21,134). One of the best-understood replication mechanisms is that of the pT181-type family. We describe the replication of pT181 as a paradigm of rolling circle replicating plasmids. A more comprehensive description of replication of plasmids in other families can be found elsewhere (13,15,21,127).

A schematic representation of the pT181 replication region and the mechanism of initiation of replication is shown in Figure 6. This plasmid, derived from *Staphylococcus aureus*, encodes a 38-kDa initiator protein, RepC, that has sequence-specific endonuclease and topoisomerase I–like activities (137). To initiate replication, RepC nicks one of the pT181 DNA strands (leading strand) at a specific site, generating a free 3′-OH end that is used as primer for subsequent DNA synthesis (137). The functional structure of the RepC protein is a homodimer (RepC/RepC) (135,138) that recognizes and binds to a site (Rep binding site) that encompasses an inverted repeat (IR III in Fig. 6b) (136). A domain of six amino acids has been identified in RepC that is important in the recognition and interaction of the Rep binding site (Fig. 6) (139). The binding efficiency of RepC is increased by the presence of *cmp*, a 100-bp cis-acting replication enhancer located about 1 kb from the nicking site (140,141). It has been recently demonstrated that an *S. aureus* protein, CBF1, binds *cmp* and increases distortion of the already bent *cmp* locus (142). Whether this binding is associated with the enhancing activity of *cmp* is still not known. Upon binding of the RepC homodimer to IR III, DNA in this region is induced to bend (143) (Fig. 6b). This is closely followed by a change in structure of RepC, DNA melting, and formation of a cruciform structure at the IR II region (Fig. 6b) (139). The melting step is facilitated by the presence of an AT-rich inverted repeat region (IR I) located upstream of IR II (Fig. 6b) (16). The formation of a cruciform structure may result in an approximation of the nicking site of the leading strand and the active site of RepC. This process involves a tyrosine residue that appears to facilitate the generation of the nick. After the endonuclease attack, the RepC protein remains covalently bound to the 5′ end of the DNA by a phosphotyrosine bond (93), probably remaining attached throughout replication of the leading strand. This is not true for all plasmids replicating through a rolling circle mechanism, however, for it was recently shown that in a derivative of pMV158 the initiator protein does not remain covalently bound to the DNA after nicking (144). After generation of the 3′-OH terminal end by RepC, an initiation complex is formed with the probable participation of DNA polymerase III, the helicase PcrA, and single-strand binding protein (Fig. 6b) (16,145,146).

Following (or during) replication, the initiator protein RepC becomes modified (RepC*) by the addition of a 10- to 12-mer oligodeoxynucleotide identical to the sequence located immediately 3′ to the origin of the leading strand. In addition, the two enzymatic activities of RepC are lost during this time (138,147). Further analysis has demonstrated that the active initiator homodimer RepC/RepC becomes the inactive heterodimer RepC/RepC* after it has been used for replication of pT181 (135).

Replication of the lagging strand starts at a different origin than replication of the leading strand. Fig. 6a shows the location of the lagging strand origin in pT181 (148). This origin, also known as SSO (single-strand origin) or *palA*, comprises about a 160-bp palindromic DNA sequence (16,21). Synthesis of the leading strand generates a displaced single-stranded DNA that allows the origin of replication of the lagging strand to adopt the correct conformation to serve as a priming site. Replication of this strand does not require any protein encoded by the plasmid (149). In addition, some rolling circle replicating plasmids have more than one origin of replication for its lagging strand that is functional in different hosts (16). Taken to-

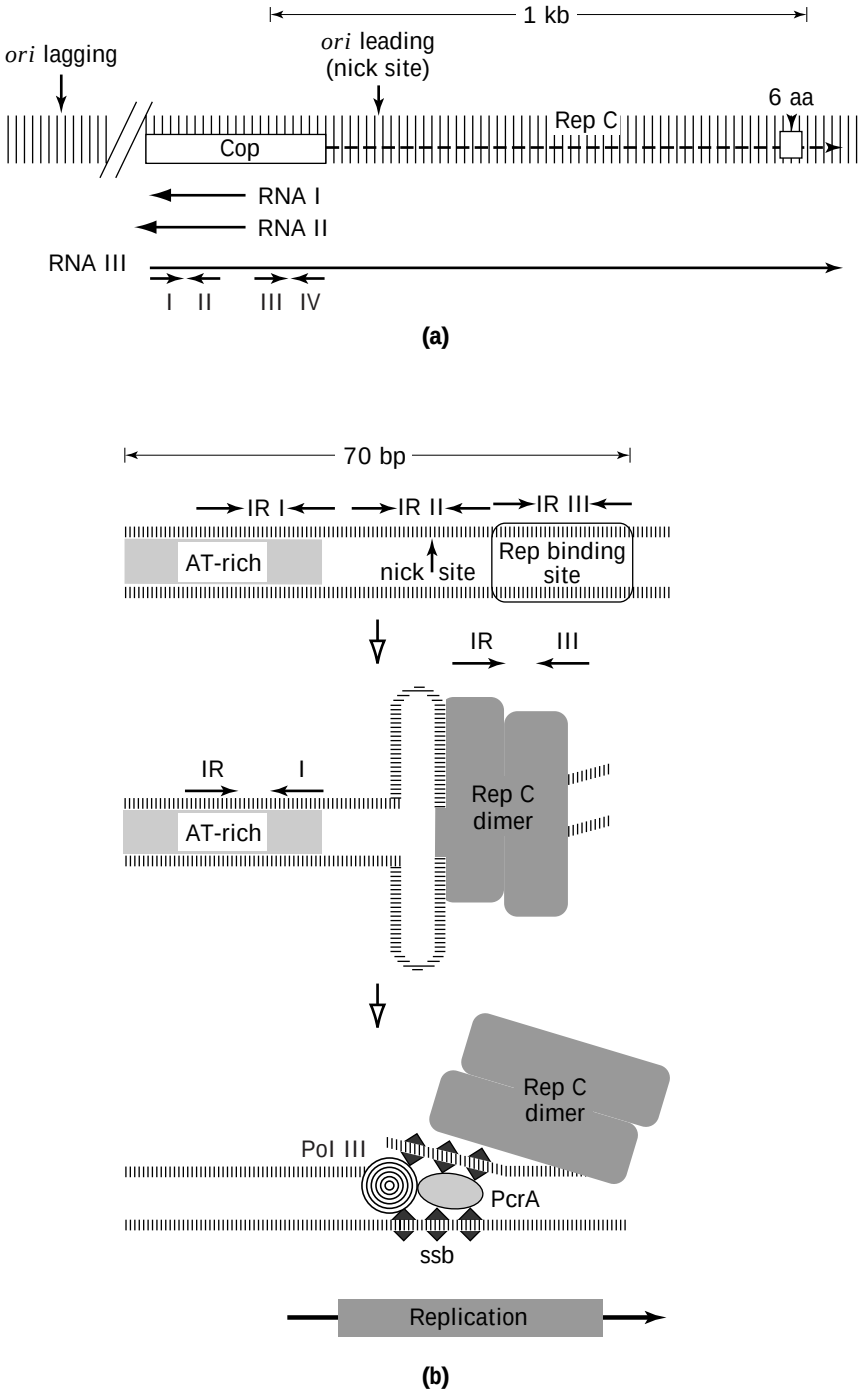

Figure 6. Replication region and model for initiation of replication of the plasmid pT181. (**a**) Diagram of the pT181 replication region. The bar represents pT181 DNA. The two origins of replication (leading and lagging strands) are indicated by different vertical arrows. The broken-line arrow represents the RepC coding region. The six–amino acid region of RepC recognized by *ori* is indicated as a white square. The two diagonal lines indicate that there is a larger distance than shown between the *ori* of the lagging strand and the *ori* of the leading strand. The black arrows represent RNA molecules. The location of the *cop* region is indicated by a box. The small arrows under RNAIII represent the inverted repeats that participate in attenuation. For the sake of clarity, these inverted repeats are not at scale. (**b**) Model for initiation of replication of pT181. The first diagram shows the region encompassing the origin of replication of the leading strand and the three inverted repeats. This region is also referred to as the DSO (double-stranded origin). The RepC binding site located at IR III is boxed. The second diagram shows the formation of the cruciform structure after binding of the RepC homodimer, the bending of the DNA at the binding region, and the change in structure of RepC. The melting process is facilitated by the presence of an AT-rich region that includes IR I. The third diagram shows that after nicking, a replisome is assembled at *ori*, and presumably, DNA polymerase III initiates replication in the presence of the helicase PcrA and single-strand binding protein (ssb). *Source*: Adapted from Refs. 16, 135, and 136.

gether, these facts suggest that lagging strand origins of replication may be important in determining the host range of the plasmid (16).

Termination of synthesis of the leading strand occurs at the nick site by a strand transfer mechanism that is mediated by the replication initiator protein RepC (150). In pT181, once the nick site has been replicated and extended a few nucleotides beyond this site, one of the subunits of the RepC dimer contacts the growing strand. This interaction initiates a strand transfer reaction, resulting in the formation of a single-stranded monomer (old strand), a double-stranded molecule where one of the strands is newly synthesized, and a dimer in which one of the monomers is attached to the oligonucleotide resulting from the extension of replication beyond the nick site (16,21). Although the presence of the nicking site is required, the initiator protein recognition site is not essential for termination (21).

Regulation of initiation of replication of pT181 is achieved through the control of the synthesis of RepC (16,21,151,152). The organization of the pT181 replication regulation region *(cop)* is shown in Fig. 6a. The mRNA

(RNA III) encoding RepC contains a leader sequence typical of genes that are regulated through attenuation (153). This leader sequence has four interacting sequences (I–IV). Sequence I, a nine-nucleotide sequence called *preemptor* can form duplexes with sequences II and III (Fig. 7). In addition, there are two antisense RNA species (RNA I and RNA II) complementary to the leader sequence of RNA III. Analysis of the secondary structure of the leader portion of RNA III in the presence or absence of antisense RNA indicated that upon interaction of the two complementary RNA species, a stem-loop structure between inverted repeats III and IV is formed followed by an AUUUUUU sequence that acts as a transcription termination signal (Fig. 7) (154). On the other hand, if antisense RNA is not present, the interaction between inverted repeats I (the preemptor) and III generates a structure that prevents the formation of the III-IV stem-loop (Fig. 7) (154). Under these conditions, transcription of *repC* takes place. Mutations in the preemptor have been shown to lead to an absolute requirement for RepC in trans (154,155). For example, Figure 7 shows the effect on the secondary structure of RNA III caused by a three-nucleotide replacement mutation in the preemptor. In absence of antisense RNA, the stem-loop structure involving inverted repeats III and IV is formed, no RepC synthesis occurs, leading to a plasmid that has an absolute requirement for RepC in trans (154,155) (Fig. 7).

The main incompatibility elements in pT181-type plasmids are the antisense RNA and the origin of replication of the leading strand (16,154,155). The origin of replication of the leading strand directly binds RepC, titrating the protein, which is present at limiting levels in the cytosol due to the controlling action of the antisense RNAs.

LINEAR PLASMIDS IN BACTERIA

A Unique Plasmid Anatomy

Bacterial genomes have long been considered to contain only circular DNA molecules. However, the development of orthogonal field-pulsed agarose gel electrophoresis in the mid-1980s allowed the discovery of the first linear bacterial chromosome in *Borrelia burgdorferi* (156,157), the causative agent of Lyme disease. Since then, linear replicons have been found in many bacterial genera including *Agrobacterium*, *Streptomyces*, *Thiobacillus*, *Nocardia*, *Rhodococcus*, and even *Escherichia* (158). The first linear plasmid was found in *Streptomyces rochei* in 1979 (159),

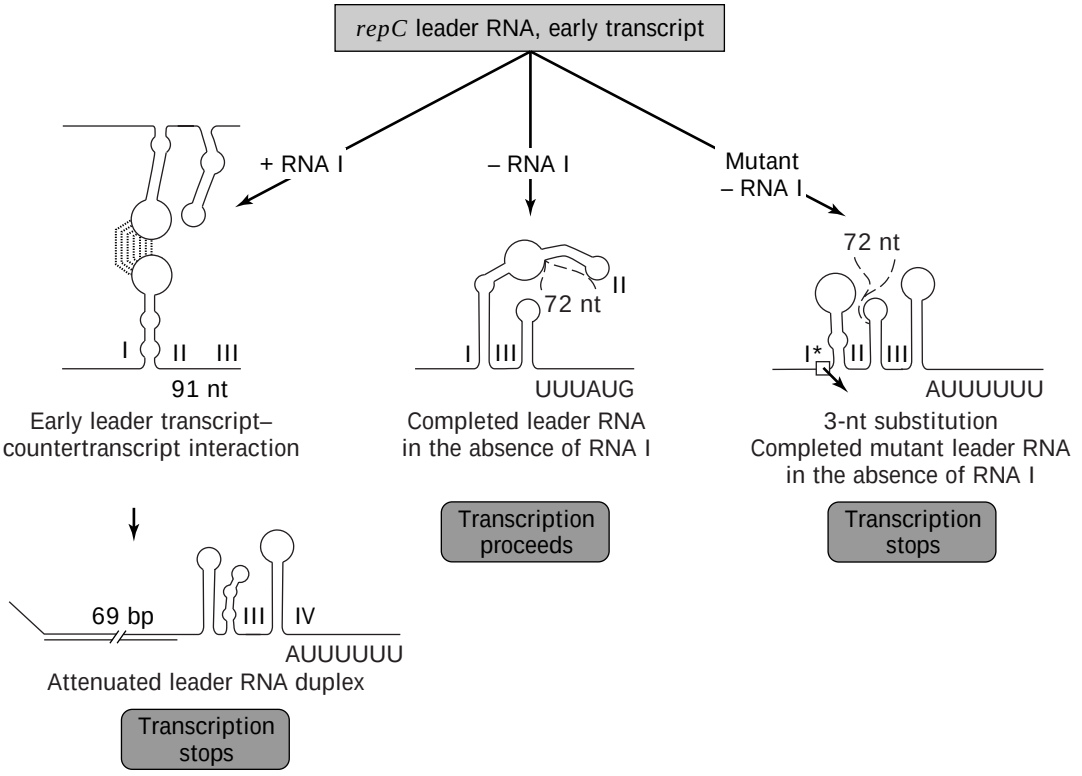

Figure 7. Mechanism of regulation of expression of RepC by antisense RNA. In this model, the early RNA III transcript can interact with antisense RNA (RNA I), allowing the formation of a stem-loop between inverted repeats III and IV that results in a transcription termination signal. In the absence of antisense RNA, the inverted repeat III is sequestered by inverted repeat I, leading to completion of the *repC* mRNA. The three-nucleotide-change mutation in inverted repeat I is also shown. The secondary structure of this mutated RNA III results in formation of the stem loop III–IV even in the absence of antisense RNA, thus leading to a complete dependence of RepC in trans for replication. *Source*: Adapted from Refs. 21 and 154.

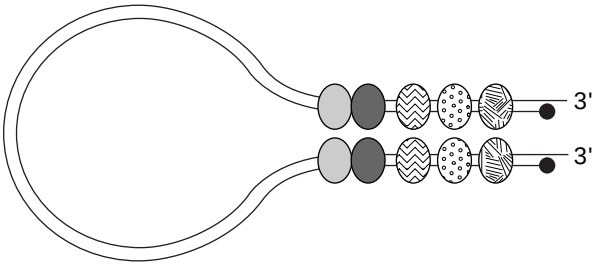
and others have been detected in the Gram-positive bacteria *Rhodococcus fascians* and *Nocardia opaca* as well as in the Gram-negative *Thiobacillus versutus* (158). The *Streptomyces* linear plasmids range in size from nine to several hundred kilobases, and all of them contain terminal inverted repeats of different lengths according to the size of the plasmids where they are present. The linear plasmids in *Borrelia* also show a wide range of sizes, typically ranging from 15 to 200 kb and are distributed widely among the members of this species. The *Borrelia* plasmids are unique among extrachromosonal elements because some of them carry critical genes such the *guaA* and *guaB* biosynthetic genes (160), as well as genes encoding the essential major outer surface Osp or Vmp lipoproteins (161–164). In addition, it was determined that some of these linear plasmids are present stably in low copy number, about the equivalent of one per chromosome, and can be cured by exposing *Borrelia* cultures to the DNA gyrase inhibitor novobiocinin (165). These characteristics suggest that the replication and partition processes of linear plasmids are well controlled during cell division. All the facts, together with the observation that the *Borrelia* chromosome has attributes of a linear DNA molecule, has led to the idea that these linear plasmids might be regarded more properly as minichromosomes (166).

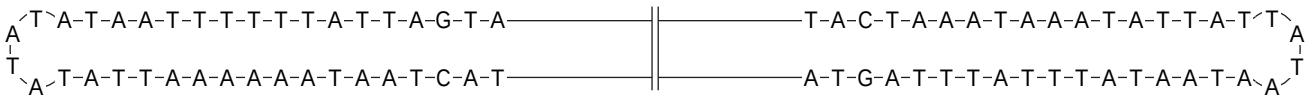
The presence of these linear DNA molecules brings an interesting biological problem associated with the protection of the DNA ends from exonuclease degradation, and the complete replication of these plasmids. These problems are solved in eukaryotes by the addition of telomere repeats by reverse transcription of a short RNA incorporated in the telomerase (167,168). On the other hand, prokaryotes can protect and replicate completely these linear plasmids using two alternative mechanisms.

The ends of linear *Streptomyces* plasmids have telomeric structures also found in adenoviruses and some prokaryotic phages as well as in almost all eukaryotic plasmids. Sequence analysis of pSL2, a linear plasmid present in *S. rochei*, revealed the presence of an inverted terminal repetition of 614 bp and 11 sites of interrupted homology (169,170). These terminal DNA structures, together with specific DNA binding proteins, are thought to be involved in the juxtaposition of the two plasmid termini containing identical or very similar nucleotide sequences. This structure, known as the racket frame–like DNA model and shown in Figure 8a, also includes a terminal protein covalently attached to the 5′ DNA termini, which is required to protect the DNA from degradation and to complete the replication of the 3′ overhanging ends, as described later.

The structure of the 16- and 49-kb linear plasmids of *Borrelia burgdorferi* consists of a double-stranded DNA chain connected at each end by a perfect palindromic AT-rich hairpin loop (Fig. 8b) (2,171). In addition, each end contains a conserved 19-bp inverted repeat sequence, a telomeric structural feature found in all linear plasmids analyzed in *Borrelia* to date (158,162,163). These features have similarities to the telomeres of other linear double-stranded replicons, including among them the genomes of vaccinia and other animal poxviruses (172), the mitochondria of the yeast *Pichia* (173), and the iridovirus, which causes African swine fever (174). The fact that the latter and at least one *Borrelia* species share a common tick vector suggests that the *Borrelia* linear plasmids may have originated by horizontal transfer between kingdoms (2). These telomeric structures indeed play a role in preserving the integrity of these plasmids, and in their replication before cell division.



(a)



(b)

Figure 8. Telomeric structure of linear plasmids. (**a**) Racket frame structure proposed for linear *Streptomyces* plasmids. The ovals represent juxtaposition proteins that recognize specific regions of palindromic symmetry, bringing together the plasmid termini. The black circles represent the terminal protein attached to the 5′ ends, which is required to complete the replication of a 280-nucleotide segment at both plasmid termini. (**b**) Structure and partial nucleotide sequence of the telomeric termini of linear plasmids isolated from *Borrelia*.

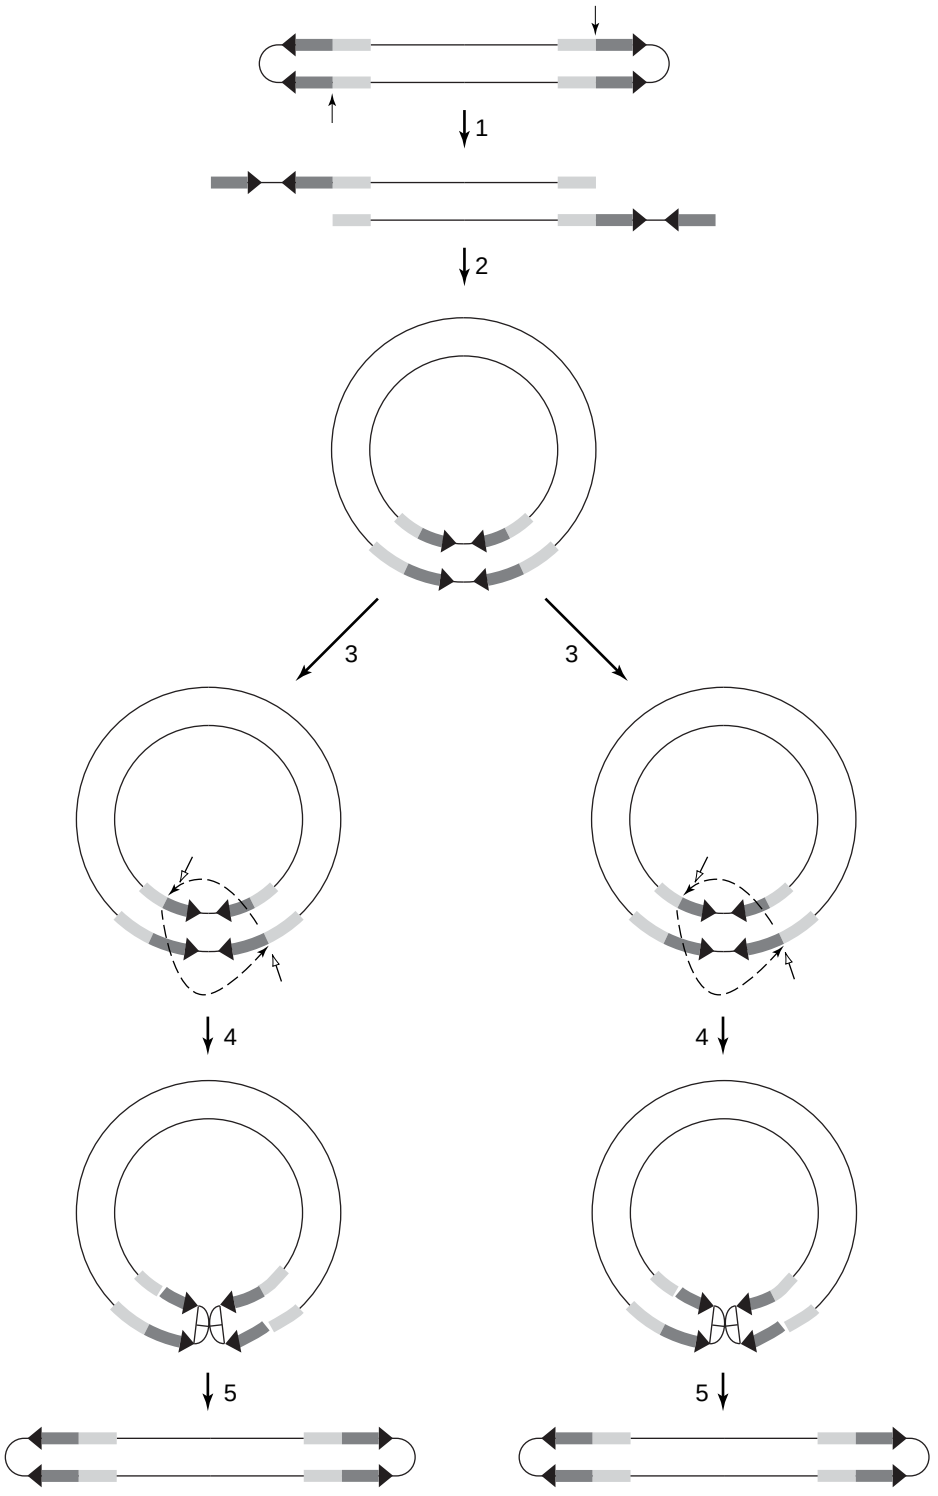


Figure 9. Model depicting the different stages leading to the formation of circular intermediates and replication of linear plasmids in *Borrelia*. According to this model, in step 1 the ends of the plasmid are open by a nick (indicated by the arrows with open arrowheads) within the inverted repeats (represented by the thick arrows) located at the plasmid termini. The open linear plasmid circularizes due to the presence of complementary sequences at its termini (step 2) and replicates as a circular replicon (step 3). A second nick is introduced within the repeated sequences, and the free single-stranded ends pair back (indicated by the dashed arrows) with their complementary copies located in the same monomer and, thus, reconstitute the hairpins at each plasmid end (step 4). After DNA ligation (step 5), two copies of the original linear plasmid are generated. *Source*: Adapted from Ref. 157.

Replication of Linear Plasmids

It was proposed initially that the linear plasmid of *Streptomyces* replicates by a protein-primed replication mechanism (158,175) that has been well characterized for adenovirus, phage ø29, and *Bacillus subtilis* (168). In this mechanism of DNA replication, the telomere is the origin of replication, and it is recognized by specific DNA binding proteins that promote the unwinding of the double helix and serve as the primer for a specific DNA polymerase. However, it was later observed that the *S. clavuligerus* linear plasmid pSCL can replicate as a circular DNA molecule when the telomeres are removed and the ends are ligated (176). This observation was further confirmed by the de-

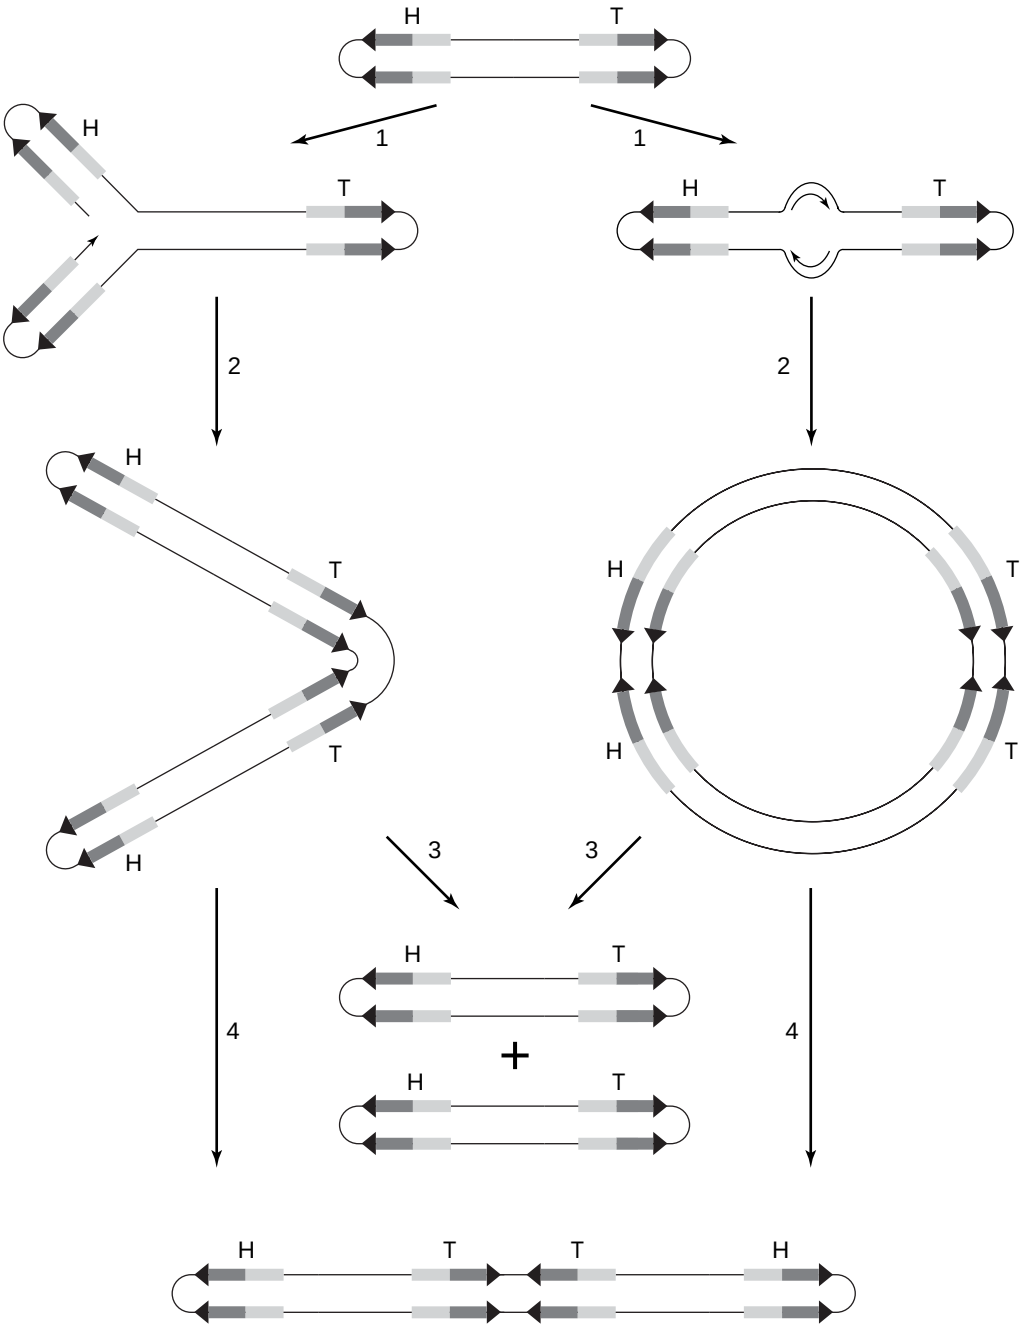

Figure 10. Model showing an alternative replication mechanism and the formation of tail (T)-to-tail dimers of linear plasmids in *Borrelia*. The model depicted in the left half starts with the cleavage of the head (H) telomere and the initiation of DNA replication (step 1). The replication of the entire linear replicon results in a tail-to-tail dimer (step 2) that can result in either two copies of the original monomers (step 3), after resolution of the tail telomeres, or remain as a tail-to-tail dimer due to a failure in the plasmid segregation mechanism (step 4). The model shown in the right half predicts the initiation of DNA replication from an internal origin (step 1) that results in the formation of a circular intermediate (step 2). Segregation of this intermediate by independent DNA cleavage events at each telomere junction leads to the generation of two copies of the original linear replicon (step 3). Conversely, a failure of the cleavage of the tail telomere results in the formation of a tail-to-tail dimer (step 4). *Source*: Adapted from Ref. 178.

tailed analysis of the mechanism of replication of pSLA2, another *Streptomyces* plasmid that contains protein covalently attached to the 5′ end (175). Ligation of pSLA2 deletion derivatives lacking the telomeric termini to a selectable marker resulted in a high-copy-number circular extrachromosomal element. This observation suggested that this linear plasmid must contain an internal site capable of promoting DNA replication. Two-dimensional agarose gel electrophoresis analysis showed that this plasmid is indeed replicated primarily bidirectionally from an internal origin located near the center of the plasmid, toward the ends, rather than by full-length strand displacement initiated at the telomeres. However, pSLA2 still requires a protein-primed strand-displacing mechanism to complete the replication of a 280-nucleotide segment at both plasmid termini. It was suggested (175) that the synthesis of the 5′ terminal segment of the lagging strand of this linear plasmid uses as a template the 3′ overhang of the leading strand and is primed by the protein covalently attached to the 5′ end of the mature plasmid.

