The single bioreactors with a completely mixed biophase analyzed here have an obvious drawback: all of the microorganisms are exposed to the same physicochemical environment, it is the worst possible environment for metabolism, with the lowest nutrient concentrations and the highest concentrations of metabolic products. One consequence appears in Figure 2. Even with no mass transfer resistance ($G = \infty$), no product inhibition ($F = \infty$), and no wastage of biomass ($D = 0$), the analysis suggests that complete contaminant removal is still impossible. With no biomass outflow there is no net cell growth, and all of the contaminant is used for maintenance metabolism (equation 2 with $\mu = D = 0$ gives $q = k$). Under these conditions, the dissolved contaminant concentration is not zero, but the stationary phase concentration, S_s, so the partial pressure in the effluent gas cannot be less than HS_s, and the fractional removal, x, can never exceed $(1 - HS_s/n_i)$, even with perfect mass transfer (equation 4 with $G = \infty$). This maximum removal also exists for completely mixed biological wastewater treatment systems, but in that case it does not matter because S_s is much less than common effluent standards. It may matter for some insoluble gas-phase contaminants because the corresponding minimum-achievable partial pressure, HS_s, may be significant, even when S_s is small. Bioreactors with a completely mixed biophase are a poor choice for such contaminants.

The simplest improvement would be two bioreactors through which the gas flows in series and between which the microbial culture is continuously recirculated. Reactor 1 would have a relatively high effluent partial pressure and dissolved contaminant concentration, providing a good environment for metabolism and cell growth. If the process variables are fixed correctly (a complete analysis is beyond the scope of this chapter) reactor 2 could run with a dissolved concentration $S < S_s$. The biomass in reactor 2 would then be in an endogenous state, but this would no longer matter because fresh, viable cells would be continuously supplied from reactor 1, and the dying cells would either flow back there to recover or be lost in the liquid effluent. The liquid inflow would go to reactor 1, where the growth nutrients are needed, and where it would dilute the concentrations of any metabolic products.

The more bioreactors in series, the better the average physicochemical environment for metabolism. Columns containing many sieve trays or bubble-cap trays have long been used for gas–liquid contacting in the chemical process industry and should be considered for the biological treatment of gases in cases where the biomass grows best in suspension and the contaminant is relatively dilute, insoluble, and a poor microbial substrate (i.e., HS_s/n_i is large). These columns are inherently countercurrent contacting devices with the gas flowing upward while the microbial culture falls down from tray to tray. An individual microorganism experiences a series of environments with ever-increasing dissolved contaminant concentration, S, until it is suddenly pumped back to the top tray where conditions are endogenous ($S < S_s$), but where it can continue metabolizing contaminant and survive long enough to start through the cycle again. Nutrient addition and pH control can be done on each tray as needed, and the liquid effluent can be taken from near the top of the column where cell viability is lowest.

A similar effect, with the gas closer to the theoretical optimum of plug flow, can be achieved in an upflow biotrickling filter with a small liquid recycle ratio. The only drawbacks are that pH control and nutrient addition can now only be done at the top of the bed, and the liquid can only be removed from the bottom, which is not necessarily the best arrangement. If all the microbial cells are suspended, the concentration profiles of viable biomass and contaminant will be as shown in Figure 3d. In real trickle beds some of the biomass remains attached, which is a great advantage over tray columns when a nonvolatile metabolic product is generated, because it allows a large

liquid outflow to remove the product without the danger of washing out the biomass. (Mathematically, D is small because z is small, even though f is large.) Biotrickling filters can also be operated in the gas-downflow, cocurrent mode, which gives concentration profiles (again assuming suspended biomass) more like those shown in Figure 3c. Now, the microorganisms moving down the bed experience an ever-worsening environment for metabolism, with lower S and higher product concentration S_m. They leave the bottom of the bed in an endogenous, low-viability state, which is very suitable for the liquid outflow stream, but which may cause a significant lag phase when cells are recycled to the better environment at the top of the bed. The question of whether the cocurrent mode works better can only be answered definitively by experiments on a particular gas stream.

In biofilters the biophase is far from being completely mixed. It consists of an immobilized mass of up to xXe_b viable cells per unit bioreactor volume (less if cell growth has been limited by some nutrient other than the contaminant), and one of the goals of media selection is to provide sufficient surface area so that these cells can be distributed as a biofilm thin enough to avoid mass transfer limitation due to diffusion through the film. However, simple models (38) suggest that biofilters should share the minimum effluent partial pressure, HS_s, predicted earlier for bioreactors with a completely mixed biophase, because biofilms exposed to any lower partial pressures near the biofilter effluent would be in an endogenous state and eventually die. Experience suggests otherwise, probably because the adsorption of the contaminants on the media increases their effective concentration in the microorganisms' immediate environment. It follows that highly adsorptive support particles, such as compost or activated carbon, will work best, and that biofilters can treat very insoluble, hydrophobic contaminants if they adsorb well.

Scale-Up

First-stage scale-up experiments can be done in a reactor of any size that is convenient or available, as long as it is large enough so that the flows of gas and liquid are not significantly altered by entrance effects, channeling, or wall effects. Ideally, several different bioreactor types or packing materials are studied, but this is not always possible. The objective is to vary the gas flow, g, the liquid flow, f, nutrient addition, Sji, and so on, to determine how the specified contaminant removal can be achieved most economically. The scale-up problem is then to extrapolate the results in order to calculate the necessary volume (volume = gas flow to be treated/g) and shape (specifically the height, L) of the commercial-scale bioreactor, which must satisfy the process requirements without further experimentation immediately after start up. The best combination of process variables found in the experiments must be close to the optimum identified by the point at the right end of the operating region in Figure 2. To preserve this solution at the commercial scale, the dimensionless numbers D, F, and G that define this point must be kept the same between scales. Scaling up a gas treatment bioreactor is thus an example of Reynold's similarity principle, which states that two physical situations are similar only if the all of the relevant dimensionless numbers are identical.

Consider first the case where there is no inhibitory metabolic product and the process needs little or no liquid outflow. $F(\rightarrow\infty)$ and $D(\rightarrow 0)$ both drop from the list of relevant dimensionless numbers, and the scale-up problem reduces to finding combinations of gas flow, g, and bioreactor height, L, that keep G constant between scales. Given a mass-transfer correlation of the form of equation 7, G can be written $ARTL^c/Hg^{(1-c)}$. The problem is illustrated graphically in Figure 4, where lines of constant G are drawn on a log–log plot of g versus L. If the small-scale experiments have found different combinations of g and L that produce the specified contaminant removal, x, then this data should fall on such a line, labeled *empirical* in Figure 4, because the theory suggests that "constant x" implies "constant G." Also shown in Figure 4 is an upper limit on the gas superficial velocity, $U_g = gL$, caused by physical phenomena such as slugging of bubble columns, fluidization of the media in upflow biofilters, or flooding of the impeller in stirred tanks. This limit may be slightly different at different scales. Two extreme cases of the scale-up problem can be identified.

For a biofilter or a biotrickling filter treating sparingly soluble contaminants, the mass-transfer factor is little affected by the gas velocity, implying that $c = 0$ and making the empirical line horizontal. Several important phenomena are lumped into the parameter A, but there is no reason to expect them to vary with scale because microorganisms cannot "know" if they are in a small or large bioreactor. Consequently, performance on the large scale is defined by the same horizontal line, meaning that scale-up is done at constant g, or equivalently at constant gas-residence time ($=1/g$). Because $g = U_g/L$, constant g can be achieved either with a deep bed and a high gas velocity, the right end of the $c = 0$ line in Figure 4, or with a shallow bed and a low velocity, the left end of the line. Although the former are easier and cheaper to build, they have a much higher pressure drop though the bed, meaning higher costs for gas compression and possibly subsequent

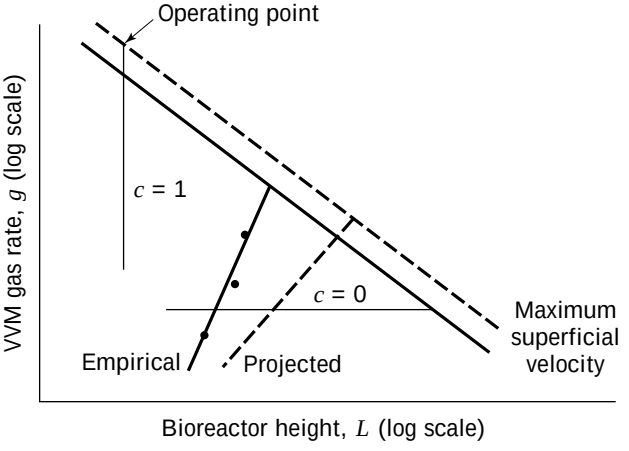

Figure 4. Dotted line, large scale; solid line, small scale.

cooling to return the gas to a temperature tolerable to the microorganisms. The latter are much cheaper to operate and work well as long as the beds are deep enough (at least several hundred times the particle size) to avoid problems of channeling and short-circuiting of the gas flow. Many biofilters consist of shallow beds of media on trays arranged in various configurations in a reactor designed to ensure an even flow of gas into the beds.

At the other extreme is the ideal bubble column described in the section "Gas Biophase Mass Transfer" for which $c = 1$. The value of G, and thus the contaminant removal, is now independent of gas flow but proportional to bioreactor height. Scale-up must therefore be done by keeping L constant but increasing the reactor width, the large-scale bioreactor operating at maximum g in order to minimize its volume (the *operating point* in Figure 4). Although this ideal bubble column is an abstraction, it illustrates a paradox that can arise in scaling up practical bubble columns (for which $c \cong 0.7$); if the desired removal can be achieved in a small-scale column, then a bubble column is probably not the best solution at the commercial scale. For very soluble contaminants, the L needed to obtain the desired fractional removal may be in the range of laboratory reactors, around 1 m. Scale-up would produce a very unusually shaped large-scale bioreactor, a similar height but several meters wide. There would be no point in making it any deeper, except to provide a safety factor in the design, and it could not be made any narrower and still meet the process requirements. For insoluble contaminants the necessary L may be several meters. The conclusion from laboratory experiments would then be that a bubble column is not a feasible bioreactor, even though the desired contaminant removal may be achievable (albeit with a high pressure drop) with the reactor heights used at the commercial scale.

All practical situations fall between these two extremes, so neither simple scale-up rule, constant g or constant L, is necessarily appropriate. The empirical line will have a positive slope, and a similar line for the same G at the larger scale can be projected from it if any variations of the parameters A and c with scale can be estimated from the published literature, experience, consultations with equipment manufacturers, and so on. The design of the large-scale bioreactor can be anywhere along this projected line in Figure 4, the exact design point again being constrained by the maximum U_g line, but essentially an economic trade-off between the large bioreactors demanded by a small g and the large pressure drops associated with a large L. The essential point is that the shape, and the size of the large-scale bioreactor are fixed by this procedure and should not be chosen based simply on guesswork or convenience.

Some bioreactor types allow design flexibility because they have variables that can be adjusted when drawing the projected line. Both A and c tend to decrease with scale in any bubble-gasified reactor due to poorer gas dispersion, but in mechanically agitated tanks, A is a function of the power input per unit volume, which can be varied to some extent. For trickle beds and biofilters, both A and the bed permeability are predictably related to packing size, allowing the packing to be chosen to give the large-scale reactor both a convenient shape and a reasonable pressure drop. Note that, whether or not such changes are made between scales, the estimates on which the projected line in Figure 4 is based should always be conservative in order to provide a factor of safety in the large-scale design.

When product inhibition is significant, the liquid outflow, f, becomes a critical variable, and all three dimensionless numbers D, F, and G must be kept constant if the physicochemical environment of the biomass (S, S_m) and the optimum bioreactor performance established in the small-scale experiments are to be extrapolated to the large scale. An exact solution is possible only when the retention of the biomass by cell immobilization or recycle (the z parameter) can be controlled, although when retention is almost complete ($z \to 0$) only the product DF (from which z cancels) is important, implying that the liquid flow, f, must be kept proportional to the gas flow, g. Biotrickling filters have an extra dimensionless number, the liquid recycle ratio, RR, which introduces the extra difficulty that increasing the bed height, while keeping f and RR constant increases the liquid superficial velocity [$U_l = Lf(1 + RR)$], thus changing the mass-transfer situation and possibly flooding the bed. The procedure just described will not work in these more complex situations (constant x no longer implies constant G), but the general considerations still apply, including the physical limits on the gas superficial velocity, the desirability of tall small-scale bioreactors to reduce uncertainties, the need for compromise between capital and energy costs, and the possibility of predicting a very inconvenient aspect ratio for the large-scale bioreactor. Judgment and calculation are needed in each case because the trivial solution to the scale-up problem—"build a bigger bioreactor with the same shape, f, and g as the small one"—is unlikely to be the best. Gas treatment bioreactors are one of the few devices whose performance tends to improve with scale, but taking advantage of this tendency in practice is not straightforward.

NOMENCLATURE

a	Gas–biophase interfacial area per unit bioreactor volume
A,c	Constants in mass-transfer correlation
D	$zf/e_b Yk$ = dimensionless liquid flow rate
e	Hold-up
f	Liquid outflow rate per unit bioreactor volume
F	$YS'_m/zy_m X$ = dimensionless product-inhibition number
g	Volumetric gas outflow rate per unit bioreactor volume (the VVM gas rate)
G	$k_1 aRT/Hg$ = dimensionless mass-transfer-effectiveness number
h	Gauge pressure (atm) at gas inlet
H	Henry's law constant
k	Cell maintenance coefficient
k_1	Gas-to-biophase mass-transfer coefficient
L	Bioreactor height
n_i	Mole fraction of contaminant in feed gas

p Partial pressure (atm) of contaminant in effluent
q Specific consumption rate of contaminant
R Gas constant
S Dissolved concentration in biophase
S_s Stationary phase contaminant concentration (concentration at which $\mu = 0$)
S'_m Product concentration that totally inhibits metabolism
T Outlet gas temperature
U_g Superficial gas velocity at bioreactor outlet
U_1 Superficial liquid velocity in a trickle bed
X gn_i/ke_bRT = maximum possible cell concentration in biophase
x $1 - p/n_i$ = fractional removal of contaminant
w Evaporation rate per unit bioreactor volume
y Mole of nutrient consumed or product formed per unit of contaminant metabolized
Y Cell-yield coefficient
z Cell concentration in liquid effluent/cell concentration in biophase
γ Available electrons per carbon equivalent of biomass
μ Specific growth rate of biomass

Subscripts

i Inlet conditions
j Any nutrient or product
m Metabolic product
x Biomass

Microalgae mass cultivation
Photobioreactors
Phototrophic microorganisms

OUTLINE

INTRODUCTION

Photobioreactors are bioreactors in which phototrophic microorganisms or plant cells are grown or used to carry out a photobiological reaction. In a broad sense, the open shallow basins used for microalgae cultivation could also be viewed as photobioreactors (1). In this article, however, the term *photobioreactor* is used to indicate only closed systems, that is, reactors that do not allow direct exchange of gases (e.g., CO_2, O_2) or contaminants (dust, microorganisms, etc.) between the culture and the atmosphere.

At present, commercial production of phototrophic microbial biomass is limited to two microalgae (*Dunaliella* and *Chlorella*) and one cyanobacterium *(Arthrospira)*. Mass cultivation of these species is carried out in open ponds by means of a selective environment (high bicarbonate and high pH for *Arthrospira*, high salinity for *Dunaliella*), or by making use of large amounts of inoculum produced under strictly controlled conditions and taking advantage of a high growth rate *(Chlorella)*. Most microalgal species cannot be maintained long enough in outdoor open-culture systems because of contamination by heterotrophic microorganisms (fungi, bacteria, protozoa) and competition by faster-growing microalgae that tend to dominate, regardless of the species used as inoculum. With the few exceptions mentioned earlier, virtually all attempts at mass cultivation of specific species of phototrophs in outdoor open ponds for prolonged periods have failed. An alternative choice is to use photobioreactors, which can provide an environment that is protected from direct fallout, are relatively safe from invasion by competing microorganisms, and in which conditions (pH, pO_2, pCO_2, temperature) can be better controlled so that dominance of the desired species is established for a sufficient period of time.

The use of photobioreactors could extend the exploitation of microbial phototrophs from the few strains commercially grown today to the more than 50,000 known species, many of which are potential sources of high-value products. Examples of such products are specialty lipids (sterols and polyunsaturated fatty acids); antifungal, antibacterial, or antiviral compounds; radioactively or isotopically labeled molecules (such as ^{13}C-labeled glucose and amino acids); vitamins (e.g., vitamin E); pigments (such as β-carotene, astaxanthin, and phycobiliproteins); pharmaceuticals (e.g., antineoplastic agents); and aquaculture feeds. The latter represent a good example of a case that could benefit in a decisive manner from the introduction of new photobioreactor concepts.

Understanding photobioreactors requires background knowledge on the fundamentals of the growth of phototrophs. The first part of this article therefore describes the principal characteristics of phototrophic microorganisms and their growth kinetics. The second part deals with photobioreactor designs, advantages, limitations, and commercial applications.

The topic of photobioreactors has also been reviewed by Lee (2), Chaumont (3), Prokop and Erickson (1), and more recently by Torzillo (4), Tredici and Chini Zittelli (5), and Pulz and Scheibenbogen (6).

PRINCIPAL CHARACTERISTICS OF PHOTOTROPHIC MICROORGANISMS

Photosynthesis and the Photosynthetic Apparatus

All organisms require a source of energy for growth to take place. Phototrophic organisms, or phototrophs, use light as

an energy source. Light, or visible radiation, is the electromagnetic radiation in the 400- to 700-nm range, to which the human eye is sensitive. Because it is used by algae and plants for photosynthesis, visible radiation is also called photosynthetic active radiation (PAR).

Photosynthesis is the process by which phototrophs capture and convert the energy of photons (quanta of electromagnetic radiation, i.e., the smallest "packets" of light energy) to biochemically usable energy. It is through photosynthesis that phototrophs obtain the energy (ATP) and the reducing power (NADH or NADPH) necessary to incorporate CO_2 and to manufacture the organic molecules they require for growth.

Photosynthesis is generally associated with higher plants, yet about half the photosynthesis on earth is carried out by microorganisms. There are three major groups of phototrophic microorganisms: the photosynthetic purple and green bacteria, the cyanobacteria (also referred to by botanists as blue–green algae), and the microalgae. Photosynthetic bacteria, and cyanobacteria are prokaryotes; microalgae have a eukaryotic-cell-type organization. Photosynthetic bacteria differ from cyanobacteria and microalgae because of their photopigments and photosynthetic processes.

The ability to perform photosynthesis depends on the presence of light-absorbing pigments, the chlorophylls: large planar molecules composed of four substituted pyrrole rings with a magnesium atom coordinated to the four central nitrogen atoms. Chlorophylls absorb light primarily in the blue–violet and red regions of the spectrum and absorb weakly in the green region; this is why many phototrophs are green in color. Photosynthetic bacteria differ from cyanobacteria and microalgae in that their chlorophylls, called bacteriochlorophylls, have different molecular structure and absorption characteristics. For example, bacteriochlorophyll *b* of some purple bacteria has an in vivo maximum absorption in the infrared region between 1,020 and 1,040 nm. For purple bacteria, photosynthetic active radiation covers a much wider wavelength range than it does for microalgae and cyanobacteria, from the near ultraviolet to the long-wave infrared region (Fig. 1).

Besides the chlorophylls, other photosynthetic pigments, called accessory pigments, are also involved in the capture of light. Accessory pigments absorb light in the blue–green through yellow–orange range where chlorophylls absorb poorly and transfer the trapped energy to the chlorophylls, making photosynthesis more efficient over a broader range of wavelengths. The most widespread accessory pigments are the carotenoids, fat-soluble molecules that absorb light in the blue region of the spectrum, and the water-soluble phycobiliproteins of red algae and cyanobacteria that absorb in the green–yellow region. The accessory pigments also protect phototrophs from sunlight, which can damage the photosynthetic apparatus when it is too intense.

Cyanobacteria and microalgae also differ greatly from photosynthetic bacteria because of their photosynthetic process. Like higher plants, cyanobacteria and microalgae are oxygenic phototrophs; that is, they exhibit a type of photosynthesis that involves two photosystems (PSI and PSII), uses H_2O as electron donor, and evolves oxygen as

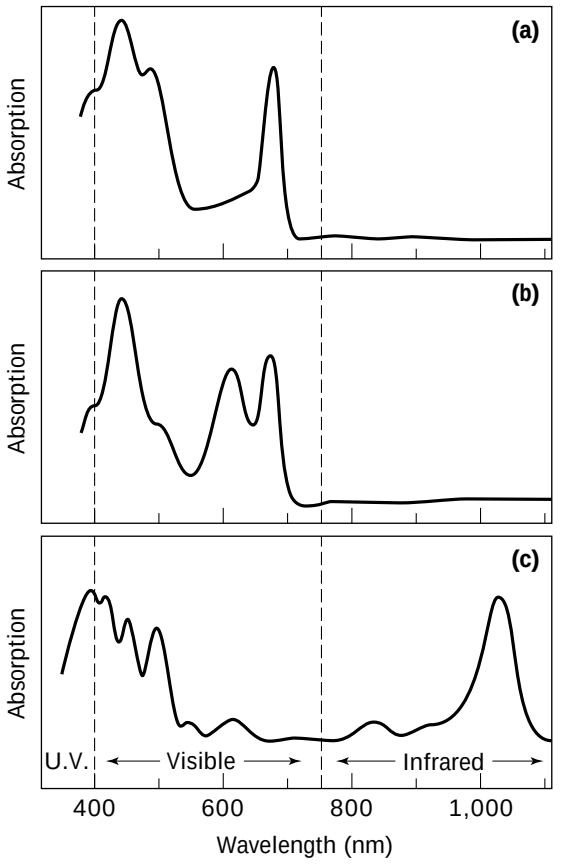

Figure 1. *In vivo* absorption spectra of (**a**) a microalga (*Scenedesmus acutus*), (**b**) a cyanobacterium (*Synechocystis* sp.), and (**c**) a purple bacterium (*Rhodopseudomonas viridis*).

a result of water photolysis. Green and purple photosynthetic bacteria lack photosystem II and cannot use water as an electron source; hence, they do not produce oxygen photosynthetically. For this reason they are called anoxygenic phototrophs. These definitions apply irrespectively of whether the organism obtains its cellular carbon principally from inorganic (autotrophically) or organic (heterotrophically) sources. Microalgae and cyanobacteria are mostly aerobic (they use oxygen as electron acceptor for respiratory metabolism) and autotrophic; purple bacteria are mainly anaerobic and heterotrophic; green bacteria are prevalently anaerobic and autotrophic. For a clear, comprehensive treatment of both plant and bacterial photosynthesis, see Hall and Rao (7).

Although this article deals exclusively with photobioreactors for the cultivation of oxygenic phototrophs (microalgae and cyanobacteria), some of the aspects covered and most of the conclusions can be extended to other phototrophic groups. For brevity, the term microalgae is used here in its botanical meaning, which includes cyanobacteria.

Response of Phototrophs to Light Quality and Quantity

The rate of photosynthesis achieved by a phototrophic cell depends on the rate of photon absorption and on the effi-

ciency with which the absorbed photons are used. The rate of absorption and the efficiency of conversion of absorbed photons are in turn determined by the characteristics of the photosynthetic apparatus and by the spectral quality and intensity* of the incident light.

Photosynthesis as a Function of Light Quality. The wavelengths absorbed by a phototroph depend on its primary and accessory pigment content as shown by its absorption spectrum (Fig. 1). Only absorbed wavelengths are used, but not all the wavelengths absorbed are equally efficient for photosynthesis. Therefore, the spectral suitability of a light source for a phototroph is better represented by the *action spectrum* of photosynthesis (i.e., the curve obtained by plotting the *specific rate of photosynthesis [P]*† against wavelength across the photosynthetic range for the cultured organism). Although action spectra give more information than absorption spectra, the latter are more commonly reported because they are easier to determine and interpret. The curve obtained when growth, rather than photosynthesis, is plotted against wavelength is called a *growth action spectrum*.

Photosynthesis as a Function of Light Intensity. The rate of photosynthesis is not simply proportional to the rate of photon absorption, since photons may be captured by the pigments much faster than the photosynthetic apparatus can make use of them. If photosynthesis is measured at different light intensities, the specific photosynthesis rate *(P)* can be plotted as a function of light intensity *(I)* in the well-known light response curve of photosynthesis, or the *P–I* curve (Fig. 2). In the dark, where there is, of course, no photosynthetic activity, O_2 is consumed and CO_2 is released due to cellular respiration. As the light intensity gradually increases, photosynthetic O_2 evolution (and CO_2 consumption) takes place and a light intensity value, called the light compensation point or compensation irradiance *(I_c)*, is eventually reached, at which value photosynthetic O_2 evolution balances respiratory O_2 consumption. Beyond this value, production exceeds consumption and net photosynthesis is achieved. From here on, *P* increases linearly with *I* up to a certain point, beyond which the rate of increase of *P* per increment in light intensity declines and eventually levels off. The slope of the linear portion of the curve, called alpha (α), represents the rate of photosynthesis per unit incident light or relative quantum yield (also called maximum photosynthetic efficiency or maximum quantum yield), and is a measure of the efficiency

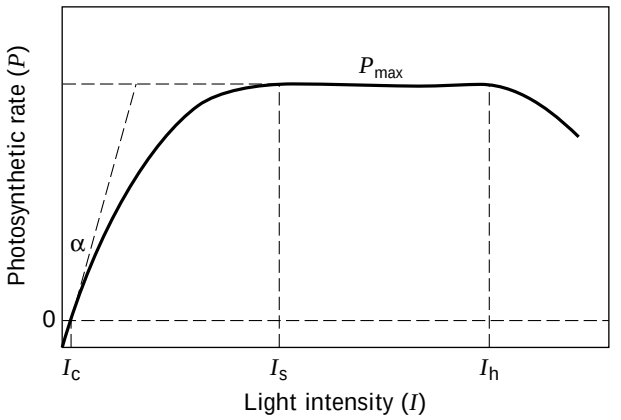

Figure 2. Light-response curve of photosynthesis (known as *P–I* curve). The intercept on the vertical axis is the measure of O_2 uptake due to dark respiration. I_c, light compensation point; I_s, light saturation intensity; I_h, light intensity value at which photoinhibition occurs. For details refer to the text.

with which the organism uses low light intensities. The relative quantum yield is expressed as moles of O_2 evolved per mole of photons of incident PAR. Plotting the absorbed light (incident light minus reflected and transmitted light) instead of incident light will give the absolute quantum yield. The reciprocal of the quantum yield (i.e., the number of photons required to evolve one molecule of oxygen) is called the quantum requirement of photosynthesis. In the range of intensities where *P* does not vary with *I*, photosynthesis is said to be light saturated and the light intensity is said to be saturating *(I_s)*; *P* reaches its maximum value (P_{max}) in this range. If light intensity further increases, *P* may decrease again. This phenomenon involves damage to some components of the photosynthetic apparatus and is referred to as photoinhibition. At low light intensities, *P* is limited by the light reactions of photosynthesis (thermodynamic constraint). At saturating light intensities, *P* (P_{max}) is limited by the so-called dark reactions, in which the products of light reactions are used to fix CO_2 (metabolic constraint). *P–I* curves are species specific and must be determined under conditions such that all the cells receive the same photon flux and are not mutually shaded.

Hill and Bendall's widely accepted Z-scheme of oxygenic photosynthesis incorporates two photosystems (PSII and PSI), and establishes that it is necessary to move four electrons through each photosystem to evolve one molecule of O_2 and fix one molecule of CO_2. Since the transfer of each electron requires two photons (one in PSII and one in PSI), it follows that the theoretical minimal quantum requirement cannot be lower than 8 (i.e., not less than eight photons are needed to move four electrons from water to NADP through the two photosystems) and the maximal quantum efficiency cannot be higher than 0.125 (1/8).

The curve relating growth to light intensity has a pattern similar to the *P–I* curve (with growth rate increasing proportionally to light intensity when intensity is limiting and being independent of intensity when saturating values are reached), since phototrophic growth is a direct consequence of the photosynthetic rate.

*The spectral quality of light depends on the wavelength of each single photon. The energy content of a photon varies with its wavelength according to $\epsilon = hc/\lambda$, where ϵ is energy content, h is Planck's constant, c is the speed of light, and λ is the light wavelength in nm. Light intensity is given by the number of photons impinging on unit area in unit time (expressed as μmol photons m^{-2} s^{-1}). More properly the incident photon flux on a unit area in unit time is defined as photon flux density (PFD).

†Photosynthesis can be measured in terms of either CO_2 uptake or O_2 release. Rates of photosynthesis can be expressed per unit biomass, or any quantity proportional to it, to obtain the specific photosynthetic rate *(P)*. Typical units for *P* are μmol evolved O_2 (or fixed CO_2) mg Chla^{-1} h^{-1}.

Growth of Microbial Phototrophs in Batch Culture

Phototrophic microorganisms can be grown in batch or continuous culture. A batch culture is initiated by the transfer of a small amount of cells (inoculum) into fresh growth medium; after the inoculum, nothing is added to (except light and carbon dioxide), or removed from (except oxygen), the system.

Growth Rate. Growth can be defined as the orderly increase of all the cell constituents. During this process, unicellular organisms grow to a maximum size, then divide to form two daughter cells. The daughter cells in turn repeat the process, and the number of cells doubles at regular intervals of time. The time required for a growing population to double is called the generation time, g. The rate of increase in biomass concentration is generally expressed as the specific growth rate, μ, which is related to the generation time by $\mu = \ln 2/g$. The specific growth rate, which can be defined as a proportionality constant for the autocatalytic growth reaction, is described by the following equation:

$$\mu = 1/X(dX/dt) \qquad (1)$$

where μ is the specific growth rate (h^{-1}), X is the biomass concentration (g L^{-1}), t is time (h), and dX/dt is the variation in biomass concentration with respect to time (g L^{-1} h^{-1}), that is, the culture productivity per unit volume. The volumetric productivity ($dX/dt = \boldsymbol{\mu}X$) of a culture in a pond or a flat reactor can be easily normalized on a per-unit-area basis by considering the culture volume *(V)* corresponding to the unit of illuminated surface area *(A)*. Therefore, the areal productivity can be calculated as $\mu XV/A$, or, since V/A is the depth d of the culture, as μXd.

Growth Curve. When a phototroph grows under suitable conditions in batch culture, its growth curve follows a sigmoidal pattern showing six principal phases (Fig. 3a). Each phase is characterized by a particular value of the specific growth rate (Fig. 3b) and reflects a particular metabolic state of the cell population. After the inoculum, growth does not necessarily start right away since most cells may be viable, but not in condition to divide, especially when the parent culture is old. The interval necessary for the transferred cells to metabolically adapt to the new situation and start to grow is called the lag phase. After the lag phase, the culture enters into the acceleration phase, during which μ increases continuously. When a constant growth rate is reached, the culture is said to be in the exponential growth phase. During exponential growth, all the cells are light saturated (if a saturating light intensity is provided at the culture surface) and growth proceeds according to equation 1. The maximum μ is achieved in this phase, and in this respect phototrophs do not behave differently from chemotrophs. (*Note*: Organisms that obtain energy for growth from oxyreduction reactions involving either organic or inorganic electron donors.) The exponential growth phase of phototrophs in batch culture normally lasts for a relatively short period because the cells start to shade each other as their number increases; growth becomes light limited and μ decreases (deceleration phase). Self-shading and the fact that the energy source is instantaneously provided at the culture surface and cannot be stored in the reactor are the two fundamental factors that differentiate photobioreactors from reactors for chemotrophs. During the deceleration phase, although μ decreases continuously, the culture productivity may remain stable at maximum value because of the continuous proportional increase in cell concentration *(X)*. Since the increase in cell biomass becomes almost linear, sometimes the initial part of this phase is called linear phase. Conditions of linear growth are typically sought in mass cultures of phototrophs, since they lead to the highest productivity. Following the linear growth phase, the cell population continues to increase, but μ decreases until it reaches zero, at which point the culture enters the stationary phase, during which the cell concentration remains constant at its maximum value. The stationary phase is followed by the death phase, in which the population of viable cells decreases.

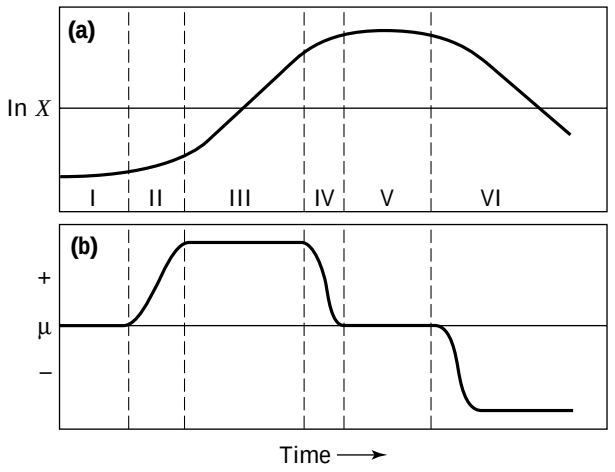

Figure 3. (**a**) Growth curve of a phototrophic microorganism in batch culture. The following six phases are shown: I, lag; II, acceleration; III, exponential; IV, deceleration; V, stationary; VI, death (after Ref. 8). (**b**) Changes in growth rate (μ) during the six typical growth phases.

To achieve continuous exponential light-saturated growth, the culture process has to be changed from batch to continuous; this is accomplished by continuously removing the newly formed cells. This condition is not adopted in photobiological process targeting production of biomass or related products, since it leads to low efficiency of conversion of the irradiance impinging on the culture surface and to low productivity (see later section).

Light distribution, Growth Rate, and Volumetric Productivity in Phototrophic Cultures

If nutrients are provided in suitable amounts and temperature is maintained at the optimum value, the productivity of phototrophic cultures becomes a function of light availability and cell concentration. In dilute cultures, self-shading is minimal and all the cells receive the same amount of light, independent of their position. It is self-

evident that, at these low densities, even if the light intensity provided would permit the maximum growth rate, the culture will achieve low efficiency of light conversion and low productivity, since most of the impinging photon flux will pass through the culture unabsorbed (Fig. 4, upper curve). Mass phototrophic cultures, in order to obtain maximum productivity, must be kept dense enough to absorb all the light impinging on their surface. Under these conditions, self-shading, due to light absorption by cell pigments and scattering by the cells causes light intensity to fall off exponentially with the culture depth (Fig. 4, lower curve). In dense cultures, the light availability for each single cell is much reduced; this brings about a significant diminution of the specific growth rate, but productivity is, in any case, higher than in dilute cultures because the decrease in growth rate is more than compensated by the increase in cell concentration. For achieving maximal productivity in mass cultures it is mandatory to operate at a proper combination of culture depth and cell concentration. This concept, known as operating at the optimal population density (OPD), has been investigated by many researchers, most recently by Richmond and coworkers (9–11). In general, maximal productivity is obtained at relatively high population densities and at specific growth rates that are about one-half of the maximum. Increasing the cell concentration above the OPD is generally associated with a reduction in productivity because of the presence of a large dark zone inside the reactor, which leads to high maintenance requirements in relation to the overall photosynthetic activity of the culture. Given the nonuniformity of the light environment that dominates in dense cultures, one requirement for achieving high photosynthetic efficiencies is that the individual cells be intermittently moved into and out of the illuminated zone. Although it has been shown that conventional mixing can do little to improve photosynthetic efficiency through what is known as the "flashing light effect,"* mixing is, in any case, required to provide intermittent exposure of the cells to light and darkness. A means to increase volumetric productivity in phototrophic cultures without increasing the light intensity at the culture surface is to shorten the light path by increasing the illuminated surface-to-volume ratio (S/V ratio) of the reactor.

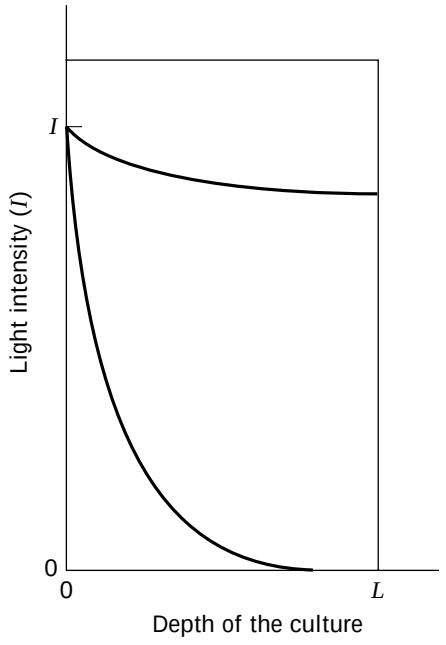

Figure 4. Light extinction in a phototrophic culture illuminated from one side with saturating light intensity. The upper curve represents a condition of low-cell concentration in which light absorption is negligible and all the cells receive almost the same light intensity. The lower curve describes a condition of high cell density in which the impinging photon flux is fully absorbed at two-thirds of the culture depth.

Modeling Photosynthetic Growth in Photobioreactors

Mass phototrophic cultures are normally light limited, even though the light intensity striking their surface may be several times above saturation. For example, in outdoor algal cultures at midday, cells in the top layers will receive light at intensities above I_s (they will be photosaturated), or may even be photoinhibited, but a considerable portion of the culture will be photolimited or even below the compensation point (bottom layers). The rate of photosynthesis will thus be different in different regions of the culture, since it depends on the local environment experienced by the single cells, but the photosynthetic rate of the culture as a whole will be an average of all the individual rates. In the same way, while for a single cell the instantaneous specific growth rate, which depends on the instantaneous rate of light absorption and of photosynthesis, varies depending on the position of the cell, the average specific growth rate of the culture depends on the average amount of light received by the cells. It is hence a function of the culture depth (or light path) and of the cell concentration, as well as of the intensity of the incident light.

The exponential decay of the intensity of light as it penetrates into dense cultures is generally described by Lambert–Beer's law. This equation, however, accounts for the sole absorption by pigments and neglects light scattering by cells. More sophisticated models, (e.g., the radiative transfer theory developed in astrophysics), have been proposed to obtain radiant energy profiles inside reactors with a reasonable accuracy (13). Models of photosynthetic growth are based on the assumption that growth rate is closely related to the light availability inside the culture. It is thus necessary to consider both the effect of the light intensity available at each point of the reactor on growth rate and how the light environment is modified by absorption and scattering. This creates a high degree of complexity for the modeling of phototrophic cultures. A complete treatment of the kinetics and energetics of photosynthetic growth in photobioreactors has been presented by Cornet et al. (13). Accurate models for calculating local and average irradiance inside photobioreactors as functions of the design and of the impinging irradiance, and for relating

*The phenomenon, first described by Kok (12), by which the photosynthetic efficiency is increased when cells are exposed to light flashes instead of continuous light.

growth rate and productivity to average irradiance have been developed by Molina Grima and coworkers (14,15).

Light Utilization and Productivity in Phototrophic Cultures

Photosynthetic Efficiency of Outdoor Cultures. The photosynthetic efficiency of phototrophic growth is defined as the energy stored in biomass per unit of light energy absorbed (9). This parameter is of fundamental importance in mass cultures, since high photosynthetic efficiency leads to high biomass production per unit of illuminated area. As mentioned earlier, according to the current model of photosynthesis, eight photons are required to transfer four electrons from water to NADP and bring about the reduction of one molecule of CO_2 to carbohydrate in the dark reactions of photosynthesis. Since one mole of photons in the visible range contains on average about 50 kcal of free energy, and since the energy stored in carbohydrate during photosynthesis is about 114 kcal/mol of reduced CO_2, the theoretical maximum photosynthetic efficiency is approximately 28.5% [114/(8 × 50)]. The biosynthesis of the other macromolecules making up the microbial cell (lipids, protein, nucleic acids) requires additional reducing power and ATP and hence additional photons per CO_2 incorporated; this brings the quantum requirement for growing cells to 10–12, rather than 8, and reduces the maximum efficiency to about 20%. In practice, this efficiency cannot be reached with sunlight because of several losses and limitations, which include the fact that PAR represents only 43% of the total solar radiation at the earth's surface, the loss of part of the incident radiation by reflection at the culture surface, and the fact that part of the absorbed energy is invested in cell maintenance. Another major limitation, often ignored, is represented by the light saturation effect, that is, the fact that the photosynthetic apparatus of most phototrophs saturates at only 10–20% of full sunlight (about 2,000 μmol photons m^{-2} s^{-1}). According to the equation derived by Bush ($f = I_s/I\,[\ln I/I_s + 1]$) (16), which expresses the fraction (f) of the thermodynamic efficiency that can be attained as a function of the incident light intensity (I) and the saturation intensity (I_s), the quantum efficiency comes very close to the theoretical at low light intensities (<100 μmol photons m^{-2} s^{-1}). When the light intensity approaches that of full sunlight, utilization drops to less than 20% and most of the light energy absorbed by the culture is dissipated as fluorescence and heat. There are not many options available to overcome the limitation imposed by the light saturation effect. In dense phototrophic cultures, mixing partially compensates for the limitation imposed by the light saturation effect, but does not overcome the substantial inability of phototrophs to use effectively high irradiances (17). Benemann (18) discussed the alternative concept of increasing the light intensity at which photosynthesis saturates by decreasing the amount of accessory pigments in the cells. This however, is not easy to achieve and may lead to another problem: Contaminating algae with higher pigment content, because of their ability to absorb more light in the light-limited zones of the culture, will overgrow the cultured alga. Based on studies that took this direction in the 1950s, Tredici and Chini Zittelli (19) have recently proposed spatial light dilution as a means to increase the photosynthetic efficiency of outdoor algal cultures (see later section). Considering all of these limitations, it is reasonable to assume that only about 4–5% of solar energy can be converted to the chemical energy of biomass, under even the best conditions (17). For locations characterized by an annual average insolation of 4,500 kcal m^{-2} d^{-1} (e.g., southwestern United States), and assuming a caloric content of the biomass of 5.4 kcal g dry wt^{-1}, this efficiency will result in a calculated average annual productivity between 33 and 42 g m^{-2} d^{-1}.

Productivity of Outdoor Cultures of Phototrophs. The productivity of outdoor cultures is one of most debated issues connected with mass cultivation of phototrophs. Extrapolations from efficiencies of light conversion obtained in the laboratory had led to predict annual productivities as high as 140 g m^{-2} d^{-1} (20), but actual productivities are only one-tenth or less these figures, with about 40 g m^{-2} d^{-1} being considered the highest value obtainable by outdoor algal cultures under favorable conditions (17,18). A common mistake made (more or less consciously) in this respect is that the results obtained on a small scale over short periods and under optimal conditions are extrapolated to all-year-round, full commercial scale. As a matter of fact, despite statements in the early years of algal biotechnology, large algal cultures are not much more productive than terrestrial systems, and generally are much less reliable. In the author's opinion, however, productivity should not be considered as being the decisive factor in determining the viability of algal biotechnology. It is true that productivity greatly influences the economy of the process, but other factors, like sustainability and reliability, are just as, or even more, important.

Several models have been proposed to predict the productivity of outdoor cultures of phototrophs both in open ponds (21,22) and in photobioreactors (13,15).

How Productivity of Phototrophic Cultures Is Expressed. In the case of algae cultivation in open ponds, it is common to evaluate productivity as areal yield (i.e., productivity per unit of occupied land area per unit time, expressed either as g m^{-2} d^{-1} or tons ha^{-1} $year^{-1}$). This is both practical, since it makes comparison with terrestrial systems easy and immediate, and correct, since areal productivity in ponds is proportional to the amount of light entering the system per unit illuminated area. In a pond this corresponds substantially to the land surface area occupied by the system.

With photobioreactors the situation is much more complex. Except in the cases of flat horizontal systems and tubular horizontal photobioreactors with no empty space between contiguous tubes (in both these cases the areal productivity referred to the occupied land is correct and easy to interpret), expressing productivity on a per land surface area basis is misleading. For example, in some horizontal serpentine bioreactors it is difficult to decide whether and how to compute the empty space between contiguous tubes and how to account for the fact that the reactor intercepts a different proportion of the radiation impinging on the horizontal, depending on the elevation of the sun and, hence, on the hour of the day. With elevated

systems, the inadequacy of the areal yield is even more evident, since the amount of radiation intercepted by a vertical or sharply inclined reactor is not related to the land surface area it occupies. Expressing the productivity of elevated systems on a per unit occupied land surface area basis (i.e., with reference to the horizontal projection of the reactor on the ground) may lead to high unrealistic figures (see later section). Productivity can also be referred to the illuminated surface area of the reactor (biomass produced per unit illuminated surface area per unit time, in g m^{-2} d^{-1}), but this parameter is also not adequate for all situations, since it can be difficult to define the correct illuminated surface area to which to refer productivity. In tubular reactors, for example, the illuminated surface area generally corresponds to half the total surface area of the reactor; using it as basis for calculation of productivity in most cases underestimates reactor performance. In some vertical reactors (e.g., large-diameter coils that receive a significant amount of radiation on their inner central part at midday, but not in the early morning nor in the evening), the illuminated surface area changes during the day with sun elevation. Another complication with vertical reactors is determined by the fact that they intercept a significant amount of diffuse radiation on the surface not directly illuminated by the sun, and this is not always taken into account.

For these reasons, photobioreactor performance, like that of fermenters, is frequently reported in terms of volumetric productivity (amount of biomass produced per unit reactor volume per unit time, commonly expressed in g L^{-1} d^{-1}). But volumetric productivity is a function of the number of photons that enter the unit reactor volume in the unit time and, as such, is dependent on the illuminated S/V ratio of the reactor. The higher this ratio, the higher the volumetric productivity. It is well known, for example, that small-diameter tubular reactors or thin flat systems achieve high volumetric productivities, even if they perform poorly. We should be aware of the fact that a volumetric productivity of 1 g L^{-1} d^{-1} assumes a completely different significance if obtained in a tubular reactor of 1 cm or of 5 cm diameter.

To overcome these limitations, Tredici and Chini Zittelli (19) suggested evaluating the performance of vertical photobioreactors on the basis of the photosynthetic efficiency achieved by the culture. Unfortunately this parameter is not always easy to calculate (e.g., in coiled reactors) and since it depends heavily on the irradiance (the lower the irradiance, the higher the efficiency) favors experiments carried out under low light intensities, such as in winter.

The productivity of a photobioreactor could be expressed on a per shaded surface area basis (the productivity of the reactor divided by the average ground surface area shaded by the reactor). This parameter, never suggested before, substantially reflects the efficiency of light utilization, but also takes the actual irradiance conditions into account and offers the possibility to compare very different culture systems. For example, the performance of an open pond and of a vertical coiled reactor could be compared on this basis, whereas it is rather difficult to envisage any other suitable comparison parameter for these two very different systems. The per shaded surface area parameter cannot be used alone, however, since in some cases (e.g., serpentine reactors) it does not give a correct evaluation of the efficiency of land utilization.

In conclusion, each method for expressing productivity has its own limitations, and complete evaluation of a reactor performance in terms of productivity will be achieved only by a combination of the different available methods. For example, expressing the productivity on the basis of unit shaded area, unit occupied area (including eventual empty spaces), and unit volume will allow evaluation (and comparison) of photobioreactors in terms of efficiency of light conversion, efficiency of land use, and efficiency with which the unit volume of reactor is used. This combined approach is highly recommended.

Artificial Light Sources. Solar energy is a relatively cheap energy source, but given the low photosynthetic efficiency attainable under full sunlight, and the fluctuations in supply determined by the weather, the time of the year, and the natural day/night cycle, the use of artificial light sources to grow phototrophs has been taken into serious consideration, at least for production of high-value compounds.

The use of artificial illumination offers the possibility of selecting light quality and intensity, as well as the length of the illuminated period, and thus of significantly enhancing the reliability of the production process. This, together with the higher photosynthetic efficiency attainable (a photosynthetic efficiency of 15% is not uncommon with artificial light of relatively low intensity), may compensate in many cases for the higher cost.

One of the fundamental factors guiding choice of the light source should be the efficiency of conversion of electric energy into PAR energy. This efficiency varies considerably with the type of lamp; for example, it is only about 5% in tungsten–halogen (incandescence) lamps, 10–15% for fluorescent tubes, and 20–25% for high-pressure sodium lamps. Only with xenon lamps and light-emitting diodes are very high efficiencies attained (50% and up to 80%, respectively). Considering both the efficiency of conversion of electrical energy into PAR and the efficiency of conversion of light energy into biomass, an overall efficiency of conversion of electrical energy into the energy of biomass between 0.7% and 2% has been attained by *Arthrospira* cultures grown under fluorescent lamps (13). Another aspect to consider is the spectral quality of the emitted light, which ought to match the action spectrum of the cultivated organism as closely as possible. For example, tungsten lamps have a low output in the blue region and are therefore not appropriate for oxygenic phototrophs. High-pressure sodium lamps are relatively efficient as regards electrical energy conversion but emit in a limited yellow–orange region. Practicality often prevails over efficiency considerations in the choice of an artificial light source. For example, fluorescent lamps are widely adopted, independently of the spectral quality of their emission, because they provide a relatively uniform irradiance over a large surface.

A SURVEY OF PHOTOBIOREACTORS

Classification of Photobioreactors

Photobioreactors can be classified on the basis of both design and mode of operation. In design terms, the main categories of reactors that can be envisaged are *(1)* flat or tubular; *(2)* horizontal, inclined, vertical, or spiral; and *(3)* manifold or serpentine. An operational classification of photobioreactors would include *(4)* air or pump mixed and *(5)* single-phase reactors (filled with media, with gas exchange taking place in a separate gas exchanger), or two-phase reactors (in which both gas and liquid are present and continuous gas mass transfer takes place in the reactor itself). Construction materials provide additional variation and subcategories—for example, *(6)* glass or plastic and *(7)* rigid or flexible photobioreactors.

Axenic photobioreactors are reactors operated under sterile conditions. Although a major characteristic of photobioreactors is their ability to limit contamination, it must be made clear that an effective barrier, and thus operation under truly sterile conditions, is not achieved, except in the few special designs developed expressly for that purpose. This is a major difference between photobioreactors and bioreactors for chemoheterotrophs, which typically operate under sterile conditions. Like fermenters, photobioreactors can be divided into laboratory photobioreactors used for research, pilot-plant photobioreactors used to scale-up and optimize the process, and production units. Unlike fermenters, there are only a few examples of commercial photobioreactors in operation. Some companies sell photobioreactors in a variety of sizes for use in teaching, research, and commercial applications. The emphasis in this article is on pilot-culture systems and the two commercial-scale plants realized to date. Laboratory systems, such as illuminated carboys and fermenters, immobilized cell systems, and optical-fiber reactors are not considered. Cell-immobilization techniques have been reviewed by Brouers et al. (23), whereas optical fiber reactors have been discussed by Pulz and Scheibenbogen (6).

Early Photobioreactors

The use of photobioreactors for microalgae mass culture dates back to the late 1940s and was a logical consequence of the investigations carried out with *Chlorella* on the fundamentals of photosynthesis. In those early days of algae culture, the emphasis was on continuous controlled cultivation; hence, closed reactors were given priority. Open systems were considered inappropriate to guarantee the necessary degree of control and optimization of the process.

One of the first closed systems was set up at Stanford University in California in the late 1940s and involved use of vertical tubular reactors (24). The units consisted of glass columns 1.8 m in height and 10 cm in diameter, constricted at the bottom to prevent algal settling. The system was operated turbidostatically, with medium addition being regulated by a photoelectric cell. Culture temperature was maintained constant by means of a cooling coil inserted into the reactor. Carbon dioxide–enriched air was injected at the bottom of the column to obtain mixing and pH/pCO_2 control. The system was experimented with in the cultivation of *Chlorella* under both artificial light and sunlight. Maximum volumetric productivity indoors was 0.48 g L^{-1} d^{-1}. Outdoors, productivity averaged 0.28 g L^{-1} d^{-1}, with a maximum of 0.35 g L^{-1} d^{-1}. The reason for the lower outdoor productivity was not clear.

In the early 1950s, the Arthur D. Little Company at the Massachusetts Institute of Technology, under contract with the Carnegie Institution of Washington, developed two basic types of photobioreactors: an array of 10 vertical rigid plastic tubes and a 50-m^2 horizontal flexible tubular unit (25). The vertical units, which were essentially the same as those operated at Stanford University, provided inoculum to the larger horizontal unit and were reported to operate satisfactorily, although no productivity data were actually presented. The horizontal tubular unit may be considered the first pilot plant for microalgae production. It consisted of 4-mm-thick polyethylene tubes that, once filled with algal culture up to a depth of about 8 cm, assumed a more or less elliptic shape of 1.2-m width. The tubes were joined at the ends to form a raceway 21 m in length, for a total surface area of about 56 m^2. The culture (*Chlorella*) was circulated by means of a centrifugal pump. The pumping system was not capable of generating circulation velocities over 7.5 cm s^{-1} and there was considerable settling of the culture. With the same pump and a tube width of 0.43 m, flow rates of 25 cm s^{-1} were achieved and problems of settling were eliminated. Leakage and contamination by *Chlorococcum* and protozoa were the major problems encountered in the operation of the system. Spray cooling proved inadequate for temperature control, and it was necessary to install a heat exchanger. Despite these difficulties, a 40-day run attained an average areal productivity of 9 g m^{-2} d^{-1}. The data collected with this pilot plant provided the material for an economic analysis of algae production in photobioreactors (26), which concluded that the cost of products obtained in photobioreactors was excessive in comparison to that of equivalent materials obtained using conventional methods. Cooling of the culture was found to be a major cost factor.

At about the same time in Japan, Tamiya and coworkers (27) developed a system consisting of a serpentine tubular reactor immersed in a water bath for temperature control and an external column for gas exchange. This system provided the basic design criteria for all subsequent, essentially identical, serpentine reactors (e.g., those adopted by Gudin in France and Molina Grima and coworkers in Spain) (see later section). The reactor was made up of 3-cm-diameter glass tubes joined to form a serpentine and had a total length of 33 m. The total culture volume was 40 L. The culture *(Chlorella ellipsoidea)* was circulated at a linear velocity of 15–30 cm s^{-1}. A separate column, in which a mixture of 5% CO_2 in air was injected at a rate of 1–1.5 L min^{-1}, provided mixing and gas exchange. Productivity was directly related to solar irradiance with the highest value, achieved at the maximum irradiance, of about 0.6 g L^{-1} d^{-1}. After several months of experimentation, the authors concluded that one of the main limitations was temperature control and that a significant increase of productivity could be attained through cultivation of algae exhibiting higher temperature optima

and through vigorous mixing aimed at increasing growth by providing intermittent illumination. These concepts still guide most of our research.

Following these initial studies in the 1950s, little work was carried out in this field for several decades. Two exceptions were the work of Setlik in Czechoslovakia (28) and Jüttner in Germany (29). The reasons for this almost total abandonment of research activity on photobioreactors are not clear, although the successful production of *Chlorella* in open ponds in Japan, the development of microalgae-based wastewater treatment in California, and later success with open-raceway systems for outdoor production of *Spirulina* (*Arthrospira*) and *Dunaliella* perhaps explain the relative lack of interest in closed systems. The difficulties experienced by the A.D. Little Co. and Fisher's negative conclusion in his economic analysis also contributed to discouraging further studies on the application of photobioreactors.

Recent Types of Photobioreactors

Several types of photobioreactors have been designed and experimented with since the work of Pirt and coworkers sparked renewed interest in closed systems in the early 1980s (20). Most of these are small-scale systems; some are at the pilot or prepilot stage of development. Only in a very few cases has scale-up to commercial size been attempted. For convenience, these systems are described herein by categories: *(1)* axenic photobioreactors, *(2)* vertical tubular photobioreactors, *(3)* serpentine photobioreactors, *(4)* manifold photobioreactors, *(5)* helical photobioreactors, and *(6)* flat photobioreactors. Small systems and reactors for which experimentation has been conducted prevalently indoors with artificial light are not considered.

Axenic Photobioreactors Setlik (28) and later Jüttner (29) and Krüger and Eloff (30) developed glass tubular reactors for the axenic cultivation of microalgae. Jüttner's system, which substantially reproduced Setlik's design, was an all-glass, 110-L vertical flat coiled photobioreactor that could be sterilized by steam. The reactor, made of 4-cm-ID tubes, had a total length of 79 m. The algal suspension was circulated by a glass centrifugal pump at a flow rate of 20 to 60 cm s^{-1}. The temperature was regulated through a 2-m water-jacketed section. Gas exchange took place in an external exchanger in which a CO_2–air mixture was injected at a rate of 300 L h^{-1}. The system attained a maximum productivity of about 0.5 g L^{-1} d^{-1} under artificial illumination. Cell damage caused by the centrifugal pump was a problem in the case of fragile cyanobacteria; other problems encountered were foam formation and cell adhesion to the glass walls. Jüttner concluded that cell adhesion was the most discouraging feature and suggested that cultivation ought to be limited to "nonsticky" algae. Wall growth and fouling are still today major limitations in photobioreactors, although the problem is not always recognized as such because experiments generally do not last long enough for these effects to become evident.

A similar 60-L system, composed of 12 5-cm-ID glass tubes each 2 m in length, coupled by U-bends to form a vertical flattened spiral, was operated by Krüger and Eloff (30), who reported a productivity of about 0.13 g L^{-1} d^{-1} with a nontoxic species of *Mycrocystis*.

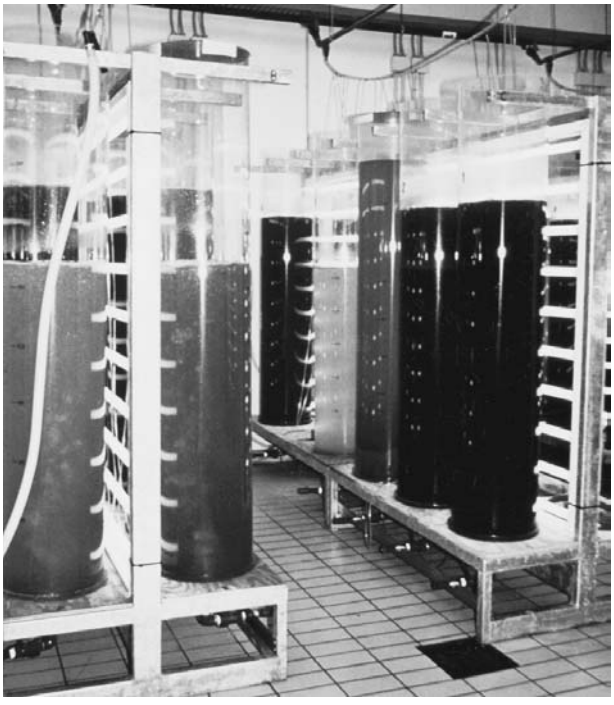
Soeder et al. (31) devised a rocking tray for the sterile cultivation of *Scenedesmus*. It consisted of a flat horizontal unit (inner dimensions 59.5 × 36 × 9 cm) made of stainless steel and covered with a glass lid. The tray was placed on a support connected to a rocking device. Temperature was controlled by circulating thermostated water through the double bottom of the unit.

Although these systems appear difficult to scale up and are rather expensive, they are mentioned here since with the exclusion of laboratory reactors they are the only systems that allow sterile cultivation of phototrophic microorganisms.

Vertical Tubular Reactors. Vertical tubular reactors (or column reactors) are simple systems in which mixing is achieved by injecting compressed air at the bottom of the column. Several vertical tubular photobioreactors were developed following Cook's first design. An example is the 30-L (2-m height, 15-cm ID) tower-type glass reactor devised by Jüttner (29). The main characteristic of this system was a wide, hollow glass finger inserted from above into the column to reduce dark space inside the reactor. Since the finger was open at the upper end, it could also be used to regulate the culture temperature. A thickness of the annular culture chamber of about 3.5 cm was found to be optimal for the growth of the light- and shear-sensitive *Microcystis aeruginosa*.

The rigid vertical columns, typically 2–2.5 m in height and 30–50 cm in diameter, that are extensively used in hatcheries to produce algal biomass for feeding the larval stages of marine bivalves and fishes must be included in this category (Fig. 5a). Most commonly, these systems are made of translucent fiberglass sheets formed into cylinders. Air is bubbled at the bottom for mixing, and either artificial illumination or natural light (or a combination of both) is provided. James and Al-Khars (32) cultivated *Chlorella* and *Nannochloropsis* in 200-L, 30-cm-diameter fiberglass cylinders of this type. Five such units were connected in series and operated continuously. Illumination was provided externally by a vertical bank of daylight fluorescent lamps. Although as a consequence of the low S/V ratio of the cylinders, mean volumetric productivities (0.17 g L^{-1} d^{-1} with *Chlorella* and 0.05 g L^{-1} d^{-1} with *Nannochloropsis*) were not high, exceptionally high productivities per unit occupied area were reported (up to 200 g m^{-2} land area d^{-1} for *Chlorella*). However, these values must not be taken as constituting a valid parameter for evaluation and comparison of this system, since they suffer from the limitation inherent in expressing the productivity of elevated reactors on a per occupied land area basis, as discussed earlier.

Cylinders illuminated from inside, which may be considered a variation of the annular reactor devised by Jüttner (29), have been proposed for the production of marine microalgae biomass in hatcheries (33). Although internally lit cylinders have high construction costs, they are less expensive to operate than completely filled columns. They also typically attain higher volumetric productivity and greater efficiency of light utilization since the photon flux



(a)

(b)

Figure 5. Vertical cylinders (**a**) and polyethylene sleeves (**b**) used in hatcheries to produce algal biomass for the larval stages of marine bivalves and fishes (photographs by G. Chini Zittelli).

provided to the culture is completely trapped by it. A patented internally illuminated annular airlift column is used by Martek Co. for specialty chemicals production from microalgae (34).

Miyamoto et al. (35) experimented with vertical tubular reactors (2.35-m height, 5-cm ID) made from the low-cost (about $2.50 per tube), mass-produced glass tubes used in the fluorescent lighting industry. Volumetric productivities of about 0.6 g L^{-1} d^{-1} were obtained with *Nostoc* and *Anacystis* in outdoor cultivation. Although these systems do not represent an innovation, they are materially useful because of their low cost and relatively high S/V ratio in comparison to previous reactors of this type. Using a similar system consisting of 32 glass tubes 1.5 m in height and with a 2.6-cm ID, Hu and Richmond (36) obtained a volumetric productivity of 1.6 g L^{-1} d^{-1} with *Isochrysis galbana* cultivated outdoors.

Transparent polyethylene tubing of various diameters and thicknesses is available in long rolls at very low cost. A disposable vertical reactor can be easily built by cutting a suitable length of tubing and heat-sealing one end. This bag or sleeve reactor can be suspended from a framework (Fig. 5b) or supported within a mesh frame. Such reactors are used indoors with artificial illumination (generally vertically mounted fluorescent lamps) or outdoors under sunlight. The temperature reached in the manufacturing of the polyethylene tubing is high enough to sterilize the material. These systems have a relatively short life because of biofouling but are easy and inexpensive to replace at the end of the culture run. Two-meter-long transparent polyethylene sleeves sealed at the bottom and hung on an iron structure have been used to grow *Porphyridium* and *Dunaliella* outdoors (in Israel), obtaining a significantly higher productivity compared to open ponds (37). The main drawbacks of sleeve reactors are the relatively low S/V ratio and the low efficiency of utilization of artificial light when it is provided from outside of the reactor.

Serpentine Photobioreactors. Serpentine photobioreactors are systems in which several straight culture tubes are connected in series by U-bends to form a flat loop that can be arranged either vertically or horizontally. Gas exchange and nutrient addition take place in a separate vessel. Circulation between the flat loop and the gas exchanger is achieved by the use of a pump or of an airlift. Several reactors of this type have been developed in the last two decades following the original design by Tamiya (27).

In the early 1980s, Gudin and coworkers (3,38), working at the Centre d'Etudes Nucléaires de Cadarache, France, devised (and since that time have further developed) a horizontal serpentine reactor the main characteristic of which is the use of a water pond to obtain temperature control (a method anticipated by Tamiya). After a first 1-m^2 version consisting of glass tubes of 3-cm diameter, a 10-m^2 and then a 100-m^2 plant were built using larger diameter flexible plastic tubes. The 100-m^2 system, experimented with from 1986 to 1989, was composed of five identical 20-m^2 units, each of which consisted of 20 tubes, 20 m in length and 6 cm in diameter, made of 0.25-mm-thickness low-density polyethylene. The total culture volume was about 7 m^3. Temperature control was attained by floating or immersing the reactor in a water bath by inflating or deflating a second layer of tubes placed below the reactor. Initially, the culture was circulated by means of a pump, but later airlift systems were adopted to limit damage to shear-sensitive cells and at the same time provide CO_2 supply and O_2 degassing. Productivities from 20 to 25 g m^{-2} d^{-1} were obtained with *Porphyridium cruentum* in a 2-month continuous run. The use of rigid rather than flex-

ible tubes in the more recent work by Gudin's group has permitted operating a self-cleaning system consisting of two plastic balls, one with higher density than the culture medium and one lighter, which are hydraulically pushed through the system. Although flotation immersion in a water basin can provide efficient thermoregulation, the cost of such a system is prohibitive for most applications.

In 1992, Dr. Gudin founded the Heliosynthese S.A. company for development of tubular photobioreactor technology in France. In 1996, Heliosynthese changed its name to Thallia Pharmaceuticals S.A. Thallia presently makes use of serpentine reactors to produce high-value algal compounds for the nutriceutical and pharmaceutical markets. The major products under development are polyunsaturated fatty acids, carotenoids (zeaxanthin from *Porphyridium cruentum*, astaxanthin from *Haematococcus pluvialis*) and antioxidants (superoxide dismutase).

Reactors of the type developed by Gudin are also being operated by Molina Grima and coworkers in Spain (Fig. 6a) (14,15,39,40). These systems consist of a horizontal loop, made of Plexiglas® tubes (about 100 m in length and 2.6 cm in diameter), which is connected to a 3- to 3.5-m-high airlift. The tubular solar receiver is immersed in a shallow pond for temperature regulation. Dissolved oxygen, pH, and temperature probes are connected to an online control unit and a computer for data acquisition. The Spanish group has made important improvements to the reactor originally purchased from Heliosynthese, and with it has carried out, and is still conducting, extensive research activity with the dual aim of shedding light on basic aspects of tubular photobioreactor technology (e.g., mass transfer and light distribution), and of defining guidelines for application of closed systems to production of specialty chemicals from microalgae (e.g., polyunsaturated fatty acids).

In the early 1980s, Pirt and coworkers developed a serpentine tubular reactor at the University of London's Queen Elizabeth College (20,41). The photobioreactor consisted of a photostage formed of 52 Pyrex glass tubes (each approximately 1 m long and with a 1-cm ID) horizontally stacked. The tubes were connected to Pyrex glass U-bends by silicone-rubber tubing to form a vertical loop. The loop outlet was connected through a vertical riser to a degasser. A second tube connected the degasser to the inlet of the loop. The reactor covered an area of about 0.5 m^2. The culture suspension (about 4.6 L) was circulated by either a peristaltic pump, a rotary positive-displacement pump, or an airlift; the latter method was preferred because of the adverse effects observed with the two pumps. With a defined consortium consisting of a chlorella-type green alga and three chemotrophic bacteria, cell concentrations in excess of 20 g L^{-1} and a very high productivity of 2.2 g m^{-2} h^{-1} were achieved at a light intensity of only 38 W m^{-2} (PAR). The work carried out by Pirt and coworkers was remarkable for three reasons: It provided the first detailed analysis of the fundamental engineering parameters of a closed photobioreactor, introduced the concept of high S/V ratio reactors (127 m^{-1} in this case), and attained extremely high light-conversion efficiencies. It is worth noting that the about 40% reported efficiency for *Chlorella* growth corresponds to a quantum yield of about 6, as compared to the theoretical value of 8 (see earlier section). Pirt's analysis, however, did not consider the issue of the accumulation of photosynthetically generated oxygen, which represents a key limiting factor in large-scale tubular reactors (see later section), and ignored the light saturation effect, assuming that the efficiencies observed at low light intensity could be achieved in full sunlight as well. Although Pirt's serpentine reactor did deal efficiently with, and solve, many of the problems commonly encountered in closed systems, the concept of very high S/V ratio reactors revealed all its drawbacks when the experimental setup was scaled up to industrial level (see later section). The vertical serpentine reactor designed by Pirt was patented in 1983 (41). The patent also covers the design of a full-scale, near-horizontal manifold system according to which the culture flows from a tank through a descending conduit to the higher ends of a set of 50-m-long transparent tubes supported by a slightly inclined framework. Each tube communicates at its lowest point with its own riser, which leads up to the common reservoir. The tubes are arranged close together so as to intercept a high portion of the solar radiation impinging on the area occupied by the reactor. Both this manifold and the vertical serpentine design were scaled up to commercial size in the late 1980s by PBL (see later section).

In the mid-1980s at the Centro di Studio dei Microrganismi Autotrofi (Florence, Italy), Florenzano and coworkers started their experiments with horizontal serpentine tubular photobioreactors for the cultivation of *Arthrospira* (42). One of the first pilot reactors they set up was made of 14-cm-diameter, 0.3-mm-thick flexible polyethylene tubes. Because of problems of leakage, these collapsible sleeves were later replaced with rigid Plexiglas® tubes. The standard unit consisted of straight tubes, with a 13 cm ID and 4 mm thick, laid parallel on a white sheet and joined by PVC U-bends to form a loop 500 m in length (Fig. 6b). As it exited the reactor, the culture suspension flowed into a receiving tank, from which a diaphragm pump raised the suspension to a feeding tank placed at 3 m above ground level. The feeding tank was provided with a siphon that allowed discharge of about 340 L of culture into the photobioreactor every 4 minutes, thus sustaining a culture flow of 26 cm s^{-1}. The photobioreactor had a total volume of 8 m^3 and covered an area of 80 m^2. The productivity of *Arthrospira* in this system was 50% higher than in open ponds, due both to the better diurnal temperature profile and to the extended cultivation period. More recently, the same group developed and experimented with a 145-L two-plane serpentine reactor (43) (Fig. 6c). The system consisted of a 245-m-long loop made of 2.6-cm ID Plexiglas® tubes arranged in two planes to maximize capture of the radiation impinging on the horizontal, and thus increase areal yield. The two planes were connected to form a single loop and the culture, circulated by means of two airlifts, flowed from one plane to the other. A maximum areal productivity of 27.8 g m^{-2} d^{-1} was achieved in July. It would appear that for such a high-cost system, the loss of volumetric productivity due to shading by the upper plane would exceed the benefits deriving from improved areal yield and land saving. It must be noted, however, that the volumetric productivity achieved with this

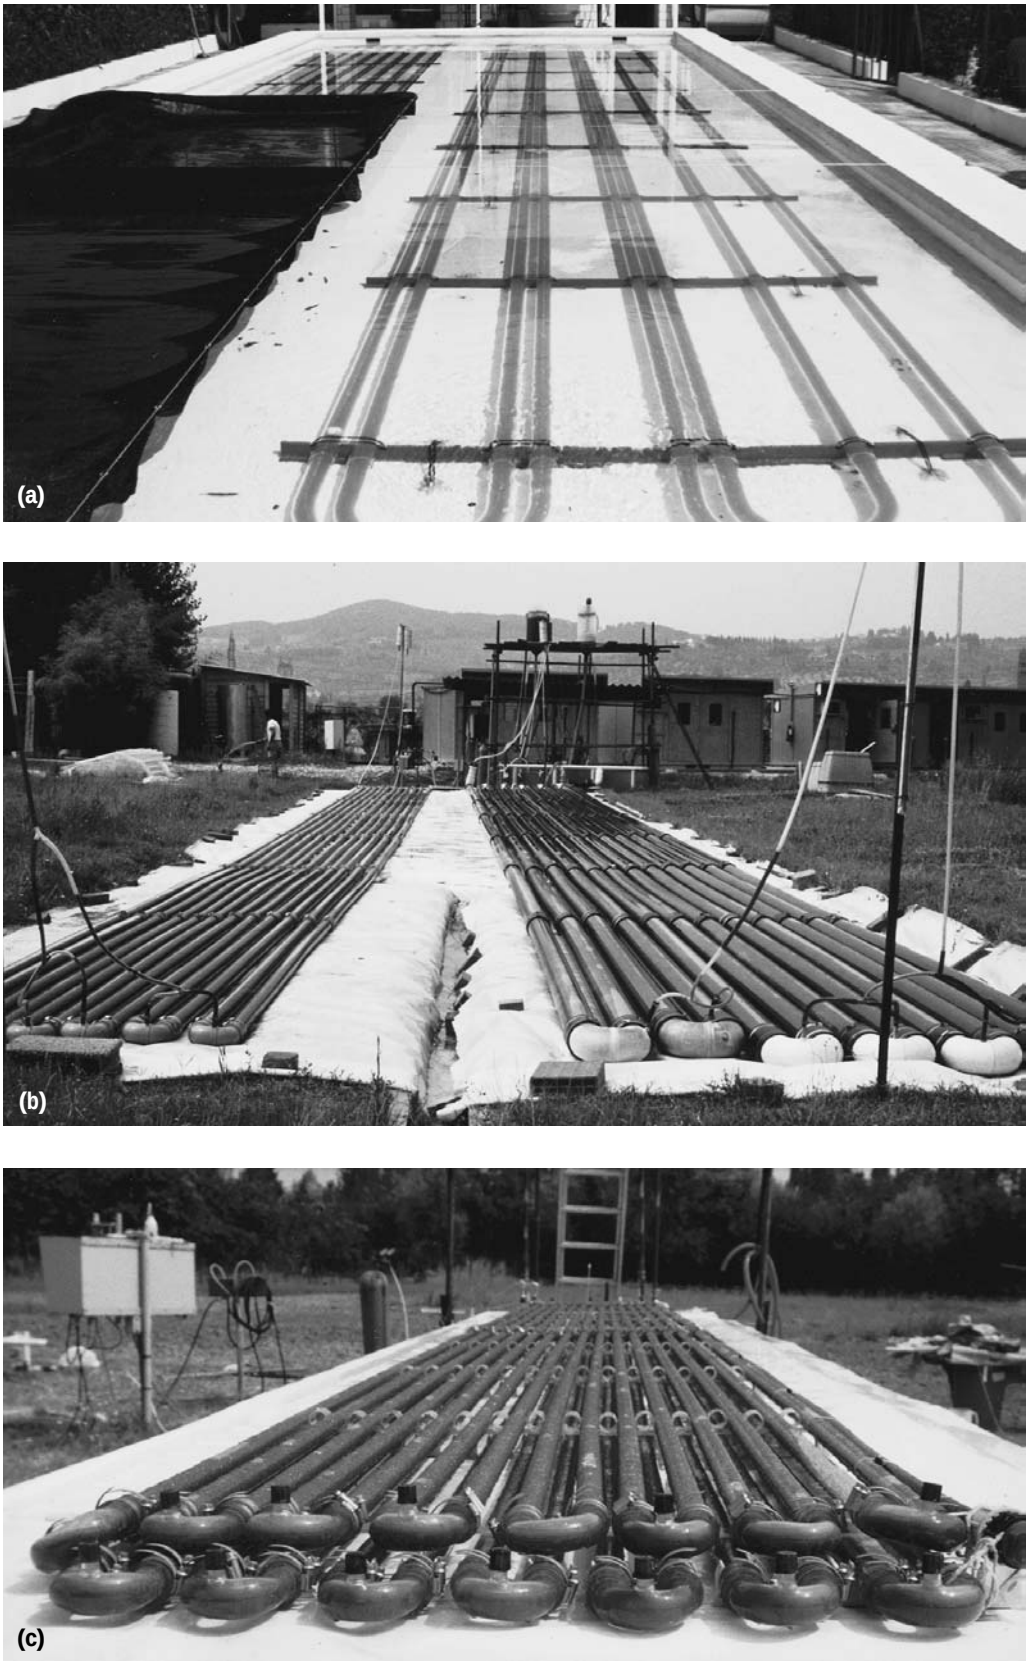


Figure 6. Horizontal serpentine photobioreactors set up at the University of Almeria, Spain (**a**) (photograph courtesy of E. Molina Grima) and at the Centro di Studio dei Microrganismi Autotrofi of Florence, Italy (**b, c**) (photographs courtesy of G. Torzillo).

two-plane photobioreactor (1.5 g L d^{-1}) was relatively high. The main merit of this study was that it addressed fundamental engineering parameters such as the effect of the rheological behavior of the algal culture on the mixing characteristics of the system, and the energy requirement for turbulent flow, which are often ignored.

Aquaserch (Kona, Hawaii) has recently devised and patented (44) a serpentine tubular reactor made of low-density polyethylene tubes. As in several previous serpentine designs, cooling is obtained by immersion of the reactor in a pond. The system, called the Aquaserch Growth Module (AGM), has been tested with different microalgae and is presently used to grow *Haematococcus* for astaxanthin production. The AGM is claimed to be the largest commercial-scale photobioreactor ever devised and one of the least expensive.

Manifold Photobioreactors. In manifold photobioreactors, a series of parallel tubes is connected at the ends by two manifolds, one for distribution and one for collection of the culture suspension. This type of photobioreactor represents one of the simplest configurations possible. As shown by Pirt et al. (20), about 15% of the energy consumed for recycling the culture in serpentine reactors is spent in moving the culture suspension around the bends; thus, in comparison to serpentine reactors, in which the culture inverts the direction of motion at each turn, manifold systems allow a significant saving of energy.

In 1991 in Javan (Tadshikistan), Sagdiana PGT built and used a large-scale glass reactor of the manifold type (Fig. 7a) (45) for cultivation of *Chlorella*. The system, very likely the largest glass reactor ever built, comprised 10 units consisting of two banks of 28 5.7-cm-ID tubes, each 73.5 m long, for a total of about 41,000 m of tubing. The tubes were connected in parallel to two metal headers each 20 cm in diameter. The culture suspension (13 m^3 in each unit) was circulated between the two banks of tubes at a speed of 1.1 m s^{-1} by a 290-m^3 h^{-1} capacity pump. Each unit was provided with one 3.6-m-high, 2.4-m-diameter gas exchanger. Temperature control was obtained through circulation of water from a single cooling tower serving all 10 units. The reactor was operated from August to October 1991, during which time it produced 0.5 ton of *Chlorella* biomass. Instability of the production process and contamination by *Scenedesmus* were reported to be the main problems.

Tredici and coworkers, working at the University of Florence (Italy), have developed several types of near-horizontal manifold-type photobioreactors (NHTR) (Fig. 7b). Units made of rigid or flexible tubes ranging from 6 to 85 m in length and from 4 to 5 cm in diameter have been built and used to grow *Arthrospira platensis*, *Anabaena siamensis*, and *Nannochloropsis* sp. under the climatic conditions of central Italy. Two eight-tube reactors of this type, 20 m in length, have been installed at the University of Hawaii as part of a joint project (Fig. 7c) (46). Typically, a NHTR consists of some 10–15 flexible tubes, each 45 m long and 4 cm in diameter, connected by two manifolds; the upper manifold, about 30 cm in diameter, acts as the degasser. The tubes are placed side by side on white corrugated plastic sheeting, facing south and inclined at a slight angle to the horizontal (4–6°). The corrugated sheeting keeps the tubes well aligned at a uniform inclination, reflects light onto the culture, and also provides drainage for rain and cooling water. Temperature control during the day is obtained by water spraying; the cooling water is collected and reused. The largest unit experimented with thus far occupies an area of 30 m^2 and contains about 600 L of culture. The main characteristic of the NHTR reactors developed in Florence is the use of air injection, at rates between 0.02 and 0.1 L L^{-1} min^{-1}, to attain mixing and gas exchange. The air is injected at the lower end of each tube by means of a perforated pipe inserted into the bottom manifold. In a different configuration used more recently, a number of tubes (typically one out of four) are not gassed, and are used as return flow tubes to increase the circulation speed of the culture and to obtain better mass transfer. Carbon dioxide addition to the air stream or in the return tubes is regulated through a pH-stat system. This reactor is shown in schematic form in Figure 8. Volumetric productivities of up to 1.4 g L^{-1} d^{-1} and areal productivities of more than 28 g m^{-2} d^{-1} have been obtained with *Arthrospira platensis* grown in these manifold systems. Besides simplicity of operation and low maintenance cost (due to the absence of moving parts), this internal gas-exchange reactor has other advantages: low shear stress compared to pump mixed reactors; no need for pumping the culture to a gas exchanger; and reduced fouling and wall growth due to the scouring effect of the gas bubbles. Moreover, this system appears to have potential for unit scale-up to about 100 m^2, and is relatively low cost in comparison to other designs. A preliminary estimate for a unit of 30 m^2, built and tested at Montepaldi (near Florence), sets the cost of this type of reactor at about \$60/m^2 (M.R. Tredici and G. Chini Zittelli, unpublished material, 1997), with the following cost per square meter: land, \$1.50; site clearing, grading, and leveling, \$6; liners, \$3.50; support framework, \$14.50; corrugated sheeting, \$5.50; tubing, \$13; manifolds, connectors, and piping, \$11.50; cooling system, \$1.50. A cost analysis for a large NHTR system for biological hydrogen production was recently presented (47).

A parallel-flow tubular photobioreactor was devised and experimented with in outdoor cultivation of cyanobacteria at the Microalgal Biotechnology Laboratory of Ben Gurion University (Israel) (48). The system consisted of eight 20-m-long, 3-cm-ID polycarbonate tubes laid parallel on the ground or on a horizontal platform and connected by manifolds made of 6.3-cm-diameter black polyethylene tubing (Fig. 7d). Circulation and gas exchange were obtained by means of a 2.2-m-high, 4.6-cm-ID airlift connected to a 20-L gas separator. A manifold received the culture from the separator and distributed it among a first series of culture tubes. At the far end of these tubes, the culture suspension was collected by a second manifold and distributed among a second series of returning tubes through which the culture ran back to the airlift riser and the gas separator. Small differences in flow rates were measured between the tubes. Temperature control was provided by water spraying. A productivity of 0.55 g L^{-1} d^{-1} was obtained with *Arthrospira platensis* and *Anabaena siamensis*. The main advantages of the system over serpentine reactors are the reduction of head losses and lower oxygen

concentrations; these two factors facilitate scale up to industrial size.

A manifold elevated system called the α-type tubular photobioreactor was devised and experimented with in Singapore (Fig. 7e) (49). The reactor consisted of two sets of 10 parallel transparent PVC tubes (25 m long with a 2.5 cm ID), both placed at an angle of 25° to the horizontal but inclined in opposite directions. The algal suspension was lifted by air injection through a series of vertical PVC air-riser tubes (3.5 cm in diameter, 5 m in height) to a receiver tank from where it flowed down the first set of 25°-inclined tubes. These were connected to the base of a second series of air risers that lifted the culture to another receiver tank, from where the culture descended again through the second set of 25°-inclined tubes to the base of the first series of risers. The reactor thus looked like the Greek letter α. This elevated reactor, containing about 300 L of culture and covering a land area of about 12 m^2, was shown to be particularly well-suited to operation at low latitudes. *Chlorella pyrenoidosa* was grown for several months and reached very high cell densities (>10 g L^{-1}). The major problems were biofouling, solved by injecting air from the upper end of the inclined tubes, and foam formation at the higher cell densities. An areal productivity of 72 g m^{-2} occupied land d^{-1} was reported; as mentioned previously, the latter parameter can be misleading when referred to elevated systems.

At the University of Manchester (UK), Applied Photosynthetics Limited (APL) has recently developed a photobioreactor known as the Bio-Fence (Fig. 7f). The company offers several sizes of modular reactors of this type, designed specifically for the cultivation of the marine algal species used in aquaculture or for waste treatment with either microalgae or photosynthetic bacteria. The Bio-Fence consists of rigid transparent tubes racked together in banks and connected by manifolds in a fencelike structure. The culture suspension is circulated continuously between the photostage and a holding tank by a centrifugal pump or by an airlift. A patented scouring mechanism provides continuous cleaning of the inner walls of the tubes. The pH of the culture is controlled automatically by injection of CO_2 in the photostage. The most distinctive feature of the Bio-Fence is the stacked manifold configuration, which provides optimal gas exchange with elimination of pressure drops within the reactor. A 100-L unit requires a tube stack 5 m long by 0.75 m high. Units with a total volume of 500 L, with a tube length of 5 m, or 1,000 L volume, with a tube length of 10 m, can be assembled. The Bio-Fence is produced and marketed as units of from 50- to 1,000-L capacity that can be connected in parallel to any scale. Small steam-sterilizable systems for axenic operation are also available. In the case of systems connected in parallel, the units can be placed as close as 30 cm apart, as in the vertical system built by PBL in Spain and Pulz's alveolar plates (see later section). This arrangement will reduce volumetric productivity in case of outdoor utilization because of shading among the units but will attain two important results: high efficiency of land utilization (due to the very compact structure) and high photosynthetic efficiency (due to dilution of sunlight). The possibility of installing fluorescent tubes between the parallel units for additional lighting has also been considered. Typical cell concentrations achieved in the Bio-Fence are about 1 g L^{-1}. Productivity data are not available. The Bio-Fence is an accurately designed, well-engineered reactor. The only limitation seems to be the presence of a large dark tank that might reduce productivity in case of an excessively high ratio between darkstage and photostage volume.

Helical Photobioreactors. Helical photobioreactors consist of small-diameter, generally flexible tubing wound around an upright structure. This design is not new; it was used in the 1950s by Davis to grow *Chlorella* (50) and later adopted, in a flattened version made of glass tubes, by Setlik (28), Jüttner (29), and Krüger and Eloff (30). This coiled arrangement allows deployment of relatively long tubes on a small land area.

Helical photobioreactors called Biocoils were devised and patented in the late 1980s by Biotechna Ltd. (51). The Biotechna reactor consists of low-density polyethylene or clear food-grade PVC tubing, 2–3 cm in diameter, wound in a helix around an upright cylindrical core structure, typically 8 m in height with a core diameter of 2 m. Compressed air or peristaltic or centrifugal pumps may be used to induce culture circulation, with the culture being pumped downward through the coiled tube or upward through the tube to a header tank. Temperature control is achieved by a heat exchanger placed between the photostage and the pump. Pilot "biocoil" facilities have been installed at Luton (UK) and in Australia (52). Biotechna-Graesser A.P. Ltd. (based in the UK) marketed biocoils of different sizes (from a few liters capacity up to 10,000 L) for microalgae cultivation or for use with algae and heterotrophic bacteria in the treatment of wastewaters or toxic wastes. Small biocoil units are being operated for experimental and teaching purposes at King's College (London) (53) and at Murdoch University (Murdoch, Australia) (54).