The replication mechanisms of linear plasmids in *Borrelia* are poorly understood; however, our knowledge of these novel replicons encoding essential genes has been extended by a series of very recent publications (166,177,178). The replication of some of the *Borrelia* linear plasmids involves circular intermediates. In addition, it was recently reported that the 180-kb plasmid of *Borrelia hermsii* can exist and replicate either as a linear or a monomeric circular element (166). According to these observations, it was proposed that the monomeric circular intermediate is formed by a head-to-tail junction, after a nick introduced in the inverted repeat opens the plasmid termini (Fig. 9). Because the termini are complementary, the plasmid circularizes and can replicate as any other well-characterized circular replicon. This circular intermediate is then resolved into a linear double-stranded DNA structure by a second nick within the terminal inverted repeats. Because the terminal repeats are complementary, a linear molecule should be reconstituted.

More recently, it was found that *B. burgdorferi* sensu lato contains atypical large linear plasmids ranging from 92 to 105 kb (178). These plasmids carry *p27* and *ospAB*, genes that were also detected in other isolates on the 50-kb linear plasmid pAB50. A more detailed analysis of the larger plasmids demonstrated that they are formed by tail-to-tail dimerization of pAB50. The presence of such dimers can explain the unusual plasmid variability observed among different isolates and may provide new information regarding the replication mechanism of these linear replicons. It was postulated (178) that these linear dimers are the result of failed segregation after DNA replication by a mechanism similar to that described for vaccinia viruses. In this model proposed by Marconi et al. (178) and shown in Figure 10, initiation of plasmid replication proceeds from one of the termini, after the head hairpin loop in this particular case is nicked, allowing the formation of tail-to-tail dimer intermediates. Alternatively, these dimers can arise by DNA replication initiated from an origin located within a linear monomer that results in a circular replication intermediate. In the normal replication process, the circular intermediate is resolved into two linear monomers by independent cleavage events at each telomere junction. Cleavage failure at the tail hairpin by a specific DNA cleavage system results in two monomers linked tail to tail (Fig. 10), a possibility that was confirmed experimentally by restriction analysis and Southern blot DNA hybridization experiments (178). However, this same analysis demonstrated that not all *Borrelia* large plasmids were originated via dimer formation, and alternative DNA replication systems that are still uncharacterized must exist.

Some of the proteins involved in the replication of the linear plasmids in *Borrelia* were identified by determining the complete nucleotide sequence of the 16-kb plasmid lp 16.9 isolated from *B. burgdorferi* B31 (177). This study revealed the presence of 15 open reading frames named A to O. The predicted proteins encoded by OrfM and OrfN showed homology to proteins involved in plasmid and cell replication. OrfM is homologous to MinD, a cytoplasmic membrane protein with ATPase activity required for the correct placement of the division site (179,180). OrfM also has homologies with plasmid partition proteins such as ParA or SopA (181,182), and the RepB protein encoded by the pheromone-responsive plasmid pAD1 in *Enterococcus faecalis* and involved in the control of the copy number of this extrachromosomal element (183). The predicted features and the primary sequence of the OrfN hypothetical polypeptide are similar to those of the CopB DNA binding proteins, also known as RepB or RepA2, involved in the control of plasmid copy number in Gram-negative bacteria (184). This sequence analysis also led to the hypothesis that OrfN may interact with the short repeat sequence located within the promoter region of OrfM and, thus, control the expression of the latter (177).

In summary, sequence analysis of *Borrelia* plasmids showed that the few proteins identified are similar to prokaryotic proteins involved in plasmid replication and maintenance in Gram-positive and Gram-negative bacteria. In addition, these results do not support the previous conclusion that the linear plasmids in *Borrelia* are indeed derived from animal viruses. Furthermore, it seems that circular and linear plasmids of this bacterial genus have a common origin and share DNA replication mechanisms.

Cell culture scale-up
Pluronic polyols
Sparging protection

OUTLINE

INTRODUCTION

In recent years, it has become apparent that there is a need for animal cell cultures to produce some products (e.g., complex recombinant DNA proteins) because of the inability of other expression systems (e.g., bacteria) to properly

perform post-translational modifications (e.g., glycosylation and proper folding). Unfortunately, animal cells lack a protective cell wall and thus are subject to damage from sparging and other environmental stresses. In large-scale bioreactors, however, aerating the cultures through direct sparging is the most practical method of supplying oxygen to the culture medium. Therefore, in order to realize the full potential of using animal cells to produce recombinant DNA proteins on an industrial scale, there is a critical need for large-scale sparged bioreactors capable of supporting animal cell growth. Currently, the generally accepted approach to solving this problem is to supplement the medium with a protective agent, such as the commercially available surfactant Pluronic F-68.

PROPERTIES OF PLURONIC POLYOLS

A wide range of Pluronic polyols are available that are capable of protecting animal cells in suspension cultures from the adverse effects of sparging. Of these, Pluronic F-68 is by far the most widely used. Properties of Pluronic polyols that are relevant to the selection of a protective agent are discussed in this section.

Synthesis and Structure

Pluronic polyols, commercially available from the BASF Corporation (Wyandotte, Mich.), are block copolymer nonionic surfactants consisting of a center block of poly(oxypropylene) (hydrophobe) and end blocks of poly(oxyethylene) (hydrophile). They are synthesized by the two-step process shown in Figure 1 (1). In the first step, a poly(oxypropylene) block is synthesized by the addition of propylene oxide to propylene glycol. The poly(oxyethylene) blocks are then added to both ends by reacting the resulting poly(oxypropylene) with ethylene oxide. The oxyalkylation steps are carried out in the presence of an alkaline catalyst (e.g., potassium hydroxide) that is subsequently neutralized and removed from the final product. The properties of the Pluronic polyols are altered by varying the relative sizes of the poly(oxypropylene) and poly(oxyethylene) blocks (note that the sizes of the two poly(oxyethylene) blocks are statistically identical). The properties of a variety of Pluronic polyols are given in Table 1.

Nomenclature

The letters L, P, and F in the Pluronic polyol nomenclature represent liquid, paste, and flake, respectively (Table 1) (1). The first two digits of the three-digit polyol number, or the first digit of a two-digit polyol number, are indicative of the hydrophobe [poly(oxypropylene)] molecular weight, for example, 6, 8, and 12 represent average hydrophobe molecular weights of 1,750, 2,250, and 4,000, respectively. The last digit in the polyol number represents approximately one-tenth the percentage of hydrophile [poly(oxyethylene)] in the molecule. For example, Pluronic F-68 is a flake (i.e., a white powder), has a hydrophobe molecular weight of approximately 1,750, and contains approximately 80% hydrophile.

Impurities

Commercial-grade Pluronic polyols have been demonstrated to contain low molecular weight impurities, including aldehydes, formic acid, and acetic acid (2,3). In addition, peroxide derivatives of the Pluronic polyols can be formed during steam sterilization. The formation of the peroxide derivatives can be prevented by filter sterilizing the Pluronic polyol solutions instead of using steam sterilization. The low molecular weight impurities can be removed from aqueous solutions of Pluronic polyols by silica-gel column absorption (2).

Hydrophilic–Lipophilic Balance

The hydrophilic–lipophilic balance HLB is an empirical measure of the emulsifying capabilities of surfactant mol-

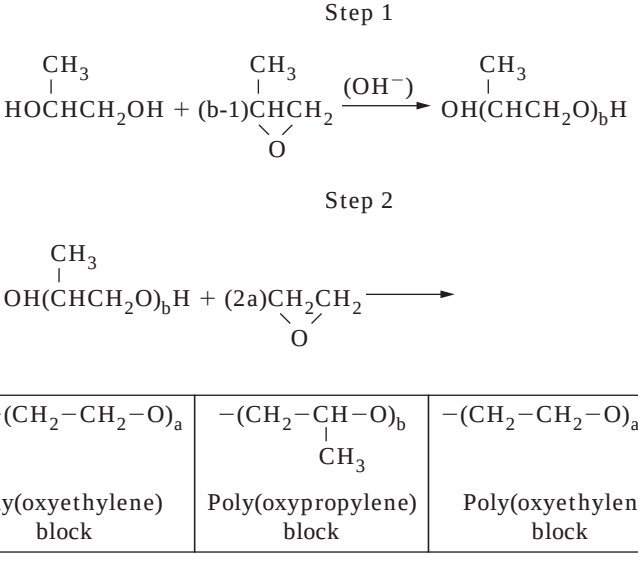

Figure 1. Pluronic polyol synthesis.

Table 1. Pluronic Polyols Tested for Their Effect on *Spodoptera frugiperda* Sf-9 Insect Cell Growth in the Absence and Presence of Sparging

Pluronic polyol	Average MW	wt % hydrophobe	HLB range	Effect on cell growth in the absence of sparging	Protects from sparging?
L-61	2,000	90	1–7	Cell lysis	N/A
L-121	4,400	90	1–7	Cell lysis	N/A
P-103	4,950	70	7–12	Cell lysis	N/A
P-123	5,750	70	7–12	Cell lysis	N/A
P-84	4,200	60	12–18	Cell lysis	N/A
P-104	5,900	60	12–18	Cell lysis	N/A
P-65	1,900	50	12–18	Inhibition	N/A
P-105	6,600	50	12–18	Inhibition	N/A
L-35	1,900	50	18–23	None	Yes
F-127	12,600	30	18–23	None	Yes
F-38	4,700	20	>24	None	Yes
F-68	8,400	20	>24	None	Yes
F-108	14,600	20	>24	None	Yes

ecules (4). Lower values of the HLB are representative of molecules with a higher degree of hydrophobicity. In general, molecules with high HLB values tend to be water soluble, and those with low HLB values tend to be oil soluble. The HLB values given in Table 1 are given in terms of ranges to indicate that the effective HLB of the Pluronic polyols varies with the emulsion system (5). From the results given in Table 1, it is clear that Pluronic polyols with low HLB values are unsuitable for use as protective agents because medium supplemented with 0.2% (w/v) of these Pluronic polyols either lysed *Spodoptera frugiperda* Sf-9 cells or significantly inhibited their growth in the absence of sparging, specifically in 50-mL spinner flasks oxygenation by surface diffusion (6). It was further demonstrated that at higher HLB values that Sf-9 cell growth was not inhibited in the absence of sparging and that protection from the adverse effects of sparging was provided in airlift bioreactor studies. Thus, the key to finding a Pluronic polyol that served as a protective agent for the Sf-9 cells in a sparged environment corresponded to finding one that did not inhibit cell growth in the absence of sparging. It should be noted that the results may be different with other cell lines.

Foaming Characteristics

Excessive foaming is generally undesirable in animal cell cultures. Therefore, if Pluronic polyols are used that exhibit unacceptable levels of foaming, then an antifoam should also be added to the medium (6). Of the Pluronic polyols given in Table 1, F-68, P-105, and P-65 are the best for foam generation (5). Therefore, a number of other Pluronic polyols may be preferable if foaming is problematic (e.g., L-35 or F-127).

Surface Tension

Because the Pluronic polyols are surfactants, it would be expected that they would reduce the air–water static surface tension. Indeed, according to BASF literature (5), the addition of 0.1% (w/v) Pluronic polyols to aqueous solutions reduces the static surface tension from 72 dyne/cm for pure water to a range of 33 (L-121) to 52 dyn/cm (F-38). In addition, the static surface tension of a 0.1% (w/v) aqueous solution of Pluronic F-68 is 50 dyn/cm. Michaels et al. (7), however, have given a convincing argument that the dynamic surface tension is a more suitable measure for sparged systems since interfacial properties are sensitive to the physical state of the interface. They found that the reduced dynamic surface tension afforded by Pluronic F-68 addition correlated well with reduced cell–bubble interactions and thereby provided cell protection.

Oxygen Transport

Zhang et al. (8) found that the addition of Pluronic F-68 to growth medium had minimal effect on $K_L a$ values for large bubbles (~5 mm diameter), but significantly enhanced $K_L a$ for intermediate (~1 mm diameter) and micron-sized (~100 μm diameter) bubbles. It is generally accepted that surfactants can affect oxygen transport from bubbles in two different ways: affecting the diffusional resistance and affecting the interfacial area. The first affects the K_L, and the second affects the a in $K_L a$. The addition of surfactants usually results in a decreased K_L (9) and an increased a (10). Consistent with this expected behavior, Zhang et al. (8) found that there was a significant reduction in the Sauter mean bubble size for the intermediate and micron-sized bubbles, thereby resulting in an increased a. Pluronic F-68 addition, however, had minimal effect on the size of the large bubbles. No direct measurements directly related to the K_L term were taken in this study, although the results clearly demonstrate that the presence of the Pluronic F-68 resulted in a greater increase in a than decrease in K_L.

PROTECTIVE EFFECTS OF PLURONIC POLYOLS

It has been clearly demonstrated that Pluronic polyols can protect insect and mammalian cells from the adverse effects of sparging. There is also some evidence, although not as conclusive, that Pluronic polyols can provide protection

from shear forces resulting from agitation. Evidence supporting these protective effects and the corresponding mechanisms are discussed in this section.

Sparging Damage

In 1968, Kilburn and Webb (11) were the first to report the use of Pluronic polyols to protect animal cells from sparging. Specifically, they found that supplementing the medium with 0.02% (w/v) Pluronic F-68 protected mouse LS cells from the adverse effects of sparging in short-term studies. They did not, however, show any results from long-term tests, such as an entire bioreactor run. No comprehensive studies regarding the use of Pluronic polyols to protect animal cells from the adverse effects of sparging were conducted until the late 1980s, when Handa-Corrigan et al. (12,13) and Murhammer and Goochee (6,14,15) demonstrated the ability of Pluronic F-68 to protect mammalian and insect cells, respectively. Handa-Corrigan et al. (12,13) demonstrated that the survival of a variety of mammalian cells (hybridomas, NS1 myeloma, BHK-21, and lymphoblastoid [RAJI]) in the presence of sparging depends on cell type and bubble size and frequency (i.e., small bubbles and high flow rates are more detrimental). They further demonstrated that the protective effect of Pluronic F-68 was concentration dependent, with 0.1% (w/v) being sufficient to protect cells under the most severe conditions reported. Murhammer and Goochee (14) investigated the protective effect of Pluronic F-68 in both airlift and sparged agitated bioreactors. It was found that supplementing the medium with 0.1% (w/v) Pluronic F-68 resulted in a major protective effect and that 0.2% (w/v) provided full protection to Sf-9 cells grown in both types of bioreactors. It was also demonstrated that recombinant protein synthesis (produced after infection of the cells with a recombinant baculovirus) in the airlift bioreactor was significantly reduced compared to the unsparged control even after increasing the Pluronic F-68 concentration to 0.5% (w/v). This was hypothesized to result from the increased susceptibility of virally infected cells to lysis in a sparged environment. Murhammer and Goochee (6) further demonstrated that many other Pluronic polyols could serve as protective agents in airlift bioreactors (Table 1).

After the development of conclusive evidence regarding the ability of Pluronic F-68 to protect mammalian and insect cell cultures from the adverse effects of sparging, the research focus in this field shifted to the mechanisms of this protective effect and of cell damage in the absence of protective agents. In regards to bubbles in sparged bioreactors, there are three regions in which cell damage could potentially occur: (*1*) the bubble formation region at the gas distributor, (*2*) the rising bubble region between the gas distributor and medium surface, and (*3*) the bursting bubble region at the medium surface. The results of Handa-Corrigan et al. (13) and Tramper et al. (16) clearly demonstrated that the primary source of cell damage is not in the region of rising bubbles. Specifically, they demonstrated that cell damage decreased as the height of the bioreactors increased. In addition, Michaels et al. (17) demonstrated that cell-to-bubble interactions in the bulk of the bioreactor are not responsible for cell damage in studies in which the headspace above the medium where bubbles can burst was eliminated. Murhammer and Goochee (15) demonstrated that it is possible to have cell damage in the sparger region and that this damage correlates with a high pressure drop across the sparger. In most practical applications (i.e., when the sparger is properly designed), however, significant cell damage only occurs at the medium surface in the bursting bubble region, as first proposed by Handa et al. (12). It has also been demonstrated that cells tend to adhere to air–medium interfaces and that fatal damage occurs to these attached cells as the bubbles burst at the medium surface, that is, the energy released by the bursting bubbles results in extensive cell lysis (18–21).

Michaels et al. (22) suggested that the protective effect of Pluronic polyols could result either from a biological mechanism (i.e., through changes in the cells' ability to resist shear) or from a physical mechanism (i.e., through changes in the medium properties that affect the level or frequency of forces experienced by cells). They concluded that the protective effect of Pluronic F-68 in sparged bioreactors is caused by a physical effect. Consistent with this hypothesis, it was later demonstrated that the protective effect of Pluronic F-68 resulted from its ability to cover the medium–bubble surface and thereby prevent cell adhesion to the bubbles (21,23). Thus, cells are not in the immediate vicinity of bursting bubbles at the medium surface.

It has also been demonstrated that Vero cells grown on microcarriers are damaged in sparged bioreactors (24). It was suggested that the addition of Pluronic F-68 to the medium may be able to protect cells grown on microcarriers from the adverse effects of sparging. Corresponding studies, however, were not conducted. This is certainly an issue that needs to be addressed in future research.

Agitation Damage

Although a few studies have reported that supplementing the medium with Pluronic F-68 can protect attachment-independent cells growing in suspension from agitation damage (25), this is generally not a relevant issue because insect (15) and mammalian (17) cells are commonly tolerant to relatively high agitation rates. For example, it was found that Sf-9 cell damage did not occur unless the agitation rate was high enough to induce bubble incorporation via cavitation or vortexing (15). Further, supplementing the medium with Pluronic F-68 protected the cells from damage caused by bubble incorporation by either of these mechanisms. It is assumed that the corresponding mechanisms of cell damage without Pluronic F-68 and protection by Pluronic F-68 are similar to those reported above for sparged bioreactors.

In spite of the lack of evidence demonstrating that Pluronic F-68 can protect cells from agitation damage, there is some evidence that Pluronic F-68 can make cells more resistant to shear damage. For example, Goldblum et al. (26) demonstrated that the addition of Pluronic F-68 (0.2 and 0.3% [w/v]) to the medium protected Sf-9 and *Tricho-*

plusia ni Tn-368 insect cells from shear damage in viscometer studies in a concentration-dependent manner. In contrast to these results, Michaels et al. (22) found that Pluronic F-68 did not make CRL-8018 cells more shear tolerant. These results suggest that the ability of Pluronic F-68 to increase a cell's shear tolerance may be cell dependent. Direct interaction with the cell (e.g., incorporation of the hydrophobic portion of Pluronic F-68 with the cell membrane) is a possible mechanism through which Pluronic F-68 may increase the shear tolerance of cells. Several lines of evidence are consistent with an interaction of Pluronic F-68 with the cell membrane. First, Pluronic polyols of low HLB values lysed cells (Table 1). Second, Pluronic F-68 inhibits the uptake of trypan blue dye that would normally be taken up in the absence of Pluronic F-68 (14). Third, treating sickled erythrocytes with Pluronic F-68 reduced their rigidity (27). Fourth, Pluronic F-68 increases the fluidity of hybridoma membranes, which correlated with increased shear sensitivity (28).

APPLICATION

If attachment-independent insect or mammalian cells are to be grown in sparged bioreactors, then it is recommended that the medium be supplemented with a Pluronic polyol. Many commercially available serum-free media already contain Pluronic F-68; therefore, additional supplementation may not be necessary. If supplementation is necessary, then a 10% (w/v) aqueous solution of Pluronic F-68 (obtained from BASF Corp.) can be prepared and filter sterilized. This solution can then be used to supplement the medium at 0.1 to 0.2% (w/v) Pluronic F-68. Ready-made solutions of Pluronic F-68 are also commercially available (e.g., Sigma Chemical Company, St. Louis, Mo.). The resulting medium should first be tested in the absence of sparging (e.g., in spinner or shaker flasks) to detect any potential inhibitory effects. Note that purification of the Pluronic F-68 (as mentioned above) may be necessary to remove inhibitory impurities. The next step is to test the ability of the medium to protect cells in small-scale sparged bioreactors. Success in protecting the cells at this scale is a good indicator of similar success in larger-scale sparged bioreactors. The use of Pluronic F-68 allows sparging with micron-sized bubbles that significantly enhance culture oxygenation. If Pluronic F-68 is not successful, many other Pluronic polyols are available for testing (Table 1). Another concern is that Pluronic polyols may interact with the protein of interest and interfere with downstream purification (29). Winzerling et al. (30) have demonstrated, however, that recombinant insect transferrin can be purified from Sf-9 cell supernatant containing 0.1% (w/v) Pluronic F-68 by using high metal ion capacity gel chromatography.

OUTLINE

INTRODUCTION AND HISTORY

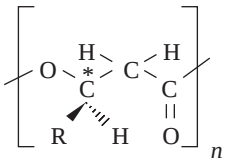
Plastics have been produced by the chemical industry since the early 1930s. They constitute a very important group of materials, because their high molecular weight and low reactivity make them especially suited for applications for which durable, inert materials are required. However, these very same properties have recently been recognized as major drawbacks of plastic materials. Whenever plastic is disposed of, it remains at the site of disposal, and its resistance to biological breakdown causes it to accumulate in the environment. The recognition of this undesired property has led to a search for new plastic materials that disappear after their disposal, the so-called biodegradable plastics. Several biological polymers that could fulfill this requirement are currently under investigation. Most of these biopolymers belong to the class of polysaccharides or polyhydroxyalkanoates (PHAs). In this review, we focus on the second class, the PHAs.

The first example of PHAs to be discovered was polyhydroxybutyrate (PHB). In 1926, Lemoigne isolated and characterized PHB from *Bacillus megaterium* (1). Since this first report, PHB accumulation has been found in many microorganisms: representatives of Gram-negative and Gram-positive species (i.e., autotrophs, heterotrophs, phototrophs, aerobes, anaerobes) and archaebacteria (as reviewed elsewhere [2–4]). Bacteria synthesize and accumulate PHAs as carbon and energy storage materials or as a sink for redundant reducing power under conditions of limiting nutrients in the presence of excess carbon source. When the supply of the limiting nutrient is restored, the PHA can be degraded by intracellular depolymerases and subsequently metabolized as a carbon and energy source.

In 1976, Imperial Chemical Industries (ICI Ltd., UK) recognized the potential applicability of PHB to replace some of the oil-derived commodity plastics. Although the bacterially produced PHB was relatively expensive compared to petrochemical plastics, it was expected that the price of crude oils would rise to high levels, making the production of PHB economically feasible. Because no rise in oil prices occurred, PHB came to be seen as a biodegradable and biocompatible plastic material. Mainly because of their high price, PHB and PHB/HV (a copolymer consisting of hydroxybutyrate and hydroxyvalerate) known under the tradename Biopol™ have only recently found their way to the market. In 1990, the German company Wella released a new shampoo packaged in bottles made of Biopol™. Early in 1996, Monsanto (USA) bought the Biopol™ business from ZENECA BioProducts, a daughter company of ICI. Monsanto is now in the process of generating transgenic plants (i.e., soybean and rapeseed) for future agricultural production of PHB and PHB/HV, which is expected to result in a significantly lower price of the final product.

The discovery of a polyester that consists mainly of hydroxyoctanoate monomers by de Smet et al. (5) in 1983 was the first example of a new group of polymers that can contain a wide variety of different monomers. Thus far, more than 90 different monomers have been found in the polymers (6). Among these are 3-hydroxy acids of 6 to 14 carbon atoms with saturated, unsaturated, straight, or branched aliphatic side chains. Furthermore, monomers with various different functional groups in the side chain, such as halogen atoms, hydroxy-, epoxy-, cyano-, carboxyl-, and esterified carboxyl groups, have been introduced into medium-chain-length (MCL) PHAs (4,6,7).

PHAs can be classified into two groups depending on the number of carbon atoms in the monomer units: short-chain-length (SCL) PHAs, which consist of 3–5 carbon atoms, and MCL PHAs, which consist of 6–14 carbon atoms (8). The general structure of PHAs is shown in Figure 1.



R = CH_3-C_2H_5 Short-chain-length PHAs
R = C_3H_7-$C_{14}H_{29}$ Medium-chain-length PHAs

Figure 1. General structure of polyhydroxyalkanoates (PHAs). PHAs are polyesters with (*R*)-3-hydroxy acids as monomer unit. The monomers of short-chain-length (SCL) PHAs consist of 3–5 carbon atoms, and those of medium-chain-length (MCL) PHAs consist of 6–14 carbon atoms. The molecular weights of these biopolymers range from 2×10^5 to 3×10^6, and the number of monomers (*n*) varies between 1,000 and 30,000.

The monomer units in these microbial polyesters are all in the *R*-configuration because of the stereospecificity of the biosynthetic enzymes. The molecular weights of PHAs range from 2×10^5 to 3×10^6, depending on the specific PHA, the microorganism from which the PHA was obtained, and the growth conditions. In this review, the term *PHA* refers to polyhydroxyalkanoates generally. PHB (or PHV) refers to specific SCL PHAs, and MCL PHA refers to all PHAs that contain monomers with six or more carbon atoms.

SCL PHA

PHB, the best-known of the SCL PHAs, not only appears in microorganisms as storage material but is also ubiquitous in nature. A fascinating development in recent years has been the discovery of the very wide distribution of PHB as a low molecular weight oligomer (120–200 monomers) in microorganisms, plants, and animals, including humans (9,10). In many cases this form of PHB is found as a PHB–calcium polyphosphate complex in membranes that seems to function as an ion channel through cell membranes (11,12). In *Escherichia coli*, the complex has been found to occur in large amounts in the membrane of cells made competent for genetic transformations (13–15). In addition, PHB of similar molecular weight has been found in eukaryotes, for example, in various plant tissues, in organs of animals (such as beef heart, chicken liver, porcine kidney), and in human blood plasma (16). In this review, we focus on the high molecular weight polymer that has considerable potential as an industrial biodegradable plastic.

Physiology and Biosynthesis of PHB

The biochemistry of PHB biosynthesis is very well studied. In most bacteria, such as *Alcaligenes eutrophus*, PHB is synthesized in a three-step reaction starting with acetyl-CoA when cultivated on carbohydrates, pyruvate, or acetate (Fig. 2) (17,18). Two acetyl-CoA molecules are coupled to form acetoacetyl-CoA in a condensation reaction catalyzed by 3-ketothiolase. The product is subsequently stereoselectively reduced to (*R*)-3-hydroxybutyryl-CoA in a re-

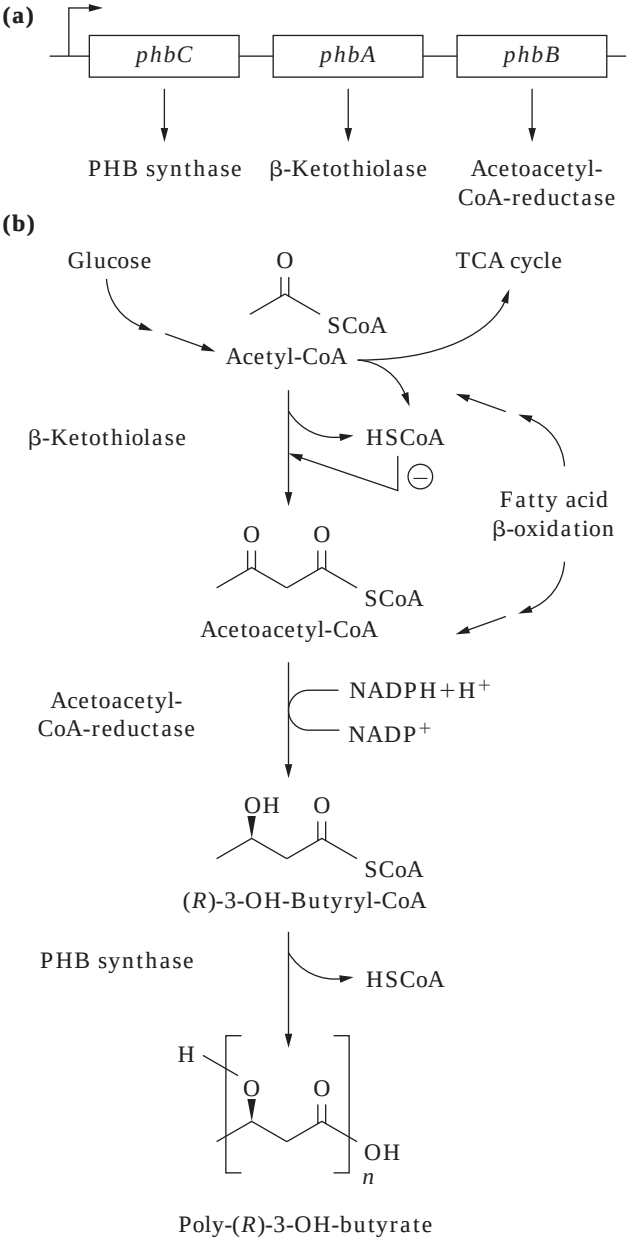


Figure 2. Polyhydroxybutyrate (PHB) synthetic genes and PHB synthesis pathway of *Alcaligenes eutrophus*. (**a**) The genes *phbA*, *phbB*, and *phbC* of *Alcaligenes eutrophus* are located in one operon and code for the *β*-ketothiolase, acetoacetyl-CoA-reductase, and PHB synthase, respectively. (**b**) In the three-step PHB synthesis pathway, two acetyl-CoA molecules are coupled to form acetoacetyl-CoA in a condensation reaction catalyzed by *β*-ketothiolase. The *β*-ketothiolase is negatively regulated by the product coenzymeA (HSCoA), which is also a product when acetyl-CoA enters the TCA cycle under nonlimited conditions. The product is subsequently stereoselectively reduced to (*R*)-3-hydroxybutyryl-CoA in a reaction catalyzed by NADPH-dependent acetoacetyl-CoA reductase. Finally, PHB is synthesized by polymerization of (*R*)-3-hydroxybutyryl-CoA molecules by the PHB synthase. *Source*: From van der Leij et al. (103).

action catalyzed by NADPH-dependent acetoacetyl-CoA reductase. Finally, PHB is synthesized by polymerization of *(R)*-3-hydroxybutyryl-CoA molecules by the PHB synthase (19). A few exceptions to this general pathway are known, such as *Rhodospirillum rubrum*, where (*S*)-3-hydroxybutyryl-CoA is generated and converted to *(R)*-3-hydroxybutyryl-CoA by two stereospecific enoyl-CoA hydratases (20).

As pointed out in the introduction, PHB biosynthesis and accumulation occur in most bacteria if a carbon source is provided in excess and if another nutrient, such as nitrogen, sulfur, phosphate, iron, magnesium, potassium, or oxygen, is limiting (21,22). PHB synthesis is regulated at the enzymatic level, and the availability of suitable substrates for PHB synthesis routes results from an imbalanced supply of nutrients to the cell via physiological regulation pathways than have been studied in *Azotobacter beijerinckii* (23) and *Alcaligenes eutrophus* (24,25). It was found that the intracellular concentration of acetyl-CoA and free coenzyme A play a central role in the regulation of polymer synthesis (26). Under balanced growth conditions acetyl-CoA is oxidized via the tricarboxylic acid (TCA) cycle. In this reaction sequence, NADH is generated and is used for biosynthetic purposes. When growth ceases the NADH concentration increases, which reduces the activity of the TCA cycle enzymes citrate synthase and isocitrate dehydrogenase. As a result acetyl-CoA cannot be oxidized via the TCA cycle and enters the PHB synthetic pathway. The 3-ketothiolase enzyme of this pathway is inhibited by free CoA, which is generated by oxidation of acetyl-CoA via the TCA cycle during normal growth.