A 120-L helical bubble reactor was devised and operated by Tredici and Chini Zittelli (19) to grow *Anabaena siamensis* and *Arthrospira platensis* outdoors (Fig. 9a). The reactor consisted of three 49-m-long transparent PVC tubes (3-cm ID, 0.5-cm wall thickness) wound around a vertical structure with an inclination of 2° to the horizontal in such a manner as to form a 1.65-m-high, 1.1-m-OD coil. The higher ends of the tubes were connected to a 20-L degasser. From the degasser, the culture flowed down through a single pipe connected to the lower ends of each tube. In this system, as in the NHTR devised by the same group, air was injected at the bottom of each tube and the bubbles flowing up the tubes provided mixing and gas exchange and prevented biofouling. Cooling was achieved by water spraying. With *A. platensis*, a mean volumetric productivity of 0.9 g L^{-1} d^{-1} and a photosynthetic efficiency of 6.6% (PAR) were achieved. The system operated with remarkable stability. The cost of a unit of this type was estimated at about $150.

A coiled, internal gas-exchange photobioreactor of about 3,000 L total volume was built in 1996 by Inalco S.p.A near Vicchio (Florence, Italy). The system consists of straight polycarbonate tubes, 5 cm in diameter, secured to an upright hexagonal frame with an inclination to the horizontal of 1.4°. The reactor is about 7 m high and occupies an area of about 40 m^2. Culture circulation is obtained by air injection at the base of the tubes. Temperature is controlled by a water-jacketed section. The reactor has been successfully experimented with in the cultivation of *Arthrospira platensis*.

Flat Photobioreactors. Flat photobioreactors and flat culture chambers have often been used to grow phototrophic microorganisms in the laboratory because they provide a simple geometry and greatly facilitate the measurement of irradiance at the culture surface. Despite their apparent simplicity, few such systems have been used for mass cultivation of algae.

The first flat culture unit devised for mass production of algae was the "rocking tray" used by Milner in 1953 (50) to grow dense *Chlorella* cultures in a thin turbulent layer. This system consisted of a 2.65-m^2, 9-cm-deep tray covered with transparent wire-reinforced plastic sheeting and supported on a shaker. At a mean culture depth of 1.7 cm, an average productivity of 8.2 g m^{-2} d^{-1} was obtained in a 20-day run. Following this experience, flat reactors were practically neglected until the 1980s.

Anderson and Eakin (55) cultivated *Porphyridium cruentum* outdoors for polysaccharide production using 3-m^2 flat plates 5–20 cm in depth (made of stainless steel and covered with glass or plastic) that were inclined to the horizontal to maximize interception of solar irradiance. About 20 g of polysaccharide m^{-2} d^{-1} were produced during the summer, when temperature control was provided.

In the mid-1980s, two groups working independently in France and in Italy introduced flat alveolar panels in algae cultivation. These systems are constructed from transparent PVC, polycarbonate, or polymethyl methacrylate sheets that are internally partitioned to form rectangular channels called alveoli. These sheets are commercially available in standard thicknesses from 4.5 to 40 mm.

Alveolar plates as culture systems for algae were first used by Ramos de Ortega and Roux (56) at the Centre d'Etudes Nucléaires de Grenoble (France). These authors experimented with 6-m-long, 0.25-m-wide, 4-cm-thick, double-layer panels made of transparent PVC for growing *Chlorella* in a greenhouse and outdoors. The plates were laid horizontally on the ground; the upper layer of channels was used for algal growth and the lower for thermoregulation. The culture suspension was circulated through a pump. A productivity of 24 g m^{-2} d^{-1} was achieved in the summer using units of 1.5-m^2 surface area. The authors stressed the fact that the double-layer plate permitted efficient thermoregulation of the culture and that significantly higher performances were obtained with the panels than with flexible sheets and semirigid tubes.

The first panel reactors built and experimented with in Florence by Tredici and coworkers were placed vertically, with the channels (and hence culture flow) running parallel to the ground, a design later adopted in Germany by Pulz. A pump was used to circulate the suspension. In 1988, the Consiglio Nazionale delle Ricerche (CNR) of Italy presented this reactor at the ITALIA 2000 exhibition, held in Moscow. The same year saw the awarding of a patent to a different design (57) in which the plate was placed vertically, but with the channels perpendicular to the ground; mixing was achieved by bubbling air at the bottom of the reactor. This latter version (Fig. 9b) has been used extensively in Florence for outdoor cultivation of cyanobacteria (5,19,58–61). The plates used in Florence are constructed from 16-mm-thick Plexiglas® alveolar sheets commonly available on the market at a cost of $30–40 m^{-2}. The main features that characterize these reactors are the high *S/V* ratio (80 m^{-1}), the vertical or tilted inclination from the horizontal of the channels, and the fact that no mechanical device is used to mix the cell suspension, circulation and degassing of the culture being attained through bubbling air at the base of each channel. Elevated "bubble column" plates of 2.2-m^2 surface area have been used to study the influence of some of the main cultural parameters, such as areal density, turbulence, oxygen tension, and orientation of the photobioreactor, on productivity and biomass composition of *Arthrospira platensis* (5). Alveolar plates, due to their high *S/V* ratio, attain high volumetric productivities (>2 g L^{-1} d^{-1}) and permit operation at high cell concentrations (4–6 g L^{-1}); these systems, however, have typically attained lower areal yields (about 24 g m^{-2} d^{-1}) compared to tubular reactors (about 28 g m^{-2} d^{-1}) (19). The lower performance achieved by cultures in plates has been attributed to the fact that these systems, unlike tubular reactors, do not achieve light dilution (unless they are placed at a high inclination with the horizontal) and thus cultures in plates suffer more strongly because of the light saturation effect and from photoinhibition (19). Alveolar plates, like other small flat systems, may be used profitably for research or in small production plants, however, due to the fact that the surface area of the cultivation unit is limited to a few square meters, they are not suitable for use in large commercial plants.

More recently, at the IGV Institut für Getreideverarbeitung (Bergholz-Rehbrücke, Germany), cultivation units based on 32-mm-thick alveolar panels were developed and

operated by Pulz and coworkers (6). Typically, the plates are placed vertically with the channels arranged horizontally, just 20 cm apart, to form a compact structure called PBR (Fig. 9c). The culture, circulated by a piston pump, must reach a velocity adequate to maintain turbulent flow inside the channels. The distance to the degasser is critical in avoiding toxic concentrations of oxygen. Units from 100 to 10,000 L, made of closely packed plates, have been developed and tested both indoors and outdoors with different microalgae and cyanobacteria. Productivity levels of 1.3 g l^{-1} d^{-1}, corresponding to 28 g m^{-2} of illuminated surface d^{-1}, have been obtained with *Chlorella* under natural illumination. Among the problems that have emerged are buildup of oxygen (up to 30–40 mg L^{-1} at the outlet of the circuit) and fouling. The main characteristic of the PBR is the closely packing of the panels: 42 plates, for a total volume of 6 m^3, can be packed on 100 m^2 of land. Areal productivities of up to 130 g m^{-2} d^{-1} have been reported for such compact units, but these figures seem excessive and indeed confirm the incorrectness of referring the yield of vertical reactors to unit of occupied land. The main merit of the PBR, besides its high degree of technical development, is the achievement of significant light dilution. PBR reactors are sold commercially by B. Braun Biotech Int. in sizes from 10 to 6,000 L (6).

Richmond and coworkers (62) developed an inclined modular photobioreactor consisting of a series of flat glass chambers, 0.7 m high, 0.9 m long, and usually 2.6 cm in internal width, connected in cascade and tilted at the proper angle to maximize solar radiation capture (Fig. 9d). The culture volume varied from 6 to 50 L according to reactor width. Two mixing methods were tested: an airlift system consisting of five transparent PVC columns inserted vertically into the reactors with compressed air injected at the base of the columns, and air-bubble mixing by means of two perforated tubes running horizontally along the entire length of the reactor, one at the bottom and the other at midheight. The latter method yielded better performance. By adopting a reactor width of 2.6 cm and vigorous mixing (2.5 L air L^{-1} culture suspension min^{-1}), a record areal productivity of 49.4 g m^{-2} illuminated surface d^{-1} was achieved. When the back and side surfaces of the reactor were covered to avoid entry of diffuse light, productivity was reduced by about 20%. Nevertheless, this figure is the highest ever reported for a cyanobacterium cultivated outdoors. Using this flat modular system, the Israeli group has addressed and contributed to clarifying such fundamental aspects of photobioreactor design as optimal cell density with reference to the light path, the effect of reactor inclination, and the importance of the mode and intensity of mixing.

Commercial-Scale Photobioreactors

Only a few large commercial-scale photobioreactors have been built and operated: the PBL photobioreactors (based on the two different designs described in Pirt's patent) in southern Spain in the late 1980s and the Hidrobiologica SA manifold photobioreactor (probably inspired by previous similar designs devised in Italy by the Centro di Ricerca Agro-Industriale and Montedison) set up in the mid-1990s in northern Argentina. Despite the very different designs, both the plants suffered from similar mistakes with respect to some fundamental technical aspects and the scaling-up phase.

Photo Bioreactors Ltd. Plant. Although Pirt's measurements and extrapolations were not flawless, the quality of the basic work done at Queen Elizabeth College and the high projected productivities attracted investments and led to the creation of a company, Photo Bioreactors Ltd. (PBL UK), in 1986. A pilot plant was built and experimented with at the Reading University Research Farm (Sonning, UK). Three years later, PBL Spain (PBL SA) was founded with investments from private industries (among which the Danish Chr. Hansen Laboratory) and public Spanish sources (Instituto de Fomento de la Region de Murcia and Centro de Desarrollo Tecnico Industrial). A second pilot plant was set up in Santomera (Murcia, Spain), and finally a commercial plant for *Dunaliella* production was established in Santa Ana near Cartagena (Murcia, Spain). Full-scale activity started in May 1990, with a vertical system made of 50 rows, each of which contained 50 1.2-cm-diameter, 50-m-long polyethylene tubes (for a total tubing length of 125,000 m) (Fig. 10a). Circulation was provided by an airlift, and temperature was controlled by shading the reactors with nets or by water spraying. A near-horizontal system was built later according to the full-scale design patented by Pirt, using about 200,000 m of polyethylene tubing. Several major technical errors are apparent in these two systems: The tube diameter was too small for effective mixing considering the design (Fig. 10b), the tube material degraded quickly under sunlight, oxygen degassing was inadequate, wall growth was almost unavoidable, and control of temperature was problematic.

The very high S/V ratio in relation to the length of the tubes, together with the insufficient circulation and the improper management of the culture, led to poor growth of the alga, biofouling, and heavy contamination. But, as far as we know, the main reason for failure was inadequate piloting: although the pilot plants had been carefully planned and constructed with an appropriate 10-fold increase factor in the different stages, the problems encountered during the pilot stage were not taken into due consideration and had not been solved by the time commercial activity started. In September 1991, after an almost complete crash of the culture, the workers were dismissed and PBL closed without ever entering into production (63).

Hidrobiologica SA Plant. In 1996, Hidrobiologica SA, with an initial investment of about $2 million, built the largest known photobioreactor (Fig. 10c) about 15 km south of La Rioja (northern Argentina). The system consisted of 96 0.4-mm-thick polyethylene tubes, each 120 m long and 25.5 cm in diameter, laid parallel and horizontally on the ground and arranged like a manifold with feeding, connecting, and collecting channels made of concrete. The tubes, only partially filled, were maintained at very low positive pressure so that they assumed a roughly elliptical shape (about 35 cm wide and 9 cm high). The plant was divided into four modules, each of which comprised four six-tube submodules. An interspace of 0.5 m was allowed

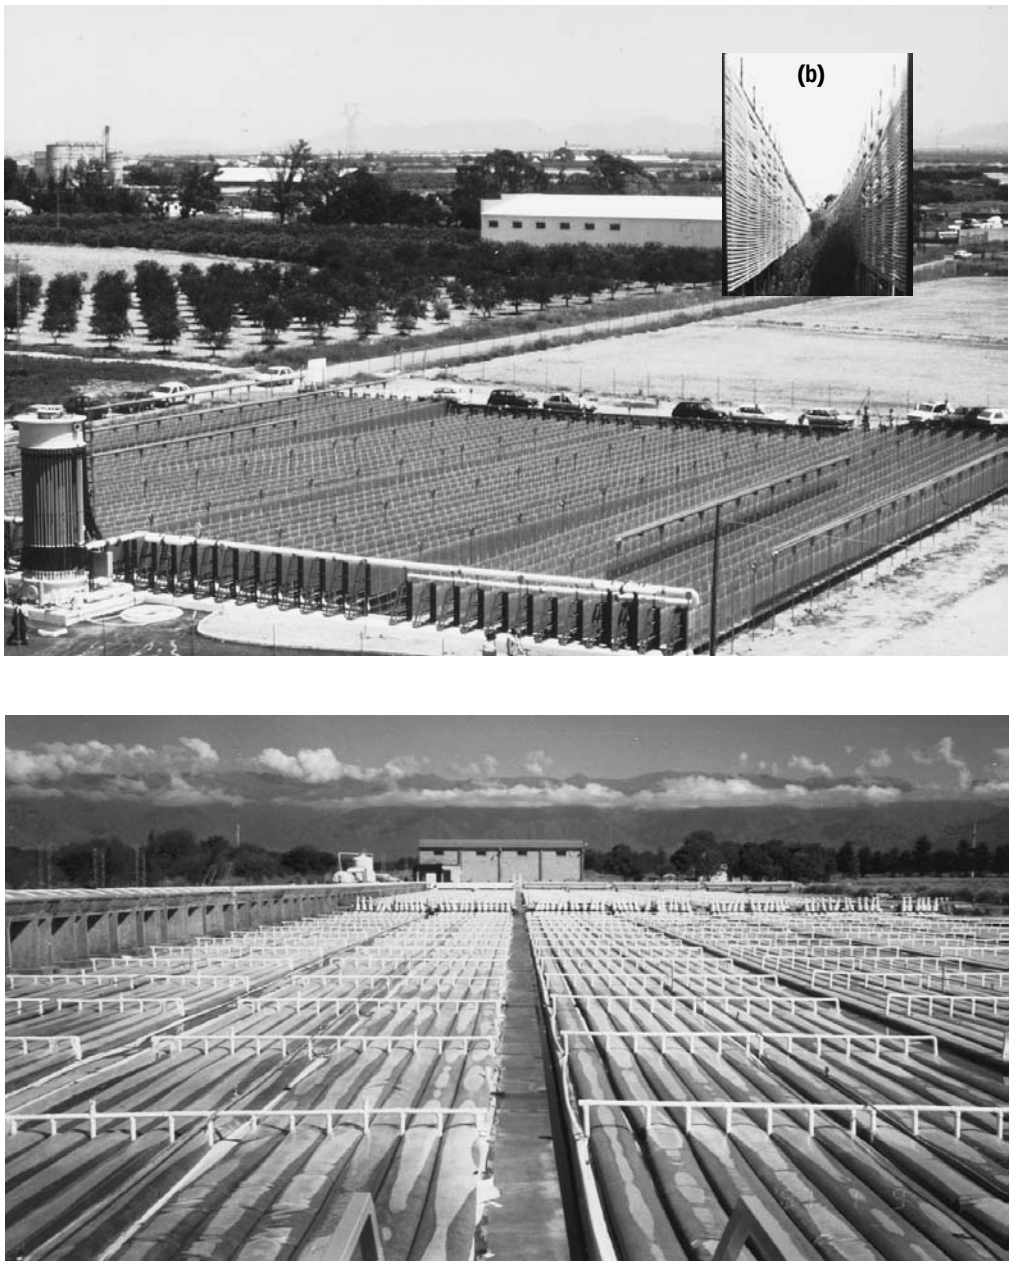

Figure 10. Commercial-scale photobioreactors: (**a**) vertical system set up by Photo Bioreactors Ltd (PBL) in Santa Ana, Murcia, Spain (photograph courtesy of D. Hall); (**b**) a particular of the PBL vertical system as it appeared in July 1995, four years after shutdown (photograph by the author); (**c**) the Hidrobiologica SA plant built at La Rioja, Argentina (photograph by G. Chini Zittelli).

between one submodule and the next, while about 1 m separated the modules. The four modules were connected to common feeding and collecting channels. The surface occupied by the whole plant, including the gaps between tubes, was about 5,000 m^2, and the total culture volume was 600 m^3. The culture (*Arthrospira platensis*) was circulated at a flow speed between 6 and 10 cm s^{-1} by a single axial flow pump with a maximum capacity of 900 $m^3\ h^{-1}$. The pump lifted the suspension from the collecting channel, into which it was fed by the culture tubes, up to a second raised, sloped channel. The suspension flowed by gravity through this second channel, which ran parallel to the culture tubes for 120 m, to the feeding channel at the opposite end of the reactor. The feeding channel, about 42 m long, distributed the culture suspension to the inlets of the single culture tubes. During the initial period of activity, the cell concentration was typically maintained at about 1 g L^{-1} and the productivity was calculated to be around 0.2 g $L^{-1}\ d^{-1}$; the biomass produced was of excellent quality. In the long run, however, several problems became evident; the most significant were poor mixing and biofouling deriving from the low flow speed and the un-

equal distribution of the culture among the tubes. The limited capacity to control temperature was also a major drawback in summer. It is likely that oxygen built up to dangerous levels despite the gas outlet provided halfway along the tubes, but no data are available. The plant is at present undergoing complete restructuring; the main objectives of this effort are to subdivide it into separate units, reduce the tube diameter, and improve mixing and culture circulation. The major errors, besides poor mixing and limited temperature control, were probably the absence of accurate piloting and the fact that only one large single unit was built and operated.

DESIGN CRITERIA FOR PHOTOBIOREACTORS

The basic function of a photobioreactor is to provide a controlled environment in which to achieve optimal growth and maximum, sustainable biomass and/or product synthesis with a specific phototroph (4). This means that a photobioreactor cannot be properly designed without adequate knowledge of the growth physiology of the organism to be cultivated. Besides, since phototrophic microorganisms are highly diverse as concerns their morphology, biology, nutritional and light requirements, and resistance to stresses, a single photobioreactor design cannot adapt to all organisms and all conditions.

Design criteria for photobioreactors should aim at achieving high efficiency of light conversion and at providing the necessary reliability and stability to the cultivation process by solving the main problems encountered in photobioreactor operation, such as overheating, oxygen buildup, biofouling, contamination, and photostage material deterioration. The fundamental design criteria for photobioreactors include reactor configuration, S/V ratio, mixing and degassing devices, temperature regulation, orientation, and the material used to build the photostage. These aspects are briefly discussed in the following sections. Reliability, ease of operation and scale-up, and construction and operating costs also take on particular relevance in relation to commercial application of photobioreactors.

Surface-to-Volume Ratio

The surface-to-volume ratio of the photobioreactor (i.e., the ratio between the illuminated surface of the reactor and its volume) determines the amount of light that enters the system per unit volume and the light regimen to which the cell population is subjected and is consequently one of the most important issues in photobioreactor design. The higher the S/V ratio, the higher the cell concentration at which the reactor is operated and the volumetric productivity of the culture. The cell concentration, in turn, greatly influences medium handling and harvesting costs and, to some extent, contamination level. The temperature profile and the hydrodynamic behavior of the culture suspension are also affected by this parameter (4,5,64). For example, in small-diameter tubular systems operated outdoors, the time required to reach the optimal temperature in the morning is reduced, and in the evening the relatively low culture volume cools down more quickly to ambient night temperatures, resulting in lower respiratory losses (4). For these reasons, in recent years we have witnessed a general trend toward a reduction of the diameter of tubular reactors and of the thickness of flat panels. Yet, it must be pointed out that although high S/V ratio reactors may work well in the laboratory, they may become extremely inefficient when scaled up. In high S/V ratio photobioreactors, all the volumetric activities that depend on the input of light energy per unit volume (such as O_2 evolution, CO_2 absorption, nutrient depletion, metabolite excretion, and heat production) change at a high rate, and this could have long-term negative effects on the stability of the process. These effects are rarely observed because experiments do not last long enough for them to become evident (63). The industrial systems set up by PBL (see earlier section) provide clear examples of the kinds of problems that may be absent at laboratory scale and yet arise when high S/V ratio photobioreactors are adopted in large-scale plants. It is not possible to fix an optimal S/V ratio for large-scale photobioreactors, since this parameter depends on the organism to be grown, on the type of mixing, and on other specific conditions. However, my laboratory experience suggests that a light path between 3 and 6 cm may represent a reasonable compromise.

Oxygen Accumulation

Accumulation of photosynthetically generated oxygen is one of the main factors that limit scale-up of photobioreactors. Dissolved oxygen concentrations over 35 mg L^{-1} (equivalent to about four times air saturation at 25 °C) may be easily reached in outdoor dense algal cultures at midday. Such high oxygen levels are toxic to many phototrophs and, if coupled with prolonged exposure to full sunlight, may lead to the photooxidative death of the culture (4,9). Since volumetric oxygen production is directly related to volumetric biomass productivity (about 1 g of oxygen is evolved per gram of biomass synthesized), oxygen buildup becomes an especially serious problem in high S/V ratio photobioreactors operated outdoors. At maximal rates of photosynthesis, a 1-cm-diameter tubular reactor would accumulate about 8–10 mg of oxygen L^{-1} min^{-1} (64). In such systems, the maintenance of dissolved oxygen below the toxic concentration requires adoption of very short loops and this fact makes the serpentine design difficult to scale up. The situation is less dramatic in tubes of greater diameter, since the volumetric rate of oxygen evolution falls in proportion to the decrease of the S/V ratio, but it has been shown that even in 14-cm-diameter tubular reactors dissolved oxygen may reach levels that significantly reduce productivity (42). In serpentine reactors, the time cycle (time required for the culture to reach the degassing point), the speed of circulation, and the length of the loop must be very carefully chosen in relation to the expected volumetric productivity to prevent buildup of toxic oxygen concentrations. For example, in a tubular reactor with a 2.6-cm ID and a culture flow speed of 0.3 m s^{-1}, the time cycle should not exceed 6 min, hence, the length of the reactor must be less than 100 m (4). To increase the length of the reactor it is necessary to increase the culture circulation speed or reduce the S/V ratio. Internal gas-exchange systems (bub-

ble columns) offer some advantage in this respect. Unlike serpentine reactors, in which oxygen accumulates during the loop cycle and is removed only at the degasser, bubble columns present the advantage that the whole culture is subjected simultaneously to the degassing action of air.

Mathematical models can be employed to predict the effect on oxygen concentration of various design variables, such as the length of the loop, the tube diameter, and the liquid circulation speed. A useful model for prediction of dissolved oxygen and carbon dioxide axial concentration profiles in serpentine tubular reactors has been developed and verified experimentally with *Porphyridium cruentum* in outdoor continuous culture by Camacho Rubio et al. (40).

Mixing

The type of device used to mix and circulate the culture suspension is essential in the design of a successful photobioreactor. Both the productivity of a photobioreactor and the cost of its construction and operation are influenced to a great extent by the type of device used for mixing (65). The beneficial effects that mixing has on growth and productivity of mass cultures of phototrophs are well known (9). Mixing is necessary to prevent cells from settling, to avoid thermal stratification, to distribute nutrients and break down diffusion gradients at the cell surface, to remove photosynthetically generated oxygen, and, above all, to ensure that all the cells experience alternating periods of light and darkness. It has been postulated that cells quickly brought into and out of the lighted portion of the culture could take advantage of the "flashing light effect" to increase photosynthetic efficiency. Conflicting results have been reported, however, for the light–dark fluctuations of medium frequency (i.e., in the order of seconds to minutes) that prevail in mixed-mass cultures as regards their stimulatory effect on productivity, and the true role of the mixing rate in determining algal productivity still remains to be clarified (9,64–66). With a few exceptions, significant positive effects of intense stirring on productivity of algal mass cultures have been observed only in paddle-wheel-mixed raceway ponds (9,67). Carlozzi and Torzillo (68) observed a 30–40% increase of the productivity of *A. platensis* grown in tubular reactors when the flow speed was increased from 0.18 to 0.75 m s^{-1}. Tredici and Chini Zittelli (5,60) studied the influence of the bubbling rate on productivity of *A. platensis* in inclined flat plates. At an air supply rate of 1.21 L L^{-1} min^{-1}, productivity increased by 35% over that at a rate of 0.36 L L^{-1} min^{-1}. The authors suggested that the higher bubbling rate enhanced productivity by providing a more adequate light regimen to the cells, as well as by reducing the oxygen level in the culture. Hu and Richmond (62) have recently attained astonishingly high productivities with *A. platensis* cultivated in flat plates by adopting ultrahigh cell densities (higher than 15 g L^{-1}) and providing mixing at the maximal rate permissible without causing cell damage. The choice of the intensity of mixing and of the mixing system must be dictated by the characteristics of the organism to be cultivated. Unlike *Chlorella* or the marine *Nannochloropsis*, which are endowed with strong cell walls, cultures of filamentous cyanobacteria and fragile dinoflagellates cannot be mixed by pumps that subject the cells to high shear stress and so lead to fragmentation of thricomes and to cell lysis. There is general agreement that bubble columns and airlift systems are low-shear-stress mixing systems and therefore are recommended for shear-sensitive organisms. Gudin and Chaumont (69) have reported that productivity may increase up to 75% when pumps are replaced by airlift systems. However, it is known that even air bubbling produces some stress on the cells at the level of bubble formation and breakup, bubble coalescence, and bubble-bursting at the culture surface (4). Other noticeable advantages of bubble columns and airlifts, from the point of view of industrial application, are their simplicity of operation and low maintenance costs due to the absence of moving parts. Mixing devices and power requirements for mixing have been dealt with by Weissman et al. (64) and by Torzillo (4). Torzillo has also analyzed the influence of the rheological properties of the culture on mixing and mass transfer (4). Gas–liquid mass transfer in a serpentine airlift photobioreactor has been described in detail by Camacho Rubio et al. (40).

Temperature Control

Although photobioreactors are said to provide a better process control than do ponds, the maintenance of optimal temperatures in closed reactors is not an easy task, especially when the systems are operated outdoors. Photobioreactors behave as solar collectors: Any light absorbed by the reactor walls or by the culture and not used in photosynthesis is converted into thermal energy, and may lead to an increase of the culture temperature of up to 30 °C or more above ambient temperature, causing the collapse of even rather tolerant species (59). With a few exceptions (e.g., cultivation of thermophilic species) photobioreactors operated outdoors require cooling. Among the solutions experimented with to control overheating in outdoor photobioreactors are shading, water-bath immersion, and water spraying. Shading, to be effective, requires that a large proportion of the reactor be covered for several hours a day, and this greatly reduces the irradiance at the culture surface and, consequently, the productivity (4). Cooling by water spraying has been shown to be reliable and cost-effective when used in dry climates (4,5). Immersion of the reactor in a cooling water basin is very efficient, but its cost-effectiveness is rather doubtful. It may, however, be the sole available option in humid climates, where water spraying does not provide evaporative cooling. Although it varies with the reactor design, the local climate, and the specific organism used, the need for cooling can significantly increase operating costs. In cold climates and in temperate regions during winter, heating may instead be required to maintain the optimal growth temperature.

Orientation of the Photobioreactor and Light Dilution

One of the main impediments to the efficient use of solar energy is the continuous variation of the available solar radiation throughout the day. Solar irradiance is very low in the early morning and in the evening hours and strong enough to inhibit photosynthesis at noon. Although the di-

urnal pattern of the solar irradiance incident on a horizontal reactor cannot be easily modified, some elevated systems can be oriented at various angles to the sun and thus offer the possibility to vary, continuously or discontinuously, the distribution of the light that strikes the reactor surface. The effect of the photobioreactor orientation on productivity of outdoor algal cultures was investigated by Lee and Low (70), who did not find the angle of inclination of the bioreactor to have any significant influence on the productivity of *Chlorella pyrenoidosa*. Because of the particular reactor design (two tubular panels were connected by hinges, erected at an angle to the ground, and placed in an east–west direction) and, above all, due to the location of the experimental facilities (about 1° latitude north), the findings of these researchers cannot be generalized. The influence of the orientation of flat photobioreactors in higher latitude regions has been studied by Tredici and Chini Zittelli (5) and by Hu et al. (11). These studies have shown that the reactor tilt angle exerts a significant effect on both productivity and photosynthetic efficiency. Systems that are sun oriented so as to intercept the maximum solar radiation on a daily basis (e.g., south-facing plates inclined at 10–30° in summer and at about 60° in winter) typically achieve the highest productivities, even if a culture placed perpendicularly to the rays of the sun at midday may suffer due to excessively high irradiance (19). Vertical plates or systems oriented so as to dilute the impinging radiation achieve lower productivities but higher photosynthetic efficiencies (19). A major objective of photobioreactor design should be to reduce the so-called light saturation effect of photosynthesis (see earlier section). One approach has been to install systems vertically (like Pulz's PBR series) or at a high inclination to the horizontal so that the reactor is at a large angle to the sun rays and solar irradiance is attenuated (diluted) at its surface (19). Another approach involves transmitting sunlight into the photobioreactor through light-diffusing prisms or optical fibers (6,71), but this option appears too complex to be effectively scaled up and applied commercially in the near future. By operating a near-horizontal flat panel and a near-horizontal tubular reactor in parallel, Tredici and Chini Zittelli (19) have shown that tubular reactors can achieve, per se, higher photosynthetic efficiencies and productivities than flat reactors because their curved surfaces achieve a certain degree of sunlight dilution and thus reduce the light saturation effect.

Materials

Materials for photobioreactors must have several properties: high transparency, high mechanical strength, lack of toxicity, resistance to weathering (durability), chemical stability, antifouling surface, and low cost. G. Chini Zittelli and M.R. Tredici (unpublished material, 1998) have carried out a preliminary investigation of the durability of some plastic materials. In Figure 11, the loss of transparency of six different tubing materials exposed to natural weathering in central Italy is shown. Polyethylene and polypropylene tubes are inexpensive, but both lose transparency very quickly and present serious limitations as regards biofouling and mechanical strength. Polycarbonate tubes are seriously weakened by alkaline solutions and become brittle and break easily after 2–3 years of exposure outdoors; they lose transparency mainly in the 300- to 500-nm range. Tubes of polymethyl methacrylate or Teflon have been shown to possess high resistance to weathering and good overall properties. PVC tubes lose transparency significantly after hydration. Some of the flexible plastic materials tested have shown limited mechanical strength that has led to trivial problems (such as leakage due to punctures inflicted by cats and wild animals) that could become rather serious in large-scale systems. Glass might be an excellent material for photobioreactors, due to its high transparency, chemical stability, and durability. Glass tubular systems, however, would require mostly field assembly and numerous connections, and this would greatly increase installation costs; furthermore, fragility may constitute a serious limitation to the use of glass tubes in large-scale installations. The tubes required for building the photostage represent a major cost component of the photobioreactor but not as high as commonly thought. Suitable long-lasting tubular material is available for about $1 per meter or about $15 per square meter of photobioreactor.

CONCLUDING REMARKS AND PROSPECTS

Photobioreactors are considered to have several major advantages over open ponds: They can *(1)* prevent or minimize contamination, *(2)* offer better control over cultural conditions (pH, pCO_2, pO_2, temperature, etc.), *(3)* prevent evaporation and reduce water use, *(4)* lower CO_2 losses due to outgassing, *(5)* permit higher cell concentrations that result in reduced operating costs, and *(6)* attain higher productivity. However, the ultimate and most important advantage is that photobioreactors permit cultivating algal species that cannot be grown in open ponds. On the other hand, certain requirements of photobioreactors, including the need for cooling, the need for strict control of oxygen accumulation and biofouling, and the need for frequent replacement of the material of the photostage, make these systems more expensive to build and operate than ponds. Thus, despite their advantages, the use of photobioreactors must be limited to production of very-high value compounds from phototrophs that cannot be cultivated in open ponds (18,52). Photobioreactors and open ponds should not be viewed as competing technologies, since it is very unlikely that photobioreactors will have a significant impact on any product or process that can be attained in large outdoor open ponds.

In recent years, significantly higher photosynthetic efficiencies and a higher degree of system reliability have been achieved due to better understanding of the growth requirements of phototrophic microorganisms in mass culture. Despite these advances, no photobioreactor has yet proven to be commercially successful, even for very-high-value products. This certainly does not depend on a lack of photobioreactor designs: There exist several valid basic concepts and myriad variations. The principle obstacle to

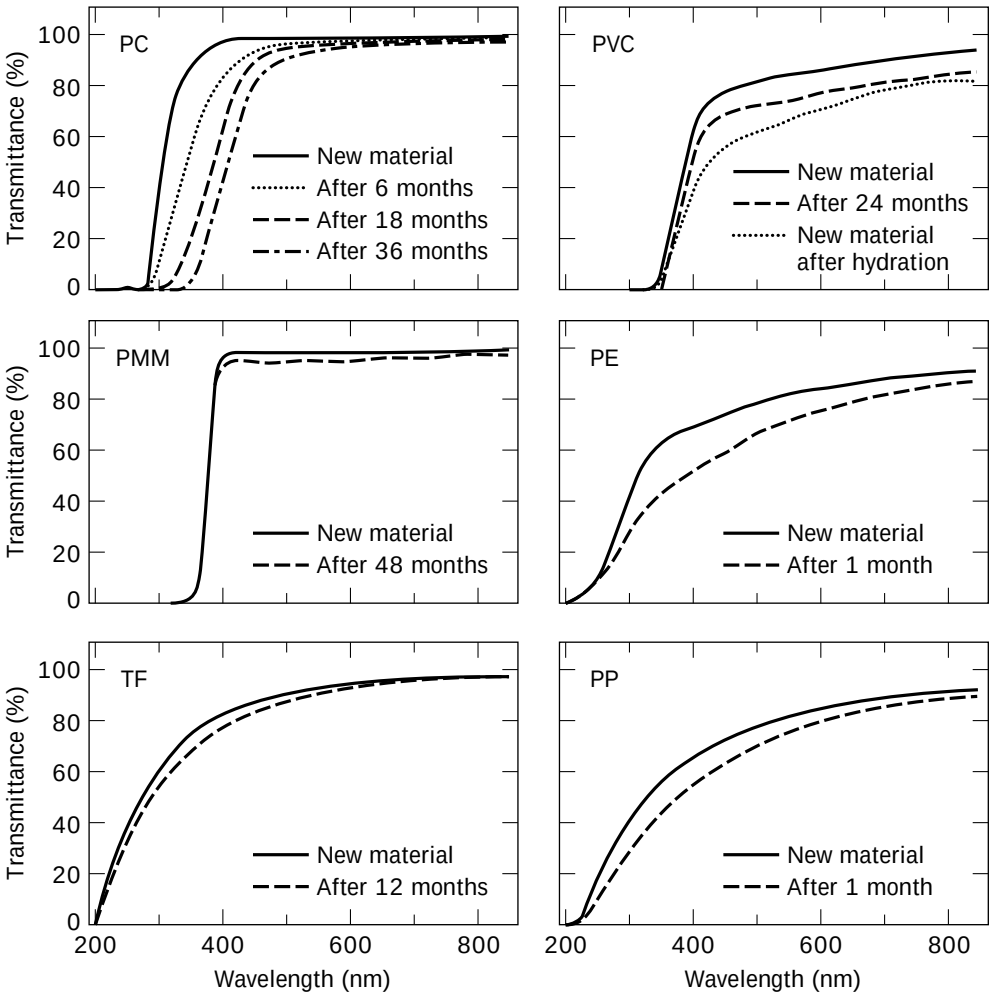

Figure 11. Loss of transmittance of different plastic tubing exposed outdoors to the climatic conditions of central Italy. PC, polycarbonate; PVC, polyvinyl chloride; PMM, polymethyl methacrylate; PE, polyethylene; TF, Teflon; PP, polypropylene. commercial application of this biotechnology seems instead to lie at the level of scaling-up. Transferring those processes developed at the laboratory scale to the industrial scale is never a simple proposition, and it is particularly difficult in the case of photobioreactors because of the peculiar problems of these systems. One of the major causes of the failures of photobioreactor technology at commercial scale is a lack of adequate piloting. The old rule of thumb used in the chemical industry, and still valid in fermentation technology, that each individual increase of scale should not surpass a factor of 10 (52,72) has been ignored in practice. This was especially true in the case of Hidrobiologica SA, where the full-scale plant was set up after only limited experimentation on a very small scale. At the small scale, the photobioreactor performance is usually evaluated in terms of productivity, whereas issues such as contamination, material degradation, and the reliability and sustainability of the production process, which more than the productivity determine the failure or success of the industrial-scale activity, are ignored. Only accurate piloting can shed light on the key problems and provide adequate solutions. It is not clear how much the failure of the PBL photobioreactors in Spain and of the 600-m^3 plant in Argentina depended on system design flaws or on management errors. However, in neither case had the basic technical and biological problems (mixing, oxygen buildup, temperature control, biofouling, contamination) that must be solved for successful full-scale operation been subjected to rigorous investigation at an adequately scaled pilot level. Another mistake, common to both plants, is that to keep operating costs low, the units built and operated were very large. This deprived the systems of necessary flexibility and negated the possibility of making improvements by trial and error. Under these conditions, any problem that might arise (e.g., contamination or toxic oxygen tensions) affects the whole culture and jeopardizes all of production. It is worth pointing out that both industrial plants failed in the cultivation of two phototrophs (*Dunaliella* and *Arthrospira*) that are commonly grown in the much less rigorously controlled open ponds.

The establishment of a commercial activity based on the cultivation of phototrophic microorganisms requires realizing that a photobioreactor design that is efficient at the laboratory level is not necessarily so at the level of industrial production—hence, the importance of accurate piloting. A few simple guidelines should be followed during piloting (63):

1. Experiments must last long enough to reveal the "aging" problems, including contamination, biofouling, and material deterioration, that become evident only after several months of continuous operation.
2. The units experimented with should be similar in size and type to the cultivation units envisaged for the full-scale plant.
3. The productivity of the system must be correctly evaluated and extrapolated.
4. Experiments must be carried out under the climatic and operating conditions that will prevail in the final commercial process.
5. Unless true axenic conditions are adopted, the possibility of contamination must not be underestimated.
6. Appropriate solutions to the main problems commonly encountered in photobioreactors (overheating, biofouling, oxygen accumulation, etc.) must be provided before beginning operation of the commercial plant.
7. The data obtained during the scaling-up stage must be subjected to rigorous analysis and used to reevaluate the economics of the process.

Today the efforts of many researchers, from both academia and industry, are directed toward development of new photobioreactor designs. In the majority of cases, such designs are anything but new and remain an academic exercise with little or no practical value. What we really need is a serious evaluation of the performance of photobioreactors at a relatively large scale. Through such analysis, and together with likely further improvements in engineering design, the development of new materials with suitable characteristics, and the improvement of cultivation techniques derived from a better knowledge of the physiology of phototrophs in mass culture, we can reasonably expect to achieve a degree of reliability in large-scale cultivation of phototrophic microorganisms such as to bridge the gap between laboratory experimentation and commercial application.

ACKNOWLEDGMENTS

I wish to express my sincere gratitude to my colleague Dr. Graziella Chini Zittelli, with whom I have been working on microalgae mass culture and photobioreactor development since 1989. I also wish to thank Dr. Susan Blackburn and Dr. Laura Barsanti for critically discussing the manuscript. Parts of this article have been influenced by exchange of ideas over the years with Dr. John Benemann, to whom I feel particularly indebted.

OUTLINE

INTRODUCTION

Bioreduction is one of the important biological transformations catalyzed by whole cells. The reducing action of fermenting baker's yeast (*Saccharomyces cerevisiae*) was first reported during the reduction of furfural to furfuryl alcohol. Since the early twentieth century, numerous bioreductions using microorganisms other than baker's yeast have been studied by both biotechnologists and organic chemists. Though the ketone, C═C double bond, azide, and nitro compound are reduced, synthetic chemists have mainly applied the microbial reduction of prochiral ketones to the synthesis of chiral alcohols in an enantiomerically pure form. Until now, a large number of references to scientific studies in this area have been reported.

During the bioreduction of carbonyl compounds, carbonyl reductases in microorganisms catalyze the stereospecific reduction using NADH, NADPH, and, sometimes, the flavine mononucleotide as hydrogen donors. The microorganisms can reduce many types of ketones and aldehydes. However, this useful bioreduction has the disadvantage of needing regeneration system of cofactors, such as NAD(P)H, in addition to the reductases in whole cells. To overcome this problem, it is important to utilize the ability of the living microorganism to regenerate NAD(P)H from $NAD(P)^+$ by their natural process of respiration (Fig. 1).

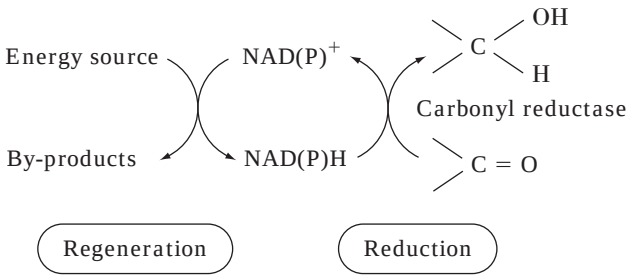

Figure 1. Outline of bioreduction.

This article describes the bioreduction of ketones with microbial cells, including reductases and nicotinamide coenzyme regeneration. An application of the bioreduction to the synthesis of an optically active alcohol is then described.

REDUCTASES OF KETONE

The most important microorganism catalyzing bioreduction is baker's yeast. The scientific studies devoted to bioreduction using baker's yeast have gradually increased since the 1950s. The transformations of various classes of synthetic organic molecules were examined. These transformations were reviewed from the viewpoint of their chemical reactions in three excellent articles published in 1990, 1991, and 1992 (1–3). In these reviews, the uses of baker's yeast in synthetic organic chemistry are fully covered.

Other microorganisms also catalyze the bioreduction of ketones. However, the reports on other microorganisms do not outnumber those on baker's yeast. The main difficulty in the widespread use of microorganisms among the organic chemists' community certainly depends on their familiarity with microbiological techniques. Therefore, good cooperation between synthetic organic chemists and microbiologists oriented toward such applications can be fruitful.

Baker's Yeast

Baker's yeast can be used by people not trained in microbiology and can be considered a useful "reagent," easily accessible in every laboratory. Fermenting baker's yeast using glucose in tap water as an energy source is generally used for highly enantioselective reactions. However, when the process is not completely enantioselective, simple modifications of the experimental conditions may influence the stereochemistry and the enantiomeric excess of the product. For instance, the use of organic media, the addition of other compounds, a change in energy source, and immobilization techniques are helpful.

Traditionally, baker's yeast can reduce variously substituted carbonyl groups to the corresponding hydroxyl compounds, the stereochemical outcome of these highly enantioselective reductions depends on the presence of dehydrogenases, which generally follow the so-called Prelog's rule. Several exceptions have been found, which can be due to the presence of competing dehydrogenases with different stereochemical requirements.

The baker's yeast–mediated reduction of acetol and ethyl acetoacetate afforded (*R*)-propylene glycol and (*S*)-ethyl 3-hydroxybutanoate, respectively. The large-scale preparations of these compounds were accomplished by using a bubble-column reactor and ethanol as the energy source in more than 98% enantiomeric excess (4). The usefulness of the yeast-mediated reduction was also shown in the diltiazem synthesis. The transformation of a racemic ketone (*RS*)-2-(4-methoxyphenyl)-1,5-benzothiazepin-3,4(2*H*,5*H*)-dione afforded only the desired (2*S*,3*S*)-2,3-dihydro-3-hydroxy-2-(4-methoxyphenyl)-1,5-benzothiazepin-4(5*H*)-one, a key intermediate in the diltiazem synthesis. The difficulty in its industrial application because of its low productivity, which is due to the low solubility of the substrate in water, was overcome by changing its physical properties. Thus, 100 g of the substrate in 1 L of reaction medium was reduced to produce the chiral intermediate with over 99% ee in 80% yield (5) (Fig. 2).

Other Microorganisms

Bioreduction using other microorganisms was systematically examined by Shimizu and Yamada using ketopantoyl lactone as the substrate (6). They found that about 10% of the microorganisms tested (yeasts, molds, bacteria, actinomycetes, and basidiomycete) reduced ketopantoyl lactone to pantoyl lactone in the presence of glucose. Their enantioselectivities varied at random and were independent of genus and species.

D-(−)-Pantoyl lactone, the γ-lactone of D-(−)-pantoic acid, is an important starting material for the synthesis of the vitamin D-(+)-pantothenic acid. The conventional synthesis involved the tedious chemical resolution of racemic pantoyl lactone. In this synthesis, the enantioselective bioreduction of ketopantoyl lactone to D-(−)-pantoyl lactone was examined. When *Candida parapsilosis* or *Rhodotorula minuta* cells were incubated with ketopantoyl lactone (more than 50 g/L) and glucose, D-(−)-pantoyl lactone was produced in excellent chemical and optical yields. In this reaction, the asymmetric reduction is catalyzed by a newly found carbonyl reductase specific to conjugated polyketones, which requires NADPH as a cofactor. Another approach is the enantioselective reduction of ketopantoic acid. *Agrobacterium* sp. was screened and incubated with ketopantoic acid and fructose to give D-(−)-pantoic acid. The acid was easily cyclized with hydrochloric acid to afford the D-(−)-pantoyl lactone (Fig. 3).

For the stereospecific reduction of 4-chloroacetoacetate, each stereoisomer of the product (*R*)- or (*S*)-4-chloro-3-hydroxybutanoate is a useful compound. Shimizu and Yamada also screened a microorganism for the asymmetric reduction of 4-chloroacetoacetate. Almost all microorganisms, such as *R. minuta* and *Paecilomyces marquandii*, reduce to (*S*)-4-chloro-3-hydroxybutanoate, which converts to (*S*)-1-benzyl-3-hydroxypyrrolidine. In the carnitine synthesis, 4-chloroacetoacetate should be reduced to (*R*)-4-chloro-3-hydroxybutanoate, which would be converted to carnitine by the chemical method. *Sporobolomyces salmonicolor, Micrococus luteus*, and *Cellulumonas* sp. predomi-

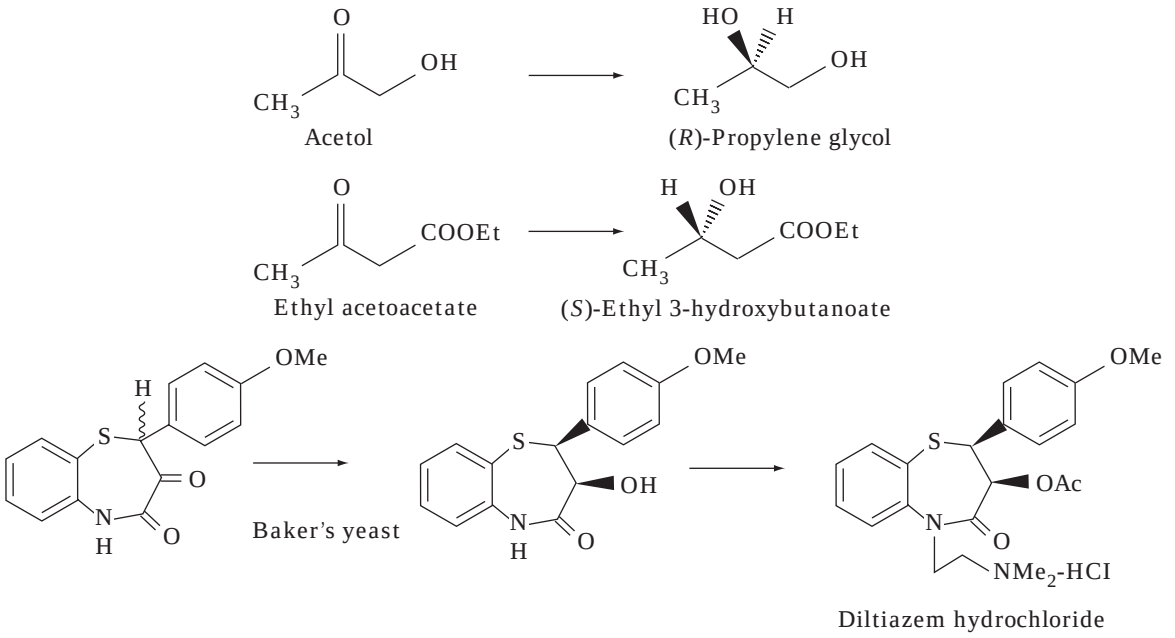

Figure 2. Production of optically pure alcohols through the baker's yeast–mediated reduction.

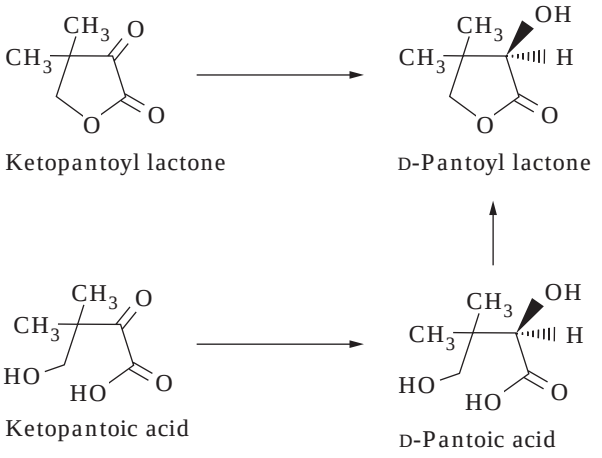

Figure 3. Production of D-pantoyl lactone.

nantly afforded the (*R*)-compound. However, they could not obtain a sufficient result for the enantiomeric excess. Therefore, *S. salmonicolor* was treated with acetone to remove (*S*)-reductase. The treated cells were used for the stereospecific reduction of ethyl 4-chloroacetoacetate to afford (*R*)-4-chloro-3-hydroxybutanoate in a water–organic solvent two-phase system. In this synthesis, NADPH must be regenerated from $NADP^+$. The regeneration was accomplished by using glucose and glucose dehydrogenase in the aqueous phase. This process can be used in the carnitine synthesis (Fig. 4).

NAD(P)H REGENERATION

During bioreduction, NAD(P)H coenzymes must be successively regenerated from the corresponding oxidized form in the cells. The system responsible for the coenzyme regeneration is coupled with the reduction of a substrate. A large amount of work has been devoted to developing and testing various types of systems for NAD(P)H regeneration.

D-Glucose Derivatives

Yamada et al. characterized the enzymes responsible for the NADPH regeneration system using glucose as the energy source (7). They examined the NADPH-forming ability of the cell-free extracts of *S. cerevisiae, Candida parapsilosis*, and *Mucor ambiguus*, with several sugars as the substrate. NADPH was not formed from D-fructose 1,6-diphosphate. This suggests that NADPH could not be produced after D-fructose 6-phosphate was phosphorylated to D-fructose 1,6-diphosphate. They found that NADPH is produced from the hexose monophosphates, D-glucose 1-phosphate, D-glucose 6-phosphate, or D-fructose 6-phosphate. Thus, with *S. cerevisiae*, *C. parapsilosis*, and *M. ambiguus*, the enzymes were shown to be D-glucose 6-phosphate dehydrogenase and 6-phospho-D-gluconate dehydrogenase in the hexose monophosphate pathway. By means of these systems, endogenous NADPH can be efficiently regenerated by the simple mixing of microbial cells with glucose. The reductions of various carbonyl compounds by microorganisms in synthetic organic chemistry will be mainly based on this system.

Ethanol

During the baker's yeast–mediated reduction using ethanol as the energy source, NAD(P)H is regenerated from $NAD(P)^+$ through the oxidative pathway of ethanol to carbon dioxide, and the system is also efficiently coupled with reduction of a ketone (4). The enzyme system responsible for NAD(P)H regeneration was investigated by studying the reduction of acetol and ethyl acetoacetate, catalyzed by NADH- and NADPH-dependent carbonyl reductases, respectively. NAD^+ formed during the reduction of acetol is reduced to NADH through the oxidative pathway of ethanol to acetate, catalyzed by alcohol dehydrogenase and aldehyde dehydrogenase. On the other hand, $NADP^+$ formed during the reduction of ethyl acetoacetate is reduced to NADPH through the oxidative pathway of acetate to carbon dioxide under aerobic conditions. The enzyme responsible for NADPH regeneration must be malate dehydrogenase (decarboxylating) in leaving the TCA cycle. By using the NAD(P)H regeneration system, the baker's yeast–mediated large-scale productions of (*R*)-propylene glycol from acetol and (*S*)-ethyl 3-hydroxybutanoate from ethyl acetoacetate were efficiently accomplished. Other yeasts also use ethanol as the energy source for the NAD(P)H regeneration system in the same manner (8).

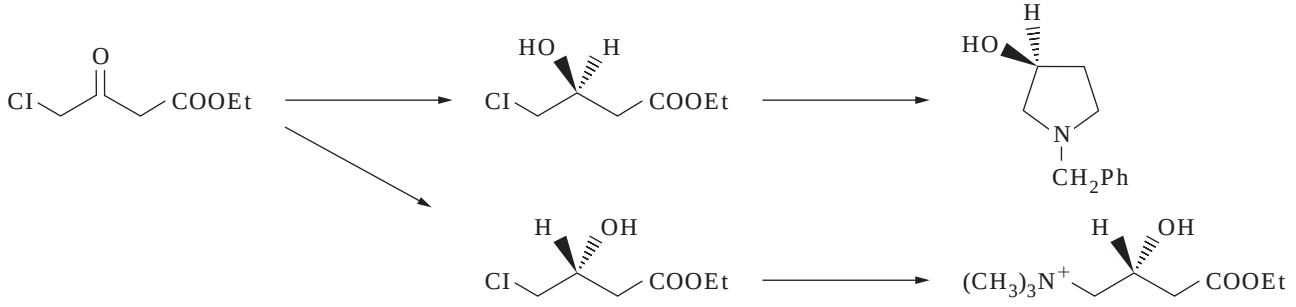

Figure 4. Production of (*S*)-1-benzyl-3-hydroxypyrrolidine and (*R*)-carnitine.

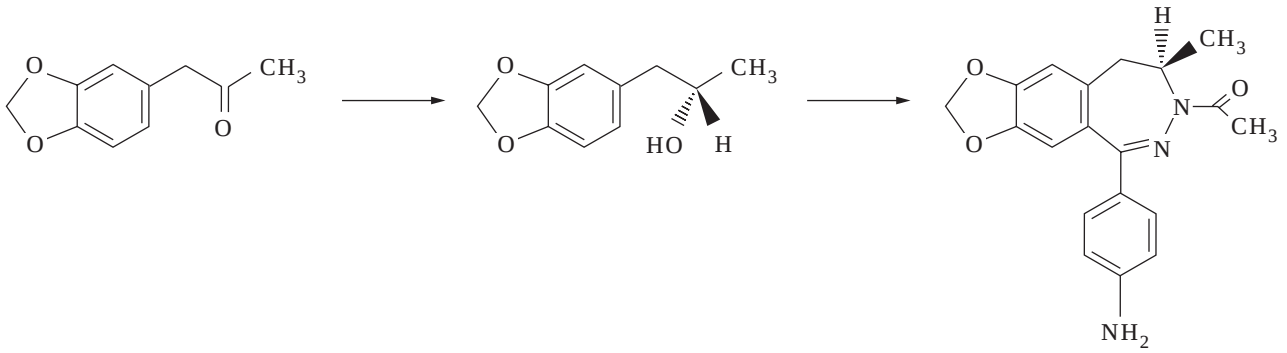

Figure 5. Production of (*S*)-3,4-methylenedioxyphenyl isopropanol for the synthesis of LY300164.

Methanol

Similarly, the reaction involved in the oxidation of methanol to CO_2 by methylotrophic microorganisms, methanol dehydrogenase, formaldehyde dehydrogenase, and formate dehydrogenase is considered to be a very useful system for NADH regeneration.

BIOREDUCTION OF 3,4-METHYLENEDIOXYPHENYLACETONE

The clinical potential for the (*R*)-isomer LY300164 has led to interest in developing syntheses that would not be limited by the inherent inefficiency of the resolution methods and would be amenable to large-scale execution. The retrosynthetic strategy required the synthesis of the benzodiazepine nucleus by intramolecular cyclization of a suitably functionalized hydrazone. This disconnection was chosen because it was anticipated that the required stereocenter could be accessed from the relatively simple alcohol. Asymmetric reduction of the corresponding ketone was considered the most desirable option for the preparation of the optically active alcohol (9,10) (Fig. 5).

Screening of Microorganisms

The chemical method for the enantioselective reduction of methyl benzyl ketones is typically nonselective or requires the stoichiometric use of costly reagents. Unlike closely related examples, however, selectivity and conversion with baker's yeast, as well as other common microorganisms, were unsatisfactory. After an extensive screening of microorganisms, the yeasts *Candida famata* and *Zygosaccharomyces rouxii* could catalyze the reduction of 3,4-methylenedioxyphenylacetone to 3,4-methylenedioxyphenyl-(*S*)-isopropanol with >99% enantiomeric excess in the presence of glucose. However, the productivity number using *C. famata* was too low to be practical and the microorganism was extremely sensitive to concentrations of both the ketone and the alcohol greater than 2 g/L. On the other hand, *Z. rouxii* was more tolerant to higher substrate concentrations and had a higher productivity number.

Practical Application

In this bioreduction, both the product and substrate were toxic to *Z. rouxii*, and this limited the maximum substrate concentration to only 6 g/L. It should be noted that toxicity to the substrate alone would not have been a problem, since this could be readily overcome by the slow addition of the substrate. However, the only way to overcome product toxicity was to devise a method to remove the product from the reaction as it was formed.

For in situ product removal, immiscible organic solvents are commonly used. This type of system is called a two-liquid-phase bioreactor. However, one of the major difficulties is that many organic solvents are highly toxic to microorganisms. In this reaction, polymeric hydrophobic resin (Amberlite XAD-7 from Rohm and Haas, Philadelphia, PA) was used to both supply substrate to, and remove the product from, the reaction mixture. The overall effect is that a high reaction concentration is achieved (40 g/L) while never exposing either the substrate or the product to more than 2 g/L. Thus, in many cases, a polymeric adsorbent resin will provide an attractive alternative to the use of organic solvents in whole cells.

OUTLINE

INTRODUCTION

As a result of the manufacture, use, spillage, and improper disposal of anthropogenic chemicals and their waste products during past decades, toxic chemicals have become ubiquitous contaminants of soils and waters around the globe. These compounds include everything from petroleum and synthetic organic chemicals to heavy metals and radionuclides. Governments throughout the world now require that the worst of these contamination problems be cleaned up to eliminate, insofar as possible, their hazards to human health and the environment. Traditional methods such as excavation and incineration of contaminated soil or pumping and aboveground treatment of groundwater are proving to be either too expensive, politically unpopular, or both. Thus, innovative technologies are being sought to address the needs of the environmental restoration industry. *Bioremediation* is such a technology.

Bioremediation involves the use of microorganisms, plants, or products yielded by living organisms to degrade, detoxify, or permanently sequester toxic chemicals present in environmental systems. Bioremediation can be used either ex situ or in situ to treat soil, sediment, sludge, water, or air. In ex situ bioremediation procedures, contaminated materials are first removed from the polluted site and then treated, whereas in situ techniques are used to treat contaminants in place without relocating them to a treatment facility. Bioremediation can be promoted by augmenting natural systems with exogenous biological materials or by stimulating indigenous contaminant-transforming microbial populations. Natural systems can be augmented by the introduction of bacteria that degrade the targeted contaminants or plants that sequester pollutants. Native microbial populations are stimulated by adding nutrients or modifying environmental conditions to favor the growth and activity of appropriate organisms. Although intrinsic bioremediation, or microbial processes that occur without human intervention, may ultimately be able to clean up a contaminated site, a great variety of techniques are used by the bioremediation industry to enhance and accelerate degradative processes.

BIOREMEDIATION TECHNOLOGIES

Bioreactors

Bioreactors, or vessels of various configurations (1) containing degradative microbes, are a common means of ex situ treatment of contaminated materials, typically soil that has been excavated from a polluted site or groundwater that has been pumped from a polluted aquifer. A bioreactor may contain, for example, a slurry of soil and water to which nutrients have been added, such as sources of nitrogen, phosphorus, and/or carbon that support the growth and metabolism of degradative microorganisms. Sometimes the microorganisms themselves may have to be added (40). Slurry reactors can be run either aerobically, by stirring and mixing in air or pure oxygen (2), or anoxically, with little or no mixing (3,4). Slurry phase reactor treatment cells can be designed to hold a few thousand to millions of gallons. Aeration systems for aerobic slurry reactors must be able to maintain dissolved oxygen concentrations at 2.0 mg/L or higher. Aeration is a major expense for such systems. To increase oxygen transfer rates, such systems may be sparged with pure oxygen. Often reactor designs include a series of eductors to oxygenate the mixed liquor while minimizing air emissions. Anaerobic slurry systems usually require some mixing devices to evenly distribute soil or sediment materials throughout the aqueous phase, but they spare the need and cost of transferring large amounts of oxygen to the solution phase. Aerobic slurry reactors have been used to treat materials contaminated with chemicals such as polynuclear aromatic hydrocarbons (PAHs) and chlorinated phenols (35). Anaerobic slurry reactors have been used to treat materials polluted by compounds such as chlorinated solvents, polychlorinated biphenyls (PCBs), nitrated munitions like 2,4,6-trinitrotoluene (TNT) (Fig. 1) (4), and nitrated herbicides such as dinoseb (37).

Figure 1. Pilot-scale anaerobic slurry reactor for treating TNT-contaminated soil. *Source*: University of Idaho, with permission.

Water may be treated in simple batch reactors that hold a few hundred to many thousands of liters; nutrients and microorganisms may be added as required. Fluidized beds that contain biomass-bearing carriers are popular for water treatment (5) and can be run aerobically or anaerobically, depending on the contaminants being treated (6,7). Even normally recalcitrant compounds such as aniline and nitrobenzene can be treated in such systems. Alternatively, biomass can be grown on a supporting matrix that is packed into a vessel such as a column, and the water to be treated can be passed through the packed bed to remove contaminants by degradation or absorption (8). Packed beds can also be used to treat vapor-phase contaminants such as chlorinated solvents, which are sparged through the reactor as a separate gaseous stream (9). A novel, mechanically mixed packed-bed reactor that works as a biotrickling filter is a variation on packed-bed technology for treatment of vapor-phase contaminants (43). Another variation on reactor design for water treatment is the upflow sludge blanket reactor using granules containing anaerobic bacteria acclimated to the degradation of a particular waste stream (38). Bioreactors can be used in treatment trains that vary conditions, for example, by alternating anaerobic and aerobic conditions (36), so that mixtures of contaminants or highly chlorinated compounds can be treated successfully.

Biofiltration

Biofiltration is an ex situ treatment for vapor-phase contaminants (44,45). Typically, it involves passing contaminated air through a bed of soil, peat, or compost that has been preacclimated to develop a microbial population that completely degrades the targeted pollutants (10). This type of technology works well for volatile components of petroleum, and for many years it has been used in Europe for odor control (11). Biofilters have been developed for toxic airborne industrial contaminants as diverse as styrene (46), pentane and isobutane mixtures (47), toluene (48), chlorinated benzenes (49), dimethylsulfide (50), and volatile organic compounds (VOCs) (51). For example, a biofiltration process was developed for styrene-containing industrial offgases. This process used peat as filter material. Styrene reduction after 190 days of operation was 70% to 98%. The styrene elimination capacity was 12 g m^{-3} h^{-1} (maximum, 30 g m^{-3} h^{-1}). Degradation required addition of nutrients to the peat, adjustment of the pH, and control of humidity. The optimum operation temperature was about 23 °C, but the styrene removal was still satisfactory at 12 °C (46). Composting of leaves and alfalfa was used for the treatment of toluene-contaminated air in a biofilter. During the thermophilic phase (45–55 °C), toluene biodegradation rates reached 110 g toluene m^{-3} h^{-1} at an inlet concentration of about 5 g/m^3 and a gas residence time of 90 s (48). Removal rates by biofilters for chlorinated benzenes reached 300 g solvent vapor h^{-1} m^{-3} of filter volume (49).

Air Sparging

The biodegradation of many contaminants in groundwater is limited by the shortage of electron acceptors for oxidative processes. The most effective electron acceptor for the bioremediation of many contaminants is oxygen, which is present in groundwater at only 8–10 mg/L even under optimal conditions. Air sparging is an in situ technology for introducing oxygen into contaminated aquifers (12). Air or pure oxygen is injected into the aquifer through sparging wells or infiltration galleries (13). Potential problems associated with the introduction of oxygen into groundwater include biofouling, in which injection wells become plugged with biomass, and obstruction of well screens or subsurface geologic formations by iron complexes that precipitate as a result of the oxidation of Fe(II) to Fe(III). Hydrogen peroxide, which decomposes in the presence of iron or biomass to produce oxygen (14), is sometimes substituted for air or pure oxygen. Even when oxygen is supplied by sparging, it can be used so rapidly that its supply can still be rate limiting for bioremediation processes. Thus, the bioremediation industry has developed oxygen-releasing compounds (ORCs) composed of materials such as magnesium peroxide that allow controlled, long-term release of oxygen when introduced into boreholes as a slurry (15). Most successes with air sparging, as with many other bioremediation systems, have been reported in petroleum-contaminated aquifers. The reintroduction of indigenous microorganisms isolated from a contaminated site after culturing is one approach to in situ hydrocarbon bioremediation. It is effective especially when microorganism growth is supplemented by addition of oxygen and nitrogen (52). At the Moffett Field (Sunnyvale, Calif.) groundwater test site, in situ removal of *cis*-dichloroethene (*c*-DCE) and trichloroethene (TCE) coincided with biostimulation through phenol and oxygen injection and utilization, with c-DCE removed more rapidly than TCE. Greater TCE and c-DCE removal was observed when the phenol concentration was increased. More than 90% removal of *c*-DCE and TCE was observed in a 2-m biostimulated zone (53). Thus, introduction of oxygen into contaminated aquifers can be of use even for recalcitrant compounds such as VOCs.

Bioventing

Bioventing is related to air sparging in that the objective of this in situ technology (17) is to provide oxygen to the microbial populations in the subsurface. Bioventing systems use equipment similar to that used in soil vapor extraction (SVE) processes. Air injection or extraction wells or trenches are connected by pipes to blowers or vacuum pumps which either push or pull air through the vadose zone (unsaturated soil horizons) to stimulate microbial populations capable of degrading contaminants. The objective is to provide sufficient oxygen to the subsurface to promote in situ contaminant degradation, but not so much that volatile contaminants are released undegraded to the atmosphere. Thus, bioventing is best used with contaminants that are moderately volatile, such as diesel or jet fuels or residues of aged petroleum (13,21). For bioventing to succeed, the vadose zone must be sufficiently permeable to allow air exchange at least every 24 h (16), so this process is not suitable for all sites. It may be possible in some instances to open up impermeable soils by fracturing them with hydraulic or air pressure injections (26), allowing bioventing strategies to be employed. Bioventing has produced excellent results at hundreds of sites worldwide in recent years (13,18–20).

A typical bioventing system (Fig. 2) involves soil vapor extraction followed by bioventing via vent wells located within an aquifer in areas of high pollutant contamination. Monitoring wells in both the vadose zone (unsaturated soils above the aquifer) and within the aquifer are used to monitor bioventing progress. Neutron probes may sometimes be used for soil moisture monitoring, to assure that venting does not dry out the soil so that microbial populations are inhibited. A plastic liner is usually installed over the surface of part or all of a contaminated area to prevent infiltration of air that might bypass the desired path of air to the vent wells. A catalytic incinerator to destroy extracted vapor that was not degraded by microbes in the vadose zone is often installed as a safety device, especially at sites near populated areas. If bioventing proceeds effectively, there may be no need for treatment of extracted vapors because the concentration of contaminants in the vented gases may be very low. In bioventing, as with all biological processes in soil, soil moisture must be maintained within a range of 6% to 12%, and supplemental phosphorus or nitrogen may be needed (e.g., N as ammonia provided in the gas phase) to maintain a C:N:P ratio of about 100:10:1.

Not all sites are amenable to bioventing. The Battelle Corporation has used a special site evaluation protocol to

Figure 2. Petroleum bioventing operation. *Source*: University of Idaho, with permission.

determine the suitability of a site for remediation by this technique (41). Four steps are performed sequentially for characterization of a potential bioventing site:

1. A soil-gas survey is conducted to determine if the subsurface is oxygen limited. Soil gas is analyzed for concentrations of oxygen and carbon dioxide. Oxygen is, of course, required for successful bioventing of many contaminants, such as petroleum hydrocarbons.
2. A soil-gas permeability test is conducted to see if air can be injected at rates sufficient to aerate the vadose zone. This test requires injection and withdrawal of air for measuring changes in subsurface pressures at discrete distances from the point of injection. Soils must be sufficiently permeable to be candidates for bioventing. "Tight" soils (e.g., clay-rich soils) can usually be eliminated at this stage.
3. Oxygen-limited but sufficiently permeable soils are then subjected to an in situ respiration test to measure biological contaminant degradation rates for comparison to respiration rates in similar, but uncontaminated, soils. This involves aerating the soils for 24 h and then monitoring the oxygen and carbon dioxide concentrations in the soil-gas phase after the final air injection. An oxygen utilization rate is calculated and used to estimate a contaminant degradation rate, which can in turn be used to estimate the time that will be required to biovent the site.
4. Finally, a pilot- and/or full-scale field bioventing remediation demonstration is conducted at the site. There may or may not be a need for pilot-scale testing before a full-scale process is implemented. This is determined on a site-specific basis according to the prior testing.

Landfarming

Landfarming is an aboveground ex situ process in which contaminated soils are excavated, supplemented with nutrients (primarily sources of nitrogen or phosphorus), and spread in relatively thin layers on a prepared site so that biodegradation of contaminants is promoted. These soils are aerated by periodic tilling and kept moist by irrigation, thus explaining the name of this procedure (13). Sometimes soils are spread directly on the ground at a graded site, if there is no danger that the contaminants will leach through the soil to groundwater or vaporize to dangerous levels in the atmosphere. More commonly, soils are spread on sites with preinstalled plastic liners or clay barriers and leachate collection systems to prevent any possible leach-

ing of contaminants offsite or to groundwater, as well as vapor containment enclosures, especially if the site is located near populated areas. Petroleum is commonly treated in this manner (20). Highly toxic or biologically recalcitrant compounds generally should not be landfarmed, and the presence of heavy metals such as lead usually indicates that landfarming is not an appropriate technology for a particular soil. Some advantages and disadvantages of landfarming of petroleum-contaminated soil are shown in Table 1 (data from U.S. EPA).

The presence of vegetation can enhance the degradation of contaminants during landfarming of contaminated soil. Greenhouse experiments have shown the degradation of PAHs to be greater in the presence of plants than in their absence. PAHs were detectable in the plant tissue, but overall uptake was not significant. Enhanced microbial activity appeared to be responsible for the increased removal of PAHs. Thus, planting of vegetation is promising as an inexpensive means of speeding landfarm-based remediation of sites contaminated with petroleum (42).

Biopiles

Biopiles are basically soil-heaping operations, a variation on landfarming. The primary advantages of biopiles over landfarms are that biopiles save land space, and air emissions can be more inexpensively captured and treated (20). In this technique soil is excavated and piled into a mound within a lined treatment cell. The pile is typically covered by a plastic sheet, and an internal system of perforated pipes is usually installed to draw air in by means of vacuum pumps. Alternatively, air may be blown into the pile through the internal pumping system, or supplied from oxygen-releasing compounds (ORCs; see "Air Sparging") incorporated into the piles. Water, nutrients, and microbial inoculants are added as needed, and leachates and gaseous emissions are collected for separate treatment. In theory, biopiles can be used for most biodegradable contaminants, but the limitations of landfarming generally apply. In practice, most biopile operations have treated petroleum-contaminated soils (20).

Table 1. Advantages and Disadvantages of Landfarming for Treatment of Petroleum-Contaminated Soil

Advantages	Disadvantages
Relatively simple to design and implement	Concentration reductions >95% and constituent concentrations <0.1 ppm are very difficult to achieve
Short treatment times (usually 6 months to 2 years under optimal conditions)	May not be effective for high constituent concentrations (>50,000 ppm total petroleum hydrocarbons)
Cost competitive: $30–60/ton of contaminated soil	Presence of significant heavy metal concentrations (>2,500 ppm) may inhibit microbial growth
Effective on organic constituents with slow biodegradation rates	Volatile constituents tend to evaporate rather than biodegrade during treatment
	Requires a large land area for treatment
	Dust and vapor generation during aeration may pose air quality concerns
	May require bottom liner if leaching from the landfarm is a concern

Source: U.S. Environmental Protection Agency (*http://www.epa.gov/swerust1/cat/landfarm.htm*).

"Biomounding" is a low-technology, low-cost variation of biopiles. It has been used to treat petroleum-contaminated soil, with the addition of bulking materials like animal manure and wood chips to promote good conditions (sufficient moisture retention, good aeration, source of nitrogen, etc.) for building up microbial populations capable of hydrocarbon degradation. This simple process usually is well accepted by local governments and the general public. Biomounding can reach fairly stringent soil cleanup standards in the range of 10 ppm as total petroleum hydrocarbons (TPH). Generally, indigenous bacteria present in petroleum-contaminated soil proliferate under biomounding conditions, so inoculation with exogenous microbes is not normally needed. By engineering a favorable environment for microorganisms in a contaminated soil, it is possible to construct biomounds that are reasonably inexpensive to manage, yet allow fairly fast breakdown of petroleum compounds in soil, without the need for continually turning of the soil as in composting. Simple passive aeration systems normally are used in biomounds. For example, a grid of horizontal piping constructed of flexible perforated drain tile, along with vertical piping (risers) of PVC, can be used in the system. Multiple layers of piping can be employed, depending on the volume of soil to be treated. Moisture and heat loss from biomounds are usually controlled by covering the mounds with plastic sheeting.

Composting

In composting, excavated soil is mixed with bulking agents such as straw, horse manure, or other agricultural residues to form compost piles, which are then managed for good aeration by periodic turning with specially designed machines. Vigorous microbial activity generates considerable heat, so the piles are termed thermophilic, operating at temperatures around 50–60 °C. Composting has been examined as a treatment for a variety of contaminants, including petroleum sludges (22), chlorophenols (23,24), and munitions residues (25). This approach is still experimental, since some questions remain as to its overall efficacy in treating some contaminants. For example, nitroaromatic compounds such as 2,4,6-trinitrotoluene (TNT) tend to be polymerized or incorporated into soil humus fractions, with little or no conversion to carbon dioxide or products that might themselves be degradable to carbon dioxide (25). The long-term stability and potential for release of toxic compounds from such uncharacterized materials in soil is not known.

In one study, a reduction in direct lethality of TNT to earthworms reflected the removal of explosive compounds by composting, as indicated by chemical analysis. How-

ever, assays by the Mutatox procedure indicated increased mutagenicity, a result that would not have been shown by chemical analysis alone, which implied that mutagenic metabolites of explosives were formed during composting and were incompletely degraded (54). In another study, [^{14}C]TNT was subjected to composting during which much of the ^{14}C becomes incorporated into the "humic" fraction of the compost where it supposedly becomes unavailable. The composted TNT resulting from this process was then fed to rats. Although only 2.3% of the total ^{14}C dose appeared in the rats' urine during the first 3 days after feeding, low levels of ^{14}C continued to be excreted in urine from compost-treated rats for more than 6 months. The total amount of ^{14}C excreted in the urine was comparable to that excreted by animals treated with pure TNT (55). Thus, it is clear that composted TNT is not irreversibly immobilized, but that TNT or its biotransformation products in compost are bioavailable. Thus, composting may not be the treatment of choice for some wastes where there is little mineralization of the target pollutant.

Despite the experimental nature of composting, it is likely to become a useful tool for treatment of some chemically polluted soils. Variations on composting appear to be possible to overcome some of these problems. For example, TNT is degraded more effectively when the compost is allowed to first undergo a fairly long anaerobic treatment phase before traditional aerobic composting (39). The critical stage of the traditional composting process is the thermophilic (hot) phase. The fate and mechanism of removal of chemicals such as pesticides and other xenobiotic compounds in composting processes are largely unknown and in need of comprehensive analysis (57–59).

The hazards of composting stem not only from chemical agents but also from microbiological agents (61,62), whose presence depends heavily on composting methods. Further research clearly is needed on the risks related to human exposure to chemical residues and microorganisms in composted wastes (56). The fate of toxic heavy metals in compost applied to land is of particular concern (60), as is the danger to the public health from pathogenic microorganisms such as *Aspergillus fumigatus*. Spores of *A. fumigatus* (the causal agent of the lung disease aspergillosis) are abundant in the outdoor air at some composting sites (61,62), indicating the importance of site location among process and design criteria for composting operations. In summary, although composting is basically a simple, affordable process, its efficacy and safety for treatment of hazardous wastes are still open to question.

Intrinsic Bioremediation

Intrinsic remediation has been defined as the combined effect of natural destruction and other nondestructive processes to reduce the mobility and mass, and therefore the associated risks, of a contaminant (27). The mechanisms that mediate intrinsic remediation of a contaminant include biodegradation by indigenous microbial populations, sorption to, or trapping within matrixes that make the compound nonbioavailable, and loss of mass by dilution or volatilization (Fig. 3).

Intrinsic remediation of petroleum hydrocarbons is well documented (28,29), and it has also been confirmed for

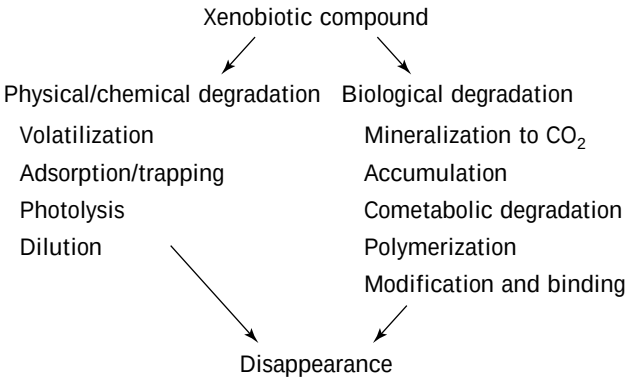

Figure 3. Intrinsic Bioremediation Processes.

chlorinated hydrocarbons, typically under anoxic environmental conditions that favor reductive dehalogenation processes (27,28). Before intrinsic processes can be accepted as a cleanup option for a particular site, regulators must agree to accept exposure and risk assessment analyses as the basis for determining cleanup end points. Therefore, in sites undergoing intrinsic remediation, the distributions of contaminants (e.g., the extent of contaminant plume migration in relation to sensitive receptors) must be thoroughly characterized, and it must be possible to confirm that pollutant remediation is proceeding at a rate sufficient to reduce risks to human health and the environment in an acceptable period. To confirm that intrinsic processes are effectively removing contaminants from soil or groundwater, several factors can be periodically measured, including the following:

- Contaminant mass and its environmental distribution
- Quantity of contaminant degraders or transformers, as indicated by microbial counts
- Temperature and pH, to ensure that they are conducive to microbial activity
- Types of electron donors and acceptors and changes in their concentrations; for example, nitrate, nitrite, metal species (especially iron), methane, ammonia, carbon dioxide, and sulfate
- Redox potential
- Other factors determined by site and contaminant

Ideally, the long-term efficacy of intrinsic remediation processes could be predicted at individual sites through modeling. It is obvious that intrinsic remediation requires specific, extensive, and long-term activities at a site and is far from a "do-nothing" option.

Phytoremediation

Phytoremediation, in which plants are used to remediate contaminated soils or waters, has been studied mainly for the removal of toxic metals but has also been proposed for remediation of some organic contaminants (30). Phytoremediation can take place through the phytoextraction of

contaminants from soil or water, where contaminants are taken up by a plant and concentrated in the plant tissues (31,32). The plant materials can then be harvested, removing the sequestered contaminant from the environment. Bacteria associated with the root zones of plants may in some instances degrade organic contaminants, although more study in this emerging area of research is required to confirm which plants promote degradation of which contaminants. Plants may remove contaminants from soil by transpiration of water to the atmosphere, carrying volatile contaminants along. Plants can help in the management and stabilization of polluted sites by reducing soil erosion caused by wind and water and by reducing the infiltration of water into soil, which will in turn slow down or eliminate the leaching of mobile contaminants into groundwater (30,32). An especially promising line of phytoremediation research concerns the use of plants to remove radionuclides from soil or water (33).

After plants or trees have concentrated metals or radioactive compounds, they can be harvested and then burned, which reduces the volume of the collected material by about 95%. Concentration and volume reduction makes disposal of the ash far less expensive than disposal of the original material itself. Alternatively, useful heavy metals might be extracted from the ash as industrial products, especially if the ash contains one or a few valuable metals. It has been suggested that if a plant contained 1% by weight of a metal, then its ash would contain 20% by weight of that metal, a higher metal content than is found in most ores. Any remaining residue after metal recovery would be disposed of as a toxic material.

Phytoremediation does have limitations. It can be slow, so it is not an option for sites that represent an immediate public health or environmental threat. Plant roots also may not penetrate the soil as deeply as necessary to access the targeted contaminants. The roots of most plants generally reach depths of only 30 cm to about 10 m, although a few plants, such as certain varieties of poplar trees, may send their roots somewhat deeper. Thus, deep contamination can be inaccessible to phytoremediation. Furthermore, as living organisms, plants have specific environmental and nutritional needs. They require a rather narrow range of growth temperatures, grow well only in the presence of favorable soil qualities (texture, water-holding capacity, pH, etc.), must obtain enough water to support growth and metabolism, and usually require the presence of oxygen. Plants may also be inefficient at taking up some pollutants, allowing contaminants to reach groundwater.

Some plants proposed for use in phytoremediation (*http://www.ecological-engineering.com/phytorem.html*) include alfalfa (symbiotic with hydrocarbon-degrading bacteria); *Arabidopsis* (genetically engineered to carry a bacterial gene that transforms mercury into a gaseous state); bladder campion (accumulates zinc and copper); *Brassica juncea* (Indian mustard greens; accumulates selenium, sulfur, lead, chromium, cadmium, nickel, zinc, and copper); Buxaceae (boxwood; accumulates nickel); the Compositae family (symbiotic with bacteria; accumulates cesium and strontium); Euphorbiaceae (succulent; accumulates nickel); tomato (accumulates lead, zinc, and copper); poplar (used in the absorption of the pesticide atrazine, and solvents such as carbon tetrachloride); and *Thlaspi caerulescens* (alpine pennycress; accumulates zinc and cadmium).

White-Rot Fungi

White-rot fungi (Fig. 4) produce enzymes that degrade the plant polymer lignin and oxidize a great variety of chemicals, including many environmental pollutants (34). Because these fungi degrade such a broad range of anthropogenic compounds, they have been examined extensively as potential bioremediation agents. The peroxidases of the basidiomycete *Phanerochaete chrysosporium* are the most thoroughly investigated of the xenobiotic compound–degrading fungal enzymes. These and other oxidative fungal enzymes such as laccase are thought to be the primary catalysts responsible for initiation of degradation of many xenobiotics. For example, enzyme measurements indicated that both high and relatively stable activities of Mn-dependent peroxidase, Mn-independent peroxidase, lignin peroxidase, and laccase characterized efficient PCB degraders among a selection of white-rot fungi (63). For application in the field, white-rot fungi grown on a substrate of wood chips or other specially formulated lignocellulosic materials are mixed into a polluted soil. The soil is tilled, watered, and generally managed to encourage the growth and lignin-degrading activity of the introduced organism. As the fungus degrades the lignocellulosic carrier, it simultaneously degrades the contaminants. This technology is considered experimental, because the fungi so far examined are often inhibited by the contaminant concentrations found in some polluted soils, and even when degradation does take place, it may be incomplete. Clearly, more development work needs to be done in contaminated soil systems.

The focus of one recent study was to determine whether *P. chrysosporium* could effectively operate in an actual field sample of oil tar–contaminated soil. The soil was supplemented with [^{14}C]phenanthrene to serve as a representative polynuclear aromatic compound (PAH). This study confirmed earlier work showing that the native soil microflora could acclimate to provide full mineralization of PAHs in some contaminated soils. However, this mineralization could be enhanced by supplementation with *P. chrysosporium* (64). In another soil study, investigators examined the role of fungal oxidative enzymes in the degradation of soil contaminants by looking at gene expression in the soil matrix. Among the genes implicated in pollutant degradation were two closely related lignin peroxidase genes, whose mRNA transcripts were detected in the soil under study (65). Thus, the use of white-rot fungi appears quite promising for certain pollutants such as the PAHs (64) and chlorinated phenols (34). However, more proof of efficacy is required before this becomes a commonly used bioremediation technique. Hundreds of species of white-rot fungi have not yet been examined as bioremediation agents, so the possibility of identifying strains more suitable for fungal bioremediation is good.

LIMITATIONS OF BIOREMEDIATION

As a biological process, bioremediation has the limitations inherent in any biological system, so it may not always be

Figure 4. The white-rot fungus *Ganoderma aplanatum* (common name, Artist's conk). (Photographed by University of Idaho Photo Services.)

an appropriate technology for treating a contaminated site. For a site to be treatable by bioremediation, environmental conditions must support biological activity because extremes of pH, temperature, radioactivity, or redox potential may not be tolerated by degradative organisms. Essential nutrients such as nitrogen, phosphorus, sulfur, and trace elements must be present and available. The soil or water to be treated by bioremediation must be free of extremely high concentrations of certain toxic chemicals (e.g., the heavy metals mercury, lead, and zinc) and other antimicrobial substances. The concentrations of contaminants may be too low to provide sufficient energy for microbial growth, and cometabolism may not be an option. Contaminants may not be bioavailable, or accessible to microorganisms, but they may still be subject to remediation standards required by regulatory agencies. In complex mixtures of contaminants, the feasible bioremediation processes may be unable to remove all the components. The site to be treated, a vast, deep aquifer, for example, may not be accessible to engineers. Finally, some xenobiotic compounds simply are not biodegradable. Thus, bioremediation must be viewed as only a single tool in the environmental restoration toolbox, one that will be used frequently but not for all sites or situations.

OUTLINE

BIOSORPTION OF METALS

It has been known for decades that some types of microbial biomass tend to accumulate metals rather effectively. This is the case even when the biomass is dead, that is, metabolically inactive, since it is the chemical composition that is responsible for sequestering metal ions and/or metal complexes from solutions. This fact obviates the necessity to maintain special growth-supporting conditions to make the biomass sequester metals. This metal-sorption phenomenon can find enormous applications wherever metals would need to be removed from solution and concentrated.

Rather than searching among thousands of microbial species for biomass with this particular metal-sequestering feature, feasibility dictates us to look first at biomass types that are readily available and in quantities to support the potential demand. Copious quantities of seaweeds, which could easily be collected, grow in the oceans and, indeed, some of them have been identified for their especially outstanding metal-sorbing properties. Other quantities of biomass are generated as by products of large-scale industrial fermentation processes. Often posing disposal problems, some of these readily available industrial-biomass types have been found to be excellent metal sorbers.