PHB/HV Copolymer Biosynthesis

A copolymer of PHB and PHV can be synthesized by *Alcaligenes eutrophus* and many other microorganisms from either a mixed substrate of glucose and propionic acid or a direct precursor of 3-hydroxyvalerate (e.g., valeric acid) (27). If propionate is fed, essentially the same biochemical pathway as for PHB synthesis is used, but propionyl-CoA and acetyl-CoA are condensed by the ketothiolase to give 3-ketovaleryl-CoA, which leads to the incorporation of 3-hydroxyvalerate monomers in the polymer. 3-Hydroxybutyrate arises in the normal way. Alkanoic acids of odd-number carbon chain length can also serve as carbon source (28,29). In this case, the 3-hydroxyvalerate in the polymer arises directly from the β-oxidation of these fatty acids. Recently, it was shown that low dissolved oxygen concentrations enhance 3-hydroxyvalerate incorporation into the polymer produced by *A. eutrophus* (30).

Several microorganisms have been isolated that are capable of accumulating PHB/HV from substrates apparently unrelated to, and not immediate precursors of, 3-hydroxyvalerate. These organisms include *Corynebacterium*, *Nocardia*, and *Rhodococcus* strains (31) and mutants of *A. eutrophus* (32). When supplied with hexanoic acid as substrate, *Rhodococcus* sp. was able to accumulate a terpolymer containing 3-hydroxybutyrate, 3-hydroxyvalerate, and 3-hydroxyhexanoate monomers. In addition, *Rhodococcus* sp. NCIMB40126 and *Chromobacterium violaceum* are capable of producing a homopolymer consisting of 3-hydroxyvalerate when grown on valeric acid as sole carbon source (31,33).

Copolymers of 3-hydroxybutyrate and 4-hydroxybutyrate can be synthesized by *A. eutrophus* from 4-hydroxybutyric acid, 1-4-butanediol, butyrolactone, and 4-chlorobutyric acid (34). Terpolymers of 3-hydroxybutyrate, 3-hydroxyvalerate, and 5-hydroxyvalerate can be produced by *A. eutrophus* fed with either 5-chlorovalerate alone or 5-chlorovalerate or 5-hydroxyvalerate in combination with valeric acid (35). Polymers that contain 4-hydroxyvalerate and 3-hydroxypropionate have been synthesized by a variety of organisms, including *A. eutrophus* (36). The substrates used were 4-hydroxyvalerate, 4-valerolactone, and 3-hydroxypropionic acid. Most *Alcaligenes* strains tested and *Pseudomonas oxalaticus* accumulated a terpolymer of 3-hydroxybutyrate, 3-hydroxyvalerate, and 4-hydroxyvalerate from 4-valerolactone or 4-hydroxyvalerate as sole carbon source (36). *Alcaligenes eutrophus* and *Burkholderia cepacia* are able to synthesize terpolyesters that consist of 3-hydroxybutyric acid, 3-hydroxyvaleric acid, and 2-methyl-3-hydroxybutyric acid when tiglic acid is used as sole carbon source or in combination with gluconic acid (37).

Molecular Biology and Enzymology of SCL PHA Synthesis.

In *A. eutrophus*, the structural genes for PHA synthesis are organized in the *phbCAB* operon (see Fig. 2), coding for PHB synthase, β-ketothiolase, and NADPH-dependent acetoacetyl-CoA reductase, respectively (38–40). The transcription start of *phbC* was identified 307 base pairs upstream from the translation initiation codon by S1 nuclease protection assay, and a sequence that exhibits a striking homology to the *E. coli* σ^{70} promoter consensus sequence was found (39).

The PHB synthase structural genes have been cloned and sequenced from various bacteria (8). Comparison of the protein primary structures revealed that PHB synthases represent a group of highly homologous enzymes. The PHB synthase of *A. eutrophus* has been studied in detail in several laboratories. It is a large enzyme with identical subunits that exhibit a relative molecular mass of 63.9 kDa (38) and specificity for 3-hydroxyacyl-CoA of C_3 to C_5 units (41). Site-directed mutagenesis demonstrated that the cysteine$_{319}$ residue is required for PHB synthase activity in *A. eutrophus* (42). Furthermore, evidence has been obtained that the enzyme requires posttranslational modification by phosphopantetheine to provide a second thiol group per PHB synthase subunit (42), which could support the mechanistic model for the polymerization process that depends on the presence of two thiol groups (43).

A putative model for the polymerization process based on de novo fatty acid synthesis is presented in Figure 3. This model illustrates only one possible reaction mechanism, and other models are also possible. In an initiation or priming process (Fig. 3a), the 3-hydroxybutyric acid moiety from 3-hydroxybutyryl-CoA is transferred to the thiol group of the phosphopantotheine-modified serine, coupled with the release of coenzyme A. This 3-hydroxybutyryl moiety is then translocated to the thiol of the cysteine. It has been shown recently that acylation of cysteine$_{319}$ causes a shift of the monomeric form of the synthase to its dimeric form, and this shift is accompanied by an increase in its specific activity and a decrease in the lag

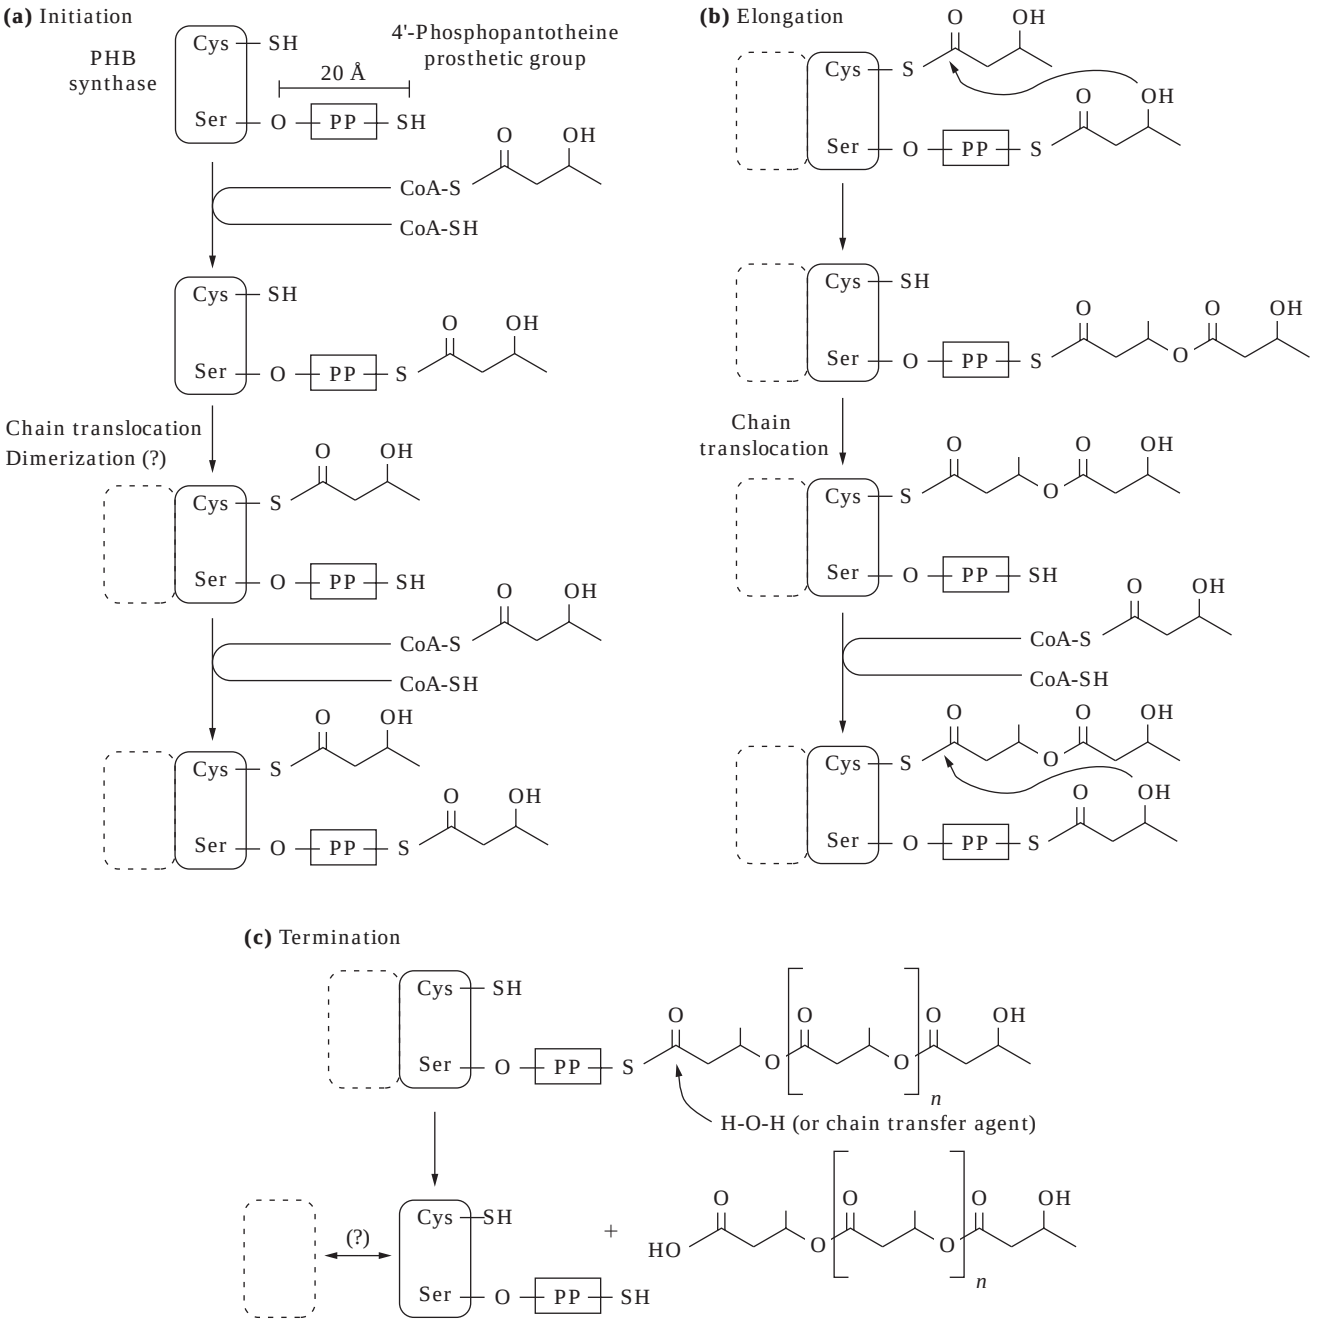

Figure 3. The hypothetical model of the catalytic PHB synthase mechanism is based on analogy to the de novo fatty acid synthesis and on information available about PHB synthases. The conserved cysteine$_{319}$ and the posttranslationally modified serine$_{259}$ of the PHB synthases that are likely to be involved in the reaction mechanism are indicated. In the initiation step (**a**) the 3-hydroxybutyric acid moiety from 3-hydroxybutyryl-CoA is transferred to the thiol group of the phosphopantotheine modified serine, coupled with the release of coenzyme A. It is supposed that this 3-hydroxybutyl moiety is translocated to the thiol group of the cysteine and that a shift of the monomeric form of the synthase to its dimeric form takes place. A second 3-hydroxyacyl moiety is added to the thiol group of the phosphopantotheine modified serine. During chain elongation (**b**) the 3′-hydroxy group of the entering monomer attacks the thiol ester of the previously entered monomer to form a covalently bound dimer/oligomer. Termination takes place when a chain transfer with water occurs, and the polymer chain is released from the enzyme (**c**). A chain transfer agent might be involved in this process. This model does not show that the polymer chain might be translocated from the posttranslationally modified serine to the thiol group of the cysteine of the other subunit as is the case in de novo fatty acid synthesis.

phase of polymer formation (44). A second monomer is then again added to the thiol group of the phosphopantotheine-modified serine, and its 3′-hydroxy group attacks the thiol ester of the first monomer to form a covalently bound dimer (Fig. 3b). After translocation of the formed dimer to the thiol group of the cysteine (either of the same subunit as shown in Fig. 3b or of the other enzyme subunit), the thiol group of the posttranslationally modified serine can accept a new 3-hydroxybutyric acid moiety, and by repeated propagation steps the covalently bound oligomer or polymer grows by one unit during each cycle. It is assumed that the polymer is released from the enzyme if a chain transfer with water occurs that terminates polyester biosynthesis (Fig. 3c). Doi and coworkers have postulated that a chain transfer agent, which might be an enzyme with a water molecule in its active site, could be involved in the termination process (45–47).

A combined chemical and enzymatic procedure has been developed to synthesize PHB granules in vitro (48). Purified PHB synthase from *A. eutrophus* was exposed to synthetically prepared *(R)*-3-hydroxybutyryl-CoA, and PHB was formed, thereby establishing the minimal requirements for PHB formation. The in vitro polymerization system yielded PHB with a molecular mass higher than 10×10^6 Da, exceeding by an order of magnitude the mass of PHB typically extracted from microorganisms. Furthermore, the molecular mass of the polymer could be controlled by the initial PHB synthase concentration.

The PHB synthases of *Chromatium vinosum* and *Thiocystis violacea* represent a different class of synthases that consists of two different types of subunits encoded by *phaE* and *phaC* (49,50). Together, these genes constitute one single operon. The C-terminus of PhaC contains high homology to the central region of the PHB synthase of *A. eutrophus*. However, the PhaC protein lacks the N-terminal part and is much smaller than the other synthases. The PhaE protein may take over essential functions of the larger PHB synthases in the polymerization process (8). The PHA synthase of *Thiocapsa pfennigii* is also composed of two different subunits, similar to those of *Chromatium vinosum* and *Thiocystis violacea*. From the substrate range, however, this synthase seems to be clearly distinguished from all other PHA synthases because it can synthesize copolyesters that consist of 3-hydroxyalkanoates ranging from C_3 to C_{14}, or even 4- and 5-hydroxyalkanoic acids (51).

Granule Structure

The PHA polymers are accumulated in the bacterial cells as defined granules (Fig. 4). Because the granule structure of SCL and MCL PHAs produced by different organisms seems to be very similar, both types of polymer granules are discussed together. Nuclear magnetic resonance (NMR) spectroscopy of various bacteria has clearly demonstrated that the polyester in the cells occurs in a metastable amorphous state and that it is stored as a mobile elastomer (52–54). The bouyant density of PHB granules is about 1.18–1.24 g cm^{-3} (55–57), in contrast to MCL PHA granules, which have a bouyant density of approximately 1.05 g cm^{-3} (58). The isolated granules consist of polyester,

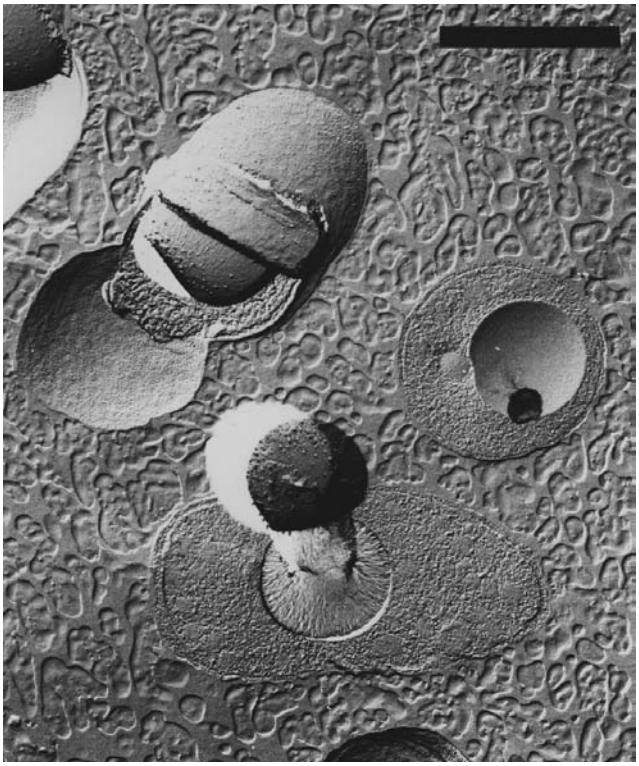

Figure 4. Polyhydroxyalkanoate (PHA) granules in *Pseudomonas oleovorans*. Freeze-fracture electron micrograph of octane-grown *P. oleovorans* cells containing PHA granules that were deformed during the fracture process and show the typical mushroom-type deformation of granules consisting of MCL PHA. The bar represents 0.5 μm.

proteins, and lipids. The composition was first determined for PHB granules of *Bacillus megaterium*, which consist of 97.7% polyester, 1.87% proteins, and 0.46% lipids or phospholipids (43).

Several different models of granule structure have been proposed. First indications that the native PHA granules in *Pseudomonas oleovorans* might be surrounded by a phospholipid monolayer in which the polymerase enzymes are embedded have been found by Witholt and coworkers (59,60). In contrast to this model, Stuart et al. (61) presented a model in which the hydrophobic PHA core is surrounded by two protein layers with a phospholipid layer in between. In this model, the polymerase is supposed to be embedded only in the inner layer. Recently, determination of the thickness of the boundary layer surrounding the polymer inclusions of different bacteria confirmed that a lipid monolayer is more likely than two protein layers with a lipid layer between them (62). In addition to the polymerases, other proteins such as depolymerases, granule-associated proteins (GAPs, also called phasins), and proteins of unknown function seem to be embedded in the phospholipid layer (63,64). Phasins are in general low molecular weight proteins and are assumed to form a close protein layer at the surface of the granules, providing the interface between the hydrophilic cytoplasm and the hydrophobic core of the PHA inclusion (63). In *A. eutrophus*,

the first evidence was found by mutant studies for the structural importance of a 24-kDa GAP (called GA24) (65). Mutants lacking the GA24 protein synthesized only one large PHB granule per cell in contrast to 10–30 granules as found in the wild type. The amino acid sequence of the GA24 protein revealed two closely related stretches consisting exclusively of nonhydrophilic amino acids at the C-terminal region, which are presumably involved in the binding of GA24 to the granules. Similar granule-forming proteins were identified and isolated from various other strains, such as *Acinetobacter* sp., *Rhodococcus ruber*, *Chromatium vinosum*, *Methylobacterium extorquens*, and *Pseudomonas oleovorans* (64,66–73).

Industrial Production of PHB and PHB/HV

Many bacteria have been screened to produce PHB or PHB/HV. However, only a few have been used for biotechnological production of these polyesters on a large scale. Here, we focus on the two examples that have found application in an industrial process.

The suitability of a bacterium for PHA production depends on many different factors such as stability and safety of the organism, growth and accumulation rates, achievable cell densities and PHA contents, extractability of the polymer, molecular weights of accumulated PHA, range of utilizable carbon sources, costs of the carbon source and the other components of the medium, and occurrence of by-products (74). Recently, the theoretical yield (the yield based on the reaction stoichiometry) of PHB has been estimated for several substrates (75). Regeneration of nicotinamide nucleotides, which are used as cofactors for PHA synthesis, has been taken into account in this analysis.

In the production plant of ZENECA BioProducts at Billingham (UK), the PHB homopolymer and the copolyester PHB/HV have been produced at scales up to 200,000 L (74). The process utilized a mutant of *A. eutrophus* (76), and the fermentation was carried out in a two-step fed-batch process. During the first step, the cells were grown in a mineral salt medium with glucose as sole carbon and energy source and with a calculated amount of phosphate based on the known requirements of the organism to allow production of a given amount of biomass. As the culture grew, phosphate was depleted from the medium, and during the second step when phosphate was limiting, the culture started to store polymer. Glucose was fed to the culture, and the fermentation was continued until the required polymer content was reached. Each phase lasted for approximately 48 h, and final biomass dry weights of 100 g/L were achieved (77). The copolymer of PHB/HV was made by substituting a mixed feed of glucose and propionic acid in the polymer accumulation phase. The 3-hydroxyvalerate content of the copolymer was controlled by adjusting the ratio of the two substrates in the feed (77).

A different industrial process has been developed at the Biotechnologische Forschungsgesellschaft in Linz (Austria) for the production of PHB homopolymer (78,79). In this process strain *Alcaligenes latus* DSM1124 was employed, which can accumulate PHB during balanced cell growth up to 80% of the cellular dry matter. Therefore, a one-step fed-batch fermentation process was carried out using a mineral salts medium with sucrose as sole carbon source. A biomass of 60 g/L was achieved (79). In 1993, however, the company stopped the production of PHB/HV.

Recovery

The cells that contain PHB/HV must be separated from the broth by conventional procedures such as centrifugation, filtration, or flocculation–centrifugation. After the biomass is harvested, cells must be disrupted to recover the polymer. Several methods have been developed for the recovery of PHAs. The method most often used involves extraction of the polymer from the biomass with solvents (e.g., chloroform, methylene chloride, propylene carbonate, dichloroethane). Large amounts of solvent are required in this process. Several other methods have been developed, such as sodium hypochloride treatments for the differential digestion of non-PHA cellular materials (80). Although this method is effective, it causes severe degradation of PHB, resulting in a reduction in the molecular weight (81).

ZENECA has developed a nonsolvent-based recovery process as an alternative to solvent extraction for the commercial production of PHB and PHB/HV by *A. eutrophus* (77,82). In this process the cells were first exposed to 80 °C and subsequently treated with a cocktail of various hydrolytic enzymes consisting of lysozyme, phospholipase, lecithinase, the proteinase alcalase, and others. Most of the cellular components were hydrolyzed by these enzymes, whereas the polymer remained intact. After washing, flocculation, and drying, the polymer was recovered as a white powder that was melted, extruded, and converted into chips, the form in which the polymer was supplied to the fabricators.

In contrast, the Biotechnologische Forschungsgesellschaft has applied a solvent-based process for the recovery of PHB from *A. latus*. The cells were harvested by centrifugation, and subsequently the PHB was extracted with methylene chloride from the suspended cells and precipitated out of the solvent by the addition of water. After drying of the polymer, a polyester with 99% purity was obtained (79). The process also included recovery of the solvent.

Properties of PHB and Its Copolymers

Comprehensive overviews on the physical properties of PHB and its copolymers, or on the material properties of the manufactured objects from those polymers, have been published previously (27,74,83–85) and are summarized next.

The PHB homopolymer is a completely stereoregular polyester, with all asymmetric carbon atoms in the (*R*)-configuration, and it is therefore highly crystalline. The high crystallinity (typically 55–80%) makes it relatively stiff and brittle. The glass transition temperature (T_g of PHB lies between 5 and 9 °C, and the melting point (T_m) lies between 173 and 180 °C (Table 1). PHB polymer decomposes at approximately 200 °C, which is close to its melting temperature. In its solid, crystalline state, the polymer is a right-handed helix, a condition that is retained in chloroform solution. The mechanical properties

of PHB including Young's modulus (3.5 GPa) and the tensile strength (40 MPa) are similar to those of polypropylene (Table 1). However, the elongation to break for PHB is about 3%, which is significantly lower than that of polypropylene (400%).

The flexibility of the material is greatly improved when 3-hydroxyvalerate units are incorporated into the polymer, resulting in a decrease of Young's modulus below 0.7 and a decrease of tensile strength below 30 MPa. The elongation to break also increases as the comonomer fraction increases. The melt temperature is greatly depressed, down to 130 °C, dependent on the 3-hydroxyvalerate content (Table 1), but the degradation temperature is little affected. This property generates a relatively wide window of conditions that allow thermal processing as a melt without degradation of the material. PHB/HV copolymers with different 3-hydroxyvalerate content, ranging from 0 to 30%, are commercially available as Biopol™ resins.

Copolymers of 3-hydroxybutyrate and 4-hydroxybutyrate monomers cannot form isomorphic crystals because of the extent of the structural differences between the monomer units. The glass transition temperature decreases from 5 to −50 °C, and the melting temperature decreases from 180 to 54 °C as the mol% of 4-hydroxybutyrate increases from 0 to 100%. Young's modulus, tensile strength, and % elongation at break (for 94 mol% 4-hydroxybutyrate) are reported as 55 MPa, 39 MPa, and 500%, respectively. The T_g and T_m of copolymers consisting of 3-hydroxybutyrate and 3-hydroxypropionate decrease with an increase in the 3-hydroxypropionate (from 0 to 26 mol%) from 4 to −8.1 °C and 180 to 85 °C, respectively. The degree of crystallinity also decreases with an increase of 3-hydroxypropionate.

Recombinant Organisms

Successful biosynthesis of PHB in *E. coli* was independently achieved by two different groups (39,40). Polymer formation was only observed when all three PHB biosynthesis genes of *A. eutrophus* were expressed in *E. coli*; expression of *phbC* alone did not result in PHB production. These studies were extended by the production of the copolymer PHB/HV in recombinant *E. coli* (*fadR atoC*) mutants containing the PHB biosynthetic genes and using glucose and propionic acid as carbon source. The *E. coli* (*fadR atoC*) mutants produce the enzymes required for the catabolism of SCL fatty acid constitutively. 3-Hydroxyvalerate contributed up to 39 mol% to the accumulated polyester (86). Synthesis of PHB by recombinant *E. coli* does not require limitation of a specific nutrient, but is dependent on the amount of acetyl-CoA available and is significantly enhanced by the addition of various complex nitrogen sources, amino acids, or oleic acid (87). Application of recombinant *E. coli* in fed-batch culture resulted in cell densities of 101 g L^{-1}, containing approximately 80% PHB per cell dry weight (88) after 39 h of cultivation.

Under specific conditions, such as pH 6.0, *E. coli* produced PHB with an extremely high molecular mass of 20 MDa (47). Furthermore, it was shown that the amount of PHB synthase in recombinant *E. coli* plays a key role in controlling the molecular weight and the polydispersity of the polymer (89). With an increased amount of PHB biosynthetic enzymes, a decrease in polyester molecular weight was observed.

For the first time, PHB biosynthesis was successfully conferred to *Arabidopsis thaliana*, a small oil seed plant,

by introducing the *phbB* and *phbC* gene from *Alcaligenes eutrophus* (90). When the enzymes necessary to catalyze the synthesis of PHB from acetyl-CoA were produced in the cytoplasm, only small amounts of PHB were synthesized. Plants were viable but growth was very poor, possibly because of a reduction of acetyl-CoA needed for growth. Targeting of all three required proteins to the plastids of *Arabidopsis thaliana* resulted in normal growth, active enzymes, and PHB accumulation up to 14% of total cell dry weight (91). However, the molecular weight distribution of the plant-produced PHB was much broader than that of typical bacterial PHB (92).

The *phbC* gene of *Alcaligenes eutrophus* has also been introduced into *Saccharomyces cerevisiae*, which enabled this yeast to accumulate PHB to up to 0.5% of cell dry weight (93). A novel pathway for PHB synthesis has been engineered in insect cells (*Spodoptera frugiperda* (94,95). In these insect cells, a heterologous dehydrase-deficient fatty acid synthase from rats is produced in addition to the PHB synthase of *A. eutrophus*. The multifunctional fatty acid synthase effectively replaces the *β*-ketothiolase and acetoacetyl-CoA reductase activities of the natural prokaryotic PHB pathway and, therefore, provides the precursor 3-hydroxybutyryl-CoA for conversion to PHB (Fig. 5). This strategy suggests a new method for generating structurally diverse polyhydroxyalkanoates by metabolic engineering.

MCL PHA

Although many species of bacteria are reported to synthesize PHB and PHV, including some *Pseudomonas* strains, the ability to store polymers that contain monomers of 3-hydroxy acids of carbon chain length C_6 and longer, here referred to as MCL PHAs, is unique to the group of pseudomonads.

Physiology and Biosynthesis of PHA

Three main pathways are involved in the synthesis of PHA precursors in *Pseudomonas putida* (96,97). These were revealed by labeling studies, NMR spectroscopy, and gas chromatography–mass spectroscopy (GC-MS) analyses of PHA from cells that were grown on simple carbon substrates such as glucose and/or fatty acids. *P. putida* derives PHA from precursors made via the following routes. *(1)* Chain elongation, in which acyl-CoA is extended with acetyl-CoA, is comparable with the major route for PHB monomer synthesis, where the acyl-CoA is one of the two acetyl-CoA molecules (Fig. 6). It has been found that about 3–10% of the monomeric units of PHA are one C_2 unit longer than the fatty acid used as substrate (98–100). However, this route is less important for PHA synthesis than it is for PHB synthesis. *(2)* Fatty acid degradation by *β*-oxidation is the main pathway when fatty acids are used

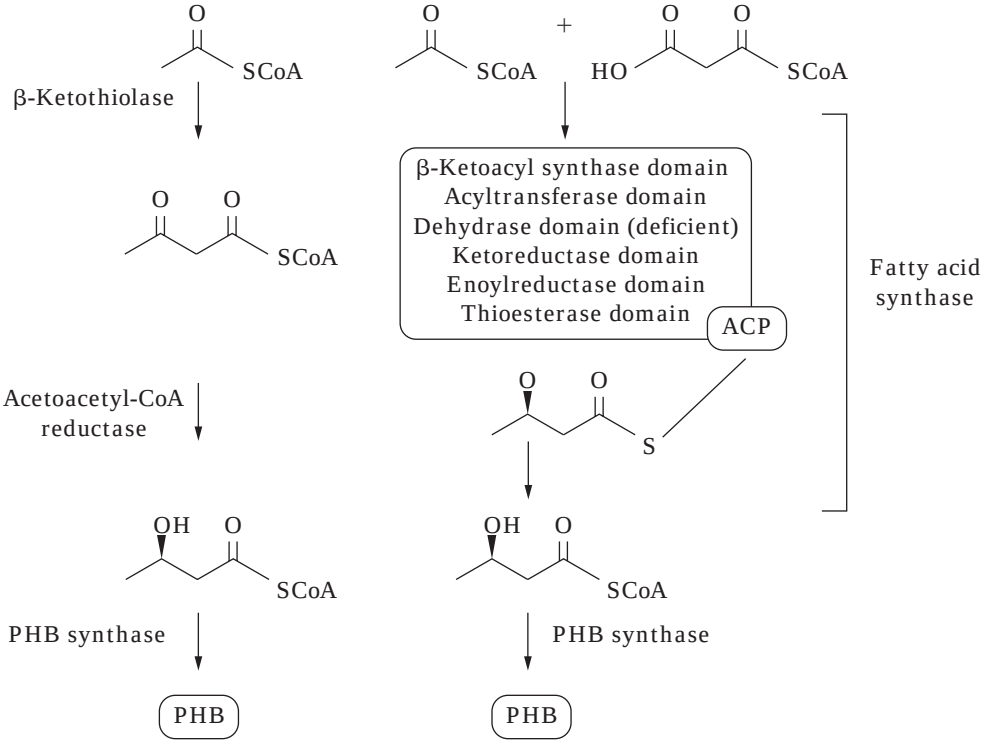

Figure 5. Engineered polyhydroxybutyrate (PHB) synthesis pathway in insect cells. The bacterial PHB synthesis pathway described in Figure 2 is shown on the left, and the engineered PHB synthesis pathway in insect cells on the right. The condensation of acetyl-CoA and malonyl-CoA followed by ketoreduction of acetoacetyl-acyl carrier protein (ACP) are performed by the fatty acid synthase multifunctional protein. The different catalytic domains of the enzyme are listed. The dehydrase domain is not functional. *Source*: From data of Williams et al. (94).

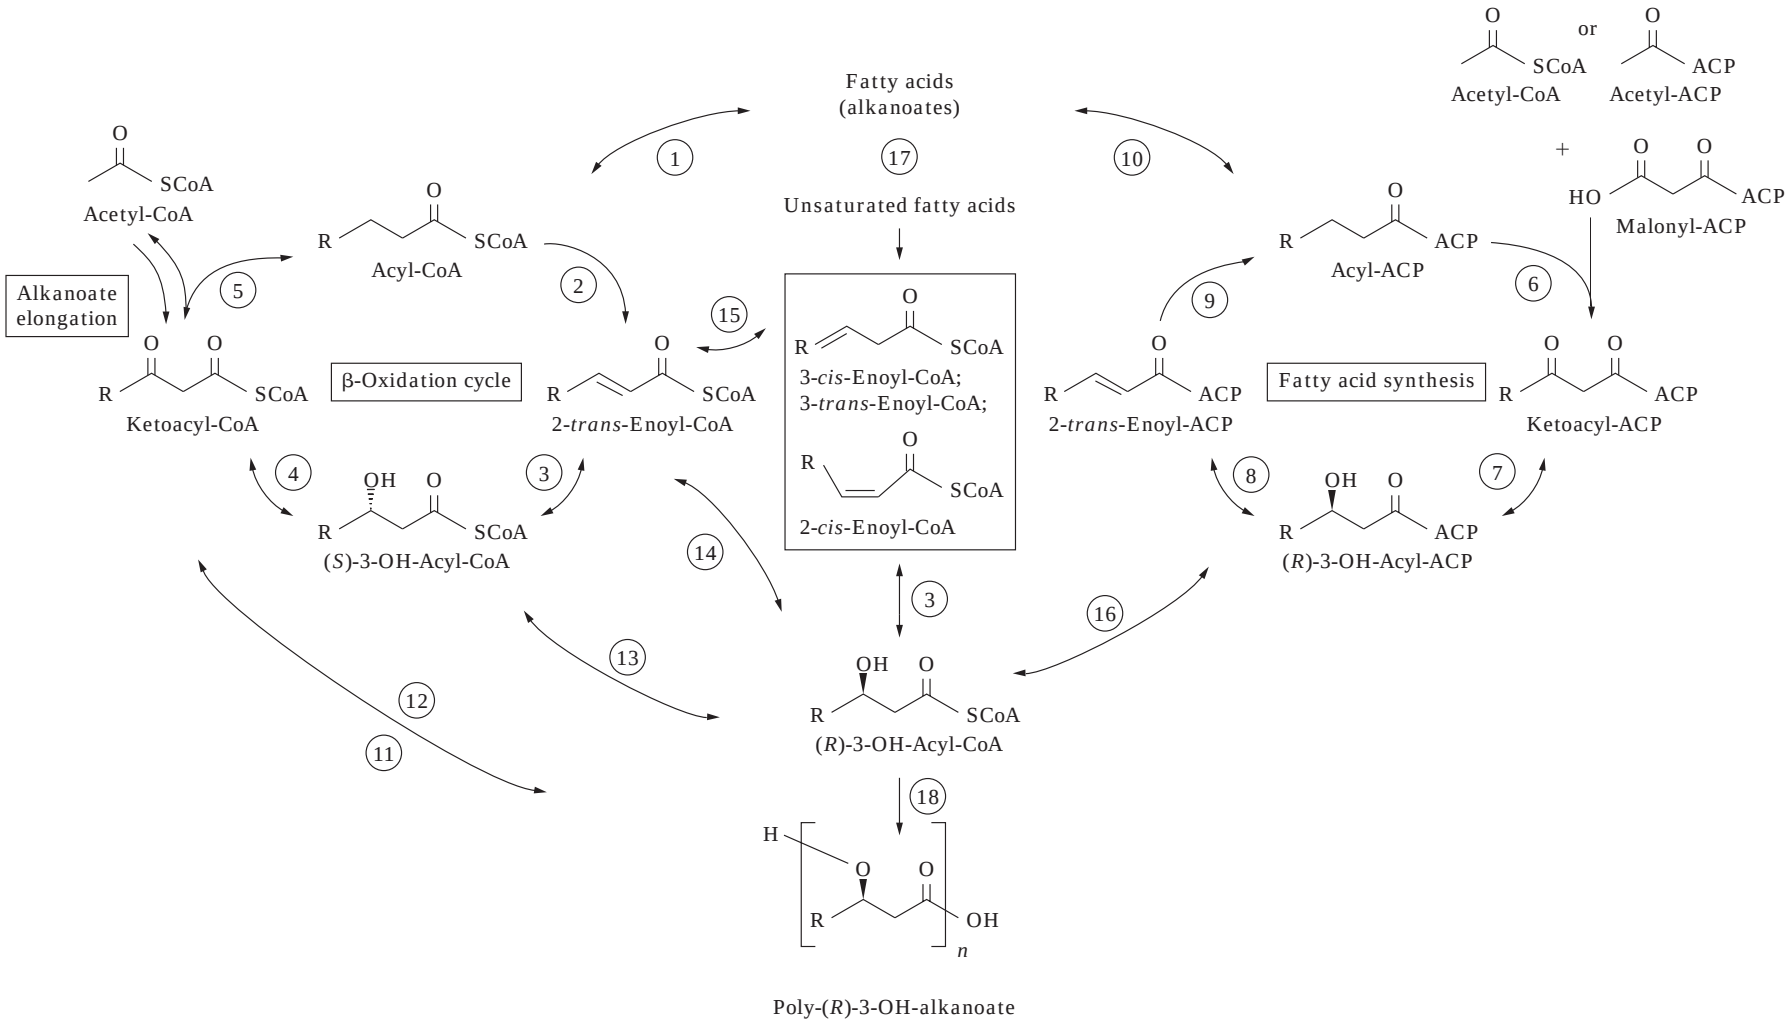

Figure 6. Major pathways involved in MCL polyhydroxyalkanoate (PHA) synthesis in *Pseudomonas*. Alkanoate elongation, *β*-oxidation, and fatty acid biosynthesis are involved in MCL PHA synthesis in *Pseudomonas*. The numbering of the enzymatic activities is as given in Table 2. *Source*: From van der Leij et al. (103).

as substrate. *(3)* De novo fatty acid biosynthesis is the main route during growth on simple carbon compounds. The enzymes involved in the pathways depicted in Figure 6 do not have the same activity for different chain length substrates. Thus, the PHA polymerase seems to have a preference for the incorporation of C_8 to C_{10} monomers. Such preferences might have substantial influences on the fluxes and the contributions of each pathway.

The intermediate precursors of PHA are either ketoacyl-CoA, (*S*)-3-hydroxyacyl-CoA, enoyl-CoA, or (*R*)-3-hydroxyacyl-acyl carrier protein (ACP). Regarding the similarity between the PHB polymerase and the PHA polymerases (see following), it seems likely that the ultimate substrate for polymerization is the (*R*)-form of the CoA-activated 3-hydroxy fatty acid intermediates. Because the monomeric units in PHA, like those in PHB, are in the (*R*)-form, and the PHB and PHA polymerases are homologous, the intermediates in fatty acid metabolism must presumably be converted to the (*R*)-form of 3-hydroxyacyl-CoA before transesterification (Fig. 6). The PHA precursors are generally considered to be available in a much lower in situ concentration than the PHB precursors because they are intermediates of ongoing fatty acid metabolic cycles.

Molecular Biology and Enzymology

Knowledge of the genetic and physiological regulation of PHA biosynthesis is relatively limited compared to what is known about PHB biosynthesis because PHA synthesis has only been studied since 1983 (5). The *pha* loci of *Pseudomonas oleovorans* (101) and *Pseudomonas aeruginosa* (102) consist of four ORFs: the ORFs *phaC1* and *phaC2* code for polymerases and are separated by an ORF called *phaZ*, which encodes a depolymerase; downstream of these genes is an ORF called *phaD*, which encodes a putative granule surface protein (103) (Fig. 7). Subsequently, more ORFs have been identified downstream and in opposite orientation to the *pha* locus of *P. putida* and *P. oleovorans*, which presumably encode granule-associated proteins (H. Valentin, unpublished results, 1996). The sequence of this region has not yet been published.

At least two promoters are involved in the transcription of the *pha* genes in *P. aeruginosa* (102). Two promoters are upstream of the *phaC1* gene and resemble the consensus sequences for σ^{54}-dependent and σ^{70}-dependent promoters. It is not clear whether a third promoter upstream of the *phaC2* gene in *P. aeruginosa* is active (102). Northern blot experiments indicated the presence of two mRNAs, one carrying *phaC1* and *phaZ*, the other *phaC2* and *phaD*. However, a transcriptional start site accompanying the putative promoter upstream of *phaC2* could not be experimentally shown, suggesting that this promoter may not be functional.

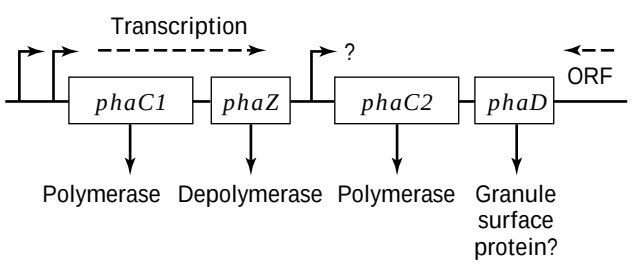

Figure 7. Organization of *pha* genes in *P. oleovorans* and *P. aeroginosa*. Two polymerases and one depolymerase are encoded by *phaC1*, *phaC2*, and *phaZ*, respectively. The *phaD* gene may encode a granule-associated protein. More open reading frames (ORF) in opposite orientation were found downstream of these genes. Putative promoters are indicated with open arrows (see text for details). *Source*: From Steinbüchel et al. (8) and van der Leij et al. (103).

The two PHA polymerases show identities of 54–59% at the protein sequence level when compared within each species. When corresponding PHA polymerases from different species are compared, they show 69–80% identity at the amino acid level. The identities between these PHA polymerases and the *A. eutrophus* PHB polymerase are nearly 40% (101,102). According to the gene sequences, the *Pseudomonas* PHA polymerases have molecular weights of 62–64 kDa. The enzymes show a small difference in substrate specificity (104).

The *phaZ* gene product, a PHA depolymerase with a predicted molecular weight of 31.5 kDa, shows homology with a range of hydrolytic enzymes (59,101). It contains the common lipase box Gly-X-Ser-X-Gly, which is also found in extracellular PHA depolymerases (105).

Production of MCL PHA

Pseudomonas strains such as *P. oleovorans, P. putida, P. aeroginosa*, and *P. resinovorans* are the major strains used for MCL PHA production (100,106,107). Batch, fed-batch, and continuous cultivation techniques have been extensively investigated at the laboratory scale (60,108,109), but MCL PHA production up to a 200-L scale has also been carried out (110). Efficient PHA production requires rapid formation of biomass and product. In batch and fed-batch fermentations, similar to the PHB production process, cells are first grown to a desired concentration without nutrient limitation, after which an essential nutrient is limited to trigger efficient PHA synthesis. During this nutrient limitation stage the residual cell concentration (defined as the cell concentration minus the PHA concentration) remains almost constant, and the cell concentration increases only because of the intracellular accumulation of PHA.

P. oleovorans has been used to produce MCL PHAs in two-liquid-phase cultivations (111,112). The organism was cultured in media consisting of an aqueous phase containing all minerals necessary for growth and a second liquid phase containing *n*-alkanes as sole carbon and energy source. Two-liquid-phase, single-stage chemostat, and fed-batch cultivations of *P. oleovorans* using *n*-octane as the carbon source resulted in highest volumetric productivities of 0.58 g L^{-1} h^{-1} (108) and 0.25 g L^{-1} h^{-1} (109), respectively. In a two-liquid-phase, two-stage continuous cultivation a volumetric productivity of 1.06 g L^{-1} h^{-1} with a final cellular PHA content of 66% per total cell dry weight has recently been reported (113). The monomer composition of the synthesized polymer is mainly dependent on the strain used and the carbon source applied. The cultivation conditions have only a minor influence on the composition of the polymer. However, it was shown that temperature

and concentration of the substrate has an influence on the molecular weight of the polymer (45). The monomer composition of PHAs produced from different alkanoates using *P. oleovorans* is shown in Table 3 (100). Recently, it was reported that *Pseudomonas putida* U grown on octanoic acid as the sole carbon source accumulated a homopolymer of poly-3-hydroxyoctanoate (114).

Different *Pseudomonas* strains have been used to produce MCL PHAs from renewable resources, such as fatty acids (29,100) and carbohydrates (96,107,115). In fed-batch cultivations, *P. putida* KT2442 was cultivated to high cell densities (92 g/L) with oleic acid as a substrate. With this process, an overall volumetric productivity of 1.6 $g\ L^{-1}\ h^{-1}$ was achieved with a final cellular PHA content of 40% per total cell dry weight (116). Furthermore, MCL PHAs could be produced from glucose, fructose, and glycerol using *P. putida* KT2442 (96). In addition to the major constituent 3-hydroxydecanoate, six other monomers were found to be present: 3-hydroxyhexanoate, 3-hydroxyoctanoate, 3-hydroxydodecanoate, 3-hydroxydodecenoate, 3-hydroxytetradecanoate, and 3-hydroxytetradecenoate (Table 4). The degree of unsaturation of PHA was slightly influenced by the cultivation temperature (96).

Various functional groups can be introduced into the polymer by applying different substrates in the growth medium. Olefin groups were introduced by adding *n*-alkenes (111,112) or alkenoates (29,117,118) to the medium. Furthermore, different halogen atoms were incorporated in the polymer when halogenated alkanoates were used as substrates (119–122). A homopolymer of 99% purity consisting of 3-hydroxy-5-phenylpentanoate is synthesized by *P. oleovorans* when grown on 5-phenylvalerate (123). Polymers containing different mol% of phenyl groups (124,125), or other aromatic compounds such as phenoxy groups (126,127) or cyanophenoxy groups (128,129), were produced by adding phenyl alkanoates, phenoxy alkanoates, or cyanophenoxy alkanoates, respectively, as a cocarbon source.

Table 3. Composition of MCL Polyhydroxyalkanoates Produced by *Pseudomonas oleovorans* Grown on Different Alkonoates as Sole Carbon Source

	Composition (mol% of total 3-hydroxy fatty acids)						
Carbon source	C6	C7	C8	C9	C10	C11	C12
Hexanoate	95		5				
Heptanoate		100

Recently, it was shown that MCL PHAs can be produced by specific recombinant *E. coli* strains that are deficient in fatty acid *β*-oxidation and in addition contain the PHA polymerase-encoding gene of *P. aeroginosa* or *P. oleovorans* (130,131). The recombinant strains were cultured on LB medium or mineral salt medium supplemented with yeast extract and alkanoates as additional carbon source. Up to 21% PHA per cell dry weight could be achieved by these recombinant *E. coli* strains.

Recovery

Recovery procedures for MCL PHA resemble those originally developed for the production of PHB. A number of solvent extraction processes have been assessed to separate MCL PHAs from biomass. These usually involve the use of a chlorinated solvent such as chloroform (111) or methylene chloride. An alternative, nonsolvent-based extraction process was developed as well to make the overall production process more attractive (132,133). The biomass is separated from the medium by centrifugation, and treated with a protease cocktail and a detergent to solubilize all cell components. Removal of the solubilized cell material and concentration of the resulting PHA suspension is achieved by cross-flow microfiltration. The submicrometer MCL PHA granules display a density close to that of water (58), as a result of which a MCL PHA suspension does not settle (134); in fact, it forms a highly stable polymer latex. The overall purity of the latex amounts to 95%. MCL PHAs produced for applications that require higher purity, like those in biomedicine, must be further purified by extraction of PHA from the latex using methylene chloride and subsequent precipitation in a methanol–water mixture.

The applicability of MCL PHA as a latex product has been evaluated by Marchessault et al. (135). A typical latex product would be a coating. Unlike that reported for PHB and its derivatives (135), additional treatments (e.g., heat, solvent vapor) to enhance coalescence into a film are not necessary, because MCL PHA does not readily crystallize. Heat, UV, or electron beam sources have been applied to cross-link polymer chains and fix the film. Mcl-PHA coat-

ings are transparent with good clarity and exhibit excellent barrier properties to water.

Properties of MCL PHAs

Owing to their enzymatic synthesis, as is the case for PHB, MCL PHAs have an exceptional stereochemical regularity and therefore are fully isotactic. This allows MCL PHAs to achieve some crystallinity, which can be as high as 25% (136). The molecular weight is of the order of 2×10^5 g/mol (Table 5) (45,112). The glass transition temperature is usually well below room temperature, ranging from −43 °C to −25 °C for MCL PHAs (112). Melting temperatures depend on both the thermal history and the nature of the pendant chain. Values reported vary between 39 °C and 61 °C with MCL PHA, based on *n*-octane or *n*-octanoate (PHO) (112,136,137). The glass transition temperature of PHO is −35 °C (112,138,139). Depending on the thermal history and the test conditions, the tensile modulus varies between 2.5 and 9 MPa, the tensile strength between 6 and 10 MPa, and the maximum elongation between 300 and 450% (138,139). These data classify PHO as a thermoplastic elastomer (136).

Because the low melting temperature and crystallization rate hamper the applicability of MCL PHAs as thermoplasts, cross-linking was anticipated to overcome both limitations (138). Cross-linking was achieved by conventional techniques, namely electron-beam irradiation (138), peroxide cross-linking (140), or vulcanization (141). In all three studies, the presence of olefin groups was shown to enhance chemical cross-linking.

Sufficient cross-linking appeared to prevent polymer crystallization, so a true rubber was produced. Properties were therefore constant over a wide temperature range from the glass transition temperature (T_g, − 30 °C) up to the decomposition temperature (∼180 °C) (138). The rubber modulus could be controlled up to 10 MPa by varying the cross-link density (138). Similar to PHO, maximum elongations amounted to more than 300% for the irradiated material, but other cross-linking techniques produced lower values. Peroxide cross-linking even resulted in a loss of material integrity (140). The tensile strength of the cross-linked material never exceeded 1 MPa and tear resistance was poor (140,141).

BIODEGRADATION

PHAs can be degraded either intracellularly by intracellular depolymerases of the accumulating strain, to supply accumulated carbon and energy in the absence of a suitable exogenous sources (43), or extracellularly by extracellular depolymerases for consumption of oligomers or monomers by fungi, yeast, and bacteria. Relatively little is known about intracellular degradation of PHAs. It was shown that intracellular PHA depolymerases are unable to hydrolyze extracellular PHAs, and extracellular depolymerases cannot hydrolyze intracellular granules (142), apparently as the result of differences in the physical structures of the completely amorphous intracellular granules and the partially crystallized extracellular PHA. Under sterile or aseptic conditions, PHA is degraded by a hydrolytic mechanism, especially at high pH and high temperature (143,144). This type of degradation is important for medical applications, such as the use of PHA in drug release carriers or surgical sutures.

Because PHAs are so abundant, a wide range of bacteria and fungi have developed the capability to utilize PHAs (145). It has been shown that PHA degradation occurs in a large variety of complex ecosystems, including oxic and anoxic environments such as soil, seawater, or sludge. Microbiological parameters of the ecosystem, like population density, microbial diversity, microbial activity, and spatial distribution of microorganisms, can influence the degradation of the polymers. Furthermore, physicochemical parameters of the ecosystem, such as temperature, pH, water content, oxygen content, redox potential, and nutrient supply, can all affect biodegradation. The polymer itself influences biodegradability as well. The most important factors are (*1*) the stereoregularity, (*2*) the crystallinity, (*3*) the molecular mass, and (*4*) the monomeric composition of the polymer. Finally, material processing can also affect the extent of biodegradability.

The effect of different environments on the degradation rate of PHB and PHB/HV has been studied by different groups (146–154). It was shown that the polymer (1-mm molding) was completely degraded after 6 weeks in anaerobic sewage, after 75 weeks in soil, and after 350 weeks in seawater. Concerning functional MCL PHAs, it could be shown that even after cross-linking of unsaturated side chains the polymer remained biodegradable (138). However, it should be noted that at higher cross-link densities the rate of degradation was reduced.

Eleven groups of PHA-degrading bacteria can be distinguished by their substrate (PHA) specificities (155). In addition, 95 genera of fungi capable of degrading PHAs have been identified (155). The synthesis of PHA depolymerases is highly regulated. Most PHA-degrading bacteria repress depolymerase synthesis in the presence of a soluble carbon source that permits high growth rates. However, after exhaustion of the nutrients, the synthesis of depolymerase is derepressed (156,157).

Table 5. Physical Characteristics of Saturated and Unsaturated MCL Polyhydroxyalkanoates Isolated from *Pseudomonas* Strains

Strain	Substrate	Mw	Mn	Mw/Mn	T_g (°C)	T_m (°C)	Reference
P. oleovorans	*n*-Octane	178,000	99,000	1.8	−36.5	58.5	112
P. oleovorans	*n*-Octene	242,000	101,000	2.4	−36.6	—	112
P. putida KT2442	Oleic acid	140,000	70,000	1.9	ND	ND	96
Pseudomonas sp. NCIMB40135	Glucose	143,000	61,900	2.32	<−60	54.8	115

Note: Mw, weight-average molecular weight; Mn, absolute number of average molecular weight; ND, not determined.

The extracellular PHA depolymerases of many bacteria have been purified and characterized. Depending on the depolymerase, the hydrolysis products are monomers [e.g., *Comamonas* sp. (156)] or monomers and dimers [e.g., *Pseudomonas fluorescens* (157)] or a mixture of oligomers (monomers to trimers) as in the case of *Alcaligenes faecalis* and *Pseudomonas lemoignei* depolymerases (158). In a second step, the oligomers are hydrolyzed to monomers by oligomer hydrolases (159,160). All PHA depolymerases analyzed so far are specific for polymers that consist of monomers in the (*R*)-configuration. Chemically synthesized poly-(*S*)-hydroxybutyrate is not degraded by PHB depolymerases (161).

Nine bacterial PHA depolymerase genes that encode depolymerases with specificities for SCL PHAs have been cloned and analyzed (Ref. 155 and references cited therein). The enzymes contain a signal peptide (which is cleaved off during passage across the plasma membrane), a large catalytic domain at the N-terminus, a C-terminal substrate-binding domain, and a linking region in between. Three strictly conserved amino acids, namely serine, aspartate, and histidine, constitute the active center of the catalytic domain. The serine is part of the lipase-box motif Gly-X-Ser-X-Gly, which has been found in all known serine hydrolases such as lipases, esterases, amd serine proteases (162). The oxygen atom of the serine side chain is the nucleophile that attacks the ester bond and is supported by the imidazole ring of the histidine. The positive charge of the latter is stabilized by the carboxyl group of the aspartate.

Only one gene that encodes an extracellular MCL PHA depolymerase has been cloned and analyzed so far (157,163). In contrast to most SCL PHA depolymerases, the MCL PHA depolymerase of *P. fluorescens* GK13 consists of two identical subunits, and except for small regions adjacent to the lipase-box motif there are no significant homologies to SCL PHA depolymerases.

APPLICATIONS

PHAs display an unique combination of features. First, in contrast to synthetic polymers, the natural PHAs have the fundamental advantage of being renewable resources not dependent on the supply of petroleum. Second, as described in the previous section, they are genuinely biodegradable, that is, they can be completely metabolized into harmless, naturally occurring molecules. Although complete degradation can easily be achieved, the shelf life of the PHA products is virtually unlimited. Colonization of the hydrophobic surface is an arduous task for the degrading organisms, and thus a high biological activity is a prerequisite for biodegradation. Cheaper biodegradables, such as the starch-based plastics, are available however. Therefore, the most important feature of these polyesters may well be their hydrophobicity, which allows them to surpass carbohydrate-based biodegradable competitors in moisture resistance.

Applications of PHB

As mentioned previously, PHB and its derivates are all highly crystalline materials and therefore possess a high modulus, making them suitable for polypropylene-type applications including injection molding, extrusion blow molding, and fiber-spray gun molding. The polymers can be manufactured into many different materials with a wide range of applications (164). The first commercial application of PHB or PHB/HV, sold under the trade name Biopol™, was in packaging for personal hygiene products, for example, as biodegradable shampoo bottles. Later applications included packing containers, bottles, tubes, wrappings, bags, tubes, and disposable razors. In these cases the rather costly Biopol™ was used for its environmentally friendly image to increase product sales. In addition, applications that require biodegradability for functional reasons were developed. Among those, garbage bags, which should ideally be composted together with their contents, fishing nets, which can cause severe damage once they are lost in the marine environment, and agricultural delivery devices for nutrients, fertilizers, herbicides, and insecticides are important examples.

Applications of MCL PHA

No applications for MCL PHAs have been reported yet. Complementing the intrinsically rigid and brittle properties of PHB and its derivates, MCL PHAs are expected to support applications that require flexibility and elastomeric properties. MCL PHAs will have very limited applicability as thermoplasts. Amorphous MCL PHAs, cross-linked and non-cross-linked, are more likely to penetrate the plastics market (110). The capability of pseudomonads to incorporate many different monomer units into MCL PHAs suggests various possibilities to produce tailor-made polymers. Incorporation of unsaturated pendant groups to enhance cross-linking is one example (138). A recent study reported that nitrophenoxy groups have been introduced, aiming to create chiral polymers for nonlinear optical applications (128). Specific functionalities for surface modification could be introduced as well. In the long run, it should be feasible to custom design new polymers and then program the bacteria to produce them.

PHA Application in Blends and Composites

Polymer blending offers interesting possibilities of preparing inexpensive (biodegradable) materials with useful mechanical properties. In this context, PHAs could form an important source of biodegradable additives. Several blending studies have been performed on PHB or PHB/HV copolymers with other dissimilar compounds. For example, the miscibility and compatibility of these polyesters with chlorinated polymers, polyamides, polycarbonates, cellulose derivatives, and other functional polymers are well documented (85,165). At present, applications of PHAs as commodities are primarily limited by their high cost, and thus attention is being focused on composite products with plastics constituting only a minor part of the product, such as paper coatings like the plastic film moisture barrier in food or drink cartons and in sanitary napkins. In these cases, total product biodegradability can be attained for little extra cost.

Medical Applications

A notable feature of PHB is that it is biocompatible, producing a mild foreign-body response to any implant. Degradation of PHB in vivo is significantly faster than the in vitro hydrolysis in neutral buffer at body temperature, indicating that enzymes present in vivo catalyze the degradation process (166). The only degradation product is (*R*)-3-hydroxybutyric acid, which is a normal mammalian metabolite and is resorbed without metabolic or histological disturbance. Like PHB, MCL PHA might be biocompatible and useful in biomedical applications. The rigid PHB might be useful in bone fracture fixation (167), whereas the flexible elastomeric MCL PHAs might find uses in vascular grafts, surgical swabs, wound dressings, breast prostheses, and other implants (110).

Chiral Synthons

Hydrolysis of PHAs yields chiral (*R*)-3-hydroxy fatty acids, which could be a feedstock for stereospecific synthesis and the associated pharmaceutical industry (27,168). Concerning the enormous number of monomers that have been incorporated into various polymers, many different synthon precursors could be provided by hydrolyzing the polymers.

ECONOMICS

The market price of Biopol when produced by ZENECA BioProducts was about \$16 kg^{-1} (169). Current advances in fermentation and purification technology, as well as the application of metabolic engineering techniques for expanding the spectrum of utilizable substrates and for improving polymer concentration in the cells, are likely to lower the price of PHB to \$4 kg^{-1} (169). A preliminary economic study for the production of mcl-PHAs showed that the price for octanoate-based PHAs would be of the order of \$20 kg^{-1} for an annual production of 1,000 tons (110,132). Optimizing the polymer content of the cells, using cheaper carbon sources as substrates, reducing the chemicals used during downstream processing, and reducing energy consumption is expected to lower the MCL PHA price to a minimum of \$5 kg^{-1} (110,132).

It can be assumed that production of PHAs by using native or recombinant bacteria is in the long term only required for development purposes and for the production of specific functionalized PHAs. It is more likely that efforts in generating transgenic plants for PHA production purposes will succeed in ultimately reducing the price of the polymer to that of other large-scale agromaterials such as starch or conventional commodity plastics, or less than \$1 kg^{-1} (103,170). Therefore, an approach to insert the PHB biosynthesis genes into crop plants (e.g., soybean and rapeseed), which have the agronomic properties to provide high yields of PHB per hectare, has been undertaken by CEREGEN/Monsanto and is currently under way.

OUTLOOK

The development of PHAs as a commercial product remains limited to PHB and its copolymer, PHB/HV. As yet, no applications in the fabrication of articles made of MCL PHAs have been reported. There are probably at least two reasons for this. There has been little material available for development work, and the lower polymer concentration in the cells and the different recovery process means that the material cost of MCL PHA will remain even higher than for PHB for the foreseeable future.

Alternative strategies for PHA production are shown in Figure 8. Future large-scale production of PHB (and MCL PHA) in transgenic plants should ultimately provide a cheaper and sustainable technology for the production of these materials. This advance is essential if PHAs are to be used for commodity purposes and must compete on the plastic market. Improvements in the competitiveness of PHAs on the market could also derive from environmental legislation and from decreasing availability of oil and concomitant rising prices of synthetic plastics.

The development of polymers containing exotic monomers into commercial products will depend on the identification of niche applications that will support the high cost of production arising from both the cost of the monomers used and the small scale of the operation to make these specialty materials. Such applications are likely to include nonlinear optical devices or medical implants of the isotactic polymers, and the use of the stereospecific monomers as chiral synthons for the production of fine chemicals. Furthermore, capsules made of PHA for controlled release of bioactive agents, such as drugs or fertilizers, could find broad application in medicine and agriculture.

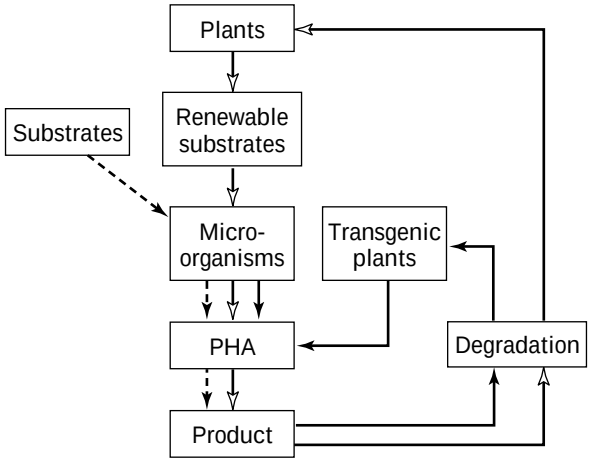

Figure 8. Overview of alternative polyhydroxyalkanoate (PHA) production strategies for different applications. Dependent on the application purpose, three different PHA production strategies can be considered. Bacterial fermentations can be used mainly for production of smaller amounts of functionalized, high-cost PHAs for specialties (- - ▶). Application of renewable sources as sole carbon source in bacterial fermentations or in addition to cosubstrates containing a specific functional group will reduce the price of the product (——▷). Low-cost products with specific properties could be produced by this strategy. Production of inexpensive and biodegradable PHAs for commodities (——▶) will be best achieved by large-scale cultivation of transgenic plants.