A whole new family of metal (bio)sorbing materials appears to be on the horizon, serving as a basis for the new technology of biosorption aimed specifically at metal removal and recovery from metal-bearing industrial solutions and/or effluents.

REMOVAL AND RECOVERY OF HEAVY METALS BY BIOSORPTION

Need for Heavy-Metal-Removal Processes

By far the largest demand for particularly cost-effective metal-removal technologies from dilute solutions is in ecoapplications. Metal ions in the environment are biomagnified in the food chain and accumulated in tissues. Cd, for example, has a half-life of 10–30 years in the human body (1). Therefore, their toxic effects are especially pronounced in animals of higher trophic levels, particularly humans. From the ecotoxicological point of view, the most dangerous metals are the so-called big three: Hg, Pb, and Cd. Following well-documented and publicized disasters and problems with Hg and Pb, the large-scale use of these metals by various industries has been either eliminated or very curtailed. Technological processes making use of these metals have recently been phased out, particularly in developed countries, and replaced by environmentally safer technologies. A major step in limiting the amount of lead discharge into the environment, for instance, has been made by the elimination of leaded gasoline.

On the other hand, the use of Cd has been steadily increasing in growing applications such as in electroplating, pigments, and batteries. Cd toxicity causes kidney damage, bone disease, and cancer (1). Other common heavy metals, such as Cr, Cu, Zn, Ni, and V are less toxic, but are among the most widely used metals (after Fe and A1) (1). Cu is mainly employed in the electrical industry (e.g., wires) and brass production. The major applications of Zn are galvanization and production of brass and other alloys (1). Mine tailings and effluents from nonferrous metal industry are the major discharge sources of different combinations of dangerous heavy metals.

Therefore, it would be beneficial to devise separate pretreatment facilities for the elimination of heavy metals from wastewater, ideally at the site of those plants that discharge significant amounts of heavy metal ions with

their wastewater. Such on-site treatment of waste streams contributing a load of heavy metals would be more efficient than treating large volumes of mixed wastewater in a general sewage plant. Additionally, from a policy viewpoint it seems reasonable that those who cause metal pollution should be responsible for its elimination. While industrial enterprises are presently obliged to meet certain discharge standards, drinking-water quality (Table 1) cannot be considered since such treatment would be prohibitively costly.

Natural-metal recycling in the environment makes metal recovery the only effective way of preventing heavy metals from poisoning the environment. Yet if a cost-effective way of completely eliminating heavy metals could be found, this goal could be attainable. Current research activity in the field attempts to evaluate whether biosorption may eventually provide such an effective and economical treatment-process alternative.

While biological treatment is reasonably effective in removing organic pollutants, heavy metals tend to accumulate in biological sludges (5), which are considered unsafe as fertilizer and require incineration. The accumulation of metals by the microbial biomass is a result and typical example of combined metabolism-dependent active bioaccumulation and passive biosorption of metals.

Possible Applications of Metal Biosorption

The term *biosorption* commonly refers to the passive binding of metal ions by biomass, which may even be dead. It must be distinguished from bioaccumulation, which is usually understood to be an active, metabolically mediated process occurring in living organisms.

It has been known for decades that different types of microbial biomass bind trace metal ions, achieving very high concentration factors. Black and Mitchell (6) reported a 1,000-fold increase of metal concentration in biomass of some brown marine algae as compared to the seawater. The biomass-metal-uptake phenomenon has been made use of in, for example, electron microscopy, to visualize cellular components. The focus in early studies of microbial-metal uptake has been almost exclusively on the nutritional and toxicological aspects of metal presence.

Recently, however, efforts have been made to develop the process of metal accumulation by biomass into a technique for the treatment of toxic metal-bearing industrial effluents, or for the recovery of precious elements from processing solutions, or even seawater. The process of gold sorption by *Sargassum* has been patented, and the immobilized biosorbents AlgaSORB™ and AMT-BIOCLAIM™ are being commercially developed (7).

Biosorption removal of toxic heavy metals is especially suited as a "polishing" water-treatment step because it is possible to reach drinking water quality of the treated water (initial metal concentrations, e.g., 1 to 100 mg/L, final concentration <0.01 to 0.1 mg/L), especially in packed-bed flow-through sorption column applications. To prevent unnecessarily rapid exhaustion of the sorption capacity when the metal concentrations in wastewater to be treated are high (>100 mg/L), it may be desirable to use a different pretreatment technique, such as precipitation or electrorecovery, for removal of the bulk of the metal content. However, generation of toxic sludges during pretreatment must be considered, since these represent another type of hazard and the eventual recovery of metals from them may not be feasible.

The metal-laden biosorbent can be regenerated, incinerated, or stored in landfills. The biosorption process basically serves to reduce the waste volume. Alternatively and preferably, regeneration of the biosorbent material or multiple (re)use is desirable to increase the process economy. It can be accomplished by metal desorption with, for example, acids or salt solutions. The resulting highly concentrated metal solution can be processed by other techniques such as precipitation or electro winning to remove or concentrate the metal, which could be the recovered and resold. The latter process, in particular, is aimed at recuperation of the metal. The overall achievement of the biosorption (complete adsorption + desorption cycle) process is to concentrate the metal solution, possibly by at least a factor of 100 or more. The flowchart of the biosorption process with in situ regeneration of the biosorbent is quite similar to the use of ion-exchange resins (Fig. 1).

Compared to conventional wastewater "polishing" techniques such as ion-exchange, activated carbon treatment,

Table 1. Drinking Water Standards and Discharge Limits of Heavy Metals

Metal	Drinking water standards WHO (2) (mg/L)	Discharge limits Canada (3) (mg/L)	Discharge limits United States (4) (mg/L)
Cd	0.003[a]	1.5	0.1

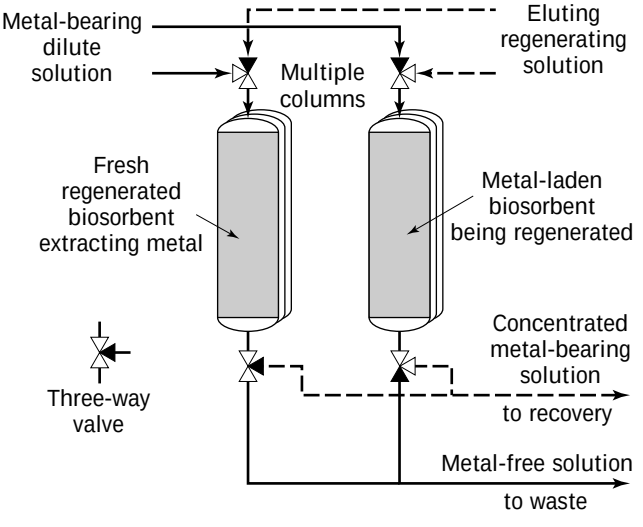

Figure 1. Schematic flowchart of a continuous-flow column biosorption process.

or membrane technologies (electrodialysis, reverse osmosis), the advantage of biosorption is not only that it can be operated under a broad range of conditions (pH, temperature), but especially that it may be economically attractive due to the cheap raw materials that can be used as biosorbents (7). These include waste products from other industries (e.g., fermentation by-products) or naturally abundant biomass (e.g., ubiquitous marine algae). Recent studies show that for certain types of seaweed biomass, for example, virtually no pretreatment may be necessary: Untreated *Sargassum* biomass was successfully applied in packed-bed column biosorption of Cu (8). This means that the sole costs of the seaweed-based biosorbent may be only those of collection and transport.

To evaluate the expected performance of biosorption for treating typical waste waters, it is desirable to reliably predict how much metal could be bound under different operating-process conditions. Computerized process simulations could effectively and economically provide this relevant information, which is essential for the engineering process design and scale-up.

Characteristics of Metal Biosorption

Biomass Types. A multitude of biomass types (9), comprising fungal biomass (10), bacterial biomass (11), algae (12–14), peat (15,16), and so on, have been studied for their biosorption of metals. It was observed that not only the species but also growth conditions such as culture medium, as well as physiological state and age of the organism, influence the biomass-sorption performance (17). In many cases, the sorption by dead material proved to be more effective than that by living organisms (18,19). Biomass of some marine brown algae has been found to be particularly effective in metal-ion binding (20,21), showing similar or better performance than industrial ion-exchange resins. Gold accumulation by the brown alga *Sargassum* can constitute up to 40% of the biomass dry weight (22). Further encouraging results with this sorbent material were obtained by Kuyucak and Volesky (22), Holan et al. (20), Leusch et al. (23), and Ramelow et al. (24).

The particular amount of metal bound in the biosorbent depends, however, not only on the chosen biosorbent but also on the type of metal ion, its concentration, and other physicochemical parameters of the solution (e.g., pH, ionic strength).

Temperature Effect. Simple physical sorption processes are generally exothermic (i.e., the equilibrium constant decreases with increasing temperature). Biosorption ion exchange among alkaline earth metals in binding to alginate was observed to be exothermic (25). However, when Cu was the replacement, the reaction exhibited a positive enthalpy change (i.e., it was endothermic—the equilibrium constant rose with temperature). The driving force in this case was attributed to a large positive entropy change, possibly caused by a larger ordering effect of Cu (than Ca) on the water molecules in the hydration sphere. This is illustrated by the following equation:

$$K = \exp\left(\frac{-\Delta G^0}{RT}\right) = \exp\left(\frac{-\Delta H^0 + T\Delta S^0}{RT}\right) = \exp\left(\frac{-\Delta H^0}{RT}\right)\exp\left(\frac{\Delta S^0}{R}\right) \quad (1)$$

A rise in K with increasing T means that $\Delta H^0 > 0$, that is, that the reaction is endothermic. But since a reaction can only proceed when $\Delta G^0 = \Delta H^0 - T\,\Delta S^0 < 0$, it follows that ΔS^0 must have been >0, that is, the system's entropy must have increased.

Similar results were obtained by Weppen and Hornburg (26) in calorimetric studies of the binding of divalent metal ions by potassium-saturated microbial biomass. The reactions were slightly endothermic and therefore driven by an increase in the entropy of the system. For most metals, the heat of reaction was constant, independent of the degree of site occupation. For Cu, however, the heat of reaction decreased with increasing degree of site occupation from 27 kJ/mol to 14 kJ/mol, which may indicate the involvement of different binding sites or the formation of different types of Cu complexes with the biomass. For other heavy metals, the heat of reaction was between about 7 and 11 kJ/mol, for light metals between about 2.5 and 6 kJ/mol (26).

Overall, however, the effect of temperature in biosorption is relatively small and perhaps only slightly more pronounced in the lower temperature range: the binding of Co by the brown alga *Ascophyllum nodosum* increased by 50–70% when the temperature was raised from 4 °C to 23 °C. With further temperature increase to 40 °C the binding increased only slightly, whereas temperatures of 60 °C or more caused a change in the texture of the sorbent and a loss in the sorption capacity. The distribution ratio (metal bound/metal in solution) for biosorption of Cd, Zn, Pb, Ni, and Cu to *Spirulina* algae increased by only about 20% when the temperature was raised from 4 °C to 55 °C. It is reasonable to expect that possible application of biosorption will be in a rather narrow temperature range (~5 to 50 °C) to avoid decomposition of biosorbent materials.

Presence of Anions (Ligands). Theoretically, the presence of ligands (at levels that do not cause precipitation) can lead to the following (27):

1. Formation of complexes that have a higher affinity to the sorbent than the free metal ions (i.e., an enhancement of sorption)
2. Formation of complexes that have a lower affinity to sorbent than the free metal ions (i.e., a reduction of sorption)
3. Interaction of anions with the biomass, changing the state of the active sites such that the binding is either enhanced or reduced

There are no indications of the third kind of interaction reported in the biosorption literature. Additionally, these are unlikely to occur in brown algal biomass since the probable binding sites (negatively charged carboxyl and sulfate groups) are not expected to interact with anions such as sulfate, nitrate, and so on.

It has been reported for sorption of Cu^{2+} and Ag^{+} to inorganic oxide surfaces that metal binding at low pH was enhanced in the presence of certain ligands. Since the ligand itself was able to bind to the oxide, and since a 1:1 stoichiometry of ligand and bound metal was noted, it was concluded that some metal complexes may bind more strongly than the respective free ions (28). Negatively charged metal–EDTA complexes were bound to oxide surfaces (probably releasing OH^{-}), with sorption decreasing with increasing pH (29).

Chen et al. (16) report that up to 50% of Cu binding by peat occurred as complexation of copper nitrate [$Cu(NO_3)_2$] with the binding sites. The remaining metal binding was due to ion exchange such that the overall charge neutrality was conserved. The data allow, however, another interpretation as well: Instead of up to half of the Cu being bound as $Cu(NO_3)_2$ and the other half as Cu^{2+}, up to 100% could have been bound as $Cu(NO_3)^{+}$. Glaus et al. (30) found that the binding of Co and uranyl (UO_2^{2+}) to humic substances could be modeled better when binding of metal–ligand (oxalate) complexes was included in the model.

In most cases of biosorption, however, metal binding tends to be reduced in the presence of ligands (exception: OH^{-}) (22,27,31). This means that the biomass apparently has less affinity for many metal–ligand complexes than for free hydrated metal ions. Therefore, the influence of ligands in solution can be understood as a competition with the biomass for binding of the metal ions.

This effect is, however, not very pronounced unless these anions show a strong complexing power for the metal ions of interest (e.g., EDTA) (24,27), which at only 1.5 times excess caused 100% inhibition of metal binding. The addition of 0.1% EDTA resulted in >90% reduction of binding for most cases of Cd, Cu, Zn, and Pb biosorption by seaweeds (also *Sargassum*) (24). A large excess (1,000 times) of the ligands glutamate, sulfate, phosphate, carbonate, or chloride resulted in the maximum reduction of, for example, Cd binding to *Rhizopus arrhizus* biomass of only 21% (27).

Since significant concentrations of strong complexing agents are rare in typical metal-bearing industrial effluents, the effect of the presence of ligands is of secondary importance.

Influence of pH. Of great importance in sorption is the pH value of the solution. It is commonly agreed that the sorption of metal cations (e.g., Cd, Cu, Zn, Pb, Ni, Mn, Al, Co) increases with increasing pH (14,20,24,32–35) as the metal ionic species become less stable in the solution. Only those metal ions that can occur as negatively charged complexes or that have a strong "b" character (i.e., tendency to form strong covalent bonds), such as Ag, Hg, or Au (e.g., as tetrachloroaureate), may show either a decrease in binding with increasing pH or may have no significant pH effect at all (24,31,33). There are three ways that the solution pH can influence metal biosorption, as described in the following.

First, the state of the active sites may be changed. When the binding groups are acidic, the availability of free sites depends on pH: At lower pH the active sites are protonated, therefore, competition between protons and metal ions for the sorption site occurs (36,37). At a low enough pH, virtually all sites become protonated and complete desorption of the bound metal ions is possible (38), which is why acid treatment is a method for metal elution and regeneration of the sorbent material. Decreasing the pH value by 2 units can in some cases result in a ~90% reduction of metal binding (14,24,31,32,38).

Second, extreme pH values, as they are employed in the regeneration (desorption) of the sorbent, may damage the structure of the biosorbent material. Microscopic observations have shown distorted cells; significant weight loss and decrease in the sorption capacity have been observed (39).

Third, the speciation of the metal in solution is pH dependent. Whereas metals in aqueous solutions occur as hydrated cations in solvation shells when the pH is low, hydroxides may form at a higher pH, especially for cations of high charge and small size (40–42). The formation of metal oxide and hydroxide complexes and precipitates is often called hydrolysis (i.e., decomposition or conversion by water) (43).

Adsorption depends not only on the attraction of the sorbate to the solid surface but also on its lyophobic behavior (44). This means that sorption increases with decreasing solubility. Since the solubility of many metal complexes in solution decreases with increasing pH, this provides an additional possible explanation as to why sorption increases with increasing pH. In the narrow pH range where the metal ions are hydrolyzed, sorption is especially enhanced, so that even a charge reversal of the surface to positive values can occur (44,45). Further possible explanations of increasing sorption with increasing pH are that hydrolyzed species have a lesser degree of hydration, that is, less energy is necessary for removal or reorientation of the hydrated water molecules upon binding. Furthermore, OH shows affinity for some sorbents (46).

With further increase of pH, the solubility of metal complexes decreases enough for precipitation to occur. Although precipitation may contribute to the overall removal of metals from solution (and therefore be desirable for metal-removal applications), it renders the study of the biosorptive binding more difficult. For scientific purposes it is therefore recommended to study biosorption at pH values where precipitation does not occur.

Presence of Other Cations. Other sorbable ions in the solution may compete with the metal ion of interest for sorption sites. The binding of this metal ion is then decreased. The amount of inhibition depends on the binding strength of the respective ions to the biomass.

For example, Mg and Na are effective in competing with Zn for binding sites of green algae [90% reduction of Zn binding at 200 mM NaCl or $Mg(NO_3)_2$], but they interfere less strongly with the binding of Pb or Cu [<50% reduction of Pb or Cu binding at 200 mM NaCl or $Mg(NO_3)_2$] (14).

The inhibition by alkali metals (K, Na) of heavy-metal-ion binding to microbial biomass was much less pronounced than the inhibition by heavy metals (Zn, Cu, Fe) of uranium or radium binding (19).

For *R. arrhizus* fungal biomass, the presence of uranium reduced the binding of Cd, Zn, and Ag more strongly

than vice versa; Ag in particular was a weak competitor, but nevertheless its binding was unaffected by the presence of Na (47).

In the sorption of Cd, Cu, and Zn on formaldehyde crosslinked biomass of the brown alga *A. nodosum*, the presence of each ion reduced the binding of each other ion, with Zn being the weakest binding, and Cu the most strongest binding, of the three cations (48).

From the different literature sources it can be generally concluded that the light metals (alkaline and alkaline earth metals) bind less strongly than the heavy-metal ions or radioactive elements. Therefore, the former do not strongly interfere with the binding of the latter. There are indications that among the heavy metals, Zn binds rather weakly and its binding is therefore more strongly affected by other ions.

In order to understand why some ions bind more strongly than others, it is useful to look at the properties of different metals, to be discussed later. Such knowledge can also serve to estimate how strongly an ion may bind that has not yet been investigated. This knowledge serves as a basis to better understand the metal-binding mechanism.

Mechanism of Biosorption

The effect of any of the previously mentioned influencing factors can be best quantitatively estimated when the mechanism of biosorption for different ions is known and when a mechanism-oriented mathematical model is used for predicting the effect of these factors.

Classification of Binding Mechanisms. The metal binding in biosorption has been attributed to a number of different sequestering mechanisms, such as complexation, coordination, chelation, adsorption, ion exchange, or microprecipitation (as metal or metal complex) (49). It is a recognized fact that a combination of several mechanisms, each functioning independently, can contribute to the overall metal uptake. In the studies of biosorption conducted so far, very little attention has been paid to examination of a well-defined metal uptake (by a specific mechanism) as opposed to the overall uptake where several types of sequestration may be taking place simultaneously. Systematic understanding of the metal-uptake mechanisms and their relationships may greatly clarify the otherwise confusing broad definition of biosorption mechanisms in the literature.

For example, some mechanisms can be submechanisms of other overall mechanisms. The claim of an ion-exchange metal-binding mechanism for a specific system may not necessarily be contradictory to reports of chelation being the relevant mechanism. The overall mechanism of ion exchange can be based on the submechanism of complexation. This means that one complexed ion exchanges against another one.

A systematic presentation of the relationships between different mechanisms is compiled in Figure 2. The classification of bond types (Fig. 2, bottom) as described by Myers (50) was used, as well as information on sorption processes from Westall (51) and Pagenkopf (44).

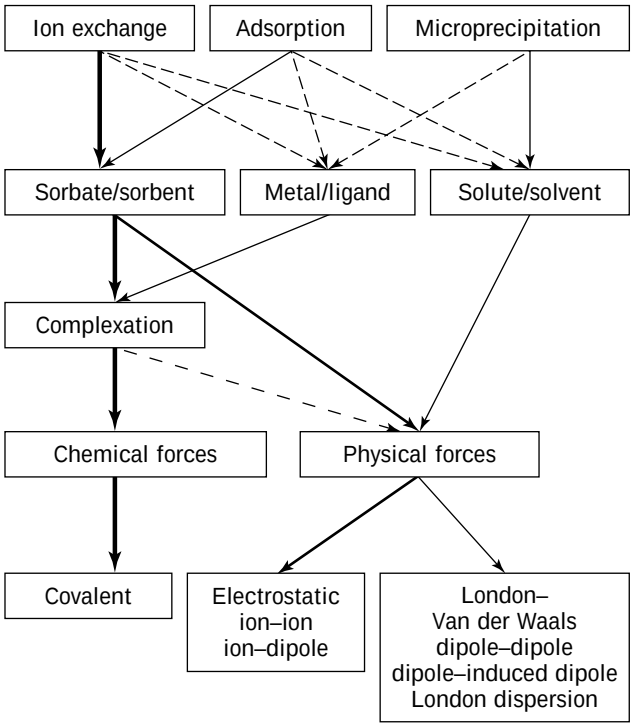

Figure 2. Metal biosorption mechanisms: bold lines, mechanisms probably important in biosorption by *Sargassum* biomass; dashed lines, biosorption binding relations of secondary importance.

In the context of this work, the term *sorption* refers to binding of a solute (usually a metal cation) to free sites that previously were not occupied by another cation. If the sites are initially occupied by another cation (regardless of the submechanism, i.e., whether covalent or electrostatic binding is involved), and if this second ion is released on the binding of the first ion, then the term *ion exchange* is used.

Microprecipitation is the deposition of electrically neutral material (metal or metal salt) at the surface of the biomass, and does not necessarily involve a bond between the biomass and the deposited layer. Microprecipitation may, however, be facilitated by initial binding of metal ions to reactive sites of the biomass, which serve as nucleation sites for further precipitation (52). This process is not limited to a monolayer (or saturation of sites): Cells can accumulate several times their dry weight in metal (53,54). Microprecipitation is based on interactions between the solute (dissolved solid) and the solvent, and occurs when the local solubility is exceeded.

Ion exchange and adsorption can be the result of three different interactions (which can act in combination): The main contribution for free metal ions (which are highly soluble in water) is usually attraction of the sorbate (metal ion) to the sorbent (biomass). In the case of binding of metal–ligand complexes, or in the case of ligand exchange (where the metal ion in solution is complexed with a ligand that has to be released when the metal ion is bound to the biosorbent [51]), interactions between ligands and metal cations must be taken into account. Additionally, hydrophobic (or, generally, lyophobic) expulsion (which is an interaction between sorbate and solution) may also play a

role (44,51), especially in the adsorption of organic dipoles and large organic ions because of their low affinity to the aqueous phase (46). Among inorganic ions, the less hydrated ones are more readily accumulated at the interface (46). The hydration effect is further discussed later.

Complexation plays an important role in both metal–ligand and sorbate–sorbent interactions (51). A complex (also referred to as a coordination compound) is a polyatomic molecule that consists of one or more (then called polynuclear complex) central atoms (usually metal cations) surrounded by ligands (other atoms or groups, usually of negative or neutral charge) that are attached to it. Complexes can be neutral, positively charged, or negatively charged. The number of coordinating atoms in the ligands that are directly attached to the central atom is called the coordination number, and can be larger than the valence of the central atom. (The most common coordination numbers are 4 and 6, but 2 and 8 also occur frequently.) If one ligand is attached to the central atom through two or more coordinating atoms, then the complex is called a chelate. The bonds between the central atom and the coordinated groups can be arising from principal or auxiliary valence forces (55,56).

Binding Forces. In general, the forces between atoms or molecules can be classified into chemical and physical ones. Chemical forces extend over very short distances (0.1–0.2 nm) (50). This type of bond is rather strong: Stumm and Morgan (46) report an energy of $\geqslant$40 kJ/mol, Myers (50) 150–900 kJ/mol, Smith (57) for chemisorption 20–400 kJ/mol and Pagenkopf (44) 40–400 kJ/mol. Covalent bonds are formed by merging electron clouds such that a nonionic molecule is formed. These bonds are directional (characteristic bond angles and lengths) and localized (50).

Physical forces can be subdivided into electrostatic and London–van der Waals forces (50). The energy of physisorption is reported as 2–20 kJ/mol and 20–40 kJ/mol by Smith (57) and Pagenkopf (44), respectively. In the resulting bonds, the electrons stay in their original systems. Electrostatic (or coulombic) forces between ions or between ions and dipoles extend over a long range and are the strongest among the physical bonds (50), with energies $\geqslant$40 kJ/mol (46). The interaction is repulsive for ion charges of the same sign and attractive for unlike charges. The magnitude of the force is proportional to the charge of each ion and inversely proportional to the square of the distance between the ions.

London–van der Waals forces can be divided into three categories: dipole–dipole interactions (creating orientational energy), dipole-induced dipole interactions, and the London dispersion force (50). The first two are closely related to coulombic forces, while the last is of quantum–mechanical nature and acts over a long range, of up to about 10 nm (50). The energy of the dispersion force (8–40 kJ/mol) is larger than the one of orientational or induced dipole (or polarization) (51) energy ($<$8 kJ/mol) (46). An example of untypical strong (almost ionic) dipole interactions is hydrogen bonding (which may even display some covalent bond character). It occurs between molecules in which H is bound to a very electronegative atom such as O (e.g., in H_2O) (58).

The mechanisms and forces that are probably (as pointed out later) the most important ones in the case of metal binding by, for example, brown algal biomass are indicated in bold type in Figure 2, that is, complexation by chemical covalent bonds based on ion exchange (for which the driving force is the affinity of the sorbate [metal ion] to the sorbent [biomass]) supported by physical electrostatic interactions between positively charged metal ions and negatively charged biomass.

Ion Exchange versus Sorption. There have been some indications that ion exchange plays an important role in metal-ion sorption by algal biomass. Kuyucak and Volesky (59) noted that the amount of ions (K, Na, Ca, Mg) released from the marine brown alga *A. nodosum* was much more pronounced in metal (Co) bearing than in metal-free solutions. A linear correlation between Ca release and Co uptake (2:3) was found when the biomass had been previously washed with CaCl and HCl. It was concluded that ion exchange was responsible for the sorption (59). If ion exchange was responsible, an exchange ratio of 1:1 should, however, be expected for two divalent ions such as Ca and Co. Since it can be expected that some sites would have been protonated due to the pretreatment with a CaCl and HCl mixture, and since some proton release was noticed, it would have been more appropriate to relate the Co binding to the sum of Ca and H released (in milliequivalent not mole). This would have led to an exchange ratio much closer to 1:1.

Crist et al. (60) included protons in the quantitative study of ions (Ca, Mg, H) released during metal (Cu) uptake by the freshwater alga *Vaucheria* and found that the amount of divalent metal ions taken up equaled the amount of other divalent ions plus protons released (in milliequivalent terms). Treen et al. (61) reported that in column application of *Rhizopus* fungal biosorbent 2 mol of protons were released for 1 mol of uranyl sequestered.

According to Chen et al. (16), the Cu binding to peat at low metal concentrations was predominantly ion exchange (with H, Ca, Mg), while at higher concentrations, binding of copper–nitrate complexes occurred. The latter mechanism was dominant above 6 mM of Cu.

It appears reasonable that in many cases ion exchange rather than sorption to free sites is the relevant overall mechanism for the binding of metal ions in biosorption. Since the overall charge of the biomass particle has to be neutral, any binding of one cation must be accompanied by either a stoichiometric release of other cations or by the binding of anions. Since the charge of algal biomass is negative (see "Surface Charge"), it appears unlikely that free anions will be bound by the biomass. If complexes in solution occur, double exchange of cations and anions or binding of the complex may take place. Generally, sorption of neutral (metal cation + anion) complexes would be possible. However, it is unlikely to be the case at the moderate pH and metal, as well as the ligand concentrations, relevant to the biosorption process.

Desorption/Ion Exchange of the Metal from Biosorbent. Due to the weak nature of metal-binding forces, it is possible to wash the bound metal from the sorbent in a small

volume of solution offering another cation (e.g., H^+, Ca^{2+}) in higher concentrations. From the process point of view, this enables the reuse of the biosorbent in multiple uptake/desorption cycles allowing for a greater process economy. Desorption can be achieved by acids (e.g., HCl, H_2SO_4) and/or salt solutions (e.g., $CaCl_2$) (38,39). The effectiveness of desorption depends in this case on the binding strength of the added cation to the biosorbent. A different approach to desorption is the addition of a complexing agent (e.g., EDTA, KSCN) (39) that binds free-metal ions and thereby lowers their concentration in solution to the extent that they are released from their binding sites on the solid. In this case the driving force is the complexation of the metal ion. The efficiency of the desorption depends on the binding strength of the desorbed ion to the complexing ligand. Nevertheless, a charge balance of the sorbent particle has to be maintained, that is, ion exchange still occurs. That means some cation (e.g., the one that was added along with the complexing ligand, often Na) has to replace the desorbed ion at the binding sites, even if its affinity toward the binding sites is lower.

Chemical (Covalent) versus Physical (Electrostatic) Binding. The proportion of protons among the released species varied with the metal taken up (25,62) and corresponded to the binding strength: More protons were released by the stronger binding ions. It could be concluded that in those cases where no protons were involved, as for most alkaline and alkaline earth metals, electrostatic attraction was the binding mechanism (63), whereas covalent binding occurred when protons were released (62).

It appears plausible that the number of protons released increases with the binding strength of the metal ion because it can more effectively compete with protons. Also, as a general rule, the force of electrostatic binding alone is weaker than binding with covalent contribution (especially since alkaline earth ions have similar radii to those of many divalent heavy metal ions, so that large differences in the binding strength are due to different amounts of covalent binding). However, it does not necessarily follow that proton release indicates covalent binding; part of the protons (depending on the relationship between pH and $p^{BH}K$) may also be bound by electrostatic attraction and therefore be easily replaceable by electrostatically bound ions.

Binding Sites. Biosorption has been attributed to different types of groups such as carboxylate, carbonyl, hydroxyl, amine, amide, imidazole, phosphate, thio, and thioether groups (33). Which binding mechanism applies in any specific case depends, of course, largely on the type of biosorbent used and on the types of binding sites it contains. Crist et al. proposed that, for example, carboxylate, sulfate, and amino groups may be responsible for metal binding by freshwater algae (62). Indications for carboxyl- and sulfate-group participation were found by titration of marine algal biomass (64). The chelating ability of polysaccharides from green freshwater alga *Chlorella* was connected to their content of uronic acids. Their carboxyl groups would be negatively charged and could bind metal ions (65). Tobin et al. (37) concluded that in *R. arrhizus* fungal biomass at pH 4, carboxylate and phosphate groups offered the primary metal-binding sites, supported by hydroxyl groups. Greene et al. (31) noticed a complete loss of available sulfhydryl groups (determined by polarimetric titration) after the binding of Au(III) to the freshwater alga *Chlorella*, thus giving evidence for the involvement of this group, but it could only account for a small amount of total gold binding. Cell modifications with succinic anhydride indicated the relevance of amine groups, since the sorption of tetrachloroaureate decreased by 50% after their modification (31).

The modification of carboxyl groups by esterification with acidic methanol resulted in a significant decrease in the binding of Cu and Al, but a slight increase in Au binding by five different algae (66). The decrease in sorption was more pronounced for Al, which as a hard metal is expected to bind preferably to hard sites, such as carboxyl groups, whereas Cu as a softer metal may bind to nitrogen- or sulfur-containing group instead. The binding of the negatively charged Au complex increases, probably due to a decrease in the negative surface charge.

For brown marine algae it is assumed that alginates play a key role in metal-ion binding (59). Fourest and Volesky (67) investigated the binding of H, Cd, and Pb by alginic acid and *Sargassum fluitans* biomass before and after modification of the carboxyl groups using acidic methanol or propylene oxide. A linear correlation between the binding capacity for Cd and the content of weak acidic groups (probably carboxylate) resulting from different degrees of active-site blocking was noted. The maximum metal-binding capacity of different algae was linearly correlated with their titer of weak acidic groups, with a stoichiometric relation between metal bound and acidic titer of 0.36 to 0.5 mol/mol. This means that about two acidic sites are necessary per bound metal ion (E. Fourest and B. Volesky, personal communication, 1997).

Surface Charge. The relevance of electrostatic attraction in biosorption depends on the types and amounts of sites present in the biomass and on whether they are ionized or occupied by protons or other ions. That, in turn, depends on the pH and on the pK_a of the respective group. Usually, a good agreement between the pK_a values of inorganic acids and their corresponding acidic groups in biomolecules exists, as evident from Table 2. Amine groups are positively charged in their protonated form and neutral

Table 2. K_a Values of Inorganic Acids and Acidic Groups in Biomolecules

when deprotonated. Carboxyl, sulfate, and phosphate groups are neutral when protonated and negatively charged when deprotonated.

If the freshwater alga *Chlorella* could be taken as an example, its isolelectric point (zero overall charge) is at pH 3 (33). At lower pH, the positive charge (possibly of amine groups) leads to an attraction of anions; at higher pH, the negative charge (probably of carboxyl groups) attracts cations and repels anions (33). Biomass of the marine brown alga *Ascophyllum nodosum* bears a negative charge whose magnitude sharply increases from pH 3 upward. It is probable that this surface charge originated from deprotonated carboxyl groups of the alginate in the cell wall (34).

Location of Bound Metal. Knowledge pertaining to the location of metal uptake in the cell can provide some indication about the relevance of binding groups if it is correlated with information about which biomolecules occur in the respective parts of the cell. Electron micrographs of bacterial (70,71), fungal (72,73), and algal (74) metal-bearing cells in the literature indicate that the cell wall plays an important role in metal-ion biosorption. While the basic biomass metal-sequestration process is usually very fast, some time-lapse electron micrography indicates slower metal penetration into cell interiors and/or building up of external metal deposits (18,31,59,63).

For a better understanding of the relevant mechanisms in metal binding by microbial biomass, more detailed and accurate knowledge about the biomolecules and binding sites offered by different types of cells is necessary.

PROPERTIES OF METAL IONS IN BIOSORPTION

Biosorption Affinity Sequence Trends

Studying metal-ion binding to alginic acid from *Laminaria digitata* Haug (75) reported that the amount of protons released into solution decreased in the order Pb > Cu > Cd > Ba > Sr > Ca > Co > Ni > Zn > Mn > Mg. This was explained by a better ability of strongly binding ions to compete with protons for organic binding sites. The affinity sequence for metal-ion binding to alginate from *L. digitata* followed a similar trend Cu > Ba > Ca > Co (76), and for binding of alkaline earth metals to polymannurate and polygulurate the binding strength decreased in the order Ba > Sr > Ca > Mg (25). According to Haug and Smidsrod, the preferential binding of the heavier ions could have been due to stereochemical effects, as larger ions might better fit a binding site with two distant active groups. The amount of proton displacement by metal ions decreased in the order Pb > Cu > Ba > Sr > Ca > Cd > Zn > Ni > Mg > Co, Mn for polyguluronic acid, and in the order Pb > Cu > Cd > Ba > Ni > Sr > Ca > Mg > Zn, Co, Mn for mannuronic acid (25). Again, the trend was concurrent with the one in binding strength.

Schweiger (77) found a different order of complex stability for binding to alginate as being Ba > Cd > Cu > Sr > Ni > Ca > Zn > Co > Mn > Mg, but still the binding of alkaline earth metals increased with their weight. For the elements Cu, Ni, Co, and Mn of the third period, an increase of binding strength with increasing atomic number was noticed. In binding to fucoidan, the affinity sequence Pb > Ba > Cd > Sr > Cu > Fe > Co > Zn > Mg > Cr > Ni > Hg > Ca was reported (78).

For *R. arrhizus* biomass, the maximum metal-binding capacity decreased in the order $UO^{2+} > Cr^{3+} > Pb \sim Ag^{+} > Ba > La^{3+} > Zn > Hg > Cd > Cu > Mn$ (37). The metal-binding capacity increased linearly with the crystal ionic radius, and no correlation to the charge was noticed, except that the binding of alkaline metal ions was negligible (37).

The observations of higher binding (both capacity and binding constant) with increasing ionic radii were interpreted as a consequence of the binding-group conformation: Assuming that binding groups are distant from each other, large ions could not only be more easily dehydrated, but could also bind to several groups simultaneously (79). This could explain the binding strength; however, it does not explain the higher binding capacity. To the contrary, if several groups are involved in the binding of one large ion, the binding capacity of small ions, each binding to one site, could be higher.

Avery and Tobin (80) found that the amount of proton displacement decreased in the order Cu > Cd > Zn > Mn > Sr. It was assumed by these authors that proton release occurred only when the metal was covalently bound, and that the release of Ca and Mg indicated ionic binding. The ratio of (Mg + Ca) released per H^{+} released was used as an index for the relative amount of ionic/covalent binding (80). It was, however, not considered that, for example, Cu might bind covalently to a site from which Ca, which had been bound electrostatically, was released. This index should therefore not be used in a quantitative way.

Evans (81) states that the affinity sequence in alkali-metal binding to soil (Cs > Rb > K > Na > Li) reflects an increase in the hydrated radii of these ions; for divalent ions the binding strength to soil organic matter at pH 5.8 decreased in the order Hg = Pb = Cu > Cd > Zn > Ni > Co > Mn.

For freshwater algae, Crist et al. observed a trend in binding strength Cu > Sr > Zn > Mg > Na being similar to the one for proton replacement Cu > Zn > Mg > Sr > Na, and concluded that a trend from covalent to ionic bonding was responsible (62). As pointed out earlier, however, electrostatic effects could have contributed to proton binding on the one hand and, on the other hand, covalent binding to sites previously occupied by a light metal could be possible.

For binding of light metal ions to freshwater algae, the affinity sequence was Na > K > Li > Cs and Mg > Ca > Ba > Sr (63). It was concluded that if the affinity between biomass and metals was high, the binding should increase with increasing charge density, that is, with decreasing radius. If binding was weak, it would be controlled by dehydration energy and the larger ions would be preferably bound because they could be dehydrated more easily. The observed sequence, which does not show a clear preference for large or small ions, was interpreted as resulting from these opposite trends, indicating medium to strong bonds (63). It is questionable, however, whether the use of crystal ionic radii for characterizing the ionic binding of the hydrated ion is appropriate.

Leusch et al. determined the affinity sequence for untreated *Sargassum fluitans* as Pb > Cu > Mi ~ Cd > Zn

(82). Fourest and Volesky (67) observed that the binding capacity for divalent metal binding to *Sargassum* decreased in the order Pb > Cu > Cd > Zn > Ca, and related this to decreasing electronegativity. However, the binding strength, rather than the maximum binding capacity, should be influenced by the electronegativity. Possibly, the maximum binding was not reached under the conditions employed by these authors.

Conclusion. Generally, these binding-strength trends, except for the work of Crist et al. (63), follow the pattern for monovalent ions—Cs > Rb > K > Na > Li—and for divalent ions—Ba > Sr > Ca > Mg; Cu > Ni > Co > Mn; Pb > Cd > Zn. While the preceding expresses basic trends, no fixed relation between these series can be established. Whether, for example, Cu or Cd happens to be more strongly bound depends on the sorbent material.

Factors Influencing the Binding Strength

There are three factors that can determine the affinity of a metal ion (because they contribute to the free energy of binding of hydrated metal ions to biosorbent binding groups).

1. *Hydration effects:* A change in the orientation of the hydrated water molecules occurs in conjunction with electrostatic binding (69), but in such "outer-sphere" complexes both partners retain their hydration spheres (69). Complete or partial dehydration takes place for "inner-sphere" complexes resulting from covalent binding (69).

   Both types of changes in the hydration state can occur more easily if the hydrated water molecules are not held strongly by the metal ion. Williams and Hale (83) showed that a good correlation (Born equation) between the ion hydration energy and the term (z^2/r) exists. For estimating the strength of hydration, the radius of the nonhydrated cation should be used, of course. This is usually taken as the ionic crystal radius (listed in Table 3).

   Taking into account the hydration sphere, the effective hydrated radius is larger than the crystal-ion radius. In general, the larger the hydration energy of an ion (i.e., the smaller the crystal radius) the larger the effective hydrated radius (58). Consequently, the hydrated radii follow a reverse trend as the ionic crystal radii, both for the groups of alkali and alkaline earth ions (see Table 3). It is difficult to quantify the radius of the hydrated ion, but some values have been compiled (84,85).

   According to Jain (86), hydration effects can be dominating when the electric field of the sorbent is weak (i.e., weak binding). In this case, larger ions (comparing crystal radii of ions of the same charge) that exert a smaller ordering influence on their hydrated water molecules (i.e., that are less strongly hydrated) are preferably accumulated at the interface.
2. *Ionic (electrostatic) binding:* If the binding groups are negatively charged, they can attract metal cations. The interaction is stronger the higher the charge density of both biosorbent and metal ion. If a strong electric field is present, electrostatic effects may become the dominant factor such that small ions that have a higher charge density are bound more strongly (86). In the past, ionic-crystal radii have been used in estimation of the ionic binding strength, as well as in aqueous solution (69,87). However, since the cation retains its hydrated water molecules, the hydrated cation radius is more characteristic for electrostatic attraction (as opposed to hydration). According to Marcus and Kertes (85), the selectivity increases with increasing charge and decreasing hydrated radius.
3. *Covalent binding:* This type of bond involves sharing of the electrons. Therefore, the more similar the electronegativities of the metal ion and the coordinating atom of the ligand, the higher the covalent character of the bond (88). The selectivity (or binding strength) increases with increasing polarizability of the ion (i.e., softness) (85).

Conclusion. Overall, the binding strength increases with increasing ionic radius and decreasing charge if binding is weak and largely due to hydration effects, decreasing hydrated radius and increasing charge if binding is intermediately strong and due to electrostatic effects, and decreasing electronegativity difference if binding is strong and covalent.

Since the first two criteria are almost opposed to each other, the affinity sequence can be reversed with changing electric field strength of the sorbent (86), except that the ionic and hydrated radii can exhibit opposite trends. Therefore, it is possible that for the alkaline and alkaline earth metals, for example, the affinity sequences Cs > Rb > K > Na > Li and Ba > Sr > Ca > Mg > Be observed in industrial ion exchangers are due both to decreasing crystal and increasing ionic radii (85).

The Concept of Hard and Soft Ions

In order to classify the behavior of metal ions, a division into so-called hard and soft ions was introduced by Pearson (89). Hard ions are characterized by predominantly electrostatic bonds where the entropy gain in the change of the orientation of the hydrated water molecules makes an important contribution to the free energy change ΔG (69). Hard ions have a weak polarizing power and retain their electrons strongly. Williams used the charge density (z^2/r) (with z being the charge and r the cation radius) as a measure for the strength of ionic binding (90,91). Table 3 shows that the ionic binding strength of most divalent metal ions is similar and that it is higher than the one for monovalent ions. This is also illustrated in Figures 3 and 4.

The characteristics of hard ions resemble the ones of class "a" cations in the "a"–"b" categorization of metal ions. Type "a" ions form their strongest bonds with the first element of each group, "b" ions with the second or higher (92). Type "a" ions tend to form strong bonds with highly electronegative donors that are difficult to polarize (i.e., hard) (93). The difference between the electronegativity (x) of the

metal ion and that of oxygen has been used as a measure for "a" (i.e., ionic bond) character, which increases with $\Delta x^2 = ({}^{M}x - {}^{0}x)^2$ (69). According to Pauling (94), the fraction of ionic bond character is $1 - \exp(-\Delta x^2/2)$, that is, equal contributions of covalent and ionic binding occur when $\Delta x = 1.7$. As seen in Table 3, the ionic bond character is larger than 70% for alkaline (earth) metals and about 50% for most heavy metals. Dean (88) describes a similar criterion: The ionic bond character increases with Δx and 100% ionic bonding occurs for $\Delta x > 2$ (but according to Pauling's criterion the ionic-bond character at $\Delta x = 2$ is 63%, not 100%). Table 3 shows that the Δx criterion is fulfilled for alkaline and alkaline earth ions.

Soft ions participate in more covalent bonding where the free energy is mostly enthalpic (69). The characteristics of soft ions are opposite those of hard ions, resulting in a reversed affinity sequence. The affinity sequence of soft, or class "b", ions for ligands is I > Br > Cl > F and S > N > O (97). A combined affinity sequence was described by Buffle: S > I > Br > Cl 39 N > O > F (69). Therefore, the difference between complexation constants for F and Cl, respectively, has been introduced by Turner et al. (87) to characterize softness, which increases with decreasing ΔK

$= \log({}^{F}{}^{M}K) - \log({}^{Cl}{}^{M}K)$. Type "a" ions are characterized by $\Delta K < 2$ and type "b" ions by $\Delta K > 2$; among the border elements, tendencies for "a" or "b" character are present for $\Delta K <$ or > 0, respectively (87). Typical hard, or class "a," ions are the alkaline and alkaline earth metals, transition elements up to class VI, and, for example, Zn (93). As opposed to the original classification of Pearson, who considered Cd a soft ion and H a typical hard ion, these two are now regarded as borderline ions (97). Table 3 and Figure 3 confirm that light metals and Mn can be classified as hard, and that most of the heavy metals may be listed as intermediate, except for Zn, which is just on the threshold to being hard, and Ag, which is soft.

For any donor (and especially for soft ones) the binding strength increases with cation softness (69). Soft cations form more stable complexes with soft donors (S, P, or As), while hard cations prefer hard donors (F or O) (89). N donors have intermediate characteristics. For O or N donor atoms, the Irving–Williams order of complex stability for divalent ions in the first series is Mn < Fe < Co < Ni < Cu > Zn (93). This can be explained by the electronegativity differences with respect to the donor atoms O or N.

Examples of hard ligands are carbonate, phosphate, sulfate, or hydroxide ions (1,94) as well as sulfate, carboxylate, alcohol, or hydroxyl groups (97). Soft ligands include sulfhydryl, thioether, and amino groups (97).

The relevant parameters for different metals are listed in Table 3. The hardness parameter (z^2/r_{hyd}) for different metal ions is plotted over the softness parameter $X^2(r_{cryst} + 0.85$ Å) in Figure 4. Since the parameter (z^2/r_{hyd}) expresses the ionic, binding strength, and the parameter $1 - \exp(-\Delta x^2/2)$ is supposed to characterize the relative contribution of ionic bonding to the total binding strength, one can obtain an indicator for the total binding strength by dividing (z^2/r_{hyd}) by $[1 - \exp(-\Delta x^2/2)]$. This parameter is called ξ; it is listed in Table 3 and plotted in Figure 4 as the total height of the bar. The lower part represents the ionic binding strength; the upper part represents the covalent binding strength. The graph should, however, be used only for illustrative purposes, rather than in a quantitative way, because the exact magnitude of the contribution of ionic bonding is disputable. According to the Δx criterion, for example, there is no covalent bonding for the light metals, while this plot, using Pauling's criterion, shows ~20% covalent binding.

The binding trends summarized in the section "Need for Heavy-Metal-Removal Processes" can now be explained: The tendency of stronger binding for the heavier elements in both the alkaline and alkaline earth metals can be explained as being due to lower charge density (z^2/r_{cryst}) (i.e., weaker hydration) of the ions themselves and higher charge density (z^2/r_{hyd}) of the hydrated ions (i.e., stronger electrostatic bonds) in the heavier elements of each series (see Table 3). Since these ions are hard, there is little contribution of covalent bonding; therefore, the electronegativity differences between them are irrelevant. The trend among the elements in the second period (Cu > Ni > Co > Mn) and the trend Pb > Cd > Zn are probably mainly due to a decrease of the covalent binding [characterized by $x^2(r_{cryst} + 0.85)$], but a decrease in the electrostatic binding (z^2/r_{hyd}) (except for the relation between Ni and Cu) and increasing hydration strength (z^2/r_{cryst}) (except for Mn) may also contribute.

Since the binding trends in biosorption by algal biomass or its constituent molecules indicate that there is significant electrostatic and covalent binding, the latest biosorption models described at the end of the next section ("Modeling") attempt to incorporate these stronger interactions and neglected hydration effects, which are weaker.

MODELING

In order to evaluate the feasibility and effectiveness of biosorption in wastewater treatment, it is essential to make predictions of the sorption performance (e.g., for facilitating process design). Therefore it is necessary to develop appropriate mathematical models of biosorption. Modeling the biosorption-binding equilibrium is a prerequisite for all further work involving batch kinetic studies and, in particular, for the continuous-flow sorption-column applications that represent the most effective configuration of the sorption-based process.

The amount of metal M (or in general, sorbate) bound per mass of sorbent is called the binding (or uptake), ${}^{M}q$. The binding is not only dependent on the sorbent material but also on the equilibrium concentration $[M]$ of the sorbate in solution and on other parameters, such as pH and equilibrium concentration of other ions in solution. The relationship between the equilibrium binding and the concentration of an ion (at constant temperature) is depicted in an isotherm plot of ${}^{M}{}_{q}$ versus [M]. With increasing metal concentration in solution its binding increases from zero to the maximum (Figure 5). It is desirable for a sorbent to possess a high sorption capacity (maximum binding obtained at high equilibrium concentrations) and a high affinity for the sorbate species, which is reflected in a steep slope of the isotherm curve at low equilibrium concentrations.

Langmuir and Freundlich Isotherms

Most mathematical biosorption models used in the literature describe simple Langmuir (13,14,20,59,63,64) or Freundlich (16,35,98) sorption isotherms, where the metal-ion binding is determined as a function of the equilibrium concentration of that metal ion in the solution, without reference to pH or other ions in the same solution system.

The Freundlich isotherm (99) is originally of empirical nature, but has later been interpreted as sorption to sites with an affinity distribution; that is, it is assumed that the stronger binding sites are occupied first and that the binding strength decreases with increasing degree of site occupation. More specifically, the Freundlich isotherm is obtained when a log-normal affinity distribution [i.e., a normal distribution of log (K)] is assumed (57p.319;100). The Freundlich isotherm is defined by the following expression:

$$ {}^{M}q = k[\mathrm{M}]^{1/n} \qquad (2) $$

where k and n are empirically determined constants, with

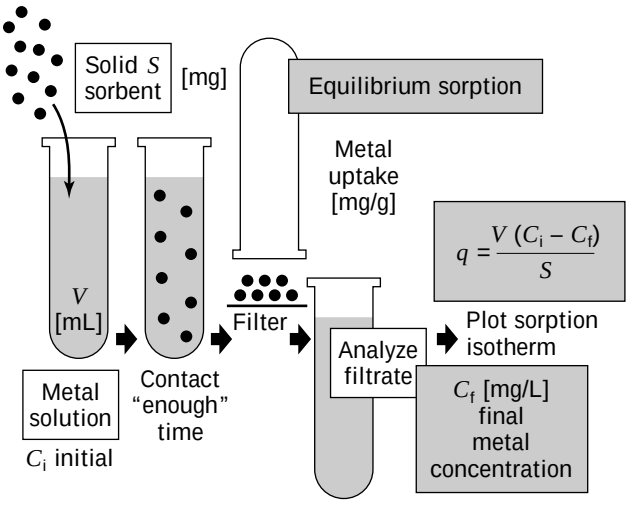

Figure 5. Experimental methodology for deriving the biosorption isotherm.

k being related to the maximum binding capacity, and n related to the affinity or binding strength (19,101).

The Langmuir isotherm (102) is based on considering sorption as a chemical phenomenon. It is assumed that the forces exerted by chemically unsaturated surface atoms (total number of binding sites B) do not extend further than the diameter of one sorbed molecule, and that therefore sorption is restricted to a monolayer. In the simplest case the following assumptions are made.

- All sorption sites are uniform (i.e., constant heat of adsorption).
- There is only one sorbate.
- One sorbate molecule reacts with one active site.
- There is no interaction between sorbed species.

The rate of adsorption is proportional to the rate constant of the forward reaction ${}^{BM}k_f$, the number of free sites ($B = {}^tB - {}^Mq$), and the number of sorbate molecules hitting the surface per unit time (i.e., proportional to their concentration [M]). Under the same conditions, the rate of desorption is proportional to the rate constant of the backward reaction ${}^{BM}k_b$ and the number of occupied sites ${}^Mq$. The equilibrium is attained when the rate of adsorption equals the rate of desorption:

$$ {}^{BM}k_f B[M] = {}^{BM}k_b {}^Mq \quad \text{(mol/s)} \tag{3} $$

With the equilibrium constant ${}^{BM}K$, indicating the affinity for the sorbate, defined as the ratio of adsorption and desorption rates ${}^{BM}K = {}^{BM}k_f / {}^{BM}k_b$, it follows:

$$ {}^{BM}q = \frac{{}^tB \cdot {}^{BM}K[M]}{1 + {}^{BM}K[M]} \quad \text{(mmol/g)} \tag{4} $$

Both Langmuir and Freundlich isotherms have been used to describe the equilibrium of metal biosorption. While it is possible to obtain good agreement between predictions of these models and the experimentally determined metal binding, their simple hyperbole-based equations have significant limitations: They cannot describe a more complex sorption behavior often reflected by nonhyperbolic relationships and they cannot predict the effect of pH or of other ions in the solution, among other shortcomings.

pH Effect. Although the crucial role of protons in biosorption is generally known, it is usually neglected in the mathematical description of the process. The complex nature of biosorbent materials that may contain a multiplicity of binding groups makes the modeling of the pH effect in biosorption difficult. As a consequence, it has been common practice to determine a separate isotherm and a new set of parameters, for each pH value (15,103,104) or for each initial biomass saturation state (e.g., protonated or loaded with ions from the seawater). This has been necessary because the most frequently used Langmuir or Freundlich sorption models do not take into account the fact that metal-ion biosorption is largely an ion-exchange phenomenon. They do not allow the prediction of the remaining binding of those ions (e.g., protons or sodium) that were initially loaded onto the biosorbent, and neither do they incorporate the concentration of the exchanged species (e.g., protons) as a parameter, normally not allowing reliable calculated predictions of the biosorbent performance.

Some attempt has been made, assuming a simplified linear relationship between the metal uptake and pH difference, to empirically model the biosorptive binding of metal ions by a Freundlich isotherm, which was modified by a factor proportional to the pH difference (105). This approach could not represent the change of proton binding in the presence of metal ions. Though protonation reactions for two acidic sites (alga) have been considered (106), the model simplification by lumping pH and proton- and metal-binding constants into one parameter for each resulted in a standard two-site Langmuir isotherm. A rare example of a Langmuir model including protons and one or two binding sites (104,107) assumed a 1:1 stoichiometry of metal binding and proton release, although it was recognized that metal binding with a 1:2 stoichiometry probably occurred. A modified Langmuir model for competitive Cu and H binding to two sites on alginate (108) required

iterative calculations of each cation uptake as a function of the binding of the other one. Another two-site model (109) based on a 2:1 proton–metal exchange constant allows direct calculation of the metal binding as a function of the concentration ratio $[H]^2/[M]$, but it does not account for free sites and it cannot easily be extended to include more species.

Competing Ions in Solution. Often, the prediction of metal-sorption equilibria is complicated by the presence of several sorbed ions, requiring the use of multicomponent isotherm equations. This is especially relevant when the sorption of one ion influences the binding of another when different ions compete for the same binding site. A variety of multicomponent sorption isotherm models is presented in a review by Yu and Neretnieks (110).

The use of multicomponent Langmuir isotherm models was demonstrated in describing the equilibrium metal biosorption (48,111,112). However, biosorption was not regarded as an ion-exchange process; the ions with which the biomass had originally been saturated were not considered.

Instead of using multicomponent isotherm models, more complex systems involving different cations and ligands can be modeled by incorporating binding constants for metal-ion–biomass complexes into a computer program for the calculation of the chemical equilibrium. Reviews of different computer programs for calculating the equilibrium speciation have been presented (44,113). These programs take acid/base reactions, coordination, and dissolution/precipitation into account. Their use is advantageous if complexation in solution is expected or if final concentrations are to be predicted from the initial state (27,47).

Ion-Exchange Constants

There have been indications that ion exchange is an important biosorption mechanism. However, this does not preclude an adequate use of simple sorption isotherms (16,59,64) instead of appropriate ion-exchange models with equilibrium constants taking into account the reversibility of the ion-exchange reactions: The ion that is displaced into the solution can compete with the sorbed metal ion for the sites (25,62,76,114).

The Langmuir equation and the ion-exchange constant for the binding of a metal ion M (for simplicity here a monovalent ion) replacing a proton H on a complexing site B are related as follows:

Langmuir: $B + M \rightleftharpoons BM$

$$^{BM}K^* = \frac{BM}{B[M]}\,[B]_t = [B] + [BM] \qquad (5)$$

Ion exchange: $BH + M \rightleftharpoons BM + H$

$$^{BM}K = \frac{BM[H]}{BH[M]}\,[B]_t = [BH] + [BM] \qquad (6)$$

therefore:

$$^{BM}K^* = {}^{BM}K/[H] \qquad (7)$$

The difference between the two approaches is that the first one assumes that all sites are initially free and does not consider any reverse reaction of a displaced ion, in this case a proton, with the site. The second model assumes that all sites to which metal ions are sorbed are initially occupied, that is, the number of free sites stays constant. Crist et al. (114) compared the fit of the Langmuir sorption isotherm model and the one using ion-exchange constants. The differences between the two models were especially pronounced at low metal-ion concentrations because the reverse reaction involving the displaced ion is most noticeable if the concentration of the bound cation is low.

The ion-exchange approach is probably somewhat closer to reality than the simple Langmuir model, but it is not completely satisfying either. Although the constant number of free sites [in other words, the number of sites occupied by the bound ion is equal to the number of sites from which the exchanged ion is released so that $^tB = (B^1M) + (B^2M)$ can be assumed] may be a reasonable working assumption for a constant pH system, it may not hold for systems with changing pH values. According to Stumm and Morgan (46), the cation-exchange capacity increases with increasing pH above the isoelectric point. Therefore, one cannot simply model the competitive binding of metals and protons by using only a metal–proton-ion-exchange constant. It is necessary to include at least one reaction where a cation reacts with a free site.

In the modeling of industrial ion exchangers, protons have been considered (115,116). However, these synthetic resins are chemically rather simple compounds that mostly contain only one active group. Biosorbents, on the other hand, can be heterogeneous and contain different acidic groups active in metal ion binding. The $p^{BH}K$ value, the quantity of binding sites, and the metal-ion binding constant must be known for each of these sites.

Models Including Ionic Strength Effects

Ubiquitous ions such as sodium may interfere with heavy metal biosorption through the effect of ionic strength. In biosorption, no modeling of the effects of ionic strength and electrostatic attraction has been done. Several models of ionic-strength effects, however, have been published concerning metal binding to humic and fulvic acids. The physical characteristics of these molecules, which are degradation products of organic matter, are quite different from microbial biosorbents. Humic and fulvic acids are small water-soluble molecules. However, since these molecules contain carboxyl groups as one of their main functional groups they may in some aspects be comparable in particular to those biosorbent materials based on seaweeds.

Buffle (117) systematically described possible models for complexation equilibria, including site protonation, multiple sites, and secondary effects such as the influence of the electric field in polyelectrolytes on the local concentration. The simplest approach to modeling the influence of Na in the biosorption system consists of the introduction of a binding constant for Na, as done by Westall et al. (118) for the binding of H, Co, and Na to humic acids. This approach enables derivation of a multicomponent sorption isotherm model so that the binding of each species can be directly calculated. This was done for biosorbents only re-

cently in the work of Schiewer and Volesky (119–121). Although the Na binding constant can easily be incorporated into computer programs for the calculation of chemical equilibria in aqueous solutions, such as MINEQL + (122), the disadvantage of this approach can be that the Na binding constant is purely empirical and does not reflect the electrostatic nature of the Na binding.

Another possibility is the use of the Donnan model (123). An application of this approach for different charged polymers has been pioneered by Marinsky (124) and coworkers, who established the use of Donnan models for interpreting protonation equilibria in organic polyelectrolytes including humic and fulvic substances and some metals (125–127) and alginic acid (128). The latter contribution also involves an estimation of the water uptake (swelling) using osmotic coefficients. Unfortunately, this modeling work did not include model predictions of proton or metal binding under different conditions. More Donnan-based model work done with alginate considered competition of Cu and H for the same sites (129,130).

Güntelberg activity coefficients have been used to account for ionic-strength effects in conjunction with fulvic acid and Cu–alkaline earth metal binding competition (131). Although this method may be suitable for rather small molecules, it would not be appropriate for polyelectrolytes, such as the alginic acid found in seaweed-based biosorbents. While the isotherm sorption model did not include a term for free sites, it was noticed that increasing ionic strength (Na) or presence of Ca or Mg can reduce Cu binding.

A model that is suitable for both oligo- and polyelectrolytes was used only for modeling pH titrations and Cu binding of humic acid molecules (132). Two of the sites were assumed to be diprotic and able to bind metal ions and one was assumed to be monoprotic and not to bind metals. In this approach, the humic acid molecules were assumed to be penetrable or impenetrable spheres of two size classes (assuming that the total charge is proportional to the volume of the sphere). The advantage of this approach is its generality concerning the size of the molecule. It is particularly suited for oligoelectrolytes that show a behavior intermediate between simple ions and polyelectrolyte gels. Most biosorbent materials could be considered true polyelectrolytes. However, the semiempirical correlation used in this approach required three fitting parameters for the electrostatic effects for each of the two particle sizes. Moreover, the fitting parameters had to be determined individually for each ionic strength. This means that the effect of ionic strength could not be predicted.

A Helmholtz metal-sorption model for the charged interface (133) requires only one fitting parameter, the constant capacitance, for modeling the electrostatic effects, but not the ionic strength effects. Another model considering eight sites of two general types for light-metal binding to humic acids used relatively few fitting parameters for the prediction of a wide range of experimental conditions (134,135). Unfortunately, it also relies on an empirical relationship involving the ionic strength. A Poisson–Boltzmann model for proton binding to humic substances (136) incorporates the effect of ionic strength on the concentration factor in a realistic manner and requires only one fitting parameter for electrostatic effects (the particle radius). The assumption of small impermeable spheres or cylinders, however, does not appear applicable to the large, penetrable particles as in the preferable case for biosorbents.

Recently, Schiewer and Volesky (119–121) presented a series of equilibrium biosorption models gradually incorporating the metal-ion concentration, pH, and ionic strength. The models proposed had only one fitting parameter, instead of up to six as in some of those already mentioned. The formation of $BM_{0.5}$ complexes was assumed, and a combined Donnan–biosorption–isotherm equation was derived that allowed for direct calculation of cation binding without iterations when swelling proportional to the number of free sites was assumed. Using the parameters (number of binding sites, proton binding constant, and specific particle volume) obtained from pH titrations, it was possible to predict the effect of pH, ionic strength, and Ca concentration on Cd binding for a seaweed biosorbent.

BIOSORPTION PROCESS DESIGN

Because biosorption is just another form of a basic sorption operation, the same principles apply for the design and sizing of the equipment. The approach is always a combination consisting of basic equilibrium sorption tests (batch) and dynamic continuous-flow apparatus studies, which can become very sophisticated if empiricism is to be minimized. Invariably, numerical computer methodologies provide a powerful tool for the design of a continuous-flow (bio)sorption process.

Equilibrium Sorption Process Basis

When contacting the solid-phase biosorbent with the sorbate species (i.e., metal ions) in solution, a sorption equilibrium will become established after an appropriate length of time. When equilibrium between the species sorbed on the solid and the portion remaining in solution is established, the solids are separated and the supernatant analyzed for the residual, final, equilibrium concentration of the remaining sorbate (Fig. 6). The metal uptake by the solid sorbent is calculated (according to the formula in Fig. 6) and used for the sorption isotherm plot, which serves to compare the sorption performance of different systems. This is easily done for one-sorbate (one-metal) systems. The situation becomes more complicated when there are more than one sorbed species in multisorbate systems.

Of interest is often the case of "interference" assessment when the uptake of one key metal (e.g., toxic Cd) may be affected by the presence of a ubiquitous metal of no major interest (e.g., Fe). This situation can be still depicted by three types of three-dimensional sorption isotherm surfaces, depending on what particular metal uptake appears in the plot: (*1*) Cd uptake, (*2*) Fe uptake, and (*3*) combined (Cd and Fe) uptake. The base two axes are always the equilibrium concentrations of the two metals, respectively.

Since the experimental equilibrium (final) concentrations are the product of the experiment, there is no control

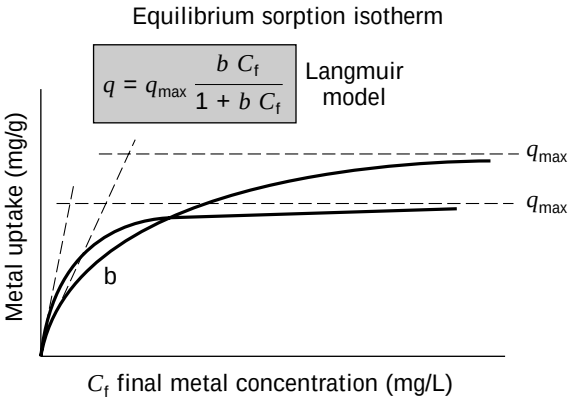

Figure 6. Biosorption-isotherm relationship curves; *b* is related to initial slope and indicates the sorbent "affinity."

over their values and they are generated more or less randomly. Consequently, the sorption isotherm surface needs to be fitted to the date points. Finding a suitable mathematical model capable of representing reasonably well the two-metal sorption behavior enables this and more; it can facilitate the summarizing of the effect of one metal on the uptake of the other for the desirable conclusion such as depicted in Figures 7 and 8 (137).

For many metal biosorption cases an equilibrium model considering only one type of binding site would be adequate assuming the following reaction (138):

$$M^{2+} + 2B = 2BM_{0.5} \quad H^+ + B = BH \tag{8}$$

The model provides explicit formulas for metal uptakes as functions of final concentrations of the species present in the system, even for the case of heterovalent exchange, which makes it especially suitable for use in numerical simulations of dynamic sorption systems. The model equation for the equilibrium uptake of a bivalent metal ion M1 present in a binary system with hydrogen protons can be written as follows:

$$q^*_{M1} = \frac{0.5M_{WM1}C_t(K_{M1}C_{fM1})^{1/2}}{1 + K_H C_{fH} + (K_{M1}C_{fM1})^{1/2}} \tag{9}$$

Similarly, for a binary system containing bivalent species M1 and M2, the expressions for uptakes of each of the species can be written as follows:

$$q^*_{M1} = \frac{0.5M_{WM1}C_t(K_{M1}C_{fM1})^{1/2}}{1 + (K_{M1}C_{fM1})^{1/2} + (K_{M2}C_{fM2})^{1/2}} \tag{10}$$

$$q^*_{M2} = \frac{0.5M_{WM2}C_t(K_{M2}C_{fM2})^{1/2}}{1 + (K_{M1}C_{fM1})^{1/2} + (K_{M2}C_{fM2})^{1/2}} \tag{11}$$

The values of the parameters K_H, K_{M1}, and $K_{M2}$are normally determined by fitting of the model to the experimental data using, for example, the method of weighed least squares. The constant $C_t$in equations 9–11 may be obtained from pH and/or conductometric titration of protonated biomass with NaOH (67). Metal biosorption can often be viewed as a simple ion exchange; hence, the classical ion-exchange concept based on exchange-equilibrium constants and separation factors (139,140) can be applied to this case. For the ion-exchange reaction:

$$bA^{+a} + aB^{+b} = bA^{+a} + aB^{+b} \tag{12}$$

the equilibrium constant K_{AB} and the separation factor r_{AB} are defined as

$$K_{AB} = \frac{q_A^b C_{Bf}^a}{C_{Af}^b q_B^a} = \frac{y_A^b x_B^a}{x_A^b y_B^a} \cdot \frac{C_0^{a-b}}{Q^{a-b}} \tag{13a}$$

$$r_{AB} = \frac{y_a x_B}{x_a y_b} \tag{13b}$$

for the case of ideal behavior of the exchanging species in both of the phases. As can be seen from equation 13a, the total normality C_0 of the solution affects the equilibrium of a heterovalent exchange (i.e., when $a \neq b$), but it does not affect the equilibrium when the valence of the exchanging species is the same (i.e., $a = b$). Consequently, the ion-exchange isotherms of a species in a binary heterovalent system vary in shape depending on the total normality of the solution (141).

Ion-Exchange Equilibrium Relationships. The term *equilibrium sorption isotherm* is commonly used in biosorption to refer to a line connecting equilibrium metal uptakes plotted against the final concentrations of the metal. Typically, biosorption equilibrium data are obtained under the same pH. However, this is not the case in ion exchange where the sorption isotherm represents data points obtained at a constant normality of the solution. Furthermore, in compliance with the established convention, ion-exchange isotherms for binary systems usually display dimensionless uptakes as functions of dimensionless concentrations for the species of interest (Fig. 9):

$$\frac{q_M}{Q} = f\left(\frac{C_{ML}}{C_0}\right) \tag{14}$$

Connection between Equilibrium and Dynamic Sorption in Columns. Unlike the biosorption isotherm, the ion-exchange isotherm depicts an equilibrium situation that is relevant to the case of the metal biosorption in a fixed-bed adsorber in which the concentration of the species released from the biosorbent increases monotonically in the direction of the flow. In fact, the ion-exchange isotherm represents the "equilibrium line" that is, together with the "operating line," sometimes used for assessing design and performance of fixed-bed adsorbers (142,143). According to the shape of the ion-exchange isotherm, the equilibrium is classified as (*1*) favorable when the isotherm is concave, (*2*) linear when the isotherm is linear, or (*3*) unfavorable when the isotherm is convex. It is known that the favorable isotherm leads to the development of a self-sharpening dynamic sorption zone (front) in the fixed-bed adsorber, whereas the unfavorable isotherm causes its broadening (144,145). As an alternative to ion-exchange isotherms, tables of values of separation factors for the compositions

existing in an adsorber can be used to represent the equilibrium for the purpose of computer simulation of the fixed bed (146).

Continuous-Flow Fixed-Bed Column Biosorption Process

In process applications, the most effective apparatus for cyclic sorption/desorption making the most effective use of the reactor volume is a fixed-bed column that also optimizes the concentration difference known to be the driving force in sorption processes. The process of metal biosorption in a fixed-bed column is influenced by three key regimes: the sorption equilibrium, the sorption particle mass transfer, and the flow pattern through the packed bed. Combination of these three determines the overall performance of the sorption column, which is judged by its ser-

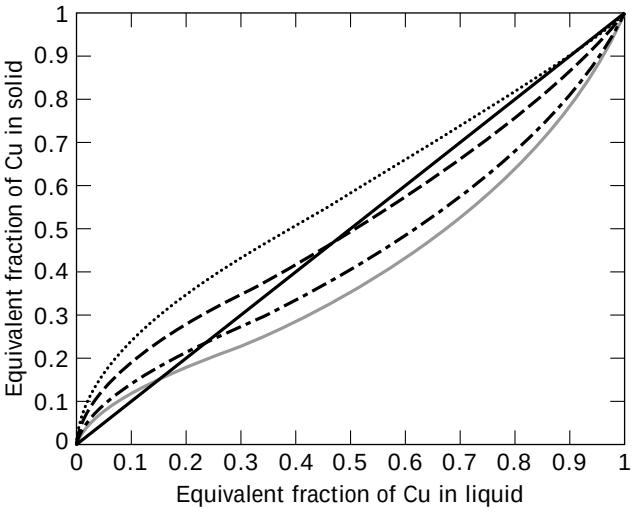

Figure 9. Calculated Cu^{2+} ion-exchange sorption isotherms for *Sargassum* biosorption system. C_o: —, 6 mequiv/L; —·—, 4 mequiv/L; — —, 2 mequiv/L; ..., 1 mequiv/L.

vice time, that is, the length of time until the sorbed species breaks through the bed to be detected at a given concentration in the column effluent (Fig. 10). At that point, the bed is considered for all practical purposes saturated, and the equipment has to be taken out of operation for some kind of regeneration (Fig. 1).

The lack of design information on biosorption in columns is due, in part, to the fact that the metal uptake by different biomaterials is still not fully understood, as well as because most of the biomasses have to be immobilized, granulated, or otherwise processed before their use in a column to provide good flow-through conditions and an acceptable pressure drop across the bed. This process condition must eventually be balanced and optimized against the maximum-sorption-performance requirement.

As opposed to activated carbon-sorption cases, metal biosorption is much closer to the heterovalent ion-exchange model because a considerable number of ions is being released from the biosorbent in exchange for the sorbed metal ion. The most universal approach seems to be that adopted by Tan and Spinner (146), who numerically solved a mixed system of partial differential, ordinary differential, and algebraic equations describing the dynamics of multicomponent ion exchange in a fixed bed. A term can be added to the differential molar balance equation to account for axial dispersion of the fluid in the packed bed. For ionic species M the molar balance is

$$\frac{C_M}{\partial z} - \frac{1}{Pe_c}\frac{\partial^2 C_M}{\partial z^2} + \frac{\partial C_M}{\partial t} + D_{gM}\frac{q_M}{t} = 0 \qquad (15)$$

The sorption rate equation can be written as

$$\frac{q_M}{t} = Sh_M(q_M^* - q_M) \qquad (16)$$

assuming a linear driving force for the sorption process and combined film and intraparticle mass transfer resistance: The equilibrium relationship for a metal species represented by equations (9) and (10) can be written schematically for a general counterion, either proton or metal, as

$$q_M^* = f(C_M, C_{CNT}) \qquad (17)$$

and the electroneutrality equation for binary systems is

$$\frac{C_{M0} - C_M}{M_{WM}} = \nu\frac{C_{CNT0} - C_{CNT}}{M_{WCNT}} \qquad (18)$$

To obtain equations 15–18, the original set of equations was transcribed with dimensionless variables using the following transformations of the variables:

$$C_M = \frac{C_{ML}}{C_0}\; q_M = \frac{q_{MS}}{Q}\; t = \frac{\tau v}{L_0}\; z = \frac{l}{L_0}$$

and yielding the following dimensionless groups:

$$D_{gM} = \frac{\rho_b Q}{C_0 \epsilon}\; Sh_M = \frac{K_{fM} L_0}{v}\; Pe_c = \frac{L_0 v}{D_z}$$

The initial and boundary conditions pertaining to the situations under question are specified as follows:

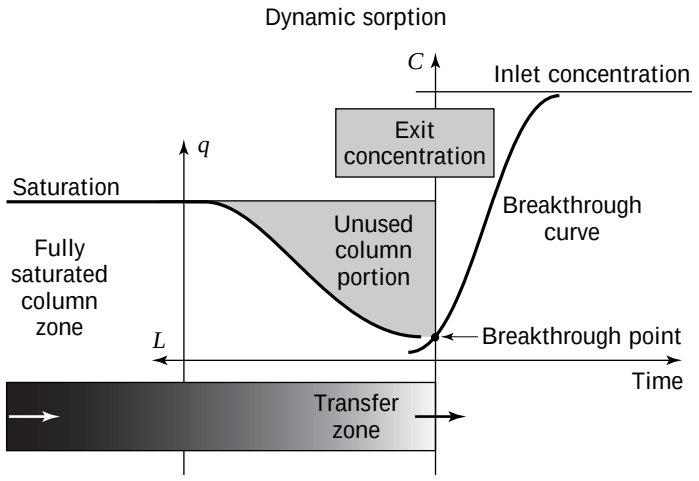

Figure 10. Biosorption column operation: the breakthrough point and the breakthrough curve for the column exit concentration.

$$t = 0 \quad l = (0, L_0) \quad C_M = 0$$

$$t > 0 \quad l = 0 \quad C_M = C_{M0} + \frac{1}{Pe_c}\frac{C_M}{z}$$

$$t > 0 \quad l = L_0 \quad \frac{C_M}{z} = 0$$

The system of equations 15–18 can be solved numerically using the Galerkin finite element method (147), combined with the implicit Euler method for time integration. Linear-basis functions would routinely be used for space discretization of both concentration C and uptake q, ensuring that the solution is mesh independent.

Fitting the Equilibrium Model and Calculation of Ion-Exchange Isotherms. Equilibrium data provide the experimental basis for the fitting of the biosorption model (148). First, the concentration of binding sites C_t can be determined from the uptake experiments; equilibrium constants for the three ions considered here (K_H, K_{Cu}, and K_{Ca}) can then be found by the least square fitting.

Once these parameters are known, the biosorption model can be used to calculate ion-exchange isotherms as follows: First, the normality of a binary mixture C_0 was fixed and the uptake Q, at the concentration of the sorbing species C_0, was calculated from equation 2 or 3. Second, a series of liquid-phase compositions was selected in such a way that the dimensionless concentration C/C_0 of one of the species covers the interval of interest. Finally, a series of dimensionless uptakes corresponding to the series of compositions was calculated using equations 2, 3, and 7.

Fitting and Use of the Flow-through Fixed-Bed Sorption Column Model. The dimensionless groups Sh, Dg, and Pe, together with the equilibrium parameters for a given binary system, represent the parameters of the fixed-bed model. However, because the equilibrium parameters can be determined from batch equilibrium studies, the values of C_0, v, L_0, and ρ_b are usually known, and Q can be calculated from equations 2 and 3, the only remaining unknown elements in the model are K_{fM}, D_z, and ϵ. The values of the three unknown elements K_{fM}, D_z, and ϵ must be determined simultaneously by fitting the fixed-bed model to an experimental breakthrough curve.

The value of an overall mass-transfer coefficient for a given species generally depends on the flow rate, the axial dispersion coefficient, and the values of the diffusivities of the species in the liquid and solid phases. The diffusion coefficients of metal ions in diluted aqueous solutions can often be obtained from the literature (149,150).

Conclusion. In preparation for the biosorption process design the sorption/desorption performance and characteristic properties (mass transfer, pressure and attrition resistance, chemical stability, etc.) of the biosorbent should be reasonably well known. Although equilibrium sorption tests yield some basic information, the sorption system behavior is invariably examined under continuous-flow conditions. The fixed-bed sorption column arrangement is usually the most effective process configuration. Its performance assessment and prediction based on both equilibrium and dynamic studies eventually leads to sizing of the equipment. Advanced methodologies used for this purpose are based on sophisticated computer-based modeling and optimization of the (bio)sorption process.

NOMENCLATURE

a,b	stoichiometric coefficients in the ion-exchange reaction equation 12
$\bar{b}$	Langmuir constant related to affinity
A,B	species in the resin phase
A,B	species in the liquid
B	biosorbent binding site
B_t	total number of binding sites on the biosorbent
BH	biosorbent–proton complex
BM	biosorbent–metal complex
C_i	initial metal concentration
C_0	normality of the solution [mequiv/L]
$C_M = x_M$	equivalent fraction of species M in liquid phase
C_{ML}	concentration of species M in liquid phase [mequiv/L]
$C_{Mf} = C_f$	equilibrium final concentration of species M in liquid phase [mequiv/L]
C_{M0}	equivalent fraction of species M in the feed to a column
C_{CNT}	equivalent fraction of counterion in liquid phase
C_{CNT0}	equivalent fraction of counterion in the feed to a column
C_t	concentration of binding sites in biomass [mequiv/L]
D_z	axial dispersion coefficient [cm^2/s]
G	free (Gibbs) energy
H or H^+	proton
H	enthalpy
${}^{BM}k_f$	rate of adsorption
${}^{BM}k_b$	rate of desorption
K_{AB}	ion-exchange equilibrium constant
${}^{BM}K$	biosorbent–metal ion-exchange equilibrium constant
K_H, K_{M1}, K_{M2}	equilibrium constants of biosorption equilibrium model
K_{fM}	overall mass-transfer coefficient of species M [min^{-1}]
l	vertical distance from the top of a column
L_0	length of the column [cm]
M	metal ion in solution
M_{WM}	molecular weight of the sorbing metal
M_{WCNT}	molecular weight of the counterion
n	Freundlich sorption isotherm model constant

$q_{MS} = {}^{M}q = q$	uptake of species M [mequiv/L]
q_{max}	maximum uptake (Langmuir parameter)
$q_M = y_M$	equivalent fraction of species M in solid phase
q_M^*	dimensionless equilibrium uptake of species M at C_M
Q	equilibrium uptake of M at $C_{ML} = C_{M0}$. C_0 [mequiv/L]
r	ionic radius (subscripts: hyd = hydrated; cryst = crystalline)
r_{AB}	ion-exchange separation factor
R	gas constant
S	weight of biosorbent solids (Fig. 5) or entropy (equation 1)
t	dimensionless time
T	absolute temperature (K)
v	interstitial velocity of the fluid [cm/min]
V	volume of solution
x	electronegativity
z	ionic charge

Greek Symbols

Δ	difference (equation 1)
ϵ	column void fraction
ν	stoichiometric coefficient of the exchange reaction
ρ_b	packing density [g/L]
τ	time [min]
ξ	parameter in Table 1 $\xi = (z^2/r_{hyd})/(1 - \exp(-\Delta x^2/2))$

Dimensionless Groups

$D_{gM} = \dfrac{\rho_b Q}{C_0 \epsilon}$	solute distribution parameter
$Pe_c = \dfrac{L_0 v}{D_Z}$	column Peclet number
$Sh_M = \dfrac{K_{fM} L_0}{v}$	modified Sherwood number

OUTLINE

INTRODUCTION

The use of biotransformations in food, pharmaceutical, and chemical industries has increased steadily since the early 1970s. Applications range from synthesis on the milligram scale for precious oligosaccharides, to the multiton scale for bulk chemicals using either whole cells or isolated enzymes. This process has been documented in numerous reviews and textbooks (1–5). When new processes are being developed, the special properties of the biocatalyst must be considered, as well as the basic elements of chemical engineering. There are strong interactions among the individual aspects, which may be considered for process optimization. These are summarized in Figure 1.

The aim of this article is to outline the basic strategy for the development of a biocatalytic step. For some selected examples the beneficial role of (bio)chemical engineering is demonstrated. A more detailed description can be found in textbooks of (bio)chemical engineering (1,3, 6–8).

WHOLE CELLS OR ISOLATED ENZYMES?

Whole microorganisms or their components, enzymes, may be used for biotransformations. Both approaches have specific advantages and requirements, as summarized in Table 1. Commonly, the word *biotransformation* is used to describe the transformation of a substrate or precursor into a certain product in only a few steps. Fermentation processes, for example, production of amino acids from glucose and ammonia or production of (recombinant) proteins, are normally not regarded as biotransformation. Litera-

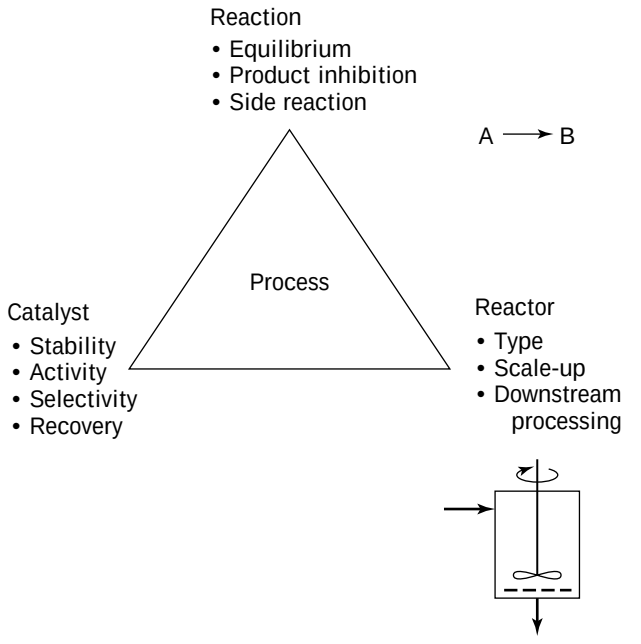

Figure 1. Elements of process development.

Table 1. Comparison of Biotransformations Using Whole Cells vs. Isolated Enzymes

Whole cells	Isolated enzymes
Large amounts of catalyst easy available	Additional step for obtaining the catalyst required
No stability problem when growing cells are used	Catalyst stability strongly influenced by reaction conditions
Limited volumetric catalyst activity	High volumetric catalyst activity possible
Multistep processes	Multistep processes difficult
Cofactor recycling solved	Cofactor recycling so far only for NADH and ATP
Side reactions may occur	Few to no side reactions
Toxicity of substrate/product may be complex	Enzyme stability may be influenced by substrate or product, but can be enhanced by choosing the appropriate reactor
Oxygen supply may control scale-up	Nonnatural substrates and reaction conditions possible
Normally no cosolvent, possibly leading to low concentrations of hydrophobic compounds	Cosolvents possible, but often reducing enzyme stability
Transport in and out of the cell may be limiting	Mass transport limitations only with immobilized enzymes

ture describing those processes can be found elsewhere in this volume or in external references (2,9–13).

Examples of industrial biotransformations using whole cells or isolated enzymes are given in Table 2. Some special information about process characteristics is given as well. When isolated enzymes are used for biotransformations, the purity must only be such that no side reactions occur. There is no need to purify the enzyme to homogeneity, as is required for biochemical characterization. On the contrary, many enzymes show reduced stability with increased purity. In some cases, the addition of inert proteins, such as bovine serum albumin, may be used as a simple way to increase the stability of the production enzyme. In others, enzyme stability may be increased by immobilization on a support. Covalent attachment fixes the conformation of the enzyme often limiting denaturation. However, the increase of stability must be balanced against the losses during the immobilization step, as well as the additional work and material costs. A method introduced quite recently for the stabilization of enzymes and their immobilization is the formation of cross-linked enzyme crystals (CLECs) (22). Reactors for immobilized enzymes are discussed elsewhere in this volume (see ENZYME, IMMOBILIZED, REACTOR). However, the engineering approach, as outlined in the following sections is the same for all forms of biocatalysts. Specific requirements and properties such as oxygen delivery, mass transport limitations, or particle size must be considered for individual cases.

CLASSIFICATION OF DIFFERENT REACTORS

There are three basic types of reactors, which have several variations (Fig. 2):

1. Stirred-tank reactors (STRs) or batch reactors
2. Continuously operated stirred-tank reactors (CSTRs)
3. Plug-flow reactors (PRFs)

Unlike the stirred-tank reactor, which is operated batchwise, the latter two are operated continuously. By knowing the main characteristics of these fundamental reactors and some of their variations, for example the cascade reactor of Figure 2, it is possible to choose the appropriate reactor for a specific application. This is especially important when dealing with a kinetically or thermodynamically limited system, as demonstrated later. In the following analyses, only the basic terms are explained. For more details the reader is referred to textbooks (6–8).

The stirred-tank reactor is operated in an instationary way (Fig. 2a). Assuming ideal mixing characteristics, the instantaneous concentration of every species is the same in every volume element. With advancing conversion the substrate concentration is decreased and the product concentration is increased. A steady state is reached only at equilibrium conversion.