OUTLINE

POLY-3-HYDROXYALKANOATES AS BIODEGRADABLE PLASTICS

Microbially produced biodegradable plastics can be divided into four classes: polysaccharides, polymers of amino acids, naturally occurring polyesters, and semisynthetic polyesters (Table 1). All possess linkages that are susceptible to nonspecific, extracellular, microbial enzymes that exist in nature and thus are inherently environmentally degradable. Their structures can be used as the basis for the design of synthetic biodegradable polymers. Unlike many common synthetic plastics, those microbially produced are often at least partially water soluble or tend to be easily hydrolyzed, especially at extremes of temperature and pH. These characteristics aid in their biodegradability but greatly limit their use as plastics. Although their properties as plastics may be greatly improved through chemical modification, care must be taken to maintain environmental degradability.

The ideal plastic is durable, biodegradable, recyclable, and produced from renewable resources such as carbohydrates. Poly-3-hydroxyalkanoates (PHAs) are a family of intracellular polyesters produced by a wide variety of microorganisms. They are water insoluble, relatively resistant to aqueous hydrolysis, and readily environmentally degradable. They can be produced from renewable resources, and, although temperature sensitive, they are potentially recyclable. PHAs have mechanical properties similar to those of some common synthetic plastics. Like conventional thermoplastics, PHAs can be recycled with some loss of molecular weight and mechanical properties. Unlike many conventional polymers, PHAs are completely environmentally degradable and will decompose rapidly to CO_2 and H_2O during composting. Degradation has also been demonstrated in soil burial studies and in the marine environment.

PHAs whose polymeric units are predominantly five carbons or fewer are classified as short-chain-length (SCL) PHAs, and all others are referred to as medium-chain-length (MCL) PHAs. Homopolymeric poly-3-hydroxybutyrate (PHB) has properties that are frequently compared to those of polypropylene, except that it is more brittle and its melting temperature is high enough that there may be significant thermal degradation on melt extrusion. Lower-melting, more-flexible PHB can be obtained by annealing or addition of plasticizers. However, copolymers of 3-hydroxybutyrate and 3-hydroxyvalerate (P[HB-co-HV]) and of 3-hydroxybutyrate and 4-hydroxybutyrate (P[3HB-co-4HB]) are more flexible and have lower melting temperatures than PHB, making them more suitable for the manufacture of extruded products. MCL PHAs have even lower melting points and glass transition temperatures; they are tough, rubberlike thermoelastomers, especially after cross-links between the polymer chains have been formed by heat or chemical induction.

PHAs would seem to be ideal biodegradable plastics, but their production is much different from that of conventional plastics. The following sections describe how PHAs may be produced by widely varying methodologies, with details of diverse approaches to PHA fermentation processes and the separation of the polymer from the biomass. Existing commercial processes and future possibilities for PHA production with an emphasis on cost reduction are also discussed.

Table 1. Classes of Microbially Produced Biodegradable Plastics

Class	Linkage	Example	Effects of H_2O at different pH and temperature	Fermentation characteristics
Polysaccharides	Glycosidic	Pullulan	Often soluble or hydrolyzed	High yield, simple separation but cost increases with purity; production limited by O_2 transfer
Polyaminoacids	Peptide	Poly-γ-glutamate	Often soluble or hydrolyzed	Still experimental; separation simple; yield should be high
Polyesters	Ester	Polyhydroxyalkaoates	Not soluble; resistant to hydrolysis	Yield depends on type of polymer and on the process; separation can be expensive
Semisynthetic polymers of organic acids	Ester	Polylactides	Generally not soluble but are hydrolyzed	High yield

THREE ROUTES TO PHA PRODUCTION

Chemical Synthesis

PHB can be produced synthetically from racemic β-butyrolactone, and P(HB-co-HV) is made from a similar mixture of β-butyrolactone and β-valerolactone with triethylaluminum and water as catalyst (1). Although the stereospecificity of the resulting polymer can be controlled to a certain extent by adjusting the ratio of triethylaluminum and water, synthetic PHAs are usually optically inactive and hence only partially biodegradable.

Synthesis in Transgenic Plants

SCL PHA. PHB can be synthesized in plants in which the bacterial reductase and polymerase genes have been introduced. Although virtually all organisms possess the remaining gene in the SCL PHA pathway, coding for 3-ketothiolase, its activity and specificity vary and it may not be present in all eukaryotic organelles. Production is usually increased by cloning the 3-ketothiolase gene with the other two. Although transgenic plants are easily created, productivity remains problematic. The SCL PHA pathway was first cloned into *Arabidopsis thaliana*, the *Escherichia coli* of plant biotechnology (2). The yield was low, 0.1% dry weight, and the plants were stunted. However, granules similar to those found in bacteria were produced. The initial cloning strategy targeted the cytoplasm, and granules were even found in the cell nucleus (Fig. 1). Subsequent work has targeted the plastid, which is also the site of starch and oil synthesis in plants, resulting in increased yields of up to 14% dry weight in the leaves of *A. thaliana*. These plants grew well but were chlorotic, possibly because of large amounts of PHB in the chloroplasts. Present research centers on oil- and starch-producing plants because these are already adapted to have large amounts of storage material in the plastids (3), but other strategies are also being assessed.

MCL PHA. Because of its high melting point and brittle nature, the PHB homopolymer might have limited application even if its production cost in transgenic plants was low. Although SCL PHA copolymers such as P(HV-co-HB) have been synthesized in plants (H. Valentin, personal communication), it is not obvious how the metabolic pathways of plants can be manipulated to maximize their production. It may be easier to produce MCL PHA in plants. Unfortunately progress is limited by a lack of understanding of the link between fatty acid synthesis and MCL PHA synthesis. Nevertheless, small quantities of MCL PHA have recently been produced in recombinant *A. thaliana* (Y. Poirier, personal communication).

Microbial Synthesis

SCL PHA. Many bacterial species accumulate PHB, but PHA copolymers are more commercially valuable. Most PHB-accumulating bacteria will produce P(HB-co-HV) under the appropriate conditions. When propionic acid is supplied during a fermentation process, some of the acid is converted to propionyl-CoA. A portion of this propionyl-CoA is condensed with acetyl-CoA via β-ketothiolase to produce five-carbon monomers; this is the most common pathway of P(HB-co-HV) production. Because acetate is needed for this synthetic route and some propionic acid is decarboxylated before monomer synthesis, usually less than 50% of the monomers will be HV even if a feed of pure propionic is added (i.e., no glucose or acetate). This yield can be increased in *Ralstonia eutropha* (previously *Alcaligenes eutrophus*) by decreasing the dissolved oxygen concentration in the bioreactor during the accumulation phase (4).

High yields of HV are obtained when pentanoic acid is used because pentanoic acid is metabolized directly to L-(3)-hydroxyvaleryl-CoA, which is subsequently racemized (at least in *R. eutropha*) to D-(3)-hydroxyvaleryl-CoA (5). Although some acetate is produced leading to HB monomer formation, PHAs with greater than 90% HV content can be obtained. SCL PHA producers have not been reported to accumulate monomers with side chains longer than C_2 or C_3 but can produce P(3HB-co-4HB) when fed 4-hydroxybutyric acid or 1,4-butanediol. *R. eutrophus* accumulates terpolyesters of 3HB-, 3HV-, and 5HV-monomers when fed a mixture of pentanoic and 5-chloropentanoic acids. Even among SCL-accumulating microorganisms, there may be differences in the PHA synthetic pathway. For example, in *Rhodospirillum rubrum*, L-(+)-3-hydroxybutyrl-CoA is racemized to D-(−)-3-hydroxybutyrl-CoA using enoyl-CoA hydrases that have not been found in *Azotobacter beijerinckii*.

In most SCL PHA–accumulating bacteria, high intracellular levels of reduced nicotinamide adenine dinucleotide (NADH) and acetyl-CoA greatly stimulate the rate of PHA synthesis. Thus, if the growth rate is limited by a nutrient other than the source of carbon and energy, PHA is accumulated in the cell. For this reason, PHA production is usually divided into two phases. In the first phase, balanced growth proceeds with relatively little PHA accumulation. When the concentration of the limiting nutrient in batch culture falls below a critical value, the rate of PHA synthesis increases while synthesis of other cellular components decreases during the second phase. Because cosubstrates such as propionic acid are expensive and can be used for the synthesis of biomass other than PHA, these chemicals are only added during the accumulation phase. This limitation probably results in nonhomogeneity of polymer composition in different PHA granules with some (produced during the growth phase) containing almost exclusively PHB. There is still debate about the existence and importance of monomer turnover in PHA granules. In contrast, carbon and energy limitations increase depolymerase activity, leading to a decrease in cellular PHA content. The control of these biochemical pathways varies greatly among different bacterial species. For example, *Alcaligenes latus* does not require nitrogen or phosphorous limitation; it can accumulate large amounts of PHB during balanced growth (6).

The most important economic considerations are substrate costs, reactor productivity, and separation costs. SCL PHA can be produced from hydrolyzed starch (glucose), lactose (using recombinant *E. coli* on cheese whey), cane or beet molasses (using *Azotobacter vinelandii* or *Al-*

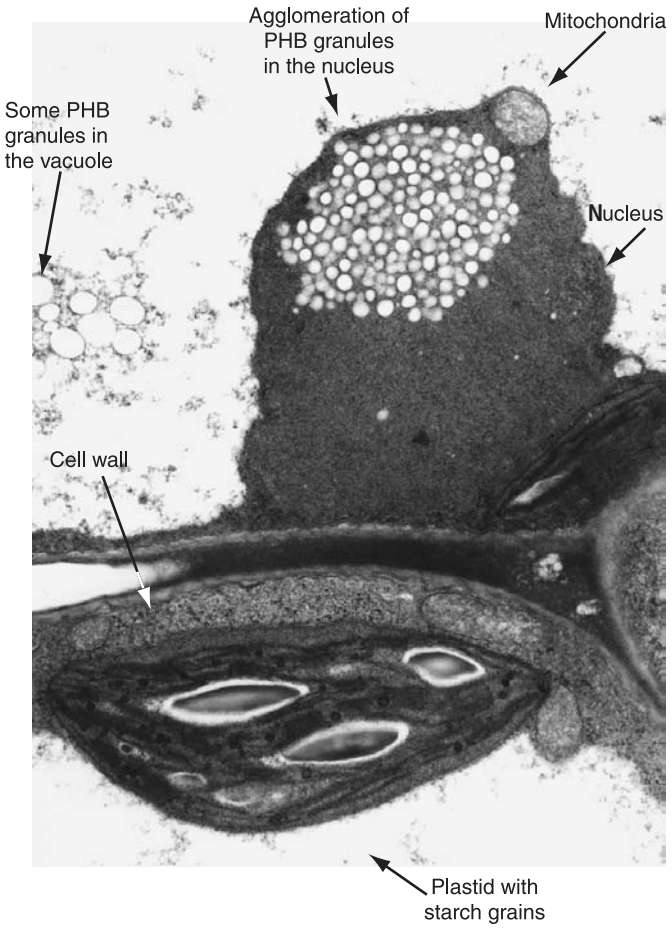

Figure 1. Polyhydroxybutyrate (PHB) granules in *Arabidopsis thaliana* (electron micrograph courtesy of Yves Poirier, Université de Lausanne; Chris Somerville, Carnegie Institute; and Karen Klomparens, Michigan State University).

caligenes latus on sucrose), waste wood (fermented, hydrolyzed hemicellulose), methanol, and even mixtures of hydrogen and carbon dioxide (using *R. eutropha*). Addition of the appropriate cosubstrate such as propionic acid can result in P(HB-co-HV) synthesis in any of these processes although the %HV can vary considerably depending on the bacterial strain. High productivity have been reported for several of these substrates. Using *R. eutropha* growing on glucose, 164 g L^{-1} of biomass containing 76% PHB has been produced in a fed-batch process in only 50 h (7). Densities well in excess of 100 g L^{-1} have been reported for fed-batch processes using *E. coli* strains with multicopy plasmids containing the key SCL PHA synthetic genes (8) as well as for methylotrophs growing on methanol (9). In recombinant *E. coli* strains, PHB content is frequently reported as being in excess of 90% of the biomass dry weight, making the separation process much simpler.

MCL PHA. The highest productivity results from using octanoic or nonanoic acids, but these are toxic at concentrations of several grams per liter and their low solubility limits the growth rate as the result of poor mass transfer. The salts of these acids are much more soluble, but the final product concentration in fed-batch culture is limited by accumulation of toxic concentrations of sodium ions in the medium. In any event, the present cost of both the salts and the acids prohibits their use in commercial production. Most microorganisms that make MCL PHA produce lipases and grow well on vegetable oils. If the lipase concentration limits the production rate, the oils can be chemically hydrolyzed to liberate their fatty acids. A *Pseudomonas putida* strain has been grown in fed-batch culture from oleic acid (a fatty acid commonly found in plant oils) to a biomass concentration of 92 g L^{-1} containing 45% PHA in 26 h (10). If of sufficient low density, these PHAs may float to the surface after breakage of the bacterial cell and can thus be easily and cheaply separated from the rest of the biomass.

SEPARATION OF PHA FROM BIOMASS

General Considerations

All separation processes to date have been developed for microbial rather than plant biomass, but many of these approaches could also be applied to recovery of PHA from plants. As a first step in the recovery from microbial biomass, the cells are separated from the fermentation broth, usually by centrifugation or flocculation. In the latter case, the pH of the fermentation broth is adjusted to 9; it is heated, then the pH is readjusted to 5 (11) and the biomass recovered by centrifugation or filtration. The wet biomass may be freeze- or spray-dried to remove water. Processes to separate the intracellular PHA from the rest of the mi-

crobial biomass may be divided into two categories: *(1)* selective solubilization of PHA in an organic solvent, leaving the majority of the other biomass components in suspension, and *(2)* destruction (i.e., enzymatic solubilization) of cellular components other than PHA, leaving the PHA granules in suspension.

Physical treatments such as drying, heating, freezing and thawing, repeated centrifugation, and exposure to acids and organic solvents change the amorphous nature of native PHA to a semicrystalline state.

Selective Solubilization of PHAs: Solvent Extraction

The majority of the patented separation processes describe the extraction of PHB from microbial biomass using organic solvents such as chlorinated hydrocarbons (e.g., chloroform or 1,2-dichloroethane), azeotropic mixtures (e.g., 1,1,2-trichloroethane with water [12]), chloroform with either methanol, ethanol, acetone, or hexane (13), and cyclic carbonates (e.g., hot [120–150 °C] ethylene carbonate or 1,2-propylene carbonate [14]) in which the polymer is soluble. With the wider variety of PHAs that can be produced today, the choice of solvents should be carefully considered. In general, solvents that are suitable for PHB should be equally good for any SCL PHA and MCL PHA. The reverse may not be true. For example, while semicrystalline PHB is insoluble in acetone, MCL PHA will dissolve in it.

Cells may be pretreated to make the polymer more accessible to the extraction solvent. This may be done by washing in a hydrophilic solvent in which the polymer is insoluble such as methanol or acetone for SCL PHA and methanol for MCL PHA or by means of physical disruption such as grinding, wet-milling, French press, or freezing and thawing cycles. Pretreatment with acetone has been shown to have the added advantage of removing certain polar lipid impurities and increasing the amount of PHB recovered (15). After solvent extraction, the polymer solution is separated from the cellular residue by filtration or centrifugation. PHB is then precipitated from the chlorinated hydrocarbons or azeotropic mixtures with a cold nonsolvent such as methanol. In the case of ethylene carbonate and 1,2-propylene carbonate, most of the PHB precipitates on cooling (14).

Difficulties are encountered at polymer solution concentrations greater than 5% by weight because these concentrations tend to be very viscous. As a result, large amounts of solvent are required to obtain sufficiently dilute solutions to enable easy separation. Even with efficient solvent recovery procedures, some solvent loss is expected. This method is not considered economical as solvent recovery and raw material costs are high. However, solvent extraction is useful when the PHA content of the biomass is low or when high polymer purity is required. A significant portion of the PHB may remain in the biomass after solvent extraction (15).

Although thermal degradation of PHB in air or a nitrogen atmosphere has been well studied (16), few examples show that PHB degrades in organic solvents. The molecular weight of PHB decreased in propylene carbonate and ethylene carbonate at 110–140 °C (14), in a chloroform–methanol mixture at room temperature (17), and in methylene chloride, chloroform, and 1,2-dichloroethane at their boiling points (15).

Although solvent extraction is commercially uneconomical, it is a commonly used laboratory technique for PHA recovery, especially for molecular weight determination. Usually, methanol-pretreated (or ethanol-pretreated), lyophilized biomass is heated in chloroform under reflux conditions for about 1 h, the polymer solution is recovered by filtration or centrifugation, and the polymer is precipitated by cold ethanol or methanol. The polymer may be further purified by redissolving in chloroform and reprecipitating with cold ethanol. It should be noted that about 25% of the original molecular weight (determined by chloroform extraction under ambient conditions) was lost when refluxed in chloroform for 1 h (15).

Solubilization of Cellular Components Other than PHA

Enzymatic Methods. Classical enzymatic treatment (involving lysozyme, proteinases, DNAses, etc.) with or without a surfactant step can be used to solubilize the cellular biomass (18). Biologists have used these methods to prepare native PHB granules to study intracellular enzymatic degradation. On a commercial level, Holmes and Lim (19) described a process in which the fermentation broth may be first heated to 80 °C to denature DNA and some proteins. A series of enzymes (such as lysozyme, phospholipase, lecithinase, or alcalase [proteinase]) are then used to obtain a product that is 90–95% pure with 6–7% proteins and some peptidoglycan as major impurities. There may be a final wash with hydrogen peroxide to make a whiter product. This is the reported method of choice for the current production of P(HB-co-HV) (20), which is sold under the tradename Biopol by Monsanto plc. When PHA granules recovered by enzymatic treatment are freeze-dried, they have a hard, crystalline shell and a noncrystalline core (21).

Chemical Methods. Strong oxidizing agents such as sodium hypochlorite have been used to dissolve the cellular biomass under conditions that result in significant loss of PHA molecular weight. However, by optimizing the operating conditions, PHB with an average molecular weight of 600,000 g/mol and 95% purity has been obtained from *R. eutropha* biomass containing 50% PHB with an initial molecular weight of 1,200,000 g/mol. When the biomass is pretreated with a surfactant, a reduced contact time with hypochlorite is needed to obtain PHB with the same purity. This method allows an even higher molecular weight (800,000 g/mol) to be obtained (22). Never-dried granules obtained by surfactant–hypochlorite treatment also have an external crystalline shell and an amorphous core (23).

Physical Methods. Although there are many methods (e.g., reciprocating pump, ball mill) to physically disrupt microbial cells, few processes that are based on these principles have been proposed for the large-scale recovery of PHAs. Holmes and Jones (24) patented a process in which a biomass suspension was heated to 220 °C under nitrogen in an autoclave, then forced through a fire-jet into a tank

of cold water. Cell breakage occurred, releasing PHB granules, which were suspended in 50% aqueous acetone to remove lipids and to cause flocculation.

COMMERCIAL PRODUCTION

History

PHB remained an academic curiosity until the 1950s and 1960s when W.R. Grace and Co. in the United States produced small quantities for commercial evaluation. They obtained patents for production processes and manufactured articles such as sutures and prosthetic devices (25) but eventually abandoned the project because of low PHB yields and difficulties in the separation process. About 10 years later, Imperial Chemical Industries (ICI) began a program in PHA production and product development. They patented the first commercial process to produce P(HB-co-HV) (26).

Current Production Methods

Tredegar Industries has used recombinant *E. coli* to produce more than 100 g L^{-1} of biomass containing at least 80% PHB by dry weight at the pilot-scale level. Mild detergent treatment and washing steps followed by spray-drying result in a white product that is 98% pure (27).

Fermentation and separation processes were developed for the pilot-scale production of PHB using an *Alcaligenes latus* strain. As much as 1 ton per week of PHB has been produced in Austria in a 15,000-L bioreactor (28). This technology is currently owned by the German company, Biomer. The Biomer fermentation process is relatively simple with multistaging from the petri dish to a shaker flask to a small fermenter, which is then used to inoculate the production reactor (Fig. 2a). If sufficient carbon source (molasses) is added during the fed-batch process, as much as 60 g L^{-1} of PHB may be obtained. The resulting biomass is washed in water. The concentrated cell suspension is then subjected to methylene chloride extraction (Fig. 2b). The resulting slurry is separated in a decanter. The solvent phase is then injected into hot water in a precipitation vessel where the methylene chloride evaporates and the PHB precipitates. After water removal (drying), the PHB can then be processed into a marketable product.

Biopol has been produced by Zeneca from glucose and propionic acid in 35,000-L airlift reactors and in stirred tank reactors up to 200,000 L (29). Monsanto uses conventional stirred-tank fermenters to produce 1,000 tons of Biopol per year. Phosphate limitation (after about 60 h of growth) is used to trigger the accumulation phase in a strain of *R. eutropha*. Phosphate limitation was found to give better results than nitrogen limitation (30). Although solvents (chloroform or methylene chloride extraction after a hot methanol wash) may be used when high purity is required, the P(HB-co-HV) is usually obtained by treatment of the biomass with a series of surfactants, enzymes, and possibly oxidizing agents to dissolve the non-PHA biomass. The product is essentially a latex that may then be washed, spray-dried, compounded with nucleating agents and plasticizers, and extruded in the form of pellets. Several grades of Biopol are available at a cost of about $8 per pound. Based on process development at IPT (Sao Paulo), Copersucar, the Brazilian ethanol cooperative is now using hydrolyzed sucrose and NH_4^+ limitation to produce SCL PHA. these are purified by solvent extraction. Pilot-scale production capacity is currently 30 to 60 tons per annum. Cost savings from the burning of bagasse to supply energy and from cheap cane sugar allow Copersucar to sell PHA for much less than $8 per pound.

PROCESSING TO FINAL PRODUCTS

Conventional equipment used to process polyethylene can be used for Biopol to form blow-molded, injection-molded, and film products. A key requirement is temperature control. It is recommended to operate at the lowest possible temperature and to keep the residence time at a minimum because the melting point of PHB is about 178 °C and its degradation temperature begins at 180 °C. The melting point of the copolymers decreases as the HV content increases, which allows HV copolymers to be processed at lower temperatures with less risk of thermal degradation. Plasticized high-HV Biopol can have a melting point as low as 136 °C. For most applications, Monsanto suggests processing at a maximum temperature of 170 °C and a maximum residence time of 3 min, and that molds and blow-pin temperatures be kept at 60 ± 5 °C (31). Mechanical properties deteriorate rapidly if the average molecular weight falls below 400,000 g mol^{-1}.

PHAs are moisture resistant and have gas barrier properties similar to the best coated films, so that they have potential use in products which require a plastic moisture barrier. Possible markets include mulch films, food and agricultural packaging, drink cartons, feminine hygiene products, disposable diapers, and disposable kitchen items such as plastic films that are difficult to separate for recycling. Coatings may be applied with PHA as an amorphous latex, which can be reconstituted from the crystalline form of the polymer or obtained directly from a bacterial suspension by dissolving the other cellular macromolecules (cell wall components, DNA, etc.). In the latter case, it is important that the granules are not dried before use as they would become crystalline. The latex may be applied as a spray to a material such as paper, dried, and cross-linked using heat or ultraviolet light. The MCL PHAs are promising as coatings because they are less crystalline than the SCL PHAs (in their crystalline state), and the microorganisms that synthesize them can introduce different functional groups on the molecule to make specific polymers (32,33).

The mechanical properties, morphology, biodegradability, and thermal and crystallization behavior of PHAs blended with nonbiodegradable polymers (such as polyvinyl acetate) and with biodegradable materials (such as wood cellulose fibers and starch) have been reviewed (34). In general, immiscible blends or blends with other biodegradable polymers are more biodegradable than miscible blends or blends with a nondegradable polymer.

FUTURE PROSPECTS

Economic Considerations

Cost of production is not a major consideration if PHA is to be used exclusively for specialty applications. However, if PHA is to be economically competitive with synthetic plastics, it must be produced on a far larger scale than any other aerobically produced microbial product. An additional problem arises from the fact that PHAs are intracellular products. Thus, the amount that can be produced per cell has physical limitations.

In a typical PHA fermentation process, the cost is divided fairly evenly between substrate cost, capital and operating expenditures in the fermentation process, and the cost of separating the PHA from the microbial biomass. Typically the yield of dry biomass from a hexose sugar such as glucose is about 42% for *R. eutropha*. If the final biomass contains 75% by weight of recoverable PHA, then the yield of PHA from the total amount of substrate supplied is about 32%. Thus, if carbon substrate was available at $500 per metric ton, the cost of the carbon source alone would be $1,560 per metric ton, mak-

ing the product twice as expensive as bulk synthetic plastics.

New methods such as the incorporation of temperature-sensitive plasmids for the production of autolytic enzymes should reduce separation costs. The direct use of PHA-containing bacteria in melt processing (i.e., no separation process apart from water removal) has also been proposed. However, even assuming a negligible cost for the carbon source by using a waste material such as cheese whey permeate, and neglecting the separation costs, studies have shown that PHA produced in bioreactors could not be economically competitive with synthetic bulk plastics in the foreseeable future. The volumetric production rate cannot compete with chemical processes, and this rate is limited by the oxygen transfer rate of present-day bioreactors. New technologies must be developed for commercial PHA production.

New Technologies for the Production of PHA

In vitro synthesis of PHA granules may be commercially feasible. In *R. eutropha*, the maximum rate of PHA synthesis occurs early in the accumulation phase and deteriorates slowly thereafter. One would therefore expect that the maximum amount of PHA accumulation would depend on enzymatic activity or on NADPH or substrate supply. However, the most detailed study on this process points to a physical limitation (30) where polymer synthesis slows to a virtual stop simply because there is no more space available in the cell. If this is indeed the case, then a solution is to produce the polymer outside of the cells as has been achieved previously (35,36). Economic exploitation of this concept would require a source of the biosynthetic enzymes, substrates, NADP, and a method for NADP reduction. This would eliminate separation costs because the product could be used directly as a latex.

It is likely that, in the near future, starch, oilseed, or leguminous plants will be used to produce PHAs. Other plant materials such as cellulose and starch are already used to make plastics or plasticlike materials. Hemicelluloses have been used directly or converted to organic acids for PHA production at a laboratory scale. Thus, any waste from the separation of PHA from plants could be hydrolyzed, fermented to lactic, acetic, and propionic acids, and then fed into bioreactors for the production of specialty PHAs. Polylactides and other polymers of organic acids could be produced in the same plant as could polysaccharides. Plant materials may become a major source of plastic materials in the next century, with PHAs leading the way.

OUTLINE

INTRODUCTION

Industrial-scale biotechnological processes have progressed vigorously over the past decades. Generally speaking, the problems arising from the implementation of these processes are similar to those of more classical industrial processes, and the need for monitoring systems and automatic control to optimize production efficiency, improve product quality, or detect disturbances in process operation is obvious. Nevertheless, automatic control of industrial biotechnological processes is clearly developing very slowly. There are two main reasons for this slow development:

1. The internal working and dynamics of these processes are as yet poorly grasped, and many problems of methodology in modeling remain to be solved. It is difficult to develop models that take into account the numerous factors that can influence the specific bacterial growth rate. The modeling effort is often tedious and requires many experiments to produce a reliable model. Reproducibility of experiments is often uncertain because of the difficulty in obtaining the same environmental conditions. Moreover, because these processes involve living organisms, their dynamic behavior is strongly nonlinear and nonstationary. Model parameters cannot remain constant over a long period; they vary, for example, due to metabolic variations of biomass or to random and unobservable physiological or genetic modifications. It should also be noted that the lack of accuracy of the measurements often leads to identifiability problems.
2. Another essential difficulty lies in the absence, in most cases, of cheap and reliable instrumentation suited to real-time monitoring. To date, the market offers very few sensors capable of providing reliable on-line measurements of the biological and biochemical parameters required to implement high-performance automatic control strategies. The main variables (i.e., biomass, substrate, and synthesis product concentrations) generally need to be determined through laboratory analyses. The cost and duration of the analyses obviously limit the frequency of the measurements.

Figure 1 shows a schematic view of a computer-controlled bioreactor. In the illustrated situation, the influent flow rate is modulated via a control algorithm implemented in the computer. As explained later, the control algorithm combines different informations about the process provided by on-line measurements and some knowledge about the process dynamics. The on-line measurements may undertake some mathematical treatment via software sensors to provide extra information about some key process parameters (such as specific growth rates) and unmeasured variables.

The article is organized as follows. The basic concepts of automatic control of bioprocesses, with a particular emphasis on the notions of optimization, stability, and disturbances, are discussed first. Then I introduce the basic in-

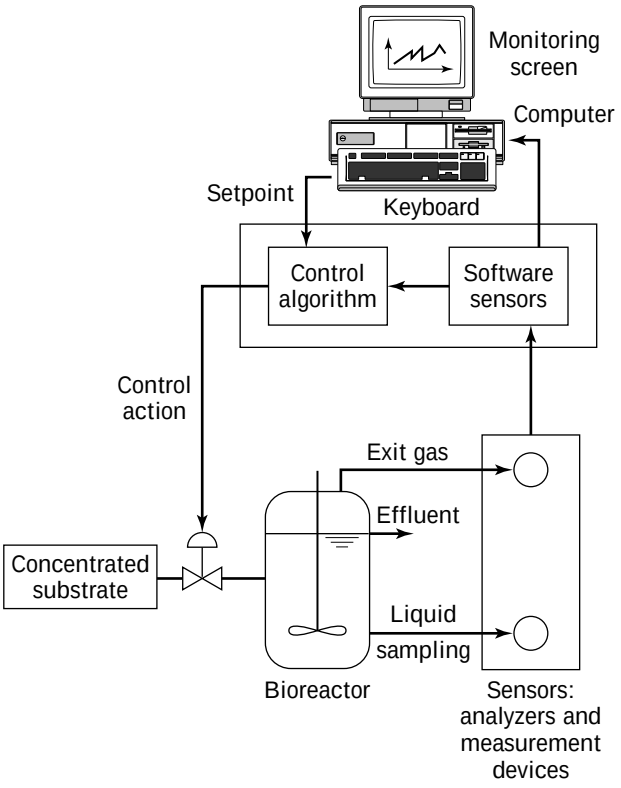

Figure 1. Schematic view of a computer-controlled bioreactor.

gredients of automatic control (dynamical model; feedback; proportional, integral, and feedforward actions), and briefly compare linear and nonlinear control and adaptive and nonadaptive control.

BIOPROCESS CONTROL: BASIC CONCEPTS

The objective of automatic control when applied to any process (including bioprocesses) is to run and maintain the process in stable, optimal operating conditions in spite of disturbances.

Let us first give some more insights about the concepts that are covered by the words *stable*, *optimal*, and *disturbances*. And let us consider the following simple example to illustrate these concepts: a simple microbial growth reaction in a stirred tank reactor. The microbial growth reaction is characterized by the following reaction scheme:

$$S \rightarrow X \tag{1}$$

with S the limiting substrate and X the biomass. Mass balances for both components S and X lead to the following set of dynamic equations:

$$\frac{dS}{dt} = -DS - \frac{1}{Y_{X/S}}\mu X + DS_{\text{in}} \tag{2}$$

$$\frac{dX}{dt} = -DX + \mu X \tag{3}$$

where D is the dilution rate (h^{-1}) (i.e., the ratio of the influent flow rate F_{in}[L/h] over the volume V[L] occupied by the reacting medium in the reactor), $Y_{X/S}$ is the yield coefficient, μ is the specific growth rate (h^{-1}), and S_{in} is the influent substrate concentration (g/L). Note the following:

1. The model is a dynamic model in order to capture the time evolution of the process: this is an essential ingredient of automatic control (discussed in more detail later).
2. The model is valid whether the operation mode is continuous (then the reactor is sometimes called a chemostat or a continuous stirred tank reactor [CSTR]), batch (then D is equal to zero), fed batch (then the volume is not constant and its time variation is given by the following equation: $dV/dt = F_{\text{in}}$).
3. We use the same notation for the components (in reaction scheme 1) and their concentration (in equations 2 and 3).

Let us now consider that the specific growth rate here is of the Haldane type:

$$\mu = \frac{\mu^* S}{K_S + S + S^2/K_I} \tag{4}$$

with K_S is the Monod constant, K_I is the inhibitor constant, and μ^* is a constant connected to the maximum specific growth rate $\mu_{\max}$ as follows:

$$\mu^* = \mu_{\max}\left(1 + 2\sqrt{\frac{K_S}{K_I}}\right) \tag{5}$$

Let us also consider that the objective is to control the process by using the dilution rate D (or, more precisely, the influent flow rate F_{in}) or the influent substrate concentration S_{in} as the control action.

Disturbances

Let us illustrate the notion of disturbances with the preceding example. If the dynamic model (equations 2–4) is assumed to be perfect, and if the dilution rate D is the only manipulated input, then the influent substrate concentration S_{in} is a disturbance: variations of S_{in} will disturb the process by inducing variations in the time evolution of the variables S and X.

Assume now that the dynamic model is not perfect, for example, that some of the parameters μ^*, K_S, and K_I of the Haldane model (equation 4) are changing with time (e.g., due to microorganism adaptation): these variations are also disturbances with regard to the considered process model. Another similar disturbance may come from the presence of a side reaction (e.g., maintenance or microorganism death) that has been neglected in the earlier dynamic model but that may not be negligible under some operating conditions. Then, in case of maintenance, for instance, the true dynamic model of the process is described by equation 3 and the following modified mass balance equation for S:

$$\frac{dS}{dt} = -DS - \frac{1}{Y_{X/S}}\mu X - k_m X + DS_{in} \qquad (6)$$

where k_m is the maintenance coefficient.

Finally, typical disturbances may be due to process failures (e.g., actuator, sensor, or even stirring system). Even if those disturbances are inherently different, it is important to consider all the disturbances that are likely to take place during the process operation when analyzing and testing the performances of a designed controller that has to be implemented on a real bioprocess.

Stability

The notion of stability has been largely considered and studied in dynamic systems and automatic control and has led to different mathematical definitions and tests (see Ref. 1). Here we shall concentrate on Lyapunov stability. Qualitatively the notion of stability can be roughly explained as follows. Let us consider that the process is at some equilibrium point (or steady state). The equilibrium point will be stable if the process does not go far from this state for small deviations. It will be unstable if the variables of the process move away from the equilibrium point and if their variations become larger and larger as time increases. Stability is obviously of vital concern in automatic control: it is essential to design controllers that keep processes in stable conditions on the one hand and that are capable of stabilizing unstable processes on the other hand.

Let us illustrate the concept of stability on the microbial growth example and how to test it. The Haldane model is represented in Figure 2. What we shall now show is that values of the substrate concentration on the left-hand side of the maximum specific growth rate

$$\mu^* \Big/ \left(1 + 2\sqrt{\frac{K_S}{K_I}}\right)$$

correspond to stable equilibrium points, whereas the ones on the right-hand side correspond to unstable equilibrium points.

Equilibrium Points. An equilibrium point is, by definition, a constant state (denoted here $[\bar{S}, \bar{X}]$) that satisfies the equation of the dynamic model, the following algebraic equations in our example:

$$\frac{dS}{dt} = 0 \Rightarrow -\bar{D}\bar{S} - \frac{1}{Y_{X/S}}\mu(\bar{S})\bar{X} + \bar{D}\bar{S}_{in} = 0 \qquad (7)$$

$$\frac{dX}{dt} = 0 \Rightarrow -\bar{D}\bar{X} + \mu(\bar{S})\bar{X} = 0 \qquad (8)$$

for given constant values of $\bar{D}$ and $\bar{S}_{in}$. If we consider the Haldane model (Fig. 2), it is straightforward to check that there are three possible equilibrium points:

1. Operational equilibrium point 1: $\bar{S}_1 \leq \sqrt{K_S K_I}$, $\bar{X}_1 = Y_{X/S}(\bar{S}_{in} - \bar{S}_1)$
2. Operational equilibrium point 2: $\bar{S}_2 > \sqrt{K_S K_I}$, $\bar{X}_2 = Y_{X/S}(\bar{S}_{in} - \bar{S}_2)$
3. Washout equilibrium point: $\bar{X}_3 = 0$, $\bar{S}_3 = \bar{S}_{in}$.

The washout may occur for any value of $\bar{D}$ and $\bar{S}_{in}$. It is also the only possible equilibrium point for $\bar{D} > \mu_{max}$. It is obviously an undesirable steady state. The values of $\bar{S}$ of the last two equilibrium points correspond indeed to the two solutions of the second-order algebraic equation obtained by introducing the Haldane equation (equation 4) into the equilibrium point equation of X (equation 8):

$$\frac{\bar{D}}{K_I}\bar{S}^2 + (\bar{D} - \mu^*)\bar{S} + \bar{D}K_S = 0 \qquad (9)$$

Stability Analysis. For the stability analysis, let us consider the linear approximation of the model (equations 2–4) around the equilibrium points (i.e., the linearized tangent model). Whatever the input u (D, S_{in}, or both), the linearized tangent model around each operational equilibrium point is written as follows:

$$\frac{dx}{dt} = Ax + Bu \qquad (10)$$

where x is the vector of the deviations of S and X from the equilibrium values

$$x = \begin{bmatrix} S - \bar{S} \\ X - \bar{X} \end{bmatrix} \qquad (11)$$

and the matrix A is given by the following expression:

$$A = \begin{bmatrix} 0 & \Omega \\ -\dfrac{1}{Y_{X/S}}\bar{D} & -\dfrac{1}{Y_{X/S}}\Omega - \bar{D} \end{bmatrix} \qquad (12)$$

with

$$\Omega = \frac{\mu^*\bar{X}\left(K_S - \dfrac{\bar{S}^2}{K_I}\right)}{\left(K_S + \bar{S} + \dfrac{S^2}{K_I}\right)^2} \qquad (13)$$

The stability of the equilibrium points is determined by the

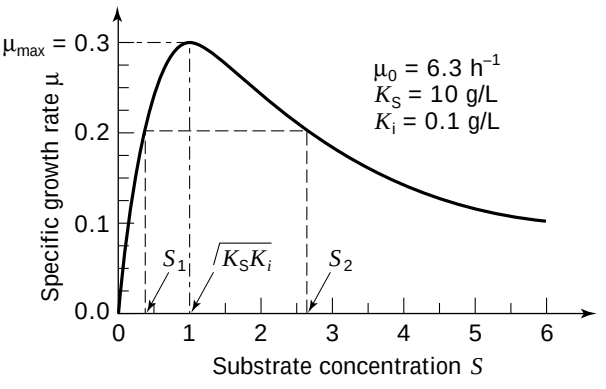

Figure 2. The Haldane model.

eigenvalues of the matrix A: the equilibrium point will be stable if the real parts of all the eigenvalues are negative, it will be unstable if one eigenvalue has a positive real part. In our example, the eigenvalues are equal to $(-\bar{D})$ and $(-1/Y_{X/S}\Omega)$. If the first eigenvalue is always negative, the second one is negative for the first equilibrium point ($\bar{S}_1$, $\bar{X}_1$) and is positive for the second one ($\bar{S}_2$, $\bar{X}_2$). This means that ($\bar{S}_1$, $\bar{X}_1$) is a stable equilibrium point and that ($\bar{S}_2$, $\bar{X}_2$) is an unstable one.

Regulation versus Tracking

Two typical situations are usually considered in automatic control: constant setpoint control (regulation) and trajectory tracking. Regulation is typical of the control of continuous reactors, where the objective is usually to maintain the process in an a priori chosen steady state despite the disturbances. But in many instances, such as in batch and fed-batch reactors but also for start-up of reactors and in case of production grade changes, regulation is not appropriate: the objective is then to drive the process from some initial state to some final desired state by following some predetermined trajectory. In the simple microbial growth example, if we consider a fed-batch reactor and if the objective is to optimize the production of biomass, then an optimal trajectory is an "exponential" profile for X: the controller must then be designed so as to maintain the process as close as possible to the optimal profile.

Optimization

The optimal conditions in which the controller is supposed to run the bioprocess are typically defined so as to optimize production efficiency, improve product quality, or improve the economic profit of the plant. Optimization is obviously a helpful tool for determining the optimal operating conditions. Static optimization techniques can be used for the determination of optimal constant setpoints, whereas dynamic optimal control techniques will be useful for determining the best operating profile.

It must be stressed, however, that the results obtained via optimization have to be handled with great care. The reason lies in the high sensitivity of the optimization techniques on the quality of the process model (including the model structure, i.e., its equations, and the precision on the values of the parameters of the chosen model). Indeed the models used for describing the dynamics of bioprocesses (often mainly more specifically the kinetics) are typically characterized by a large uncertainty (as already mentioned).

Let us illustrate these ideas with our simple microbial growth example with Haldane kinetics. Assume that only the substrate concentration S is accessible for on-line measurement (and will therefore be used for feedback control) and that the objective is to maximize the production of biomass X.

In a CSTR, the objective is to operate the process in a steady state that maximizes the productivity (i.e., the quantity of biomass per unit time). This means that the objective function is

$$J = \bar{D}\bar{X} \tag{14}$$

The solution of the optimization requires the knowledge of the process model in steady state (equations 4, 7, and 8) (equality constraints), as well as (physical) inequality constraints on the process variables

$$0 \le \bar{S} \le \bar{S}_{in},\ 0 \le \bar{X} \le Y_{X/S}\bar{S}_{in} \tag{15}$$

The value of the substrate concentration that maximizes J

$$J = \bar{D}\bar{X} = \frac{\mu^*\bar{S}}{K_S + S + S^2/K_I} Y_{X/S}(\bar{S}_{in} - \bar{S}) \tag{16}$$

is obtained by calculating the derivative of J with respect to $\bar{S}$ and by setting its value to zero

$$\frac{dJ}{dS} = 0 \rightarrow \bar{S}_{optimal} = \frac{-K_S K_I + K_I\sqrt{K_S^2 + \bar{S}_{in}(\bar{S}_{in} + K_I)}}{S_{in} + K_I} \tag{17}$$

and then by checking that the sign of the second-order derivative is negative (to have a maximum):

$$\frac{d^2J}{dS^2}(\bar{S}_{optimal}) < 0 \Rightarrow \bar{S}_{optimal} \text{ is a maximum} \tag{18}$$

and that the inequality constraints are fulfilled. This optimization problem was originally treated by D'ans et al. (2). (Indeed there is another value of $\bar{S}$ for which dJ/dS is equal to zero, but it is negative and therefore obviously rejected.)

In a fed-batch reactor, the optimization problem is somewhat different. Assume that the time of the fed-batch reactor operation is fixed. Then the objective is to obtain the highest value possible at the end of the fermentation. The objective function is then

$$J = X(t_f)V(t_f) \tag{19}$$

Intuitively, it is obvious that the optimum will be obtained when the biomass is produced at its maximum production rate, that is, if the value of substrate concentration is kept at the value that maximizes the specific growth rate

$$S_{optimal} = \sqrt{K_S K_I}$$

This result can be formally obtained as follows by considering optimal control theory.

The general problem of optimal control is to find an optimal trajectory of the control input $u(t)$ that drives the process from its initial state to its final state and at the same time minimizes a cost function

$$J = g[x(t_f),\ t_f] + \int_{t_0}^{t_f} h[x(t),\ u(t),\ t]dt \tag{20}$$

where x is the state vector, t_0 and t_f are the initial and final

time, respectively, and the process dynamics are described by the following ordinary differential equation:

$$\frac{dx}{dt} = f[x(t), u(t), y] \tag{21}$$

and the input $u(t)$ obeys the following practical constraints:

$$U_{\min} \leq u(t) \leq U_{\max} \tag{22}$$

The optimal control solution is based on the Hamiltonian H:

$$H \triangleq \lambda(t)^{\mathrm{T}}(f_1(x) + b(x)u) = \varphi + \psi u \tag{23}$$

where λ represents the adjoint variables, or costates. They are the solution of the following differential equation:

$$\frac{d\lambda}{dt} = \frac{\partial H}{\partial x} \tag{24}$$

For time-invariant systems linear in the input

$$\frac{dx}{dt} = f_1(x) + b(x)u \tag{25}$$

and the cost function J without integral term ($J = g[x(t_f), t_f]$), it can be shown that the optimal control has the following form:

$$u(t) = U_{\min} \quad \text{if } \psi < 0 \tag{26}$$

$$= U_{\max} \quad \text{if } \psi > 0 \tag{27}$$

$$= u_{\text{sing}} \quad \text{if } \psi = 0 \tag{28}$$

The optimal control solution consisting of applying only $U_{\min}$ and $U_{\max}$ is called bang-bang control. The so-called singular control input u_{sing} is obtained by computing the first- and second-order time derivatives of ψ and equating them to zero.

In our fed-batch reactor example, assume that the control input is F_{in}. The dynamics of the process are given by equations 2 and 3 plus the volume equation ($dV/dt = F_{\text{in}}$) and a Haldane specific growth rate model (equation 4). Then the Hamiltonian H is given by the following expression:

$$H = \lambda_1\left(-\frac{F_{\text{in}}}{V} S - \frac{1}{Y_{X/S}} \mu X + \frac{F_{\text{in}}}{V} S_{\text{in}}\right) + \lambda_2\left(-\frac{F_{\text{in}}}{V} X + \mu X\right) + \lambda_3 F_{\text{in}} \tag{29}$$

It is routine to check that $d\psi/dt = 0$ if $\partial\mu/\partial S = 0$ (i.e., u_{sing} corresponds to the value that maximizes μ). If we choose the initial value of the substrate concentration $S(t_0)$ corresponding to the one that maximizes μ

$$(S(t_0) = \sqrt{K_S K_I})$$

the optimal trajectory is obtained by applying the singular control input from t_0 to t_f; that is,

$$F_{\text{in,sing}} = \frac{\mu^* X V \sqrt{K_S K_I}}{Y_{X/S}(2K_S + \sqrt{K_S K_I})(S_{\text{in}} - \sqrt{K_S K_I})} \tag{30}$$

with X and V computed via the mass balance equations:

$$\frac{dX}{dt} = \frac{\mu_{\max}\sqrt{K_S K_I}}{2K_S + \sqrt{K_S K_I}} X - \frac{F_{\text{in}}}{V} X \tag{31}$$

$$\frac{dV}{dt} = F_{\text{in}} \tag{32}$$

Figure 3 illustrates the high sensitivity of optimal control to modeling errors in numerical simulation. We have considered the fed-batch example with the following model parameter and initial values:

$$\mu^* = 5\text{h}^{-1},\ K_S = 10 \text{ g/L},\ K_I = 0.1 \text{ g/L},\ Y_{X/S} = 1 \tag{33}$$

$$S(0) = 0.9 \text{ g/L},\ X(0) = 0.1 \text{ g/L},\ V(0) = 10 \text{ L},\ V(t_f) = 20 \text{ L},\ S_{\text{in}} = 10 \text{ g/L} \tag{34}$$

We have also considered the optimal control when 10% error is made on the value that maximizes μ; that is, the operator believes that the optimal substrate concentration is equal to 9 (instead of 10) g/L. This has been done by setting the saturation constant K_S to 8.1 (instead of 10) g/L in the optimal control law (equation 30). Note that even in the presence of a reasonable model error, the optimal control is moving far away from the optimal substrate concentration.

Let us mention among the large body of scientific literature on optimization and optimal control the following references: Ref. 3, which the treats the optimization of chemical processes, and Ref. 4, which covers the essential items of the optimal control of bioprocesses and treats it then in an original manner.

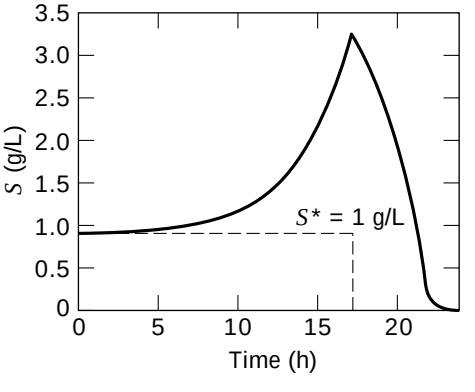

Figure 3. Sensitivity of the optimal control of a fed-batch reactor to modeling errors.

BIOPROCESS CONTROL: BASIC INGREDIENTS

Dynamic Model

The first essential basic ingredient for the design of automatic control algorithms is a dynamic model of the process. The need of dynamic models for the control design is motivated by the intrinsic need to handle transients for transferring the process from one state to another or from one setpoint to another, for following a desired trajectory, or for rejecting or reducing the effect of disturbances. In the latter, disturbances influence the dynamic behavior of the process: knowledge of the process dynamics, and in particular of the dynamic effect of the disturbance, is helpful in selecting the appropriate strategy to reduce and possibly reject their negative influence on the process operation.

The dynamic models to be considered for control design can take different forms. The preceding sections suggest that the most obvious model forms are the mass balance models. But many other forms are possible, including linear models deduced, for example, by linearization of the mass balance models or by identification from input–output data (e.g., Ref. 5) (such models are also called black-box models). The input–output models may be nonlinear; neural network models are presently a quite popular version of nonlinear black-box models (e.g., Ref. 6). A possibly attractive form of dynamic models of bioprocesses are hybrid models, which are an intermediate form between mass balance and neural network models (e.g., Ref. 7). In the following, mainly for conciseness and pedagogical reasons, we concentrate on mass balance models.

Feedback

Another essential basic ingredient of automatic control is the introduction of a feedback loop: On-line (real-time) information about the process (typically on-line measurement of the variable to be controlled) is provided to the controller, which then provides the control action to the process. The concept of feedback loop is illustrated in Figure 4.

Proportional Action

Most feedback control algorithms (except very simple controllers such as on-off controllers) modulate the amplitude of the control action proportionally to the control error (i.e., the difference between the desired value of the controlled variable and its measured value), which is known as the proportional action.

Integral Action

The proportional action is usually not sufficient to guarantee a control error equal to zero in steady state: this motivates the introduction in the control scheme of an integral action (i.e., a term proportional to the integral of the control error).

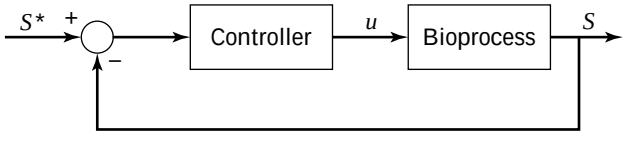

Figure 4. Feedback loop for the control of S in a bioprocess.

Feedforward Action

If the effects of a disturbance on the bioprocess dynamics are known, the controller may be designed by also incorporating a feedforward action to anticipate the possibly negative effects of the disturbance. We shall illustrate in the following how to incorporate feedforward action when the influent substrate concentration S_{in} is a measured disturbance.

Linear versus Nonlinear Control

The controller can be designed on the basis of either a linear or nonlinear model of the process. As earlier, let us illustrate the design with a simple example: the control of the substrate concentration S by acting on the dilution rate D (or more precisely the influent flow rate F_{in}) in a stirred tank reactor with a simple microbial growth reaction.

Let us start with the first option: linear control. The control design is based on a linear model of the process (e.g., the linearized tangent model [equations 10 and 11] around some steady state $[\bar{S}, \bar{X}, \bar{D}, \bar{S}_{in}]$. If we consider the control of S at a prescribed value S^* (e.g., equal to $\bar{S}$), a linear proportional integral (PI) regulator will then typically have the following form (see, e.g., Ref. 8):

$$D = \bar{D} + K_P\left[(S^* - S) + \frac{1}{\tau_i}\int_0^t (S^* - S(\tau))d\tau\right], \quad K_P > 0,\ \tau_i > 0 \qquad (35)$$

where K_P is the controller gain and τ_i is the integral time, or reset time.

Indeed a similar PI regulator can be computed on the basis of a nonlinear model of the process (e.g., the mass balance equation of the substrate concentration S) (2). The control algorithm will then be written as follows:

$$D = \frac{C_1(S^* - S) + C_2\int_0^t (S^* - S(\tau))d\tau - k_1\mu X}{S_{in} - S}, \quad C_1 > 0,\ C_2 > 0 \qquad (36)$$

The preceding controller equation could have been obtained by combining the mass balance equation, equation 2, with the following desired closed-loop second-order dynamic equation:

$$\frac{d(S^* - S)}{dt} = -C_1(S^* - S) - C_2\int_0^t (S^* - S(\tau))d\tau \qquad (37)$$

for S^* constant. (Indeed by differentiating equation 37 once with respect to time, one obtains the usual second-order linear equation $d^2x/dt^2 + C_1 dx/dt + C_2 x = 0$ with $x = S^* - S$.) In simple terms, equation 37 imposes that if at some time instant the substrate concentration S is different from its desired value S^*, the controller will force S

to converge to S^* with a rate determined by the design parameters C_1 and C_2.

Let us present at this point the advantages and drawbacks of the approaches introduced. Before doing so, it is important to note that the second algorithm (equation 36) is more sophisticated than the first one (equation 35). In particular, the second controller requires the knowledge (on-line measurement) of the biomass concentration X and of the influent substrate concentration S_{in} and the knowledge of the specific growth rate model. When comparing both approaches, it is important to keep these differences in mind.

Linear Control. The linear controller, if it is correctly tuned (see, e.g., Ref. 8 for tuning rules), will most probably do a good job if it is used for regulation around a steady state. It also has the advantage to be easily implemented via standard industrial PI regulators. However, its performance (in particular, its transient performance) might be degrading if the process is moving away from the steady state for which it has been calibrated and tuned. This typically happens for start-up and grade changes in CSTRs and might be even more critical for batch and fed-batch reactors in which the process state typically follows large variations (just think of the "exponential" growth of the biomass in this type of reactor). This is illustrated in Figure 5, where the PI regulation of S has been numerically simulated with the same model as in Figure 3 and under the following conditions:

$$S^* = 1 \text{ g/L}, K_p = 2, \tau_i = 0.5, S(0) = 0 \text{ g/L} \quad (38)$$

The values of the design parameters of the PI have been chosen so as to correspond to a closed-loop dynamics close to the mean open-loop dynamics. We note that the controller gain is too high at the beginning (and induce large variations of the controlled output S) and then too small (the controller is not able to maintain the controlled output S to its desired value during the second part of the "exponential" growth phase).

Nonlinear Control. The main advantage of the nonlinear controllers is directly related to the mentioned drawback of the linear controllers: if correctly designed and tuned, it will be able to handle a larger spectrum of the operating domain of the bioprocess. In the example, the main source of nonlinearity is the term $k_1\mu X$. The presence of this term in the controller is particularly important in the control of fed-batch reactors; as pointed out by Axelsson (9), the integration of a term that characterizes the "exponential" biomass growth is a key factor for the efficiency of the control action. The other term, $S_{in} - S$, also plays an important role; if S_{in} is a disturbance in the context of the control of the bioprocess, then this term is indeed a feedforward term that allows anticipation of the effect of variations of S_{in} on the performance of the closed-loop system (process plus controller).

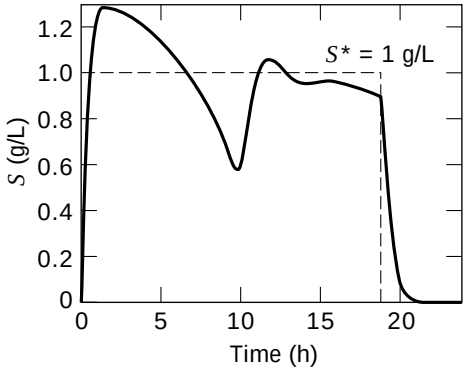

Figure 5. Numerical simulation of a linear proportional integral control of a fed-batch reactor.

However, first the implementation of the control algorithm requires a computer instead of a standard industrial PI (which today can hardly be considered a drawback). Secondly (as for any controller), the performance depends on the quality and reliability of the model on which the design has been based. In other words, in the given example, this means that we assume that the hydrodynamics in the reactor are fairly represented by completely mixed conditions and that the simple growth reaction is largely dominant with regard to possible other side reactions. Besides the implementation as such of the controller, equation 36 requires the values of X and also of S_{in}. In many cases one may expect that if S is measured on-line, it should not be difficult to also measure S_{in} (in many instances, you do not even need to measure it because the influent substrate concentration is known by user's choice). But the situation is usually different for the biomass concentration: very often X is not measured on-line, or, to say it differently, S and X are not often available at the same time for on-line measurement. Finally, the nonlinear controller (equation 36) relies on the knowledge of (the model of) the specific growth rate μ; as suggested previously, this is a major source of uncertainty in bioprocess models.

Adaptive versus Nonadaptive Control

One possible way to handle the previously mentioned difficulties (lack of on-line measurements, uncertainties on the kinetics models) is to use adaptive (linearizing) control (see Ref. 10). In the example, this means that the control law will be implemented by considering on-line estimates of X and μ. An on-line estimate of the biomass concentration can be provided by an asymptotic observer (for a systematic design, see Ref. 10). In our example, it will take the following form. We first define an auxiliary variable Z:

$$Z = S + \frac{1}{Y_{X/S}} X \quad (39)$$

The dynamics of Z are readily derived from the mass balance equations of X and S:

$$\frac{dZ}{dt} = DS_{in} - DZ \quad (40)$$

The on-line estimate $\hat{X}$ of X is then given by computing Z from equation 40 and by rewriting equation 39:

$$\hat{X} = Y_{X/S}(Z - S) \tag{41}$$

or equivalently, one can replace the term $X/Y_{X/S}$ in the controller equation with $Z - S$.

Let us now consider the on-line estimation of μ. Different methods can be used to give an on-line estimate $\hat{\mu}$ of μ. One possible estimator is the observer-based estimator (see Ref. 10), which specializes in our example as follows:

$$\frac{d\hat{S}}{dt} = -\hat{\mu}(Z - S) + DS_{in} - DS + \gamma_1(S - \hat{S}), \gamma_1 > 0 \tag{42}$$

$$\frac{d\hat{\mu}}{dt} = -\gamma_2(S - \hat{S}), \gamma_2 > 0 \tag{43}$$

$\hat{S}$ is an estimate of S whose role is to drive the estimation of the unknown value of the specific growth rate μ on-line; this is achieved by comparing $\hat{S}$ with the measured value S (this is the role of the correction terms $S - \hat{S}$ in equations 42 and 43). γ_1 and γ_2 are design parameters that have to be calibrated to obtain the best on-line estimates (10).

Because the parameter estimation introduces an integral action in the control loop (10,11), the term $C_2\int_0^t(S^* - S(\tau))d\tau$ in the control law (equation 36) is not necessary anymore. Then, in our example, the adaptive linearizing controller is given by the following equation:

$$D = \frac{C_1(S^* - S) - \hat{\mu}(Z - S)}{S_{in} - S}, C_1 > 0 \tag{44}$$

with Z given by equation 40 and $\hat{\mu}$ given by 42 and 43.

Different applications of adaptive linearizing control to bioprocesses have been described (12–15). One of the key features of adaptive linearizing can be illustrated on the basis of the example; it allows incorporation of the well-known characteristics of the process dynamics while keeping the usual features of classical controllers:

- Proportional action via the term $C_1(S^* - S)$
- Integral action via the adaptation mechanism (equations 42 and 43)
- Feedforward action via the presence of S_{in}; the controller is capable of anticipating the effect of a variation of the influent substrate concentration; for instance, an increase of S_{in} results in a decrease of the control input D inversely proportional to this increase.

As for the nonadaptive, nonlinear PI, the controller contains a state estimate via the term $k_1\mu X$ (or more precisely $\hat{\mu}[Z - S]$). If the process is in good working condition, in particular if the biomass is in a good state, then it is possible to treat large amounts of substrate, because the control action D is proportional to X.

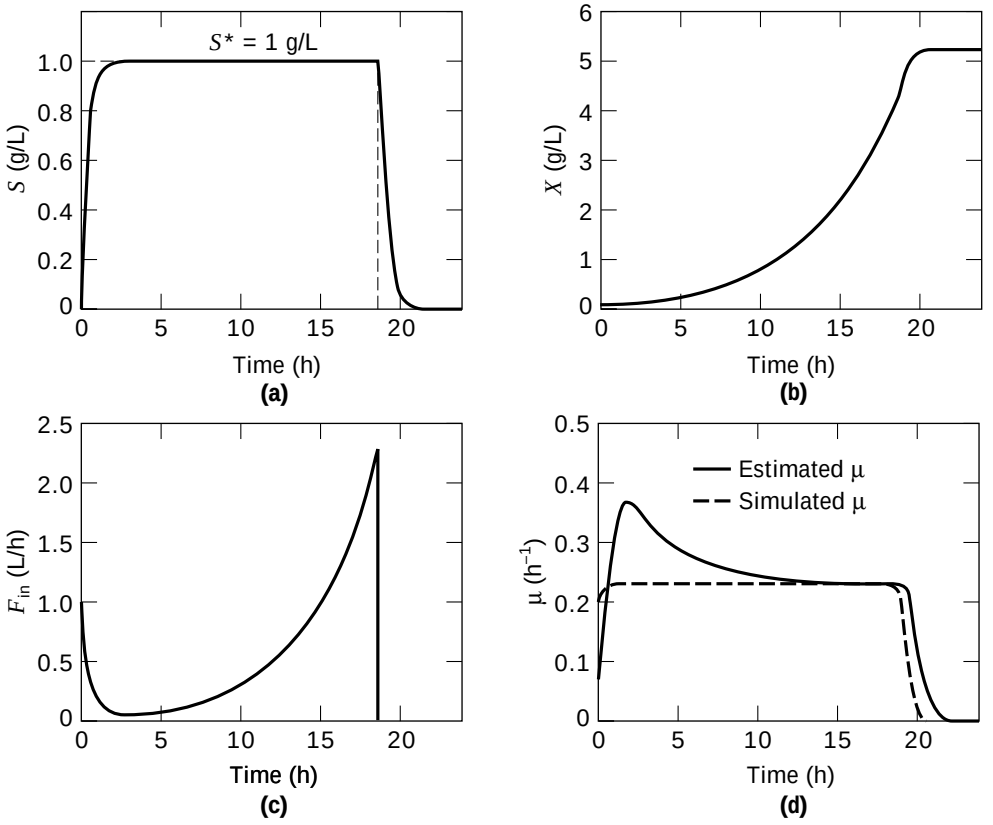

Figure 6. Adaptive linearizing controller of a fed-batch reactor. (**a**) Controlled output S; (**b**) biomass concentration X; (**c**) control input F_{in}; (**d**) specific growth rate μ.

Finally, note that besides the integral action, the estimation of physical parameters (here μ) has the further advantage of giving useful information that can be used for monitoring the process and possibly also for analyzing the internal working of the process.