In the plug-flow reactor the product concentration increases slowly over the length of the reactor (Fig. 2b). Therefore, the average reaction velocity is faster than in the continuously operated stirred-tank reactor. In each single-volume element in the reactor, the concentration is constant in the steady state. In other words, the dimension of time is exchanged with the dimension of place in comparison to the stirred-tank reactor.

The continuously operated stirred-tank reactor works under product outflow conditions, meaning that the concentrations in every volume element are the same as those at the outlet of the reactor (Fig. 2c). If the steady state is

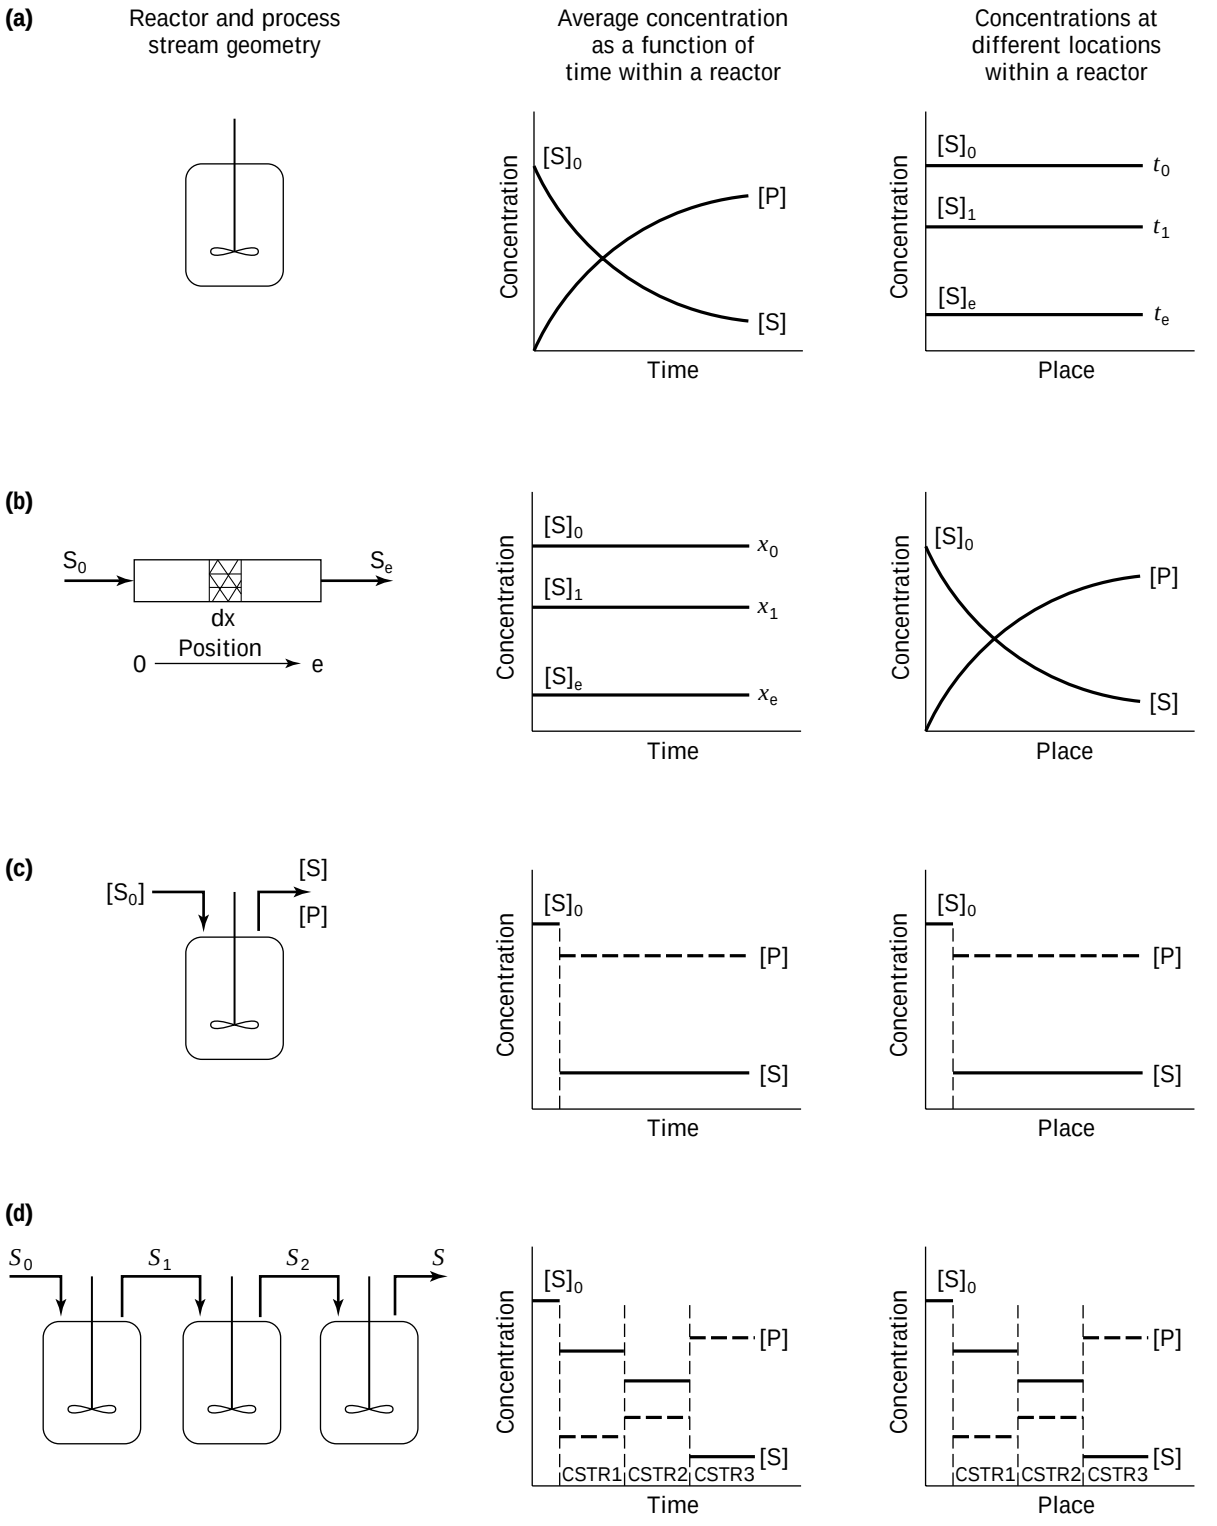

Figure 2. Characterization of different reactors. (**a**) Stirred-tank reactor. (**b**) plug-flow reactor. (**c**) continuously operated stirred-tank reactor. (**d**) Cascade.

reached, the concentrations are independent of time and place. The conversion is controlled by the catalyst concentration and the residence time, τ:

$$\tau = \frac{V}{F}$$

where $\tau[h]$ is the residence time, $V[L]$ is the total reactor volume, and F is the $[L/h]$ substrate feed rate.

One very common variation of the CSTR is the cascade of n CSTRs (Fig. 2d). With an increasing number, n, of reaction vessels, the cascade approximates the plug-flow reactor (23). The product concentration is increased stepwise from vessel to vessel.

Mass Balances

The performance of the different reactor types concerning the reaction can be simulated mathematically. This is also the verification of the kinetic model of the reaction because it should describe the course of the concentration for each compound with only a small error. The main part of the simulation model is the coupled system of differential equations of first order, which are the mass balances of all substrates and products. The change in the concentration of one compound in time and in a volume element (called the accumulation) is the sum of convection, reaction, and diffusion (equation 1).

$$\text{accumulation} = \text{convection} + \text{reaction} + \text{diffusion} \quad (1)$$

The convection term describes the change of the concentration of one compound in the reactor as the difference of the influx into the reactor and the efflux. The reaction term describes, by use of the kinetic model, the change of the concentration of one compound as result of the reaction. The reaction velocity, V_s, is the sum of the individual reaction velocities describing consumption of a substrate or formation of a product. Diffusion occurs only in the case where nonideal mixing is stated.

With regard to the chosen reactor type the mass balance can be simplified by assuming ideal mixing or ideal plug-flow behavior.

Stirred Tank Reactor

Diffusion = 0	At a defined time the concentrations are the same in every volume element.
Convection = 0	There is no influx or efflux of substrates or products to a single volume element in time.

The mass balance is simplified to

$$-\frac{d[\mathrm{S}]}{dt} = v_s \rightarrow t = [\mathrm{S}]_0 \int_0^{\text{desired conversion}} 1/v \, dx \quad (2)$$

Continuously Operated Stirred-Tank Reactor

Diffusion = 0	See previous.
Accumulation = 0	In the steady state the concentrations will not change with time.

The mass balance is simplified to:

$$0 = -\frac{d[\mathrm{S}]}{dt} = \frac{[\mathrm{S}]_0 - [\mathrm{S}]}{\tau} + v_s \quad (3)$$

Plug Flow Reactor

Diffusion = 0	Diffusion is neglected in an ideal plug-flow reactor.
Accumulation = 0	In the steady state the concentrations will not change with time.

The mass balance is the same as for the stirred-tank reactor. In the integrated form the time, t, has to be replaced by the residence time, τ.

Kinetics

The fundamental equation (equation 4) for the description of enzyme kinetics was derived by Michaelis and Menten (24).

$$v = [\mathrm{E}] \frac{A_{\max} \cdot [\mathrm{A}]}{K_m + [\mathrm{A}]} \quad (4)$$

The enzyme activity is expressed as a function of the substrate concentration for an irreversible one-substrate reaction without inhibition. As this is rarely found in nature, equation 5 gives the rate for a reversible reaction A ↔ B. In this form the product inhibition is considered as a competition of A and B for the active sites, as expressed by the two K_m values. This form might be extended to cover substrate surplus inhibition as well as multisubstrate reactions by adding additional terms to the numerator and denumerator (6,25–27).

$$v = [\mathrm{E}] \cdot \frac{\dfrac{A_{\max,A} \cdot [\mathrm{A}]}{K_{m,A}} - \dfrac{A_{\max,B} \cdot [\mathrm{B}]}{K_{m,B}}}{1 + \dfrac{[\mathrm{A}]}{K_{m,A}} + \dfrac{[\mathrm{B}]}{K_{m,B}}} \quad (5)$$

The determination of the kinetic parameters can be performed either by initial reaction velocity measurements or by batch experiments at different substrate concentration, such that substrate limitation is encountered. The kinetic parameters are determined by fitting the kinetic model to the experimental data by use of nonlinear regression; in the case of the batch experiments, numerical integration of the reaction velocity equations is required.

PROCESS DEVELOPMENT, STEP BY STEP

Figure 3 shows different phases and topics to be addressed during development and optimization of a biotransformation. The main focus is on the use of isolated enzymes, but for whole-cell processes a similar scheme must be followed. A more detailed description can be found in Ref. 6. In practice, some of the investigations listed here stepwise will be performed simultaneously. For example, first experiments should hint to possible problems from side reactions. Other factors may be considered as well.

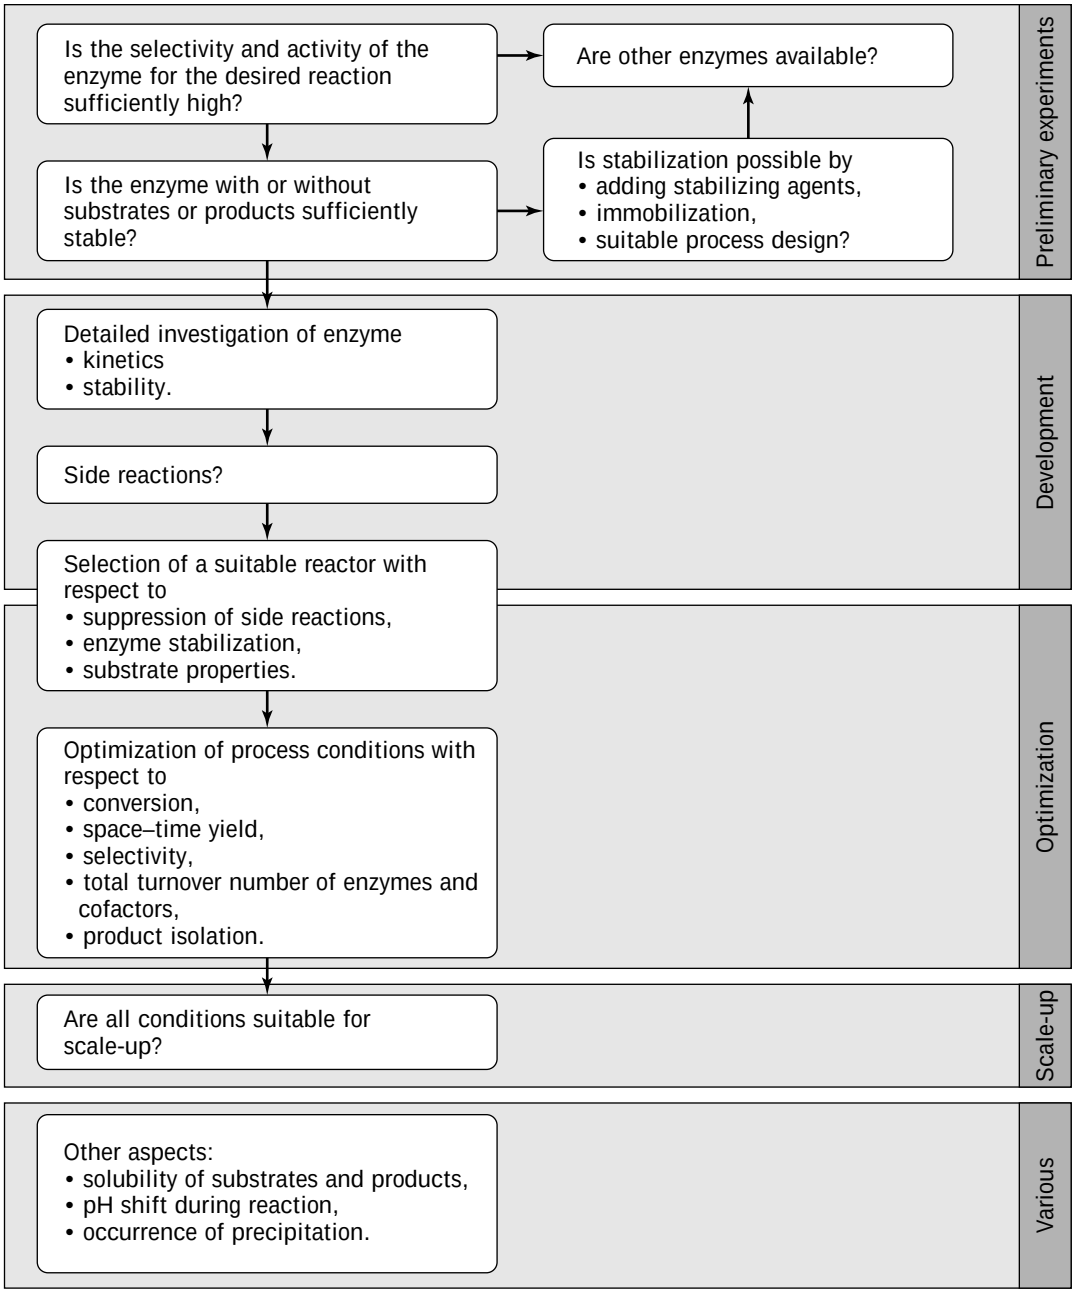

Figure 3. Process development, step by step.

- Buffer compounds may be important for enzyme stability, but must be removed during product isolation. Avoiding them may simplify product isolation and save costs.
- Any reaction exhibiting substrate surplus inhibition should not be carried out in a batch-reactor setup, since this results in longer reaction times due to the high substrate concentration at startup, which lowers the initial reaction velocity. In such a case, a continuously operated stirred-tank reactor that is operated at a high conversion in the steady state is preferred, resulting in a low substrate concentration. Another possibility is the use of a fed batch reactor, which means that the substrate is added in small portions as a function of time, also resulting in a small substrate concentration. One example of such a system is the enzymatic synthesis of L-phenylalanine by reductive amination, which can be found in the literature (25,29).
- If product inhibition occurs, either a stirred-tank reactor, a plug flow reactor, or a cascade of n continuously operated stirred-tank reactors should be chosen. In all these reactors the product concentration increases over time. Another possibility is the use of

a differential reactor with integrated product separation (30). These two possibilities will be discussed in more detail in the section titled "Examples".

- The biocatalyst may be recirculated in and between reactors by various means to enhance catalyst concentration. Whole cells are often concentrated by microfiltration membranes or centrifugation. Isolated enzymes are much smaller, but can be retained by an ultrafiltration membrane. This type of equipment is commercially available for the processing of volumes of a few microliters up to the cubicmeter scale. If the enzyme is immobilized on a support, its size determines the separation step. For example, penicillin amidase is immobilized on a support suitable for separation using a stainless steel mesh in a stirred tank reactor. Also, whole cells might be immobilized on a support, most often simply by adsorption, or by entrapment in alginate gel or similar material.
- The optimization process shown here and discussed later (see "Examples") is based on a kinetic model of the whole reaction system, including side reactions. This model, together with the mass balance for the reactor, can be used for simulation. By a variation of feed concentrations, catalyst concentration, and residence time, conditions can be found that result in high conversion and high space–time yield. When enzyme deactivation is known, the product-specific catalyst consumption may be calculated as well. Alternatively, an empirical optimization can be performed using a simplex method or a generic algorithm. The latter have been successfully applied to fermentation processes (31), but only tested in preliminary studies for optimization of multienzyme systems. These methods are especially powerful for optimization of processes where a direct connection between input and output values cannot be given.
- A discussion of the influence of organic solvents on the solubility of reactants and on enzyme stability can be found in literature (32–36).

Figure 4 summarizes some measures that can be taken to overcome or modulate against enzyme deactivation caused either by thermal condition or by the reaction partners. Whereas in the first case lowering of the temperature, application of stabilizers, or immobilization on a support may be helpful, the deactivation caused by the reaction partners, may be overcome with the help of the tools of reaction engineering. For the deactivation caused by substrates or products, different tools can be used. The different reactor types are discussed in "Classification of Different Reactors".

EXAMPLES

By choosing the appropriate fundamental reactor type on the basis of the individual reaction kinetics, the production of the fine chemicals as given in Table 3 is possible even in processes that exhibit a strong inhibition by one of the reaction compounds.

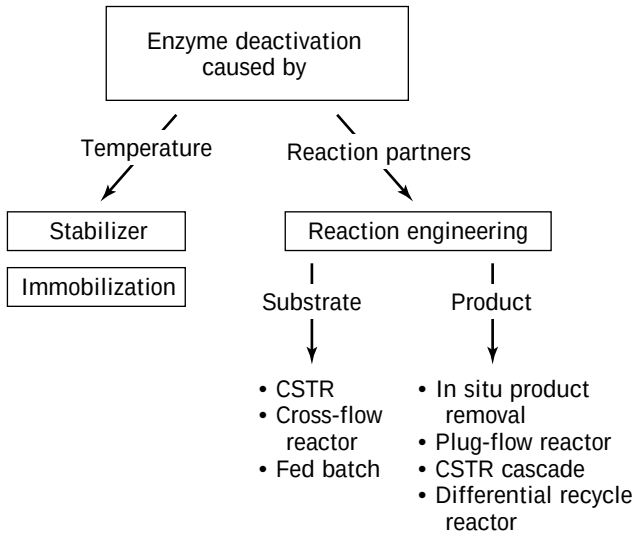

Figure 4. Tools used to overcome enzyme deactivation.

Product Inhibition

Product inhibition is the consequence of the competition of a substrate and a product for complexation in the active site of a catalyst. This kind of inhibition is not only observed with enzymes, but is also found for reactions that are catalyzed by homogeneous soluble and heterogeneous chemocatalysts (28). Whereas the reaction velocity is reduced by product bonding in the case of an irreversible reaction, the situation is more complex for reversible reactions ("principle of the microscopic reversibility"). In terms of the mathematics, product inhibition is expressed as an additional term in the denominator of the Michaelis–Menten equation (equation 6). This form of the equation describes competitive inhibition. An explicit discussion of other types of inhibition can be found in the textbooks of enzyme kinetics (6,25,26). By transformation of equation 6, equation 7 is can be obtained, which is similar in its structure to the common reaction velocity equation (equation 8), derived for chemical systems by Hougen and Watson in 1947 (28,41).

$$v = [\mathrm{E}] \cdot \frac{A_{\max} \cdot [\text{substrate}]}{K_{\mathrm{m}}^{\text{educt}} \cdot \left(1 + \dfrac{[\text{product}]}{K_i^{\text{product}}}\right) + [\text{substrate}]} \tag{6}$$

where v(kat/L) is reaction velocity (1 kat = 1 mol/s), [E](g/L) is enzyme concentration, [substrate](mol/L) is concentration of substrate, $A_{\max}$(kat/g, U/mg) is maximal mass specific activity of the reaction, $K_{\mathrm{m}}^{\text{substrate}}$(mol/L) is Michaelis–Menten constant of substrate, and K_i^{product}(mol/L) is competitive product inhibition.

$$v = [\mathrm{E}] \cdot \frac{\dfrac{A_{\max}}{K_{\mathrm{M}}^{\text{substrate}}} \cdot [\text{substrate}]}{1 + \dfrac{[\text{substrate}]}{K_{\mathrm{M}}^{\text{substrate}}} + \dfrac{[\text{product}]}{K_i^{\text{product}}}} \tag{7}$$

$$v = \frac{(\text{kinetic term}) \cdot (\text{potential term})}{(\text{adsorption term})^n} \tag{8}$$

where n is the number of centers, which are part of a velocity-limiting elementary reaction.

The decrease of the reaction velocity with increasing product concentration is described by the ratio of K_m to Ki. The relative reaction velocity is plotted as function of the conversion in Figure 5. Three different ratios of K_m to Ki are plotted, which relate to strong (curve A), moderate (curve B), and weak (curve C) product inhibition.

In 1985, Lee and Whitesides suggested, using the example of an oxidoreductase-catalyzed alcohol oxidation, that the feasibility of a process can be judged by the ratio of $K_m^{substrate}$ to $K_i^{product}$ (42):

- If $K_m^{substrate}$: $K^{product} \leq 1$, it is, in principle, possible that the reaction can proceed with practicable conversions (Fig. 5, curves B and C).
- If K_m^{educt}: $K_i^{product} > 1$, the reaction is unusable with regard to preparative syntheses (Figure 5: curve A).

This clearly is a simplified view. It is also important to note, that the kinetic parameters of a given reaction cannot be changed.

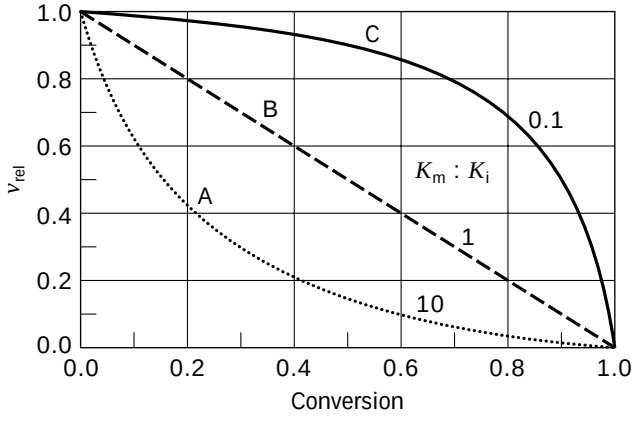

Figure 5. Influence of product inhibition on reaction velocity as function of conversion. Curve A, strong product inhibition with the ratio of Michaelis–Menten constant, K_m, and the product inhibition constant, K_i; K_m:K_i = 10. Curve B, moderate product inhibition with K_m:K_i = 1. Curve C, weak product inhibition with K_m:K_i = 0.1.

Overcoming Product Inhibition by Product Extraction

Chiral diols are important building blocks for the synthesis of chiral ligands, agrochemicals, and pharmaceutical intermediates (43–45). Using the example of the oxidative resolution of 1-phenyl-1,2-ethanediol, it is demonstrated that product inhibition can be overcome in the case of hydrophobic products. The enantioselective oxidation of the (*R*)-enantiomer to ω-hydroxyacetophenone (1-oxo-1-phenyl-2-hydroxyethane) is catalyzed by glycerol dehydrogenase (GDH) from *Enterobacter aerogenes* [EC 1.1.1.6] (46). Because GDH needs β-nicotinamide adenine dinucleotide (NAD^+) as a cofactor, a cofactor regeneration carried out by lactate dehydrogenase (LDH) [EC 1.1.1.27] was incorporated, as depicted in Figure 6. LDH reduces pyruvate to (L)-lactate enantioselectively. The cofactor regeneration must proceed faster than the racemic resolution in order not to become the limiting step. The remaining (*S*)-enantiomer of the diol is the desired product for further synthesis.

Detailed investigation of the reaction conditions and kinetics revealed strong product inhibition by the hydroxyketone, as well as by the NADH (30). This resulted in a ratio of $K_m^{substrate}$: $K_i^{product}$ = 43.2 for the ω-hydroxyacetophenone. The inhibition by NADH was not taken into account, because NADH is converted in situ to NAD^+ by LDH. Utilizing the above-determined criteria, the reaction as investigated here would never proceed efficiently. Additionally, it was observed that the hydroxyketone reacted in a chemical side reaction with NAD^+. Thus, ω-hydroxyacetophenone not only reduced the GDH activity due to its inhibition, it furthermore reduced the available NAD^+ concentration. Therefore, it is very important that the ω-hydroxyacetophenone concentration is kept as low as possible. One possibility is an integrated extraction of the inhibiting compound. Best results were obtained using hexane as the extracting solvent. In contrast to phenylethanediol, which was not extracted, up to 98% of the hydroxyketone was extracted after eight extraction steps.

The flow sheet of the two-phase membrane reactor is shown in Figure 7. The reactor consists of three different loops. The membrane reactor (loop I) integrates the stirred-reaction vessel and the membrane module (48,49). A hydrophilic ultrafiltration membrane (YM 10, cutoff 10,000 Da, Amicon GmbH, Witten, Germany) is used to retain the glycerol dehydrogenase and the lactate dehy-

drogenase. The consequence is the decoupling of the residence times of the catalysts and the reactants. Prior to the membrane reactor, an extraction module is positioned in a closed-loop arrangement (loop II). The aqueous phase is continuously extracted by means of liquid–liquid extraction using a hollow-fiber module (Liqui-Cel® 5PCM-106, Hoechst, Frankfurt, Germany) consisting of Celgard® microporous, hydrophobic hollow-fiber membranes (50). The module was circulated countercurrently by a hexane stream. The best ratio of the flow rates of the aqueous phase to the organic phase was determined to be 1:6. To reduce the amount of organic solvent used, a distillation

(not shown) is incorporated in the extraction loop III. The oxidation product ω-hydroxyacetophenone is collected in the bottom of the distillation. The entire reactor behaves as a batch reactor with recirculation, meaning that only a low conversion per cycle is reached, corresponding to a small amount of oxidation product, which is directly extracted (30). The consequence is a continuous low concentration of ω-hydroxyacetophenone in the membrane reactor. This reactor represents a modification of the continuously operated bimembrane reactor that was constructed for the conversion of sparingly soluble substrates (47,51,52). In Figure 8, two experiments are compared, one with the integrated extraction and the other without. When no extraction is incorporated, an enantiomeric excess of only 58% and a conversion of 37% was reached after 170 h. The reason for this unsatisfactory result was the accumulation of the reaction product, which lowers the reaction velocity of the GDH and also reduces the concentration of the NAD^+ by the chemical side reaction. With integrated product extraction a conversion of 50% and an enantiomeric excess >99% is reached after 64 h.

This process example demonstrates that by means of reaction engineering, kinetically unfavorable reaction can still be used on a preparative scale. By application of the integrated extraction, a transition from curve A to curve C in Figure 5 is reached.

Overcoming Product Inhibition by a CSTR Cascade

D-Mannose can be found as building block of numerous glycoproteins and glycolipids, for example, in the common core structure of N-glycans (53). For the enzymatic in vitro synthesis of oligosaccharides, guanosine-5′-diphospho-α-D-mannose (GDP-Man) is used as donor for mannosyltransferases. Recombinant mannosyltransferases have been used for the synthesis of the trisaccharide Manβ1-4GlcNAcβ1-4GlcNAc (54). The enzymatic synthesis of GDP-Man starting from mannose-1-phosphate (Man-1-P) and guanosine-5′-triphosphate (GTP) using a recombinant GDP-Man pyrophosphorylase [E.C. 2.7.7.13] has been recently described (55) (Fig. 9). Both reaction products show a very strong inhibition of GDP-Man pyrophosphorylase. The inhibition by pyrophosphate can be overcome by cleaving it to phosphate using an inorganic pyrophosphatase [E.C. 3.6.11]. The product inhibition by the product GDP-Man itself can be reduced in a CSTR-cascade, as shown below. Additionally, the cofactor Mg^{2+}, required by the GDP-Man pyrophosphorylase, is complexed by the substrate GTP. Its influence on enzyme activity and the preferable use of a continuously operated reactor to establish a constant Mg^{2+} to GTP ratio, together with a complete set of kinetic data for the pyrophosphorylase, has been recently published (43). For the ratio $K_m^{\text{Man-1-P}}/K_i^{\text{GDP-MAN}}$, a value of 4.4 is obtained. According to the classification outlined in the section "The Problem of Product Inhibition", this reaction would be of only limited use. Unfortunately, the substrates and products are quite similar with respect to size, hydrophilicity, or charge, prohibiting a selective removal of the inhibiting product. However, simulations on the basis of the kinetic model and various reactor configurations revealed that a cascade of two CSTR in series reduces the required amount of enzyme by >50% (23). A two-stage cascade is a good compromise: plug-flow behavior is approximated to a large extent, and the experimental setup does not require too much effort (7). Figure 10 compares the conversion of Man-1-P as function of the product of enzyme concentration and residence time for a single CSTR and a two-stage CSTR cascade. In a two-stage cascade 98% conversion is reached for 4.5 (U/mL)min, whereas a single CSTR requires 9.0 (U/mL)min. That means that at a constant enzyme concentration the residence time can be cut in half, resulting in a doubling of the space–time yield. When the enzyme deactivation is only a function of time, by an increase of the space–time yield at

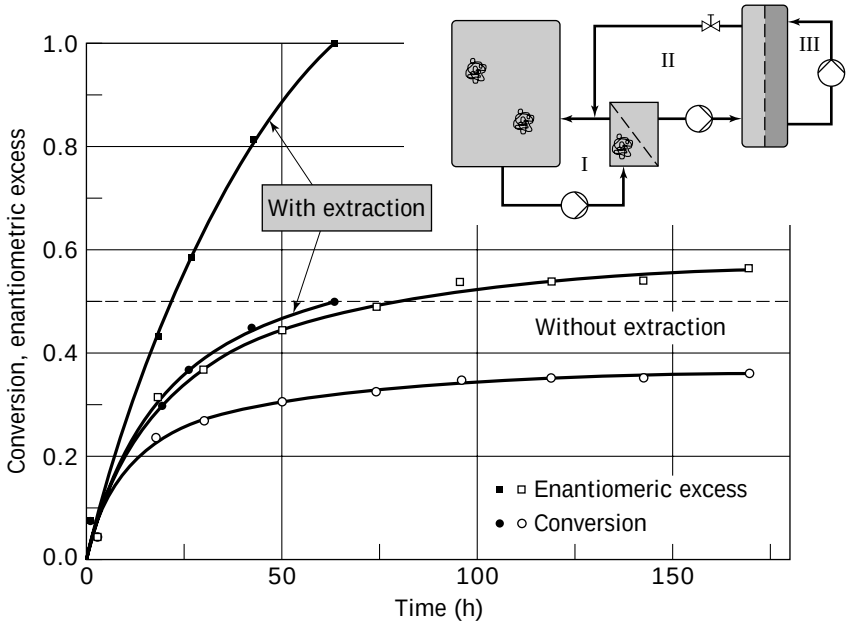

Figure 8. Increase of enantiomeric excess and conversion for the kinetic resolution of 1-phenyl-1,2-ethanediol due to product extraction. Residence time in the membrane reactor: 15 min; pressure difference: 2 bar; total volume 500 mL; 100 mM glycine/KOH buffer; pH 9; T = 25 °C; 0.054 U/mL GDH; 0.6 U/mL LDH; 200 mM ammonia; 40 mM (*R*,*S*) 1-phenyl-1,2-ethanediol; 2 mM NAD^+; 25 mM pyruvate.

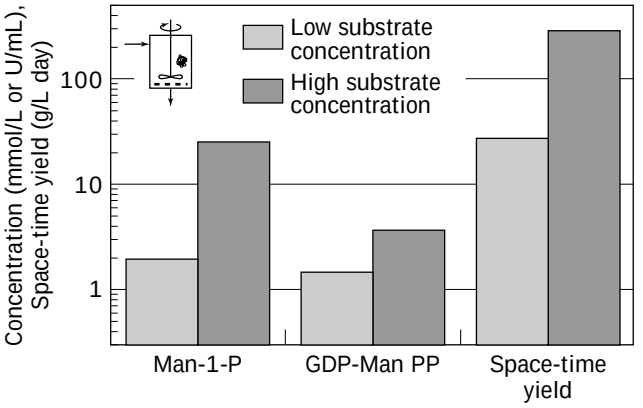

Figure 11. Improvement of space–time yield of GDP-Man by higher substrate and enzyme concentration in a one-stage CSTR; [GTP] 2.5 mmol/L or 25 mmol/L, [Mg^{2+}] 1 mmol/L or 9 mmol/L, residence time 1 h; conversion >98%. Black bars high substrate concentration, gray bars, low substrate concentration.

constant enzyme concentration, the product-specific enzyme consumption can be decreased. The experimental verification revealed good agreement between calculated and experimental values (37). At a conversion at 98%, a space–time yield of 28 g/(L day) and an enzyme consumption of 900 U/kg$_{product}$ was obtained. For a single CSTR, an enzyme consumption of 2,000 U/kg$_{product}$ was reached due to the higher enzyme concentration required to reach the desired conversion under otherwise identical conditions. The relatively low space–time yield is caused by the low substrate concentrations. Complex interactions between K_m values of the substrates and the K_i of GDP-Man require simulation to show that the space–time yield can be increased 10-fold by a corresponding increase of the substrate concentration (Fig. 11). In order to keep a high conversion at >98%, the enzyme concentration must be increased at the same time, but only 2.5-fold. This clearly demonstrates the potential of process optimization based on a model and a complete set of kinetic data.

OUTLINE

INTRODUCTION

The cell cycle is the name given to the process by which a cell "matures," synthesizes DNA, and divides to form daughter cells. Thus the cell cycle is a fundamental process with analogous mechanisms found in all cells, from the most primitive bacterium to higher animals and plants, from the unicellular to the most complex multicellular organism. Here we describe the mammalian cell cycle, highlight its importance in biotechnology, and describe some cell cycle applications in animal cell biotechnology.

The cell cycle model (G_1-event model) currently accepted by authors of the major cell and molecular biology books (1–4) describes the cell cycle as discrete phases controlled by cell cycle proteins interacting with each other and directing cellular events including DNA synthesis and cell division. However, the validity of this model and the interpretation of many experiments that underpin the current established view of the cell cycle and cell cycle regulation have been questioned (5,6). The proposed alternative, the continuum model, suggests that the cell cycle does not exist as currently recognized but takes the form of a continuum from one cell division to the next, rather than discrete phases with discrete groups of regulatory proteins. A hypothetical initiator of DNA replication is synthesized by the cell during all phases of the cell cycle, and its concentration reaches a critical level that initiates DNA synthesis. Thus the cell can control its rate of division by regulating the amount of initiator. Nevertheless, until discussion of these competing models is concluded, with perhaps more work to determine the correctness and applicability of the continuum model, it is only reasonable to accept the weight of evidence for the established view of the cell cycle and its regulation. Thus the established model is summarized here and is the basis for the process biotechnology applications that are described.

The pathways of cell cycle regulation are, unsurprisingly perhaps, shared with another important cell process: apoptosis, or "programmed cell death," which is, in effect, the opposite of the cell proliferation cycle. Because the cell cycle and apoptosis share some common pathways, regulatory imbalance can lead to cancer in multicellular organisms (7). Regulation of the cell cycle is also crucial in embryology and ontogeny, where features such as limb formation, tissue differentiation, and growth are a function of the balance between proliferation and apoptosis. Therefore, much of the cell cycle (and apoptosis) literature is from the field of biomedical science, particularly cancer and anticancer chemotherapy research. General texts, as well as much of what is written here, provide a consensus of information describing a hypothetical typical cell and thus, by implication at least, describe what is true of all eukaryotic cells.

THE CELL CYCLE

Overview

The cell cycle and its control mechanisms are highly conserved, so most of what is described in general terms for a "typical mammalian cell" is also true for other animal cells, such as insect and plant cells, although there is the obvious exception of the cell wall and its effect on cell division. The

cell cycle and its control in yeast are essentially similar to but much simpler than the analogous mechanisms in higher eukaryotes; where one protein pair exerts a particular control function in a yeast, several may be required for the same function in an animal cell. As a result of this less complex system and the fortuitous discovery of cell cycle control mutants (cdc mutants) in which the cell cycle is inhibited at specific stages, many early discoveries about cell cycle control were made using the budding yeast *Saccharomyces cerevisiae* and the fission yeast *Schizosaccharomyces pombe*. Subsequent research has shown homology between cell cycle control proteins in yeast and those in mammalian cells.

However, the bacterial cell cycle is markedly different from the eukaryotic cell cycle, and its control mechanisms are (to date) less well understood than the analogous processes in eukaryotes. Given a hypothetical typical bacterial cell, its structure and thus the function of its cell cycle are very different from those of a eukaryotic cell. Bacteria, like all cells, are enclosed in a cytoplasmic membrane, but in addition, they have a cell wall outside the cytoplasmic membrane. Within the cell there are no organelles, only free ribosomes and the nucleus, which is actually an area that contains DNA but is not segregated from the cytoplasm by a membrane. The entire genome is contained in a single, circular, double-stranded DNA chromosome; one strand is a closed circle and the other is open. There are no histone or similar DNA-associated proteins; instead there is a relatively high proportion of small, basic polyamines whose function may be to counteract the acidity of the DNA. The "joint" in the closed DNA strand, the origin of replication, is attached to a mesosome, an invagination of the cytoplasmic membrane. When DNA replication starts, the 5′ end of the open strand attaches to the cytoplasmic membrane and starts to form a second mesosome; meanwhile, the DNA unwinds in one direction from the origin of replication and splits into two single strands to form a replication fork. As the replication fork progresses along the chromosome, complementary strands of DNA are synthesized until two daughter chromosomes of double-stranded DNA are formed, each with an origin of replication attached to its mesosome. While the chromosome replicates, the cytoplasmic membrane and cell wall are synthesized in the region between the two mesosomes, enlarging the cell. After chromosome replication, a septum forms across the middle of this region, finally separating the two daughter cells. However, it takes about 40 minutes to duplicate the single chromosome; hence, to allow doubling times as low as 20 minutes, each daughter chromosome must start to replicate in exactly the same way before the parent has finished replication. Thus instead of one there will be three origins of replication operating at once. In addition, when the doubling time of a culture is less than about 40 minutes, DNA synthesis is continuous, so it may be that DNA replication and cell division cycles are independent in bacteria (8). However, despite the essentially continuous DNA synthesis and cell division shown in the fast-growing cultures likely to be used in process biotechnology, it has recently been shown (9) that slowly growing *Escherichia coli* cells (doubling time up to 5 hours) display cell cycle phases analogous to eukaryotic G_1, S, and G_2 phases, *vide infra*, followed by cell division. Furthermore it was shown that initiation of DNA replication was related to cell mass. Two genes, *seqA* and *dnaA*, were shown to be involved in the regulation of replication initiation; gene mutants exhibited decreased and increased mass, respectively, at initiation of replication. Recent work with *Caulobacter* (10) described a protein, CtrA, that has sequence homology with response regulatory proteins in other bacteria including *E. coli* and is involved in cell cycle control including cell division, and cell cycle–specific transcription. It was proposed that CtrA is part of a phosphorelay signal transduction system responsible for transcriptional-level control of bacterial cell cycle events.

The mammalian cell cycle is best described by illustration (Fig. 1a). Starting from a recently divided daughter cell, untransformed, or "normal," cells may enter gap phase 0, or G_0. This is an offshoot from the cell cycle in which cells may remain viable and nondividing but retain the potential to divide given the appropriate stimulus. A cell, depending upon its type, can remain out of the cell

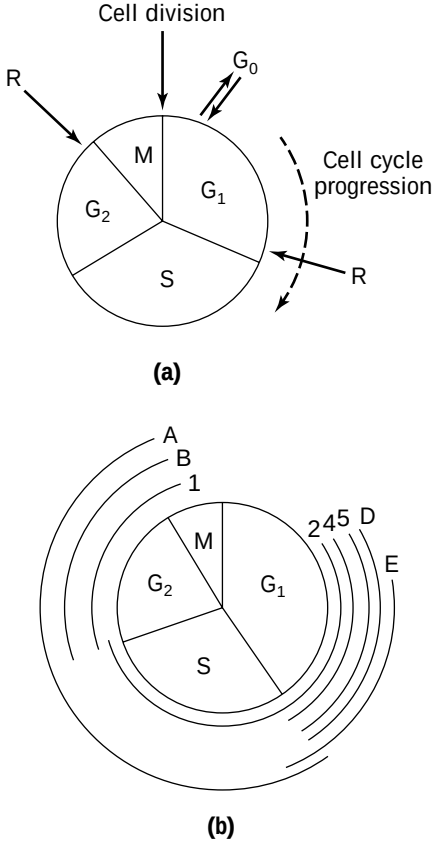

Figure 1. (**a**) A simple diagrammatic representation of the cell cycle. G_0, gap phase 0; G_1, gap phase 1; S, synthesis phase, in which the DNA and cell cytoplasmic components are duplicated; G_2, gap phase 2; M, cell division by mitosis (or meiosis); R, restriction point (check point). (**b**) A simple diagrammatic representation of cyclin and cyclin-dependent kinase activation during cell cycle traverse. cycle, in G_0, for extended periods but can return to gap phase 1, or G_1, due to cell maturation after a certain time has elapsed, after a critical mass/size is reached, or as a response to an external stimulus. In contrast, cells from continuous, sometimes called *established* or *immortal*, cell lines and transformed cells (which includes most animal cells used in biotechnology) do not enter G_0 after division but restart their cell cycle after mitosis by progressing directly to G_1. During G_1, cells prepare to duplicate themselves. When a cell enters the synthesis, or S phase, it starts to precisely and accurately duplicate its genome by synthesizing DNA and the associated nuclear protein components, so that daughter cells carry a genome identical to each other and to the parent. During this time, ribosomes, mitochondria, endoplasmic reticulum, and all the other subcellular organelles are also replicated in preparation for cell division. Thus by the end of S phase, a normally diploid ($2n$) cell will be tetraploid ($4n$), containing enough DNA (and cellular components) for two cells. After S phase, the cycling cell enters the second gap, or G_2, phase. During G_2 the cell synthesizes the proteins required to direct chromosome segregation and cell division in the following mitosis, or M phase. After mitotic division the daughter cells return to G_1 at the beginning of a new cell cycle or exit the cycle to G_0. In a typical cell cycle of 24 hours' duration, G_1 would last 10 hours, S phase 9 hours, G_2 would last 4 hours, and mitosis 1 hour. However, the duration of the cell cycle varies both between cell lines and between individual cells within the same culture. Variation in cycle time is usually due either to cells exiting the cycle and arresting in G_0 or to a variation in the duration of G_1. It has been suggested that the intercellular variability of the postmitotic early G_1 period is smaller than that seen with initiation of DNA replication (presynthetic late G_1) (11). It is also postulated, by the same author, that cells that make the "yes or no" decision in the postmitotic early G_1 period about whether to proceed through the cell cycle also have the capacity to decide, in the presynthetic late G_1 period, when the cell will enter S phase. Heterogeneity in the duration of G_1 is the main reason why a synchronized culture loses synchrony with time to the extent that the culture is completely asynchronous within three or four cell cycles.

This apparently simple cell cycle is subject to complex control mechanisms. Some of the molecular pathways have been understood only in recent years and there may be others that have not yet been described. Mammalian cells periodically transcribe cell cycle genes that encode proteins directly involved in cell cycle regulation. These include the cyclins and the cyclin-dependent kinase (Cdk) families. The cyclin-dependent kinases are phosphorylating enzymes that are inactive when not associated with an appropriate cyclin; it is the associated cyclin that determines the substrate specificity of the complex. The activity of this heterodimeric complex is then regulated by phosphorylation/dephosphorylation of specific activation and/or inhibition sites, as well as by further binding with inhibitory proteins. Many of the cyclins, cyclin-dependent kinases, and related regulatory proteins are expressed or form active complexes only during particular cell cycle phases. Cdk4–cyclin D1 drives cells through mid G_1, Cdk2–cyclin E drives late G_1, Cdk2–cyclin A controls entry into S phase, and Cdk1–cyclin B drives the G_2–M transition; their phase-related activities are summarized in Figure 1b and Table 1. Others, including Cdk4 (13,14) are expressed throughout the cell cycle. The noncyclic proteins exert their cell cycle–controlling effects by association with phase-specific cyclins or cyclin-dependent kinases, association with Cdk-cyclin inhibitors, and specific amino acid phosphorylation/dephosphorylation to form active complexes in specific phases. A family of genes encoding proteins related to the retinoblastoma susceptibility gene, *RB*, and genes for transcription factors including *BYMB*, *E2F1*, and *JUN* are all induced in late G_1 or early S phase and have been shown to interact with cell cycle regulatory complexes. In addition, there are restriction points in the cell cycle that, once past, commit the cell to continuing the division cycle. There are also check points where, in effect, the cell ensures that the previous phase has been completed properly before proceeding or that there has been no DNA damage. To continue to mitosis before the genome is properly duplicated, for example, would be catastrophic for the cell; one if not both daughters would not be viable. It has been suggested that induction of the p53 tumor suppressor gene and its transcriptional activation of the Cdk inhibitor $p21^{WAF1/CIP1}$ with subsequent cell cycle arrest, following DNA damage, allows time for DNA repair before entering S phase (15). Activation of p53 in cells with unrepaired DNA damage may lead to apoptotic cell death.

Gap Phase 1, or G_1

G_1 was originally thought to be a gap in the cell cycle—a resting phase while the cell recovered from division before starting a new cell cycle by synthesizing more DNA—although this is now known not to be so. Rather, complex control processes are preparing the cell to synthesize the cellular machinery required for DNA synthesis in S phase. There is also a "point of no return" near the end of G_1 called the restriction point (R), which is analogous to START in yeast. Once cells pass this point they are committed to the next stages of the cell cycle. Signals for passing this point include adequate cell size and a favorable environment, including the presence of growth factors. The transition at the R point from growth-factor dependence to growth-factor independence in normal cells, as opposed to cancer or transformed cells, is likely to reflect a stringent growth regulatory mechanism that is defective in the latter cell types. Coordination between cell cycle commitment, START (or R), and cell size, involving the G_1 cyclins, has been suggested as a regulatory mechanism for cell growth in yeast. During early G_1, immediately after G_0 cells are stimulated to reenter the cell cycle, a critical step occurs involving the induction of cell cycle–specific genes including *myc, cyclin D, and fos*, and Cdk genes. It is now apparent that Cdk 2, Cdk 4, and Cdk 5, despite constitutive expression of Cdk4 thoughout the cell cycle, start to complex with cyclins D1, D2, and D3 and become active in early to mid-G_1 (possibly at a point when or soon after noncycling cells return from G_0). The level of activation of the G_1 Cdk-cyclin complexes peaks at about R; so it is possible that, by reaching a threshold activity, it is these complexes that allow cells to pass R. Cdk2 also forms active complexes

Table 1. Cyclin-Cdk Complexes, Stability, and Associated Proteins

Cyclin	Associated Cdk	Cell cycle activity	Associated proteins	Stability	Degradation
A	Cdk2 and cdc2 (Cdk1)	S and $G_2 \rightarrow M$	p107, E2F, p21, PCNA	Unstable in mitosis	Ubiquitin
B1	cdc2 (Cdk1)	$G_2 \rightarrow M$	(p21), (PCNA)	Unstable in mitosis	Ubiquitin
B2		$G_2 \rightarrow M$	(p21), (PCNA)	Unstable in mitosis	Ubiquitin
C-type	Cdk X	?	ND	ND	PEST
D1	Cdk4(2, 5, 6)	G_1	pRb, p21, p27, PCNA, p16, p15	Rapid turnover	PEST
D2	Cdk4(2, 5, 6)	G_1	pRb, p21, p27, PCNA, p16, p15	Rapid turnover	PEST
D3	Cdk4(2, 5, 6)	G_1	pRb, p21, p27, PCNA, p16, p15	Rapid turnover	PEST
E	Cdk2	G_1 and $G_1 \rightarrow S$	p107, E2F, p21, PCNA and p27 after TGFβ treatment	Rapid turnover	
F			ND	ND	
G			ND	ND	
H	Cdk7	All phases	ND	ND	ND

with cyclin E starting from mid-G_1 and peaking later than the Cdk–cyclin D complexes, in other words, between R and the G_1–S phase transition.

The primary substrate of the cyclin D complexes is the retinoblastoma tumor suppresser gene product pRB. Active, unphosphorylated pRB complexes with and inhibits the transcription factor E2F. When pRB is phosphorylated and inactivated, the complex dissociates, releasing active E2F; the cell cycle is not stopped at the G_1 checkpoint, and cells are allowed to proceed to S phase (16). E2F was originally characterized as an activator of the adenovirus early region 2 transcription unit (16). It is now recognized that E2F promotes the transcription of enzymes associated with DNA synthesis (18,19). It has been proposed that the cyclin E complex also phosphorylates pRB, with similar effects (20).

Synthesis Phase, or S

The transition from G_1 to S phase is marked by the transcription (as already described) and activation of the many synthetic enzymes required for cellular duplication, including DNA polymerase α, thymidine kinase, and dihydrofolate reductase (DHFR) (21). This is followed by the exact duplication of the genetic material and replication of organelles and structural proteins. At the same time there is a marked change in regulatory proteins activated. At the onset of S phase, the activation of the G_1-phase Cdk-cyclin complexes decreases in the same temporal order as it increased, and the complexes dissociate. As Cdk2 disassociates from cyclins D and E, it complexes with cyclin A, which starts to be synthesized at about the G_1–S transition. The Cdk2–cyclin A complex retains its activity until the end of S phase. Disruption of cyclin A function inhibits DNA synthesis, suggesting that a threshold activity of the Cdk2–cyclin A complex is essential for the maintenance of S phase.

Gap Phase 2, or G_2

As with G_1, G_2 was originally thought to be a gap in the cell cycle—a resting phase while the cell recovered from DNA synthesis before dividing. This has now been shown not to be so, although G_2 remains analogous to G_1 in that, once the appropriate control signals are received, genes encoding for the proteins responsible for cell division are transcribed and ready for cell division. At the end of S phase the activity of the Cdk2–cyclin A complex decreases as the components dissociate. Cyclin A and cyclin B then form complexes with Cdk1 (also often referred to as cdc2 because of its homology with the product of *S. pombe* cell division cycle gene 2). It is these complexes, increasing in activity throughout G_2 and continuing into mitosis, that mediate activation of the cell division machinery. At the transition point between G_2 and M is a second check point that, in effect, ensures that the cells are big enough, the environment is favorable, and DNA synthesis has been fully and accurately completed before the cell continues to mitosis and division.

Mitosis, or M: Cell Division

Mitosis is the division of one normally diploid, or $2n$, somatic cell into two genetically identical (both to each other and the parent) cells. Mitosis, like the cell cycle itself, displays distinct phases that are best represented diagramatically (Fig. 2). When the cell leaves interphase at the end of G_2, it enters prophase. The nucleolus disappears (disperses), and nuclear DNA condenses into chromosomes. Following DNA synthesis in S phase, a normally diploid ($2n$) cell is now tetraploid ($4n$) and contains an identical pair of each chromosome, which in turn is organized as a pair of identical chromatids joined to each other at the centromere. During late prophase, the nuclear envelope is broken down. At the same time, the centrioles divide; one pair migrates to each cell pole with spindle fibers, which are microtubular structures, linking each pair. The transition from prophase to metaphase is marked by alignment of all the chromosome pairs on an equatorial plane, the metaphase plane, with their centromeres connected to each polar centriole pair by spindle fibers. The cell progresses into anaphase when the chromosomes separate and one chromatid from each homologous chromosome pair migrates along the spindle fibers toward each centriole. In the next phase, telophase, when the chromatids (one

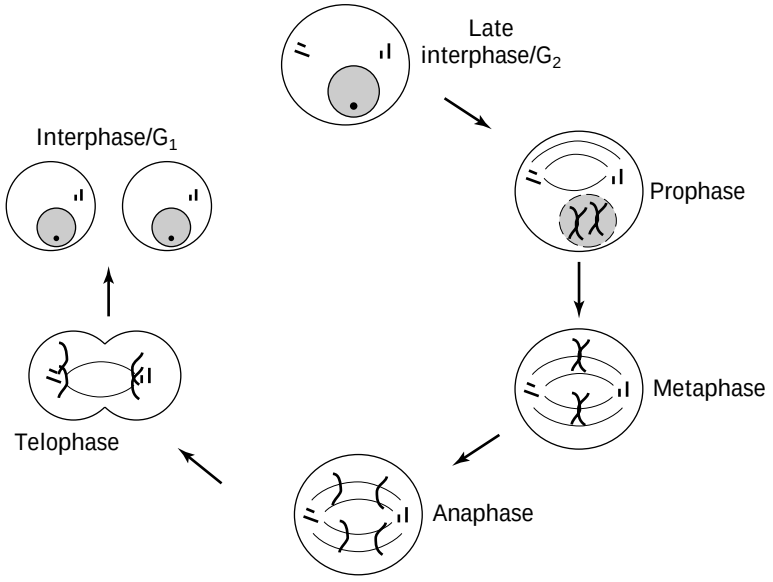

Figure 2. A simple diagrammatic representation of mitosis.

from each homologous chromosome pair) arrange at each pole, the spindle fibers depolymerize, and cytokinesis (division of cytoplasm) begins as a cytoplasmic cleavage furrow begins to form. Further changes follow: the cytoplasm cleaves completely, chromosomes uncoil, the nuclear envelope reforms around each nucleus, and the nucleoli reappear to give two genetically identical daughter cells in interphase. The final telophase changes, in which the cytoplasm divides and the cells separate, are markedly different in plant cells and in animal cells due to the constraints of the rigid cellulose cell wall. As with other cell cycle phases, Cdk-cyclin complexes perform a major regulatory function in mitosis. The activity of Cdk1–cyclin A and Cdk1–cyclin B, which started in G_2, continues to increase until the middle of mitosis, at the metaphase–anaphase boundary. At this point the activity of both complexes declines abruptly to zero, allowing the cell to complete mitosis. It is also thought that the rapid decrease in G_2 cyclin-Cdk complexes is necessary for cells to start a new cell cycle at G_1.

Meiosis. Although unlikely to be encountered in process biotechnology, it is useful to point out that germ cells may undergo an alternative form of division to form zygotes, which may also be considered to be a form of terminal differentiation, called *meiosis*. Assuming a normally diploid ($2n$) cell, initial cell division occurs exactly as in mitosis until the end of anaphase, or in this case the first meiotic anaphase. At telophase the cell may divide or partially divide and enter a brief meiotic interphase comprising two identical diploid ($2n$) daughter nuclei (if not cells). Otherwise the cell progresses directly to the second meiotic prophase. Now there is only a single copy of each chromosome, still comprising two chromatids. During the second meiotic anaphase, the chromatids separate again to each of four poles. The cell then progresses to (the second meiotic) telophase and on to interphase to give four haploid (n) daughter cells instead of the two diploid ($2n$) cells produced by mitosis.

Gap Phase 0, or G_0

The term G_0 was first used in the early 1960s when three types of cell were recognized: static cells, incapable of further division (for example, a terminally differentiated adult neurone); renewing, constantly dividing cells (for example, bone marrow cells); and conditionally renewing cells, which do not normally divide but can respond to an appropriate extraordinary stimulus (for example liver cells starting to proliferate after partial hepatectomy). G_0 is used to describe this last category of cells, which have "opted out" of the cell cycle after a mitosis because of, for example, growth factor depletion. In this circumstance, in contrast, transformed or tumor cells do not enter G_0 but continue through the cell cycle until they die through nutrient exhaustion, often by apoptosis. It has been argued that G_0 should not be used to describe cells, for example, in the stationary phase of a hybridoma, or CHO batch cultures, which are in a pseudo-steady-state of growth and death due to nutrient depletion and/or accumulation of toxic metabolites. Unlike the normal cells, they have not downregulated themselves; they have been closed down by their environment. Cells that lose their ability to respond to growth factor depletion or do not exit the cell cycle to G_0 may have a defective G_1 program, which is different from the cyclin-Cdk4-pRB phosphorylation mechanism involved in R regulation in normal cells. However, G_0 is commonly used today, some claim inappropriately, to describe any cell (containing a G_1 amount of DNA) that is not expected to proceed to S phase for any reason, including the result of any means of artificial interference with the cell cycle. Markers of G_0 include reduced RNA, reduced ribosome content, and an absence of cyclins D and E (22).

External (Environmental) Influence on the Cell Cycle

Extrinsic cell cycle regulation may be considered at two levels. At the more basic level is the effect of the physical environment and nutrient availability; the more complex level of extrinsic cell cycle control is through growth fac-

tors. The physical environment has a great effect on the cell cycle. When temperature is reduced from the optimum, the length of the cell cycle increases, and growth rates slow down. When temperature exceeds the optimum, even by a few degrees, profound changes in cell behavior occur, including the expression of heat shock proteins, and cells eventually die. Alternatively, if appropriate nutrients such as amino acids and glucose are not available in the medium, cell cycle duration and even progression will be influenced due to lack of energy and the precursors for protein and DNA synthesis.

Serum starvation, in the presence of appropriate nutrients and physical conditions, may also affect the cell cycle, but this is more likely to be caused by the absence of specific growth factors that serum provides. Most, if not all, cell lines were originally grown in medium containing animal serum, usually newborn or fetal bovine serum. The main contribution to the cell cycle and, hence, growth of a culture from these undefined and heterogeneous supplements is the supply of growth factors that promote or enhance the cell cycle. Thus, because G_0 cells reenter the cell cycle as a result of serum addition, serum is regarded as a source of positive regulatory growth factors. The presence of growth factors in the environment, their binding to specific transmembrane receptor proteins, and subsequent signal transduction effects changes in cellular processes, including the cell cycle. Expression of cyclin D, important in progression through G_1, is induced by growth factors (23). These effects are cell-type dependent because cells do not all express the same growth factor receptors. Furthermore, different cell types/lines may not only require different individual growth factors but may require a specific cocktail for optimal proliferation. Fibroblast growth, for example, requires growth factors including fibroblast growth factor (FGF), epidermal growth factor (EGF), and platelet-derived growth factor (PDGF). Other growth factors that promote cell division include insulin-like growth factor (IGF) I and II, macrophage–granulocyte colony stimulating factor (G-CSF), and endothelial cell growth factor. Each growth factor stimulates a specific receptor on the plasma membrane, which in turn activates protein kinases, many of which phosphorylate tyrosine residues on their substrates, so they are generically called tyrosine kinases. Subsequent signal transduction by phosphorylation/dephosphorylation cascades can lead to an increased rate of protein synthesis, influence the activity of DNA topoisomerase, or modify the glucose transport system—all with the similar effect of promoting cell division. Transformed cells are known to have a reduced (or no) requirement for external growth factors compared with normal cells. However, through adaptation of cell lines and extensive development of medium formulation, many cells can now be grown in protein-free medium, indicating that it is possible to bring about cell proliferation and support long-term culture in media free of (extrinsic) growth factors, hormones, and other contaminating proteins. This absence of extraneous protein is particularly important in large-scale process biotechnology for facilitating downstream processing and product recovery.

It is commonly accepted that the accumulation of toxic metabolites (ammonia and lactate, for example) inhibits culture proliferation. However, in addition to the positive growth-promoting (cell cycle–promoting) factors, there are also negative, growth-inhibiting factors, although these may be the same growth factors displaying opposite effects under different conditions. Transforming growth factor $\beta 1$ (TGF-$\beta 1$), in addition to its strong positive stimulatory effect, has been shown to produce a density-independent negative response that prolongs G_1 in the NIH-3T3 mouse embryo cell cycle and has a similar effect on mortal human fibroblasts (24).

METHODS FOR DESCRIBING THE CELL CYCLE

Mitotic Index

There are three main approaches to describing the cell cycle. The first and most historically established approach is to determine the percentage of cells in mitotic cell division. This method, called the *mitotic index*, is simple and can be applied to attached cells grown on a microscope slide or any other appropriate substratum, as well as cells in suspension. There are many fixation and staining methods described in any textbook of cytology methods, from which a protocol appropriate to animal cell biotechnology can be selected. A generic protocol is as follows. Take cells grown on a glass microscope slide (or coverslip) or prepare a smear of suspended cells on a microscope slide, using an attachment agent such as polylysine if necessary. Fix the cells with a fixative appropriate to the proposed staining method. Stain the cells with either a standard cytological or histological stain that differentiates DNA, such as Feulgen staining, or alternatively, stain with a fluorescent DNA stain such as ethidium bromide (EB), Hoechst 33258, or DAPI. Examine stained slides by conventional or fluorescence microscopy, as appropriate; count the number of nuclei in mitosis and express the result as a percentage of the total. A recent publication, investigating mitosis in a hydrodynamically stressed environment, described the use of the fluorescent DNA-intercalating stain propidium iodide (PI) with cells fixed with 3:1 ethanol:glacial acetic acid, followed by fluorescence microscopy (25). A major disadvantage to measuring the mitotic index is that, although it gives information about cell division in M phase, it can give no information about the other cell cycle phases or their associated processes. Measuring the mitotic index also exhibits disadvantages common to all manual microscopic methods, including sampling error because a small proportion of the total population is examined, and interobserver variation resulting from subjective discrimination between mitotic and interphase cells. Furthermore this slow and labor-intensive method is not appropriate for online automation or use in integrated process control.

Labeled Nucleotide Uptake in S Phase

An alternative approach for describing the cell cycle is to document the incorporation of labeled nucleotide into nuclear DNA during S phase. This method relies on [^{3}H]thymidine incorporation followed by autoradiography and can be used in one of two ways: continuous labelling, in which the cells are exposed to the label for a fixed time,

usually 24 or 48 h followed by analysis at that time; or pulse–chase labeling, in which the cells are exposed to the label for a short pulse (0.5–1 h), then analyzed at regular intervals for 24–48 h. Continuous labeling gives information about the growth fraction of a culture, which is the percentage of the cells that are in the cell cycle during the labeling period. However, this information is not likely to be of great use to the process biotechnologist because most cells under optimum conditions, when viability is close to 100%, will also have a growth fraction close to 100%. A simple generic protocol for continuous labeling is as follows: [^{3}H]thymidine is added to the culture medium, and the culture continues for a specified period; cells are fixed and subjected to autoradiography; when the autoradiograph has developed, the number of radiolabeled nuclei is counted and expressed as a percentage of the total.

In contrast, pulse–chase labeling is used to determine the average duration of each cell cycle phase. A generic protocol for [^{3}H]thymidine pulse–chase labeling is as follows: [^{3}H]thymidine is added to the culture; after a short period (1–2 h), cells are removed to fresh medium without [^{3}H]thymidine; the culture is sampled regularly at times greater than the length of one cell cycle (24–48 h); each sample is subjected to autoradiography; and the number of labeled mitoses is counted as a percentage of the total. The average duration of G_2, S, M, and the total cell cycle is measured from the plot of labeled mitoses against time, then G_1 is calculated. Details of using [^{3}H]thymidine incorporation for determining growth fraction and cell cycle phase duration are summarized elsewhere (26). As with the mitotic index, any autoradiographic technique exhibits inherent disadvantages including sampling error because a small proportion of the total cell population is examined; the technique is slow, labor intensive, and not appropriate for on-line automation or use in integrated process control; and the use of radioisotopes requires additional containment and waste disposal facilities.

In recent years the thymidine analogue bromodeoxyuridine (BrdU) has been used as a safer, nonisotopic alternative to [^{3}H]thymidine for DNA labeling. BrdU can be used in exactly the same way as [^{3}H]thymidine, as either a continuous or pulse–chase label. The only difference in the protocol is that BrdU incorporation is detected by immunostaining with fluorescent anti-BrdU antibodies followed by fluorescence microscopy instead of autoradiography, so the method still suffers the disadvantages of any manual microscopic method. Alternatively, BrdU incorporation can be measured by flow cytometry, *vide infra*.

Measuring DNA Content

The third and probably easiest approach to adopt for cell cycle analysis is to measure the DNA content of each cell in a population by flow cytometry and thus determine the proportion of cells in G_0/G_1, S, and G_2/M at the time of sampling. A major and obvious advantage to this approach is that heterogeneous nonsynchronized cultures can be analyzed easily and rapidly, with the useful bonus that sub-G_1 apoptotic populations can also be identified. Other advantages include minimizing sample error by analyzing a large number of cells, and minimal interobserver variation because of the objective discrimination between G_1, G_2, and S cells. Furthermore, the method is appropriate for near on-line automation and use in integrated process monitoring or control. Although this approach is not able to resolve G_0/G_1 or G_2/M because DNA content is the same, this is of little concern in most process biotechnology applications because the (transformed) cells commonly used do not enter G_0. Furthermore the G_2/M cell subpopulation can be resolved, if necessary, by measuring the mitotic index of the population (as already described) to determine the proportion of cells in M phase.

Flow Cytometry for Cell Cycle Analysis

Flow cytometric cell cycle analysis by measuring DNA content may follow any one of many protocols. A generic protocol is as follows: fix/permeablize the cells; stain with a fluorescent DNA stain; measure stained DNA content by flow cytometry; and analyze data by simple gating or using dedicated cell cycle analysis software. Variations include pretreatment of cells; altered fixation/permablization protocols; postfixation treatment of cells; different stains, although stains such as PI or EB, which intercalate into double-stranded nucleic acid, are commonly used; and methods for data analysis. A typical flow cytometric measurement of PI-stained DNA in ethanol-fixed recombinant CHO cells and the subsequent cell cycle analysis, using software based on a polynomial S-phase algorithm with an iterative nonlinear least squares fit, is shown in Figure 3. By fitting the G_1 and G_2 peaks as Gaussian distributions, and the S-phase distribution as a Gaussian broadened distribution, the cell cycle phase distribution can be deconvoluted.

Flow cytometry can also be used with BrdU incorporation to measure the growth fraction or to determine average cell cycle phase times. For flow cytometric analysis, BrdU incorporation can be detected by either fluorescent immunostaining or its quenching effect on Hoechst DNA stains. Thus BrdU incorporation can be analyzed simultaneously with DNA content. The advantage of this method is that it can recognize arrested but non-DNA-synthesizing cells during S phase. Cell size and/or protein content can also be analyzed simultaneously to give further related information. Again, there are many variations on a theme, details of which and other flow cytometric methods for cell cycle analysis have been summarized elsewhere (27). Flow cytometry is also very useful for analyzing specific cell cycle–related proteins, following appropriate fluorescent immunostaining. For example, the absence of cyclin D or E in G_0 cells, shown by flow cytometry, has been used to distinguish G_0 from G_1 cells (22), and flow cytometric measurement of the Ki67 nuclear antigen has been shown to correlate with [^{3}H]thymidine and BrdU incorporation (28). Multiparameter flow cytometric analysis of G_1 and G_2 cyclin expression and DNA content has also been shown to be a useful tool in cell cycle analysis (29) because G_1 cells can be differentiated from G_0 cells, and cells with unusual karyotypes (for example, G_1 tetraploid) can be distinguished from G_2 diploid cells. Flow cytometry can also be applied to investigating the relationship between the cell cycle and recombinant protein expression in

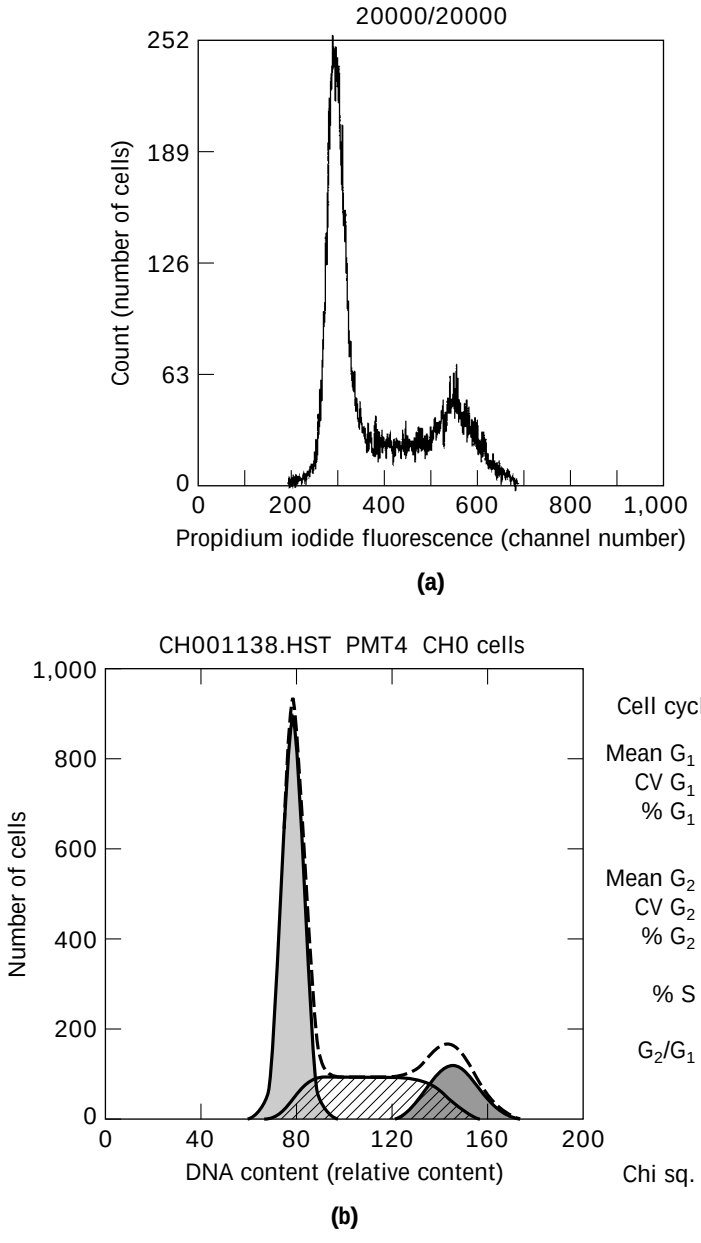

Figure 3. (**a**) Typical flow cytometric measurement of fluorescent (propidium iodide–stained) DNA content in recombinant CHO cells. (**b**) Resolution of cell cycle fractions from the fluorescent DNA content of recombinant CHO cells, using dedicated cell cycle analysis software (Multicycle®, Phoenix Flow Systems).

economically important cell lines as a means of optimizing medium and environmental conditions for successful commercial operation.

THE IMPORTANCE OF THE CELL CYCLE IN PROCESS BIOTECHNOLOGY

Culture Proliferation and Growth

The cell cycle is the means by which a culture proliferates. Cell division and cell death, both active programmed cell death (apoptosis) and passive necrosis, are responsible for the change in the number of cells present. In addition to the cell cycle control genes, the transcription of genes coding for proteins involved in nucleotide and DNA synthesis is also cyclic. However, the progress of the cell cycle is costly in nutrient utilization and energy expenditure, particularly during S phase, which is when the nucleic acid content of the cell is duplicated, but also during other phases because regulatory proteins are continuously synthesized and degraded. In theory it should be possible to arrest cells, in other words, stop them from cycling, thus preventing the "wastage" of energy and nutrients that could otherwise be directed into product synthesis. The maintenance energy model (30) states that energy (as adenosine triphosphate [ATP]) consumption is divided into that needed for cell growth (cell cycle progression, as determined by increase in cell number) and that needed for cell maintenance. Based on this model it has been determined that the maintenance energy requirement of a hybridoma is 14.4×10^{-9} mmol ATP/(cell day) at a specific growth rate (μ) of 0.66 per day (31), corresponding to 62%

of the energy (ATP) consumed. These values were confirmed by work that showed that the maintenance energy requirement of the same cells under slightly different nutrient and specific growth rate conditions was 11.4×10^{-9} and 12.0×10^{-9} mmol ATP/(cell day), again, corresponding to approximately 60% of the estimated ATP consumption rate (32). These observations agree with the value of 65%, which was determined as the proportion of energy consumption used for maintenance by mouse LS cells grown at $\mu = 0.60$ per day (33). Thus it is apparent that about two-thirds of the energy used by a culture is for its own maintenance, and this proportion is not likely to be readily altered. However the remaining third, which is used for growth (and product elaboration), may be exploited. If the growth (cell cycle progression) requirement was removed, all of the remaining resources could be directed toward product elaboration, or alternatively, cultures would require up to one-third less energy and nutrient resources for the same product yield.

Two main approaches have been used to prevent cells from cycling. The first is chemical blockade. For example, the addition of thymidine to culture medium causes cells to arrest at the G_1–S phase boundary, so cells accumulate in G_1, and specific productivity increases. However, this production advantage is short lived because the imbalanced growth state leads to culture death (usually by apoptosis) within a few days of the onset of the chemical blockade (D. C. Edwards and M. Al-Rubeai, unpublished data, 1997). The second approach is not to arrest the cell cycle but to substantially reduce its progression by reducing the culture growth rate. Using a custom-built total cell recycle bioreactor system, where the growth rate of a mouse hybridoma was substantially reduced ($\mu < 0.05\ \mu_{max}$), Flickinger et al. (34) showed that specific monoclonal antibody secretion remained constant as the specific growth rate decreased. This demonstrated that production could be uncoupled from growth (cell cycle progression), although there was no evidence that the energy saved by substantial (>95%) reduction of growth was diverted into production. However, using this method for production-scale processes may have the advantage of less medium (energy/nutrient) expenditure per unit product, although the total product yield per unit of production (from each bioreactor) would not be increased. Furthermore, questions of product fidelity, especially with respect to glycosylation, are raised when growth is limited by the stress of nutrient deprivation or limitation.

Until recently, these were the only means available for controlling the cell cycle (i.e., preventing cycle progression). In 1997, Fussenegger et al. (35) described a novel cytostatic process that enhances productivity. This was achieved by adopting a completely different approach compared with previous work. Metabolic engineering was used instead of the application of an external stress to the cells to prevent cell cycle progression. A series of transient CHO transfects was produced containing inducible dicistronic expression vectors, each of which contained a model product gene (human secretory alkaline phosphatase [hSEAP]) and a tumor-suppressor gene coding for an intracellular regulator of cell cycle progression (either p21, p27, or a mutant p53 [p53175P] that is said to have lost its proapoptotic properties while retaining its cell cycle regulation properties (36)). When the expression vector was induced, cells arrested and began to accumulate in G_1. The arrested cells showed a fourfold increase in hSEAP production compared with cells transfected with a control expression vector coding for the product only. Using stable dicistronic transfects, only p27 overexpression successfully induced cell cycle arrest (in G_1), but with it came a 10-fold increase in specific hSEAP productivity (35). Building on the success of these discistronic vectors, the tricistronic pBluescript®-based pTRIDENT family of vectors was developed (37), allowing the possibility of a single stable transfection coding not only for a product but also for cell cycle control (cell cycle arrest) and enhanced culture survival using an antiapoptosis oncogene such as *bcl-2* or *bcl-*x_L (38–40). Subsequent work with pTRIDENT vectors containing genes encoding for hSEAP with either p21 and the CCAAT/enhancer binding protein α (which induces and stabilizes p21 (41,42)) or p27 and Bcl-x_L showed even greater benefit, with specific productivities increased 15- and 30-fold, respectively, with respect to proliferation-competent controls (43).

Production in Relation to Cell Cycle Phase

It is important not to confuse the relationship between cell cycle phase and productivity with the relationship between cell cycle arrest and productivity. The substantial increases in productivity from the metabolically engineered transfects just described are most likely to exist because the arrested cells do not need to devote resources to biomass production (35). This section addresses the situation in "simple" recombinant cells that may be grown in standard industrial processes such as batch, continuous, or draw-and-fill semicontinuous culture modes. Determining the relationship between cell cycle phase and productivity is important for developing automated on-line (or near on-line) process control strategies. These strategies will be based on models that, in addition to the basic parameters of pH, dO_2, cell density, and so forth, must incorporate information concerning cell state, including cell cycle phase and its effect on productivity.

It has been shown that specific monoclonal antibody production by a synchronized mouse–mouse hybridoma culture is maximal during G_1; furthermore, the specific activity increases when the cell cycle is arrested and cells are maintained in late G_1 (44). However, apparent specific productivity also increases when the culture declines (viability decreases); this is the result of substantial passive release of intracellular product into the culture medium from dead and dying cells. Phase dependence was also found in recombinant CHO cells transfected with an expression vector containing *dhfr* and *lacZ* genes; the former was controlled by an SV40 promoter, and the latter was controlled by the constitutive hCMV promoter (45). In this study, the nonsecreted product, β-galactosidase, was produced almost exclusively during S phase. Furthermore, cell cycle arrest in S phase, by specific inhibition of DNA polymerase, did not inhibit transcription or translation and thus had no effect on β-galactosidase expression.

However, the literature on the relationship between cell cycle and protein expression, summarized in Table 2, is

Table 2. Variation in Phase Expression of Different Products with Cell Line and Promoter

Cell line	Promoter	Product	Phase expression	Ref.
Mouse leukaemia	Endogenous	DHFR	Aphasic	46
CHO	Endogenous	DHFR	Aphasic	47
Human osteosarcoma	Endogenous	DHFR	Aphasic	47
Mouse embryo fibroblast	Endogenous	DHFR	Aphasic	47
Human prostate epithelium	Endogenous	PSAP	All except early G_1	48
Hybridoma	Endogenous	MAb	G_1/G_0 (mainly)	49
CHO	AMLP	DHFR	G_1 (mainly)	50
Hybridoma	Endogenous	MAb	G_1/S	44
Mouse plasmacytoma	Endogenous	Immunoglobulin	Late G_1/early S	51
Human lymphoid cell	Endogenous	Immunoglobulin	Late G_1/S	52
CHO	Endogenous	DHFR	G_1/S[a]	22
Mouse leukemia	Endogenous	TMPS	S	46
CHO	CMV	β-Gal (*lacZ*)	S	45
CHO	SV40	tPA	S (mainly)	50
CHO	SV40	IFN-γ	S	53
Mouse L-cell	MMTV	β-Gal (*lacZ*)	S (predominantly)	54
CHO	Endogenous	DHFR	S	55
Rat adenocarcinoma	Endogenous	tPA	Shortly after S	56
Rat adenocarcinoma	Endogenous	uPA	Shortly after S	56
CHO	Endogenous	PA	G_2/M	57

Note: DHFR, dihydrofolate reductase; CHO, Chinese hamster ovary; TMPS, thymidine monophosphaste synthetase; MAb, monoclonal antibody; PSAP, prostate-specific acid phosphatase; AMLP, adenovirus major late promoter; CMV, cytomegalovirus; β-Gal (*lacZ*), β-galactosidase (product of the *Escherichia coli lacZ* gene); SV40, simian virus 40; tPA, tissuelike plasminogen activator; IFN-γ, interferon-γ; uPA, urokinase-like plasminogen activator; PA, plasminogen activator.

[a]Gene expression activates at G_1–S transition.

inconsistent. Different researchers have shown that product expression (or the maximum rate of expression) is related to different cell cycle phases. In addition, others have shown that product expression is aphasic. These observations do not necessarily contradict each other and may be a true reflection of the systems used, because a variety of cells, products, and constructs were studied. Cell cycle–dependent product expression may not be universal and could vary with cell type or cell line, the construction of the expression vector, the nature of the recombinant gene expressed, or the promoter/enhancer used to drive product expression. Other variables may include posttranscriptional regulation (mRNA level), product gene copy number, and even the culture mode, (e.g., whether the cells are attached to a substrate or are free in suspension) may be relevant. However, there are two potential flaws in studying cell cycle–related productivity: synchronizing cells using chemical means, such as thymidine block or nutrient starvation, and comparing cells of different phases from the same culture that are separated in time. The two problems often go together, for example, following a culture for a day after release from thymidine block. The difficulty with the former is that the chemical stress used (what ever its nature) may, in addition to its desired effect of cell synchrony, directly cause perturbations in productivity that could wrongfully be ascribed to the cell cycle. The difficulty with the latter is simply that if two cell populations from a culture are separated in time, they are also separated in environmental conditions; recent work (58) has shown that the effect of medium condition is dominant to any cell cycle effect on productivity. The effect of temporal separation is made more uncertain following stress synchronization; an early population may have only partially recovered from the stress, whereas a later population has fully recovered.

Cell Cycle Analysis as a Proliferation Predictor

Cells may be arrested in G_1 before the restriction point, but once past that point, they are committed to continue their cycle and divide unless prevented from doing so by catastrophe or artificial intervention. Therefore, one can presume that, once a cell enters S phase, under normal growth conditions, one single cell will in due course become two cells. This phenomenon can be used to predict culture growth. The growth-enhancing effect of peptone supplementation on hybridoma culture was predicted by cell cycle analysis 5 h after supplementation, although the effect on cell density was not apparent until 16 h later, 21 h after supplementation (59). A similar use of cell cycle analysis was made with CHO cells: the percentage of S-phase cells correlated with the specific growth rate 10.5 h later; the time difference was the average duration of S phase remaining plus the duration of G_2 and M for that population (60). Thus, the proportion of cells in S phase can be used to predict the subsequent proliferation rate of that culture.

Cell Cycle–Related Susceptibility to Hydrodynamic Damage

The effect of hydrodynamic stress, as found in stirred and sparged bioreactors, is at least in part related to cell cycle phase, and there may be a role for hydrodynamic cell damage in the induction of apoptosis (61). It has been reported that DNA synthesis (62) and the proportion of the cell population in S phase (63) were increased under conditions of hydrodynamic stress (high sparging and agitation rates). However, the cell number remained low even though the S-phase population correlated with an increase in cell number. The observed reduction in growth rate was

shown to be a consequence of a decline in the proportion of G_2- and M-phase cells, with a corresponding decrease in the cell size of the population, suggesting that the larger G_2 cells were particularly susceptible to hydrodynamic damage (61). Subsequently it was shown that mitotic cells, while also being susceptible to hydrodynamic damage due to their size, were even more sensitive to hydrodynamic damage than G_2 cells, perhaps due to cytoskeletal rearrangements, alteration of plasma membrane fluidity, or morphological changes during mitosis (25).

Cell Cycle and Apoptosis

Apoptosis (active or programmed cell death) is the means by which intrinsic or extrinsic stimuli activate a series of molecular cascades, triggering events that culminate in a particular morphologically, ultrastructurally, and biochemically defined process of cell death that is, in effect, the opposite of the cell cycle. Entry of a cell into apoptosis can be restricted to a particular cell cycle phase (54–66), although this cell cycle dependence does not appear to be universal (67). Cell cycle progression and apoptosis are not only opposite in effect, they may also be alternate outcomes from a single cell control mechanism; they are inextricably linked by common components in the signal transduction pathways for both processes. In addition, circumstantial evidence from the induction of apoptosis by DNA damage or cell cycle disruption and the existence of many oncogenes that both promote the cell cycle and induce apoptosis implies that there is an equilibrium between these two antagonistic processes in all eukaryotic cells.

OUTLINE

INTRODUCTION

The growth of eukaryotic cells is governed by a complex array of biochemical reactions that are collectively known as the cell cycle. The cell cycle controls are intimately coupled to the internal and external states of the cell and thus ultimately determine when a cell devotes the majority of its energy to growth, DNA replication, successful cell division, or cell maintenance. A recent explosion in the amount of research devoted to cell cycle controls has revealed that the activity of enzymes known as cyclin-dependent kinases (CDKs) regulates the order of cellular events that culminate in cell division. Furthermore, these CDKs are themselves subject to strict controls that govern their expression, activation, and degradation, giving a cell

the freedom to respond to a variety of situations. An overview of the findings from the numerous biological studies that have been conducted on cell cycle control is presented here. Additionally, because the cell cycle controls the most fundamental aspects of cell growth and division, it can be linked to the dynamics of many other cellular processes important to cell culture such as protein accumulation and secretion. Therefore, in order to achieve a more complete understanding of the cell cycle, a discussion of some of the investigations that have coupled the cell cycle to the dynamics of cellular process is presented. Indeed, the framework diagrammed here offers many opportunities for further research that can be used to engineer more efficient methods of cell culture.

THE BIOLOGY OF THE CELL CYCLE

The cell cycle comprises a group of complex interrelated events that exists to ensure that cells successfully divide to form two normal daughter cells. The eukaryotic cell cycle was originally divided into two stages, interphase and mitosis, as observed by light microscopy. Interphase was defined as the period between two successive rounds of cell division, whereas mitosis was identified as the period when the cell undergoes many structural changes, divides it chromosomes, and undergoes cell division. The advent of biochemical and genetic techniques later showed that interphase consists of many cellular processes necessary for the regulation of cell proliferation that can not be discerned under the light microscope. The cell cycle was then partitioned into four separate phases: G_1 (or gap 1), DNA synthesis (S phase), G_2 (gap 2), and mitosis (M phase), where G_1 refers to the gap between mitosis and DNA synthesis, and G_2 to the gap occurring after DNA synthesis and prior to mitosis.

Understanding the complex network of biochemical events that guide a cell through successful completion of cell division is of utmost importance in understanding how cells behave in response to different situations. There has been an explosion in the amount of cell cycle related research being done in the last 10 years. This is due, in part, to the fact that a wide variety cellular processes are thought to be somehow regulated by cell cycle events and proteins. Additionally, improper control of cell cycle processes in higher eukaryotes has been linked to the formation of cancerous tumors. Here we discuss the biochemical events that occur in the cell cycle and the control mechanism that maintains the temporal order of these events.

The G_1 and G_0 Phases

Upon initial inspection, it would seem that the G_1 phase of the cell cycle is a particularly uneventful time period (or gap) between the more spectacular events that occur during mitosis and DNA synthesis. Closer analysis of this interval, however, reveals that the cell is closely monitoring its environmental and internal state to determine whether the cell has sufficient resources and an intact genome to safely complete the rest of the cell cycle. In contrast to the other phases of the cell cycle, G_1 is highly variable between different cell lines and growth conditions. For example, if certain factors are not available, some cells do not progress toward S phase, but instead may enter a resting state called the G_0 phase, or quiescence. During this time, the cell undergoes a significant reduction in RNA and protein synthesis and will remain in this arrested state, with unduplicated DNA content, until the cells receive the proper stimuli.

The sequence of events that takes place during the G_1 phase has been deduced by observing how cells respond when cultured in different environments. For instance, when cultured cells are deprived of serum containing growth factors, the synthesis of new proteins is drastically reduced and a portion of newborn cells cease to advance through the cell cycle. Through observations made using time-lapse cinematography on a culture of Swiss 3T3 cells, it was determined that only those cells that exited from mitosis less than 4 h prior to growth factor deprivation were arrested in G_0, while all other cells continued to mitosis as normal (1). This observation led to the division of G_1 into two subphases. The first subphase consists of cells that are still dependent on growth factors for cell cycle progression and are referred to as G_1 postmitotic (G_{1pm}) cells, whereas cells that can proceed through the rest of the cycle are called G_1 presynthesis phase (G_{1ps}) cells. The transition point where cells pass from G_{1pm} to G_{1ps} is commonly called the restriction point in mammalian cells (2) and is analogous to "Start" in yeast. During G_{1pm}, progression through the cycle is highly dependent on growth factors and amino acids (3) that are necessary for the production of certain regulatory proteins (called cyclins) that are discussed later. It is thought that the purpose of the G_{1ps} period is to allow cells to grow, perhaps so that later in the cycle, the cell can focus its energy on other cellular processes such as DNA replication in S phase and reorganization of the cellular infrastructure during mitosis. This also explains the fact that the G_{1ps} portion of G_1 accounts for nearly all the temporal variability in the cell cycle both within a population and between cell lines (2,3). For example, after having passed the restriction point, larger cells may proceed almost immediately to the S phase, while smaller cells may linger in G_{1ps} for up to 10 h before beginning the transition to S phase (1). Additionally, although growth factors are not required to promote S phase entry once past the restriction point, the length of G_{1ps} is significantly increased when factors such as insulin and insulin-like growth factor (IGF) are lacking in the environment, presumably due to a decrease in the net protein synthesis. Under these conditions, cells undergo mitosis with a significantly reduced protein content (2), suggesting that different growth factors play an important role in growth and progression through the cell cycle.

A culture of 3T3 cells arrested in G_0 by serum deprivation can reenter the cell cycle and proceed through the restriction point only after stimulation by the addition of platelet-derived growth factor (PDGF) (1); this process is referred to as competence. Factors that initiate competence, however, vary between cell lines (4), and several other growth factor/cell-line combinations have been described (5). The biochemical effects of competency factors such as PDGF are discussed later. Time-lapse cinematog-

raphy also revealed that cell cultures that lack serum do not contain cells arrested all at one point, but at numerous times throughout G_{1pm}. Additionally, when stimulated to proliferate, arrested cells require an extra 8 h in G_1 before proceeding to S phase, presumably so the cells can recover from G_0 (2).

The DNA Synthesis Phase

The S phase is the period when the cell replicates its entire genome so that each daughter cell will receive a complete, intact set of chromosomes. Due to the immense size of mammalian genomes, multiple bidirectional replication sites are necessary for the synthesis of new DNA to be accomplished in such a short time (approximately 8 h in most cell lines). In addition to chromosome duplication, the cell must also synthesize proteins such as histones for the formation of nucleosomes and the chromosomal scaffolding. The replication of DNA has been shown to be a highly ordered process. This was observed by culturing cells with a thymidine analog called bromodeoxyuridine (BrdU). Cells in the process of synthesizing DNA take up BrdU and integrate it into newly formed DNA. Cells can then be separated by their position in S phase, based on the amount of BrdU in the DNA, to determine the exact time of replication of certain genes (6–8). These studies revealed several aspects of the replication of certain genes. First, individual genes within a cell line are replicated at defined periods in the S phase, with many of the more active genes replicated earlier than others. Furthermore, newly replicated DNA is packed into nucleosomes a short distance behind the replication fork (1).

It is also very important that the cells not replicate the same chromosome more than once; the mechanism that ensures that this does not happen is known as the rereplication block (reviewed in Ref. 2). Early cell fusion experiments on human HeLa cells showed that, prior to S phase, nuclei could be induced to undergo DNA synthesis early, whereas nuclei that have already undergone a round of DNA synthesis do not undergo another round of DNA synthesis (3). Later cell fusion experiments showed that nuclei with replicated DNA can undergo another round of DNA synthesis before mitosis after the nuclear membrane has been permeablized and then repaired (4). A model involving a replication-licensing factor (RLF) was then proposed to describe these phenomena. DNA would be replicated only if RLF was bound to the chromatin to be broken down by the replication machinery during the next S phase. During mitosis, the nuclear envelope breaks down, allowing new RLF to access the chromosomes and bind to them, thus licensing the chromosomes to undergo a single round of DNA replication. Support for this model was gained when two protein complexes, called RLF-M and RLF-B, were shown to be required to modify chromatin before replication is allowed to proceed (5). These protein complexes were shown to bind to chromatin in late mitosis and be gradually removed during S phase (6,7). The rereplication block model described earlier has recently been modified to accommodate a more detailed understanding of the proteins and mechanisms involved (2). Chromosomes in G_1 must first be "primed" by the establishment of a pre-replication complex (pre-RC) containing an origin-recognition complex (ORC), an RLF complex, and other proteins. After initiation of DNA synthesis, the pre-RC is disrupted to become the post-RC, which still contains the ORC. The ORC may be some sort of "docking" factor that allows other components of the pre-RC to assemble on the DNA.

The G2 Phase and Mitosis

Cells enter the G_2 phase upon completion of DNA synthesis, and this period lasts between 2 and 4 h, culminating with the onset of chromosome condensation. During this time, duplication of the centriole is completed, and cells produce many mRNAs and proteins that will be used during mitosis. Cells may also use this period of time before mitosis to ensure that the cell is sufficiently large and is ready to undergo cell division.

Mitosis is generally the shortest phase of the cell cycle, lasting only 15 min to 1 h, depending on the cell line. However, visual inspection of a cell culture reveals that this is a very physically active period for the cell in that it goes through many structural changes in preparation for cell division. Mitosis is traditionally divided into six stages that describe the mechanical events that occur during this period: prophase, prometaphase, metaphase, anaphase, telophase, and cytokinesis. The beginning of mitosis, known as prophase, is marked by condensation of the chromosomes into compact structures that allow sister chromatids to be more easily separated. The cytoskeletal microtubules begin to disassemble, and the mitotic spindle, a weblike array of microtubules that mediates the events in mitosis, begins to form. Also during this phase, the Golgi apparatus breaks up into tiny vesicles, and pinocytosis and RNA synthesis stop. Prometaphase begins with the disruption of the nuclear envelope, followed by the attachment of the chromosomes to the microtubules that make up the mitotic spindle. The microtubules attach to protein structures on the DNA called kinetochores, which as we shall see are very important in regulating progression through mitosis. During metaphase, the mitotic spindle arranges all the chromosomes in a single plane across the middle of the cell, called the metaphase plate. After alignment of the chromosomes, the cell enters anaphase, which is when sister chromatids are pulled to opposite sides of the cell by the microtubules so that there is a complete genome on either side of the cell. Microtubules not attached to kinetochores then elongate, pushing the spindle poles further apart. Telophase then begins, resulting in the formation of two nuclei, one around each set of chromosomes on opposite sides of the cell. The cell then begins the process of cell division, called cytokinesis, when a ring of actin and myosin that has formed around the center of the cell begins to contract. Upon completion of this process, two new daughter cells are formed, each containing a complete, intact genome and cytoplasmic organelles sufficient to support further growth and proliferation.

The temporal organization of the cell cycle phases is shown in Figure 1, where the numbers and arrows represent when the corresponding cyclin–CDK complexes listed in Table 1 are active.

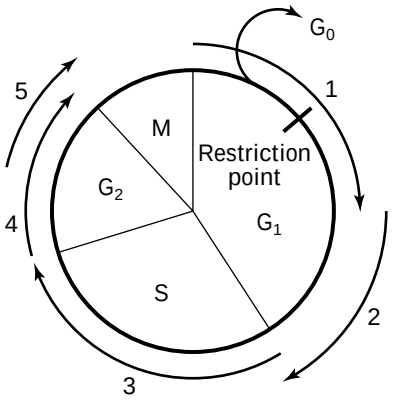

Figure 1. The temporal order of the cell cycle. Cells exit mitosis after cell division and are sensitive to the presence of growth factors until they pass the restriction point. The large block arrows depict the active period of the best-defined cyclin–CDK complexes. The numbers next to the arrows correspond with the numbers assigned to the various complexes as defined in Table 1.

CONTROL OF THE CELL CYCLE

Successful completion of cell division requires that the cell reside in an environment capable of supporting growth, and that the cell cycle proceed as normal. As discussed previously, cells require the presence of growth factors and essential amino acids to support the synthesis of new proteins. In addition, the immediate environment must not be overcrowded; daughter cells must have room to grow and subsequently divide. If any of these conditions is not met, cells enter the G_0 phase, which eventually results in cell death if environmental conditions are not improved. Similarly, if the events in the cell cycle do not occur in the proper sequence, daughter cells may not inherit the proper genetic material or organelles to properly function, and they will die. Therefore, cells must possess some means of sensing whether the environment is able to support growth. There must also be a control mechanism in place that regulates the sequence of events that make up the cell cycle. An understanding of the mechanisms that control cell growth is of interest to many scientists including oncologists and biochemical engineers. Oncologists may be able to use the knowledge of the events regulating the cell cycle to develop therapies against certain types of cancers, whereas the control network of cells in culture can be engineered to reduce the culture's dependence on serum.

Central to the mechanisms that control the events of the cell cycle are the checkpoints. Checkpoints are points in the cell cycle where certain criteria must be met before the cell cycle can proceed any further. For example, the restriction point in G_1 is a checkpoint because cells not cultured in the presence of growth factors are arrested in G_0 and not allowed to proceed through the cell cycle until growth factors are supplied. Indeed, several other checkpoints that control the order of the cell cycle phases and the events within each phase exist throughout the cell cycle. For instance, cells with unduplicated DNA do not enter mitosis, and chromosomes are replicated only once in each cycle. Additionally, cells with damaged DNA do not undergo mitosis, rather they become arrested in G_2 to allow the DNA repair machinery to correct any defects in the genetic material. Controls that mediate the order of events in mitosis also exist. For example, entry to metaphase is prevented until the chromosomes are lined up at the metaphase plate. As we will see, complexes made up of two classes of proteins are involved in regulating all these events throughout the cell cycle. These two classes of proteins are cyclins and cyclin-dependent kinases (CDKs).

Partners in Cell Cycle Regulation: Cyclins and CDKs

Cyclins were originally defined as molecules that accumulated throughout the cell cycle in marine invertebrate eggs and were then degraded during each mitosis (33). Several years later, the amino acid sequences of various cyclins were compared, and a consensus sequence of approximately 100 amino acids was found and dubbed the "cyclin box" (34). Cyclins are now defined on the basis of the presence of the cyclin box in the native sequence. Currently, 12 cyclins have been identified in mammalian cells (cyclins A–H, with two A-type, three B-type, and three D-type cyclins) (35). The cyclin box domain facilitates binding to CDKs, whose kinase activity is dependent on being bound

Table 1. Activity of the Major Cyclin–CDK Complexes

Complex (see Fig. 1)	Cyclin–CDK complex	Cell cycle phase	Function	Ref.
1	Cyclin D–CDK4	G_0, early to mid-G_1	Stimulates exit from G_0 and progression through the restriction point; phosphorylates pRb	8, 9, 10, 11–13
2	Cyclin E–CDK2	G_1–S transition	Triggers S phase entry; activates cdc25A	14, 15, 16, 17
3	Cyclin A–CDK2	S	Phosphorylates DNA synthesis machinery; inhibits E2F/DP1 transcription factor	18, 36, 37, 91
4	Cyclin A–CDK1	G_2, M	Triggers formation of mitotic spindle	22, 23, 24
5	Cyclin B–CDK1	G_2–M transition, M	Triggers entry into M; responsible for many structural changes in mitosis	18, 22, 25, 26–30
6	Cyclin H–CDK7	All cell cycle phases?	Cyclin activating kinase (CAK); phosphorylates other cyclin–CDK complexes	31, 32

Note: The numbers listed with each complex correspond with the numbers listed in Figure 1. See the text or the references for more detail on the substrates of the complexes.

to a cyclin molecule (36) and are thus defined as proteins that require binding to cyclins in order to attain activity (37). There are seven known CDKs in animal cells (named CDK1–CDK7). Different cyclins may interact with different CDKs at specific points in the cell cycle, and each of these complexes is specific for substrates with differing functions. Because several of the complexes have similar substrate specificity in vitro, the change in specificity is thought to be due not only to changes in the affinity toward different substrates, but also to localization of complexes in distinct parts of the cell by various cyclins (38). We first briefly discuss the different cyclin–CDK complexes that form throughout the cell cycle and then review the regulation of these complexes. The major cyclin–CDK complexes that are active throughout the cell cycle are listed in Table 1 along with their corresponding times of activity and their functions.

The major studies that resulted in the discovery of G_1 cyclins were performed in budding yeast (39). It was shown that three cyclin molecules, Cln1, Cln2, and Cln3, have important functions in advancing cells through the restriction point (called Start in yeast). In addition, inactivation of all three molecules is required to cause G_1 arrest of the cell cycle. By searching for factors that could complement the function of Clns in yeast, several mammalian cyclins were isolated: cyclin C, cyclin D, and cyclin E (40). Other studies revealed several other G_1 cyclins, cyclins G and F, however, neither the roles that these cyclins play nor their CDK partners are known (41). It has been shown that cyclin C mRNA synthesis reaches its peak in mid-G_1, and cyclin G mRNA synthesis starts soon after growth-factor stimulation of quiescent cells (42). Conversely, cyclins D and E are fairly well characterized and have been the focus of much attention because defects in control of these proteins have been implicated as a cause of cancer (18).

Although D-type cyclins have been shown to associate with CDK2, CDK5, and CDK6, they seem to interact primarily with CDK4 (43). Transcription of various combinations of D-type cyclins (cyclins D1, D2, and D3) is stimulated by different mitogens (growth factors), depending on the cell type, and their synthesis throughout the rest of the cell cycle is maintained by the presence of growth factors (44). Removal of growth factors halts the synthesis of D cyclins, resulting in a rapid decrease in their levels because they have very short half-lives (45). Furthermore, in cycling cells, the level of cyclin D hardly varies, and only a small peak showing its accumulation is observed. As noted previously, growth-factor deprivation has no effect on cells that have passed through the G_1 restriction point, and these cells continue to cycle until their progeny become arrested in early G_1. Additionally, microinjecting cells with cyclin D1–specific antibodies results in their cell cycle arrest only during early to mid-G_1 (8), whereas overexpression of cyclin D1 results in a reduction in the length of G_1, the size of the cell, and growth-factor dependency (46,47). These findings indicate that the primary function of D-type cyclins is to link the cell cycle machinery with the extracellular environment, which permits the cell to become committed to DNA synthesis when in a favorable environment or become arrested in G_0 under unfavorable conditions.

Cyclin E is expressed soon after cyclin D expression in G_0 cells stimulated with growth factors, and its level peaks late in G_1. It has been shown to interact with a single catalytic subunit, CDK2 (48). In contrast to D-type cyclins, cyclin E is synthesized periodically and is rapidly degraded soon after entry into S phase, thus adhering to the original definition of a cyclin (49). Similar to cyclin D, cyclin E function has been shown to be essential for progression through G_1, because microinjection of anti–cyclin E antibodies prevents cells from entering S phase, whereas its overexpression results in acceleration toward S phase (9). This acceleration is, however, balanced by an increase in the lengths of the S and G_2 phases so that the length of the entire cycle remains unchanged. Because an increased amount of cyclin E advanced progression to the S phase early, it is possible that the cyclin E–CDK2 complex is responsible for initiating the synthesis of proteins that are used during DNA synthesis. This hypothesis accounts for the increase in the length of the S and G_2 phases following increased expression of cyclin E. These findings, when taken together, suggest that the cyclin E–CDK2 complex is involved in regulating the passage from G_1 into S (41).

Upon entry into S phase, cyclin E is degraded and cyclin A takes its place as the partner of CDK2 (50). Transcription of cyclin A is begun immediately after entry into S phase, and its inhibition by microinjection of anti–cyclin A antibodies allows, at most, only 10% of the DNA to be replicated (51) and may also disrupt the temporal relationship between DNA synthesis and mitosis (10). As a cell progresses into the G_2 phase, cyclin A is no longer associated with CDK2, however, it forms a new complex with CDK1 (also known as cdc2 due to its homology with the budding yeast kinase of the same name) to regulate progression through G_2 and into mitosis. It has been shown that CDK1 forms complexes with both cyclin A and cyclin B near the G_2–M transition (52). These complexes are located in different parts of the cell because cyclin A accumulates in the nucleus, and cyclin B resides in the cytoplasm until the breakdown of the nuclear envelope during mitosis (53). Once they have completed their respective functions, both cyclins are then rapidly degraded later in mitosis.

Experiments done in fission yeast suggest that the cell monitors the presence of cyclin B, because cells undergo another round of DNA replication when cyclin B–CDK1 complexes are not present (14). This implies that the level of cyclin B–CDK1 complexes, both active and inactive, are constantly monitored, and the presence of these complexes maintains cells in G_2. Although this theory has not been investigated in other eukaryotes, it is not entirely unlikely given the high degree of conservation of cell cycle controls among eukaryotic cells.

Regulation of the Cyclin–CDK Complex Activity. Three different mechanisms allow tight control over the myriad of cyclin–CDK complexes: (*1*) cyclin transcription and degradation, (*2*) CDK phosphorylation and dephosphorylation, and (*3*) binding of the cyclin–CDK complexes to various inhibitory proteins. These three forms of cyclin–CDK regulation interact to form an intricate regulatory network that allows cells to temporally control events throughout the cell cycle and to ensure that these processes are suc-

cessfully completed. These three mechanism of cyclin–CDK complex regulation are depicted in Figure 2.

Intracellular concentrations of different cyclins, and thus the activity of cyclin–CDK complexes, are regulated by synthesis and degradation. There are two different pathways by which cyclins can be degraded, depending on the type of cyclin. Cyclins D and E, which function in early G_1 and the G_1–S transition, respectively, are inherently unstable and thus have short half-lives of approximately 30 min. The instability of these cyclins has been attributed to the presence of a PEST sequence near the C-terminus of the cyclin box (54). In contrast, cyclins A and B, which function in the S, G_2, and M phases, are stable throughout interphase, even when they are not bound with CDKs. However, these cyclins are degraded during mitosis in the proteosomes through a ubiquitin-mediated pathway (55). These proteins contain a sequence of amino acids near the amino terminus, called the destruction box, that marks them for destruction. Degradation of these proteins is also regulated so that cyclin–CDK complexes that are necessary for cell cycle progression are not inactivated before their specific tasks are successfully completed. For example, it has been shown that proteolysis of cyclin A and B does not occur in *Xenopus* egg extracts until purified cyclin B–CDK1 complexes are added (19). This suggests that the proteolysis pathway is initiated by active cyclin B–CDK1 complexes. Conversely, the addition of purified cyclinA–CDK1 complexes to the extracts had the opposite effect of delaying cyclin degradation triggered by cyclin B–CDK1 kinases (20). The fact that only cyclin B–CDK1 complexes can activate proteolysis may explain why cyclin degradation does not occur until correct assembly of the mitotic spindle is achieved in metaphase (56). The exact mechanism of regulation of cyclin degradation is unknown, but it has been hypothesized that cyclin B–CDK1 activates a cyclin-specific enzyme that catalyzes the conjugation of ubiquitin to cyclins (22).

Cyclin–CDK complexes are also regulated by phosphorylation and dephosphorylation. Specifically, phosphorylation on T160/161 (depending on the CDK) is necessary for activation of the complex, whereas phosphorylation of T14 and Y15 residues inhibits cyclin–CDK activity. The T160 residue is located on a T loop, which is conserved in all CDKs. When not phosphorylated,

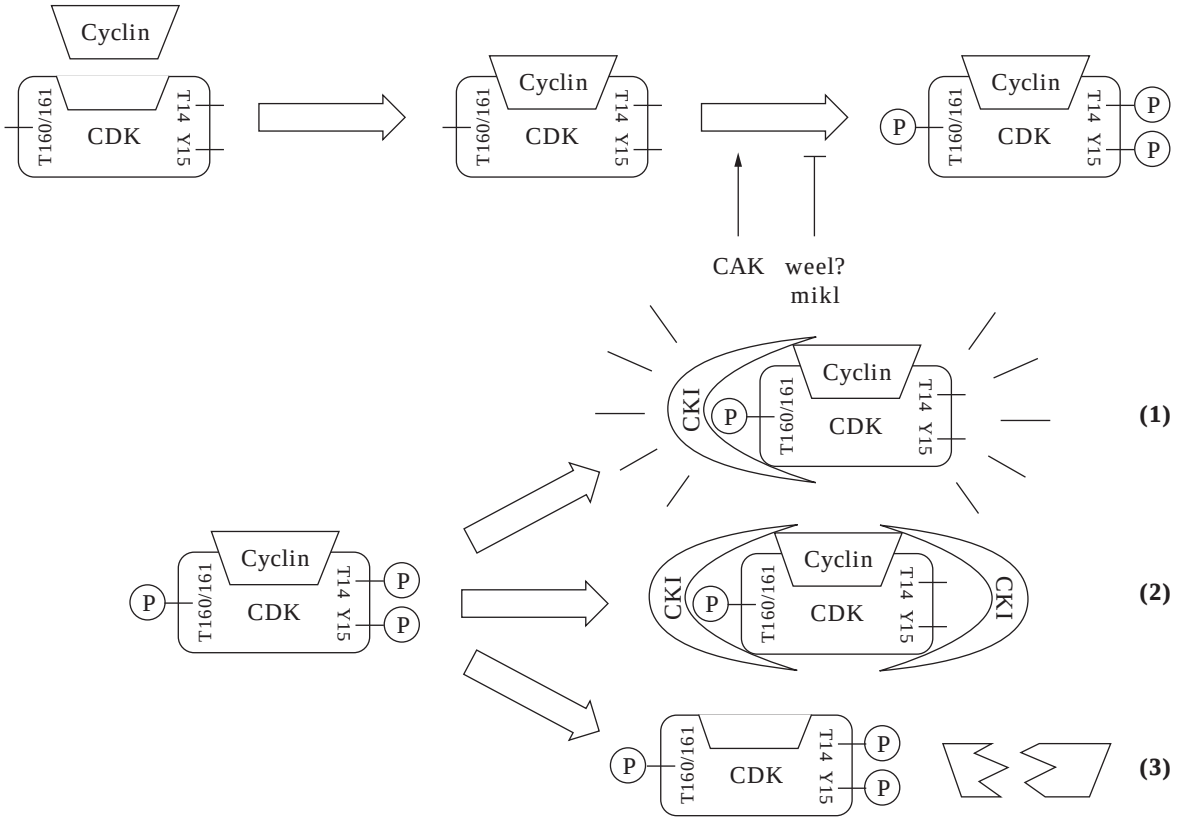

Figure 2. Control of cyclin–CDK complex activity. Cyclin–CDK activity is governed by three mechanisms: phosphorylation/dephosphorylation reactions, cyclin-dependent kinase inhibitors (CKIs), and cyclin expression and degradation. After assembly of the cyclin–CDK complex, the activity of CAK activates the complex while phosphorylation by Mik1 and Wee1 inhibits complex activity. The phosphorylated complex is then activated by the phosphatase activity of cdc25 and is denoted as complex 1 in this figure. Complex 2 has the correct residues phosphorylated, which is necessary for activation; however, it is bound by two CKIs and is inactivated. Complex 3 is shown inactivated by cyclin degradation.

this loop prevents kinase activity by covering the substrate binding domain. Phosphorylation at this site serves two purposes: it increases the affinity between the cyclin and the CDK and therefore stabilizes the complex, and it alters the conformation of the T loop, allowing access to a substrate (57).

The kinase that is responsible for phosphorylation of this residue on several CDKs is also a cyclin–CDK complex. This complex, commonly referred to as CDK-activating kinase (CAK), is made up of cyclin H, CDK 7, and a third 32-kDa protein (58). Although the level of CAK activity has not been shown to vary in a cell cycle–dependent manner, it is possible that cyclin H is regulated by its synthesis and degradation (56). The kinase responsible for activating CAK has not been identified, but it has been shown not to be an autophosphorylation process (58,59). Further studies done with this complex have shown that it may play a role in activating the RNA polymerase II C-terminus domain kinase of transcription factor IIH (60,61). This suggests that cyclin H and CDK7 may have a more diverse role than merely activating other CDKs (56).

Cyclin–CDK complexes are also subject to negative regulation through the phosphorylation of the T14 and Y15 residues. These residues are found within the ATP binding site of the enzyme. Phosphorylation of the Y15 residue inhibits kinase activity by interfering with the transfer of a phosphate group to a bound substrate (62), whereas phosphorylation of the T14 residue acts by interfering with binding of ATP (25). The regulation of phosphorylation on these residues is not yet well defined in animal cells. In addition, only the process of tyrosine phosphorylation is known in yeast because phosphorylation of the threonine residue is not necessary in this organism (35). In yeast, the tyrosine residue is phosphorylated by the Wee1 and Mik1 kinases (63). The Wee1 kinase is in turn regulated by the Nim1 kinase, which inhibits Wee1 activity. The kinase responsible for phosphorylation of the Y15 residue in animal cells has been isolated (64) and is closely related to Mik1 (35). The dephosphorylation of these residues, which is necessary for cyclin–CDK activation, is performed by the phosphatases Cdc25A, B, and C (31). Cdc25A has been shown to be activated by the cyclin E–CDK2 complex in early S phase, which then activates cyclin A–CDK2 complexes. The Cdc25C phosphatase activates cyclin B–CDK1 complexes at the transition from G_2 to mitosis (35); however, the function of cdc25B is as yet unknown.

The activity of cyclin–CDK complexes is also controlled by certain proteins known as cyclin-dependent kinase inhibitors (CKIs or CDIs) that bind to these complexes and repress their activation. Several different inhibitors have been isolated from mammalian cells that interact with either different cyclin–CDK complexes or CDKs themselves. These proteins are commonly named according to their molecular weights, such as the 21-kDa inhibitor known as p21. Other cyclin–CDK inhibitors are p27, p15, and p16. These inhibitors are intricately involved in regulating progression through the G_1 phase, and have thus been the subject of recent reviews (32,65,66).

Immunoprecipitation studies have revealed a very interesting fact: cyclin D1 is commonly found among a quaternary complex of proteins that includes either CDK4 or CDK6, p21, and proliferating-cell nuclear antigen (PCNA) (discussed later) (43). The p21 protein acts as an inhibitor by binding directly to cyclin B–CDK1, cyclin E–CDK2, cyclin A–CDK2, and cyclin D–CDK4 complexes. These cyclin–CDK complexes containing p21 are, oddly enough, still enzymatically active in vitro, which directly conflicts with studies showing that p21 is an inhibitor of CDK activity and is able to induce cell cycle arrest (67,68). It was later demonstrated that active cyclin–CDK–p21 complexes isolated from cycling cells could be inactivated by the addition of more p21 (69), suggesting that the stoichiometry of p21 binding to these complexes is very important. For example, in cycling cells, there is only enough p21 present so that each cyclin–CDK complex has a single p21 molecule and thus remains active. However, when the amount of p21 is increased or the cyclin–CDK pool depleted, the ratio of p21 to cyclin–CDK complexes increases so that more than one p21 molecule binds to each complex, resulting in inhibition of the complex's kinase activity. We explore the circumstances under which this sort of inhibition becomes important in a later section.

A second inhibitor that has been identified is called p27. p27 and p21 have been shown to have highly similar amino acid sequences near their amino terminus domains. In addition, they also share the same range of specificity for cyclin–CDK complexes. The cell cycle arrest of certain cell lines in response to some environmental signals such as contact inhibition and transforming growth factor β (TGF-β) has been shown to be due, in part, to inactivation of cyclin–CDK complexes by this inhibitor (70), and the exact mechanism of this type of arrest will be described shortly. A recent discovery has given some insight into one of the mechanisms by which this protein inhibits cyclin–CDK activity. Cyclin–CDK complexes that have not yet been activated by CAK phosphorylation can be bound by p27, which then blocks the CAK's access to the threonine residue found on the CDK subunit (71). Presumably, another mechanism exists for inhibition of active complexes.

The main function of the p27 inhibitor seems to be to prevent the G–S transition from occurring when the need arises by inhibiting the activity of cyclin E–CDK2 complexes (72). In normal cycling cells, the p27 inhibitor seems to be dispersed among the different cyclin–CDK complexes that are active during G_1, therefore it does not have a significant impact on any essential events. However, in response to stimulation by TGF-β, it has been suggested that the expression of CDK4 is downregulated, resulting in an increased amount of p27 bound to cyclin E–CDK2 complexes (73).

The p16 inhibitor was originally found associated with CDK4 in a transformed cell line (74). Unlike the p21 and p27 inhibitors, p16 was found to associate specifically with the cyclin D CDKs, specifically, CDK4 and CDK6. It competes with cyclin D for the CDK subunits and may even act to disrupt cyclin D–CDK complexes. This inhibitor is thought to play an important role in regulating growth because the p16 gene has been shown to be deleted in many tumor-cell lines (75).

Examination of TGF-β-arrested cells led to the discovery of another inhibitor, p15, because it was shown to be bound to CDK4 (76). Similar to p16, p15 binds to CDK4

and CDK6, competes with cyclin D, and may be involved in arresting cells treated with TGF-β in G_1. TGF-β stimulates the synthesis of p15 so that its level is increased approximately 30 times. This allows p15 to sequester the CDK4 complexes so that a much larger amount of the p27 inhibitor binds to and inactivates cyclin E–CDK2 complexes, resulting in G_1 arrest.

The Cyclin–CDK Complexes in Action

Now that we have discussed the events that occur in the cell cycle and defined the major regulatory proteins, we are in a position to examine the mechanisms that control cell cycle progression. Indeed, control of the activity of the cyclin–CDK complexes is at the heart of cell cycle regulation because these complexes either directly or indirectly act on cellular constituents that are capable of bringing about changes in intracellular events. This implies that the proper regulation of these cyclin–CDK complexes is essential for maintaining the temporal integrity of cell cycle events. This is accomplished by repressing the activity of the appropriate kinase through different combinations of cyclin degradation, phosphorylation/dephosphorylation of specific CDK residues, and action of CDK inhibitors. These controls not only maintain temporal stability, but also ensure that DNA synthesis is not carried out when DNA is damaged or that mitosis does not occur in the presence of damaged or misaligned chromosomes.

G_1 to S Phase Control. An important property in normal cells is their ability to sense the state of the extracellular environment, such as the presence of various growth or inhibitory factors or contact inhibition. This communication between the cell and its surroundings takes place in the G_0 and G_1 phases, and the cells respond by becoming quiescent, undergoing programmed cell death (known as apoptosis), or continuing with the cell cycle. The interaction with the environment ceases when the cell passes the restriction point, after which the cell is said to be committed to DNA synthesis. We now consider the machinery responsible for directing the path that the cell will traverse in response to signals from the environment.

Several lines of evidence indicate that the product of the retinoblastoma gene, pRb, is responsible for linking signals from the extracellular domain (77). Specifically, mutation or deletion of this gene is found in many cancerous cell lines that have lost their ability to regulate proliferation (78). Additionally, pRb accumulation was found to coincide with suppression of growth in TGF-β-induced arrest (79), whereas inhibition of pRb results in a resumption of cell cycle progression. Mammalian DNA viruses, whose main purpose is to activate quiescent cells so that they can use the cell's replication machinery to duplicate their own DNA, have been found to seek out the hypophosphorylated form of pRb (80). This led to the belief that pRb is in its active state when it is underphosphorylated, and phosphorylation of this protein results in its inactivation. This is supported by the fact that hypophosphorylated pRb is present in G_0 cells and is phosphorylated later during the G_1 phase. In its active form, pRb binds to several proteins including a heterodimer of proteins from the E2F and DP family of proteins. This heterodimer, called DRTF1/E2F (81), is a transcription factor that stimulates the transcription of numerous proteins necessary for cell cycle progression, such as CDK1, cyclin A, and a variety of proteins that are indispensable during DNA synthesis (82).

In order to further characterize G_1 events, it is necessary to find out what is responsible for inactivating pRb. A likely candidate seems to be the cyclin D–CDK4 complex. The presence of this active kinase is highly dependent on the presence of growth factors that stimulate the synthesis of cyclin D, and thus, the activity of that complex appears during the same period when pRb is inactivated. Moreover, cells that lack functional pRb do not require the presence of cyclin D–CDK4 to proceed through the cell cycle, implying that the primary function of this complex is to inactivate pRb (83). Indeed the belief that pRb is a substrate of this complex was confirmed because cyclin D–CDK4 is capable of binding to and phosphorylating pRb in vitro (84,85). The following feedback loop, involving the levels of cyclin D and the functional state of pRb, has been proposed (86). Cells that lack functional pRb have drastically reduced levels of cyclin D; however, addition of pRb to these cells results in the synthesis of cyclin D. Active kinase complexes are then allowed to form, which act by phosphorylating pRb. The hyperphosphorylated form of pRb downregulates the levels of cyclin D during late G_1, causing the inactivation of CDK4, which in turn allows pRb to be activated once again by the action of phosphatases, and the cycle begins anew upon completion of mitosis.

Because the CDK inhibitors p21 and p27 are constitutively expressed in cycling cells, these molecules are present throughout G_1. This indicates that in order for cells to advance past the restriction point, the level of cyclin D–CDK4 complexes must increase until it exceeds the number of inhibitor molecules present so that there is at most one CKI per cyclin–CDK complex to allow kinase activation (70). This model not only satisfies the timing of cyclin D–CDK4 activation, but suggests a dual role for this complex. Its primary function is to phosphorylate pRb to promote the transcription of important genes, while its secondary role is to sequester the CKIs so that the cyclin E–CDK2 complex, which is the next kinase to be active in the cell cycle, cannot be inhibited by these molecules, thus allowing the transition to S phase to occur (32). A schematic representation of the control mechanism that regulates progression through G_1 is shown in Figure 3.

As mentioned previously, the activity of cyclin E–CDK2 complexes during the cell cycle has been narrowed down to the transition from G_1 to S. Some of the possible substrates for this complex include the so-called pocket proteins, which include pRb, p107, and p130 (82). The term *pocket protein* refers to those proteins involved in binding to certain proteins, such as transcription factors, and releasing them after activation of the pocket protein by the action of a CDK kinase. The cyclin E–CDK4 complex is localized in the nucleus where it is bound to E2F, p107, and p130 (although it has not been shown to phosphorylate these proteins) (87), suggesting that it too plays a role in regulation of transcription. The E2F subunit that interacts with cyclin E–CDK4 has been shown to differ from the E2F found associated with pRb, which hints that they have dif-

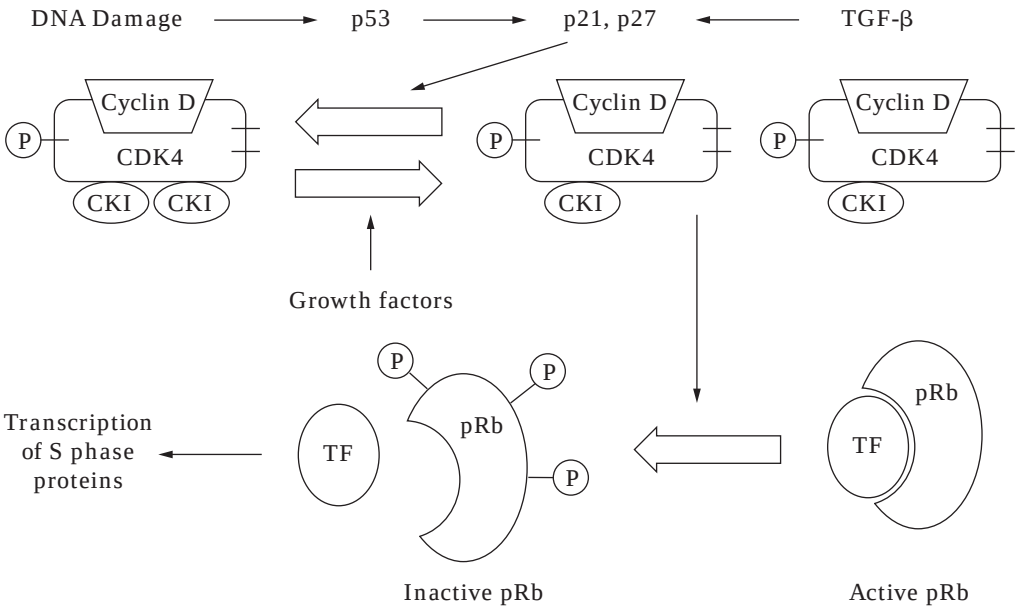

Figure 3. The G_1 control mechanism. Schematic of the control mechanism that governs the progression past the restriction point and through G_1. The presence of growth factors stimulates the expression of cyclin D to promote the formation of cyclin D–CDK4 complexes, increasing the amount of complex to a level above the inhibitory threshold of CKIs. This increase in cyclin D–CDK4 complexes results in kinase activity that then promotes the release of transcription factors. DNA damage results in the expression of p53, which increases the amount of CKIs present to arrest cells in G_1 and allow DNA repair to take place.

ferent properties (88). One confirmed substrate of cyclin E–CDK2 is the Cdc25A phosphatase that is involved in activating CDKs by cleaving the inhibitory phosphates on both a tyrosine and a threonine residue (89). The cdc25A phosphatase has been proposed to activate both cyclin E–CDK2 and cyclin A–CDK2 complexes, creating a positive feedback loop between cyclin E–CDK2 and Cdc25A (Fig. 4a). If this feedback loop does indeed exist, it has been hypothesized that the activation of Cdc25A occurs in response to the completion of some G_1 event such as the duplication of the centrosome or the accumulation of certain DNA synthesis proteins (15).

Experiments with yeast suggest that proteolysis may be involved in activating the cyclin E–CDK2 homologue that plays an important role in the G_1–S transition (11). It has been shown that a protein called Cdc34 is necessary for the G_1–S transition to take place, possibly because it is responsible for initiating the degradation of certain CKIs. Functional homologues of the Cdc34 protein have been isolated in vertebrate cells and are thought to stimulate the degradation of the p27 inhibitor (12). This, in addition to isolation of CKIs by the cyclin D–CDK4 complex, could possibly aid in beginning the onset of the synthesis phase.

In summary, a cell becomes arrested in G_0 in response to some extracellular signal that triggers a decrease in the level of cyclin D below a threshold level of CKIs. This allows p21 and p27 to bind to cyclin D–CDK4 complexes in a 2:1 ratio, resulting in an inhibition of kinase activity. Following stimulation of cyclin D synthesis due to the presence of growth factors, there is an increase in cyclin D–CDK4 kinase activity because there is no longer enough inhibitor present to inactivate all the complexes. This active CDK kinase then serves two purposes: (*1*) to inactivate pRb, allowing the release of transcription factors that induce the synthesis of other cyclins and DNA synthesis proteins, and (*2*) to isolate the CKIs to allow activation of the cyclin E–CDK2 complex. This complex then stimulates the release of additional transcription factors and initiates a positive feedback loop that triggers the onset of the DNA synthesis phase.

Once cells move beyond the restriction point, they are committed to entering the DNA synthesis phase. Cells do, however, have the power to delay the onset of later events to ensure the proper coordination of important processes. For example, failure to repair damaged DNA greatly increases the occurrence of genetic mutations, which can have disastrous consequences for the cell. Thus, an additional checkpoint exists in late G_1 phase, which ensures that the DNA is free from damage and ready to be replicated. We will now see that cells possess the means to sense when there is damage to the genetic material and then halt cell cycle progression to allow the DNA machinery time to repair any defects in the genetic material. It has been determined that the there is a single protein, p53, that is held accountable for inducing G_1 arrest in response to DNA damage (13) (see Fig. 3 for a schematic representation).

By inducing DNA damage in normal cells, it was determined that cells responded by increasing the level of p53 and the CKI p21 (90). The increase in p21 then leads to

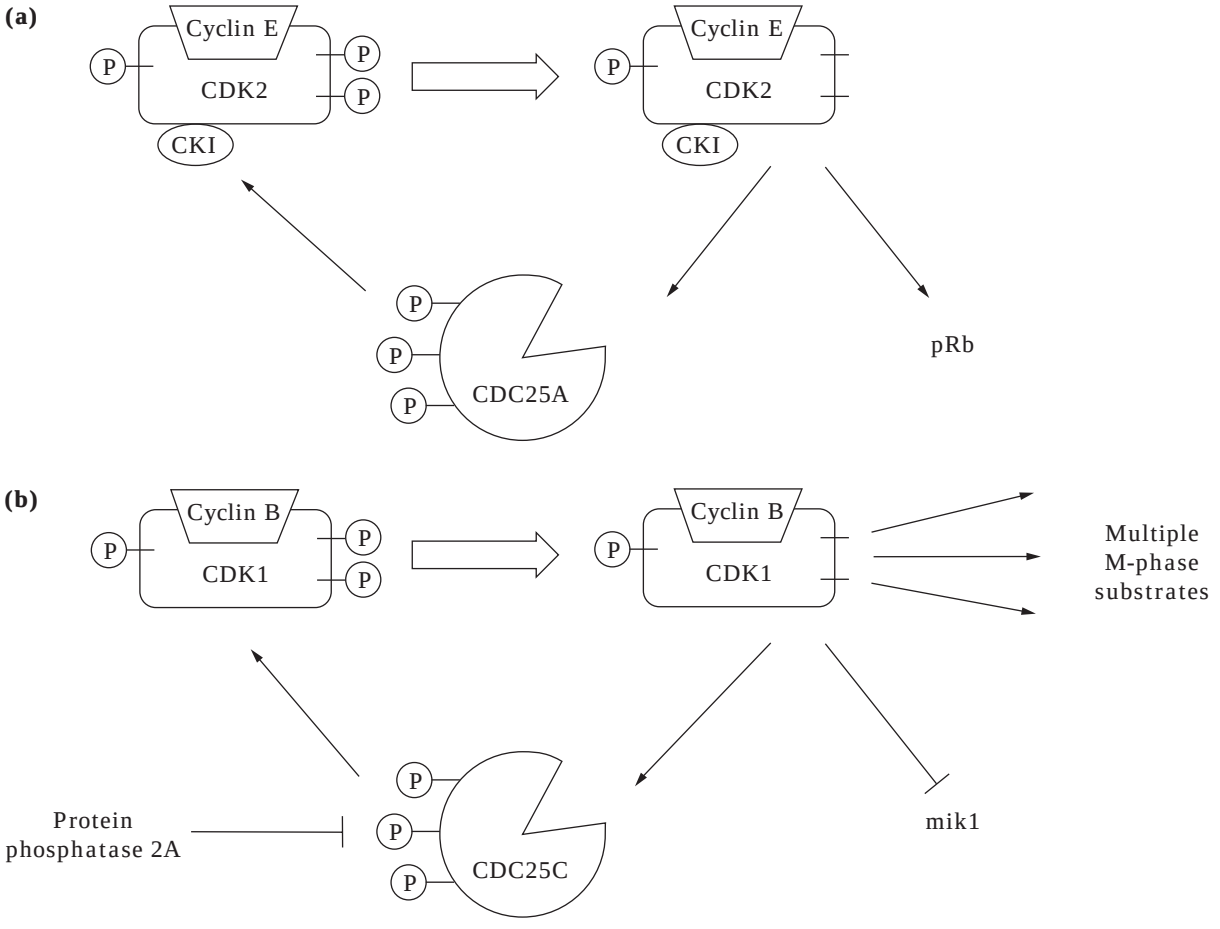

Figure 4. The S- and M-phase entry mechanisms. The positive feedback mechanisms that trigger the entry into S phase (**a**) and mitosis (**b**). The transition to S phase is triggered when an active cyclin E–CDK2 complex activates the Cdc25A phosphatase, which in turn activates more cyclin E–CDK2 complexes, causing a sharp rise in active complexes. These complexes then phosphorylate pRb to stimulate the release of transcription factors. The M-phase transition is triggered by a positive feedback mechanism between cyclin B–CDK1 complexes that is similar to that described in (**a**). In addition, the active cyclin B–CDK1 complex inactivates the mik1 kinase, which phosphorylates the complex on an inhibitory residue, thus contributing to the steep rise in cyclin B–CDK1 activity.

the inhibition of both cyclin D–CDK4 and cyclin E–CDK2 complexes to prevent entry into the S phase. Additionally, p21 also functions to oversee the proper repair of DNA by interaction with PCNA. PCNA is required for both DNA synthesis and repair. When bound with p21, PCNA is no longer able to interact with polymerase-δ, thus preventing DNA synthesis, however, the DNA repair function remains unaffected by the inhibitor (16). Therefore, p21 must inhibit both CDK activity and interaction between PCNA and polymerase-δ in order for DNA repair to be carried out before advancing to the S phase.

S Phase and G_2 Progression. Shortly after the cyclin E–CDK2 complex triggers entry into the S phase, cyclin E is degraded and CDK2 interacts with cyclin A. There is evidence that cyclin E may be degraded in a ubiquitin-mediated pathway, as in budding yeast, but this has not been confirmed (91). The cyclin A–CDK2 complex is localized in the nucleus where it associates with p107, p130, and E2F (17). Interacting with E2F allows the kinase to phosphorylate the DP1 subunit of the transcription factor complex, which inhibits its DNA binding capability (92). This suggests that when cyclin A synthesis begins in early S phase, it aids in halting the transcription of genes triggered by the E2F complex in the late G_1 phase. No other substrates of this cyclin–CDK complex have been identified except for helicase RF-A, which is one component of the DNA synthesis machinery (35).

Upon completion of DNA synthesis, CDK2 is degraded and cyclin A forms a new complex with CDK1 (93). It is not known if this complex has any function in the G_2 phase; however, its activity has been implicated in triggering initial events that occur in mitosis. During G_2, cyclin B begins associating with CDK1 in the cytoplasm and is transported to the nucleus just prior to mitosis. Mitosis begins when the cyclin B–CDK1 complex is activated, and it has been

suggested that a checkpoint mechanism exists that prevents activation of this complex until duplication of the centriole has been completed (94). One model that describes this transition involves the regulation of Cdc25C activity by downregulating protein phosphatase 2A (PP2A), which controls Cdc25C activity (15). Signals could be initiated from the DNA replication machinery or from the proper organization of chromatin, which would inhibit the action of PP2A. This allows Cdc25C to become activated and dephosphorylate the inhibitory residues on CDK1, causing its activation. A positive feedback loop is then initiated (Fig. 4b), whereby active cyclin B–CDK1 complexes activate more Cdc25C and, in budding yeast, inactivate the Wee1 kinase by phosphorylizing a residue that inhibits its action (95). This mechanism brings about a sharp transition into mitosis almost immediately after a small amount of CDK1 is activated.

Another mechanism exists that allows cells with damaged DNA to become arrested in G_2. In response to DNA damage, transcription of the CHK1 kinase is initiated. This kinase targets Cdc25C and phosphorylates the serine-216 residue, which allows formation of a binding site for the 14-3-3 protein that inhibits Cdc25C activity (96). This then allows the DNA repair machinery to work because the cyclin B–CDK1 complex can not be activated by cdc25C.

Supervising the Order of Events in Mitosis. The point when the cyclin A–CDK1 complex is most active occurs just after the cell enters into mitosis, which coincides with nucleation of the centrosomes and the formation of the long microtubular extensions of the mitotic spindle. Indeed it has been shown that cyclin A–CDK1 activity has a profound affect on the nucleating ability of the centrosomes in *Xenopus* extracts (97). Once spindle formation is complete, cyclin A begins to be degraded and the activity of cyclin B–CDK1 complexes takes over. This complex is either indirectly or directly involved in regulating almost all of the structural reorganization that takes place during mitosis.

Chromosome condensation begins in prophase when cyclin B–CDK1 phosphorylates histone H1, transcription factors, and several other proteins (98). Phosphorylation of these proteins is thought to weaken the interaction between these proteins and the DNA, allowing the chromosomes to pack more tightly (21). In addition, after formation of the mitotic spindle is complete, the cyclin B–CDK1 complex reduces the nucleating ability of the centrosomes, which causes the microtubules to shorten to a length suitable for the alignment and separation of the chromosomes (35). The breakdown of the nuclear envelope, which marks the beginning of prometaphase, and the reorganization of the cytoskeleton are also brought about by phosphorylation. The nuclear lamina are present in a hypophosphorylated form in an intact nucleus, and when phosphorylated by the cyclin B–CDK1 complex, the lamina network breaks down, contributing to nuclear disassembly (99). Lamina phosphorylation itself is not sufficient to achieve disruption of the nucleus, however, and these mechanisms remain unclear (56). Caldesmon has also been shown to be a substrate of the mitotic CDK complex, and microtubular reorganization ensues after its phosphorylation. Caldesmon binds to actin and calmodulin, and its phosphorylation weakens its affinity for actin, causing the microfilaments to dissociate (23). This process causes the cells to take on a round shape that is characteristic of anchorage-dependent cells undergoing mitosis. The activity of the cyclin B–CDK1 complex is also responsible for repressing the formation of the contractile bundle until the cell enters anaphase (100). The CDK1 complex phosphorylates myosin, which prevents its association with actin filaments so the contractile bundle is unable to form. This inhibitory function of the CDK complex stays in effect until cyclin B is destroyed in the ubiquitin degradation pathway. The activity of the cyclin B–CDK1 complex is, ironically, responsible for the initiation of its own destruction (101), which stays in effect until this pathway is shut down in late G_1, possibly by the action of the cyclin E–CDK2 complex (102).

The final regulatory mechanism that exists in the cell cycle is a checkpoint that prevents the onset of anaphase until several other structural events have taken place in the cell. Some of these events include the assembly of a bipolar spindle, attachment of the chromosomes to the spindles through the kinetochore, and the migration of the chromosomes to the metaphase plate. This suggests that proper completion of these processes is somehow monitored to ensure that anaphase does not begin prematurely (24). Several experiments (recently reviewed in Ref. 26) suggest that one of two events signals that the cell is ready to undergo the chromosome separation of cell division. These events are either the attachment of the chromosomes to the mitotic spindle (27) or the presence of tension on the kinetochores due to their attachment to a bipolar spindle (28). Because all the structural reorganization processes that occur in mitosis depend on the successful completion of the other events, failure to complete any one of these processes could result in the failure of the signaling event to occur. This would then stimulate a cascade of phosphorylation events, culminating in cell cycle arrest in mitosis.

Understanding Cell Cycle Regulation through Mathematical Modeling

Understanding the complex array of biochemical events we have outlined can be difficult at times. Moreover, our knowledge of the controls responsible for cell cycle regulation is rapidly becoming more and more complicated. This complexity makes it extremely difficult to understand the mechanisms involved through logical thinking alone. Mathematical modeling has been used for the purpose of explaining the various physiological events that are commonly observed in different situations, and the events observed in *Xenopus* oocytes and yeast cells. The cell cycle controls discussed in this review have been described for animal cells. However, the majority of initial experiments on the cell cycle were carried out in yeast cells and in *Xenopus* oocyte extracts. The components that make up the control systems in these organisms are largely identical to those of animal cells, and many findings resulting from studies on these organisms have been extrapolated to apply to animal cells. An initial review of the literature would suggest that the control systems in these organisms are

different; however, this is not the case—only the terminology used to represent the components differs. The cell cycle nomenclature used in these organisms has been reviewed elsewhere (35,56).

Modeling of the molecular controls that are thought to control the cell cycle in *Xenopus* oocytes (29) and yeast cells (30,103,104) has been done in order to determine the effect of changing the activity of various components of the regulatory network. We now believe that progression through the cell cycle is governed by the activity of cyclin–CDK complexes, in other words, a sharp rise in the complex's activity results in a transition to the next phase. The aim of the molecular modeling done by Novak and Tyson was to determine whether the control mechanisms presented here could be used to describe the observed behavior of cells in a variety of situations, or more simply stated, to compare theory with experiment. In order to do this, a set of equations (one for each component of the system) was generated, based on the mechanisms described, to describe the rate of change of each component as a function of time by translating the proposed control mechanisms into simple reaction rate equations. The resulting set of differential equations was then solved using numerical techniques; the activity of the cyclin–CDK complexes could be followed with time, and the sharp oscillations in complex activity could be varied. Because sets of equations commonly contain more than one solution (depending on rate constants and initial conditions used), phase-plane plots were constructed. Observation of limit-cycle-type behavior in these plots indicates an oscillatory solution that is characteristic of proposed cell cycle control (see Refs. 30 and 105 for details). This type of model is easily solvable by today's personal computers and has been successfully implemented to describe the observed behavior of a variety of yeast cell cycle mutants (103,104) and embryo and oocyte maturation (29).

IMPLICATIONS FOR ANIMAL CELL CULTURE

The use of large-scale cultures of animal cells is becoming increasingly important as the demand for their biological products grows. Animal cell cultures are used for the production of many different products of diagnostic and therapeutic value, including vaccines, monoclonal antibodies, and in some cases, the cells themselves (for example, to replace the function of damaged tissue). Determining the culture conditions that optimize the production and secretion of proteins is therefore of utmost importance in meeting these demands. Consequently, the key to designing such systems is not only determining the kinetics of growth, secretion, and proliferation, but also understanding how the cell cycle regulates certain cellular processes. The heterogeneous nature of cell populations has made it extremely difficult to obtain these data. Various mathematical models have been developed to describe cell behavior under different conditions; however, they are, for the most part, unable to account for the heterogeneous nature of cell populations and usually do not provide insight into variations introduced by the cell cycle. One model used to describe cell growth within a heterogeneous population of cells, known as population balances, has been developed (106–109). However, the implementation of this approach has been hampered by the difficulty in obtaining the single-cell parameters necessary for its use.

These problems are being tackled through the development and improvement of tools such as flow cytometry and fluorescent markers, which allow the examination of single-cell parameters within a heterogeneous population. Flow cytometry is a very sensitive tool that allows one to simultaneously obtain several single-cell parameters related to growth physiology from a large number of cells in the population. Collecting these data allows one to determine the size, DNA content (and thus cell cycle position), and protein content (when the protein is conjugated to a fluorescent marker) of individual cells in a population. Many flow cytometric studies relating the cell cycle to optimization of cell culture performance are available in the literature. Several of these analyses and their findings are outlined next.

Cell Cycle–Dependent Protein Accumulation

In the area of cell cycle–dependent protein accumulation, hybridoma cells have received the most attention because they are widely used in the production of monoclonal antibodies (MAbs). Numerous studies have suggested that lower rates of growth result in higher levels of protein production (110–112) (see also papers referenced in Ref. 113). It has been argued that because populations growing at slow rates have a larger fraction of G_1 cells, the G_1 phase must be a period of enhanced protein production and secretion. However, few studies have been done to give insight into the mechanism for this behavior. Additionally, other studies have been done that show a positive correlation between growth rate and protein production (briefly discussed in Ref. 113). These variations in response observed by different researchers may be explained by the fact that the overall growth rate of a culture depends on both cell growth and cell death. This means that the same overall growth can be observed in two cultures with different rates of cell loss and cell growth. The conclusion that can be made from the examination of these different investigations is that it is important to be aware of the different methods used to quantify growth and protein production in cell cultures because they may result in conflicting results.

Al-Rubeai and colleagues used flow cytometric results obtained from synchronous cultures and concluded that the rates of both immunoglobulin synthesis and secretion are at a maximum at the G_1–S transition (114). The synchronization of the culture was achieved by the addition of thymidine, which arrests cells prior to entry into the S phase. This type of analysis presents another problem, however, because factors used for cell cycle arrest have been shown to alter cell metabolism (115); therefore these results should be viewed with care. A more complete series of studies on rates of MAb production during the cell cycle was performed by Kromenaker and Srienc. The first study involved using flow cytometric data obtained in asynchronous cultures and applying these data to population balances to find the single-cell rates of protein accumulation

in various cell cycle phases for both antibody-producing and non-antibody-producing cell lines (116). It was found that during the early G_1, producer cells with low protein content have a specific rate of accumulation of protein approximately 3–5 times greater than the specific rate observed for the remainder of G_1 cells. This indicates that the rate of protein synthesis is much greater than the rates of protein degradation and secretion in G_1. The S phase of the cell cycle was shown to a have a low specific rate of protein accumulation that remained relatively steady throughout this period. Extending this analysis to the $G_2 + M$ phase yielded a negative specific rate of protein accumulation, indicating that protein is lost due to secretion and degradation during this period of the cell cycle. From these findings, it was concluded that the disruption of the secretion system that occurs during the division of the cell accounts for the extremely high rate of accumulation observed in early G_1 because the transport system probably has not had time to recover from its disruption.

A later report by Kromenaker and Srienc described the relation between growth rate and secretion rates during the cell cycle as determined using single-cell data and population balances (117). Lactic acid was used as a growth suppressor, and the concentrations were changed to vary the specific growth rate. This study brought several previously unconsidered factors to light. By analysis of the DNA distribution of the populations at different growth rates, it was found that the lengths of all the cell cycle phases were increased by the same factor that the specific growth rate was increased. This is in direct contrast to other studies that suggest that the increase in productivity is due to the increase in the length of the most productive phase of the cell cycle. Secondly, the application of population balances in this study revealed that the net specific rate of antibody synthesis is independent of growth rate. Additionally, the specific secretion rate of $G_2 + M$ cells is greater than the rate in the other two phases and remains constant with decreasing growth rates. In contrast, the specific secretion rates for G_1 and S increase with decreasing growth rate. These findings are consistent with the hypothesis that the disruption of the secretion pathway during cell division results in lower secretion throughout G_1, until the Golgi apparatus has had sufficient time to reassemble. During this time, antibodies accumulate in the cell until they can be secreted during $G_2 + M$, before the Golgi apparatus is disrupted once again. Thus, at lower growth rates, more time is spent in G_1, so an increased secretion rate is observed because the cells have had time to recover from cell division. A subsequent study tracked the amount of cell surface antibodies as a function of DNA content (118). Because prior experiments determined that the amount of cell surface antibodies observed on the membrane is a good measure of the rate of secretion, these data were used to determine the pattern of secretion during the cell cycle. The results obtained from this method also agreed with the hypothesized regulation of secretion already described.

Understanding the regulation of foreign genes in animal cells is also of great interest because recombinant DNA is commonly used to express proteins of interest in immortal cell lines such as Chinese hamster ovary (CHO) cells. This provided the motivation for studies in which the expression of foreign genes in animal cells was tracked throughout the cell cycle. One study tracked the secretion of tissuelike plasminogen activator (tPA) in recombinant CHO cultures synchronized by fluorescence-activated cell sorting (FACS) based upon DNA content (119). This study shows that secretion of tPA reaches its maximum near late S phase, while the increase in this protein is maximum in G_1. These results are fairly similar to those obtained by Kromenaker and Srienc using different methods. Gu and colleagues also measured the expression of foreign β-galactosidase during the cell cycles in recombinant CHO cells (120) and in recombinant mouse cells (121) and hypothesize that control of foreign gene expression is promoter dependent. These particular studies, however, showed that the use of either the cytomegalovirus (CMV) promoter or the mouse mammary tumor virus (MMTV) promoter causes the production of β-galactosidase mainly in S phase.

Cell Cycle–Dependent Behavior of Culture Systems

There is a steady increase in the number of reports in the literature that look to the cell cycle to explain various phenomena such as differing growth rates between cultures and cell death due to shear stress in bioreactors. For example, the effect of different inoculation sources was examined by Al-Rubeai et al. (122). Two cultures that were inoculated with cells from either the exponential or stationary growth phase were examined using flow cytometry. The culture inoculated with cells from the exponential phase grew at a much greater rate than the other culture and therefore reached the death phase more quickly due to nutrient exhaustion and buildup of toxins. Analysis of the cell cycle, cell size, and mitochondrial activity of the cultures revealed differences among the cultures. For instance, the slower-growing culture was found to have a larger proportion of its cells in G_1, while the culture with the greater growth rate had a larger fraction of its cells in S. Because G_1 cells are generally smaller than the S-phase cells, the culture with a larger fraction of cells synthesizing new DNA uses more nutrients than the one with smaller cells. Additionally, cultures with elevated mitochondrial activity were also shown to have a greater capacity for proliferation. These findings lead the researchers to conclude that examination of these parameters can provide a means of predicting how the culture will behave and a means of explaining variations in the growth patterns of cultures.

It is also of great interest to determine how cells behave in different culture systems. For cells in continuous culture (123), it has been found that the fraction of cells in the G_1 phase decreases with increasing growth rate, while the fraction of cells in the S phase increases. As expected, the G_1 phase accounts for most of the resulting variability in the lengths of the cell cycle phases; however, the S phase is affected slightly more than the G_2 and M phases. A more detailed analysis of the cell cycle was performed in cultures containing microcarriers, and the fraction of contact-inhibited cells was determined and compared to a model (124). Microcarriers are commonly employed in cultures of anchorage-dependent cells, such as CHO cells, because

these types of cells must be attached to a surface in order to proliferate. When the culture grows to the point where there is no longer any surface area available for newborn cells, contact inhibition occurs, and a portion of the cells cease to proliferate even when provided with an ample supply of nutrients. Analysis of this system yielded the distribution of cells in the cell cycle during the lag phase, exponential growth, and confluency. During the lag phase, the culture is predominantly in the G_1 and/or G_0 phases and rapidly enters the other cell cycle phases upon reaching exponential growth. As the culture reaches confluency, the culture gradually shifts back to predominantly the G_1 and/or G_0 phases; however, a portion of the cells continue cycling. These findings are similar to those of suspension cultures. Furthermore, a method was developed to determine the fraction of cells affected by contact inhibition, and the results showed good agreement with a model that had been developed.

Furthermore, when culturing animal cells in large-scale bioreactors, the cells can be injured due to the shear stress that results from agitation and sparging. There have been several studies that examined the mechanism of cell damage and sought to minimize injury to the cells through the use of various shear-protecting agents such as Pluronic F-68 and serum. However, there have been relatively few studies that examine the effect that these forces may have on cell metabolism and growth. It is evident that shear forces have an effect on the overall growth rate of the culture due to an increase in cell death. Lakhotia and coworkers (125) analyzed the rate of DNA synthesis and the cell cycle phase distributions of cultures grown in small-scale bioreactors with gas sparging and varying agitation intensities to determine the effect that these forces may have on growth kinetics of the surviving cells. Measurement of the kinetics was accomplished by measuring the uptake of BrdU and the DNA content distributions of the surviving cells with the aid of flow cytometry. They determined that, in cultures exposed to high agitation, the fraction of cells in the S phase increased by up to 45%, while the fraction of cells in G_1 decreased by up to 50%, compared to control cultures. The simultaneous analysis of the DNA synthesis rate suggests that the change in the cell cycle phase distribution is due to an increase in the DNA synthesis rate. Additionally, when cultured in the absence of shear stress, the apparent specific growth rate of the cells previously exposed to the shear forces was initially higher than and later the same as that of control cells. It was also shown that an increase in the agitation intensity resulted in a further increase of the DNA synthesis rate. By subjecting cells to extreme, short-term stresses induced by turbulent capillary flow, it was determined that larger cells are more susceptible to damage than smaller cells (126). This conclusion was made based on the preferential disappearance of S and G_2 cells when passed through the capillary. Another possible explanation for these results is that an apoptotic response triggered by the shear forces caused a decrease in the size of the cells, but verification of this hypothesis is difficult.

Engineering the Cell Cycle

Once a more complete picture of how the cell cycle regulates cell physiology and metabolism has been painted, it can possibly be manipulated in culture in such a way that cells will perform desired processes at an optimal level. For example, controlling the regulatory mechanisms of cell growth and proliferation, or controlling the rate at which cells advance through the cell cycle can lead to the enhancement of protein production, improved economic feasibility, and ease of downstream processing. Indeed there have been several studies published to date that address these issues and will undoubtedly lead to further examination of directing cellular operations through the engineering of the cell cycle in cell cultures.

Cells in culture are subjected to many different forms of stress that may ultimately lead to cell death. Cell death can be caused by external factors such as hydrodynamic forces that may cause the cell to rupture. Additionally, the response to certain stimuli such as limitation of glutamine, glucose, or serum or the buildup of toxins may result in programmed cell death, called apoptosis, which is regulated by some of the same pathways as is the cell cycle. When in culture, cells reach their maximum cell density in a few days, after which the process of programmed death is induced in the majority of the cells (127). The discovery that the product of the protooncogene *bcl-2* is able to suppress apoptosis lead to its use in cell culture to prolong the productive period of the culture (128–131). Several recent studies show that cells expressing this gene increased MAb production by 40% (129) and prolonged the viable culture time by up to 4 days by delaying the onset of apoptosis for 2 days (131). Additionally, it was determined that the increase in MAb production was equally due to both the prolonged survival of cells and the increase in protein production per cell (131). The expression of the *bcl-2* gene also allows cells to be cultured with a significant decrease in serum supplementation (130). Specifically, *bcl-2* overexpressing cells could maintain high viable cell concentrations for up to 4 days, while the control culture lasted only 1 day when supplemented with 0.5% serum. Moreover, cells cultures supplemented with 9% serum with additional 2% serum fed after 4 days sustained productivity for 10 days, while the control culture underwent apoptosis after 4 days (130). These experiments show that the cell cycle controls can be bypassed when expression of the appropriate gene is induced in culture.

A similar approach has been used in CHO cells to bypass the cell cycle controls that require the presence of growth factors for efficient proliferation. The observation that cells stimulated by growth factors possess elevated cyclin E levels led researchers to transfect the CHO cells with a cyclin E expression vector (132). The expression of this gene in cells cultured in protein-free media resulted in cell proliferation and levels of cyclin E, cell morphologies, and cell cycle phase distributions comparable to those obtained in growth-factor-stimulated cells. An approach related to the one just described employed expression of the transcription factor E2F-1 in protein-free media to bypass the growth-factor requirements for proliferation (133). Although the desired effect of eliminating growth-factor dependency of the cells was achieved in both cases, the two approaches had different effects on several cellular properties. For instance, the cells expressing cyclin E rapidly round up and move into suspension, whereas the

E2F-1 cells adhered more tightly to the surface. Additionally, the same doubling time was observed for both cell types; however, the cyclin E cells resided in G_1 for approximately 20 min longer, while the S phase was reduced by 2 h as compared with the E2F-1 cells. Finally, the expression of certain proteins varied between the two cell types. The expression of cyclin A was shown to be 2 times higher in the E2F-expressing cells, and these same cells expressed a greater number of proteins at higher levels than wild-type cells than did the cyclin E–expressing cells. These results present two different ways of circumventing growth-factor-dependent controls and show different effects on cellular processes. Additionally, these findings may give some insight into the roles that these factors play in the regulation of the cell cycle.

Another recent study involved increasing protein production in cultured cells by arresting cells in G_1 (134). This was done by transfecting CHO cells with a gene coding for either p21, p27, or p53175P controlled by a tetracycline-regulated promoter. The p53 protein used in this study is a mutant that has lost its apoptotic function, resulting in a culture that undergoes G_1 arrest rather than programmed cell death. The culture was allowed to proliferate until it reached the desired cell density, after which expression of the cell cycle arrest molecules was stimulated, thus blocking proliferation. This sort of cytostatic process has several advantages over other processes involving uncontrolled growth of cultures, including slower rates of nutrient exhaustion, higher levels of protein production, and low genetic drift.

Gene Therapy

A firm grasp of the events that control the cell cycle will also yield significant advances toward the treatment of various illnesses including cancer and genetic disorders. The connection between the cell cycle and some cancers has been reviewed elsewhere (18,65,135,136). Many genetic disorders that alter the way cells function result from either the absence of an enzyme or the presence of a flawed enzyme. This situation may be remedied by the introduction of the appropriate genes into a target cell, a procedure known as gene therapy. Although cells that have incorporated the desired gene into their genome have displayed the desired effects, this technique is limited by low rates of gene transfer (reviewed in Ref. 137). Numerous studies have attempted to uncover the factors that determine transfer efficiency, resulting in the hypothesis that gene transfer is cell cycle dependent (reviewed in Refs. 138 and 139). More specifically, the most widely used method for gene transfer is recombinant retroviruses, and genes introduced into cells in this manner are not integrated into the host's genome until mitosis. It has been postulated that nuclear envelope breakdown is necessary for the viral integration complexes to act. Based on these studies, Andreatis and Palsson suggested that transfer efficiency depends both on cell cycle and retroviral life cycle events and developed a mathematical model describing the interplay between the two (140). This model aided in the design of experiments that allow the direct measure of intracellular retroviral decay (138). Furthermore, they developed a method to monitor the cell cycle dependence of gene transfer by using the transduction of β-galactosidase as a marker. Thus it was determined that almost all transduced cells show up in the early G_1 phase, supporting the hypothesis that only mitotic cells are susceptible to gene transfer (139). These studies reveal the importance of the kinetics of both retroviral decay and cell cycle progression of the target cells in the efficiency of gene therapy.

CONCLUSIONS

An overview of the mechanisms by which cells respond to different environmental stimuli has been presented. It is evident that even after the commitment to synthesize new DNA is made, the cell possesses the ability to monitor and direct internal events. For instance, the transcription and activation of key enzymes are regulated by cell cycle controls to ensure that necessary cellular processes are carried out successfully. The existence of this type of control suggests that almost every cellular process is somehow linked to the cell cycle machinery to guarantee the proper coordination of events throughout the cell cycle. A failure to maintain the order of these events may result in cell death or a disruption of normal cell behavior. Thus, a more complete understanding of factors that have an effect on cell cycle regulation would allow one to gain insight into better directing the cellular processes bound to cell cycle control. This fact is characterized by the recent increase in the number of studies that have focused on better understanding the components involved in directing cell division and their influence on fundamental cellular processes. It seems that obtaining a better understanding of the cell cycle and understanding how the cell cycle directs fundamental components of cell growth, such as protein production and secretion, may provide the missing link that will allow researchers to not only improve cell culture, but develop treatments for many types of ailments and dysfunctions such as cancer, which are indubitably cell cycle related.

OUTLINE

INTRODUCTION

Currently, biological products of commercial interest are excreted by producer cells into the surrounding medium, but the larger proportion of cellular products, many of which have a real or potential value, remain inside the cell (1). These intracellular products must be released into the medium before they can be recovered and purified. There are several strategies for accomplishing this: the cells can be genetically engineered to excrete the products, the cell wall can be made more permeable, cell lysis may be induced, or the cell wall can be disrupted. In preparative-scale applications the disruption of the cell wall is the most common method.

The cell wall is a rigid and complex structure that protects the cell from the environment, maintaining cell shape and providing osmotic stability, while performing biochemical functions of regulation and selective control of the exchange of nutrients and metabolites with the medium. However, microbial cell wall characteristics vary widely in composition and structure according to species; it is important to recognize the effects of these differences on the strength of the wall and their implications which disruption techniques should be adopted. Mammalian tissues, halophilic bacteria (which do not possess a true rigid cell wall), and the Mycoplasma bacteria (which lack a wall) have the lowest mechanical strength and can be easily lysed under osmotic stress in hypotonic media. The more structured and stronger cell walls in some bacteria and fungi are more difficult to disrupt, and more energy is required to overcome the toughness of the wall. Moreover, the cell age and physiological state are also important differences that contribute to the strength of a given species' cell wall.

THE CELL WALL

Chemical Composition and Structure

The diversity of cell wall composition and structure is well documented (2–5). Purified cell walls (6) can be hydrolyzed, and the different components can be identified.

Bacterial Cell Walls. Bacteria differ with respect to their ability to retain a crystal violet–iodine stain when treated with organic solvents (alcohol or acetone). Accordingly, they can be classified into two main groups: Gram positive if they retain the stain, and Gram negative if the stain is not retained. This difference reflects the diversity in cell wall composition and structure as well as differences in biochemical, physiological, or genetic features. Common to all cell walls is the element of rigidity, which is provided by a supramolecular structure known as a peptidoglycan, or murein (Fig. 1). This is a regular heteropolymer of alternating *N*-acetylglucosamine and *N*-acetylmuramic acid (the lactyl ether of *N*-acetylglucosamine) linked by β-(1–4) glycosidic bonds in linear chains of up to 65 disaccharide residues. A tetrapeptide side chain, consisting of at least three amino acids (some of the unusual D-amino acids), is attached to the carboxyl group of the *N*-acetylmuramic acid. The tetrapeptide chain of one polysaccharide chain is linked to a tetrapeptide chain of an adjacent polysaccharide chain, either directly (the terminal D-alanine of one to the *meso*-diaminopimelic acids in position 3 of the other, as in *Escherichia coli*), or indirectly through a pentaglycine peptide (the terminal D-alanine of one to the L-lysine in position 3 of the other, as in *Staphylococcus aureus*). Not all pairs of these tetrapeptide chains are involved in the cross-linking of the glycan chains; the degree of cross-linking, as well as the nature of the amino acids in positions 2 and 3 are dependent on the species.

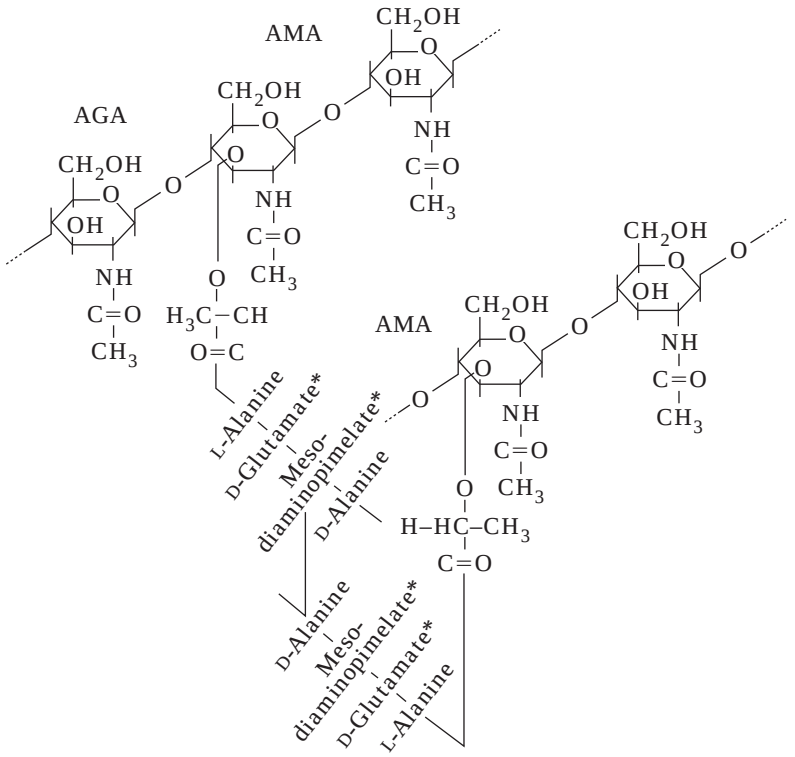

Figure 1. Structure of the building blocks of peptidoglycan in *E. coli*. The nature of the amino acids at positions 2 and 3, as well as the degree of cross-linking differ among species. AGA, *N*-acetylglucosamine; AMA, *N*-acetylmuramic acid.

Murein is the skeletal component of the cell wall in Gram-positive bacteria; it has a multilayered architecture that is 20–80 nm thick. In addition, teichoic acids (polymers of glycerol or ribitol phosphate) are associated with murein on the external side of the wall and are unique to Gram-positive cells. Teichoic acids do not contribute to wall strength but provide antigenic activity or serve as an attachment anchor. Gram-positive cell walls are devoid of significant amounts of lipids and proteins.

In Gram-negative bacteria the cell wall is thinner and more complex and stratified. Mechanical resistance is provided by an inner layer of murein, which is much thinner than in Gram-positive bacteria. This murein is covered externally by a bilayered lipid membrane, the internal leaflet being lipoprotein, containing phospholipids, and the outer leaflet being lipopolysaccharide (LPS), which has toxic properties and is able to resist the chemical aggressions of the environment.

Fungi and Yeasts. Under the electronic microscope, the walls of fungi and yeasts are seen to have a fibrillar structure that results from the presence of certain components such as cellulose or chitin. The main constituents are homo- or heteropolysaccharides, accounting for more than 80% of the wall, built up from different sugars (mainly D-glucose, D-mannose and *N*-acetylglucosamine, but also galactose, galactosamine, fucose, xylose, etc.). Usually, pairs of carbohydrates dominate the composition of the fungal walls, and a vast majority of fungi have a chitin–glucan combination, whereas the majority of yeasts have a glucan–mannan combination. Cellulose is also dominant in the walls of many lower fungi. Glucans are usually considered to be the main skeletal component in yeasts and consist of linear chains of β-(1–6)-linked D-glucose and side chains of D-glucose linked to the first ones through β-(1–3) bonds (Fig. 2a). Chitin is a polymer of *N*-acetylglucosamine and is always found in yeast cells, although in small amounts (Fig. 2c).

Lipids and proteins are also present in fungi and yeasts cell walls in different amounts. Proteins are now regarded as true structural wall components. In yeasts the wall appears stratified into two layers: the protein is associated with mannans in the form of mannoproteins that form an external layer covering an internal layer of glucans (Fig. 2b).

Algae. Cellulose is also the main skeletal component of the algal cell wall, but xylans and mannans (depending on which sugars are the most abundant) are also found. Algae differ considerably from the fungi with respect to cellulose content and crystallinity. The physical aspect is also fibrillar, as with other eukaryotes.

Effects of Upstream Conditions

The conditions that affect the synthesis of the cell wall constituents during the growth process will be reflected in the strength of the cell wall. For instance, cells of *E. coli* grown in a complex medium are less easily disrupted than cells grown in a simple medium (7). The ease of disintegration also depends on the batch growth of *E. coli*; the cells are weaker during the logarithmic phase and become stronger in the transition to the stationary phase (1,11). This corresponds to an increase in the murein thickness and cross-

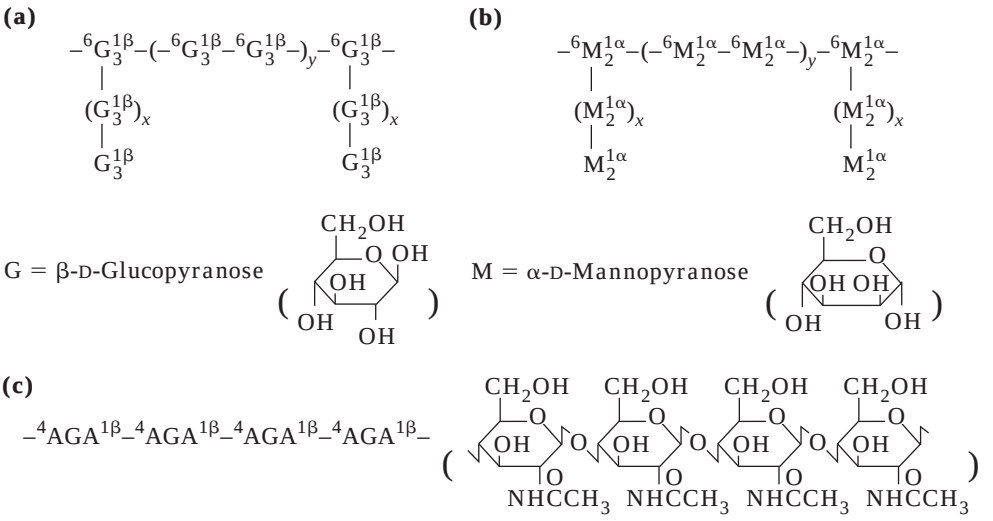

Figure 2. Structure of the building blocks of (**a**) glucan, (**b**) mannan, and (**c**) chitin in yeasts.

linking (8,10,11). A quantitative relationship has been established between mean cell strength and cell length and degree of cross-linkage (9). A higher specific rate of growth, as attained in continuous culture of *Candida utilis*, leads to a weaker cell wall, whereas a lower growth rate, as in a batch operation, allows the cells to build a stronger cell wall (12). Wall thickness and resistance to disruption in bakers' yeast increase with age, possibly due to exhaustion of the carbon source (13). Bud scars, much more frequent in a younger yeast population, may introduce local areas of lower wall strength (12,13). The compressive force required for the disruption of brewers' yeast cells was measured by using a micromanipulation technique and ranged from 40 μN for cells in the exponential phase to 90 μN for cells in the stationary phase (14).

ASSESSMENT OF THE DISRUPTION YIELD

Suitable analytical techniques are required to assess the extent of cell disruption in order to develop models for process selection, scale-up, and optimization. Different methods have been used to quantify the degree of disintegration at specified conditions; each one has its advantages and drawbacks. The number of disrupted cells must be estimated, which can be done by direct counting of nondisrupted cells or, indirectly, by determination of any intracellular metabolite whose quantitative release into the medium is proportional to the number of disrupted cells.

Direct counting of suitably diluted samples can be achieved by plating out techniques (14), microscopic counting (16,17), electronic counting (18), or using an analytical disk centrifuge (19).

Plating out techniques are time consuming, and only viable cells can be counted. However, nonviable intact cells can be present in a significant proportion and are uncountable. The situation is worsened if the cells have a tendency to agglomerate.

Microscopic counting is a faster and simpler alternative. Whole cells in suitably diluted samples of original and treated suspensions are counted in microscope hemocytometers (16,17). However, the counting process, though easier for yeasts, is tedious and difficult with very small bacterial cells, and a distinction between intact cells and cells that have been slightly damaged is generally impossible to make. Proportional counts of stained smears may be advantageous as, for instance, in the case of yeasts (20). By adopting the staining technique of Bianchi (21), it is possible to distinguish among whole intact cells, broken cells contaminated with cytoplasm, and empty debris, at 1,000× magnification. The main difficulty lies in finding a suitable staining technique for the cells concerned.

Electronic particle counters can be used to evaluate the number of whole yeast cells. The Coulter counter, for instance, was used to assess the concentration of yeast cells (18), but it is not a sensitive method for bacteria (22), and the machine tends to be fouled by cellular debris (19).

The analytical disk centrifuge was recently introduced for monitoring the disruption of *E. coli* containing recombinant inclusion bodies (19). This technique provides a size distribution in the homogenate and requires that the size distribution of the inclusion bodies be subtracted from the homogenate sample distribution by numerical or graphical deconvolution of both distributions.

Indirect counting is based on the determination of certain compounds (e.g., soluble protein, enzyme activities) that are released into the solution when the cell wall is broken: the yield of disintegration is the percentage ratio of the released material, R, to the maximum amount, R_{max}, that can theoretically be released into the solution. The most common material that has been used for this purpose is total soluble protein assayed in the sample supernatant (22–24). The "dilution method," using the Biuret method, was based on the comparison of the protein concentrations in the supernatants obtained by centrifugation of diluted and undiluted samples of homogenized suspensions (23). However, dilution interferes with protein solubility (22), because of partial denaturation. The method also fails when the protein is produced as an inclusion body (19).

Overheating, particularly during a prolonged operation to determine R_{max}, can cause thermal denaturation or enzyme deactivation.

Other bioactive products and, in particular, enzyme activities (25) released into the medium can be useful. However, the assessed value of the disruption yield under fixed conditions depends largely on the enzyme selected for analysis, its location within the cell, whether it is bound to membranous materials, and its heat or shearing lability (26), which can affect the values of both R and R_{max}. The most adequate material would be the product to be extracted and isolated, if it can be easily assayed.

Continuous monitoring of the disruption process and the performance of the equipment, particularly if wearing problems are severe, is advantageous. For instance, a relationship between the degree of cell disruption and the temperature increase of a baker's yeast suspension when passing through a mechanical homogenizer can be established. Therefore, by inserting a thermocouple in the homogenizer, continuous monitoring of its performance can be achieved (27).

METHODS OF CELL WALL DISRUPTION

Techniques for cell wall disruption have evolved over the years and are well documented in the literature (27–31). There are both mechanical and nonmechanical methods. Mechanical methods are based on shear forces that deform and rupture the cell wall. Nonmechanical methods induce the lysis of the cell by chemical, physical, or enzymatic means.

Many of these methods were developed for laboratory-scale use, with the objective of purifying biomolecules or organelles while maintaining as much integrity as possible for fundamental studies. For preparative or commercial applications, the strategy is to maximize product release, keeping the biological activity and minimizing the formation of fine cell debris, which can interfere with further downstream operations. The mechanical methods, based on solid or liquid shear, are best suited for this purpose.

High-Pressure Mechanical Homogenization

High-pressure mechanical homogenizers, typified by the APV Manton–Gaulin homogenizer (Fig. 3), have been one of the most widely used devices for the disruption of microbial cell walls in large-scale recovery of intracellular bioproducts. These devices consist of a positive displacement pump capable of generating high pressures to force the cell suspension through an adjustable discharge needle valve under high shear stresses, which disrupts the cells. The body of the valve is positioned against a valve seat by a spring-loaded rod, and the disrupting pressure is adjusted by the load that is applied, hydraulically or mechanically, to the spring. The treated suspension can be either collected or recycled for more passes through the valve.

In an earlier report (23) such a device was used to disrupt baker's yeast, and the degree of disruption was proportional to the number of passes, N, through the valve according to the model (first-order kinetics relative to N),

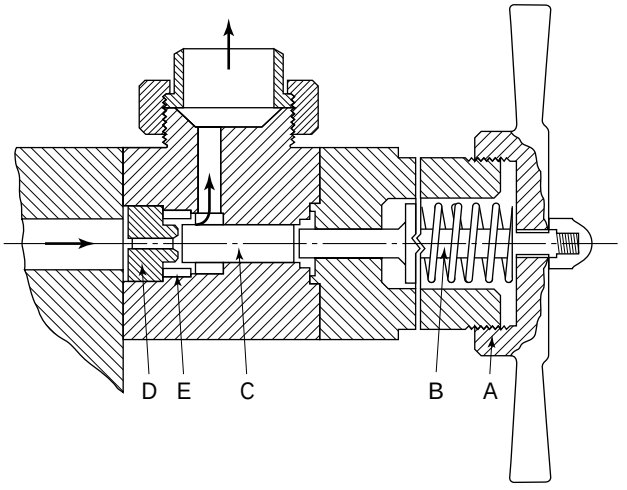

Figure 3. High-pressure homogenizer discharge valve unit. The discharge pressure is controlled by a handwheel assembly (A), which, through a spring-loaded valve rod (B) positions the valve (C) in relation to the valve seat (D). During discharge the material passes between the valve and its seat and impinges on an impact ring (F). *Source*: Reproduced by permission of the Institution of Chemical Engineers from Ref. 23.

$$\ln \frac{1}{1 - X} = kNP^a \tag{1}$$

where $X = R/R_{max}$ is the fraction of disrupted cells, k is a dimensional, machine-dependent (it depends on the geometry of the needle valve) specific rate constant $[(k) = (P)^{-a} = \text{MPa}^{-a}]$; the constant a is a measure of the cell resistance to disruption (the value $a = 2.9$ was reported for baker's yeast, and 2.2 for *E. coli*) and is dependent on the type of organism and the physiologic conditions and rate of growth (12).