Figure 6 illustrates the performance in numerical simulation of the adaptive linearizing controller. The same model parameters as in Figures 3 and 5 have been used. The following design parameters and initial values have been considered:

$$S^* = 1 \text{ g/L}, C_1 = 2, \gamma_1 = 5, \gamma_2 = \frac{\lambda_1^2}{4(Z - S)} \quad (45)$$

$$\hat{\mu}(0) = 0.1 \text{ h}^{-1}, \hat{S}(0) = S(0), Z(0) = S(0) + 0.5X(0), S(0) = 0.5 \text{ g/L} \quad (46)$$

The initial value of S has been set to 0.5 g/L, which allows the opportunity to see that the controller has no problem forcing S to converge to its desired value (see Fig. 6a). Figures 6b and 6c exhibit the exponential profile of the biomass X and the control input F_{in}. Finally, Figure 6d gives the on-line estimation of the specific growth rate μ.

Other Approaches

The (adaptive) nonlinear controller presented in the preceding section belongs to a large class of control strategies, often labeled model-based control. This includes control approaches such as model predictive control, in which constraints (such as input constraints) may be handled explicitely in the design (8). We have restricted the presentation to mass balance models, but obviously any dynamic model of the bioprocess (e.g., hybrid model), as long as it is reliable, can be considered in the control design.

CONCLUSIONS

In this article we have first concentrated on the basic concepts of automatic control of bioprocesses, with a particular emphasis on the notions of optimization, stability, and disturbances. In a second step the basic ingredients of automatic control (dynamic model, feedback, proportional, integral, and feedforward actions) have been introduced, and linear and nonlinear control and adaptive and nonadaptive control have been compared.

An appealing avenue for future applications in bioprocesses is an integrated process design approach, which is already largely used in other areas such as aeronautics and that implies the integration of the control strategies in the design of the process from the very beginning (16).

OUTLINE

INTRODUCTION

For most modern industrial production methods, process monitoring plays a key role; bioprocess systems are no exception to this rule. Effective methods of monitoring are required in order to develop, optimize, and maintain biological reactors at maximum efficiently. An optimized process should lead to streamlined performance, reductions in running and material costs, and improvements in quality control.

A number of bioprocess monitoring instruments have been regular features of the industry for many years (Fig. 1), in particular, sensors capable of measuring physical parameters. The challenge is to develop cost-effective devices capable of measuring a much wider range of parameters, providing process operators with a deeper insight into the process. Eventually effective monitoring will lead to better control systems, providing cost and quality benefits.

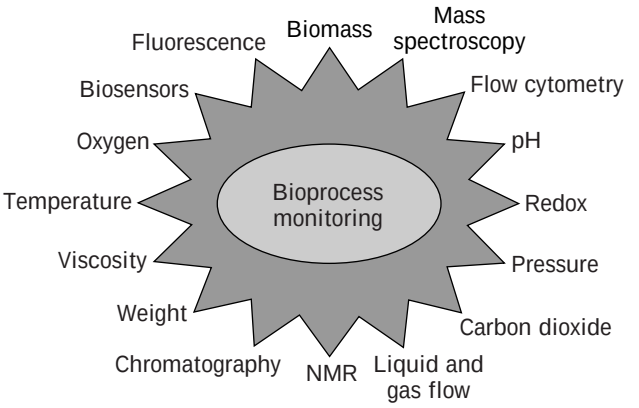

Figure 1. Major areas of bioprocess monitoring.

OPERATING FEATURES

For any measuring technique, there are a number of criteria that the device must satisfy if it is to accepted by commercial bioprocess operators (Fig. 2). The following list of desirable characteristic is not exhaustive, but does cover the main areas of concern.

Reliability

Reliability is a key issue for bioprocess monitoring equipment. Confidence in the ability of an instrument to maintain its credibility in terms of performance is a fundamental parameter. This encompasses a number of features relating to the operation of the instrument, for example, ease of use, maintenance, repair, and replacement. A successful monitoring instrument will have a low failure rate; again, this is related to reliability.

Accuracy

Accuracy can be described as the relationship between the measured value (by the instrument) and the actual value of a bioprocess variable. An accurate instrument will achieve a low percentage error between these two values. Generally this can be stated as

$$\% \text{ error} = (\text{measured value} - \text{true value})/\text{true value} \times 100\%$$

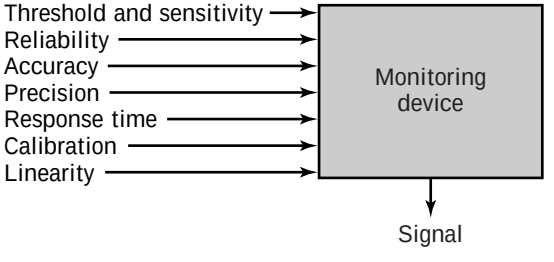

Figure 2. Main criteria for a bioprocess monitoring instrument.

Precision

Precision is a measure of instrument reproducibility, that is, the ability to obtain the same value with repeated measurements of a process variable (at a constant level). It follows that a precise instrument may not, necessarily, be accurate. Therefore it is important to distinguish between these two parameters.

Response time

The measurement of any process variable will entail a time delay between change in the parameter and display of the measured value. This response time should not be detrimental to the progress of the bioprocess, particularly if the measurement is linked to a control action. Response times will be affected not only by the type of instrument but also by the method of measurement. Off-line sampling and measuring can involve a number of time-consuming steps. In contrast, in situ devices can provide a real-time measurement.

Calibration

In order to maintain the accuracy of a sensor it is (generally) desirable to carry out a calibration step. This is carried out using set standards of comparison. The effects of calibration can impinge on the process, in other words, it may be difficult to carry out calibration of an in situ sensor, whereas an on-line device could easily incorporate a calibration step(s) during routine running.

Linearity

Under ideal conditions, the output signal from a sensor would be directly proportional to the analyte concentration. However, this is not always the case, and other models have to be used to reach a true value. Despite this drawback, linearity is not an overriding prerequisite for a successful monitoring instrument. Developments in modern software can be adapted to compensate for nonlinearity.

Threshold and Sensitivity

Sensitivity is the magnitude of the output signal per unit change in the target analyte concentration. The lowest level of detection is related to the sensitivity and the signal-to-noise ratio. A number of factors influence the sensitivity of a monitoring device, including sensor design, the operating environment, periods of maintenance, and interfering noise levels. The sensitivity will influence the dynamic range above which the device becomes saturated; the highest level of detection will be the threshold limit for the device.

METHODS OF MONITORING

In addition to the variety of monitoring devices available, a number of methods (for carrying out the measurement exist (Fig. 3). Sampling and sample handling is a vital issue, affecting both the accuracy and frequency of measurements (1). Broadly, the main approaches to sampling can be described in one of several ways.

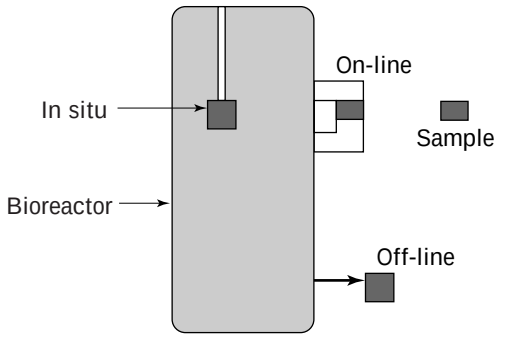

Figure 3. Methods of monitoring.

Off-Line or At-Line Monitoring

Off-line monitoring involves taking a sample from the bioreactor and carrying out the measurement at a different site, usually under laboratory conditions. Off-line sampling can be detrimental in terms of cost, efficiency, and threat to asepsis. Manually removing and measuring a sample requires technical labor. The received signal will not be "real time" because of the delays. In order to obtain the sample, the sterility of the bioreactor must be maintained. Hence, provision must be made to achieve this. In some cases, decentralized equipment has become available that allows measurements to be made simply close to the production process (at-line), reducing some of the delays associated with laboratory analysis.

In Situ or In-Line Monitoring

In situ sensors are placed directly in the bioprocess vessel. The use of in situ sensors has long been established in the bioprocess industry (2), where "dip-in" devices are used to monitor a number of parameters such as pH and dissolved gas concentrations. A number of advantages are gained by operating sensors in this fashion, including real-time monitoring (sampling-related time delays are eliminated) with the sensors operating continuously (any rapid change in the analyte concentration can be readily observed), and labor requirements and problems of contamination are both significantly reduced. However, in situ sensors can have a number of drawbacks, for example, the sensor system must be amenable to sterilization; if the lifetime is short, replacement may be difficult (during a process run); the surface of the sensor could become fouled by components of the growth medium, affecting the signal output.

On-Line Monitoring

Methods of on-line monitoring involve the automatic removal and measurement of sample or sample stream from the bioreactor. One example of this has been the development (since the early 1980s) of flow injection analysis (FIA). This is a liquid handling technique that has proved flexible in adapting to most chemical and biochemical reaction procedures (3), representing an effective compro-

mise between the desirability of in situ monitoring and the technical ease of off-line measurements. The main advantages of on-line methods include the following: sensor sterilization can be readily accomplished, sample pretreatment (e.g., gassing, dilution, removal of interferents), and sensor calibration can be built into the system. The main disadvantages are a need for an effective and reliable sampling system and the fact that the signal is discontinuous; frequency measuring rate is determined by the limitation of the overall FIA arrangement. All of these methods have their advantages and disadvantages. The choice of approach adopted depends on a number of factors, not least of which will be the availability of both sensor and system.

MEASURING DEVICES

pH Measurement

Monitoring the pH of a number of industrial biological reactions is an extremely effective way of determining their course, providing the operator with valuable information. Measuring pH, along with temperature, is one of the most common practices in bioprocess monitoring (4). Correcting action can be taken, either manually or automatically, to prevent unwanted increases or decreases in pH.

The most common form of pH sensor used for fermentation monitoring is based on the electrode design introduced by Ingold in 1947. Under operating conditions, the probe must always be overpressurized (with respect to the fermentation broth) to keep a positive flow of electrolyte out of the porous plug. A combined glass and reference electrode that is capable of withstanding repeated sterilization at temperatures of 121 °C and pressures of 138 kN/m^2 is required. In this case, the term *combined* refers to the single unit containing both electrodes. Figure 4 illustrates the main features of the pH electrode.

Typically, the reference electrodes used are silver/silver chloride (Ag/AgCl) or calomel (Hg/HgCl) and maintained in a concentrated solution of potassium chloride in a buffer solution within the body of the sensor. Under these conditions an equilibrium is established with the electrolyte:

$$Hg/HgCl_2/KCL \rightarrow 2Hg + 2Cl^- \rightarrow Hg_2Cl_2 + 2e^- \quad (1)$$

This leads to a situation whereby the reference electrode potential is dependent on the activity of the chloride ions.

Generally the sensor format is that of a single unit glass-reference design. It has been known since the early years of this century that certain forms of glass are electrically conducting. Furthermore, the electrical potential at the glass-liquid interface changes with activity of hydrogen ions. This potential is directly related to the activity of the H^+ via the Nernst equation,

$$E = E^0 + (RT/\eta F) \ln aH^+ \quad (2)$$

where E is the measured potential, R the gas constant, T the absolute temperature, F the Faraday constant, and ln aH^+ the activity. With this type of pH electrode, the potential determining process is determined by interactions between H^+ activity (in the sample solution) and sianol groups on the glass.

Autoclavable pH probes are available (for sterilization purposes), but this can lead to a reduction in useful probe life. Generally the sensor's response does degenerate over time with repeated use. Interactions with the medium constituents can lead to problems. However, proprietary cleaning agents are available to regenerate the probe. A recent advance in the field of pH monitoring has been the introduction of sensors using ion-selective field effect transistors (ISFETs). These are solid-state devices based on the use of semiconductor structures (5,6). The pH is determined by measuring the change in the voltage required to maintain a zero current between the gate and drain electrode as the transmembrane potential alters. Several commercial companies have marketed ISFET-based pH meters with potential applications in a number of areas. These sensors are robust, virtually shatterproof, and are easily cleaned. In addition, they require no filling solution and are easy to operate and maintain.

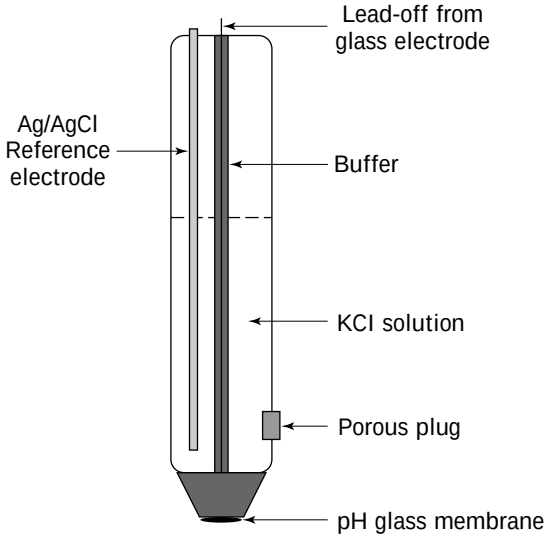

Figure 4. pH electrode.

Temperature

Maintaining optimum conditions for any bioprocess will invariably involve monitoring and controlling the temperature of the broth. Generally, bioprocesses are monitored over a temperature range of between 0 °C and 100 °C (excluding the sterilization cycle). Furthermore, this may require a control regime operating within a narrow range of temperatures. A number of devices are available for obtaining an accurate measurement of temperature conditions during a bioprocess operation, based on a range of techniques.

Thermistors. Thermistors are semiconductor devices composed of agglomerates of polycrystalline metallic oxides (e.g., magnesium oxide, cobalt oxide, ferric oxide). The operating characteristic of these devices relies on a sensitive change in resistance, resulting from temperature fluc-

tuations (7). This change is a function of the absolute temperature. The output response from thermistors is of a nonlinear temperature versus resistance curve, with the resistance decreasing as the temperature increases. Generally the response can be described by the following equation:

$$R(T) = R_0 \exp[B(1/T - 1/T_0)] \quad (3)$$

Thermistors tend to be cheap and stable, with rapid response times.

Resistance Thermometers. Resistance thermometers are based on the changes in the electrical resistance of metallic conductors, with changing temperature (8). This relationship can be described by the following equation:

$$R = R_0(1 + \alpha T) \quad (4)$$

R is resistance. T is the temperature, and α the temperature coefficient of linear expansion.

Platinum is the preferred metal for these devices, but other metals can be used (e.g., nickel, tungsten, or copper). The advantage of platinum is that it can be obtained in a highly pure form, hence the electrical properties of the metal can be well characterized. A platinum wire of 100-Ω resistance at 0 °C is typically used. Generally, calibration of the sensor is carried out at this temperature. Readings can be obtained using a Wheatstone bridge circuit. Overall, these sensors tend to be precise, accurate ($\pm 0.25\%$), reliable, and sensitive. Platinum sensors are stable in both sterilization and fermentation conditions.

Thermocouples. Thermocouples are based on the Seebeck effect, first postulated in 1821. It was noted that a circuit consisting of two dissimilar metals joined together at junctions maintained at different temperatures will generate an electrical current. The electromotive force generated will be determined by the choice of metals and the respective temperatures. For practical applications, one of the junctions (termed the *cold junction*) is maintained at a constant temperature and used as a reference point. The second junction is in contact with the media to be monitored; fluctuations in the temperature can be studied by monitoring the current response (7).

The response (E mV versus T[K]) approximates to a parabolic curve. Generally it is preferable to measure over the linear range of this response. One advantage of thermocouples is that they do not require an external electrical supply. However, they are susceptible to cold junction problems, with the need to maintain a constant temperature.

Mercury-in-Glass Thermometers. Mercury-in-glass thermometers can be used directly in small batch fermenters. However, the fragility and potential toxicity of these thermometers restricts their use. In order to overcome the problem of using mercury, alcohol can be substituted. Generally these sensors are not very accurate (especially over a wide range) and provide only an indication of the temperature. However, these thermometers have the advantage of being both portable and providing a direct reading.

Bimetallic Thermometers. Bimetallic thermometers usually consist of a bimetallic helical coil surrounded by a protective tube or wall. The coil winds or unwinds with changes in temperature and causes movement of a fixed pointer (8). By affixing a pen to the fixed point, a temperature profile of the bioprocess can be obtained. Despite being more robust than the mercury thermometer, they are less accurate (the range determined by the metals used) and, again, are limited to giving only an indication of temperature.

Pressure

Many bioprocesses operate under conditions of overpressure. Monitoring the magnitude of this pressure is an important factor, both in terms of safety and optimization of the process. Industrial and laboratory fermenters are designed to operate up to a safe working pressure. Increasing the applied pressure above the upper limit can be dangerous. Furthermore, maintaining a positive reactor head pressure can prevent contamination of the bioreactor. In order to facilitate effective sterilization, fermenters need an accurate pressure monitor. Pressure will also affect the solubility of gases (such as O_2 and CO_2). Several different approaches have been used in the development of pressure gauges.

Bourdon Tube Pressure Gauge. The Bourdon tube pressure gauge is composed of an arched or spiral-shaped tube. Part of the tube is of an elliptical shape, made of either metal or quartz. Under pressure, the elliptical section tends to become circular. The interior of the tube is influenced by the process pressure, whereas the exterior is under atmospheric pressure. The overall effect of the change in cross-sectional area is to straighten out the curved shape of the tube. One end of the tube is fixed to an inlet from the reactor. The other end is sealed and allowed to move; this is connected (via a geared section and pinion) to an indicator needle (9). Pressure can be read directly from the gauge. These devices tend to be robust and economical.

Strain Gauges. Strain gauges are based on the phenomenon that when a wire is placed under strain, the electrical resistance changes (7). This is due to both the alteration in geometry and resistivity changes. The electrical output can be related to changes in pressure. Typically the sensors are constructed using either a metallic or semiconductor element, usually in a grid structure composed of a number of conductor threads. Generally the change in resistance to pressure can be related by the following equation:

$$\Delta R/R = \Delta L/L + \Delta\rho/\rho - \Delta S/S \quad (5)$$

R is resistance, L is length of thread (a multiple of the number of threads), ρ is the resistivity of the material, and S is the cross-sectional area of the material.

Piezoelectric Manometers. Certain materials, such as quartz crystal, posses an asymmetrical electrical charge distribution. When an alternating electric field is applied

across a piezoelectric material, small mechanical deformations (to the crystal) are generated (10). Alternatively, if the crystal is subjected to pressure on one face, an electrical charge will be generated on the opposite face. This effect (the piezoelectric effect) forms the basis of operation for piezoelectric manometers. By attaching electrodes to one face of the crystal, changes in pressure can be relayed as an electrical output.

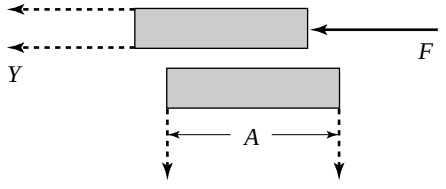
Diaphragm-Type and Pressure Bellows Sensors. Diaphragm-type sensors incorporate a membrane that deforms as a result of pressure from either a liquid or gas, forming a pressure difference across the membrane. This movement can be monitored and a corresponding readout obtained, indicating the pressure of the matter under investigation. Generally, the membranes used can be made from materials such as stainless steel, palladium, or silicon. When in operation, these sensors can suffer from the deposition of material on the surface, leading to erroneous measurements. In order to prevent this, periodic checks should be made.

Pressure bellow sensors operate, as the name implies, by monitoring the movement of a bellows when subject to a pressure. Changes in the bellows extension length can be related to pressure. The bellows can be linked directly to a variable transformer that is capable of recording the physical movement and displaying a readout.

Viscosity

Information on the rheology, or viscosity, can help in ensuring the efficiency of a biological process (11). An example of this would be the effectiveness of oxygen transfer throughout a medium and determining the degree of branching of filamentous microorganisms. In addition, viscosity can effect pumping, mass transfer, and mixing. Viscosity is the apparent shear resistance between adjacent layers of liquids or gases moving at different speeds. Typically, in fluids this is the result of molecular cohesion; rising temperatures lead to a decrease in viscosity. In contrast, viscosity increases for gases under conditions of rising temperature. This results from an increased measured molecular activity.

Newtonian Fluids. Consider two parallel surfaces with area A and distance Y apart. If a shearing force F is applied to one side, it will move with a velocity V:



It is found that for ideal or Newtonian fluids the shear stress $F/A(\tau) = dV/dY$ multiplied by a constant (μ). This constant is called the coefficient of absolute (or dynamic) viscosity. The term dV/dY is called the *shear rate* (γ). Plotting τ against γ gives the flow curve characteristics of a particular fluid. Newtonian fluids display a straight-line response, passing through the intersection of the axis. The slope of this gradient is equal to μ. Typical units of viscosity are Newtons per second per square meter ($NS\ m^{-2}$) and centipoise. Examples of Newtonian fluids include all gases, liquids with low molecular weight (notable exceptions are the colloidal suspensions and polymeric solutions with long molecules, e.g., specially developed mineral oils), water, and some oils.

Non-Newtonian Fluids. Non-Newtonian fluids are classed according to their flow curves, which may be of various shapes according to the nature of the fluid (12). For each fluid the ratio between shear stress and shear rate is not constant.

Bingham Plastic. For these fluids a certain minimum shear (τ^0) is required before viscous flow takes place, after which the relationship is linear. Examples include some fats and plastic melts, some greases, and detergent slurries. Perhaps the best everyday example is toothpaste, a certain amount of pressure must be applied to the tube before the paste begins to flow.

Pseudoplastic Fluids. Apparent viscosity decreases with shear rate, tending to a constant value at high shear rates. This behavior is typical of suspensions of long-shaped particles of high-polymer solutions such as cellulose derivatives. The process has been explained as the result of progressive alignment of particulars or molecules as shear rate increases. Examples include starch suspensions, biological fluids, and rubber solutions.

Dilatant Fluids. In contrast to the pseudoplastic fluids, dilatant fluids display an increasing apparent viscosity with increased shear rate. Examples include sugar solutions, starch, and wet cement aggregates.

Casson Plastic. These fluids display a decreasing apparent viscosity with increasing shear rate after a yield stress (τ^0) value has been exceeded. Examples include blood, printing ink, and some fruit juices.

Generally, bioprocess media display non-Newtonian behavior, that is, a nonlinear response to shear rate. These fluids do not have a constant viscosity, it varies according to the shear rate. In practice, because of the problems of maintaining sterility, most viscosity measurements are made off-line.

There are a number of commercially available instruments (viscometers), applicable to the measurement of bioprocess rheology properties (Fig. 5). Generally, these instruments can be classified into three different types:

1. *Cone and plate viscometer*. This instrument consists of a flat plate in contact with an inverted cone, the fluid to be measured fills the gap between the cone and the plate. In operation, the cone is rotated in the fluid, and the angular velocity and torque are measured. These values can be related to the shear stress and rate.
2. *Coaxial cylinder rotary viscometer*. This instrument consists of two cylinders, one located inside the other. The fluid to be measured fills the gap between the two cylinders. Again, the angular velocity and torque are measured when one of the cylinders is held stationary and the other rotated.

Figure 5. The CVO rheometer (Bohlin Instruments).

3. *Impeller viscometer*. This device is similar to the coaxial cylinder viscometer. However, the fluid measurements are made using a rotating impeller inside the stationary cylinder.

Oxygen

Generally, oxygen measurement falls into two main categories: dissolved oxygen and exit gas analysis. For most aerobic fermentations, an accurate determination of the dissolved oxygen concentration is of particular importance, for example, in maintaining the concentration above a specified minimal level. In addition, oxygen transport processes can be determined only by using an accurate method of measurement.

The exit gas analysis for oxygen, usually in conjunction with CO_2 measurement, can be used to determine the metabolic state of aerobic microorganisms and their oxygen uptake.

Dissolved Oxygen Probes. A wide range of dissolved oxygen probes based on the use of electrochemical determination are available (13). Typically these fall into two main types (14): galvanic (potentiometric) or polarographic (amperometric or Clark). In essence these electrodes measure the activity (or partial pressure) of oxygen present, rather than the concentration. The range covered by these devices is approximately 0.001 to 1000 ppm (15). Both the galvanic and polarographic electrodes use an oxygen-permeable membrane (e.g., Teflon, polyethylene, and polypropylene) to separate the electrode components from the fermentation media. Similarly, the measurement for both types is based on the electrochemical reduction of oxygen at a cathode.

Polarographic Electrodes. The principal components of the polarographic oxygen sensor (16) include a precious metal cathode (e.g., gold or platinum), a silver/silver chloride (Ag/AgCl) anode, and an electrolyte solution (e.g., sodium chloride). During operation the following reactions take place at the respective electrodes:

$$\begin{aligned} \text{Cathode:}\quad & O_2 + 2H_2O + 2e^- \rightarrow H_2O_2 \\ & + 2OH^- \rightarrow H_2O_2 + 2e^- \rightarrow 2OH^- \\ \text{Anode:}\quad & Ag + Cl \rightarrow AgCl + 2OH^- \end{aligned} \tag{6}$$

Typically, polarographic (or amperometric) sensors operate at a fixed voltage, 0.6 to 0.8V, between the two electrodes. This voltage range represents the diffusion-controlled plateau of oxygen reduction. In effect, the current recorded can be directly related to the oxygen concentration.

Galvanic Electrodes. In contrast to the polargraphic oxygen electrode, the galvanic sensor (17) employs a non–noble metal (zinc, lead, or cadmium) anode with a noble metal cathode (silver or gold). The reactions occurring at the electrodes are

$$\begin{aligned} \text{Cathode:}\quad & O_2 + 2H_2O + 4e \rightarrow 4OH^- \\ \text{Anode:}\quad & 2Pb(\text{e.g.}) \rightarrow 2Pb^{2+} + 2e^- \end{aligned} \tag{7}$$

In contrast to the polargraphic sensors, galvanic electrodes require no external voltage source. The combination of a sacrificial anode and noble metal cathode is sufficient to provide an adequate electromotive force, resulting in a spontaneous reduction of oxygen at the electrode.

Despite their differences in operation, both types of electrodes are subject to similar constraints. During steady state, oxygen flux to the cathode is dependent on a number of transport-related steps including movement of oxygen through the bulk of the fermentation media and diffusion across the membrane and through the supporting electrolyte. In relation to the fermentation media, the viscosity and local hydrodynamic characteristics (in the vicinity of the electrode face) will play an important role. An example of this would be the incorrect placing of the electrode in a highly viscous media displaying non-Newtonian characteristics. If the electrode is situated in an area of quiescent fluid, the received signal may not be an accurate representation of oxygen partial pressure throughout the bioreactor.

The design of the sensor will determine its operating characteristics. These include the membrane thickness, the membrane diffusion coefficient, and the surface area of the cathode. Temperature can also have a significant influence on the sensor response. Generally a change in temperature will affect both the solubility and diffusion of oxygen through the membrane. In order to compensate for

these effects a built-in thermistor is generally included in commercial devices.

There are several problems encountered by both types of sensor during bioprocess operations. Fouling of the sensor membrane surface by components of the bioprocess media can lead to erroneous signals. With continued use, this could include the growth of microorganisms on the membrane surface. The effect of a buildup on the membrane would be to change the diffusion characteristics of the sensor (see equation 8). Dissolved oxygen electrodes are also susceptible to signal drift during operation. In addition, gas bubbles and restricted flow toward the sensor can affect the received signal. Other important considerations are the effect of sterilization on the sensor, and calibration. Typically, calibration is carried out after sterilization, using medium gassing to obtain the full range of sensor values. In order to avoid sterilization problems, the sensor can be withdrawn into an isolating lock where it can be sterilized using milder conditions. The actual measurements can be expressed in one of several ways. One approach is to use percent of saturation on a scale of 0 to 100% oxygen saturation. Alternatively partial pressure can be used,

$$pO_2 = (p_{atm} + \Delta p - pH_2O)0.2095 \quad (8)$$

where $(p_{atm} + \Delta p)$ is the absolute pressure and pH_2O is the partial water pressure. Finally a direct concentration can be obtained using Henry's law coefficient:

$$c = pO_2/H \quad (9)$$

The coefficient value is subject to alteration through interactions with media components such as sugars, products, salts, and so forth (18). Hence, these factors must be taken into consideration when determining oxygen concentration.

O_2 Optodes. A recent development for measuring oxygen, and indeed a range of other analytes, has been the introduction of sensors based on the use of photometric transducers: optodes (19). The driving force for the development of these devices was linked to the evolution of immobilization technologies and fiber optics. The optical fibers (used to transmit information over long distances: 2–100 m) can be sited in harsh environments (e.g., high temperature and extremes of pH), allowing in situ real-time monitoring. A fiber is constructed using an optically transparent material called the *core* (this is the guide path for the light) and a cladding, surrounding the core. Light is totally reflected at the cladding-core interface, allowing it to be transported over long distances without significant loss. The light interacts with a sensitive element or layer, generating a signal.

Several spectroscopic techniques have been used in the construction of optodes; of these, fluorescence has been the most widely used in the construction of O_2 sensors. Fluorescence is the emission of light from an absorbing species that has been excited by light of a different wavelength. Optical sensors for oxygen are constructed using an immobilized flurophore that undergoes dynamic quenching. Increasing concentrations of the quencher lead to a decrease in the fluorescence. The relationship between fluorescence intensity and extent of quenching can be summarized as

$$I_0/I = 1 + K_{sv} \times [Q] \quad (10)$$

where I_O and I represent the measured fluorescence intensity in the presence and absence of the quenching agent, K_{sv} the Stern-Volmer proportionality constant, and Q the concentration of the quenching agent (20).

For a number of applications, dyes, whose fluorescent properties depend on the presence of a target analyte (e.g., oxygen), can be used. The dye can be attached directly to the surface of the fiber or onto a membrane. With the most common configuration, where sensing takes place at the end of the fiber light is returned after acting with the sensitive layer. This can occur through the same fiber or through a parallel fiber in a bifurcated device. The magnitude of the interaction is determined at the other end of the fiber using a detector system (21).

These sensors have a number of advantages compared with electrochemically based systems including that they do not require a reference signal, they can be miniaturized, multisignaling from a range of analytes measured at the same time can be achieved, and the fibers can be steam sterilized. Despite these advantages there are a number of drawbacks to these devices, including interferences from ambient light, photobleaching and washout of the sensitive indicator, and the limited range of some devices. A number of fiber-optic-based O_2 optodes have been described, using a range of indicator molecules (e.g., 22,23,24). Their use in measuring oxygen concentrations during bioprocess applications will indubitably become more widespread as the technology develops.

Tubing Methods. An alternative approach to measuring dissolved oxygen content is to use the tubing method described by Philips and Johnson (25). This method is based on the use of a polymeric tubing (e.g., permeable Teflon) immersed in the fermenter media. A stream of helium or nitrogen gas is passed through the coil. Oxygen in the fermenter medium diffuses through the tubing into the carrier gas stream. The oxygen concentration in the inert gas is then determined using a suitable detector, for example, a paramagnetic gas analyser. Despite the longer response times for this method (2 to 10 minutes for a reading) compared with the electrode approach, it is a reliable technique. In addition the tubing is robust and can withstand repeated sterilization cycles.

Exit Gas Analysis. There a number of methods available for determining the oxygen concentration of exit gas from a bioprocess reactor. Several of these are based on exploiting the strong affinity shown by oxygen to a magnetic field. The paramagnetic gases, such as oxygen, display a positive magnetic susceptibility. There are two types of detectors based on this phenomenon: the magnetopneumatic and thermomagnetic analysers.