Besides the pressure, the type of organism and the cell growth conditions, other variables such as the temperature and the cell concentration affect the specific rate of disintegration. The process has been found to be independent of cell concentration in the range 84–168 g dry matter/L and for pressures extending from 19.6 to 53.9 MPa, although lower protein recoveries for higher cell concentrations at higher pressures were obtained (23). Further studies extended the analysis of the influence of the cell concentration up to 240 g dry matter/L, and no significant effect was detected (32). However, a theoretical analysis based on the turbulence theory of Kolmogoroff (33) showed that the amount of soluble protein release in a Manton–Gaulin homogenizer was dependent on cell concentration according to

$$R = 1 - \exp\{-[(P - P_0)/z]^{\beta}\} \tag{2}$$

where z is a constant, P is the disrupting pressure, P_0 is a threshold pressure, and β is a parameter that depends on cell concentration. More recently, the disruption of *E. coli* in another type of homogenizer, the Microfluidizer (Microfluidics Corporation, Newton, Mass.), was correlated by (34)

$$\ln \frac{1}{1 - X} = kN^b P^a \quad (3)$$

where the exponent b was found to be a function of the cell concentration and the specific growth rate.

The rate of cell wall disruption has been shown to be highly temperature dependent, but a temperature increase when the cells are disrupted can lead to severe thermal denaturation of heat-labile products. An increase of about 2–3 °C (depending on cell concentration) can be expected for every 10 MPa increase in the backpressure of the needle valve (31,32). In fact, the suspension has to be precooled in order to keep the temperature under control, and cooled immediately after leaving the homogenizer. In most cases no losses of enzyme activity or protein solubility were detected if the temperature was not allowed to rise above 30 °C (12,23).

Increased productivity can be attained with higher pressures, allowing the recovery of more product with fewer passes. However, a higher disrupting pressure demands more energy and can cause severe wearing problems in the valve seat. Erosion of the valve seat is, in fact, of great concern in using this type of equipment.

Optimization of the equipment design and operation requires a deep understanding of the mechanisms of cell disruption. Breakage of the cell wall occurs as a result of normal stresses or shear forces developed during the passage of the suspension through the needle valve. One mechanism considers the magnitude and the rate of pressure drop to be responsible for cell breakage (32). A hydrodynamic mechanism in which turbulent eddies of smaller dimensions than the cells cause the intracellular liquid to oscillate with a kinetic energy large enough to rupture the cell (33). Impingement of a high-velocity jet against a flat surface, as occurs in the needle valve when the direction of the jet is suddenly and abruptly changed, has also been considered to be a cause of cell disruption (12,35). In the case of the Manton–Gaulin–type of homogenizers, this led to the redesign of the valve geometry (35); the so-called knife-edge configuration showed the best performance, whereas the flat valve configuration had the lowest yields in the disruption of baker's yeast (Fig. 4).

These homogenizers have proved to be efficient for all types of microorganisms, with high degrees of disruption even with only one pass. Blockage has, nevertheless, remained a major concern in the use of high-pressure homogenizers for the disruption of filamentous microorganisms (36). The use of a Manton–Gaulin homogenizer resulted in a severe degradation of plasmid recovered from *E. coli* (37).

Solid-Shear Methods

Ball mills, or bead mills, originally designed for nonbiotechnological applications, have also been used to disintegrate microorganisms, particularly yeasts. They are the most suitable for scaling up and can be continuously or discontinuously operated. They consist of agitator disks mounted concentrically or excentrically on a motor-driven central shaft inside a grinding chamber (Fig. 5). During operation, the chamber is filled with small glass or stainless steel beads, which are necessary to promote an abrasive action to grind the cells. In continuous operation, a bead retainer (a sieve plate, a vibrating slot, or a special rotating disk) prevents the beads from leaving the grinding chamber. Different models of the Netzsch bead mill (Netzsch Feinmahltechnik, Germany) or the Dyno-Mill (Willy A. Bachofen AG, Basel, Switzerland) have been used.

The mechanism of disintegration is very complex and results from both a liquid shearing and a solid shearing, resulting from the impacts of the beads in a field of intense turbulence. The disruption process can be properly described by a first-order kinetics law (24,38) and, for a batch operation or continuous plug flow system, the integrated rate equation is

$$\ln \frac{R_{\max}}{R_{\max} - R} = kt \quad (4)$$

where R is the amount of protein released in time t, $R_{\max}$ is the maximum amount that could be released if 100% disrupted had occurred, and k is the specific velocity of disintegration (protein released).

For a continuous operation there is a certain degree of backmixing, and n tanks (CSTR) in a series model is a better representation of the hydrodynamics in the chamber. In this case a mass balance to the released protein gives (38)

$$\frac{R_{\max}}{R_{\max} - R} = [1 + (k\theta/n)^n] \quad (5)$$

where $\theta = V/Q$ is the mean residence time, V is the total free volume of the grinding chamber, and Q is the flow rate of the microbial suspension.

Several process parameters affect the yield and the rate of cell wall disruption. Besides the design characteristics of the mill (volume and geometry of the grinding chamber, the number of disks per unit volume of the mill, and geometry and construction materials of the disks), the rate constant is influenced by a number of process parameters such as the agitator speed, cell concentration, bead size, bead load, temperature, and flow rate of the suspension (24,38,39).

The speed of the agitator disks determines the frequency of bead collisions (40) and the intensity of shear, and, within certain limits, the specific rate of disintegration is proportional to the disk tip speed, U (38):

$$k = KU \quad (6)$$

Practical limitations arising from high energy consumption, high heat generation, erosion of the beads, and inactivation of shear-labile products require that the disk tip speeds remain between 5 and 15 ms^{-1}.

The influence of cell concentration requires a more detailed investigation because contradictory results have been reported. The disruption of baker's yeast was reported to be independent of the cell concentration in the range of 4–20% w/v on a dry matter basis (25), as expected for a first-order process. However, others (38,39) have re-

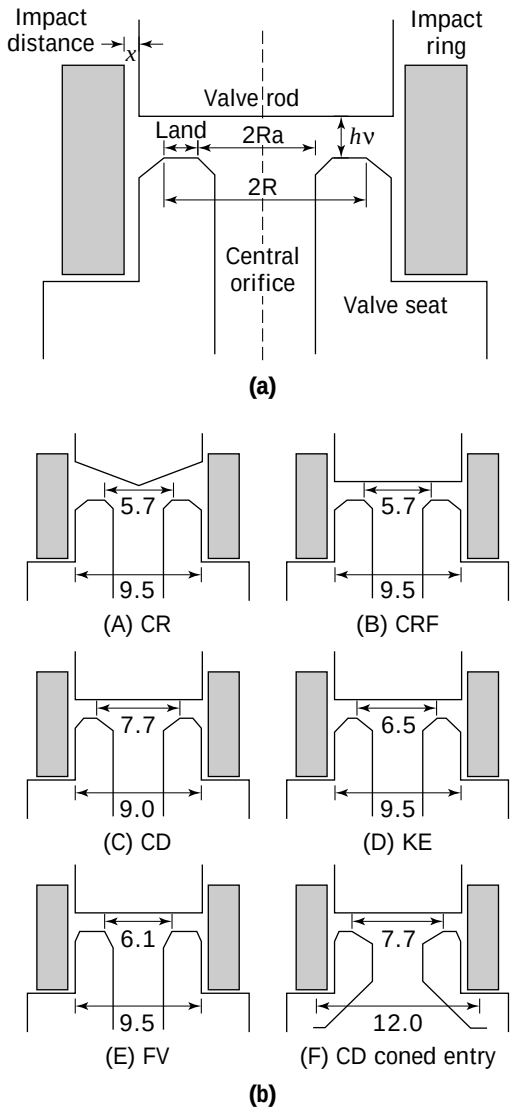

Figure 4. (**a**) Schematic diagram of a typical valve unit. ported a maximum protein release for cell concentrations of 35–40% (wet wt), and decreasing thereafter, depending on the disk materials (38), such effect being more pronounced when the agitator speed was low (39). The viscosity of the suspension increases with the cell concentration and is further increased with the progress of the disruption process, therefore increasing the rate at which the turbulence is damped out (38). However, insufficient data are generally generated or reported regarding the rheology of the suspension. The optimal cell concentration varies from case to case, and one must also consider that less heat is generated but the power consumption per unit weight of treated cells is higher for lower cell concentrations, and

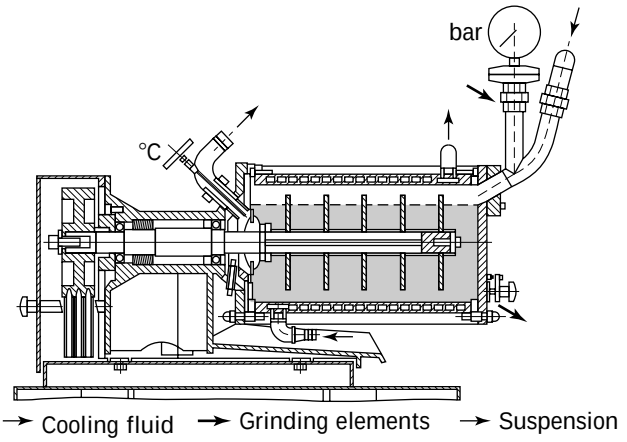

Figure 5. The Dyno-Mill. *Source*: Reprinted from a commercial brochure, by permission of Willy A. Bachofen AG, Basel/Switzerland.

that for low cell concentrations (<5% solids) increased wear is observed on the mill and beads. Hence, an optimum must be found by experiment and is generally in the range of 30–60% or, more usually, in the range of 40–50% (cell wet wt).

The bead diameters that have been reported range from 0.1 to 1.5 mm. Usually the disruption is faster with smaller beads, but the tendency of very small beads to float and difficulties in retaining them inside the grinding chamber impose practical limitations on the lower limits of size. In practice, the lower limit for batch operation of laboratory mills is 0.2 mm, whereas for production equipment working continuously the lower sizes are ≥0.4 mm. For the same bead load, larger particles correspond to fewer beads and reduced abrasive action or bead collisions. For the same bead load, there are also reports of an optimum bead size, which also has to be found by experiment and depends on the location (24,41) of the product (enzyme) inside the cells; larger beads are preferred for the recovery of enzymes located in the periplasmic region, and smaller ones for cytoplasmic material.

The rate of protein release is also enhanced by increasing the bead load (volume percentage of bead material relative to the total volume of the grinding chamber). Bead loads ranging from 30 to 90% are reported in the literature, but the packing density, depending on the bead diameter inside the chamber, is generally in the range of 80–90%. The upper limit is generally imposed by the high power consumption and difficulties in removing the heat released in the operation.

The rate constant is, obviously, dependent on the temperature that results from the balance between the heat generated during the milling process and the heat removed by a cooling liquid, brine, or a cooling liquid circulating through a cooling jacket of the grinding chamber. The heat generated in the process, if accumulated, would raise the temperature to unacceptable levels; in fact, the suspension has to be precooled and cooled immediately after leaving the chamber to avoid inactivation of heat-labile products.

The effects of the flow rate should mirror the effects of the residence time of the cells inside the grinding chamber,

and assuming a first-order process, the yield after one passage should decline as the feed rate increases. However, degree of caution should be exercised because the degree of longitudinal dispersion or backmixing increases as the flow rate decreases, and the yield of disruption is not a simple function of the flow rate. On the other hand, the power consumption per unit mass of processed cells strongly decreases as the feed rate increases, and for this reason, a high flow rate should be adopted and the decline in the yield of disruption could be alleviated by recycling part of the suspension. It should be emphasized that by increasing the residence time the viscosity may be decreased because prolonged shear may cause degradation of the shear-sensitive DNA polymer (51).

In one study (41), the disintegration rate was correlated with the specific energy as determined by the following combination of parameters: small grinding beads, moderate to high cell concentrations, and/or low to moderate agitator speeds. In this case the utilization of energy input reaches its maximum. In other words, high cell concentrations are energetically favorable. This result is considered to be the basis for scale-up. For cases of low cell concentrations in the suspension, high agitator speeds, and larger beads, the disintegration rate was no longer correlated with specific energy input but was a function of the stress frequency (which is proportional to the product of the agitator speed and disintegration time), which was experimentally proved.

Ultrasonics

Ultrasound has been used on the laboratory scale for analytical and preparative extraction and purification of cell constituents of bacteria or yeasts. The mechanism of cell disruption derives from the intensive shear induced by sonicating the suspension at sound frequencies above 20 kHz. A magnetorestrictive or a piezoelectric transducer converts the alternating current of an electric oscillator into mechanical waves that are transmitted to the suspension through a metallic probe (usually made from titanium) vibrating with the same frequency as the oscillator. The sound waves create many microbubbles at various nucleation sites in the suspension, which collapse implosively during the rarefaction period of the sound waves. This phenomenon of cavitation (formation, growth, and collapse of the vapor-filled bubbles) produces intense local shock waves, and intense local shear gradients are generated that cause the cells to deform beyond the limit of elasticity and rupture. The rate of microbial cell disintegration is usually low for preparative purposes, and the inclusion of small stainless steel or glass (Ballotini) beads will help in the nucleation for cavitation as well as with a grinding action (solid shear) that will increase the efficiency of disintegration.

The kinetics of disruption (protein release) has been reported to follow a first-order law (42,43), and for a well mixed pattern inside the disruption chamber the integrated equation is

$$1 - X = \exp(-kt) \tag{7}$$

where X is the fraction of released protein and k is the rate constant.

There are a number of variables that can markedly affect either the sample or the efficiency of the sonication process. One of these is the temperature rise. Most of the energy that is released when the bubbles collapse is absorbed by the liquid as heat. Although the value of the specific rate k increases with the temperature, the thermal energy has to be extracted to avoid temperatures that could destroy the activity of the useful bioproducts. To control the temperature within acceptable limits, the suspension should be precooled to 0–5 °C, and jacketed disruption vessels should be used with a continuous circulation of a cooling fluid. Alternatively or concomitantly, short periods of sonication can alternate with short periods of cooling. The ratio of the time of sonication to the time of cooling is known as the duty factor.

The integrity of the bioproduct can also be adversely affected if free radicals are allowed to accumulate during the intense cavitation. The addition of radical scavengers (e.g., cysteine or glutathione) or pregassing the suspension with hydrogen can alleviate this problem, particularly if a prolonged sonication is expected.

Other operating parameters affect the efficiency of the sonication process. One is the amplitude of vibrations of the sound waves (directly related to the acoustic power supplied to the suspension), which affects the rate constant according to the following relation (42):

$$k\alpha(W - W_0)^{0.9} \tag{8}$$

where W is the acoustic power and W_0 is the cavitation threshold power. However, a linear relationship between the rate constant and the acoustic power was recently reported (43).

The viscosity of the suspension affects the hydrodynamics and the rate of energy dissipation and inhibits the phenomenon of cavitation. When the viscosity is high, the operation should be started at a lower power, and the power should be gradually increased. The initial cell concentration that affects the viscosity of the suspension was reported to have no effects on the rate constant (43).

Problems of foaming can result from the presence of surface active agents (e.g., proteins released from the disrupted cells) that lower the surface tension of the liquid medium. An intense foaming, particularly when high power is applied, contributes to cavitation “unloading” (therefore decreasing the efficiency of the process) and protein denaturation at the gas–liquid interface.

High working volumes require high acoustic power, which results in violent turbulence and in the formation of large bubbles that cause cavitation unloading. Rate constants were found to decrease linearly with increasing working volumes (43). The difficulties associated with higher working volumes (100–200 mL) can be alleviated by good design of the disruption vessel. Commonly a jacketed glass beaker with a continuous flow of cooling fluid is used; inlet and outlet tubes can be inserted for continuous operation. In continuous operation, the flow rate determines the residence time of the cells in the vessel and affects the overall yield of the process. For tougher cells the

inclusion of Ballotini beads is necessary, and for further increasing the grinding action, the vessel should have internal tubing loops to circulate the suspension under the pumping energy of the sonication (27,31). The load and size of beads must in any case be optimized, but the value of the rate constant increases to a maximum and then decreases with increases in the bead diameter for the same bead load.

The shape of the probe is of particular concern. For a constant power level the amplitude of the sound waves at the probe tip is inversely proportional to the tip area. Therefore large tips dissipate the acoustic energy over a larger area, and the amplitude is smaller. However, if the tip diameter is too small the acoustic energy is dissipated over a smaller field and is less efficiently used, this is particularly important if the working volume is small because intense turbulence can lessen the power absorbed near the tip.

Manufacturing materials dictate the severity of the wearing problems that are also common with the probe tips. Titanium is a good material because of its good acoustic and mechanical properties and low toxicity to bioactive materials. However, titanium probes are expensive and difficult to machine. Pitting erosion produces deep cavities on the tip surface, particularly when Ballotini beads are included, which lessens the efficiency of sonication. The tip can usually be detached for servicing to produce a new flat surface, which is difficult with titanium, stainless or hard steels are better alternatives despite their poorer acoustic and mechanical properties.

Sonicating equipment can be found in many laboratories. In preparative applications the performance is generally not as good as with the high-pressure homogenizers or bead mills. In the case of plasmid recovery from *E. coli*, even when the disruption yield was good, sonication failed to produce intact plasmids (37). The application of this technique to large-scale purification of bioproducts is rather limited: it is difficult to transmit high acoustic power to large volumes, it is difficult to extract the large amounts of heat generated during the cavitation process, and the equipment has to be shielded to protect humans.

Other Methods

The mechanical methods are, generally, effective in disrupting tough microbial cell walls and much more efficient than the nonmechanical methods. Concomitantly, there are also several disadvantages: they are energy intensive, generate high temperatures and shear forces that can damage labile products, are nonspecific with respect to the organisms and the product to be released, and cause intense cell fragmentation. Although several attempts have been made to optimize operations and minimize these effects, process modifications that could result in a significant reduction in the overall energy requirements are still being pursued.

Nonmechanical methods are not efficient on their own, and very often they only increase the permeability of the cell envelope without breaking the wall. However, by weakening the cell wall, lytic methods can be combined with the more efficient mechanical methods, and therefore require less harsh conditions.

Among the physical methods of lysing cells, two have been reported more frequently, although they are not production oriented: osmotic shock and freeze–thawing. Osmotic stresses are generated when a cell is placed in either a hypertonic or a hypotonic medium; in the first case the cell tends to shrink (plasmolyze), and in the second case to expand. In both cases the cells can suffer potentially serious injuries. Usually the cells have osmoregulating mechanisms in addition to tough cell walls that protect them from lysis. However, if suddenly placed in a hypotonic medium (a medium of very low salt concentration), the cells suffer an osmotic shock, absorb water, and swell; eventually they reach a point of unsustainable internal pressure and burst. This bursting process is effective and upscaleable with weak animal cells. However, osmotic shocks are rather inefficient with tougher bacterial, fungal, or yeast cells, though some periplasmic enzymes and even some proteins/enzymes located near the inner side of the cytoplasmic membrane can be selectively released. Osmotic shock is frequently used to prepare membrane vesicles for studies of membrane proteins. The important operational parameter is the time to fully resuspend the cells in the hypotonic medium, which should be as short as possible to avoid the osmoadaptation of the organisms.

The release of intracellular components can also be induced by freeze–thawing the cells. The ice crystals that form and grow during the freezing step will mechanically disrupt the integrity of the inner cell membranes, which become permeable and allow several enzymes to be extracted into appropriate buffers during the thawing step. The precise mechanism for the release of proteins has not yet been elucidated; however, the formation of small transient pores (44) in the membranes is a logical explanation consistent with the facts that protein solubility is important in governing its release to the medium, the inclusion bodies remain unreleased, and large molecular weight proteins are excreted with very low yields (45). The efficiency of this method depends largely on the rates of thawing. With a large mass of frozen suspension, the rate of thawing is higher in the outside region, while the interior of the block remains frozen, allowing chemical or enzymatic (eventually, proteolytic) reactions to proceed to different degrees in different parts of the block. On the other hand, the lifetime of the transient pores (regions of discontinuity) depends on the temperature of thawing that affects the rate of membrane resealing (44) and is longer at low temperatures. This may explain the lack of reproducibility of the results in the ball mill disintegration of brewers' yeast samples that were kept frozen and separately thawed (24). The freeze–thawing process is not easily scaled up and find application mainly in laboratory-scale recovery of recombinant proteins. It can also be useful in disrupting pathogenic cells in a sealable package (7).

Chemical methods on lysis are milder and often anticipate an autolytic enzymatic activity. Organic solvents (e.g., toluene, ethanol, *n*-butanol, isobutanol, acetone, methylethyl ketone, etc.) are believed to extract, nonselectively, lipids from the cell wall or cytoplasmic membrane, therefore increasing the permeability to intracellular components. However, organic solvents might cause protein denaturation, and by diffusing into the cell, they also de-

stroy the membranes of intracellular organelles, thus allowing destructive enzymes, such as proteases, to be liberated. These harmful effects of the organic solvents were minimized in the extraction of β-D-galactosidase by mixing yeast cells (*Kluyveromyces fragilis*) with concentrated selected solvents and, following filtration, resuspending and agitating the cells in an adequate buffer for extraction (46); 95% of the enzyme was released at the end of a 20-h extraction period. The process was claimed to be suited for scale-up, and the organic solvents were beneficial in killing the viable yeast cells, therefore avoiding the need to separate them from the lysate and the addition of antimicrobial agents.

The use of concentrated organic solvents, however, imposes a fireproof environment. Other chemicals, such as detergents, chaotropic agents (e.g., guanidine HCl or urea), EDTA, phenethyl alcohol (PEA), or alkaline solutions have been used to increase the permeability of the cell walls. All chemical methods suffer from long holding times and, thus, have long been considered unattractive for larger-scale applications. Addition of glycine in low concentrations to the medium at an appropriate pH could also increase the permeability of recombinant *E. coli* immobilized in κ-carrageenan gel beads to α-amylase.

However, the recent progress in recombinant DNA technologies has renewed interest in the development of methods to increase the permeability of the cell envelope in order to avoid a detrimental accumulation of plasmid-encoded proteins in the cytoplasm. If these proteins are allowed to accumulate, further synthesis is reduced while proteolytic degradation may cause loss of protein activity, or the plasmids may loose stability. The benefits of whole viable cell immobilization may also be lost if the foreign proteins are not excreted and the cells would require a disruption step for the product to be released and further purified. Chemical methods to recover these active recombinant products in situ, with increased selectivity concerning the intracellular location, have been investigated, with great promise. *E. coli*, a Gram-negative bacterium, has typically been used as the host organism, and many high-value recombinant proteins are secreted into its periplasmic space. Treatment of *E. coli* with guanidine HCl (a chaotropic agent) increases the permeability of the outer membrane, and periplasmically expressed proteins such as β-lactamase (47) can thus be leaked into the surrounding medium with high yield (better than 80% in 5 h), free of many intracellular contaminants. After treatment of the same cells with Triton X-100, which attacks the inner membrane, the cytoplasmic proteins could be released but with low yield and only when the cells were treated with both the guanidine HCl and Triton X-100 was the yield of intracellular protein higher than 50%. The cost of Triton X-100 is high but, nevertheless, this process was claimed to be less expensive than enzymatic methods. The release of β-lactamase was also enhanced by treating recombinant *E. coli* with EDTA and PEA at appropriate concentrations; cell viability and synthesis of the plasmid encoded β-lactamase were retained (49).

Pretreatment with guanidine HCl and Triton X-100 was also used in conjunction with a high-pressure homogenization step to disrupt recombinant *E. coli* expressing human growth hormone inclusion bodies (48). A reduced number of passes through the homogenizer at lower disrupting pressure were required to recover the protein from the inclusion bodies; due to their synergistic effects, Triton X-100 was used to reduce the concentration of guanidine HCl required to weaken the cell wall and to wash the inclusion bodies from contaminant proteins.

Pretreatment of *Candida lipolytica* with an alkaline solution resulted in a weakened cell wall and increased protein solubility, and further mechanical homogenization was thus facilitated at lower pressures than with non-treated cells (20).

Enzymic methods of cell wall hydrolysis are also becoming increasingly more attractive. The advantages associated with enzymic lysis include an increased selectivity of product release (which is desirable for further product isolation and purification), an increased rate and yield of product release, the minimization of product damage, requirements for mild conditions of pH and temperature, and no debris being produced.

More than any other methodology, enzymatic lysis requires a good understanding of the details of the chemical and physical structure of the cell walls. No single enzyme is capable of fully degrading the cell walls. As already described, peptidoglycan is the structural element in bacterial cell walls. In Gram-positive bacteria a single enzyme could lyse the cell, but a mixture of several enzymes (glycosidases [endoacetylmuramidase, *endo*- and *exo*acetylglucosaminidase], *N*-acetylmuramyl L-alanine amidase or peptidases) acting synergistically would assist in the lysis of the bacterial peptidoglycan; in Gram-negative species a pretreatment with a surface-active agent is usually required to remove the outer membrane. For yeast cells a wall lytic protease and β-(1–3)-glucanase are essential, but

Table 1. Important Microbial Cell Wall Degrading Enzymes

Organisms	Enzymes	Type of hydrolyzed linkage
Bacteria	Glycosidases	β-(1,4)-linkages between AGA and AMA residues in a peptidoglycan
	Acetylmuramoyl-L-alanine amidases	Link between *N*-acetylmuramoyl residues and L-amino acid residues in certain glycopeptides
	Peptidases	Gly-gly, ala-gly, etc., peptide bonds
Fungi, yeasts	β-(1,3)-Glucanases	Random β(1,3)-linkages in glycans
	β-(1,6)-Glucanases	Random β(1,6)-linkages in glycans
	Mannanases	(1,2)- (1,3)-, (1,6)-β-D-Mannosidic linkages
	Chitinase	*N*-Acetyl-*b*-D-glucosaminide β(1,4)-B-linkages in chitin and chitodextrins
	Proteases	
Algae	Cellulases	α(1,4)-Linkages in cellulose

the inclusion of β-(1–6)-glucanase, mannase, and chitinase assist the lytic process (Table 1). Most lytic enzyme systems are active against pretreated nonliving cells (lyophilized or heat-killed cells) or against cell walls.

The main restrictions in using multienzyme systems are the availability and high costs associated with their preparation. Different sources of lytic enzymes have been investigated. Various species of *Arthrobacter* can be induced, by whole yeast cells or cell walls, to produce yeast lytic activity (β-(1–3)-glucanase, mannase, and protease) subject to catabolite repression by glucose. Yeast lytic activity was also identified in *Cytophaga* sp. and *Oerskovia xanthineolytica*. Different strains of *Streptomyces* sp., *Pseudomonas* sp., *Staphilococcus* sp., and *Cytophaga* sp. have a wide spectrum of bacteriolytic activities. Lysozyme from hen egg white is bacteriolytic against only a few bacteria.

For the extraction of a given product from an organism, the selection of the most appropriate lytic system depends on the nature of the wall to be lysed and the nature and location of the product inside the cell. The composition of a multienzyme system determines the efficiency and the selectivity of the lytic process (50). If the product is proteinaceous, a highly proteolytic system is undesirable. Thus, if the organism to be lysed is a yeast, a high proteolytic activity should be provided in only the early part of the lytic process, when the substrate is the mannan–protein complex of the wall; the protease should then be inactivated, or a protease inhibitor should be added. However, the composition of lytic systems can be manipulated in part in the production phase, using different inducers and growth conditions. For instance, in the case of the lytic enzyme system from *Cytophaga* sp., high β-(1–3)-glucanase activities and high glucanase: protease ratios were obtained when produced in continuous culture at low dilution rates under carbon-limited conditions. The quantitative data concerning the effects of pH, temperature, concentrations of lytic enzyme, and of cells on the lysis rate should also be obtained to optimize a lytic process (50).

As with all the nonmechanical methods, extensive enzymatic lysis is a very slow process, but in conjunction with others, the rate and the yield of product extraction can be much increased. Mutants that are defective in β-glucan can be produced by mutagenesis and are, therefore, more susceptible to β-(1–3)-glucanase (commercially known as zymolyase) attack (51). Enhanced disruption of *C. utilis* was obtained by high-pressure homogenization (using a microfluidizer) when the cells were pretreated with zymolyase (51). *Bacillus cereus* pretreated with 0.5 mg cellosyl (a lytic enzyme produced by *Streptomyces coelicolor*) per gram of cells (wet wt), at pH 5.5 and 30 °C, was disrupted with 98% yield in one single passage in a Manton–Gaulin homogenizer at 7×10^7 Pa, as compared with less than 40% yield when the cells were untreated. The same enzymatic treatment facilitated disruption in a bead mill (52).

Autolysis is the process by which the cells use their own lytic capabilities and produce lytic enzymes. Autolysis, as a self-digestion process, is very slow and often requires several days, which is very inconvenient. Because of that, it is not a common method of cell disruption; however, yeasts are autolyzed on an industrial scale for the production of yeast autolysates. The process can be speeded up by drying or freeze-thawing the cells. As already mentioned, autolysis can also be induced by plasmolysis with surfactants, thiol reagents, and organic solvents (e.g., toluene or butanol) or by aging or temperature. β-Lactam antibiotics are known to cause the activation of autolytic enzymes (autolysins), and this has also been suggested to be the mechanism by which surfactants induce the autolytic process. Autolysis enzymes are important for cell growth and reproduction, but once they are deregulated, they attack bacterial peptidoglycan. A key factor is the pH, which is generally optimum around 8.0 when yeast is to be plasmolyzed by organic solvents or detergents (56).

Microbial cells differ in their potential for autolysis; often they lack the genetic information to produce lytic enzymes, in which case the genetic coding must be introduced from outside. Lytic enzyme systems that can be cloned include not only the autolysins (several peptidoglycan hydrolases) but also colicin enzymes (a class of antibiotic proteins) and phages (57).

EFFECTS OF CELL DISRUPTION ON DOWNSTREAM OPERATIONS

One of the most challenging problems in solid–liquid separation is the removal of cell debris, which includes cell wall fragments, cell membranes, and protein precipitates. Disruption and lytic treatments cause a reduction in the sedimentation properties of the cells and fine debris (<0.1 μm), leading to inefficient centrifugation and/or filtration due to changes in the surface properties, high compressibility of the solids, high viscosity of the disrupted suspension, and a small difference between the densities of the solids and the suspending medium (53). *Centrifugation* has been used, but it is unsatisfactory when the particles are smaller than 0.5 μm, particularly in viscous homogenates, therefore requiring very low flow rates (on the order of 10 times less than for whole cells). A previous flocculation can improve the centrifugation efficiency. A highly selective *flocculation* of cell debris by borax (sodium tetraborate) was improved by further addition of poly(ethylene imine) to the clarified homogenate supernatant (54). *Rotary vacuum precoat filtration* has been used for the clarification of disrupted yeasts, but *crossflow microfiltration* has the advantage of preventing cake formation and avoiding the need for expensive filter aids. The separation of cell debris is, however, the most complex problem that crossflow microfiltration has been tested against. Membrane fouling and concentration polarization are some of the difficulties that contribute to a rapid flux decline and limit the concentration of debris that can be attained. Apart from the influence of the operational parameters (pressure, feed velocity, fouling factors) on the flux and transmission, which are well documented in the literature, we have to consider that strong adsorption of proteins to cell debris may occur in the lysate, depending on the concentration, temperature, pH, or ionic strength. *Aqueous two-phase extraction* is attractive for the recovery of whole cells and debris from protein solutions but involves high costs and difficult recovery of reagents. Phase

components include water-soluble polymers and electrolytes, the best-known systems being PEG-dextran and PEG-phosphate.

Separation techniques depend on many specific aspects, but the average particle size and the size distribution are crucial to all of them: the maximum amount of released protein increases with increasing micronization of the cell debris (36), but these become increasingly more difficult to separate.

Mechanical methods are generally, effective in disrupting tough microbial cell walls. The major difference among them lies in the different sizes of cell fragments that are generated; some methods disrupt the cell envelope with less overall destruction than others. This is significant because the size of the fragments has an important impact on downstream processing when they are removed from the lysate or separated from other subcellular species (37): the submicron particles are easily resuspended in the supernatant after centrifugation, hinder the fractional precipitation, and tend to foul chromatographic columns or membranes that follow (37,54).

The behavior of *E. coli* cell debris from a bead mill and high-pressure homogenizers was investigated (53). No significant differences in the yield and rate of release of protein were reported. However, the characteristics of the debris (particle size distribution, separability by centrifugation, and dead-end filtration) were quite dependent on the disruption method. The mean residence time in the bead mill did not significantly affect the particle size distribution, but the number of passes in the mechanical homogenizer broadened the debris size distribution.

The effect of operating conditions on the cell debris size distribution was investigated for bakers' yeast disrupted by high-pressure homogenization, and a two-parameter model was developed, incorporating both the operating pressure and the number of passes, to simulate the particle size distribution in the homogenate. A threshold pressure of 11.5 MPa was determined, below which no disruption of yeast cells will occur (55). Yeast cell debris particle size distribution was also reported to depend on the growth conditions (13): in batch cultivation the median diameter, d_{50}, was less in the exponential phase and greater in the stationary phase; in continuous culture the median diameter was less for higher dilution rates (younger cells).

High-pressure homogenization of of *E. coli* cells treated with a combination of guanidine HCl and Triton-X-100 produced cell debris of larger sizes than when the pretreatment was made with only guanidine HCl, which is highly desirable when the debris are to be separated by cross-flow microfiltration.

The cell suspension should also be conditioned to avoid unwanted degradation of labile products liberated from the disrupted cells. Protease inhibitors are often required and should be added to the cell slurry. Antioxidants are useful to avoid oxidation of S—S bonds. An appropriate buffer should be included to maintain the pH within the desired range. All the chemicals that are added to the system in all phases of the process (starting from the medium preparation and fermentation steps) may have effects on the product and subsequent operations; this should be taken into account.

Evolving from the recent developments in recombinant DNA technology, a large number of proteins of therapeutical importance, now in use or undergoing clinical evaluation, are produced as inclusion bodies (or "refractile" bodies) in the cytoplasm, mainly in *E. coli*, where they accumulate due to the absence of a secretory mechanism. These inclusion bodies are dense and amorphous aggregates of protein, consisting of misfolded (frequently denatured) polypeptides, often as large (0.8–1.5 μm) as a normal bacterium cell, with a relatively higher density (~1.2–1.35 kg/L) than the rest of the cell material. They require the use of chaotropic agents or detergents to be solubilized in an aqueous environment (58). The standard procedure for the purification of a protein expressed as an inclusion body begins with the isolation of the inclusion bodies, which itself begins with the disruption of the cell. The best cell disruption technique is high-pressure-homogenization. The aggregates are then separated from the soluble components and from the debris of the lysed cells, usually by centrifugation, typically using disc-stack centrifuges, at 5,000–10,000 *g* during 5–10 min; the lighter cell debris is removed along with the supernatant (58,59). Cross-flow membrane filtration has also been investigated (60). The pellets are then washed with either dilute detergents or chaotropic reagents (urea or guanidine HCl) to remove contaminants, and often reducing agents (e.g., dithiothreitol or β-mercaptoethanol) are added to disrupt incorrect disulfide bonds. The solubilized and reduced protein is then ready for subsequent purification and refolding.

OUTLINE

INTRODUCTION

Immobilized cells are defined as "cells physically confined or localized in a certain defined region of space with retention of their catalytic activities, which can be used repeatedly and continuously" (1). This definition is applicable not only to cells, but also to single enzymes, multienzyme conjugating systems, and cellular organelles, that is, to all types of biocatalysts. Bioprocesses using biocatalysts have increasingly received worldwide attention because of their benefits of low environmental pollution and economical utilization of natural resources and energy. They have also contributed to a wide variety of fields. The use of immobilized biocatalysts increases the efficiency of such bioprocesses because they catalyze biochemical reactions under more stabilized states than their free counterparts; moreover, they can be used repeatedly or continuously. In particular, immobilized cells can catalyze complicated reactions and have many useful characteristics that other biocatalysts do not have, as described later. The European Federation of Biotechnology, Working Party on Applied Biocatalysis (formerly, the Working Party on Immobilized Biocatalysts) proposed that immobilized cells should be classified as viable or nonviable, where viable includes growing, nongrowing, and respiring (2). According to this proposal, terms such as treated, resting, growing, and living should not be used. However, in general, these terms are used for classifying the condition of immobilized cells. In the definition of "treated," cells are subjected to chemical or physical treatment before or after immobilization, and resting cells do not show growth during utilization, although they have the ability to grow.

HISTORY

In 1916, Nelson and Griffin fortuitously found that yeast invertase adsorbed on activated charcoal retained its catalytic ability in the hydrolysis of sucrose (3). This is said to be the first demonstration of immobilization of a biocatalyst. Although several reports were published on the immobilization of physiologically active proteins by covalent binding on various supports after this finding, immobilized biocatalysts were not used in practice until Grubhofer and Schleith immobilized several enzymes (carboxypeptidase, diastase, pepsin, and ribonuclease) on diazotized polyaminostyrene resin by covalent binding in 1953 (4). Thereafter, many studies on enzyme immobilization have been carried out, and studies on cell immobilization became to be popular in 1970s.

The first industrial application of immobilized biocatalysts was carried out by Chibata and coworkers of Tanabe Seiyaku Co., Japan, in 1969. Fungal aminoacylase immobilized on DEAE-Sephadex through ionic binding was used for stereoselective hydrolysis of *N*-acyl-D,L-amino acids to produce L-amino acids and *N*-acyl-D-amino acids (5). The first industrial application of immobilized cells was also performed by Chibata and his coworkers in 1973, producing L-aspartate from ammonium fumarate by polyacrylamide-gel-entrapped *Escherichia coli* cells containing a high level of aspartase activity.

Several other processes, such as production of L-alanine, L-malic acid, 6-aminopenicillanic acid, milk having a low lactose content, and high-fructose syrup also have been industrialized with the use of immobilized enzymes and immobilized cells, and a vast amount of literature on immobilization is available (6–15).

SIGNIFICANCE

In biological systems, such as microbial cells, plant cells, and animal cells, various chemical reactions are carried out. These chemical reactions are catalyzed by enzymes that are water-soluble globular proteins. *Compared to chemical catalysts, enzymes as catalysts have the following superior characteristics.*

1. Enzyme-catalyzed reactions take place under mild conditions, such as ordinary temperature, atmospheric pressure, and pH value around neutrality.
2. Enzymes have strict substrate specificity, stereospecificity, regiospecificity, and reaction specificity.

These facts suggest that energy-saving, resource-saving, and low-pollution processes could be designed by using biocatalysts because such processes could be carried out at relative low temperatures and at ambient pressure with little by-product formation. However, biocatalysts are, in general, liable to be deactivated under conditions such as high temperature, extremes of pH, presence of organic solvents, or even conditions suitable for their catalysis. The repeated or continuous use of biocatalysts that are required in order to construct efficient processes is another problem faced when free biocatalysts are used. Immobilization is one of the most useful methods for eliminating some of the disadvantages described above. In general, immobilization makes biocatalysts stable and easy to use repeatedly in a long-term series of batchwise reactions, or continuously in flow systems. Therefore, the

immobilization of biocatalysts is attracting attention worldwide.

At present, immobilized biocatalysts have contributed to a wide variety of fields including (1) the production of useful compounds by stereospecific and/or regiospecific reactions, *(2)* the production of energy by biological processes, *(3)* the selective degradation or removal of pollutants to solve environmental problems, *(4)* analyses of various compounds with high sensitivity and high specificity, and *(5)* utilization in new types of drugs such as slow-releasing medications, in making artificial organs, and so on.

These processes require the immobilization not only of single enzymes that catalyze simple reactions, but also of multienzyme conjugating systems that mediate more complex reactions. These systems often require the regeneration system of ATP and/or coenzymes. Because cells contain metabolic systems that mediate such complicated reactions, immobilization of cells serves as immobilization of such multienzyme conjugating systems. Furthermore, in the case of immobilization of cells, the procedure of extracting enzymes from the cells is no longer required. This avoids the inactivation of enzymes during these time-consuming and expensive procedures, making it possible to use the enzymes in a stable state.

However, immobilized cells have some disadvantages that must be overcome to realize their practical applications.

1. By-products are easily synthesized because the cells contain the various metabolic systems and the many enzymes that catalyze undesirable reactions. To defeat this problem, selection of a proper strain, mutation, or the proper treatment of cells in order to lower the levels of enzymes participating in side reactions and increase the activities of desirable enzymes, or genetic improvement of a cell line is essential.
2. Cell walls and cell membranes of intact cells often hamper the permeation of substrates, products, and other reaction components into and out of cells. In this case, appropriate treatment of cells before or after immobilization is required to destroy the barriers to permeability.

If immobilized cells are kept in a growing state by a proper supply of suitable nutrients, and if their biological functions are useful, as in the case of conventional fermentation procedures, these immobilized cells (immobilized growing cells) seem very advantageous. Immobilized growing cells serve as self-proliferating and self-regenerating biocatalysts, and catalytic activities of immobilized growing cells are expected to be maintained during long-term repeated or continuous use of cells.

However, immobilized growing cells also have some disadvantages as biocatalysts, and ways to overcome these disadvantages must be studied.

1. Various nutrients and energy sources are demanded by immobilized growing cells to maintain the cells growing state(s), and yield may be lowered by the consumption of substrates and/or products as nutrients and energy sources.
2. Contamination of product is liable to occur by cells leaked from carriers.

In spite of these faults, cell immobilization is a key technology used to construct an efficient bioprocess, as immobilized cells have the attractive characteristics described earlier.

METHODS

For the application of immobilized cells, screening or breeding of cells having the desired activity and characteristics is very important. In addition, selection of the appropriate immobilization method is necessary. There is, however, no ideal universal immobilization method fitted to various types of cells at present, although a vast amount of literature on immobilization is now available.

The immobilization methods can be classified into four categories: carrier-binding, cross-linking, entrapment, and combined methods, in which combined methods are a combination of former three. Because each method has its own merits and faults (to be described later), selection should be carried out in consideration of the purpose of immobilization, characteristics of cells, type of reaction, type of reactor, and so on.

Carrier-Binding Method

The carrier-binding method is based on the binding of biocatalysts to water-insoluble carriers through covalent bonds, ionic bonds, physical adsorption, or biospecific binding. Carrier materials should have adequate function to bind biocatalysts, have sufficient mechanical strength; physical, chemical, and biological stability; and nontoxicity. Ease of shaping is also important for applying immobilized biocatalysts to various types of reactors. Furthermore, the economic feasibility should be considered. As carriers, various types of insoluble materials, such as water-insoluble polysaccharides (cellulose, dextran, agarose derivatives, etc.), proteins (gelatin, albumin, etc.), synthetic polymers (polystyrene derivatives, ion exchange resins, polyurethane, etc.), and inorganic materials (brick, sand, glass, ceramics, magnetites, etc.) have been developed and utilized as they are, or after proper modification or activation. The development of new carrier materials having desired characteristics is also important.

Any reactive components of the cell surface, for example, amino, carboxyl, thiol, hydroxyl, imidazole, or phenol groups of proteins or saccharides, can be used for covalent bonding between cells and a modified or activated carrier. The covalent-binding method is one of the most frequently used techniques for the immobilization of enzymes because of the following advantages: *(1)* enzymes do not leak or detach from carriers during utilization because of the tight binding, *(2)* enzymes can easily contact with substrates because enzymes are localized on the surface of carriers, and *(3)* an increase in stability is often observed because of the strong interaction between enzymes and carriers. However, this method is not as widely used for cells because of

the toxicity of the agents needed for formation of covalent bonds, and the difficulty in finding the conditions for immobilization. In the limited number of reports on cell immobilization by this method, inorganic and organic carriers have been used as follows: Navarro and Durand (16) immobilized *Saccharomyces carlsbergensis* cells by covalent binding to porous silica beads that had been treated with aminopropyltriethoxysilane and activated with glutaraldehyde. *Serratia marcescens, Saccharomyces cerevisiae*, and *Saccharomyces amurcea* cells were also immobilized by covalent binding to borosilicate glass and zirconia ceramics with an isocyanate coupling agent (17). In the case of organic carriers, *Micrococcus luteus* cells were immobilized to the carboxyl group of agarose beads in a two-step process that avoided exposure of the cells to carbodiimide (18), and the uronic acid–forming activity of these immobilized cells was retained, even though cell viability was lost. A disadvantage of this method is that leakage of the enzymes may occur due to autolysis during the reaction.

Recently, Klein and Ziehr have summarized the immobilization of cells by adsorption to carriers (19). One of the first studies on immobilized cells (20,21) is on the adsorption of *Escherichia coli* and *Azotobacter agile* cells to Dowex-1 for the oxidation of succinic acid. This adsorption method is very simple and mild, and can be applied to the immobilization of various types of cells. However, adsorption of cells to carriers is sensitive to environmental factors such as pH, ionic strength, concentration of reactants, and temperature because the adsorption phenomenon is based primarily on van der Waals forces, ionic or hydrogen bonds, or hydrophobic interactions between the cell surface and the carrier. Therefore, cells are liable to leak from carriers.

Biospecific binding with lectins introduced on carriers was also used for immobilization of cells (22,23). Lectins that are glycoproteins bind tightly to specific carbohydrate residues on the cell surface. Concanavalin A, which can be obtained from jack beans, is one of the most useful lectins.

Cross-Linking Method

The cross-linking method utilizes bi- or multifunctional reagents, but carriers are not used. Cells are linked with each other by the reagents, and the crosslinked cells form pellets.

Glutaraldehyde is one of the most popular cross-linking reagents (24,25), and combines amino groups through a Shiff base linkage. Diisocyanates, such as toluene diisocyanate and hexamethylene diisocyanate, represent another type of cross-linking reagent, forming a urea linkage with amino groups.

E. coli having high aspertase activity was immobilized by this method with glutaraldehyde or toluene diisocyanate (26). A 34% retention of aspartase activity was obtained in the case of glutaraldehyde, but the immobilized cells were inactivated in the presence of toluene diisocyanate. So far there have been very few studies on this method, but *Bacillus coagulans* immobilized by this method is commercially available for immobilized glucose isomerase and is widely used for isomerization of glucose in the industrial field.

Entrapment Method

Entrapment methods can be classified as follows: lattice type, microcapsule type, liposome type, and membrane type.

In lattice type entrapment, biocatalysts are entrapped in gel matrices of various types of polymers. Microcapsule type is entrapment in microcapsules of semipermeable synthetic polymers. Liposome type is entrapment within a liquid membrane prepared from amphiphatic compounds. In membrane type, biocatalysts are separated from the environment as spent reaction solution by ultrafiltration membranes, microfiltration membranes, or hollow fibers.

Entrapment methods are very popular for immobilization of cells. Microbial cells, as well as plant and animal cells, can be immobilized by this method. However, this method also has disadvantages, as follows:

1. High molecular weight substrates can hardly access the cells entrapped.
2. Renewal of carriers is hardly possible.

Membrane-type entrapment can avoid these disadvantages, although it has no effects on stability of cells. The lattice-type method is most widely applied for preparing immobilized cells, and there is a great deal of literature on this method. Several representative techniques for the lattice-type method are described next.

Polyacrylamide Gel Method. Bernfeld and Wan (27) reported the entrapment of several enzymes in polyacrylamide gels in 1963, and this method was applied to the cells of the lichen *Umbilicaria pustuluta* by Mosbach and Mosbach in 1966 as reviewed by Chibata et al. (28). Various types of biocatalysts have so far been immobilized by this method. This method was used for not only the first industrial application of immobilized microbial cells as described earlier, but also for the first application of immobilized growing cells, that is, the production of L-glutamic acid by *Corynebacterium glutamicum* (29).

The procedure for the formation of gel to entrap cells is identical to that employed for the preparation of gel commonly used for electrophoresis. For the immobilization of cells by this method, acrylamide, and *N,N′*-methylenebisacrylamide (BIS) as the cross-linking reagent, are mixed with a suspension of cells and polymerized in the presence of an initiator, such as potassium persulfate, and a simulator, such as 3-dimethylaminopropionitrile (DMAPN) or *N,N,N′,N′*-tetramethylenediamine (Fig. 1).

Although this method can be used for various purposes, a major disadvantage of this method is the toxicity of the acrylamide monomer, the cross-linking reagent, the initiator, and the stimulator. In some cases, cells are damaged by free radicals during polymerization. Several analogues or derivatives of acrylamide are also useful for this method.

Table 1 summarizes some examples of cells immobilized with polyacrylamide.

Alginate Gel Method. Several natural polysaccharides, such as alginate, κ-carrageenan, and agar, are excellent gel

materials and are widely used for the entrapment of various biocatalysts.

Alginate, which is extracted from seaweed, is a linear copolymer of D-mannuronic and L-guluronic acids (Fig. 2) and can be gelled by multivalent ions such as calcium and aluminum. For immobilization of cells, sodium alginate, which is soluble in water, is mixed with a suspension of cells and then dropped into a calcium chloride solution to form water-insoluble beads of calcium alginate gels (30).

However, calcium alginate gels are apt to disrupt by mechanical stress and are gradually solubilized in the presence of calcium-ion-trapping reagents, such as phosphate ion and citrate. Leakage of cells is then liable to occur, but free cells can be recovered from the immobilized preparation by this solubilization, which allows the characterization of the cells in gels (e.g., viability). Several multivalent metal ions, such as aluminum ion or strontium ion, can also be used instead of calcium ion. The treatment of formed calcium alginate gels with cationic polymers can improve gel resistivity against the solubilization by calcium-ion-trapping reagents (31). It is also reported that addition of polyacryl acid to sodium alginate in the entrapment by the procedure described can increase the mechanical strength of gels formed and prevent them from dissolving because of bridging polyacrylate chains with calcium ions (32).

The method using alginate gel is widely applicable to immobilization of various useful biocatalysts, including very fragile ones such as plant cells and animal cells, as shown in Table 2, because of the simplicity of the procedure, easy availability of sodium alginate, and mildness of immobilization conditions. It is worthy of note that the first report on immobilization of plant cells employed this method (33).

κ-Carrageenan Gel Method. κ-Carrageenan is a readily available nontoxic natural polysaccharide, isolated from seaweed. It is composed of a unit structure of β-D-galactose sulfate and 3,6-anhydro-α-D-galactose (Fig. 3) and is widely used in the food and cosmetic industries as a gelling, thickening, and stabilizing agent.

κ-Carrageenan becomes a gel by cooling or in the presence of a gel-inducing reagent, such as ammonium ion, potassium ion, calcium ion, aluminum ion, magnesium ion, diamines, or water-miscible organic solvents (34). If the proper gel-inducing reagent is used to form a κ-carrageenan gel in the presence of cells, immobilized cells can be easily obtained.

κ-Carrageenan gels can be easily solubilized in saline or in water, and a suspension of free cells can be obtained to investigate their characteristics. On the other hand, leakage of cells easily occurs by dissolution of gel when a gel-inducing reagent is not added to the reaction mixture.

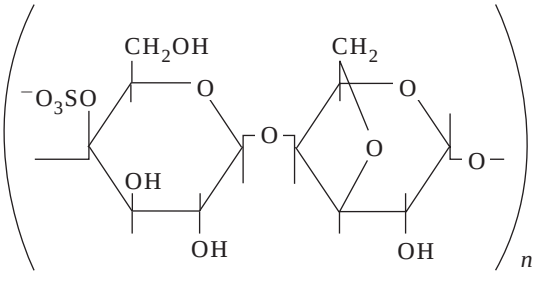

Figure 3. Structure of κ-carrageenan (molecular weight, 100,000–800,000).

In order to increase the stability of the κ-carrageenan-entrapped cells, treatment with glutaraldehyde and hexamethylenediamine after entrapment is often effective.

The conditions of immobilization by this method are also mild, and this method can be used for immobilization of various biocatalysts (Table 3). This method has replaced the polyacrylamide gel method in industrial production of L-aspartate (35) and L-malate (36) by means of immobilized microbial cells. Another advantage of this method is that various shapes of immobilized cells can be prepared (34). The typical procedures for preparing various shapes of κ-carrageenan gel-entrapped cells are as follows:

Cubic type. A suspension of cells and κ-carrageenan dissolved in physiological saline are mixed and cooled to about 10 °C to form a gel. After the gel is soaked in a cold potassium chloride solution in order to increase the gel strength, it is cut to give a cubic-type gel preparation.

Bead type. A mixture of κ-carrageenan and cells is dropped into a 0.3 M potassium chloride solution through a nozzle. Bead-type gels are obtained by this procedure.

Membrane type. A mixture of κ-carrageenan and cells is spread on a plate or sheet and soaked in a cold potassium chloride solution. Consequently, a membrane-type gel is obtained.

Synthetic Resin Prepolymer Method. With the application of a variety of bioreactions, including synthesis, transformation, degradation, or analysis of various compounds having different chemical properties under various reaction conditions, gels having controlled physicochemical properties come to be required for entrapment of biocatalysts. Selection of suitable gel materials among natural polymers for each purpose is usually difficult. For this reason, entrapment methods using synthetic resin prepoly-

mers, such as photo-cross-linkable resin prepolymers and urethane prepolymers, are promising. Synthetic resin prepolymers having desired characteristics can be synthesized chemically in advance in the absence of biocatalysts. The methods are as follows:

Photo-cross-linkable resin prepolymer method. Entrapment methods using photo-cross-linkable resin prepolymers (Fig. 4) with hydrophilic (ENT) or hydrophobic (ENTP) properties, cationic or anionic nature, and different chain lengths have been developed by Fukui and coworkers (37,38). ENT and ENTP can be prepared from hydroxyethylacrylate, isophorone diisocyanate, and poly(ethylene glycol) or poly(propylene glycol), respectively.

A mixture of the prepolymers and cells, layered (about 0.5-mm thickness) on a transparent polyester sheet is gelled by irradiation with near-ultraviolet light (wavelength rage 300–400 nm) for several minutes in the presence of a proper sensitizer, such as benzoin ethyl ether. This method has been applied for the pilot-scale continuous ethanol fermentation by immobilized growing yeast cells (39). Table 4 lists some examples of cells immobilized with photo-cross-linkable resin prepolymers and their applications. These prepolymers are available from Kansai Paint Co., Japan. Photo-cross-linkable resin prepolymers can be stored in the dark and sterilized at 120 °C.

Urethane prepolymer method. There are also various types of urethane prepolymers (PU) (Fig. 5), which have different hydrophilicities or hydrophobicities and chain length. Urethane prepolymers are synthesized from toluene diisocyanate and polyether diols composed of poly(ethylene glycol) and poly(propylene glycol) or poly(ethylene glycol) alone, although these are not commercially available. Hypol®, which has a similar structure, can be obtained from W. G. Grace Co., Boca Raton, Fla., USA.

Isocyanate functional groups at the terminals of urethane prepolymers react with each other in the presence of water to form urea bonds and liberate carbon dioxide. Therefore, gel is easily formed only by mixing the prepolymer with an aqueous suspension of cells, and entrapment of cells can be easily carried out (38,40). Some examples of cells immobilized with urethane prepolymers are listed in Table 5.

Urethane prepolymers can also be stored in a desiccator and sterilized at 120 °C, avoiding moisture.

In the cases of these synthetic prepolymer methods, the size of the network of gel matrices (which affects diffusion of substrates and products inside the gel, the mechanical strength of the gel formed, the cell-holding capacity of the gel, and the growth ability of cells inside gel matrices) can be regulated by the chain length of the prepolymers and content of the reactive functional groups.

Furthermore, a balance between hydrophilicity and hydrophobicity of gels can be optionally controlled by selecting suitable prepolymers or by mixing prepolymers that have different properties at a proper ratio. The hydrophilicity–hydrophobicity balance of the gels often has a critical effect on the bioconversion by strongly affecting the partition of reactants to the gels.

The Ionic character of the gel, which is also an important factor in bioconversion, can be introduced into the prepolymers by using ionic oligomers as the main chain for their synthesis.

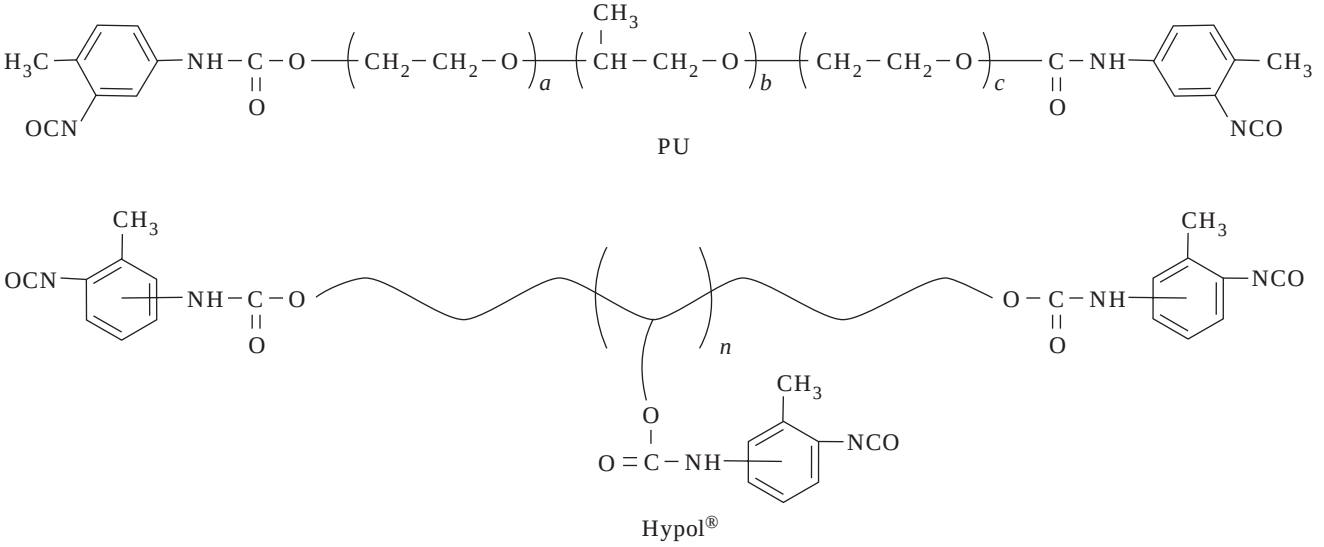

Figure 5. Structures of typical urethane prepolymers.

Other specific features and advantages of the synthetic prepolymer methods are as follows.

1. Procedures for entrapment are very simple and proceed under very mild conditions, and various types of biocatalysts can be immobilized by these methods.
2. Prepolymers do not contain monomers, which may have unfavorable effects on biocatalysts, such as cells. Therefore, the synthetic prepolymer method seems to be one of the most practically applicable immobilization methods for a wide variety of purposes.

OUTLINE

INTRODUCTION

The first application of centrifugal separation other than in milk processing was in the harvesting of cells in baker's yeast production. Centrifugation is still the only choice for cell separation and protein recovery in many fermentation processes.

CENTRIFUGAL SEPARATION

Centrifugal separation is a sedimentation operation accelerated by centrifugal force. Thus, a prerequisite for the separation is a difference in density between the phases. This applies to both solid–liquid and liquid–liquid separation.

The settling velocity (V_g) of a solids particle (or droplet) under the influence of gravity alone is given by Stokes' law (see "Nomenclature" for abbreviations and symbols):

$$V_g = \frac{\rho_p - \rho_f}{18 \cdot \eta} \cdot d_p^2 \cdot g \quad (1)$$

In the centrifuge field, the settling velocity becomes:

$$V_c = V_g \cdot Z \quad (2)$$

where

$$Z = \frac{\omega^2 \cdot r}{g} \quad (3)$$

is called relative centrifugal force (RCF) or G-number.

It is, however, not the RCF only that determines the performance of a given centrifugal separator. The residence time of the particle or droplet in the centrifugal force field is important, so a larger volume of the rotor will increase the possible flow rate. In the most common centrifugal separators, the disk bowl machines, a given bowl material can cope with a certain peripheral speed—the stronger the bowl material, the higher the speed. This leads to the fact that the maximal RCF is inversely proportional to the bowl diameter, but not necessarily that the lower RCF machine has a lower performance.

TYPES OF CENTRIFUGAL SEPARATORS

General

What determines the design of a centrifuge is the method by which the solids phase in the process material is handled. The first two types of centrifuges developed were applied to duties where the resulting products were in liquid form, such as cream and skim milk and yeast cream and cell-free wort. In the beginning of this century, centrifuges were applied to processes with solids, amorphous or crystalline. In the biotechnological industry, the solids phase is often recovered in a diluted suspension or is, even at high solids concentrations, a slurry with good flow properties.

Types of machines are described in the work by Rushton et al. (1). The most comprehensive description of centrifuges can be found in the book by Sokolov (2). Brochures and technical publications from sedimenting centrifuge manufacturers such as Alfa-Laval Separation AB also provide information on machine types and sizes.

In this article, centrifugal filtration will not be dealt with because of the limited use in this industry, with the exception of crystal recovery in antibiotic production. For a description of various centrifugal filters, see Rushton et al. (1).

Disk Bowl Machines

Solid Bowl. A solid bowl machine (Fig. 1a) has two liquid outlets, each with a paring disk. Other versions have

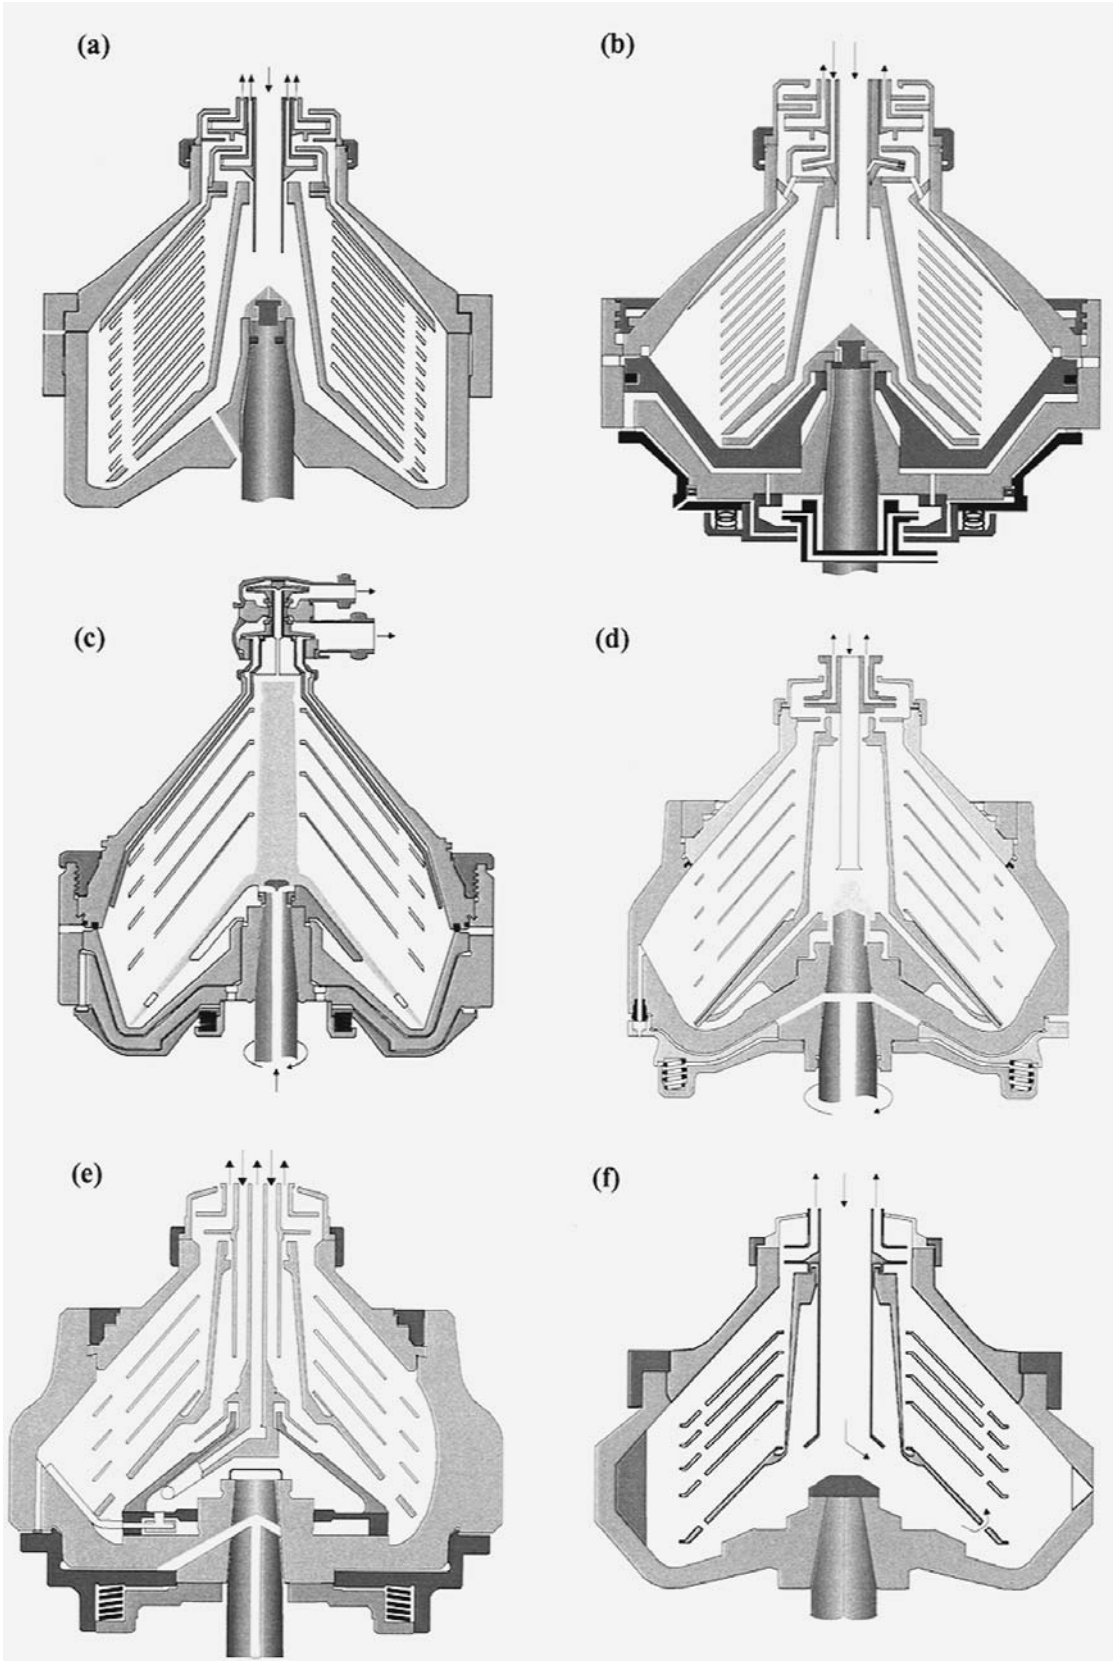

Figure 1. (**a**) Solids-retaining disk bowl, vertical cut. (**b**) Radial solids-ejecting disk bowl, top feed, vertical cut. (**c**) Radial solids-ejecting disk bowl, hermetic feed, vertical cut. (**d**) Axial solids-ejecting disk bowl, vertical cut. (**e**) Nozzle bowl with pressurized solids discharge, vertical cut. (**f**) Nozzle bowl with peripheral discharge nozzles, vertical cut.

none or one paring disk. The solids accumulate at the periphery and must be removed manually. In the separation of two nonmiscible liquids, a coalescence of the dispersed droplets takes place at an internal interface in the bowl. The positioning of this interface is very important. The nearer it is placed to the light liquid outlet, the more contaminated the light liquid will be with droplets of the heavy phase. The position is determined by a gravity disk, over which the heavy liquid flows. The gravity disk diameter is given by the relation:

$$D_h = \sqrt{D_i^2\left(1 - \frac{\rho_{fl}}{\rho_{fh}}\right) + D_l^2 \frac{\rho_{fl}}{\rho_{fh}}} \quad (4)$$

If properly designed and if the feed flow rate is high enough to prevent sedimentation in the bowl, this type of machine can be used to recover a dilute cell concentrate in the heavy liquid outlet. This is also valid for three-phase solids-ejecting machines. Solid-bowl machines are made in a large number of sizes, with bowl diameters ranging from 140 to 750 mm.

Solids-Ejecting Separators, Radial Discharge. Of all types of disk bowl machines, the solids-ejecting separators with radial discharge (Fig. 1b, c) are the most common. With an automated, periodic partial discharge of the sediment, it is possible to obtain a considerably higher concentration of the solids than in the peripheral nozzle machine (Fig. 1f). The machine is discharged in about 0.1 s by pressing a sliding bowl bottom in the bottom part of the bowl downward, thereby opening large discharge ports in the outer bowl wall. To make the discharge at the right moment, the discharge can be initiated by a self-triggering mechanism that hydraulically senses the solids level in the solids space (3). Three-phase separation units are available. The solids-ejecting machines can be equipped with hermetic seals and a hermetic feed from below in a hollow spindle (Fig. 1c). In these true hermetic machines, the split between the exiting light and heavy liquids can be made by controlling the back pressure in the outlet pipes. The heavy liquid can contain large amounts of solids (cells or proteins) if the machine is properly designed. The solids-ejecting separators are available in about 10 sizes, with bowl diameters between 180 and 900 mm. The smaller units are more often available in versions equipped for BL2-LS requirements than are larger units. A pilot-scale sterilizable separator module is seen in Figure 2. A large-scale unit is seen in Figure 3.

Solids-Ejecting Separators, Axial Discharge. When comparing axial and radial discharging separators (Fig. 1b, d), one finds that the axial machine has a different geometry. The lock ring can be placed at a smaller diameter, because no sliding bowl bottom needs to be fitted. This reduces the stresses in the winding of the lock ring. Also, the solids outlet takes place through a few small axial channels that do not induce such large stresses in the bowl shell. These two factors make it possible to increase the bowl speed considerably above that of the radially discharging machines, so that the RCF is at least doubled. The discharge system is operated by pressurized air, which forces a ring slide, equipped with valve seats, downward, opening the axial channels. To facilitate the transport of solids toward the channels, the bowl is machined to have a star-shaped inner contour. This type of machine exists at present in three sizes, with bowl diameters ranging from 500 to 900 mm. BL2-LS versions are available.

Nozzle Machines with Pressurized Discharge of Concentrate. The apparent viscosity of bacteria and yeast suspensions as well as some protein precipitates decreases with increasing velocity gradient. Therefore, they are able to flow even at high concentrations in channels or tubes from the periphery of the bowl in nozzle machines with pressurized discharge of concentrate (Fig. 1e). The tubes empty into a central chamber, where a centripetal pump, a paring tube, picks up the concentrate and pumps it out of the bowl. The nozzles are placed at the end of the concentrate tubes, just in front of the chamber. This machine type is suitable only for applications where the solids have the specific flow properties mentioned earlier and in the absence of other type of solids. In some machines, of this type of vortex chamber is placed in front of the nozzle (4). Liquid enters the chamber tangentially, creating a viscosity-dependent whirl, and leaves through the nozzle in the centre of the chamber. The viscosity effect is giving a self-regulating function so that varying solids flow rates (within limits) to the machine will result in a constant concentration of the concentrate, thereby reducing the risk of clogging the machine. One of the units of this type (Fig. 4) is available in a sterilizable, contained, and aseptic version, conforming to BL2-LS. To make this possible, the cleaning-in-place (CIP) has to be efficient. Therefore, the sterilizable machine uses the discharge system of the machine in Figure 1d during CIP. This system is also used in noncontained versions. Bowl diameters between 500 and 900 mm are available.

Nozzle Machines with Peripheral Nozzles. In nozzle machines with peripheral nozzles (Fig. 1f), nozzles with a diameter of 0.5 to 3 mm are situated at the periphery of the bowl, which has sloping walls toward the nozzles. The number of nozzles varies between 4 in small bowls and 20 in the largest bowls. It can be equipped with a recirculation device for the sediment, a separate central tube that is divided into tubes along the bowl bottom ending just in front of the nozzle. This makes it possible to increase the concentration of the solids phase without the need to decrease the nozzle size, leading to increased risk of nozzle clogging. The nozzle flow rate is proportional to number of nozzles, distance from the center of rotation, bowl speed, and square of the nozzle diameter. The peripheral nozzle machines are used for the largest flow rates; the bowl diameters are up to 1,000 mm.

Decanter Centrifuges

In the 1950s, the solid-bowl separator with scroll discharge (decanter centrifuge) (Fig. 5) was developed for large quantities of solids. It is equipped with a screw conveyor that rotates at a speed slightly higher or lower than the bowl speed.

The differential speed can be varied. Careful control of this parameter, torque control, and some newer design fea-

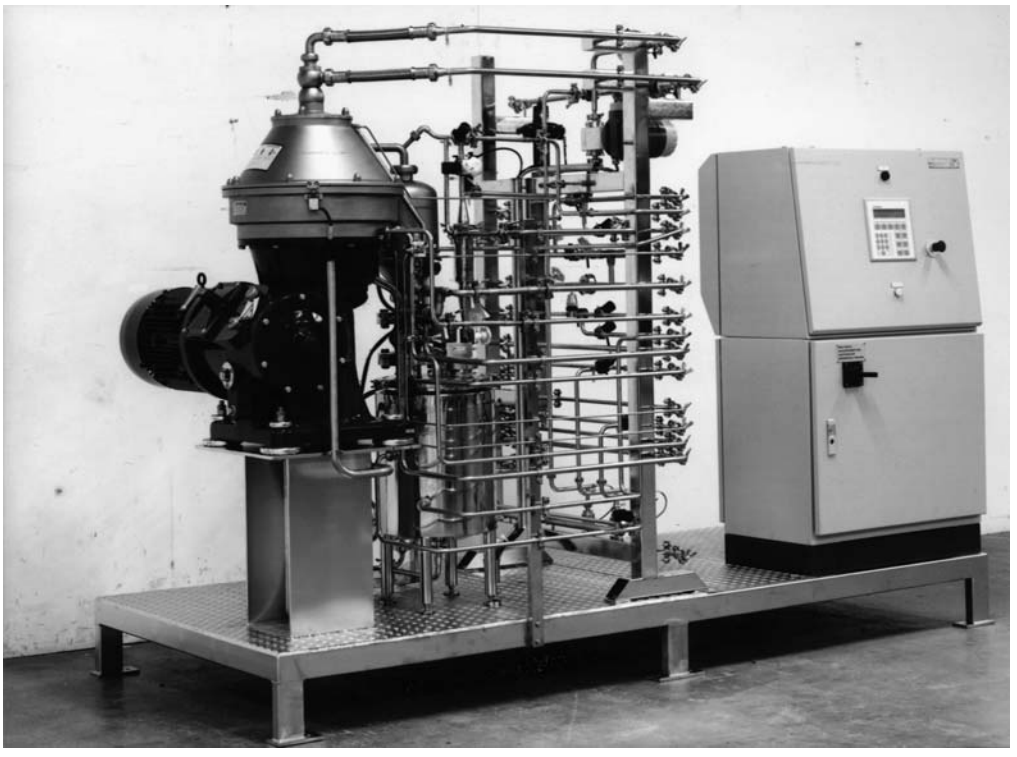

Figure 2. Solids-ejecting disk bowl centrifuge of pilot size for sterilizable contained installation. Type BTPX 205. The height of the separator only is 1.3 m. *Source*: Courtesy of Alfa-Laval Separation AB.

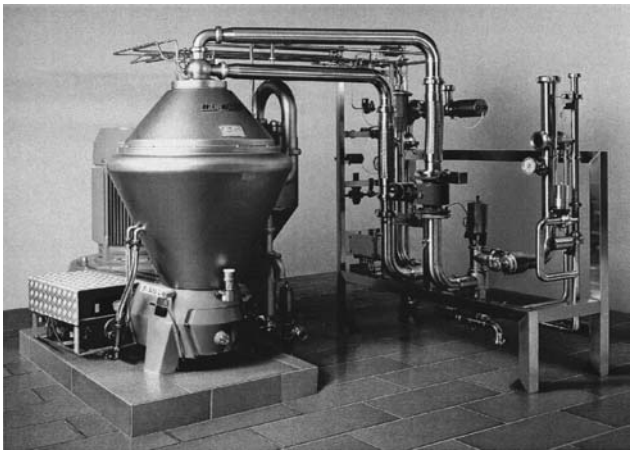

Figure 3. Solids-ejecting disk bowl centrifuge of production size. Capacity in breweries up to 75 m^3/h. Type BREW 2000. The height of the separator is 2.2 m. *Source*: Courtesy of Alfa-Laval Separation AB.

tures (e.g., the baffle disk), have recently made the decanter interesting to use also for biological sludges. However, the conventional mechanical design of these machines does not allow more than 5,000 G for a medium-diameter machine (5). To reach higher *g*-forces new design features are needed (6). With suspended main bearings, a separate gear box, and a swimming conveyor, held in place by the liquid, 10,000 G is feasible.

For three-phase decanters, the gravity disk dimensioning follows in principle equation 4. It is, however, very important to take the weir head into account, because a variation of the light-to-heavy phase ratio gives a very unstable interface position (7).

The range of bowl diameters is very wide, from 150 to 1,200 mm; the bowl length is often 4 to 5 times the diameter.

The newest addition to the decanter family is a vertical decanter equipped with a disk stack (8). The thought is to combine the best characteristics of a decanter (dry solids) and a disk bowl machine (good clarification).

Other Classical Bowl Designs

Tubular Bowl. In the tubular bowl (Fig. 6) the rotor, driven from above, consists of a long cylinder, into which liquid is pumped from below. The design shown in Figure 6 is equipped for separation of two liquid phases. Most tubular centrifuges are used for separating very valuable solids from a liquid. The liquid is pumped out by a paring disk, avoiding aerosol and foam formation. To remove the solids accumulated at the periphery, the machine must be stopped and dismantled. The bowl diameters are up to 130 mm with a solids volume of up to 6 L. In the industrial models, 20,000 G are generated. Sterilizable and contained units are available.

Multichamber Bowl. In the multichamber bowl machine (Fig. 7), the process liquid flows in the annuli between con-

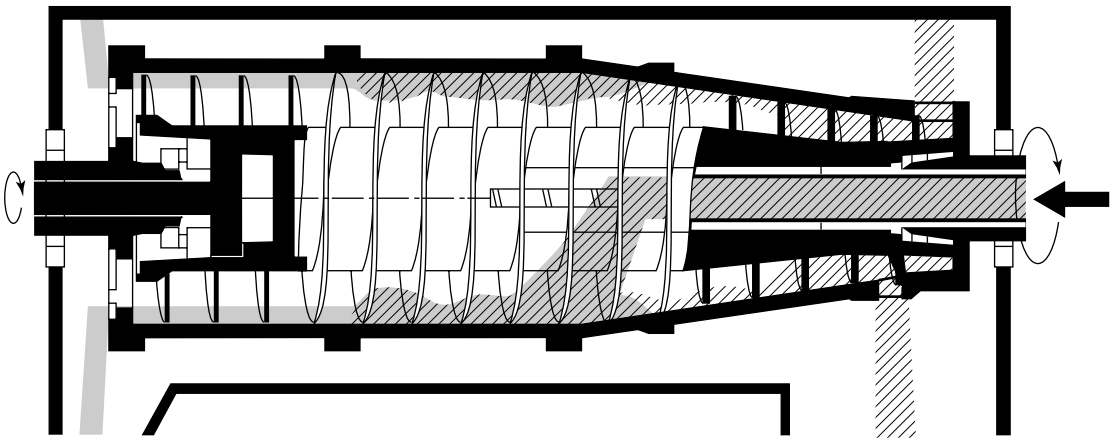

Figure 5. Decanter centrifuge, vertical cut.

centric cylinders. Having a relatively low separation capability, this type of machine is used for recovery of valuable solids, when the solids volume of the tubular bowl is too small. Some designs include cooling channels in the bowl wall, a cooling jacket around the bowl, and a cooled centripetal pump. The maximum bowl diameter is about 500 mm.

New Bowl Designs

Centritech® Machines. In the Centritech® machine (Fig. 8), a disposable separation insert in plastic is placed in a rotor. The feed liquid enters at the top of the insert, and the main liquid outflow is at the opposite end of the top of the insert. The heavy liquid phase (cell concentrate) is withdrawn intermittently through the bottom outlet. Through the principle of the inverted comma no seals between rotating and nonrotating parts are needed. The G-number is maximum 100. The mechanics are further described in Apelman et al. (9). Its only described application is separation of mammalian cells from culture fluid. Two sizes of the machine are available. The diameter of the insert is about 300 mm in the larger unit.

Inverted Chamber Bowl with Intermittently Operated Scraper. The inverted chamber bowl (Fig. 9) is a relatively new type of machine, sold under the name Powerfuge™ (10). Its bowl has its opening downward, where the centrate leaves under gravity and is collected in a chute. The feed is from the top. When the bowl is full of solids, it is decelerated. At low speed, the asymmetrically positioned scraper is engaged and removes the solids. Four sizes are available, with bowl diameters from 150 to 600 mm. They are designed for CIP and sterilization-in-place (SIP). The smallest unit can develop 20,000 G.

Summary

In Table 1, the characteristics of various separator types are found. It has to be remembered that the hydraulic capacities given by centrifuge manufacturers are the maximum possible feed flow rates that often are far above the flow rates that will give satisfactory separation results for difficult separations, such as bacteria and protein separations.

FLUID AND PARTICLE DYNAMICS

Introduction

A successful scale-up method should be based on a mathematical model that accurately describes the separation process, the hydrodynamics and particle dynamics inside the bowl. The phenomena going on inside the centrifuge bowl are, however, so complicated that no mathematical model is able to predict in absolute terms the separation efficiency as a function of machine and process media parameters. Axelsson (11) reviewed of some of the flow phenomena, which are briefly discussed in this section, along with examples of more recent findings.

Centrifuges with Conical Disks

Fluid and Particle Dynamics in the Disk Stack. The disks in the disk bowl split the flow in thin layers. The Reynold number for the flow between the disks is usually low, and the flow is laminar, resulting in an easy particle settling. The critical Reynolds number for transition to turbulent flow increases with decreasing disk spacing and increasing bowl speed (2), which is beneficial for the separation efficiency because the settling distance at a small disk spacing will be short, and the high bowl speed gives a large settling velocity. Also, a small disk spacing keeps the liquid rotating at or near the bowl speed, thus reducing the pressure drop in the disc stack.

In Figure 10 is a vertical cut of two disks in the disk stack, where the flow is driven toward the center by a radial pressure gradient. The character of the velocity profile between the disks depends on a dimensionless number, λ, which is defined as

$$\lambda = t \cdot \sqrt{\frac{\omega \cdot \sin \alpha}{\nu}} \qquad (5)$$

When λ is small, the velocity profile is parabolic, but for λ values above 5, normally encountered in industrial centrifuges, the radial velocity component splits up in two thin layers, Ekman layers (Fig. 10). In these layers, all the net transport of liquid toward the center takes place. Because separated particles (heavy phase) are collected at the underside of the disk, they are subjected to a strong shear force from the Ekman layer that drags the particle toward the liquid outlet. The velocity in these layers increases with increasing λ, such as with increasing bowl speed. Therefore, a higher bowl speed cannot always be fully used because of the counteracting shear force.

In between the Ekman layers is the geostrophic layer. In Figure 11 its streamlines have been visualized by dye

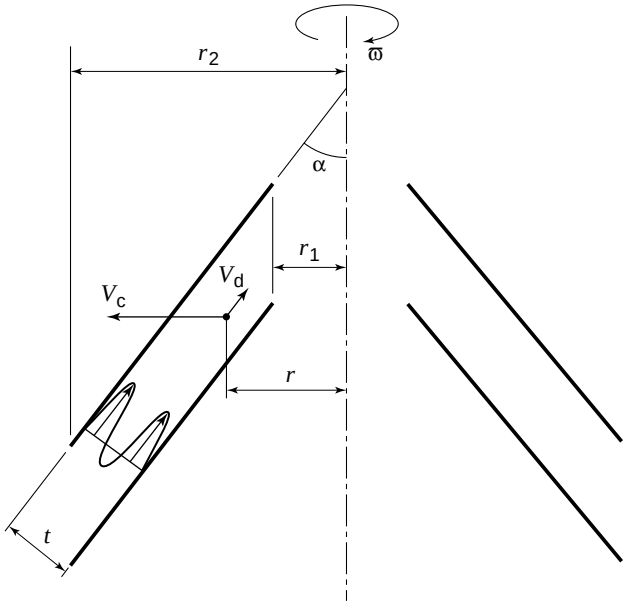

Figure 10. Flow profile between conical disks at high λ value. Particle separation.

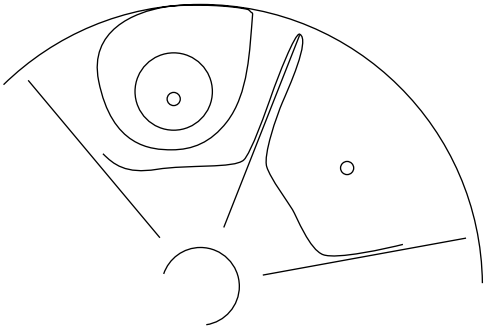
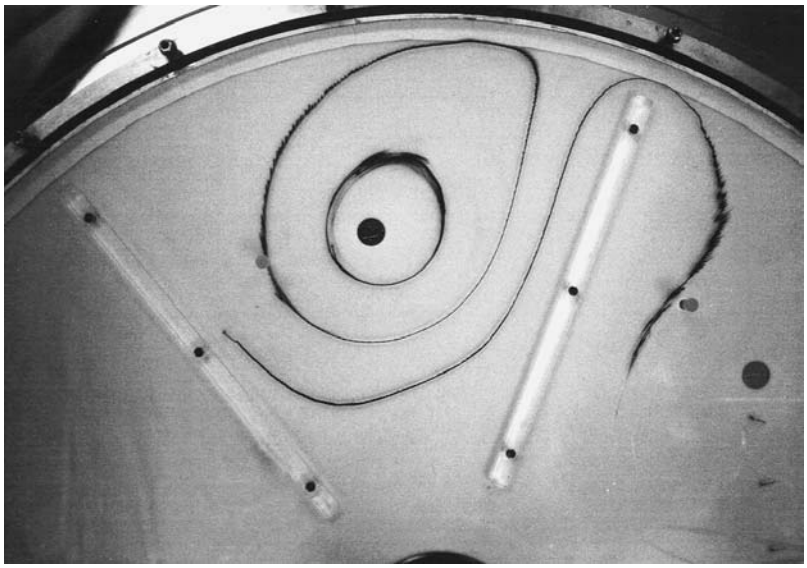
injection, and they can be compared with the calculated streamlines in a gap between two disks with radial spacers and with a distribution hole where the liquid enters the gap (12). Particle separation has also been studied in the same geometry (13). It has been found that the drag force on the particles collected at the underside of the disk depends on the position on the disk and that some particles are easily separated, whereas others are forced toward the center. The drag force can be computed (14), and the calculations of separation efficiency including the drag force verify these findings.