Magnetodynamical Analyzer. The magnetodynamical analyzer is based on a dumbbell-shaped di-magnet held in

a nonuniform magnetic field (15). The dumbbell structure is free to rotate about an axis. In the presence of oxygen, the dumbbell is rotated (under the action of the increased magnetic force) in proportion to the oxygen partial pressure. By applying a known corrective electrostatic force to return the dumbbell to its original position, the current required can be directly related to the partial pressure.

Thermomagnetic Analyzers. Thermomagnetic analysers (26) are based on the observation that changes in temperature affect magnetic susceptibility (χ). Generally this is described by the Curie law,

$$\chi T = \text{constant} \tag{11}$$

whereby χ is inversely proportional to the absolute temperature. The instrument consists of a flow-through ring element divided up into two measuring chambers. The detection site is composed of a thin-walled glass tube containing resistors that heat the incoming gases. These resistors form part of a Wheatstone bridge circuit and are used to detect changes in resistance resulting from flow-rate variations. When the gas is heated, oxygen loses a high proportion of its magnetic susceptibility. This gas, in turn, is displaced by incoming cool oxygen, generating a convection current or "magnetic wind." The flow of current (or heat transport) causes a change in resistance, imbalancing the Wheatstone bridge. In effect the convection current can be related to the oxygen concentration.

Carbon Dioxide

For many bioprocesses, the measurement of CO_2 is an important feature. Increased levels of dissolved carbon dioxide can inhibit growth and reduce the production of secondary metabolites.

Electrochemical Probe. Steam-sterilizable electrochemical probes for determining dissolved CO_2 partial pressure are commercially available. These function in a similar way to oxygen probes and are based on a pH sensor immersed in a saturated bicarbonate buffer, separated from the bioreactor fluid by a hydrophobic membrane. Dissolved CO_2 gas molecules diffuse from the bioreactor media, through the hydrophobic membrane, into the carbonate buffer. The bicarbonate buffer equilibrates with the dissolved CO_2 gas molecules:

$$\begin{aligned} &CO_2 + H_2O \rightarrow HCO_3^- + H^+ \\ &aH^+ = K(aCO_2)/(aHCO_3) \end{aligned} \tag{12}$$

Here, a is the activity. Hence, increases or decreases in pH can be directly related to the concentration of dissolved CO_2. This logarithmic relationship requires a two-point calibration, which is usually carried out by measuring the pH response, following substitution of the carbonate buffer with a reference solution.

CO_2 Optrodes. Optical sensors for the detection of CO_2 have also been described. Generally, these sensors are analogous to CO_2 electrochemical systems, whereby changes in pH resulting from the formation of bicarbonate ions are detected. One example (27) described the use of a fluorescein dye as a pH indicator. All of the advantages and disadvantages already outlined for the O_2 sensor can be equally applied to these devices. Future developments in this field should lead to a more widespread use of these sensors.

Exit Gas Analysis. With a well-mixed aerobic fermentation, the concentration of dissolved CO_2 can be estimated from analysis of the exit gas. One particularly important approach used for determining the exit gas CO_2 concentration is infrared (IR) analysis. Particular molecules absorb IR radiation at characteristic wavelengths. This absorption is related to the chemical structure of the molecule, that is, the type and number of function groups present. When these molecules absorb IR radiation, the vibrational and rotational states are altered. Observing this absorbance (in either the gas, solid, or liquid phase, or combinations of these), the concentration of the target analyte can be determined (28). In the gas phase, CO_2 absorbs strongly at wavelengths <15 μm. The main components of an IR analyzer (29) consist of a suitable radiation source, a method of selecting the range of wavelengths required, a sample and reference cell, a detector, and a means of displaying the information in terms of CO_2 concentration. Generally, CO_2 is monitored using a positive filtering method. With this method, the optical system detector is filled with CO_2. The system detects the reduced radiation energy of the measuring beam reaching the detector. Comparing the reference and sample responses provides a value for the CO_2 concentration present. One of the main problems encountered with this approach is conflicting absorbance patterns from "interfering" molecules (i.e., those absorbing over the same wavelength range).

Redox Potential

Monitoring the redox potential of a bioprocess medium can provide information about the equilibrium between oxidizing and reducing species (electron acceptors and donors, respectively) present. Measurement of redox potential is achieved using a combined metal-reference electrode system. Typically the metal electrode can be gold, iridium, or platinum; with platinum being the usual choice. The reference electrode is either Ag/AgCl or calomel. The redox sensor is linked to a pH meter that is fitted to provide a readout in millivolts. During operation, the redox potential (measured between the metal and reference electrodes) varies as the logarithm of the ratio of oxidizable and reducible components in the media. The redox value varies linearly with the pH of the media and with the logarithm of dissolved oxygen tension. This can lead to complications when trying to interpret the readout from the sensor. A full description of the use and problems associated with the redox sensor was outlined by Kjaergard (28).

Chromatography

Chromatography has proved to be a valuable tool for numerous applications in diverse areas of analysis. The principle is based the separation of a mixture of compounds by

means of a suitable matrix. Target analytes are separated by their characteristic interaction with the matrix. Following separation, the compounds can be detected using a range of detectors (7) including flame ionization (used for gas chromatography applications), UV detectors, electrochemical detectors, infrared and refractive index detectors, conductivity detectors, and mass spectrometers. A number of chromatographic methods are available, several of which can be used for bioprocess monitoring. Overall chromatographic analysis is carried out off-line. However, recent developments have shown that on-line methods of analysis can be developed.

Liquid Chromatography. For the bioprocess industry, liquid chromatography is used in sample analysis as a preparative method for the large-scale purification of biomolecules and as recovery technique for high-value products such as therapeutics and pharmaceuticals. One important development in this field has been the introduction of high-pressure liquid chromatography (HPLC). This approach to liquid chromatography involves the use of well-characterized homogeneous columns that contain small (3–5 μm-diameter) particles. In operation, these columns can withstand high pressures (up to 6,000 psi). The overall effect is to achieve a fast, accurate separation of the components in a sample. Liquid chromatography permits the separation of a sample solution into consistent components through the interaction of two phases. One type incorporates a solid stationary phase in conjunction with a fluid mobile phase containing the sample of interest. During their passage over the stationary phase, sample components are separated by their degree of solubility or, alternatively, their affinity for the solid matrix. The result is a separation profile indicative of the component mixture of the sample. There are a numerous examples of HPLC systems being used on-line to monitor bioprocess production (e.g., 30,31,32). Typically, on-line monitoring is carried out using a sampling system based on membrane filtration (33,34).

Liquid–Liquid Chromatography. With the liquid–liquid chromatography method, the stationary phase is coated with a suitable fluid. The sample is carried in the liquid phase under pressure. Partitioning between the two liquids leads to a separation of the sample components. Detection of the separated components can be carried out using detectors such as UV absorption, conductivity, or refractive index. Liquid–liquid chromatography can be further divided into normal-phase type, in which the carrier liquid is less polar than the stationary fluid phase, and reverse-phase type, in which the carrier liquid is more polar. The reverse-phase method is particularly useful for separating organic compounds in an aqueous carrier solvent.

Ion Exchange Chromatography. Ion exchange chromatography is used to separate ionic compounds; typically from an aqueous carrier. This approach is particularly suited to measuring low concentrations of ions. The method is based on the ionic interaction between cations or anions in the sample solution, with the corresponding (oppositely charged) functional group on the column matrix.

Gas Chromatography. Gas chromatography (GC) employs gas as the mobile phase and is principally used for separating and measuring the composition of volatile compounds such as aldehydes and alcohols, for example, in a bioreactor headspace. Again, this is a chromatographic approach that has been widely used for bioprocess monitoring. Connected to a suitable sampling system, GC can be used in an on-line format (35,36). An important development in the field of analysis has been the introduction of Fourier transform infrared spectroscopy (FT-IR) instrumentation (37). Combined with chromatography (e.g., GC), this approach can provide a powerful tool for the accurate, sensitive analysis of gas mixtures. This technique will undoubtedly become more important over time.

Gel Filtration. Gel filtration is a method of separation based on molecular size and is carried out using an appropriate polymeric matrix. By selecting the correct pore-size exclusion limit, molecules in a sample solution can be separated. Small molecules, relative to the gel "sieve," pass rapidly through the chromatography column. However, larger molecules diffuse into the polymer matrix, where their passage is impeded. Hence, elution time from the column is determined by molecular size.

Mass Spectrometry

The use of on-line mass spectroscopy (MS) has developed since the first report of Reus et al. (38). A wide range of gasses, both free and dissolved (e.g., CO_2, O_2, CH_4), can be measured. In addition, volatile organic compounds such as methanol, ethanol, acetone, and simple organic acids can be monitored. The technique is based on the rupture of molecules by a high-energy source into corresponding ions. Magnetic separation of the charged ions may then be achieved, based on their mass: charge ratio. Each compound produces a characteristic display pattern. Typically an instrument consists of an electron bombardment source, the magnetic ion separation system, and the detector.

There are several types of mass spectrometer available. The quadrapole MS is based on the use of a radio frequency system to separate the ions. A combination of applied voltage and frequency range produces a change in the trajectory of the ions. The term *quadrapole* comes from the four rods used to produce the radio frequencies. There is an alternative MS instrument that is potentially more precise and stable. This instrument is based on the use of a magnetic field to separate ions. Two types of magnetic instruments are available. One system uses a fixed magnetic field and several detectors. The other uses a variable controlled magnetic field with one detector system.

Mass spectrometers offer a number of advantages for process monitoring including speed, specificity, precision, and stability. The major drawback to the use of mass spectrometers is cost; in addition some peaks can be difficult to resolve using the less elaborate instruments. Despite these drawbacks, MS monitoring of volatile compounds has been widely reported (39,40,41).

Weight

Monitoring fluctuations in the weight of a vessel used for bioprocesses is an effective way of measuring the contents and flow rate of additions. There are a number of load cells available for this task. The principle of a load cell (8) is based on measuring the compressive strain that is placed on the device (e.g., a solid or tubular steel cylinder) when under an axial load. Electrical resistance strain gauges can be included in the device structure. A proportional electrical resistance to the applied load can then be measured; this varies in relation to changes in load. Obviously, a temperature compensator must be included in the instrument to account for heat effects on the resistors. These devices need to be rugged and have long-term stability. For reasons of safety, it is also desirable for the device to be accurate. A load cell designed to detect tensile forces can be used for weight measurements of suspended vessels.

Liquid Level Measurement

Liquid levels in a vessel can be determined using a number of techniques (42). Determining the level can assist in formulating mass balances and measuring nutrient additions. Hydrostatic pressure can be measured using a single sensor positioned at the bottom of the vessel. Alternatively, two sensors spaced at the top and bottom of the vessel (differential design) can be employed. These sensors are electromechanical devices based on the deformation of a spring; the resulting signal is displayed as an electrical signal (capacitance or reactance).

Conductivity Sensors. Conductivity sensors are particularly suited to monitoring levels of foam (in a number of fermentations), where in excess it can cause problems. The sensor consists of a stainless steel probe, insulated except for the tip. The device can be used with noncorrosive conducting fluids. If the liquid or foam level rises to contact with the tip, an electric current is passed through the sensor; the foam acts as an electrolyte and the vessel as a ground. The sensor can be coupled to a control device that dispenses antifoam to counter the increased level.

Capacitance Sensors. Capacitance sensors operate by detecting changes in the relative dielectric constant of the media, compared with air. Measurements are made by detecting variations in electrical capacity brought about by changes in the liquid level.

Acoustic Sensors. Acoustic sensors operate via transducers that generate and detect ultrasonic waves. Two formats are available: a single device that both transmits and receives the signal, and two separate transducers with one function. By monitoring the time it takes for the sound wave to travel, the liquid level can be determined. With the single device the sound wave is directed onto the liquid surface. When the level rises, the time delay is shortened.

Temperature Probes. Liquid levels can be measured using a series of thermistors sited vertically through the vessel. During operation, an electrical current is applied to the sensors, raising their temperature above the ambient. When the liquid (or foam) level reaches a sensor positioned lower down the vessel, the sensor cools. This causes a temperature difference and, hence, a change in electrical resistance. The resistance can be displayed as an output signal indicating the liquid level.

Flow Measurement and Control

Flow measurement is an important feature for many bioprocesses (7), for both gases and liquids. These measurements are carried out on both the influent and effluent streams.

Gas Flow Measurement. The most common form of gas measurement is carried out using a variable area flow meter, or rotameter (7). This device consists of vertically mounted (usually conical) tube enclosing a free-floating body that is able to move up (floating in the gas flow of interest) and down a tapered bore running through the tube body. Typically, the tube is constructed of glass or metal and the float is a ball or hollow thimble shape. Because the position adopted by the flow rate is dependant on both the gas flow and the viscosity of the medium, the instrument requires careful calibration.

Another important instrument is the thermal mass flow meter. The measuring principle is based on the use of a heating device situated in the gas flow, which is used to heat the gas. The mass flow rate can derived from the heat balance,

$$Q = H/C_p(T_2 - T_1) \tag{13}$$

where Q is the mass flow of the gas, H is the enthalpy, C_p is the specific heat of the gas, T_1 is the temperature of the gas before heat is transferred to it, and T_2 is the gas temperature after the transfer of heat. The mass flow detected using this approach is independent of pressure and temperature.

Liquids. A number of techniques are available to measure liquid flow rates (Pons 1991). The choice of method will be determined by the nature of the liquid (e.g., viscosity, conductivity, etc.). For nonsterile liquids, instruments such as the turbine flow meter can be used. Fluid flow over a turbine blade array is proportional to the rotation speed of the turbine, hence a direct correlation can be made.

A common approach to measuring fluid flow in ancillary pipework is to use a differential pressure device, which utilizes the pressure drop caused by a constriction in the pipeline. This approach is based on the general Bernoulli equation for fluid flow. The constriction causes an increase in the velocity of the fluid, which in turn results in a corresponding pressure drop across the constriction. The differential pressure is a function of the flow velocity and density of the fluid. Measurement of the pressure difference can be used to determine fluid velocity.

Measurement of fluid flow under sterile conditions can be carried out using a magnetic-inductive flow meter. This device can operate with a fluid that includes particulate matter in suspension. The outside of the device comprises two windings that, in operation, are supplied with an al-

ternating current. This induces a magnetic field. A pair of electrodes is placed in conjunction with the device. The average flow velocity is proportional to the electrical potential induced in the field. Potential differences in the field are detected by the electrode arrangement. Hence, accurate flow measurements can be made.

Biomass

The monitoring of biomass concentration can be carried out using a number of techniques (43,44). Conventionally, biomass concentration is measured off-line using labor-intensive, time-consuming methods such as dry weight cell, plate or microscopic cell count, and measuring the optical density of diluted samples (45). However, a number of more rapid methods have been developed. Of particular interest is the development of real-time on-line methods. Generally, methods for determining biomass concentration can be divided into two classifications: direct and indirect. The former is based on determining the physical properties of the cell and its components. In contrast, indirect methods measure factors related to the cell and its activity (e.g., respiration, electrochemical behavior, and nutrient fluctuation).

Bioluminescence and Chemiluminescence. The use of bioluminescent techniques is based on determining levels of adenosine triphosphate (ATP) concentration. Generally, levels of ATP remain constant for living cells, decreasing when the cells die. ATP concentration can, therefore, be related to biomass. A particular enzyme that has proved useful for this method is luciferase, which catalyzes the following reaction:

$$\text{ATP} + \text{luciferin} + \text{O}_2 \xrightarrow{\text{luciferase}} \text{oxyluciferin} + \text{AMP} + \text{light} \quad (14)$$

By detecting the light produced by this reaction, ATP concentrations, and hence, biomass, can be determined. This method can detect cell numbers a low as 10^5 cells ml^{-1} (46); it can be automated, and the assay time is fairly rapid (45). However, the method does suffer from several drawbacks, for example, the extraction of ATP may be incomplete, there may be free ATP present from other sources, and there maybe degradation of ATP by the extraction reagents.

Chemiluminescence is based on the detection of light produced by the protein-catalyzed oxidation of luminol in the presence of hydrogen peroxide.

Acoustic Resonance Densitometry. Acoustic resonance density is based on determining the change in a resonant frequency that results from changes in cell density (47). This is a noninvasive method that does not require contact between the instrument and the culture medium. The method incorporates an oscillatory circuit, amplifier, and test cell. Theoretically, the fluid density of the sample can be calculated from the square of its oscillation. Recent reports have described using this approach to monitor cultures of hybridomas and human lymphoma cells (48). Further advantages for this method include independence from flow rate and viscosity. However, there are disadvantages including the need for a filtration system (to enable the resonance density of the medium to be measured in the absence of cells), with the inherent problems associated with such systems, including poor sensitivity and problems caused by bubbles and particulate matter.

Capacitance, Conductivity, and Electrochemical Methods. The electrical properties of cells have been exploited in the development of a number of techniques. Changes in media capacitance have been related to biomass concentration (e.g., a decreasing capacitance coupled with an increasing biomass concentration) (49). In addition, it has been suggested that cell viability is linked to capacitance measurements (50).

Several in situ commercial instruments are currently available for determining biomass concentration based on capacitance measurements. The Biomass Monitor (Aber Instruments, Aberystwyth, U.K.) measures the radio frequency conductance and capacitance of a cell suspension using a constant voltage, four-terminal, phase-sensitive detector system (Figure 6). Furthermore, the probes can be inserted directly into bioreactors using a standard 25-mm-diameter (Ingold-type) port. The probes are fully sterilizable and can be cleaned in situ during operation.

Fluorescence. Fluorescence is a characteristic possessed by a number of important biological compounds including proteins, enzymes, and coenzymes. Simply defined, it is the absorbance of light energy at a particular wavelength, followed by reemission at a longer wavelength. After the passage of light energy, the compound returns to its ground-state level. In the field of bioprocess monitoring, fluorescence has been used, in particular, to monitor reduced nicotinamide adenine dinucleotide (NADH) and reduced nicotinamide adenine dinucleotide phosphate (NADPH) concentrations. These compounds are irradiated at 340 nm and emit at 450 nm. Both compounds are present in living organisms and are vital components of metabolic processes. By monitoring the intensity of fluo-

Figure 6. The Aber Instrument Viable Cell Monitor S20, connected to an Applikon fermenter.

rescence at the characteristic emission wavelength, it should be possible to calculate the total biomass concentration.

Unfortunately, the use of fluorescence as a marker for cell concentration does suffer from a number of drawbacks including that the fluorescence signal can originate from changes in metabolic state and not from cell concentration levels, sensitivity may be affected by the presence of compounds that can quench both the excitation and emission wavelengths, and other compounds may fluoresce at the same wavelength. Nevertheless, the use of this approach has been reported in a number of papers (51,52,53).

Flow Cytometry. Flow cytometry is a measuring technique based on the irradiation of a sample solution (containing a cell population) with a suitable light source, followed by monitoring of the scattered or absorbed light. In addition, fluorescence can be used as the measuring parameter. This technique can be used to ascertain a number of cellular features, such as the accumulation of cellular components (e.g., DNA, RNA, and proteins), and cell dynamics (e.g., cell size distribution). Furthermore, flow cytometry can be used to differentiate and quantify a range of species populations present in a mixed medium.

Light Scattering and Turbidity. Optical techniques based on either the scattering of light (nephelometry) or the degree of transmitted light or optical density (turbidity) have been developed for determining biomass (44). By monitoring the degree of light scattering using nephelometry, both cell numbers and mass can be determined. This approach is particularly suited for bioprocesses that involve low cell concentrations, where the background (compared) level is near zero. Turbidity measurement can be used for both on-line and off-line determination of biomass (54). Light scattering by a turbid medium results from a number of factors including particle size, shape, and number. Quantification is based on the Lambert-Beer law (55).

Biosensors

One possible answer to the problem of monitoring metabolites, both in situ and on-line, may be solved in the near future by the use of biosensors. Since their conception in the 1960s, these devices have generated considerable interest. This has spread to a diverse range of fields including clinical diagnostics, environmental protection, bioprocess monitoring, and defence applications (56). In general the operation of a biosensor is characterized by three functional steps: recognition, physiochemical signal generation, and signal processing. The biological component (e.g., enzyme, whole cell, antibody, and cell receptor) imparts a high degree of selectivity on the biosensor. Coupled to the biological component; the transducer is designed to respond to the changing physicochemical parameters caused by the specific interaction of the biological component with the substrate. A range of transducers have been used in the development of biosensors and include the electrochemical (potentiometric and amperometric), optical, calorimetric, piezoelectric, and thermometric (57). Most of these types have been adopted in the development of biosensors intended for bioprocess monitoring. For a more detailed insight into both the fundamentals and potential for biosensors, a number of specialized publications are available (58). Enzyme-modified field effect transistors (FETs), whereby the biologically active layer is positioned on top of the ion electrode membrane, have also been used for bioprocess monitoring (59).

An off-line biosensor system (Yellow Spring, Inc.) has been available for a number of years (Fig. 7). The instrument can be used to determine a range of metabolites (e.g., glucose, lactate, and ethanol). Recently the company has introduced an on-line instrument. Indeed, on-line biosensor systems have been demonstrated using a variety of biological-transducer systems (60,61). A wide range of metabolites have been monitored using various bioprocess regimes (62). Commercially, a significant number (63) of biosensor devices are available for measuring a range of analytes. However, at present, the majority of these devices are aimed at the medical diagnostic market. The goal is to develop cheap, reliable sensors that can operate under a range of bioprocess conditions for extended periods with a minimum of maintenance.

Nuclear Magnetic Resonance

Nuclear magnetic resonance is based on the detection of the response from particular nuclei when exposed to a

Figure 7. The YSl 2700 biochemistry analyzer.

magnetic field and electromagnetic radiation. Following absorption, the resonance frequency is shifted in a characteristic response pattern, according to the environment of the sample under detection. This approach can be used to determine a range of intracellular factors such as ATP, ADP, sugar phosphate, and polyphosphate, as well as pH. In these examples, concentrations of ^{31}P are used to characterize the compounds. This is an off-line monitoring system that is currently expensive; hence, its use is primarily in the research field, not in routine production environments.

Artificial Intelligence

The data obtained using the various measuring instruments already discussed are invariably used to control and optimize the bioprocess being carried out. Recent developments in the field of artificial intelligence have led to investigations into the use of such systems for improving bioprocess control, based on the received measurement output signals. This has included the use of both knowledge-based expert systems (64,65) and neural networks (e.g., 66,67) during bioprocess operation. A recent report (68) described the successful use of a neural network as a tool for evaluating the received measurement from an enzyme (penicillin-G amidase) pH-FET sensor linked to a flow injection system.

Undoubtedly, the adaptation of such "intelligent" systems will develop over the coming years and will play an important role in the precise control of bioprocess applications.

CONCLUSION

Although a diverse range of monitoring equipment is available, only a relatively narrow range of the more reliable instruments is used routinely in practice. As culture techniques become more elaborate and high-value-added products are produced, conventional methods will either prove insufficient or require supplementation with a range of sensors able to directly monitor key process parameters. Despite a clear demand for new sensors (e.g., lactate, glutamine, and glutamate for animal cell culture), cell cultivation represents only a modest market for analytical instrument manufacturers. Hence, while progress is to be expected, it may be slower than might be wished.

OUTLINE

INTRODUCTION

Process validation for pharmaceuticals has been defined by the U.S. Food and Drug Administration (FDA) as "establishing documented evidence which provides a high degree of assurance that a specific process will consistently produce a product meeting its pre-determined specifications and quality attributes" (1). In spite of the apparent clarity of this definition, pharmaceutical companies vary widely in their approaches to process validation. Operational definitions of process validation are often developed by firms to suit their own validation philosophies. Subcategories of process validation such as formal process validation, process characterization, process development, process evaluation, and the like can result, and the meaning of these phrases is highly specific to a particular company. For the purposes of this article, the term *process validation* refers to any activity consistent with the FDA definition. The discussion that follows is necessarily subjective, and it does not reflect the view of any particular company or the industry at large. Rather, it describes concepts used by those who practice this craft in industry.

This article is concerned with processes that produce the active ingredient in a biopharmaceutical product for use in humans as therapeutics or vaccines. Biopharmaceuticals, protein agents derived from recombinant gene expression or hybridoma production systems, include various biotechnology products such as monoclonal antibodies, enzymes, hormones, soluble receptors, growth factors, and immunogens. Pharmaceutical manufacturing processes are divided into two subprocesses. The primary process produces the bulk biological substance (BBS), also referred to as the active pharmaceutical ingredient (API). The secondary process transforms the BBS into the final product, which is what is actually sold. Secondary processing steps include formulation, sterile filtration, filling, lyophilization (in some cases), capping, and packaging. This article is limited to the validation of the primary processes which produce biopharmaceutical BBS.

Pharmaceutical manufacturers typically classify validation activities into the following broad categories: process validation, equipment and facility validation, cleaning validation, analytical methods validation, and computer validation. Equipment and facility validation is further subdivided into design qualification, installation qualification (IQ), operational qualification (OQ), and performance qualification (PQ). Process validation is viewed by some experts to be an element of PQ.

Process validation is a regulatory requirement to enable product licensure. Limited process validation is also critical for clinical trial materials to ensure product safety. Process validation regulations originated within the FDA, which was created in 1906, initially to prevent the adulteration of products. The sulfanilamide disaster led the Food, Drug, and Cosmetics (FD&C) Act in 1938 to ensure product safety. The thalidomide disaster in 1962 led to the Kefauver–Harris Amendment to the FD&C Act, which required demonstration of product safety and efficacy. It was in this revision that the concept of good manufacturing practices (GMP) originated. In 1978 the act was further revised to include the concepts underlying current GMPs (cGMPs) and good laboratory practices (GLPs). The origins for process validation derive from FDA draft guidelines and workshops that occurred in the late 1970s and early 1980s (2). *Guideline on General Principles of Process Validation* (1), published in 1987, represented the first (and still only) regulatory document focusing on this topic. The definition for *process validation* quoted earlier was taken from this FDA document and has gained wide acceptance by other regulatory agencies around the world. This guidance was specifically intended for the production of finished drug products. Today, the regulatory basis in the United States for process validation is contained within cGMPs for finished pharmaceuticals (drugs) (3). The *Code of Federal Regulations* (21 CFR 211.110 states that "control procedures shall be established to monitor the output and validate the performance of those manufacturing processes that may be responsible for causing variability in the characteristics of in-process material and the drug product." It (21 CFR 211.113) also states that "appropriate written procedures, designed to prevent microbiological contamination of drug products purporting to be sterile, shall be established and followed. Such procedures shall include validation of any sterilization process."

Until recently, these FDA validation requirements and guidelines only applied explicitly to drug products and did not apply to bulk biologics. Nevertheless, there was a trend for these regulatory principles to apply implicitly to areas more broadly than originally defined. There are numerous publications by industrial scientists, but currently no umbrella regulatory document exists on the validation of bulk production processes for biopharmaceuticals. Important aspects to this subject are captured within numerous other regulatory documents that focus on other aspects of manufacturing and control. Table 1 summarizes some of these references. Regulatory requirements that pertain to process validation are changing and are likely to continue to change for the foreseeable future. The most current information on process validation and many other regulatory subjects may be accessed on the Internet (Table 2). Proposals published recently by the FDA pertain to the cGMPs for finished pharmaceuticals and include content on process validation (18). How these proposals will be extended to bulk biological products has become clearer with the recent publication by the FDA of a draft guidance for the manufacturing of APIs (19) and the guidance for submission of the chemistry, manufacturing, and controls (CMC) section of a biologics license application (BLA) for most biopharmaceutical products (20).

In addition to being a regulatory requirement, process validation provides important benefits to the manufacturer. Biopharmaceuticals are among the most expensive products to manufacture, costing hundreds to thousands of dollars per gram to produce. The assurance of process consistency therefore enables a manufacturer to maximize plant productivity and obtain favorable cost efficiency by reducing the incidence of process failures, rejection of lots, and reworking of rejected but salvageable lots. In today's manufacturing environment where plant capacity is closely matched with product demand, unexpected process failures can lead to product shortages, with negative financial and company product image impacts, particularly

for life-saving products. Process validation is a key means to minimize the occurrence of unexpected process failures. Process validation can also provide a manufacturer with operational flexibility to respond to inevitable production problems (e.g., power failures, equipment breakdown, and scheduling conflicts). To the extent that they can be anticipated in the process validation program, ranges can be established for operational parameters that, if maintained, will ensure that the products meet specifications.

These important benefits only accrue after considerable investment because process validation is costly and time consuming. It occupies the full period from producing supplies for the first clinical trial through the start of production in the commercial plant and continues throughout the commercial lifetime of the product. During product development, for example, more resources from process development, operations, quality control, and quality assurance groups can be consumed in validating the process, equipment, and facility than were used to develop the process and to produce clinical supplies. Nevertheless, careful planning and sound scientific strategies make process validation cost effective and meet regulatory requirements.

There are several different classes of process validation. *Clearance validations* demonstrate the capability of a process to remove or inactivate contaminants to and beyond the degree necessary to ensure product safety. Of greatest concern are contaminants that have toxic, pharmacological, or infectious potential in humans. Typical contaminants in biopharmaceutical processes with these potential liabilities include DNA and proteins derived from the recombinant host cell line, certain components of culture media (e.g., methotrexate and other drugs used to maintain selection pressure, insulin, bovine serum albumin, growth factors, and animal-derived components of culture media), viruses derived from the host cell line or raw materials, additives for viral inactivation (e.g., guanidine), and affinity chromatography ligands (e.g., monoclonal antibodies, protein A). *Validation of operating ranges* involves the determination of a range for critical operating parameters through which excursions can occur without affecting the quality of the product. The usage of the term *operating parameters* here is taken very broadly to include not only compositions, temperature, pH, and related factors but also holding times of in-process intermediates, variations in raw materials, cycle limits on multiuse resins, age of

raw materials, and age limit of cells used in the process. *Validation of process consistency* must be established through the characterization of multiple lots of product produced by separate production runs operated and controlled under the same conditions. Each of these classes of validation are described in greater detail in this article.

PROCESS VALIDATION STRATEGY AND DOCUMENTATION

Process validation generally starts after a process is defined in development and evolves with the progression of clinical trials. Process validation for phase I and II trials is limited to addressing potential product safety concerns. Validations for the clearance of model viruses and retroviruses and host cell DNA are sufficient. More extensive validation activities occur in parallel with production of phase II and III clinical supplies and the conducting of the phase II and III clinical studies. At this stage, the virus clearance validations are expanded to include a greater number of model viruses spanning a greater range of virus characteristics. The full range of clearance and operating range validations are undertaken in a pilot plant or development laboratories. Process consistency validation, however, is derived from the pilot and commercial plants. License applications can be filed with consistency data derived from a pilot plant. However, the awarding of a license is contingent on the filing of process and product consistency data derived from a pilot plant or commercial manufacturing facility. In the United States, three qualification lots are usually sufficient; the European Union usually requires five lots. Process validation continues after product launch for the length of time the product is manufactured. Validation maintenance programs often call for revalidation of specific aspects of the process at regular intervals. Trending or control charting of process variables can lead to refinements of operating range limits. Revalidation is also required when the process is modified because of improvement, equipment alterations, raw material changes, process scale-up, substitution of a processing step with an alternate, resequencing process step, and so forth.