There is also an accumulation of particles at the radial spacer, along which the solids slide toward the periphery (13). At the end of the spacer, there is a wake that forces the particles back toward the center until the bulk weight of the solids becomes large enough to cause an intermittent discharge of particles into the solids space outside the perimeter of the disk.

Inlet. All bowls in the machines in Figures 1 to 9, except the hermetic machine (Fig. 1c) and the Centritech® machine (Fig. 8), have an open chamber in the center of the bowl, where the nonrotating feed liquid is received. In most inlets, the liquid forms a cylindrical interface with the gas (usually air) in the receiving chamber. The nonrotating in-



(a)



(b)

Figure 11. Comparison of calculated (**a**) and actual (**b**) flow patterns in a disk bowl.

coming liquid hitting the rotating interface results in a turbulence that entrains into the feed and splits particles that are susceptible to shear; the further out from the center the interface, the larger the turbulence. If it is not practical to use a hermetic inlet, the interface in the inlet must have as little an inner radius as possible. Also, the unavoidable energy dissipation must be distributed over a large volume, thereby diminishing the shear force. One design that allows smoother inlet conditions and a reduced air entrainment is the disk inlet (15).

A mathematical model for feed zone breakage of shear-sensitive particles has been verified for a conventional pilot-scale solids-ejecting separator (16). The extent of breakage was found to be independent of flow rate. This agrees with the finding that temperature increase in the separated liquid after the separator is also independent of flow rate.

Outlets. The liquid streams leaving the separator have picked up energy in the form of kinetic energy and heat caused by inner friction. When the liquid is decelerated outside the separator, the kinetic energy is converted to heat. The temperature increase is proportional to the square of the bowl speed and to the square of the radius at which the liquid leaves the separator. It is therefore not surprising that the discharge in a peripheral nozzle or a solids-ejecting machine causes breakage of cells because of the high kinetic energy of the fluid. A typical degree of bacterial cell breakage is 30%. The consequence of this is that if the particles to be separated are susceptible to shear and cell integrity is important, the cell concentrate should leave the centrifuge as near to the center as possible, such as in a machine according to Fig. 1c or e. It has been reported (17) that in such machines the breakage of *Escherichia coli* cells is low.

The outlet from the centrifuge is often of the paring disk type. For a good function, this outlet must be designed to avoid air entrainment and large shear forces. This is especially important for chemically sensitive substances such as proteins. A hermetic design (Fig. 1c) can be used in some applications.

Decanter Centrifuges

The objective of a decanter is usually to concentrate the solids present in concentrated suspensions. The hydrodynamics of a decanter are complicated. The conveyor adds turbulence and forces the liquid into a helical path (2). Below the top layer, vortices are formed. The transport of solids with low inner friction will influence the sedimentation process. The turbulence at the inlet zone, with possible resuspension of separated solids, and the lower solids concentration toward the liquid outlet contribute to the fact that a slender decanter will separate better than a short one with the same theoretical size (18).

THE THEORETICAL SIZE OF A CENTRIFUGAL SEPARATOR

Introduction

From the descriptions in the previous section it is evident that mathematical models describing the flow phenomena in centrifuges are very difficult to build. However, the attempts made are successful when machines of different sizes but with identical geometry are compared, for example, for scale-up purposes (see "Pilot Machine Testing").

The Σ Theory

The Generalized Σ Formula. The most-used quantity to characterize centrifuges, the Σ concept, was presented by Ambler (19,20). In its derivation he considered particles with a critical diameter (d_c) that were separated to 50%. Today, however, the most-used definition of the critical particle is the particle that is separated to 100%. This does not influence the formulas for the Σ value, but the value for the feed flow rate (Q) will be halved. Σ is defined as

$$Q_{\text{theor}} = V_g \cdot \Sigma \tag{6}$$

V_g is the Stokes settling velocity (equation 1). Σ has the general expression

$$\Sigma = \frac{V \cdot \omega^2 \cdot r_e}{g \cdot s_e} \tag{7}$$

The equation for the critical diameter becomes

$$d_c = \left(\frac{18 \cdot \eta \cdot Q_{\text{theor}}}{(\rho_p - \rho_f)} \cdot \frac{s_e}{V \cdot \omega^2 \cdot r_e}\right)^{1/2} = \left(\frac{18 \cdot \eta \cdot Q_{\text{theor}}}{\Sigma \cdot (\rho_p - \rho_f) \cdot g}\right)^{1/2} \tag{8}$$

The derivation in equation 8 is based on the following assumptions:

- Viscous drag is determining the particle movement.
- The flow in disk bowls between the disks is laminar and symmetrical.
- The liquid rotates at the same speed as the bowl.
- The particle concentration is low (no hindered settling).
- The particle always moves at its final settling velocity.
- This settling velocity (V_c) is proportional to the g-force.

Ambler uses the critical particle in his formula; therefore, his analysis is a special case of Svarovsky's grade efficiency function (21), where for each particle size the ratio of sedimented mass to the mass in the feed material is determined and integrated over all particle size to get a more realistic measure of the separation efficiency.

Σ for Disk Bowl Centrifuges. The flow system in between two conical disks is shown in Figure 10. The particle has a radial velocity component because of the centrifugal force (V_c), which increases with increasing r. It has also a drag-dependent velocity component (V_d), which can have any size or direction depending on the flow situation round the particle. In the Σ theory, it is assumed that V_d depends on

uniform radial plug flow parallel to the disks. The derivation of the equation for Σ is found in the paper by Ambler (20), and the result is shown in Table 2.

Summary. In Table 2, the resulting expressions of the Σ value for four different bowl geometries in continuous centrifuges are shown. These have been obtained by inserting actual values of V, r_e, and s_e for the various geometries.

Separation Efficiency

The assumptions in the Σ theory are not fulfilled in reality, as mentioned previously. Therefore, equation 6 should include an efficiency factor, so that in practice the flow rate is reduced at the requested separation performance. The efficiency factors have been estimated to have values according to Table 3 (11). This table was compiled in 1984 from data in literature. By careful measurement of the density difference and particle dimensions, it has been shown that in one case an efficiency factor of maximum 16% was found to fit the experimental data in a pilot-size disk bowl machine (16). However, this probably also included effects of hindered settling (see "Hindered Settling").

In the absence of hindered settling, the equation describing the relationship between the feed flow rate, the Σ value, and the settling rate, will thus be

$$Q_{act} = \mu \cdot V_g \cdot \Sigma \tag{9}$$

The KQ Formula for Disk Bowl Centrifuges

In 1961 a semi-empirical equation for the separation area was published (22). It is based on the finding that separation data fitted the relation

$$\frac{V_c}{V_g} = \left(\frac{\omega^2 \cdot r}{g}\right)^k \tag{10}$$

with $k = 0.75$ better than the classical analysis (equations 2, 3, and 6), where $k = 1$. This fact is a consequence of the increasing shear forces in the Ekman layers (see "Fluid and Particle Dynamics in the Disk Stack"). For practical purposes, the following relation is used:

$$KQ = 280 \cdot \left(\frac{n}{1000}\right)^{1.5} \cdot N \cdot \cot \alpha (r_2^{2.75} - r_1^{2.75}) \tag{11}$$

where n = bowl speed in rpm and r_2 and r_1 are the radii of the disk in centimeters. This form of the KQ formula is dimensionally incorrect, but it is mathematically possible to make it correct, expressing the KQ value as an entity with the dimension area. In practice, the difference between the KQ and the Σ for scale-up purposes is negligible, compared to other inaccuracies.

Hindered Settling

One of the few experimental investigations into hindered settling of cells (23) shows that complex phenomena occur at high concentrations. A model with several experimental constants was developed. It showed that the settling rates drop very fast with increasing solids content, by a factor of about 2 at 20% by volume, and 15 to 20 at 50% by volume. The classical model used in the work by Clarkson et al. (16) gave similar results. In the tests by Aiba et al. (23), it was also found that cells may settle flocculated at higher concentrations. Hindered settling is one further example of the difficulty to calculate theoretically the performance of centrifuges.

SELECTION OF TYPE AND SIZE OF CENTRIFUGE

Introduction

The choice of type and size of centrifuges is a combined theoretical and practical exercise. In most cases the final choice for a new centrifuge application cannot be made without a test of the type of centrifuge preliminary selected, at between 25 and 100% of the final plant flow rate. There are at least two reasons for this. One is the elimination of the technical risk. The other is most common in

Table 2. Σ Equations for Various Separator Types

Machine type	Equation for Σ	Symbols used	References
Disk bowl	$\frac{\pi \cdot \omega^2}{g} \cdot \frac{2}{3} \cdot N \cdot (r_2^3 - r_1^3) \cdot \cot \alpha$	r_2 = max radius of disk r_1 = min. radius of disk N = number of disk α = half cone angle of disk	19,20
Decanter	$\frac{\pi \cdot \omega^2}{g}\left[L_1\left(\frac{3}{2} \cdot r_2^2 + \frac{1}{2} \cdot r_1^2\right) + L_2\left(\frac{r_2^2 + 3r_2r_1 + 4r_1^2}{4}\right)\right]$	L_1 = length of cylindrical part L_2 = length of conical part r_1 = inner radius of liquid r_2 = inner radius of bowl	20,21

the pharmaceutical industry. During the preapproval inspection, those in the inspecting and license-giving institutions are concerned with the comparability between batches of product from the development phase and from the production phase (24). Because the validation procedures are costly and time consuming, it is very important to select at least the right type of centrifuge already in pilot scale. It is important that alternative process and plant designs are discussed before the centrifuge type and size are selected (Table 4).

Main Process Parameters

It is important to define at least the characteristics of the duty listed in Table 5. The *feed flow rate* is often determined by the available or necessary time to process one batch. The *separability* can be estimated on a bench scale by test tube centrifugation (spin test) (see next section). The *flow of solids* is the feed flow rate multiplied by the percent by volume of suspended solids. This solids flow rather than the suspended solids content alone influences the choice of machine type. Different machine types differ in their ability to produce high *concentration of the separated solids* (Table 1). The *required degree of separation* has a strong influence on the possible flow rate in a given machine. To increase separation efficiency of *E. coli* from 90 to 99%, the flow rate must be decreased by 30 to 35% (25). To reach 99.9%, a further reduction of about 30% is necessary. Many cell suspensions, including yeast, have the same narrow particle size distribution and the numbers are the same. With the wider distribution of cell debris, for example, the flow rate reduction percentages are much higher. *Solids rheology*, which is the reaction of the solids to pressure and shear forces, is very important for the choice of machine type. Pseudoplastic (shear thinning) solids (such as unflocculated yeast, rod-shaped bacteria, and cocci as well as some protein precipitates) will flow out of the machines seen in Figure 1c and e at 80% by volume of suspended solids, which often has positive consequences (reduced cell breakage). Shear thinning solids may have an angle of repose of close to 0 degrees (see "Important Properties of the Process Streams"), but this is not always the case, such as with flocculated or mycelium-forming bacteria. On the other hand, dilatant solids (starch or calcium carbonate) will not be discharged in concentrated form without manual handling from any machines other than those seen in Figures 1f and 5. The rheology of inclusion body concentrates is not much studied, but they are preferably discharged from the machine seen in Figure 1b. Because of the content of a valuable dissolved substance in the entrained liquid, *washing of solids* may be necessary.

Another reason for washing solids is, of course, to get rid of impurities. This is usually done by resuspension and further separation steps.

Test Tube Centrifugation (Spin Test)

Determination of Separability. The most important task for a spin test is the determination of separability, that is, the settling velocity. In practice, it is difficult to calculate, because often the information needed in Stokes' law is not complete. The spin test is done by spinning a sample of the feedstream for different periods of time or different G-numbers or both. For each of these spins, the supernatant is analyzed with regard to the important process parameter, for example, residual solids, turbidity and cell count, or water content in the case of light solvent. Thereafter, the time of the spin with the acceptable supernatant quality is recorded, and the necessary Σ is calculated according to equation 16.

The Spin Test as an Analytical Tool. The spin test is also a valuable tool for measuring the phase-to-volume ratios. The solids content in percent by volume from the spin test will be a very important parameter for the next step, which is to make a crude mass balance around the centrifuge. The spin test performed under different time and *g*-force conditions gives also an indication of solids compressibility and rheology. It is also valuable to prepare a sample of the solids phase after spinning to get a good indication of its dry solids content after the centrifugation. In cases where the fermentation substrate contains suspended solids, residues of these may be present after fermentation. A spin test will make it possible to identify the nature and amount of these, which is very important because they may obstruct the solids phase flow in nozzle and solids-ejecting machines.

Theory of the Test Tube Centrifuge. The swing-out test tube (bottle) centrifuge is shown schematically in Figure 12. In order for a particle to be separated out with 100%

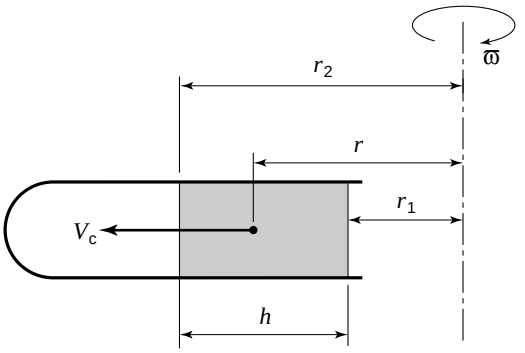

Figure 12. Separation of particles in a swing-out test tube centrifuge.

chance, it has to move from radius r_1 to radius r_2 in the spin time (T). The shaded volume with height (h) is the volume taken out for sampling of the result. The following equations describe the particle movement.

$$V_c = \frac{dr}{dt} \tag{12}$$

$$V_c = V_g \cdot \frac{r \cdot \omega^2}{g} \tag{13}$$

Insertion of equation 10 in equation 9 and rearranging and integration gives

$$\int_0^T dt = \frac{g}{V_g \cdot \omega^2} \int_{r1}^{r2} \frac{dr}{r} \tag{14}$$

$$T = \frac{g}{V_g \cdot \omega^2} \cdot {}^e\log \frac{r_2}{r_1} \tag{15}$$

In the test tube centrifuge, the efficiency factor μ in equation 9 is 100% because the settling process is considered ideal. Therefore, equation 6 is valid and

$$\Sigma = \frac{T \cdot Q_{theor} \cdot \omega^2}{g \cdot {}^e\log \frac{r_2}{r_1}} \tag{16}$$

and

$$\frac{Q_{theor}}{\Sigma} = \frac{g \cdot {}^e\log \frac{r_2}{r_1}}{T \cdot \omega^2} = V_g \tag{17}$$

For a test tube centrifuge with angle head, ${}^e\log(r_2/r_1)$ is exchanged for ${}^e\log(1 + D/r_1 \cdot \cos\beta)$.

Important Properties of the Process Streams

In Table 6, some solids phase data, such as *particle size* and *density difference*, have been collected. These data show that many important biological processes belong to the most demanding centrifuge applications regarding separability. The data given in Table 6 are very approximate. Cell size will vary with fermentation conditions. Cell debris size distribution is very wide and depends on the method of cell breakage. The density difference between cell and medium depends on the osmotic pressure and of the possible content of inclusion bodies. Apparent density and the density difference of inclusion bodies vary with size, so that larger ones have lower density (28).

As many as possible of the items in Table 7 should be defined before the selection of a centrifuge is made. Some of the items need further comments. Apart from Stokes' law, the *density* is important for the stress in the bowl material. *Low pH* and *high temperature* may, together with even a moderate chloride concentration, lead to difficulties with *corrosion*. In the biological process industries, steels 316 and 316L are often preferred (38). These steels have, however, such a low tensile strength that they are less suitable for high-speed centrifuges. Instead, duplex steel has been developed, it has high tensile strength coupled with a good corrosion resistance (39). The corrosive properties of process materials can be very serious, but it is in many cases possible to reduce the corrosion rate by intermittent washing with caustic solution every 4 to 5 hours of running to reestablish a passivating layer on the metal surfaces. *Erosion* may be a problem with silt-containing process water or other raw materials such as molasses. This may necessitate the use of hydrocyclones to remove these particles. The *angle of repose* (see "Main Process Parameters") is the angle a cone solid will form if allowed to settle, for example, between the nozzles in a nozzle bowl. If it is 0, or close to 0, degrees, the flow properties are extremely good. The *shear sensitivity* was mentioned in "Centrifuges with Conical Disks". The most shear-sensitive cells are mammalian cells, for which the shear forces must be minimized when the cells are used in perfusion systems.

In the Centritech® machines, the RCF is limited to 300, more than one order of magnitude lower than for other centrifuges. The cells may be so vulnerable that the residence time in the centrifugal force field must be minimized (40). Some protein precipitates are also sensitive to shear (16), including those formed in the maturation tanks in breweries. Many bacteria are sensitive, especially starter culture bacteria, where the activity of the cultures depends on intact cells. Yeast cells are the most robust cells, but they are also sheared to some extent at discharge in radial solids-ejecting centrifuges.

Improvement of Separability

According to Stokes' law, the settling velocity improves when the density difference and the particle density increase and when the viscosity decreases. Bowden (41) lists physical, chemical, and biological techniques for broth conditioning. The most-used techniques are coagulation and flocculation, but other methods that induce cell lysis can improve aggregation of cells, such as aging, pH, and change and addition of enzymes or other chemicals. In some cases it is possible to flocculate submicron suspensions, so that a decanter centrifuge can recover the precipitate (cell debris) with good efficiency and a dry cake (34).

Pilot Machine Testing

After maximizing the separability of the feedstream, the preliminary Q_{theor}/Σ is determined by spin tests. The ma-

chine type and size are tentatively chosen based on the preliminary mass balance and on the requested Q_{act}. With the separation efficiency μ, Q_{act}/Σ can be calculated from the equation

$$\frac{Q_{act}}{\Sigma} = \mu \cdot V_g \tag{18}$$

It is often advisable to make a test with the chosen type of machine. The purpose of such a test is to obtain a more reliable Q_{act}/Σ value, but also to assess solids flow properties, emulsification, and particle breakup tendencies and clogging risks.

Scale-Up

For all types of centrifugal separators, the Q_{act}/Σ value can be used for scale-up of the sedimentation performance if some general considerations are taken into account:

- The type of centrifuge is similar.
- The geometry is similar; for decanters, feed inlet positions, ratio of length to diameter, or beach angle, and for disk machines, cone angle, disk spacing, and number of feed holes.
- The bowl speed gives similar linear velocity of, for example, wings when treating shear-sensitive process feeds.
- The λ value (equation 5) is almost the same in the machines.
- The larger machine has no hydraulic limitations in relation to the calculated flows. The limitations could be inlet and outlet pressure drops, paring disk pumping capacities (upper and lower limit), and the upper and lower limit of solids flow.
- There are no mechanical limitations, such as power transmission and gear-box torque in decanters.

The equation to use in scale-up is

$$\left(\frac{Q_{act}}{\Sigma}\right)_1 = \left(\frac{Q_{act}}{\Sigma}\right)_2 (= \mu \cdot V_g) \tag{19}$$

where indexes 1 and 2 denote the two machines. Direct calculations of V_g and μ are thus avoided.

DESCRIPTION OF SOME APPLICATIONS

Introduction

The most important centrifuge application in biotechnology is cell harvesting, where either the liquid phase or the solid phase contains (or is) the product. Downstream of the harvesting stage the number of applications for centrifuges is growing. The operations performed are many: classification, dewatering, liquid–liquid extraction, and precipi-

tate recovery. The applications discussed in this section are examples only; there is an infinite variation in the downstream process design.

Cell Harvesting

Introduction. As can be seen from Table 5, the throughput capacity of a given centrifuge (i.e., Q_{act}/Σ) may vary by a factor of 100 depending on the microorganism used.

Yeasts. The second application of disk bowl centrifuges developed after milk skimming is concentration of *baker's yeast*. Today, nozzle machines with pressurized discharge (Fig. 1) are very common in the industry. The flow rates are the highest in the biotechnology industry, up to 150 m^3/h of fermented broth. Cell concentrations in the fermenters have increased over the years and have now reached above 25% by volume. The baker's yeast is washed, often twice and countercurrently, to increase shelf life. The pressurized discharge of the solids concentrate makes it easy to use an inline mixer to mix the wash water with the cells. The Q_{act}/Σ is about 2×10^{-7} m/s for a 99.9% reduction of the cell count.

In *distilleries*, nozzle bowl centrifuges have been used for a long time. The centrifuge has been the prerequisite for the development of new alcohol fermentation systems (11). In the continuous fermentation from spent sulfite liquor, centrifuges are used for recycling of the yeast. This is also the case in the batchwise Melle-Boinot process, where the recovered yeast inoculates the next batch. In the continuous Biostil process, in which the distillery slop is returned to the fermenter, the centrifuge recovers the yeast from the feed to the distillation column and returns it to the fermenter.

In *breweries*, centrifuges are used in several process steps. In the separation step after fermentation, *green beer separation*, the cell count can be as high as 80×10^6 cells per mL (2% by volume), but during the emptying of the fermentation tank the solids decrease. Radial solids-ejecting machines are used, equipped with self-triggering and special outlet devices to prevent air contact. At a cell reduction of 99% and 20×10^6 cells/mL, the Q_{act}/Σ is about 2×10^{-7} m/s, increasing somewhat with higher cell count. The flow rates are up to 75 m^3/h. In this step, the same machine type as for baker's yeast could be used if the solids flow to the machine could be controlled. New instruments (42–44) measuring the dielectric constant or the inductive permittivity may be used.

For the separation step after lagering and before final filtration, *preclarification*, the cell count is much smaller, and less solids handling capacity is needed. Therefore, the bowl of the solids-ejecting machine can have the shape of the bowl in Figure 1c. The hermetic inlet is an advantage because the separation of the shear-sensitive protein particles is helped by the gentle acceleration. The bowl has only one liquid outlet. The solids are ejected at the periphery. Because the emphasis is on cell reduction, the Q_{act}/Σ is about 5×10^{-8} m/s. Flow rates are up to 45 m^3/h.

The corresponding separation step is also present in winemaking. Because the same machine unit is used also in must separation before fermentation, radial solids-ejecting machines are used.

In rDNA yeast processes, the same type of machine as for baker's yeast can be used. Such machines are available for BL2-LS containment.

Bacteria. In modern biotechnology, solids-ejecting machines, nozzle machines with pressurized discharge, and decanters are used to harvest bacteria. For microorganisms with sizes about 1 μ, axial discharging machines (Fig. 1d) are used. If the solids concentration is so high that the solids discharge frequency has to be more than 1 per 60 s, a radial discharging machine (Fig. 1b) has to be used, but this is less cost effective. The vortex nozzle machine (4) (Fig. 1e) has the disadvantage of accepting only clear substrate media. Residues of substrate may clog the concentrate tubes. If a clear substrate is used, this type of machine is as cost effective as the axial discharging machine but without its solids-handling limitation. A further possibility for clear media is the hermetic machine in Figure 1c, where the cell concentrate leaves the machine continuously and under pressure. The intermittent discharge mechanism is used for CIP.

A typical Q_{act}/Σ value for 99% recovery of *E. coli* K12 in a disk stack machine is 10^{-8} m/s. But the variation between various types of *E. coli* can be very large indeed; between 30 and 300% of the above value has been encountered by the author.

Corynebacterium, somewhat larger cells used in amino acid production, are harvested in nozzle machines with pressurized discharge, often with washing of the bacteria (repulping) and a second separation to improve the yield. A typical Q_{act}/Σ is 5 times that of *E. coli*. *Actinomyces* mycelia can be harvested by radial discharging machines. As in nozzle machines, the cells are washed, often in two steps, to improve the yield.

There are cases where repulping and reseparation are not possible because the cells break up and may damage the rest of the process. To avoid losing yield, the cells must be recovered with maximum dryness. The obvious choice of machine is then the decanter. The low Σ value of this machine type makes it impossible to use it without flocculation of cells. Polymer addition gives a separation efficiency of 98 to 99% at a Q_{act}/Σ of 3×10^{-7} m/s for a spore-free *Bacillus subtilis* broth with a solids content of 12 to 15% by volume. The dry solids (DS) content of the concentrate is 27 to 28% by weight at 3,200 G. This can be compared to solids-ejecting or nozzle machines, which give around 15% by weight for bacteria. Longer residence time in the bowl or higher RCF gives still higher DS contents. At 10,000 G and similar residence time, a decanter can produce an *E. coli* concentrate of 32 to 36% by weight at a Q_{act}/Σ comparable to that in a disk bowl centrifuge.

The high DS capability of decanters is also used to concentrate solids from nozzle machines or from ultrafiltration units, working on fermenter broths in production of amino acids and antibiotics, respectively. The improvements are yield and less costly waste disposal (e.g., drying costs).

Single-cell protein production from hydrocarbons or their simple derivatives is today a not-so-profitable business, but the technology exists. Mayer and Woernle (45) presented a flow sheet for biomass downstream processing.

Bacteria are preconcentrated in large nozzle machines to about 6% by weight DS and then flocculated. This biomass is then dewatered to about 30% by weight DS in decanters and goes after granulating to drying. The liquid phase from the decanter is clarified in high-speed separators and sent to sterilization together with the clarified liquid from the preconcentration step. From sterilization it is recycled back to the fermenter.

Mammalian Cells. It is possible to use high-speed centrifuges in mammalian cell processes (46), in which the cells are discarded after removal. Usually, the inlet shear is not large enough to release DNA into the culture fluid. Care must be taken that shear and air contact in the centrate are avoided, because some protein substances may be destroyed. The centrifugation of intact cells for perfusion must be performed at very low pressure and shear forces. Special machines have been developed recently for this purpose (9,40,47,48).

Cell Debris

In those cases where the intracellular products do not form inclusion bodies, the cell debris often has to be removed after cell breakage. The separation is difficult because of the very fine particles produced (Table 6). Moreover, the viscosity may be high. Dilution of the suspension reduces the viscosity, but the Q_{act}/Σ may still be 5 to 10% of that of the whole cell. It is necessary to use high-speed solids-ejecting machines for this step. In cases where it is possible to flocculate the debris, the Q_{act}/Σ increases by a factor of at least 10 (17). It has been reported (34) that borax-flocculated yeast cell debris can be removed to about 80% in a pilot-size decanter centrifuge at a Q_{act}/Σ of 4×10^{-4} m/s.

Inclusion Body Recovery and Washing

In cases where the substance forms inclusion bodies, it is advantageous to remove cell debris and other cell constituents before the next processing step. The inclusion body has a higher settling velocity than the cell debris, so that a classifying centrifugation will recover the inclusion bodies while leaving the cell debris in the centrifugate. There is a strong interaction between, on the one hand the homogenization method (i.e., the number of passes) and the resulting particle size distribution and, on the other hand, the ease of washing the inclusion bodies (49). There exists an optimum number of passes. The classification split is not 100% sharp, making it necessary to repeat the separation a number of times. This is done either by resuspending the recovered inclusion bodies batchwise or by a continuous simultaneous feeding of the inclusion body concentrate and water into a well-mixed flowthrough feed tank, continuing until the required purity has been reached. Axial or preferably radial discharging solids-ejecting machines are applied at a Q_{act}/Σ of 1 to 2×10^{-8} m/s. To reduce the consumption of chemicals in the next stage, the final separation is often a dewatering step. This can be performed in a high-speed decanter at a Q_{act}/Σ of 2×10^{-6} m/s.

Extraction of Cell-Free Broth

Solvent Extraction. For 50 years, liquid–liquid extraction has been used to concentrate and recover penicillin from filtered broth. This was often performed in multistage centrifugal extractors. Today, the trend for filtered broth is to use a two-stage, countercurrent system with mixers in between disk bowl machines, which are of the three-phase solids-ejecting type. Many other antibiotics need only a one-stage extraction, for example, erythromycin and tetracycline.

Two-Phase Aqueous Systems. The polyethylene glycol (PEG)/dextrane or PEG/salt systems used in protein purification are characterized by a very small density difference between the phases, from 100 down to 14 kg/m^3. The viscosity of the polymer phase could be high, perhaps 100 mPa s, and a very low interfacial tension, leading to easy splitting of drops. Therefore, it is not surprising that the Q_{act}/Σ may be rather low, from 5×10^{-8} down to 1 to 2×10^{-9} m/s. The type of equipment used for the systems with low-density difference is radial solids-ejecting machines. Decanters may be used when the density difference is larger. It is important for optimum performance that the interface between the light and heavy phase in the bowl be in the right position. Equation 4 shows the relation between the three liquid levels in the bowl. The interface should usually be placed just outside of the disk stack in the disk bowl machines.

The two-phase aqueous systems can also be used for partitioning cell debris and other impurities from a dissolved protein product (50). Datar used a PEG 4,000/potassium phosphate system. No density difference data were given. The Q_{act}/Σ was 2×10^{-7} m/s.

Precipitation

Precipitation is often used to isolate and concentrate antibiotics (e.g., rifamycin, erythromycin, and tetracycline). The suitable machine is the radial solids-ejecting disk bowl type. The methods and parameters involved in protein precipitation have been reviewed (51).

Whole-Broth Extraction

Solvent Extraction. Whole-broth extraction of penicillin was the first development of this technique (52). The solids flow is so high that decanter centrifuges must be applied. Many of the constituents of the broth (e.g., macromolecules and the mycelium) have emulsion-stabilizing properties, so de-emulsifying agents must be added (53). After extraction, the rich solvent is separated to reduce the water content before further processing. The solvent-contaminated mycelium must be further treated before disposal.

Two-Phase Aqueous Systems. The two-phase aqueous systems can be applied for extraction also in the presence of cell debris. Hustedt et al. reported on three enzyme recovery processes that use cross-current extraction (54). The phase separation is made in small solids-ejecting or nozzle disk bowl machines. Provided that the density difference between phases is large enough, extraction decanter centrifuges can also be used. Among the commercial

uses of this technology on a large scale is the recovery of enzyme in a polymer–salt system, where the separation is performed in a three-phase radial solids-ejecting centrifuge.

INSTALLATION AND OPERATION

Plant Design

In modern biotechnology plants, the design philosophy must be documented as part of the validation procedure. These procedures are becoming common also in the food industry. Stringent guidelines for safe design of plants are being issued more frequently. In Europe, the draft standard for performance criteria for centrifuges in biotechnology deals with leak tightness, cleanability, and sterilizability. Centrifuge installations designed according to BL2-LS are seen in Figures 2 and 4.

Cleaning-in-Place

Automated CIP is today regarded as a quality guarantee. The validation of CIP procedures is one of the necessary protocols to obtain approval to manufacture bioproducts. An automated and logged CIP procedure is repeatable and traceable, less costly than manual cleaning, and safer for the plant personnel than manual cleaning is. Centrifuges and their peripherals are today designed with cleanability in mind. With use of modern programmable logic controllers (PLCs) for valve control, the CIP of a disk-stack centrifuge (or decanter) has been greatly simplified. A CIP cycle consists of several steps of rinsing with different cleaning liquids. The sequence could be cold water, warm (60–70 °C) 4% caustic, 3% nitric acid if necessary, hot water, and finally cold water. It is often necessary to use some type of detergent to improve the cleaning effect, mixed with the caustic or the water. In the radial solids-ejecting machines and the modern pressurized discharge nozzle machines, the discharge mechanism is activated especially during the initial stages.

Containment, Asepsis, and Explosion Protection

These three areas are related in the sense that the installation designer must define a space around the centrifuge, including tanks and piping with controlled interfaces with the environment. In the case of containment, the task is to protect process operators from harmful process substances. The National Institutes' of Health biosafety level is an attempt to classify the risks involved (55). The interface with the environment is sterile HEPA filters. This is a case of "no leaking out." The reverse case, "no leaking in," applies for asepsis and explosion protection. The barriers are formed by HEPA filters and liquid seal pots, respectively.

In both these cases, it is necessary to keep the centrifuge system under a slight, positive pressure relative to the environment, either by lowering the pressure in the room (asepsis) or increasing it in the centrifuge system. For explosion protection, this is done by filling the system with inert gas (e.g., nitrogen) and bubbling the inert gas through a water seal pot. Other measures taken with explosion hazards have been reviewed (56). Centrifuges in closed systems have to be modified in a number of ways: mechanical instead of labyrinth seals, cooling jacket around the bowl cover, and devices that can handle the pressure wave at discharge.

Sterilization

Sterilization with saturated steam at temperatures above 100 °C is by many considered to be the reliable way for avoiding contamination, and it is prescribed for BL2-LS. For the centrifuge manufacturer, this means that in addition to the modifications described in the previous section, the bowl cover must be designed as a pressure vessel. But the most complicated changes concern the installation, because the bowl internal and external surfaces, the cover, the service liquid lines, etc., must all be sterilized. To reach the desired temperature (above at least 121 °C), condensate must be drained away. Krook et al. (4) discuss the sterilizable system for a medium-sized machine with pressurized nozzle discharge in some detail. The sterilization efficiency for a radial solids-ejecting centrifuge of pilot scale was investigated (57). It was found that it was not possible to sterilize the whole system at once. By trying different combinations of open and closed valves, regimes were developed for heating different sections, and these were combined to sterilize the whole system. In the end, sterilization was validated with different chemical and biological indicators.

CENTRIFUGATION VERSUS MICROFILTRATION

After the development of sterilizable microfilters, there is available an alternative to centrifugation in separating solids and liquids. A general rule is that with increasing particle size and increasing scale of operation, centrifugation becomes more interesting than microfiltration and vice versa. It is conceivable that *E. coli* on a 200-L fermenter scale is a microfiltration application. Many factors must be considered in the choice. What is becoming more apparent is that the choice done in pilot scale becomes the most difficult one, because the scale-up and validation procedures make it easier to keep same technology on the larger scale, even if it is not the optimal choice. In many cases, a combination of a filter and a centrifuge is the best answer.

NOMENCLATURE

d_p	Particle diameter, m
D	Inner diameter of test tube, m
$D_{h,l}$	Diameter of heavy and light liquid outlet, m
D_i	Diameter of interface, m
g	Equal to 9.81 m/s^2
h	Distance between inner and outer radius in test tube, m
k	Constant in equation 10
KQ	Semi-empirical measure of centrifuge size, eq. 11

n	Bowl speed, rpm
N	Number of disks
$Q_{act,theor}$	Actual and theoretical feed flow rate, m^3/s
$r_{e,1,2}$	Equivalent, min. and max. radius, m
S_e	Equivalent settling distance, m
t	Distance between disks, m
T	Spin time, s
V	Bowl volume, m^3
$V_{g,c}$	Settling velocity at 1 g and in centrifugal field, m/s
V_d	Velocity component caused by drag forces, m/s
Z	Relative centrifugal force (RCF) or G-number
α	Half cone angle of disc
β	Angle of tube in test tube centrifuge
η	Dynamic viscosity of fluid, mPa s
λ	Dimensionless number, defined in equation 5
μ	Separation efficiency factor
ν	Kinematic viscosity of fluid, m^2/s
ρ_p	Particle density, kg/m^3
$\rho_{f,fh,fl}$	Fluid density, general, heavy liquid, light liquid, kg/m^3
ω	Velocity of rotation, rad/s
Σ	Area equivalent according to Ambler, m^2

OUTLINE

INTRODUCTION

In colloid science, flocculation is defined as an aggregation of solid particles induced by addition of polymers; coagulation refers to an aggregation due to van der Waals or electrostatic attraction between particles (1). Cell aggregation was defined by Calleja (2) as the gathering together of cells to form stable, contiguous, multicellular associations under physiological conditions. The criteria of intimate cell–cell contact and of physiological conditions are not met in the case of floc formation by the addition of flocculating agents; therefore, this definition establishes a distinction between aggregation and flocculation. However, polymers formed at a cell surface or excreted into the medium may be responsible for cell–cell interactions of the same nature as those produced by polymers added to the system.

Calleja's definition of cell aggregation involves a physical movement, either active or stochastic, which is responsible for the change from a dispersed to an agglomerated state. The criterion of stability may refer to aggregation under dispersive conditions, typically in an agitated suspension (as opposed to formation of a colony on agar), of a centrifugation pellet or a sediment. The criterion of physical movement emphasizes that a bond is being formed between distinct bodies, as opposed to chains and mycelial structures. However, certain cell aggregates of great significance in biotechnological processes are not simply formed by a gathering of initially dispersed cells. In activated sludges and in cell granules formed in anaerobic digestion, a dynamic situation is obtained in which some newly formed cells remain more or less loosely attached to each other, either by cell–cell or cell–debris interactions, or because a matrix prevents their dispersion, while free cells may be captured by an existing aggregate.

From the biotechnologist's point of view, the distinction between coagulation, aggregation, flocculation, and agglomeration is not always clear. The words *aggregate, floc, agglomerate*, and *cluster* are often synonymous. They refer

to an assemblage of individual cells, formed by initially free cells or by the lack of cell dispersion and occurring under physiological conditions or after addition of various agents to the medium.

Aggregated microbial cells are of great interest in biotechnology. They offer advantages, with respect to fully suspended cells in downstream processing, by facilitating cell-broth separation by sedimentation or filtration. They also allow continuous fermentation processes by keeping the cells in the bioreactor with an upflow of the broth. Further details concerning cell flocculation can be found in several books (2–4). Biofilms (5–8) are not considered explicitly here; however, as concerns the mechanisms of association, they have many features in common with flocs.

PHYSICOCHEMICAL ASPECTS OF AGGREGATION

Interactions between Particles

The essential features of the interactions between colloidal particles may be understood by considering three different aspects (9,10): (*1*) DLVO (Derjaguin, Landau, Verwey, Overbeek) theory (see "DLVO Theory") accounts for van der Waals and electrostatic forces; (*2*) when surfaces are close to molecular contact, solvation interactions (see "Solvation Interactions") may play an important role; (*3*) when mobile macromolecules are present at the interface, they may exert a particular influence at long distances (see "Influence of Macromolecules at the Interface") due to their interactions with the solvent, with the surfaces, and with one another. In the section "Charge Neutralization by Cationic Polymers", a particular mention is made of the possibility to neutralize the surface charge and thereby provoke flocculation by oppositely charged macromolecules.

DLVO Theory. According to DLVO theory (9,10), the free enthalpy of interaction, G_t, between two particles approaching each other may be accounted for by the sum of two contributions, corresponding respectively to electrostatic and van der Waals interactions

$$G_t = G_e + G_v \tag{1}$$

The electrostatic contribution, G_e, is due to the overlap of electrical diffuse double layers of approaching particles. For two spheres of the same nature and same radius, R, suspended in a symmetrical electrolyte solution,

$$G_e = (64\pi kTRNC\kappa^{-2}T_d^2)\exp(-\kappa D) \tag{2}$$

where k is the Boltzmann constant, T the temperature, N the Avogadro number, C the electrolyte concentration (mol/L), and D the separation between particle surfaces.

$$T_d = \tanh[ze\psi_d/4kT] \tag{3}$$

where z is the ion charge, e is the electron charge, and ψ_d the electric potential at the inner limit of the diffuse part of the double layer. It differs from the surface potential, ψ_0, due to adsorption of ions in intimate contact with the surface, that is, in the Stern layer (chemically adsorbed or retained by localized electrostatic attraction) (10,11). For computing G_e, the value taken for ψ_d is usually the zeta potential ζ, that is, the electric potential at the plane of shear between the cell surface and the solution (11). κ, the reciprocal of the Debye length, determines the rate of the variation of the electric potential as a function of the distance to the surface, within the diffuse double layer.

$$\kappa = (1000e^2N/\epsilon kT)(2I)^{1/2} = 2.32\ 10^9(2I)^{1/2}\ (\text{at } 25\ ^\circ\text{C}) \tag{4}$$

where I is the ionic strength of the bulk solution and ϵ the electric permittivity. At an ionic strength of 10^{-1}, 10^{-3}, and 10^{-5} M, κ^{-1} is close to 1, 10, and 100 nm, respectively. Note that the ionic strength is commonly in the range of 10^{-2} to 10^{-3} M for natural water supplies and near 10^{-1} M for microbial culture media.

When the surface potential is low ($<25/z$ mV), G_e simplifies as follows:

$$G_e \cong 2\pi R\epsilon\psi_d^2 \exp(-\kappa D) = 2\pi R\sigma^2 \exp(-\kappa D)/\kappa^2\epsilon \tag{5}$$

where σ is the surface density of charge (C m^{-2}). This equation is also valid for nonsymmetrical electrolytes.

For two spheres with the same radius, R, the contribution of van der Waals interactions is given by

$$G_v = -\frac{AR}{12D} \tag{6}$$

where A is the Hamaker constant. This is mainly determined by dispersion forces (surface–surface, surface–liquid) and thus by the polarizability of the surface-constituting molecules. For organic particles in suspension in water, it is reasonable to consider A values in the range of 0.2 to 1.6 kT (kT = 4.1×10^{-21} J mol^{-1} at room temperature). Values are close to 5 kT for mica and in the range of 2 to 50 kT for oxides depending on the atomic number of the metal ion (9,12).

Figure 1 presents the computed G_t vs D curves for spherical particles of 1-μm radius, A = 1 kT, $\psi_d = -20$ mV, and κ^{-1} = 10 nm. The respective influence of variation of A, ψ_d, and κ^{-1} is also illustrated. The contribution of van der Waals forces is shown in Fig. 1b (ψ_d = 0 mV). The figure shows that, even at low values of the diffuse-layer potential (Fig. 1b), a potential energy barrier appears at a distance of a few nanometers. This barrier may be very high compared with the kinetic energy associated with Brownian motion, equal to 1.5 kT. At sufficiently high ionic strength (Fig. 1c), the variations of G_e and G_v as a function of the interdistance bring about a secondary minimum that holds the particles together, although not in close contact.

The efficiency of electrolytes to provoke coagulation of colloidal particles is usually expressed by the concentration required to achieve a rapid coagulation, called critical coagulation concentration. According to the valency rule of Schulze–Hardy, this is strongly dependent upon the valency of the ion with a charge opposite to that of the surface (counterion) and the critical coagulation concentration decreases as the counterion valency increases (10). Consider a negatively charged surface; the decrease of the critical

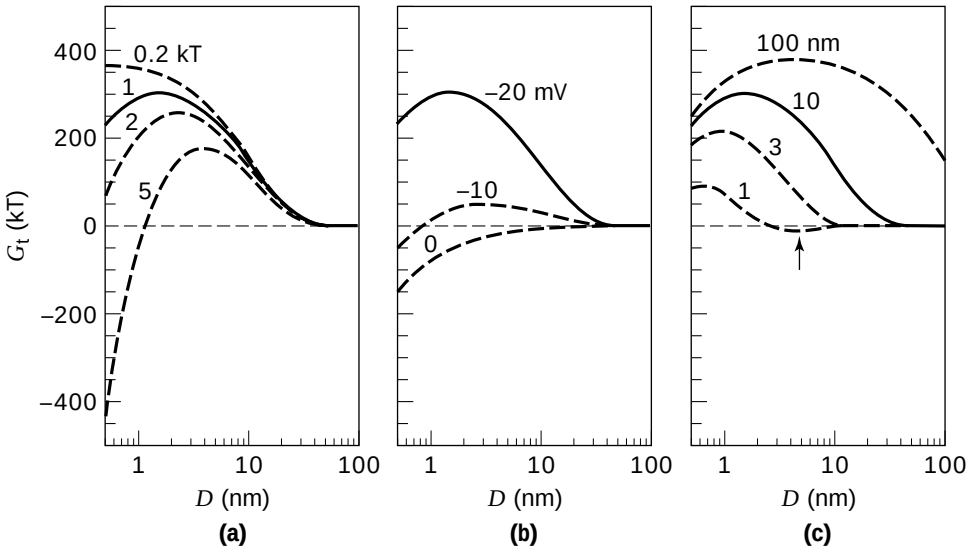

Figure 1. Variation of the free enthalpy of interaction as a function of the distance between two identical spherical particles of 1-μm radius, according to DLVO theory. Solid curve: Hamaker constant $A = 1$ kT, potential of the diffuse double layer $\psi_d = -20$ mV, $\kappa^{-1} = 10$ nm; (**a**) $\psi_d = -20$ mV; $\kappa^{-1} = 10$ nm, A varying from 0.2 to 5 kT; (**b**) $\kappa^{-1} = 10$ nm, $A = 1$ kT, ψ_d varying from 0 to -20 mV; (**c**) $A = 1$ kT, $\psi_d = -20$ mV, κ^{-1} varying from 1 to 100 nm (secondary minimum indicated by arrow).

coagulation concentration is explained by a decrease of the potential energy barrier as a result of two effects: (*1*) if the valency of the cation present in the solution is higher, its adsorption in the Stern layer rises, the potential drop in the Stern layer is larger, and ψ_d is less negative; and (*2*) as the valency of the cation increases at a given concentration, the ionic strength rises, the Debye length κ^{-1} decreases, and the potential barrier decreases (Fig. 1c). The critical coagulation concentration was found to increase in the order $Al^{3+} < Ca^{2+} < Na^+$ for *Escherichia coli* (13).

Equations 2 and 6 are restricted to situations where $D \ll R$; within this limit, the interaction energy is proportional to the particle radius. In DLVO theory, the interacting surfaces are considered as homogeneous, smooth, and rigid. This model is very rough for particles of biotechnological interest. Microbial cells may have complex shapes and bear surface appendages such as fimbriae, pili, fibrils, and flagella. As a consequence, the radius of curvature ruling the interactions may be much smaller than the overall cell radius. In particular, it is conceivable that cells become bound via appendages through a potential barrier resulting from average surface properties, as illustrated by Figure 2. It is also possible that certain zones of the surfaces of two particles are in molecular contact, and thus that solvation interactions have a significant influence, while other zones are still separated by an appreciable distance. The higher the ionic strength, the larger the possible impact of this mechanism.

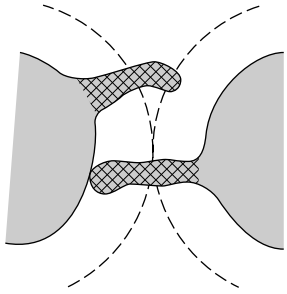

Figure 2. Schematic illustration of the penetration of a surface appendage through a potential energy barrier, the location of which is represented by dashed lines.

Solvation Interactions. Between hydrophilic surfaces in water, a short-range repulsive force arises, which tends to prevent the removal of water from the surfaces and is commonly referred to as hydration force. This has been attributed to the structuring of water molecules at the surfaces through H-bonding with hydrophilic surface groups. However, consideration of recent experimental and theoretical results has led to the suggestion of an alternative interpretation, in which the short-range force is an entropic repulsion arising from the confinement of mobile surface groups (14). The hydration repulsion G_{rh} between two hydrophilic surfaces appears to follow the empirical equation (9)

$$G_{rh} = +G_{rho} \exp(-D/\lambda_{rh}) \qquad (7)$$

where the decay length, λ_{rh}, is of the order of 1 nm for 1:1 electrolytes, and G_{rho} (3–30 mJ m^{-2}) depends on hydration of the surface, including hydration of the cations bound to a negatively charged surface, that is, held in the Stern layer.

The effect of electrolytes on the hydration forces may thus determine whether particles will coagulate or not. The effectiveness of cations as coagulants usually increases according to the so-called lyotropic series (9,10): $Li^+ < Na^+ < K^+ < Cs^+$ for monovalent cations, $Mg^{2+} < Ca^{2+}$ for divalent cations. The decrease of ion hydration is responsible for a decrease of hydration forces between the surfaces. For some surfaces, it is also accompanied by increased ion binding at the surface (11), and thus by a larger drop of the electric potential in the Stern layer.

A hydrophobic surface cannot bind water molecules via ionic or hydrogen bonds, therefore, an attractive hydrophobic interaction arises between two hydrophobic surfaces in water. This results from the strong tendency of water molecules to associate through hydrogen bonding (9,15). To a large extent, hydrophobic bonding is due to the fact that the surface reduces the degrees of freedom offered to adjacent water molecules for forming as many hydrogen bonds as possible; as a consequence, the water structure near the surface is more ordered. Hydrophobic bonding is thus entropically determined, and the resulting association of surfaces should be viewed as the result of a thermodynamic balance rather than the effect of a force, in the common sense. As a consequence of the entropic character, the effect of hydrophobic bonding increases markedly with temperature. For two surfaces in water, the hydrophobic interaction energy, G_{ah} (ignoring DLVO and other solvation forces), is given by (9)

$$G_{ah} = -2\gamma \exp(-D/\lambda_{ah}) \tag{8}$$

where the decay length λ_{ah} is equal to 1–2 nm and γ is the surface–water interfacial energy (10–50 mJ m^{-2}). The rather long-range nature of the hydrophobic interaction accounts for the rapid coagulation of hydrophobic particles in water and the folding of proteins.

Influence of Macromolecules at the Interface. A nonionic polymer dissolved in an ideal solvent (no interaction between polymer segments and the solvent) takes the shape of an "unperturbed" random coil, characterized by the radius of gyration

$$R_g = \frac{ln^{0.5}}{\sqrt{6}} \tag{9}$$

where l is the effective segment length and n is the number of segments. R_g may thus vary from a few to about 100 nm. In a real solvent, the size of the coil may be different from R_g and is given by the Flory radius

$$R_F = \alpha R_g \tag{10}$$

In a poor solvent, the segments attract each other, the coil is more compact, and α is smaller than unity. In a good solvent, the coil swells and its Flory radius is given by

$$R_F \cong ln^{0.6} \tag{11}$$

A poor solvent may become a good solvent by adding certain solutes or changing the temperature. The temperature at which $\alpha = 1$ is known as the theta (θ) temperature, and an ideal solvent is known as theta solvent (9).

Figures 3 and 4 illustrate the different situations that may be encountered when two surfaces approach each other while carrying a nonionic polymer. Once surface separation is a few times the radius of gyration, the segments overlap, which leads to a repulsive osmotic force, that is, to the decrease of entropy associated with a closer confinement of the polymer chains between the two surfaces. This is known as steric repulsion and is responsible for steric stabilization of colloids by polymer additives (9).

As a simple case, consider a low coverage of polymer molecules (no overlap or entanglement of neighboring chains), each being grafted at one end to the surface (Fig. 3 top left; Fig. 4 right, low density). This may be relevant to microbial surfaces. In a theta solvent, if the number of chains grafted per unit area is Γ, the repulsive energy per unit area is approximately given by

$$G_s \cong 36\Gamma kT \exp(-D/R_g) \tag{12}$$

In a good solvent, the coils swell and the range of repulsion is broader. When the surface density of grafted chains is high, so that they are forced to extend away from the surface much farther than R_g, a polymer brush is obtained (Fig. 3, top right). The thickness of the polymer layer, L, no longer varies according to the power 0.5 or 0.6 of the degree of polymerization but is proportional to the polymer length. Once two brush-bearing surfaces are closer than $2L$, a repulsive energy arises (Fig. 4 right, high density). For a good solvent and for $D/2L$ in the range of 0.2 to 0.9, if s is the average distance between the grafting points, the interaction energy per unit area is approximately given by

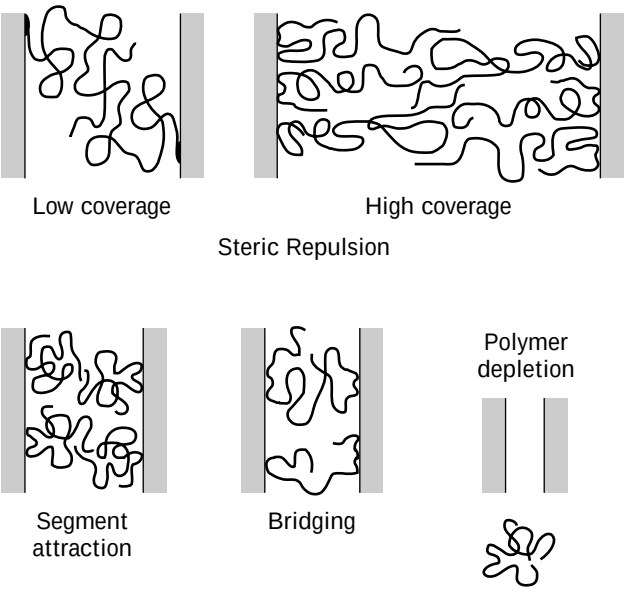

Figure 3. Illustration of steric forces generated by polymers between two surfaces (grafted or adsorbed). *Source*: Adapted from Ref. 9.

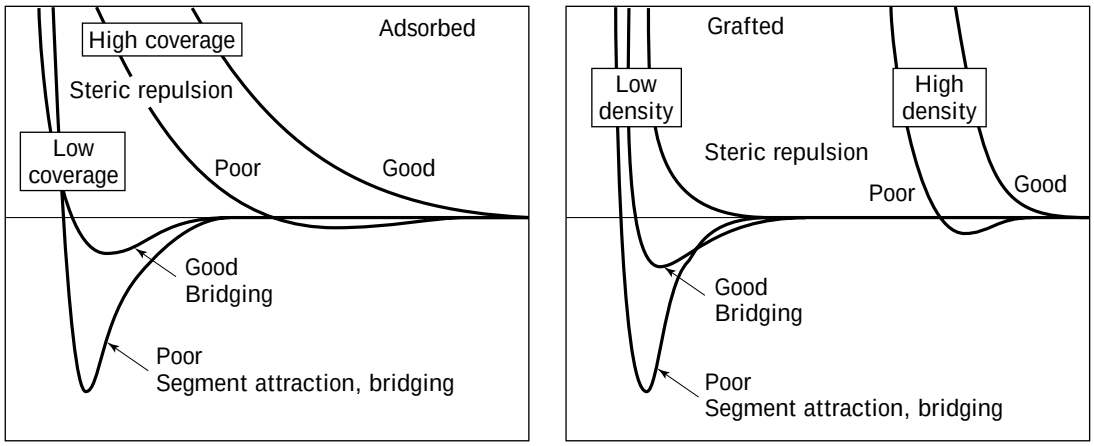

Figure 4. Variation of interaction free enthalpy as a function of the separation distance between two particles as a result of macromolecular interactions; influence of the mode of polymer retention at the surface (adsorption, grafting), polymer concentration at the surface (low, high), and solvent quality (good, poor). *Source*: Adapted from Ref. 9.

$$G_s \cong \frac{100L}{\pi s^3}\, kT\, \exp(-\pi D/L) \qquad (13)$$

In this case, G_s is the balance of an osmotic repulsion between the coils and the elastic energy that opposes chain stretching.

If the polymer is adsorbed (Fig. 3 left, bottom compared to top), a fraction of its segments (trains) are in contact with the surface; the other segments belong to loops and tails dangling in the solution. The polymer may adopt a conformation leading to an adsorbed thickness smaller than the radius of gyration. Things are more complicated than for grafted polymers due to the dynamics allowed by a multiplicity of weak bonds between the polymer and the surface, and to a possible variation of the adsorbed amount and the binding sites as the two surfaces approach each other. As a consequence, the variation of the interaction free energy as a function of distance is less sharp (Fig. 4, left compared with right). Moreover the force between two surfaces at a given separation distance may take a long time (hours) to reach a stationary value (16).

Attractive forces may also be mediated by adsorbed or grafted polymers (Fig. 3, bottom; Fig. 4) (9).

- In a poor solvent, segment attraction between molecules bound to opposite surfaces leads to overall attraction between the surfaces until a balance with steric repulsion is reached.
- When the degree of coverage is weak and the polymer is strongly adsorbed, the macromolecules may form bridges between the two surfaces. Under suitable conditions, bridging forces can extend over longer distances than van der Waals forces.
- When a polymer does not adsorb, bringing two surfaces at a distance smaller than R_g will push the coils out of the space between the surfaces. The polymer depletion is responsible for a difference of osmotic pressure between the bulk liquid phase and the liquid phase held between the surfaces. This effect is small compared to van der Waals and solvation interaction energies.

In a good solvent, the efficacy of a polymer to provoke flocculation is mainly determined by its molecular mass and its concentration, which determine the degree of coverage and the thickness of the adsorbed layer. An optimal flocculation concentration is found for a given molecular mass. It is influenced by pH and ionic strength, which determine the electrostatic repulsion between the surfaces. Flocs will form if the surface is partly covered and if the adsorbed molecules extend far enough from the surface to span the distance at which the electrical repulsion operates (16,17), as illustrated by Figure 5. On the left side of the figure, the molecular mass or the ionic strength are too low to allow bridging. On the right side, the ionic strength is higher (and the Debye length, lower) or the surface potential is weaker, the electric repulsion operates at short distances compared with the thickness of the adsorbed macromolecules, and bridging occurs.

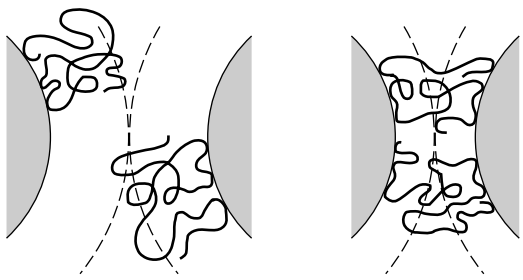

Figure 5. Illustration of the effect of ionic strength or surface potential on polymer bridging; the dashed lines represent the distance at which the electrical repulsion operates. The increase of ionic strength or decrease of surface potential from left to right allows polymer bridging. *Source*: Adapted from Ref. 18.

As polymer adsorption is slow and irreversible, flocculation may often proceed through nonequilibrium processes, which are strongly dependent on the procedure followed (manner and rate of mixing the particle suspension and the polymer solution; stirring). For instance, heterocoagulation may occur between those particles free of polymer and those that are saturated. In other situations, the surface may be partly covered by macromolecules that have not yet collapsed, thus allowing polymer bridging and producing transient flocs, the lifetime of which may vary from seconds to days, depending on the conditions (16,19).

Charge Neutralization by Cationic Polymers. As materials of biotechnological relevance are usually negatively charged, only cationic polyelectrolytes are considered here. Due to electrostatic repulsion between segments, polyelectrolytes display more or less extended conformations according to ionic strength and to their charge density, and thus to the fraction of charged segments τ. For a given molecular mass, the maximum adsorbed amount increases with τ because of the stronger polymer–surface interaction, passes through a maximum, and decreases due to increasing electrostatic repulsion between polymer segments (18,20,21). At low polymer ionicity (small τ), the maximum amount adsorbed (expressed in mass) increases as a function of molecular mass. At high ionicity, the maximum adsorbed amount and the adsorbed-layer thickness are practically independent of the molecular weight; the loop size is small and the polymer chain adopts a flat conformation on the surface. The flat conformation realizes a local neutralization of the particle surface charge, but reduces the possibility of bridging contacts with other particles.

With a cationic polyelectrolyte of high charge density, the influence of polymer molecular mass and of ionic strength can be explained by the electrostatic patch model (18,20,21) illustrated by Figure 6. The adsorbed polyelectrolyte represents patches of positive charges surrounded by the original particle surface. Particles with this mosaic surface–charge distribution may interact in such a way that positive and negative patches of different particles come into contact, causing a strong attachment. As the surface coverage increases, the particle becomes totally coated by the cationic polymer, electrostatic repulsion arises between particles, and the colloid remains in a dispersed state. The optimum flocculation concentration corresponds to a situation where the particle surface is partially covered by patches of cationic polymer. This is illustrated by Figure 7, which shows the influence of polymer concentration on flocculation of a clay, evaluated by the relative supernatant turbidity and the sedimentation time (22). The optimum flocculation concentration coincides with reversal of the zeta potential of the particles.

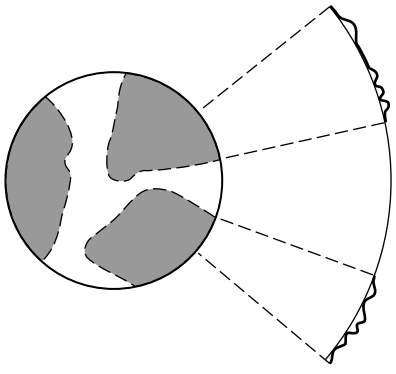

Figure 6. Patch model for a cationic polyelectrolyte (shaded area) adsorbed on a negatively charged surface. Left, view of the particle surface; right, section through a part of the surface. *Source*: Adapted from Refs. 20 and 21.

With a cationic polymer of low ionicity, the influence of charge density, concentration, and molecular mass is more complex, due to the combination of the charge-neutralization and bridging mechanisms. The influence of ionic strength is also complex because it affects the screening of segment/segment lateral repulsion (which decreases chain stiffness and increases loop size and adsorbed amount) and the screening of segment/surface attraction (which reduces the proportion of trains). In practice, increasing the ionic strength reduces the concentration at which the flocs initially appear and broadens the flocculation domain (18).

Rate of Aggregation

The rate of aggregation is determined by the probability of collision between particles, which depends on their concentration, and by the efficiency of a collision to make a bond between the particles. The collision may occur as a result of two types of transport processes: agitation and Brownian motion. If one considers the collision between two identical spherical particles of diameter D^*, the ratio between the probability of collision due to agitation P_o (orthokinetic conditions) and the probability of Brownian collision P_p (perikinetic conditions) is given by

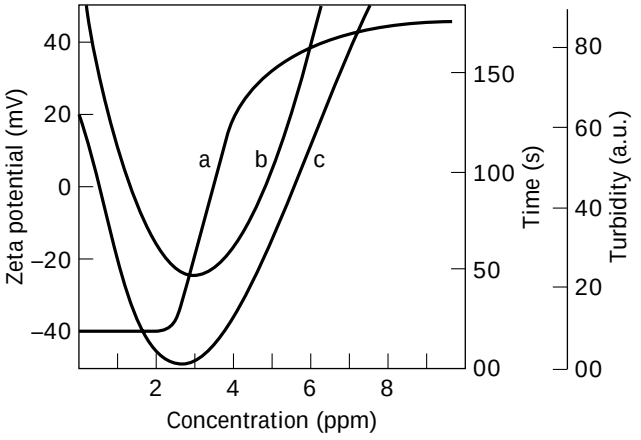

Figure 7. Flocculation of Na-montmorillonite by *N,N,N*-trimethyl aminoethyl chloride acrylate. Variation of (**a**) zeta potential, (**b**) sedimentation time, (**c**) relative supernatant turbidity, as a function of the amount of polymer introduced per unit volume. Polymer molecular weight 10^6; τ = 100%; clay concentration 0.05 g L^{-1}; NaCl concentration 1.2 mM. *Source*: Adapted from Ref. 22.

$$\frac{P_o}{P_p} = \frac{\eta D^{*3} G^*}{2kT} \quad (14)$$

where η is the dynamic viscosity, G^* the shear rate, k the Boltzmann constant, and T the temperature (23). In water at room temperature (η = 1 mPa s), with agitation typical of a magnetic stirrer (G^* = 100 s^{-1}), this ratio is about 100 for particles of 2 μm (24). The rate of aggregation of microbial cells thus depends strongly on agitation due to their relatively large size and slow Brownian motion, unlike small colloidal particles. On the other hand, agitation can also break the flocs so that a stationary state will be reached, with a characteristic distribution of aggregation numbers.

The chance that a collision gives rise to a bond between the particles is determined by the variation of the free energy of particle–particle interactions as a function of the distance. Four typical situations, illustrated by Figures 1 and 4, may be encountered: *(1)* the interaction energy is attractive at all distances, and a quick coagulation occurs (low ψ_d, high ionic strength, high Hamaker constant; Fig. 1); *(2)* the interaction is attractive at short distances but is repulsive at longer distances and passes through a maximum (Fig. 1); in this case the probability that a collision leads to bond formation is the probability of passing over the energy barrier; *(3)* the interaction is repulsive at all distances and no aggregation occurs; the colloid suspension is said to be stabilized (high ψ_d, low ionic strength, low Hamaker coefficient, Fig. 1; steric repulsion, Fig. 4); *(4)* the interaction energy curve presents a well at a certain separation distance (secondary minimum, Fig. 1; bridging, segment attraction, Fig. 4), and the aggregates will be constituted by particles maintained at a certain distance from each other.

Surface Properties of Particles

The nonspecific interactions that control particle aggregation (see "Interactions between Particles") depend on the physicochemical properties of the surfaces (electrical properties, hydrophobicity, presence of macromolecules) and consequently on their surface chemical composition. Physicochemical methods that are well-established or are being developed to investigate these properties are described in the following sections.

Electrical Properties. As discussed earlier, it appears that the electrical properties of particle surfaces strongly influence coagulation by addition of salts, or influence flocculation by polyelectrolytes. The zeta potential, ζ, is usually considered to be close to the potential relevant for DLVO computations (10,11,25,26). It can be deduced from the electrophoretic mobility, μ. For spherical particles of radius R,

$$\zeta = \frac{\eta}{\epsilon}\mu B = 12.85\,\mu B \quad (15)$$

at 298 K, if ζ is given in mV and μ in 10^{-8} m^2 V^{-1} s^{-1}. B = 1 (Helmholtz–Smoluchowski equation) when $\kappa R > 100$, which is relevant for microbial cells in suspensions of common ionic strength; B = 3/2 (Hückel–Onsager equation) when $\kappa R < 1$. In the intermediate situations, B is a function of κR.

Equation 15 implies that: *(1)* the solid plus stagnant layer together behave electrokinetically as a solid particle, *(2)* particles are nonconducting, *(3)* particle surfaces are smooth and homogeneous, and *(4)* the viscosity, dielectric constant, and ion conductivities in the diffuse part of the double layer are equal to their bulk values (11). When the surface conductance or the bulk (or cell wall) conductance are not negligible, the relationship between electrophoretic mobility and zeta potential is more complex (27). Therefore it is recommended to report experimentally determined electrophoretic-mobility values instead of ζ potentials.

Hydrophobicity. The surface hydrophobicity of microbial cells can be assessed by the water contact angle measured on particle lawns (28). A greater cell-surface hydrophobicity is of practical concern in separation: It favors cell coagulation and cell accumulation at the liquid–gas interface. The latter effect may be used for increasing cell concentration by flotation (29).

Contact angles of liquids have been used to deduce the surface energy of solids and to predict the stability of solid–solid associations. The model is based on the balance of interfacial free energies involved in the creation of a new solid–solid interface and in the destruction of the interface of each partner with water. This approach is subject to severe limitations. *(1)* There are different theoretical frames that lead to different values of interfacial energy (30), indicating that absolute values cannot be considered individually. Nevertheless, classification of different materials according to their surface free energy is the same, whatever the approach used. For polymer materials, this classification is the same as that given by the contact angle of water. *(2)* Because interfacial energies are deduced from contact angles of liquids, the energy balance does not incorporate the influence of electrostatic interactions, which act at long distances, or the influence of ionic bridges and steric interactions. *(3)* The system is supposed to be at equilibrium and thus reversible, which is not in accordance with experimental data. *(4)* A close contact is assumed to be achieved between the surfaces, which is not reasonable in view of the roughness of most surfaces.

Other methods of evaluation of microbial-cell hydrophobicity involve adhesion at hydrophobic surfaces or aggregation at high salt concentration (28).

Surface-Chemical Composition. The surface-chemical composition of solids, including microbial cells, can be determined by X-ray photoelectron spectroscopy (XPS). The technique involves irradiation of the sample by an X-ray beam, which induces ejection of electrons. The kinetic energy of the emitted electrons is analyzed, and their binding energy determined. Each peak is then characteristic of a given element. Due to inelastic scattering of electrons in the sample, the collected information concerns only the outermost molecular layers of the surface (2–10 nm). As the position of the photoelectron peak is slightly affected by the chemical environment of the element, peak-shape analysis provides further information on chemical func-

tions (31). The data can be converted into concentrations of model constituents: proteins, polysaccharides, and hydrocarbon-like compounds (32).

For microorganisms, correlations have been obtained between the surface-chemical composition obtained by XPS and surface properties, that is, hydrophobicity and electrical properties. Furthermore, the surface composition has been found to be related to the behavior of microorganisms at interfaces (aggregation, adhesion) (33).

Nanometer-Scale Surface Properties. The physicochemical methods just described have a poor lateral resolution, the information provided concerning only the overall surface properties of particles. Exciting new possibilities are now offered by atomic force microscopy (AFM) to investigate the molecular interactions and properties of surfaces on the nanometer scale. AFM, invented in 1986 (34), consists of measuring the forces acting between a sharp probe and the surface of a sample. It allows the nanoscale mapping of surface topography, as well as the direct measurement of mechanical properties, friction, and interaction forces (electrostatic, van der Waals, solvation, steric interactions). As opposed to more conventional surface analysis techniques, AFM can be operated in aqueous solutions, which makes it possible to study living cells in physiological conditions (35).

A very challenging goal for future research is to directly map the surface properties of living cells in aqueous conditions. The use of functionalized AFM probes, possessing different charges, surface energies, and solvation properties, should make it possible to measure: *(1)* the local surface hydrophobicity and electrical properties of individual cells, *(2)* the surface distribution of solvated macromolecules such as exopolysaccharides, and *(3)* steric interactions associated with these macromolecules. These data will provide new insight into the molecular mechanisms of cell aggregation.

BREWING YEAST: A MODEL FOR THE IMPLICATION OF SPECIFIC INTERACTIONS IN FLOCCULATION

Flocculation and Flocculence

Flocculation of brewing yeasts, thoroughly reviewed by Stratford (36), is the most extensively studied of all systems in which cell aggregates are of interest. It is illustrative of the diversity of approaches used to understand flocculation of microbial cells and the interplay between specific and nonspecific interactions. Spontaneous aggregation of yeast cells occurs near the end of fermentation and is of considerable importance in brewing. For instance, early sedimentation in lager beer production will provoke an incomplete or too slow fermentation; failure to sediment will complicate processing and may lead to alteration of taste.

In brewing technology, the flocculence of a strain means its ability or tendency to flocculate in industrial conditions. More broadly, flocculence is the ability to flocculate if all environmental conditions are favorable (37). The term *flocculability* has been proposed to designate the ability to flocculate in a given medium if hydrodynamic conditions and cell concentration are adequate (38). Beyond the terminology, it is essential to keep in mind that the occurrence of flocculation depends on *(1)* the nature of the biological material (strain; physiological state defined by growth conditions and growth phase), *(2)* the physicochemical environment (temperature, medium composition), and *(3)* the physical conditions (velocity gradient, cell concentration). Thus, the evaluation of the ability to flocculate must always be related to experimental conditions.

In order to test the ability of yeast to flocculate in a given medium, it is important to control the initial state of dispersion and to distinguish the conditions selected for the aggregation process from those allowing evaluation of the final state of dispersion. A screening test may conveniently be performed according to the following procedure (24,39). Introduce the washed cells into test tubes containing the desired medium and vigorously stir to ensure dispersion. Agitate gently for a given period to allow flocculation to take place, then let stand undisturbed to allow floc sedimentation. Finally, measure the absorbance of the supernatant, which reflects the concentration of cells remaining free. The volume of the sediment may also be a way to evaluate the final state of dispersion, as the bed volume of flocculated particles is larger than that of individual particles (40).

Yeast cell behavior in laboratory conditions does not always reproduce the behavior in industrial conditions. Among 45 strains noted as flocculent in brewing, only 20% did flocculate during a culture in laboratory conditions (shaken Erlenmeyer flasks) (41). This was attributed to agitation and aeration rather than to final pH or the requirement of particular wort constituents.

Several parameters were used to quantify yeast flocculation: initial rate of flocculation, rate of settling, number of free cells, floc size, and floc strength (38,42). It was estimated that the attraction force between flocculent cells is three orders of magnitude larger than the force calculated with the DLVO theory (43). The dynamic equilibrium between floc formation and floc breaking (i.e., splitting, which determines the average floc size, and erosion, which determines the number of single cells) was modeled. This showed the dependence of floc diameter and number of single cells on bond strength and agitation (44).

Yeast Behavior and Cell Surface Properties

There are two types of processes for beer brewing. Bottom fermentation, producing lager beer, is carried out at low temperature (near 10 °C) by *Saccharomyces carlsbergensis*; at the end of fermentation, the cells flocculate and settle. Top fermentation, typically producing ale, is carried out at higher temperature by *Saccharomyces cerevisiae*; when the cells flocculate, they do not settle but they tend to remain associated with CO_2 bubbles and rise to the top of fermented wort. The surface properties (electrophoretic mobility, water contact angle, and surface composition) of a collection of yeasts were investigated in order to examine their possible relationship with the type of strain, growth phase, flocculence, and occurrence of flocculation (45). There is no clear-cut distinction between surface properties of top and bottom strains; however, they differ on a

statistical basis. On the average, top strains have more protein at their surface and are more hydrophobic (Fig. 8), which may be related to their tendency to remain associated with gas bubbles and move to the top of the wort. Bottom strains contain more phosphate. The difference between the profiles of electrophoretic mobility vs. pH (Fig. 9) may be explained by modelling the surface charge according to the surface chemical composition, as given by XPS. For the bottom strains, the electrical properties are controlled mainly by phosphate, resulting in a low isoelectric point (pH 2 or below) and an electrophoretic mobility that does not change appreciably above pH 4. For the top strains, the electrical properties are determined mainly by the balance of protonated amino and carboxylate groups in proteins, which give a higher isoelectric point (pH 4) and an electrophoretic mobility changing regularly from pH 2 to 7.

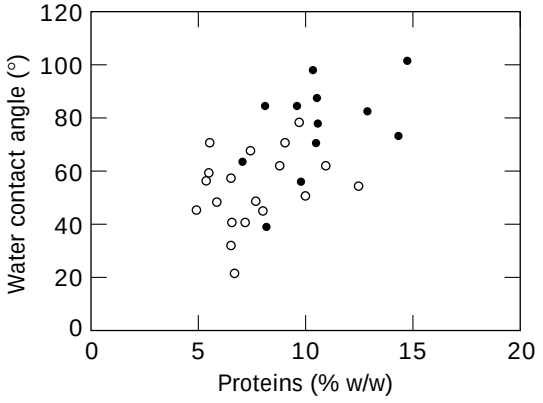

Figure 8. Water contact angles of bottom-fermenting strains (○) and top-fermenting strains (●) as a function of the cell-surface concentration (weight %) of proteins as obtained by modeling XPS data. *Source*: Adapted from Ref. 45.

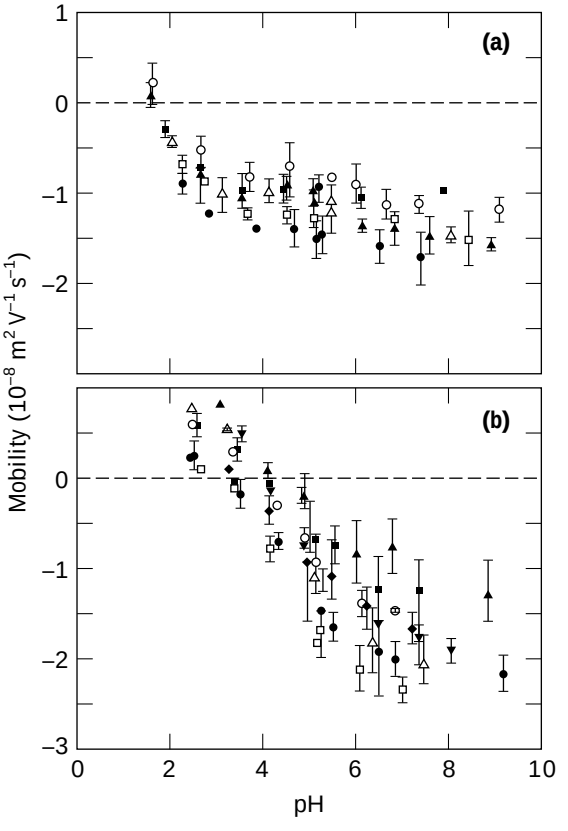

Figure 9. Electrophoretic mobility as a function of pH for bottom-fermenting strains (**a**) and top-fermenting strains (**b**) in 1 mM KNO_3 (45).

Although surface properties of brewing yeasts were statistically related to the top/bottom character, they did not show correlations with the flocculating character. No differences of surface properties were found between strains that did and did not flocculate in laboratory conditions, or between cells from the exponential and stationary growth phases, even for strains where flocculation occurred during the transition from one growth phase to the other. This is in contrast with reports (46,47) that ability to flocculate during growth coincides with an increase in cell-surface hydrophobicity correlated with the appearance of fimbriae-like structures. It was also reported (48) that flocculent cells possess a fimbriate or hairy surface, whereas nonflocculent cells are smooth.

Certain yeast strains produce aggregates with a particular geometric shape, such as cubes, lozenges, cylinders, and disks (36,49), the shape being strongly dependent on agitation. Cubic flocs, close to 1 cm in size, produced by *S. cerevisiae* used for continuous production of ethanol are shown in Figure 10. When agitation is stopped, the flocs collapse and, within a few tens of minutes give rise to a cell carpet on the bottom of the flask. This is tentatively attributed to the fact that the cells are coated by polymers that ensure a weak bridging, as schematized in Figure 11. The viscoelastic properties of the interface would be such that, upon agitation, binding prevails due to chain entanglement, with the hydrodynamic conditions controlling the floc shape; on the other hand, repulsion would prevail in resting conditions (49).

Genetic and Biochemical Aspects

According to the most widely considered mechanism of flocculation proposed by Miki et al. (50), lectinlike molecules (sugar-binding proteins that need Ca^{2+} to adopt their active conformation) recognize and bind mannans at the surface of adjacent cells (36,51), as illustrated by Figure 12(a).

Stratford and Assinder (52) distinguished two flocculation phenotypes, both based on a lectin-mediated mechanism: Flo1 phenotype strains, which included most of the laboratory strains, had *FLO1* genes and possessed mannose-specific lectins; NewFlo phenotype strains, which included most ale-brewing strains, possessed less-specific lectins, binding manno- and glucopyranoses. Masy et al. (53) found the same two phenotypes and called them MS (mannose sensitive) and GMS (glucose mannose sensitive). On the other hand, a different phenotype, called MI (mannose insensitive), representing strains that are not inhibited by sugars, including mannose and glucose, was reported (41,53).

In the last few years, much progress has been made as a result of advances in the fields of genetics and biochem-

istry. In a review (54), 33 genes involved in yeast aggregation have been reported; these include structural genes, regulatory genes, and genes involved in cell wall synthesis and mitochondrial functions. Four classes of strains were distinguished: *(1)* strains lacking an intact flocculation gene, *(2)* strains in which intact flocculation genes are constitutively repressed, *(3)* a strain with flocculation genes that are transcriptionally regulated, *(4)* strains with genes that encode for constitutive flocculence. For strains in which flocculation was regulated, induction was ascribed to nutrient limitation (46,55).

The best-studied dominant flocculation gene, *FLO1*, has been cloned and sequenced. Based on the genetic sequence, it was hypothesized that the Flo1 protein is present in the cell wall, and its N-terminus is exposed to the medium. The location of this protein in the cell wall was confirmed by the use of immunofluorescent probes. It was suggested that the exposed part of the Flo1 protein binds directly with neighboring cell wall mannans (54). The *FLO8* gene was also cloned (56); no homology was found with the *FLO1* gene. It was suggested that *FLO8* does not encode a cell wall protein, but is involved in the regulation of the transcription of the *FLO1* gene.

Two types of surface proteins involved in flocculation of bottom-fermenting strains were isolated from cell walls. A mannose-specific calcium-dependent agglutinin was isolated from a nonflocculent strain and from flocculent strains, both in nonflocculating and flocculating growth stages; it was released during the flocculation assay (57). A protein isolated from cell walls of flocculent cells only, called flocculin, showed homology to the protein coded by the flocculation gene *FLO1*; it was associated with fimbriae-like structures, did not show lectinlike activity, and was thought to act as a lectin ligand (58). The authors proposed a model (57) in which at least three factors determine the onset of flocculation: *(1)* release of agglutinin, *(2)* appearance or activation of flocculin, and *(3)* formation of fimbriae-like structures accompanied by an increase in cell-surface hydrophobicity.

For NewFlo phenotype *S. cerevisae* strains, there is evidence that lectins are synthesized continuously from an early stage of growth and rapidly inserted into the cell wall, but remain inactive until they are activated at flocculation onset (59).

Toward a Comprehensive View of the Role of Specific and Nonspecific Interactions

A comparative study of nine brewing strains flocculating in laboratory conditions (three bottom- and six top-fermenting strains) was performed (41,45). Flocculation most often occurred only in the stationary growth phase, and the onset of flocculation could not be related to a change of physicochemical properties (chemical composition by XPS, electrophoretic mobility, water contact angle).

Laboratory tests showed that flocculation of bottom strains requires the addition of calcium, is inhibited with mannose and sucrose, but not with galactose, and is not affected by ethanol. This is typical lectin-based behavior and the NewFlo/GMS phenotype. The following flocculation mechanism may be proposed: *(1)* there would basically be a repulsion between cell surfaces due to electrostatic or steric interactions (mobile polysaccharides); *(2)* in the stationary growth phase, lectins would appear at the cell surface or be made accessible; and *(3)* when the sugar concentration in the solution is sufficiently low, these lectins would bind sugar residues of adjacent cells across the repulsion barrier. The onset of flocculation thus seems to be triggered by the conjunction of the appearance of active lectin at the surface and of sugar attenuation, rather than by the calcium concentration (41,60). The occurrence of flocculation about 2 pH units above the isoelectric point in

laboratory tests, and not at the isoelectric point, indicates a major influence of pH on lectin conformation. The ionic strength has no effect on flocculation, which may be explained either by a minor role of electrostatic interactions or by a compensation of the influences of ionic strength on electrostatic interactions and lectin conformation. The penetration of the repulsion barrier will be more likely if the lectins or the lectin–ligands stick out of the surface, which is especially the case if they are located on surface hairs. Furthermore, flocculation might be favored by the release of agglutinins. The possible action of hairs and agglutinins is schematically illustrated by Figure 12b.

Flocculation of top-fermenting strains is induced by ethanol and other alcohols and does not require addition of calcium. For certain strains, there is no inhibition by mannose, sucrose, or galactose, whereas flocculation of other strains is inhibited by mannose only. The former would belong to the MI (mannose-insensitive)-flocculation phenotype, which has not been frequently reported. For this collection of top strains, there is no evidence of lectinlike interactions. Other organic solvents (methanol, *n*-propanol isopropanol, *n*-butanol, isopropanol, acetone, 1,2-propylene glycol) have the same effect as ethanol when added at a concentration provoking the same decrease of the surface tension of water. This indicates that the influence of ethanol is related to an adsorption process. The following flocculation mechanism may be proposed. There would exist a repulsion between the cells. As exponential cells, which have similar physicochemical properties as stationary cells, do not flocculate near the isoelectric point, the repulsion would be steric in nature. However, the influence of ionic strength on flocculation suggests that electrostatic interactions play a role as well. In the stationary growth phase, additional macromolecules or hairs would appear at the surface, providing binding sites for specific (lectinlike or other) or nonspecific binding. In the presence of sufficient ethanol concentration and, for the mannose-inhibited strains, sufficiently low sugar concentrations, these macromolecules or hairs would protrude from the surface and manage to bind adjacent cells across the repulsion barrier. The onset of flocculation thus seems to be triggered by the conjunction of a change of cell surface and an increase of ethanol concentration.

FLOCCULATION IN DOWNSTREAM PROCESSING

Production of fine chemicals by living cells involves a range of downstream processes, the first of which is usually the separation of cells or cell debris from the broth. This step is largely improved if flocculation can be carried out (61–63). Flocculation, as a pretreatment for the continuous centrifugal separation of whole cells, should produce flocs with high mechanical strength. In the production of microalgae, the best practical and economical way of harvesting was found to be chemical flocculation, followed by sedimentation, flotation, or filtration (64). The following sections review how flocculation can be produced in downstream processes and, to a certain extent, can be understood in the light of physicochemical theories described earlier.

Use of Colloidal Particles

S. cerevisiae forms flocs in the presence of positively charged submicrometer-sized aluminium hydroxide particles. The respective surface charges of yeast and aluminium hydroxide prevent homocoagulation and the process is a heterocoagulation of oppositely charged particles (65), which can easily be understood in the light of DLVO theory (discussed earlier).

Positively charged organic-polymer particles [poly(styrene-divinyl benzene) with quaternary ammonium surface groups; 0.27-μm diameter] were used to obtain flocs of *S. cerevisiae* and *E. coli* whole cells or cell debris. The settling time of the cells was considerably decreased in the presence of the particles, and the centrifugation energy and power required for the removal of *E. coli* cell debris were reduced by one order of magnitude. The optimal polymer particle concentration found for the clarification of suspensions of *E. coli* cells may be related to a partial coverage of the cell surface by the polymer particles, allowing the cells to be bound together by one layer of positively charged particles; complete coverage of every cell would lead to charge reversal and overall repulsion (see "Charge Neutralization by Cationic Polymers"). An optimal polymer-particle concentration was also found for the clarification of *E. coli* cell-debris suspensions. In the recovery of several enzymes by removal of cell debris following this method, complete enzyme activity was recovered in the supernatant, indicating that the polymer particles did not adsorb or inactivate the enzymes (61).

Use of Salts

Simple electrolytes favor particle coagulation by compressing the electric double layer, as explained in the section "DLVO Theory". Metal ions of higher charge are more efficient both because they have a higher tendency to adsorb

in the Stern layer and because they give a smaller Debye length. Moreover, other factors affect the efficacy of hydrolyzing metal ions, such as Al^{3+} and Fe^{3+}, which are used in water and sludge conditioning (66). Upon hydrolysis, these metal ions form positively charged polynuclear hydroxo complexes. The latter adsorb specifically and are able to reverse the surface charge. Therefore, depending on the pH and on the concentration of colloidal particles, the Al^{3+} and Fe^{3+} salts may act as coagulants only in a narrow concentration range. The concentration must be high enough to allow compression of the electric double layer or surface neutralization; however, overdosing may reverse the charge of the colloids and restabilize them. Above a certain concentration of metal ions, colloidal particles may again form flocs by enmeshing in aluminium or ferric hydroxide precipitates.

Jiang et al. (67) tested the ability of ferric and aluminium salts to coagulate algae. Hydrolized ferric species produced by oxidation of ferrous sulfate were more efficient than ferric sulfate, aluminium sulfate, or partially neutralized aluminium chloride. Floc size was larger and cell removal higher. Humic substances added to the algae suspension reduced the performances of the coagulants.

Use of Soluble Polymers

Nature and Efficiency of the Polymers. Both synthetic and biological polymers have been tested to induce cell flocculation, and results can be understood in the light of the principles presented earlier. Nonionic and anionic synthetic polymers were found to be ineffective for flocculation of *E. coli, S. cerevisiae*, and microalgae, while cationic polymers were good flocculating agents (61,64,68–70). Increasing the charge density of cationic polyacrylates and polyacrylamides enhanced flocculation (62,70). Cationic polyethyleneimine (PEI) was effective to flocculate *Chlorella ellipsoida* (68). With low molecular mass polymers, no reversal of the cell-surface charge occurred and the amount (mass) required to initiate flocculation decreased considerably as the molecular mass increased from 800 to 2,000 Da. Above 2,000 Da, the amount required to initiate flocculation did not vary much as a function of molecular mass; at high concentrations the polymer reversed the cell-surface charge; when the polymer concentration exceeded an optimal value, the flocs began to redisperse. Earlier work with silica and *E. coli* showed that an increase of pH from 4 to 6 or 9 increased the PEI concentration required for optimum flocculation, as expected from the variation of polymer ionicity. With *C. ellipsoida*, little effect of pH was observed between pH 4 and 7. The polymer concentration needed for flocculation was one order of magnitude larger for *E. coli*, compared to crystalline silica (68). With diethylaminoethylmetacrylate acrylic acid copolymers, washed cells of *E. coli* flocculated at polymer concentrations at which the isoelectric point was reached, indicating that the mechanism of flocculation was in agreement with the patch model (70).

Downstream processes are large consumers of polyacrylamide derivatives because they are economical and effective flocculating agents. However, neurotoxic and strong carcinogenic activities of acrylamide monomer were reported. Hence, there is a need to produce safe, biodegradable compounds that will minimize environmental and health risks. Several microorganisms have been reported to produce yeast-cell flocculating agents; they were effective between pH 3 and 5 and lost their effectiveness above pH 5 (71). Cultures of *Rhodococcus erythropolis* were found to flocculate *E. coli, Microcystis aeruginosa*, yeast, activated sludge, kaolin clay, and other particles. Flocculation was considerably improved by adding Ca^{2+} (72). However, the respective roles of *R. erythropolis* cells, possibly provoking heterocoagulation, and of polymers released into the suspension or at the cell surface, were not clarified. A *Paecilomyces* culture filtrate, containing a polysaccharidic compound, was shown to flocculate several microorganisms, including *Bacillus subtilis* and *E. coli*. Its effectiveness with *E. coli* did not change significantly between pH 4 and 8, and in an ionic strength range of 0.001 M to 0.1 M, except in the presence of CO_3^{2-} and Fe^{3+} ions. However, it decreased steeply below pH 4 and above pH 8, or at ionic strength of 1 M (73).

Compared to synthetic polymers, chitosan, also commercially available, possesses several advantages: monomers are not toxic, it can be heat-sterilized without degradation, and it is biodegradable. Chitosan, a partially *N*-acetylated poly (glucose-amine), is derived from chitin, the major constituent of crustacean exoskeleton (62). At acidic pH, chitosan is soluble and exists as well-extended linear chains due to repulsion of charged $-NH_3^+$ groups. At alkaline pH, the positive charges gradually disappear (the neutralization point is about pH 7.9), and chitosan tends to coil and precipitate (74).

Chitosan-induced flocculation of washed *E. coli* cells at concentrations much lower than those required to reach the isoelectric point, as opposed to the use of diethylaminoethylmetacrylate acrylic acid copolymers. This was attributed to the rigidity of chitosan, which undergoes weak deformation during adsorption and is able to form bridges between the cells (70). The optimal dose for flocculation of microalgae was about twice as low for chitosan as compared with polyacrylamides; this superiority was also attributed to the rigid backbone of chitosan (64). With washed cells of *B. subtilis* and *E. coli*, the effectiveness of chitosan and cationic polyacrylamides did not vary between pH 4 and 7. Above pH 7, the effectiveness of chitosan dropped due to a decrease of ionicity, whereas the change of polyacrylamide effectiveness was less marked. None of these compounds was effective in flocculating *Zymomonas mobilis* (62).

An optimal chitosan concentration was found near 0.2 $g\ L^{-1}$ for flocculation of *Euglena gracilis* cultures. Addition of chitosan above this concentration led to a partial cell redispersion due to repulsion of positively charged cells. With the optimal chitosan concentration, a sharp pH optimum was observed at pH 7.5, the decrease of flocculation at lower and higher pH being attributed to a lower negative charge of *Euglena* cells and to deprotonation of chitosan $-NH_3^+$ groups, respectively. At pH 7.5, flocculation did not decrease appreciably at high chitosan concentration, due to the low ionicity of the polymer at this pH (74).

Using chitosan, cell debris and nucleic acids could be separated selectively from β-D-galactosidase in *E. coli* dis-

integrates. For a highly charged chitosan, a pH decrease induced a reduction of the optimal flocculant dosage (63). Highly charged chitosan can achieve a more efficient removal of cell debris than less-charged chitosan. The required flocculation dosage of highly charged chitosan was relatively independent of the charge density, but increased with the molecular mass. At the required flocculation dosage, electrophoretic-mobility measurements showed that the flocs formed were not completely neutralized. It was therefore suggested that the main mechanism of flocculation was a "nonequilibrium" bridging process (75). This occurs when reconformation following polymer attachment to the surface is slow compared with polymer attachment or particle–particle collision (76). It is especially pronounced with high molecular mass polymers and leads to trapping of surface-negative sites between the bridges formed by the polycations. Highly charged and high molecular mass chitosan produced large and shear-resistant aggregates suitable for filtration, settling, and centrifugation, whereas highly charged low molecular mass chitosan gave smaller and more shear-sensitive flocs suitable only for centrifugation (75).

Influence of Medium Composition and Cell-Produced Polymers. Ionic strength can dramatically affect the flocculant effectiveness. Bilanovic et al. (64) studied the effect of salinity on microalgae flocculation with cationic polyacrylamides (1×10^7 and 2×10^7 Da) and chitosan (4×10^5 Da) at pH 7. For the two types of polycation, removal of more than 90% was obtained with freshwater cultures of *Chlorella*, whereas removal was very poor for cultures of marine species of the same genera. The efficiency of the cationic polymers to flocculate *Isochrysis galbana* dropped considerably as the ionic strength increased from 0.02 to 0.70 M, without appreciable alteration of the optimal dose. While the rise of ionic strength was expected to increase the screening of polymer–cell surface attraction, it also provoked a shrinkage of the macromolecule, as revealed by a decrease of the intrinsic viscosity.

The flocculation is also strongly influenced by the extracellular polymers (ECP) released by the cells in the solution and by the components of the culture media. The optimal dosage of cationic polymers was lower for washed *E. coli* cells than for the initial culture suspension. The interaction between anionic polymers in the medium and added cationic polymers led to an increase in flocculant requirement (69,70). On the other hand, it has been reported that the strongly acidic polymers released in solution by *Lactobacillus delbruekii* and *Lactobacillus fermentum* act as flocculating agents (strong anionic polyelectrolytes) that only need a small amount of cationic substances to be sensitized (69).

Polyacrylamides could flocculate *E. coli* and *B. subtilis* cells in defined media, but were ineffective in complex media because of precipitation. Chitosan did not precipitate below pH 7.5 in a complex medium and allowed flocculation of *E. coli* cells, while requiring twice the dose used in a defined medium; the flocculant efficiency decreased above pH 7 in both media and washed cells. On the other hand, flocculation of *B. subtilis* by chitosan in complex media occurred at pH 4 but dropped as the pH was increased from 4 to 7, and did not change with washed cells (62).

Flocculation of yeast by chitosan in a complex medium occurs simultaneously with the precipitation of chitosan with components of the medium. These can be regarded as competitive processes with respect to the availability of chitosan. The detrimental effect of precipitation (increase of dosage, contamination of biomass, removal of the fermentation product) can be minimized by a rapid addition and efficient mixing of the flocculant with fermentation media of high biomass concentration (77). Cells may also become entrapped in the precipitate of polyelectrolyte complexes, with the unexpected benefit that strong flocs are formed (78).

The effectiveness of flocculation is also dependent on the cell-surface constituents but is not simply related to the cell wall type (Gram positive or Gram negative). Polyacrylamide and chitosan were effective in flocculating *E. coli* (Gram negative) and *B. subtilis* (Gram positive) washed cells (62). Their inefficacy to flocculate washed cells of *Z. mobilis* (Gram negative) was attributed to the presence of nonionic extracellular polymers attached to the cell surface. It was reported that strongly acidic polymers adsorbed on *L. delbruekii* and *L. fermentum* surfaces induced an increase in the flocculant dosage, probably due to a high charge density and, therefore, a high polycation demand (69).

Combined Use of Flocculating Agents

The combined use of two flocculating agents has often proved to be an effective way to form flocs. Chitosan, polyethyleneimine, and Ca^{2+} were used simultaneously to perform flocculation of *E. coli* cell debris (79). This was applied in a process using a continuous centrifugal separator and allowed an at least 10-fold improvement in cell debris removal, compared with the same process without flocculation.

Sewage sludges were successfully flocculated by the addition of a cationic, followed by an anionic, polymer (80). The recovery of bacterial extracellular proteinases obtained in *B. subtilis* culture was investigated by adding bentonite (a clay with a negatively charged surface), followed by a cationic aminoamidic polyelectrolyte. The yield of recovery was more than 84% at the laboratory scale and up to 82% at the pilot-plant scale (81).

Polyelectrolytes used singly (62), or combined with an oppositely charged polymer (82), were inefficient in flocculating *Z. mobilis* in complex medium. However, effective flocculation could be performed by adding highly charged polyacrylamide or chitosan, followed by bentonite, providing high broth clarities between pH 5 and 8.5 or between pH 4 and 8, respectively. It was suggested that a combination of electrostatic interactions and bridging capability was responsible for the higher effectiveness of chitosan at low pH. Addition of bentonite after chitosan allowed avoidance of precipitation of the latter at high pH. Flocculation effectiveness was also influenced by the floc collision during settlement (82).

Use of Specific Interactions

Flocculation can be controlled by genetic factors, as discussed for brewing yeast earlier. Addition of starch to *E.*

coli suspension resulted in the formation of bacterial flocs, allowing a very efficient cell-broth separation by settling (83). Flocculation was dependent on the high expression of a cell-surface maltoporin receptor for starch: floc formation was evident with bacteria containing wild-type maltoporin, but was faster and occurred to a greater extent with strains expressing a high-affinity allele of the starch receptor or with strains grown at high levels of maltose. Because expression of the maltoporin receptor can be genetically controlled, its presence at the cell surface can be made largely independent of the variations in surface properties, thus avoiding the variability of classical flocculation. The optimal starch concentration was 1–2 mg mL^{-1} for a strain with a high-affinity allele. Decrease of flocculation at higher concentrations was attributed to saturation of binding sites. The optimal starch concentration was 5–10 mg mL^{-1} for a strain with a low-affinity allele. The optimal conditions for floc formation were pH 6–7 and a cell concentration of 2×10^9 cells mL^{-1}, which should be readily achievable in both laboratory and large-scale cultures. It was suggested that the presence of maltodextrin and that the lack of accessible α-1,4-linked chains in the starch preparation could decrease the starch effectiveness.

This starch-dependent aggregation is potentially applicable to other microorganisms if they comply with the following requirements: *(1)* the starch receptors are expressed, *(2)* the cell surface is not masked by a polysaccharide or a protein layer, and *(3)* the cell does not produce extracellular amylolytic enzymes. For harvesting bacteria, starch offers several advantages: *(1)* binding to cells is rapid; *(2)* it is nontoxic; *(3)* unlike electrically charged flocculating agents, it does not affect the pH, and its binding is effective in the pH range usually found in fermentation conditions; *(4)* it is a low-cost material; and *(5)* it is easily separable from bacteria, if necessary (83).

FLOCS AS A STATE OF PROLIFERATING BIOMASS

A biomass proliferating in the form of flocs is a system that is much more complex than flocs produced in a given downstream operation, due to the diversity of interfaces with respect to space and time. Brewing yeast, discussed earlier, illustrates the fact that a floc is the result of the integration of different processes and of their development on the time scale. In this section, even more complex systems of practical relevance are considered. Whenever possible, the presentation points out physicochemical features that provide a guide for understanding and controlling the biosystem behavior.

Continuous Ethanol Fermentation

The ability to flocculate is an important characteristic in the continuous production of ethanol, so that a high concentration of cells can be maintained within the fermentor (84). This has been used in upflow tower fermentors, which were successfully implemented at industrial scale (85). The yeast producing the particular flocs shown in Figure 10 was used in a gaslift laboratory fermentor (86). A more complete understanding of the phenomena controlling both the shape and size distribution of the flocs appeared to be a prerequisite for a full control of the highly promising fermentation process.

Continuous ethanol fermentation has also been performed with *Zymomonas mobilis*. In a laboratory upflow fermentor (volume of 0.92 L), flocs were obtained by starting-up (10 days) at a low dilution rate (0.065 h^{-1}) (87). After this period, the dilution rate was incrementally increased to 2.5 h^{-1}, allowing an ethanol productivity as high as 100 g $L^{-1}h^{-1}$. However, no attempt was made to evaluate long-term performance. A simultaneous addition of cationic polyacrylamide and titanium hydrous oxide was used to flocculate *Z. mobilis* (88). This provided an ethanol productivity of 16.4 g L^{-1} h^{-1} for at least 100 h in a gaslift tower fermentor (volume of 5 L). In similar conditions, productivity of unflocculated cells was evaluated to be about 2 g L^{-1} h^{-1}.

Mixed cultures of flocculent strains of *Z. mobilis* and *Saccharomyces* sp. gave higher ethanol production, yield, and volumetric productivity than pure cultures (84).

Activated Sludge

A common biological treatment of sewage waste is the activated sludge process, which is essentially a way to concentrate the organic matter of the waste. In its simplest form, it is a two-stage operation involving aeration followed by sedimentation. The aeration stage allows proliferation of different organisms and floc formation. An essential requirement for successful operation is the formation of settleable flocs (89). Among the physical characteristics of the flocs, the size distribution and structure are most important (90–94).

Influence of Physicochemical Factors. The floc behavior can be affected by hydrophobic interactions. Zita and Hermansson (95) isolated, by hydrophobic interaction chromatography, hydrophilic and hydrophobic bacteria from flocs coming from an aeration tank of a wastewater treatment plant. Attachment of these strains to activated sludge liquor containing flocs and wastewater was evaluated. The results showed a correlation between adhesion and surface hydrophobicity up to a threshold, above which bacterial attachment did not increase with surface hydrophobicity. This was attributed to an equilibrium between reversibly attached cells and free-living cells.

Urbain et al. (96) showed that a high internal hydrophobicity of the flocs is correlated with a decrease of the sludge volume index (SVI), which reveals an improvement of settleability. The internal hydrophobicity of the floc was determined by a salt aggregation test performed on a sonicated sludge sample mixed with increasing concentrations of $(NH_4)_2SO_4$ in phosphate buffer.

Bacterial strains of different hydrophobicity were separated by subjecting sonicated sludge to an octane–water mixture. The amount of exopolymers released by sonication of a hydrophilic strain cultured in the laboratory was greater than that of a more hydrophobic strain. This observation may suggest that the hydrophilic strains are not simply trapped in a matrix, but are also implicated in the floc organization (97).

No clear relationship has been established between the electrophoretic mobility of sludge particles and their settling properties. A strongly negative electrophoretic mobility of sludge particles was found to induce a high SVI (98,99). However, an inverse correlation (100) and the absence of correlation between electrophoretic mobility and SVI were also reported (101).

Floc stability was evaluated by gentle mixing in $CaCl_2$ and KCl solutions of increasing ionic strength (102). Floc dissociation decreased as the ionic strength rose from 50 μM to 5 mM; it decreased more slowly between 5 and 50 mM. This was explained by DLVO theory, the flocs being stronger as the diffuse double layer was more compressed. The reversibility of the process was tested by reflocculation of degraded activated sludge. Reflocculation increased between 0 and 5 mM ionic strength and remained constant up to 50 mM. Between 50 and 500 mM, floc dissociation increased and reflocculation decreased. According to the authors, at high ionic strength, the distance between particles is fairly constant and the floc structure appears to be influenced by mechanisms of unknown nature, unlike the mechanisms considered in DLVO theory. The influence of wastewater on floc stability was similar to that described for salt solutions.

Polyvalent ions can act by binding ECP and bacteria, or by binding bacteria with one another, through electrostatic interactions (90). The addition of Ca^{2+} to activated sludge induced a decrease of both the sludge volume and the residual turbidity in the supernatant after 30 min of sedimentation (103). Removal of Ca^{2+} from activated sludge by ion exchange (H^+, K^+, Na^+, Mg^{2+}) or by a chelating agent (EGTA) induced a sludge deterioration: small particles appeared in the supernatant, causing an increase of the specific resistance to filtration. On the contrary, exchange of Ca^{2+} by Cu^{2+} decreased the specific resistance to filtration and thus resulted in a more stable floc structure. This was attributed to the ability of Cu^{2+} ions to maintain the 3-dimensional structure of the exopolymers (90).

Influence of Biological Factors. Bioflocculation in activated sludge also involves extracellular polymers (ECP). Among the ECP, proteins (96,97,104,105), polysaccharides (96,97,104), lipids (104), humic acids (105), and DNA (96,97) were reported. Humic acids originate from wastewater itself, whereas other compounds arise from cell metabolism or from cell lysis. The influence of ECP on sludge settling (notably on SVI) has been widely studied. However, because there is no unified method of extraction (e.g., centrifugation with or without heating and/or sonication), care must be taken in comparing results from different studies. A general trend found in the literature is that an increasing concentration of ECP extracted from activated sludge is related to an increasing SVI (96,97,100,105); however, the absence of a relationship between ECP production and SVI has also been reported (101).

ECP were isolated after thermal extraction from sludge and their molecular mass was determined by gel filtration. A major fraction was found between 30 and 100 kDa, and an increase in its apparent molecular mass was correlated with an increase of the stirred specific volume index (SSVI). This could be due to steric interactions, allowing greater amounts of interstitial water to be retained in the sludge (106).

The presence of growing filamentous microorganisms is an important feature determining floc properties. It was suggested that they could form a backbone to which floc-forming bacteria could attach (107). This idea is supported by the presence of filamentous microorganisms in numerous activated-sludge samples (96). However, sludges have poorer settling characteristics when filaments grow out of the flocs. The outgrowth was quantified by the total extended filament length, that is, the sum of the lengths of filaments extending out of the flocs. An increase of SVI (94) or of SSVI (108) was observed as the total extended-filament length increased up to 10 m mg^{-1} of suspended solid. When the total extended-filament length exceeded this value, SVI increased dramatically and bulking phenomena were observed (101).

Microbial Aggregates in Anaerobic Wastewater Treatment

Anaerobic processes, resulting in the production of biogas, are used for the decomposition of organic compounds in wastewater; the main problem encountered is to efficiently retain the biomass in the reactor. Several reactor designs have been considered. Bacteria may be immobilized on a packing material or carrier particles; the ability of bacteria to aggregate can be used to produce granules with good settling properties. This latter is the case of the upflow anaerobic sludge blanket reactor (UASBR) (109). Bacterial aggregation ensures the conservation of the biomass inside the reactor, but also enhances the interactions between the various microorganisms needed for anaerobic digestion (110).

The formation of bacterial granules in UASBR is governed by the surface properties of the bacteria, which may themselves depend on the operational parameters. Hydrophobicity is the surface property that has been the most studied for bacteria originating from granules. Contact-angle measurements on cells found in the reactor effluent and on cells originating from granules led to the conclusion that more hydrophobic bacteria remain in the reactor in the aggregated state, whereas more hydrophilic bacteria are isolated and leave the reactor (111). It was also reported that the more hydrophobic bacteria found in UASBR had a better ability to flocculate (112). Moreover, the ECP produced by flocculent bacteria were more hydrophobic than those produced by nonflocculent bacteria. Different populations of bacteria found in UASBR are responsible for different steps of waste digestion and are classified as acidogens, acetogens, and methanogens. Most acidogens found in granules are more hydrophilic than the acetogens and methanogens; moreover, granules are formed of layers of different hydrophobicities, each layer being responsible for one step of the degradation process (113).

The surface charge of the bacteria is also recognized as a parameter governing the flocculation behavior in UASBR (109). The negative charge is attributed to carboxyl groups located on the ECP; it is indeed reduced when the cells are submitted to shear (112).

Divalent or trivalent metal ions, which can be added to the reactor, may influence granule properties by acting on cell–cell interactions, as described by DLVO theory, but also by affecting the conformation of ECP or by cross-linking the ECP to form a kind of matrix. It was shown that the size of the granules, and thereby their settleability, is significantly increased in the presence of Ca^{2+} (100 mg L^{-1}), which leads to shorter retention times in the reactor (111). When EDTA, a chelating agent, was added to the medium, the aggregation decreased but was not suppressed. It was thought that part of the Ca^{2+} was involved in irreversible bonds between the cells. The flocculation could also be induced in an anaerobic digestor by the addition of various divalent and trivalent cations, and the tendency to flocculate was related to a reduction in the negative charge of the cell surface. However, divalent and trivalent cations may also play a role through other mechanisms. Precipitates of calcium or iron may provide the bacteria with nucleation sites for granule formation. An alternative mechanism is by an increase in surface hydrophobicity provoked by complex formation between divalent cations and carboxyl or phosphate groups (112).

Other operational parameters may influence granule formation or the efficiency of the process. When the substrate is rich in protein, highly hydrophilic cells are favored, which leads to the formation of fluffy flocs rather than granules. On the contrary, a substrate rich in volatile fatty acids produces granules with a very hydrophobic surface; this may be detrimental to the process because such granules may be eliminated from the reactor by flotation (113). Lowering the surface tension of the medium by adding alkylbenzenesulfonate was shown to favor the formation of granules with a more hydrophilic surface, thus preventing their flotation (114).

CONCLUSION

Cell aggregation, which is of considerable importance in bioprocess engineering, can be understood and controlled to a certain extent in the light of established principles of colloid and surface chemistry. A major key is the interplay between electrostatic interactions and interactions involving macromolecules. In this respect, microbial cells represent a complex system that can be regarded as a solid surface, a surface grafted with macromolecules, or a surface with adsorbed macromolecules, depending on the strain and the approach followed. Furthermore, the extracellular polymers may constitute a matrix in which the cells are more or less loosely entrapped. For certain microorganisms, another important mechanism is provided by specific interactions between the cells, or between the cells and foreign substances.

In opposition with this complexity, most of the methods used so far to examine the physicochemical properties of microbial surfaces consider them to be, more or less implicitly, homogeneous and molecularly smooth, although key factors are clearly the spatial distribution of constituents and properties. Atomic-force microscopy is undoubtedly a very promising tool in this respect. In the near future, it may provide direct information, with molecular-scale spatial resolution, as regards chemical composition, physicochemical properties, and interactions of cell surfaces, in conditions relevant to practical interest. This constitutes an exciting field in which a strong synergy may develop between biotechnology and nanotechnology.

OUTLINE

INTRODUCTION

By definition, the bioprocessing industry uses biological cells as little factories to make a variety of products. Once they are presumed to have finished their product synthesis step, the cells need to be separated from the liquid medium containing them. During the course of research involving biological cells or during the isolation and purification of products derived from cells, cell separation is like the midgame of a chess match. Correct moves at this stage provide an excellent chance to obtain a product of the desired characteristics.

At least five general approaches are available for cell separation: centrifugation, cyclone separation, sedimentation, filtration, and microfiltration. In addition, cell flocculation can often be used to enhance the efficiency of these separation techniques. Sedimentation as a tool for cell separation is the focus of this article. It is also noted how centrifugation and flocculation, too, draw on sedimentation theory.

SEDIMENTATION AS A TOOL IN PRACTICE

The starting point in selecting a cell separation strategy is to locate the product of interest in a given suspension of cells. Is it the cells themselves? Is it all the cells or a specific cell type? Is the interest actually in a product inside the cells (i.e., intracellular) or in a product outside the cells (i.e., extracellular)? If the product is intracellular, cell removal may need to be achieved without significant cell damage. If the product is extracellular, the liquid phase must be separated while the solid content of the liquid phase is minimized, and the cells along with the other solids are merely the solid waste to be removed and disposed of. If the cells *are* the product, they must be separated without damage and their functionality kept intact. Sedimentation may be a useful tool for any of these situations.

Sedimentation is relevant in a variety of biotechnology/bioprocessing situations:

1. Production of therapeutic or diagnostic proteins via mammalian cells
2. Achievement of high cell concentrations via cell recycle in continuous fermentors
3. Biological waste or water treatment
4. Production of beer
5. Study of different cell types involved in immunological response
6. Harvesting of cells in microcarrier or suspension cell culture

Table 1 gives specific examples of research in which sedimentation has been used as a cell separation tool (1–16). Sedimentation is also utilized extensively in other fields such as water or solids removal in mineral recovery and processing (17).

SEDIMENTATION EQUIPMENT

In processing applications, the sedimentation step is usually carried out in a typical processing tank. Such tanks are designed to have the capabilities of a feed line, an output or an overflow line, and a line to allow the removal of the sedimented material. However, equipment designs other than a processing tank have been shown to be very effective in special situations. One such design uses an inclined, parallel-plate sedimentation device (5,18,19) shown in Figure 1, which can be used for cell recycle in continuous fermentations or cell culture. The inclined sedimentor design not only allows the fermentation or the cell culture to achieve high cell densities, it also offers an efficient means of selective cell retention.

A CelSep apparatus meant primarily for mammalian cell separations at the 1-L scale was commercially available (Wescor, Inc., Logan, Utah). Although the unit is no longer on the market, the autoclavable unit worked well and allowed gravity separations under a continuous density gradient (20).

ASPECTS OF SEDIMENTATION AS A CELL SEPARATION TOOL

1. Sedimentation as a separation tool is a mild technique. This is important in cell biology, where the functional capabilities of the isolated subpopulation of cells must not be altered by the separation step.
2. Sedimentation lends itself to aseptic handling if needed. Although other techniques may allow cell separation without contamination, sedimentation devices for cell separation are typically easier to assemble, clean, and sterilize. Hence aseptic handling is more easily performed with sedimentation than with other options.
3. From a practical viewpoint, "unaided" sedimentation can be too slow a process if the sedimentation rates are low. In industrial-scale cell separations, where microbial growth or enzymatic degradation can be a problem, long processing times are generally not acceptable. Such situations call for centrifugation, which "enhances" the sedimentation rates via the centrifugal force, because the problems of microbial growth or enzymatic degradation are less dominant for short processing times.
4. In its simplest form, sedimentation may be the lowest-cost technique for cell separation.
5. Sedimentation is a simple and a highly reliable separation technique; unlike other options, such as centrifugation; it does not require extensive training of the user.

Overall, sedimentation principles have broad applicability in cell separations and extend beyond simple gravity sedimentation. Sedimentation principles also apply to centrifugation and ultracentrifugation.

SEDIMENTATION THEORY AND APPLICATION

To consider the practical issues in cell separation problems, it is useful to understand the principles behind grav-

Table 1. Some Examples of Sedimentation as a Cell Separation Tool in Research

Cell and cell culture type	Sedimentation application	Ref.
Mammalian, suspension	Sedimentation chamber as a separation device in a perfusion system for hybridoma cell culture for antibody production	1
Mammalian, microcarrier	Sedimentation separator pipe as a separation device for microcarrier cell culture	2
Mammalian, suspension	Gravitational sedimentation used to separate cells aggregated with the help of high-frequency, low-energy ultrasonic resonance fields	3
Bacteria	Sedimentation rates of cells of different shapes and sizes used to develop a method for enumeration and quantitation of bacteria	4
Yeast, *Saccharomyces cerevisiae*	Gravitation sedimentation used to recycle yeast cells for alcohol fermentation	5
Yeast, *S. cerevisiae* and yeast–mouse/mouse hybridoma cells	Sedimentation chamber used to separate cells from a chemostat culture	6
Starch endosperm of barley, *Hordeum vulgare L.*	Endosperm protoplast isolation method utilized gravity sedimentation to get good preparations	7
Spleen B-lymphocytes	Hybridoma-forming immune spleen B-lymphocyte cells separated based on their size and density using gravity sedimentation	8
Yeast, *Candida rugosa*	Sedimentation velocity measured to compare cells grown at different temperatures	9
Bacteria (*E. coli*) and yeast (*S. cerevisiae* and baker's)	Differences in flocculation and sedimentation properties utilized to achieve selective separation of cells carrying a certain plasmic	10,11
Sperm cells	A migration–sedimentation technique used to study whether it is a useful method to separate sperm cells leading to improved fertilization	12,13
Mammalian cells, erythrocytes	Utility of the erythrocyte sedimentation rate studied as a possible indicator of clinical disease or health	14,15
Sulfate-reducing bacteria, *Desulfovibrio desulfuricans*	Gravity sedimentation utilized for cell recycle in a system for microbial reduction of sulfur dioxide in an anaerobic digester	16

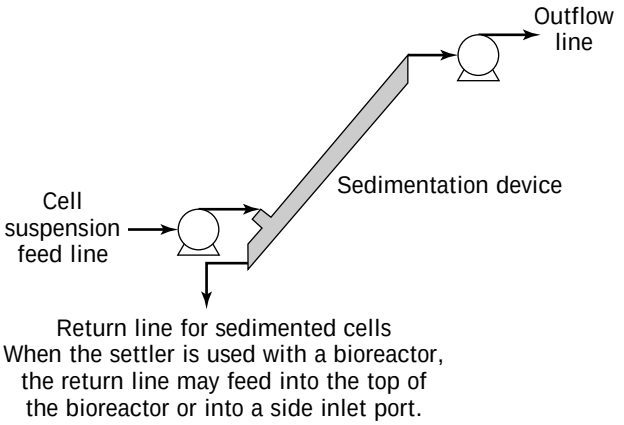

Figure 1. Conceptualized representation of an inclined, parallel-plate, cell sedimentation device used for cell recycle in a continuous fermentation or a perfusion bioreactor. When the settler is used with a bioreactor, the return line may feed into the top of the bioreactor or into a side inlet port (5,18,19).

itational sedimentation. Several factors affect the sedimentation of cells in a liquid medium:

- The *difference* between the density of a cell and that of the surrounding liquid medium
- The density of the liquid medium
- Cell size
- Cell shape
- Cell concentration
- The viscosity of the liquid medium

As a practical rule of thumb, the particle size needs to be greater than about 1 μm for gravitation sedimentation to be relevant as a separation tool. Other approaches such as centrifugation, ultracentrifugation, and membrane separation are usually needed for smaller particles.

The variables just listed are linked together by what is known as the modified *Stokes law*, named after the Ireland-born British scientist George Stokes (1819–1903), who is credited with having developed much of the general theory on the movement of a particle in a flowing fluid. Stokes was a gifted mathematician (21) who also explained the existence of fluorescence and the variation of gravity at the surface of the Earth—all during the brief span of 1845–1854. Although Stokes' law is not directly used in cell separations, it helps us understand how the various parameters affect the settling operation. For a simplified case of gravitational settling when the velocity relative to the surrounding medium is relatively modest (often expressed in chemical engineering literature via a dimensionless parameter called the Reynolds number being set at < 0.2), the Stokes' law modifications (22) suggest that

$$V_s = \frac{g(\rho_p - \rho)D_p^2}{18\mu}$$

where V_g is sedimentation rate (ft/s or m/s); g is gravitational acceleration constant (ft/s^2 or m/s^2), ρ_p is density of the particle (or cell) (s/ft^3 or kg/m^3), ρ is density of the liquid (s/ft^3 or kg/m^3), D_p is diameter of the particle (or cell) (ft or m), and μ is viscosity of the liquid [lb/(s ft) or Pa s&rsqb. Many of the factors in this equation may be beyond one's control in a given practical situation; it is not used very much for actual numerical calculation in cell separa-

tions. However, we can learn how cell sedimentation is affected under various conditions by examining this equation.

Effect of Density

In many large-scale industrial cell separation situations, the cell sedimentation velocity is too slow for sedimentation to be a practical tool. The sedimentation velocity is slow because biological cells and cell aggregates (if cell aggregates are present) tend to have a low density. The Stokes' law equation teaches us that the greater the *difference* between the densities of the cells and the liquid medium, the greater the cell sedimentation velocity. This property can be usefully exploited by a controlled increase of the liquid medium density. For illustration purposes, as shown in Figure 2, let us assume we need to separate a cell mixture containing two different cell densities in a given liquid medium. If the liquid density is increased via the addition of agents like Ficoll, fetal calf serum, or albumin, the *relative* ratio of sedimentation rates of the two cell types is increased, leading to a better separation. A refinement of this idea is to use a density gradient in the liquid medium through which the sedimentation is taking place. A technique based on this idea has been called isokinetic sedimentation (20,23,24).

Effect of Cell Size

Table 2 shows the distance traversed in 1 h by hypothetical spherical particles of specific gravity 2.0 and different cell sizes, and settling in a fluid with a specific gravity of 1.0 (25). In practice, the specific gravity of cells tends to be well below 1.2; the example merely illustrates the effect of cell size. Table 3 gives an idea of the typical sizes for the various cell types encountered in practice.

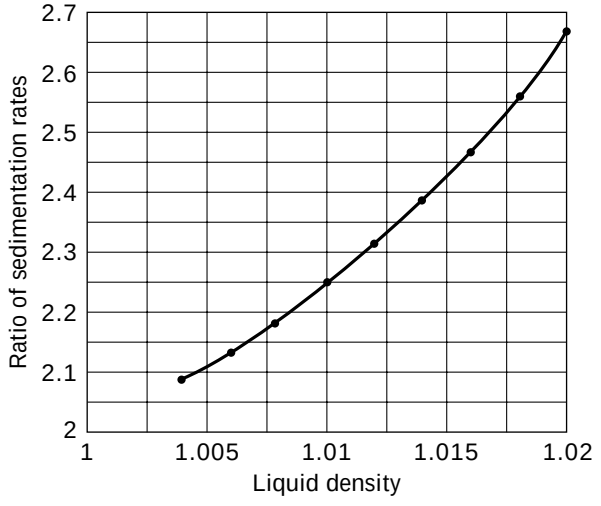

Figure 2. Effect of liquid density on relative sedimentation rate. This data assumes a hypothetical, idealized case where a mixture of two cell types, A and B (densities 1.05 and 1.10, respectively), is sedimenting in liquids of slightly differing densities.

Table 2. Effect of Spherical Particle Size on the Sedimentation Distance after 1 h in Water at 293 K

Particle radius (nm)	Distance settled
0.1	0.08 nm
1	8 nm
10	800 nm or 0.8 μm
100	80 μm
1,000	8 mm

Source: Ref. 25.

Table 3. Typical Sizes of Various Cell Types

Cell type	Size range (nm)
Bacterial virus	0.08
Bacteria	0.1–2.5
Yeast cells	2–10
Human red blood cells (erythrocytes)	6–8
Human white blood cells (leukocytes)	8–12
Filamentous fungi	10–40
Human liver cells	30
Plant cells	10–100
Paramecium, didinium (protozoa)	100–200

The sedimentation rate is proportional to the square of the diameter of the cell. Thus, any approach that leads to cell aggregation will help increase sedimentation substantially—albeit not as much as the "diameter square" relationship would seem to imply. The relative increase is less than that implied by the "square" relationship if the cell aggregate is porous and its density turns out to be less than that of the individual cells. In one study, the settling of larger-diameter activated sludge flocs was found to be proportional only to (floc diameter)$^{0.55}$ (26).

Bacterial cells are often difficult to separate owing to their small size and low density, and so flocculants such as sodium polyacrylate (27), polydimethyldiallyl ammonium chloride (28), and carboxymethyl cellulose (28) are added in some situations to achieve just this benefit. Ultrasound has been used to enhance the sedimentation of monoclonal antibody producing hybridoma cells (29) because the acoustic treatment aggregates the cells. Addition of ferromagnetic particles to a bacterial cell suspension (gluconic acid producing *Acetobacter methanolicus*) followed by an exposure to a magnetic field has been shown to enhance sedimentation (30) as a result of aggregation of cells with the magnetic particles. Two commercially products, Dynabeads® and DETACHaBEAD®, offer another way to achieve the immunomagnetic separation of cells (31). In this approach, sedimentation is enhanced by forming rosetted cells on the antibody-coated Dynabeads. The rosetted cells are washed and concentrated using a magnetic device. The positively isolated cells may then be detached for further study.

Because of the dramatic sensitivity of the sedimentation rate to the cell size, clinical researchers have attempted to determine whether the sedimentation rate of erythrocytes can be a useful indicator of patient health (19,15,32,33), results have been mixed, however.

Size differential between cells can thus also be a useful tool when one is trying to separate a specific cell type from a mixture of cells. If one were to take samples at a fixed point below the liquid surface from a container in which sedimentation of otherwise identical but differing cell sizes is under way, the initial samples would contain the largest cells. With time, smaller and smaller cells would be in the sample. This principle is useful in the separation of lymphocytes from erythrocytes where sedimentation through a dense medium in a centrifuge is one approach (32,33).

Effect of Viscosity

The sedimentation rate is inversely proportional to the viscosity of the liquid medium. This property can also lead to some practical options. Because the viscosity change with dilution is often nonlinear, one may dilute the liquid medium by 25–50% to achieve a greater decrease in viscosity, and hence, better sedimentation rate. Conversely, one may add something that increases the viscosity of the liquid medium to slow down the sedimentation of cells. An example of this is the use of 4% dextran (of average molecular weight 500,000 Da) as a viscosity-increasing agent in the study of antibody-binding rates by FACScans in immunology (34), where suspended cells must be prevented from settling.

Effect of Gravity

Cell separation via centrifugation (see CELL SEPARATION, CENTRIFUGATION) seeks to increase the sedimentation rates hundreds or thousands of times over simple sedimentation, by operating at a force much greater than the normal gravity. Because normal gravitational sedimentation is limited by the gravitational constant g, the relative efficiency of centrifugal separations has been examined by measuring the sedimentation velocity of disrupted yeast cells with and without a flocculent (35).

Effect of Chemical and Environmental Factors

It was pointed out earlier that polymers and other flocculating agents can aid sedimentation by increasing the effective cell size. In addition, the following factors can affect the behavior of particles in solution, hence can influence sedimentation rates:

- pH and temperature of the solution
- Presence of salts (e.g., of calcium, magnesium, manganese, sodium, potassium)
- Presence of sugars

Although in most cases the interaction of these parameters is complex, the question is one of how the chemical environment affects the surface charge of the cells and their tendency to form cell aggregates. The idea is that the surface interactions will control the degree of cell aggregation, and hence, the sedimentation rates. Most microbial cells usually have a negative surface charge (36,37). The system pH or temperature can affect this charge (37,38). Divalent cations, especially calcium, and certain pH ranges can promote cell aggregation, leading to better sedimentation rates (39–41). Monovalent cations and sugars can reduce the tendency of cells to aggregate, thus reducing the likely sedimentation rates (41,42). The overall effect depends on the specific cell type and the physiologic state of the cells involved.

OUTLINE

INTRODUCTION

With the emergence and growth of animal cell bioprocesses during the past 15 to 20 years, the need has arisen for unit operations that gently and effectively separate animal cells at the process scale. Centrifuge-based separation systems available today are especially well suited to this task. By its nature, centrifuge separation is inherently robust and delivers consistent separation performance. Centrifuge systems now incorporate a number of design changes, including some that are quite novel, aimed at tailoring their performance to the special requirements of animal cell bioprocesses. As a result, today we have a powerful array of options available for centrifuge-based unit operations for use in both the animal cell processes under development and the existing processes that are being improved for added efficiency and productivity.

ANIMAL CELL BIOPROCESSES

As biotechnology's commercial success has grown, it has created the need for highly regulated, effective, and, most recently, efficient production processes. Such biotechnology production processes (bioprocesses) have historically drawn heavily from other process industries, such as the chemical process industry for concepts, practices, and equipment, including centrifuges. Bioprocess has therefore become, in some cases, a hybrid field where established process techniques are intermingled with laboratory methods that have been multiplied manyfold for the required

process scale. Nowhere does this appear to be more the case than for the bioprocess of animal cells.

Although bacteria or yeast has been the more common choice for biological production to date, each can have such drawbacks as producing improperly formulated product or product that is unrecoverable as insoluble inclusion bodies (1). In such cases, animal cells have often been called on to overcome these limitations. Unfortunately, animal cells do not share some of the more desirable attributes of these other organisms. By comparison, animal cells are slower growing; exhibit lower protein expression levels; are susceptible to infection by a large number of adventitious agents such as viruses, prions, and so forth; and, because of their lack of a cell wall, are much less tolerant of many traditional process operations. Numerous advances in animal cell biotechnology and fermentation have enhanced the productivity of animal cells. But the bioprocess equipment has often lagged. Animal cell bioprocess has therefore become a "force fit" of techniques and equipment originally designed and developed for other purposes.

Nonetheless, the fact that animal cells are often the only practical way to produce what is required has generated a strong push by many in the industry to develop processes and equipment tailored to animal cell bioprocess. Centrifugation is no exception.

ANIMAL CELL CENTRIFUGATION

Process Applications

Centrifugation's role in animal cell bioprocess is primarily as a unit operation immediately adjacent to the bioreactor, as illustrated in Figure 1. In this role, the centrifuge is positioned to either (*1*) clarify the cell mass exiting the bioreactor, as in the case of a batch operation, or (*2*) retain the cells for further processing, as in the case of a continuous operation. These two operating modes, however, differ somewhat depending on whether the product is intracellular or extracellular. Intracellular processes, where the focus is on harvesting the product-laden cells, require that the centrifuge concentrate the intact cells from the fermentation broth. Care is taken to avoid damaging the cells during this concentration step to maximize product recovery. Any ruptured or lysed cells also release agents into the process streams that can be harmful to the desired product, especially when that product is a protein. Occasionally, this type of care is also needed when the cells are to be stored or are otherwise required to remain viable for further processing. In many of these cases, aseptic operation is essential.

Extracellular processes, on the other hand, require a different set of operating principles where the key focus is on keeping the cells viable. Any cell damage that the centrifuge causes in these processes will have a direct deleterious effect on the process productivity. Not only would the producing cells themselves be lost, but here, too, harmful intracellular agents would be released. The situation is further aggravated by the fact that the extracellular product is relatively vulnerable to any harmful agent because both are present in the bulk fluid. It is clear that centrifugation processes that avoid cellular damage are preferable in these cases, especially when operating in a continuous or perfusion process mode.

A further distinction in animal cell bioprocess that bears mentioning is that the producing cells can be either freely suspended or immobilized. The earlier discussion relates directly to suspension systems. For immobilized systems, where, for example, the cells require that they be tethered to induce growth or production, the need for centrifugation is either at the end of the process, whenever the tethered cells are released for further processing, or for clarification of debris released by the tethered cells, or both. When called for in this manner, the centrifugation considerations are similar to those for freely suspended cells.

Fed Batch versus Perfusion

Perhaps the most prevalent bioprocess mode in use today for freely suspended cells is a simple batch system using carefully constituted media. But in the past decade or so, two more involved processes, fed batch and perfusion, have gained much of the attention. The fed-batch process tends

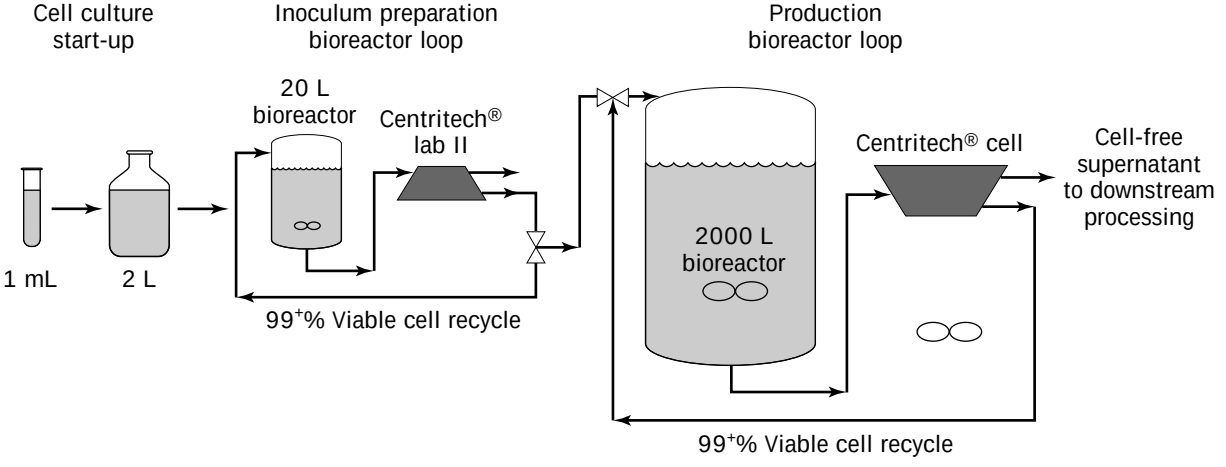

Figure 1. Centrifuge system as integral unit operation for animal cell bioprocess.

to make more efficient use of the media expense and other operating costs, whereas the perfusion process, being continuous, tends to make more efficient use of the producing cells and the physical plant investment.

The fed-batch process is currently the more prevalent of these two processes, partly because it is easier to operate in the laboratory and at the pilot and production scale. Because a batch culture is by its nature limited in its duration, process experience can be built up relatively quickly during the course of several runs. Here the need for processing the cells is confined to the end of the production run. Centrifugation may be used to concentrate the cells for intracellular product or clarify the supernatant for extracellular product. In either case, as mentioned earlier, avoiding cell damage would likely lead to important productivity gains.

Perfusion processes afford the benefits of continuous operation. To do so, however, perfusion requires an effective way to retain the cells throughout the production run with little or no cell viability loss. Centrifugation can deliver the needed performance provided it is continuous in both the liquid stream and the cell concentrate stream, can be operated aseptically, and does not damage the cells. The specific designs of centrifuges applicable to animal cell bioprocess are reviewed in the next section with reference to these important aspects. A continuous-flow centrifuge system installed in a perfusion animal cell process is shown in Figure 2.

The considerations of such processes are directly applicable to anchored cells when those cells are attached to microcarriers. Cells attached to microcarriers are, however, particularly sensitive to fluid shear forces (2–5). For example, cells that are not otherwise damaged by fluid shear are lost if the shear that is present separates them from the microcarriers and they do not reattach (6). In these cases, the bioprocess centrifuge needs to treat the process fluid especially gently.

The various roles of centrifugation in animal cell bioprocess are summarized in Table 1 for the cases discussed. Although generalizations tend to be difficult, these roles as delineated in the table are in many ways representative of the scope of possibilities.

The emergence of insect cell bioprocess has added yet another dimension to the need for gentle handling of the cells. Although insect cells have several advantages over animal cells, they tend to be even less robust than animal cells are during rough handling in the process (7–11). Coupled with the fact that insect cells typically generate intracellular product (specifically so with baculovirus systems), the centrifuge operation must generate especially low shear forces to avoid cell rupture and the resulting productivity loss.

Centrifuge Designs

Design Considerations. Centrifugation is a very robust and versatile separation technique. Because it relies primarily on density differences, centrifugation can readily account for changing process conditions by simple modulation of the intensity or duration of the *g*-field as needed during operation (12). At lower speeds and *g*-forces, the centrifuge can be used to gently remove the larger and more dense cells from the process stream; at higher speeds and *g*-forces, the centrifuge can be used to spin down ever smaller cell debris to increasingly clarify the process stream to the degree required.

The actual design of the centrifuge, however, depends on the various optimization trade-offs specific to the process application. Typical design trade-offs include high sample throughput versus instrument size, high centrifu-

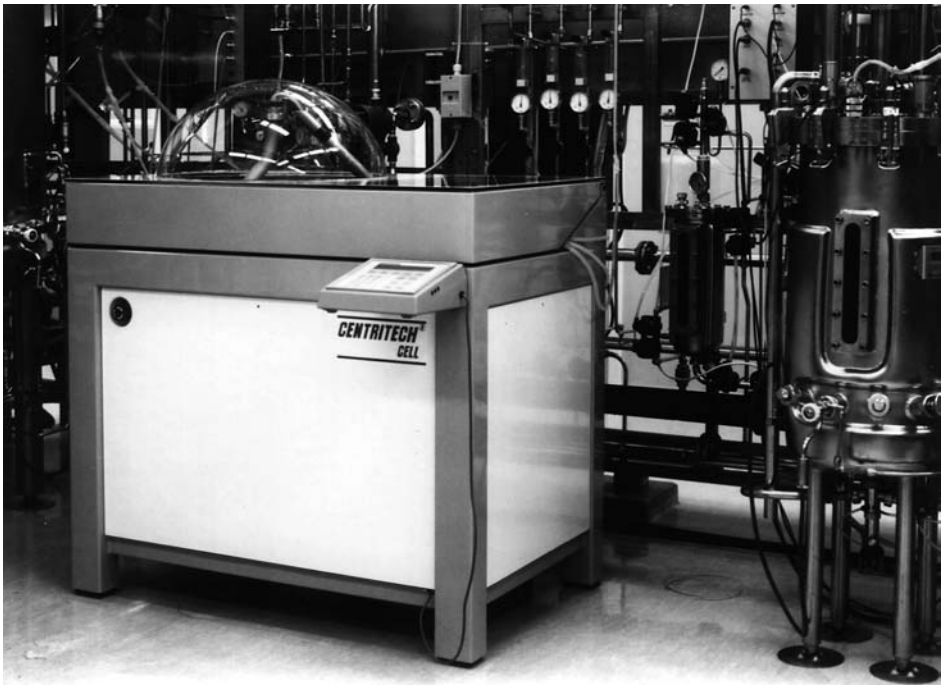

Figure 2. Continuous-flow centrifuge system installed in a production-scale perfusion process.

Table 1. Centrifugation Roles in Animal Cell Bioprocess

	Suspension cultures		Immobilized cultures	
	Fed batch	Perfusion	Anchored	Microcarriers
		Extracellular product		
During the process	N/A	Retain cells with minimal cell damage	Remove/recover cells released into the process stream	Retain the microcarriers with minimal cell loss or damage
At the end of the process	Collect supernatant with minimal cell debris	Recover the final volume of the supernatant	Recover cells with minimal damage for next inoculation	Collect supernatant with minimal cell debris
		Intracellular product		
During the process	N/A	Retain most of the cells with minimal cell damage	Remove/recover cells released into the process stream	Retain most of the microcarriers with minimal cell loss or damage
At the end of the process	Collect cells with minimal cell damage	Recover the final volume of the cells	Recover cells with minimal damage for next inoculation	Collect supernatant with minimal cell debris

Note: N/A, no centrifuge role directly applicable to this case.

gal speeds versus large load volumes, versatility versus dedicated instrument specialization, batch versus continuous operation, and, for continuous operation, solids-retaining versus solids-ejecting design. Laboratory-scale applications tend toward smaller, more versatile, batch or continuous solids-retaining systems, whereas pilot- to production-scale applications tend toward high throughput, specialized, continuous solids-ejecting systems.

When applied specifically to the separation of animal cells, centrifugation typically involves the added considerations of avoiding high fluid shears and maintaining high aseptic integrity. Additional design trade-offs are therefore involved, including (*1*) increased volume throughput versus maintaining the shear forces below critical levels that can result in cell death or damage, and (*2*) providing a totally closed aseptic system versus relying on rotating seals, a source of potential contamination and heat generation as well as generation of high shear stresses.

Design Approaches. To date, the design of animal cell centrifuges has been approached from three distinct directions. The first two directions have been through engineering extensions of other centrifuge equipment. The third is a centrifuge design specifically engineered for animal cell bioprocess.

The first direction has been to take centrifuge designs for larger process scale or bacteria and yeast and adapt them for animal cells. This approach has been more or less successful depending on whether cell damage was to be avoided or continuous operation was desired. Such centrifuges tend to spin the cells down into a paste or cake, which requires some type of cell removal process such as scraping or flushing out of the cells under high shear forces.

The second direction has been to take centrifuge designs for blood component manufacture and adapt them for animal cells. Blood component manufacturers have been making commercial use of continuous-flow centrifugation for many years now. Numerous such blood separation system designs have focused on cell concentration, supernatant clarity, throughput, and other issues that are also important to animal cell bioprocess. But there are several key differences between blood component manufacture and animal cell bioprocess. Blood cells, for example, flow much more readily than typical suspended animal cells. Animal cell centrifuges therefore require some type of low shear method to nudge the animal cells out of the centrifuge in a continuous mode. Also, formed elements of blood are more tolerant of shear stresses than are most animal cells in bioprocess. Flow channel designs in the centrifuge that work for blood therefore tend to be not at all suitable for animal cells. And the usual time frame for blood separation (on the order of a few hours) is much less than that necessary for animal cell bioprocess (on the order of days or weeks).

The third direction was taken by Alfa-Laval Separation AB (Tumba, Sweden) during the 1980s when a continuous-flow centrifuge design was developed specifically for animal cell bioprocess. Combining some of the features of larger process centrifuges and those of the smaller centrifuges, this unique design focused on maintaining a continuous flow of both the clarified supernatant and the cell concentrate. Key engineering issues that had to be overcome were (*1*) gently coaxing the concentrated animal cells to smoothly exit the system without significant cell damage; (*2*) sustaining continuous operation over days and weeks; and (*3*) creating a totally closed system for inherently safe aseptic operation.

These three approaches have had the common goal to overcome the limitations of laboratory-scale and even small production–scale centrifugation. At these smaller scales, research centrifuges have often been pressed into service. Several companies provide floor-model centrifuges that can process, for example, as much as 6 L at *g*-forces

more than adequate for cellular separations. Among these companies are Beckman Instruments, Inc. (Fullerton, Ca.), Kendro Laboratory Products L.P. (Norwalk, Conn.) (Sorvall® and Heraeus® brands), Hitachi Koki Co., Ltd. (Hitachi-naka City, Japan), Jouan S.A. (St. Herelain, France), and Hettich GmbH (Tüttlingen, Germany). Kendro, through its Sorvall® brand, has recently introduced a series of major software packages to their centrifuges to provide automatic process documentation for easier and more reliable process control and regulatory compliance. Other suppliers are now providing software as well. These centrifuges are designed for batch operation only. Some of these companies offer continuous-flow models, but they tend to have small throughput capacity, do not eject the cellular material, and are typically difficult to set up and clean.

Because one of the keys to successful animal cell centrifugation is the gentle handling of the cells, there have been over the years several research groups exploring the various aspects of flow-induced shear stress on different animal cell lines. Although it has been shown that cell damage in bioreactors can be attributed to bubble breakup and other gas–liquid interface phenomena (13–16), other findings indicate that cell damage can also occur at shear stress levels at lower levels of energy dissipation (17–19). Shear stress susceptibility, moreover, varies significantly among cell lines (8,20), thereby adding shear sensitivity to the list of key criteria for selecting a particular cell line for process scale-up.

Current Products. Several suppliers provide centrifuges for animal cell bioprocess that are based on proven designs for other applications. These designs typically provide high throughput and *g*-forces, clean-in-place (CIP) and steam-in-place (SIP) capability, and some method for removing the cellular material that accumulates in the centrifuge. Each design is discussed briefly in the following and then summarized in Table 2. More complete descriptions, including specific schematic depictions of how these systems operate, are available through the respective suppliers.

At the small, batch end of the spectrum, Alfa-Laval's AS-26 SP Super® Centrifuge is capable of high throughput rates in the range of 300 to 500 L/h. The AS-26, however, is strictly a batch centrifuge because it retains the solids that must later be removed by manual intervention. Also, the animal cells are removed as cell debris, so this centrifuge would be unsuitable for processes where cell viability after separation is desired.

At the pilot scale, Alfa-Laval's BTPX 205 system uses the classical disc-stack design to generate up to 12,800 × *g* and a maximum throughput of 1,200 L/h. The 205 has a solids-ejecting design that is tailored to produce very dry solids. It is therefore well suited for, but limited to, batch animal cell processes where cell viability is unimportant. Although its solids-ejecting capability would allow the 205 to be considered for use in a continuous animal cell process, its rough cell handling would result in unacceptable levels of cell damage.

At the production scale, Alfa-Laval's BTAX 510 system delivers up to 15,000 × *g* and a maximum throughput of 4,000 L/h. The 510, like the 205, uses a disc-stack, solids-ejecting design. So the 510 process applicability is, at its larger scale, similar to that for the 205.

Westfalia Separator AG's (Oelde, Germany) CFA-01 separator is also a continuous-flow system based on a disk-stack solids-ejecting design. Specific investigation (21) has demonstrated the effective use of this system for animal cell processing. This system, however, like the systems discussed earlier and the decanter designs discussed next, requires a rotating seal. To remove the frictional heat from its seal, the CFA-01 requires a sealing liquid that must be highly purified to maintain aseptic operation. These key considerations combine to significantly increase the complexity of the overall system. Later work with the West-

falia CSA-1 disc-stack centrifuge (22) came to mixed conclusions and reported heating issues.

Decanter centrifuges, such as Alfa-Laval's Sharples® Super-D-Canter® systems, use a solids-ejecting design that differs from that of the disc-stack systems. The decanter design displaces the solids by pushing or scraping them out of the centrifuge using a type of helical blade arrangement. Using this design, high animal cell viabilities may be obtainable in the ejected solids. But these solids are not well suited to continuous processes where the cells must be resuspended, for example, to be introduced back into the bioreactor.

Carr Separations, Inc. (Farmington, Mass.), as a relative newcomer (the company was founded in 1987), has developed a different design specifically for bioprocess as well as for other pharmaceutical and food applications. The Powerfuge® P6 Separation System uses a new solids separation design that can generate very dry solids. This new design also allows for easier CIP than traditional disc-stack designs, an issue that can be a critical drawback for the original design, especially in the larger-scale equipment. The Powerfuge® is capable of generating up to 20,000 $\times$ g and throughput rates of 60 L/h. Recently, Carr introduced a smaller, low-end bench-top version of the Powerfuge® called the Pilot Separator®. For animal cell process, the suitability of these systems is similar to that for decanter centrifuges.

Kendro, through its Heraeus® brand, offers a pair of bench-top centrifuges designed to operate with a continuous-flow rotor system that can generate 24,000 $\times$ g and a flow rate of 54 L/h. These units are compact and readily portable. They are continuous in the liquid phase but are not designed to eject the solids. Although popular for laboratory-scale work, these units can provide only qualitative support to any planned scale-up plans during process development.

Baxter International, Inc. (Deerfield, Ill.) has modified the design of one of their blood component systems to focus on animal cell bioprocess at the laboratory and smaller production scales. Called the Cell Harvester®, this system can be used to develop centrifuge-based cell separation protocols and to prove out process concepts. Because manual intervention is needed to remove the cells, the applicability of this system to continuous processes is extremely limited. One key advantage of the Baxter system, however, is its totally closed system design. This design allows for the use of a consumable to avoid the various issues that accompany the need for providing CIP/SIP.

The third, unique design approach mentioned earlier that was taken by Alfa-Laval in the 1980s, also uses a consumable insert. These disposable inserts are provided sterile so that, upon making sterile connections to the system, the user has created a totally closed, sterile flow path and separation zone for the process fluids (23). This design approach, called Centritech® by Alfa-Laval (see Figure 3), is now available through and supported by Kendro under its Sorvall® brand. Key trade-offs of the Centritech® design are very gentle cell handling and a totally closed, inherently aseptic system versus high throughput and g-force (24).

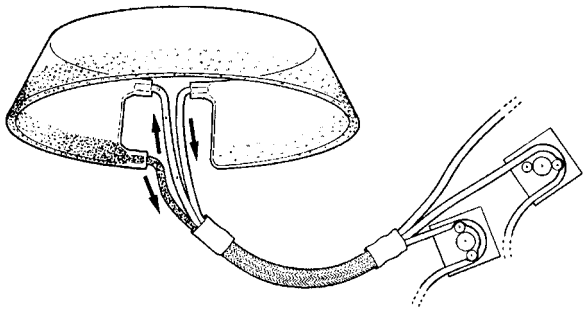

Figure 3. Sketch of the sterile, disposable insert for the Centritech® continuous-flow centrifuge system.

The Centritech® technology is embodied in both a smaller bench-top laboratory-scale system (25) and a larger floor-model pilot- to production-scale system (26). Depending on the application, however, the laboratory-scale unit has been and can be used for small production processes (27).

ALTERNATIVES TO ANIMAL CELL CENTRIFUGATION

Filtration has been the traditional choice as an alternate bioprocess unit operation to animal cell centrifugation. The most common form of filtration used to separate the cellular material from the fermentation broth is tangential flow filtration (TFF).

The foremost advantage of using TFF is that it is a technology that has been widely used to good effect (28,29). TFF does, however, have the disadvantage that, as for all filter-based systems, fouling and clogging can be a constant and often unpredictable problem if not sized properly. Filter systems also deliver performance that degrades over the course of the run, necessitating either that they be reconditioned or the run stopped to replace the filters. Even when reconditioned, filters do not usually return to their original performance, so operating them becomes a classic case of diminishing returns. Recently, issues such as documenting well-characterized products and other concerns have made the reuse of filters less desirable. In these cases, the only viable option is to stop the run, change the filters, resterilize the process, and start up again.

A further disadvantage of TFF is the inherent presence of shearing at the interface caused by the membrane. Material buildup can affect the way the system works, but a substantial shear remains across the boundary layer. Such shearing can run counter to the low shear requirements for animal cell processing and also requires that a recycle loop (with a pump) circulates the process fluid many times greater than that necessary for continuous (perfusion) operation.

Another alternative to animal cell centrifugation is the use of spin filters. Spin filters have the very attractive aspect that as a cell retention device for perfusion processes, they can be integral to the bioreactor. Thus, a single unit operation is created. Cell damage is a concern (30), but evidence suggests that with proper design and operation this issue can be minimized or even overcome (31).

A disadvantage of the spin-filter systems is that they too, like TFF, are susceptible to fouling and clogging. What can be worse, however, is that when a spin-filter system integral to the bioreactor clogs unexpectedly, the necessary maintenance typically requires that the bioreactor containment be breached. The risk of infection from such a breach can be significant. Another disadvantage is that the scaleability of spin-filter systems is limited (32). They may not be a practical unit operations choice if larger scales are anticipated during process development or once in full production.

Another device that has been used for cell retention in continuous processes is the inclined separator (33). The design of this device is mechanically simple, can be made to be relatively easy to CIP and SIP, and, because it relies on gravity (i.e., $1 \times g$), has many of the same process benefits as centrifugation. A drawback with this technology today appears to be its relative lack of throughput scaleability and, of course, that its separation efficiency is limited to that achievable at $1 \times g$ (vs. centrifugation at $100 \times g$ or more).

THE FUTURE OF ANIMAL CELL CENTRIFUGATION

Going forward, centrifugation is likely to be as commonly used for bioprocess as it is for the comparable chemical process industry. The inherent advantages of centrifugation (such as robustness and versatility) continue to fuel creative new concepts for harnessing these advantages for animal cell bioprocess. Novel centrifuge designs and the unique continuous methodologies for bioprocess will likely combine to make the centrifuge a necessary unit operation in a large number of the new animal cell bioprocesses being developed in the near future. Moreover, recent changes in the FDA regulations are conducive to the accelerated adoption of new and more efficient process methodologies. Although in the past there were often heavy disincentives to consider the type of process improvements that, for example, continuous-flow centrifugation allows, many of the regulatory-based concerns have been reduced or eliminated. As a result, we are likely to see adoption of new, higher productivity process improvements in existing processes as well as the development of new ones.

OUTLINE

INTRODUCTION

Since the discovery of penicillins in 1928 and the discovery of cephalosporin C in 1945 (1), β-lactams have become the most important class of antibiotics because of their low toxicity and their effectiveness against bacterial infection. In cephalosporins, the four-membered β-lactam ring is fused to a six-membered dihydrothiazine ring rather than to the five-membered thiazolidine ring found in penicillins (Fig. 1). The natural product, cephalosporin C, has low activity against gram-negative bacteria, but it is resistant to penicillinase hydrolysis. Many chemical derivatives of cephalosporin C have a higher and broader spectrum of antibacterial activity than cephalosporin C. After 40 years of development, cephalosporins (i.e., chemical derivatives of cephalosporin C or semisynthetic cephalosporins) have become one of the most widely used antibiotics in the world; in 1995, the world market for cephalosporins was valued at $9.3 billion at the dosage form level (2). Of this total, $6.5 billion represented products made from cephalosporin C, with the remainder derived from penicillins. In this article, we discuss the development and production of cephalosporins and their chemical derivatives.

Historical Background

Penicillin G (benzylpenicillin) was considered a miracle drug, when discovered in the 1940s, for its effective treatment of the systemic infections caused by gram-positive bacteria such as *Staphylococcus aureus*. Unfortunately, penicillin G was generally ineffective against gram-negative bacteria, and within a few years of its introduction many common gram-positive bacteria had acquired resistance to penicillin G as a result of the expression of bacterial penicillinases. At about this time, a new antibiotic, cephalosporin C, was discovered from a species of mold, *Cephalosporium acremonium*. The *C. acremonium* strain was originally isolated from seawater near a sewage outflow in Cagliari, Sardinia, by Brotzu in 1945. The culture filtrates of this fungus exhibited a broad spectrum of antibacterial activity both in vitro and in preliminary clinical studies (3). In 1948, Brotzu published his findings, which failed to attract attention. At the British Medical Research Council's suggestion, Brotzu sent his fungal culture, *C. acremonium*, which was later reclassified as *Acremonium chrysogenum* in 1971 by Gams (4), to Florey at Oxford. The work of Newton and Abraham at Oxford led to the purification of penicillin N (Fig. 1) and cephalosporin C in 1955 (5). Both compounds had activity against gram-negative bacteria. Penicillin N was as susceptible to staphylococcal penicillinase hydrolysis as was penicillin G. Cephalosporin C, however, had a high degree of resistance to hydrolysis by staphylococcal penicillinase. Further study also indicated that cephalosporin C had low toxicity in mice, but unfortunately, cephalosporin C had relatively low in vivo antibacterial activity.

In 1961, the structure of cephalosporin C was proposed by Abraham and Newton (6) and confirmed by an X-ray crystallographic analysis by Hodgkin and Maslen (7). It was found that a small quantity of the nucleus of cephalosporin C, 7-aminocephalosporanic acid (7-ACA) (Fig. 1), could be produced by gentle acid hydrolysis of cephalosporin C. Acylation of 7-ACA yielded a cephalosporin with much higher antibacterial activity than cephalosporin C against gram-positive bacteria. In 1962, Morin et al. (8) in the Lilly Research Laboratories developed a chemical method for the production of 7-ACA in kilogram quantities, and this opened the way for the extensive exploration of the synthesis of semisynthetic cephalosporins (discussed

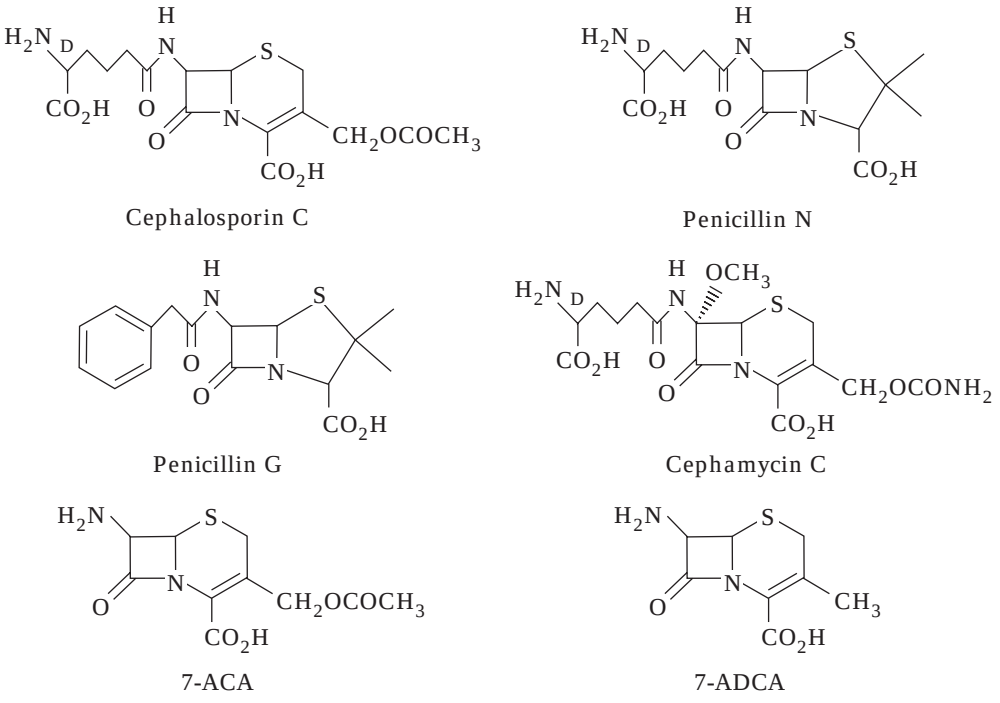

Figure 1. Chemical structure of β-lactams.

in a later section). By 1970, total synthesis of the cephalosporin double-ring system had been achieved by chemists working at Roussel Laboratories and E.R. Squibb & Sons (9).

The extensive use of semisynthetic cephalosporins resulted in the selection in nature of gram-negative bacteria containing R-plasmids that carried a gene encoding β-lactamase. This β-lactamase can hydrolyze most penicillins and all the semisynthetic cephalosporins that had been introduced in the mid 1960s. While searching for new β-lactam antibiotics that are stable in the presence of β-lactamases, culture filtrates of *Streptomyces* species yielded cephamycins (10) containing a methoxy group at the C-7α position of the cephalosporin nucleus (Fig. 1). These compounds were found to be completely resistant to the plasmid-encoded β-lactamase. Derivatives of cephamycin C will be described in "Semisynthetic Cephalosporins".

MODE OF ACTION OF β-LACTAMS

Cephalosporins and other β-lactams inhibit bacterial growth by interfering with bacterial cell wall synthesis. All bacterial cell walls have a protective layer of peptidoglycan at the outer surface of the cell membrane. The peptidoglycan layer consists of chains of alternating *N*-acetylglucosamine and *N*-acetylmuramic acid connected by peptides. These peptides cross-link adjacent peptidoglycan chains to form a net of peptidoglycan layers. In gram-positive bacteria, the cell walls are composed of peptidoglycan and teichoic acids (a polymer of glycerol phosphate or ribitol phosphate) or teichuronic acids (phosphate-free polysaccharides). In gram-negative bacteria, in addition to the peptidoglycan layer, there is a distinct outer membrane layer consisting of lipoproteins and lipopolysaccharides. During the course of bacterial cell wall synthesis, the monomers of *N*-acetylglucosamine and *N*-acetylmuramic acid peptide are linked to form the peptidoglycan chains, and three enzymes (transpeptidase, DD-carboxypeptidase, and endopeptidase) catalyze the cross-links between these peptidoglycan chains by forming peptide bridges (11). Binding of β-lactam antibiotics to the transpeptidase and the DD-carboxypeptidase enzymes, members of the penicillin-binding proteins (PBP) group, interferes with the formation of peptide bridges between peptidoglycan chains and thus inhibits the final stage of cell wall synthesis in bacteria (12).

BIOCHEMISTRY AND GENETICS OF CEPHALOSPORIN BIOSYNTHESIS

The biosynthetic pathways of cephalosporins have been well characterized (13). The current view of the overall biosynthetic scheme for cephalosporin C and cephamycin C is depicted in Figure 2. The nomenclature of genes encoding the enzymes involved in each step of the biosynthesis of cephalosporins follows the recommendation by Ingolia and Queener (14).

Biosynthetic Pathways for Cephalosporins

The biosynthesis of cephamycin C by *Streptomyces clavuligerus* and *Nocardia lactamdurans* and the biosynthesis of cephalosporin C by *A. chrysogenum* all begin with the

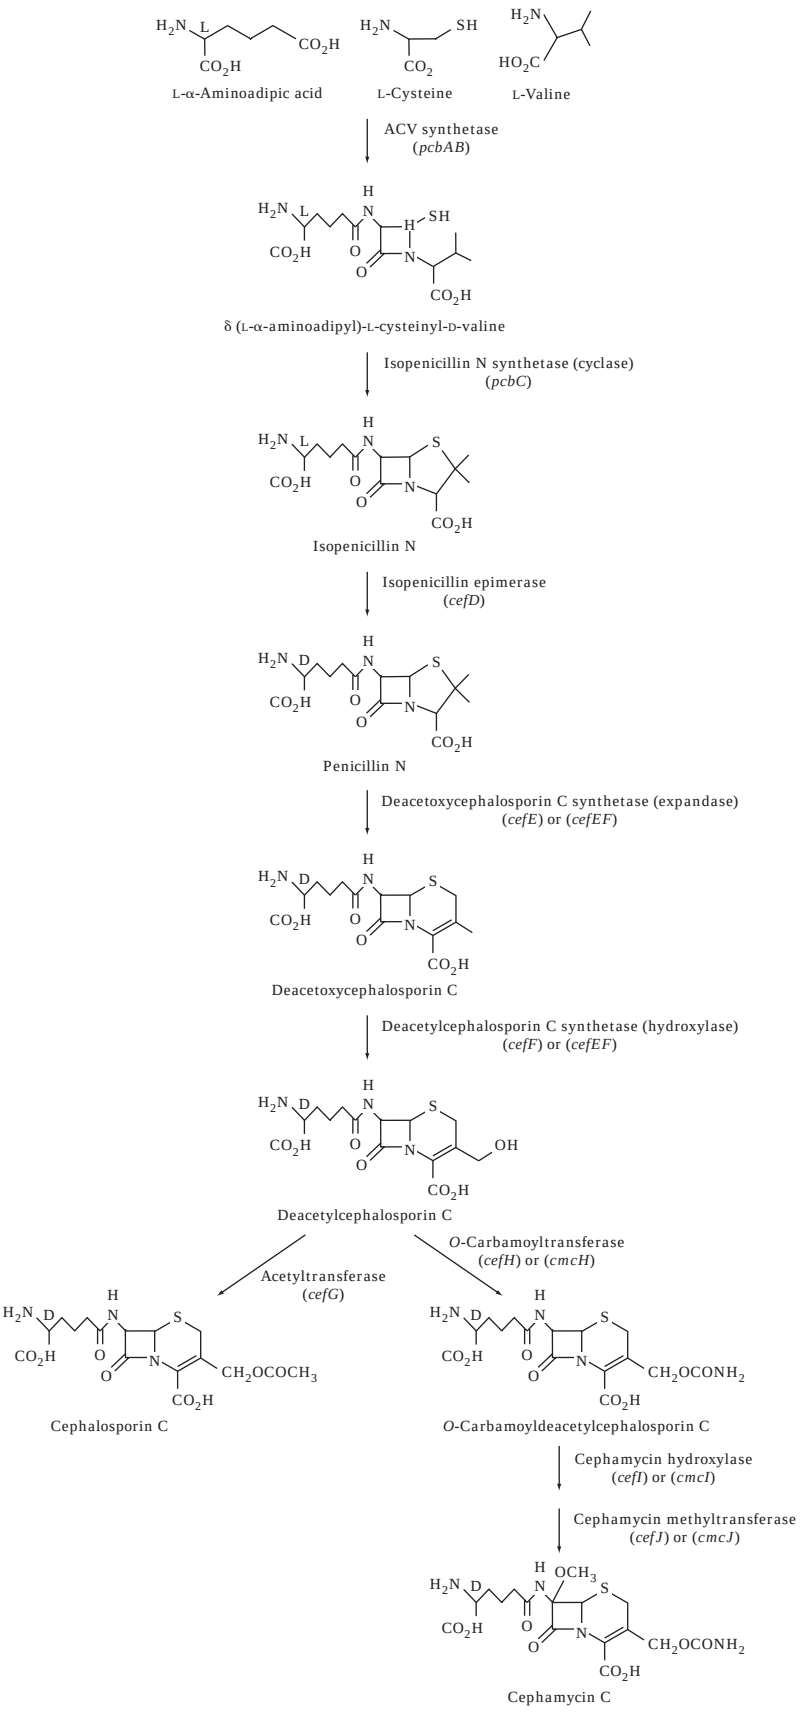

Figure 2. Biosynthetic pathways for cephalosporin C and cephamycin C.

condensation of three amino acids, L-α-aminoadipic acid, L-cysteine, and L-valine, to form the tripeptide δ-(L-α-aminoadipyl)-L-cysteinyl-D-valine (LLD-ACV) by the ACV synthetase enzyme. The racemization of valine from the L- to the D-configuration appears to take place during the synthesis of the tripeptide. The LLD-ACV tripeptide is cyclized to form the penam nucleus, isopenicillin N, by isopenicillin N synthetase (or cyclase). Both the LLD-ACV tripeptide and isopenicillin N also serve as intermediates in the biosynthesis of penicillins. The genes coding for enzymes involved in the biosynthesis of the common intermediates LLD-ACV and isopenicillin N are designated *pcb* (*p*enicillin/*c*ephalosporin *b*iosynthesis). The genes coding for the remaining enzymes involved in the biosynthesis of cephalosporins are designated *cef* (14).

The isopenicillin N epimerase (IPNE) catalyzes the conversion of the L-α-aminoadipyl side chain of isopenicillin N into the D-α-aminoadipyl side chain of penicillin N. The five-membered thiazolidine ring of penicillin N is then expanded to give the six-membered dihydrothiazine ring of deacetoxycephalosporin C by deacetoxycephalosporin C synthetase (expandase). The next enzyme in the pathway, deacetylcephalosporin synthetase (hydroxylase), catalyzes hydroxylation of deacetoxycephalosporin C at the C-3 methyl group to yield deacetylcephalosporin C. In *A. chrysogenum*, both the ring expansion and hydroxylation activities reside on the same protein, which is coded by one gene. Unlike fungi, the expandase and the hydroxylase are two distinct enzymes in *S. clavuligerus* and *N. lactamdurans* and encoded by two separate genes (13).

In *A. chrysogenum*, the last step in cephalosporin C biosynthesis, catalyzed by cephalosporin C synthetase (acetyltransferase), involves the transfer of an acetyl group from acetyl coenzyme A to the C-3 hydroxymethyl moiety of deacetylcephalosporin C.

In the cephamycin C producers *S. clavuligerus* and *N. lactamdurans*, the *O*-carbamoyltransferase catalyzes the transfer of a carbamoyl group from carbamoylphosphate to the C-3 hydroxymethyl moiety of deacetylcephalosporin C. The *O*-carbamoyldeacetylcephalosporin C is then hydroxylated at the C-7α position by cephamycin hydroxylase. The final biosynthetic step to cephamycin C (7α-methoxy-*O*-carbamoyldeacetylcephalosporin C) is the transfer of the methyl group from *S*-adenosylmethionine (SAM) to the C-7α hydroxyl moiety of 7α-hydroxyl-*O*-carbamoyldeacetylcephalosporin C by cephamycin methyltransferase. The biosynthetic pathways of other cephamycins, such as cephamycin A and cephamycin B, have not been fully investigated.

Cloning of the Cephalosporin Biosynthetic Genes

Because the DNA transformation system developed for *A. chrysogenum* is much less efficient than the bacterial systems, cloning of the cephalosporin C biosynthetic genes by complementation of blocked mutants is not feasible. However, the reverse genetics approach has been used successfully in the cloning of a number of cephalosporin C biosynthetic genes (14). This approach begins with the purification of the desired enzyme, determination of a partial amino acid sequence, and synthesis of oligonucleotide probes based on the amino acid sequence. A genomic DNA library of *A. chrysogenum* is then constructed in *Escherichia coli* and screened for clones that hybridize to the DNA probes. Sequencing of the cloned DNA will confirm that the DNA sequence matches the known amino acid sequence. The reverse genetics approach has also been used in the cloning of the cephamycin C biosynthetic genes despite the existence of highly efficient transformation systems developed for *S. clavuligerus* and *N. lactamdurans*.

In 1985, the first β-lactam biosynthetic gene, *pcbC* (encoding cyclase), was cloned from *A. chrysogenum* (15). The *A. chrysogenum pcbC* gene has no intron and encodes a polypeptide of 338 amino acids. When the open reading frame of the *A. chrysogenum pcbC* gene was expressed in an *E. coli* expression vector, the purified recombinant cyclase protein was able to convert LLD-ACV to isopencillin N with identical kinetics to the authentic protein, and it also converted ACV tripeptide analog substrates to novel β-lactam antibiotics. Recombinant cyclase is readily produced in the recombinant *E. coli* and can be used for in vitro synthesis of novel β-lactam antibiotics (16). Other *pcbC* genes have been cloned by reverse genetics or heterologous hybridization from *Aspergillus nidulans, Penicillium chrysogenum, S. clavuligerus, S. griseus, S. jumonjinensis, S. lipmanii, N. lactamdurans, Flavobacterium* sp., and *Lysobacter lactamgenus* (17). When these genes were compared at the DNA sequence and the predicted amino acid sequence levels, a high degree of similarity was found to exist among the *pcb*C genes from different sources.

The reverse genetics approach was also used to clone the *pcbAB* (encoding ACV synthetase), *cefD* (isopenicillin N epimerase), *cefE* (expandase), *cefF* (hydroxylase), *cefEF* (*A. chrysogenum* expandase–hydroxylase bifunctional enzyme), *cefG* (acetyltransferase), *cefH* (also known as *cmcH*, *O*-carbamoyltransferase), *cefI* (*cmcI*, cephamycin hydroxylase), and *cefJ* (*cmcJ*, cephamycin methyltransferase) genes (14,17–20). The only gene of the cephalosporin biosynthetic genes that has not been cloned is the *cefD* gene from *A. chrysogenum*. Most of the cephalosporin C biosynthetic genes cloned from *A. chrysogenum* do not have introns and have a high degree of similarity with their bacterial counterparts, suggesting a bacterial origin for these genes. The *cefG* gene is the exception with two introns. All the fungal genes and some of the bacterial genes encoding for the enzymes involved in cephalosporin biosynthesis have their own promoter for transcriptional control. However, the *Streptomyces cefD* and *cefE* genes are transcribed from the same promoter, with the *cefD* gene located upstream of the *cefE* gene and a 130 base pair (bp) intergenic region separating them (18). In *N. lactamdurans*, a 7-bp separation between the *cefI* and *cefJ* genes and the presence of a putative ribosome binding site upstream of the *cefI* gene suggests that the two genes are cotranscribed from the same promoter and also cotranslated (19).

Organization of the Cephalosporin Biosynthetic Genes

In 1988, Chen et al. demonstrated that a cloned 29.3-kb DNA fragment from *S. cattleya* carried the entire set of genes encoding enzymes involved in cephamycin C biosyn-

thesis (21). No further characterization of this cloned DNA fragment was reported. Subsequent work on other bacterial cephamycin C producers also indicated that the cephamycin C biosynthetic genes are clustered in one region of the bacterial chromosome (17–20) (Fig. 3a). However, in *A. chrysogenum*, the two early cephalosporin C biosynthetic genes, *pcbAB* and *pcbC*, reside on a different chromosome from the two late biosynthetic genes, *cefEF* and *cefG*. Eight chromosomes have been detected by pulsed-field electrophoresis, an electrophoretic technique that allows separation of chromosomes in an agrose gel system. The *pcbAB* and *pcbC* genes are located on chromosome VI and transcribed in opposite directions. The *cefEF* and *cefG* genes are located on chromosome II and are also transcribed in opposite directions (17) (Fig. 3b). Because the *cefD* gene of *A. chrysogenum* has not been cloned, it is not known whether it is linked to either of the two clusters.

STRAIN IMPROVEMENT

Mutagenesis and Selection

Most of the literature describing strain improvement reports the use of the cephalosporin C producer *A. chrysogenum*. However, similar strategies could be applied to the cephamycin C producers (i.e., *Streptomyces* spp.). Improvement in the yield of cephalosporin C has been achieved primarily by increasing the productivity of the *A. chrysogenum* culture by traditional strain mutation and selection techniques. The first significant titer improvement was achieved when in 1959 mutant 8650 was isolated. This strain enabled 100 g of cephalosporin C to be purified for structure determination and is the parent of all the industrial production strains (1).

Mutagenesis, followed by high-throughput screening of the culture, has been the traditional means of strain improvement. Conidia are prepared from the mycelial culture to increase the probability of isolating mutants derived from a single nucleus. Chemical mutagens, such as *N*-methyl-*N*-nitro-*N*-nitrosoguanidine and ethyl-methanesulfonate, or *UV* light are used to induce chromosomal mutations. Growth of the mutants on selective agents can be used to increase the probability of isolating improved clones. Toxic analogs of cysteine, valine, aminoadipate, lysine, and methionine are used to select mutants that overproduce these amino acids, providing a larger precursor pool for β-lactam biosynthesis. The toxicity to *A. chrysogenum* of heavy metallic ions, such as Cu^{2+}, Mn^{2+}, and Hg^{2+}, has also been exploited for selection purposes. Because the β-lactam antibiotics complex with these ions, one can theorize that mutants resistant to inhibitory concentrations of Cu^{2+}, Mn^{2+}, or Hg^{2+} can overproduce the β-lactam nucleus to detoxify these metallic ions. Elander et al. demonstrated the isolation of superior cephalosporin-C-producing strains from mutants resistant to mercuric chloride (22).

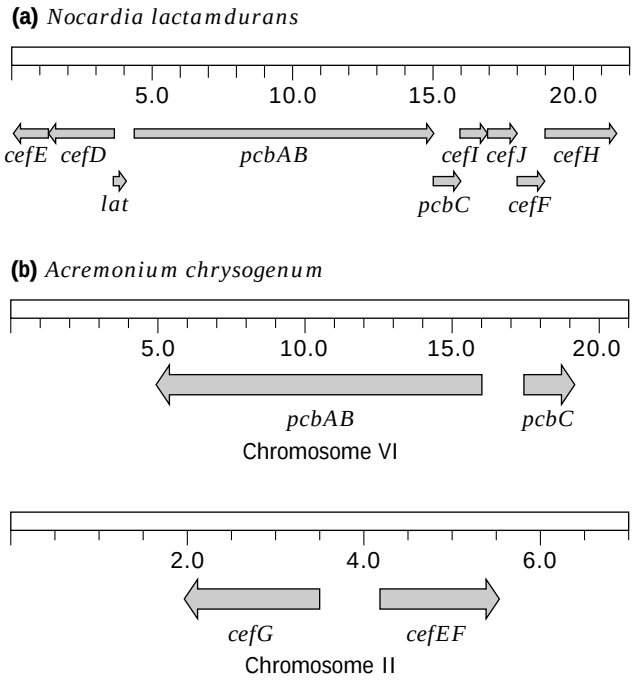

Figure 3. Organization of the cephalosporin biosynthetic genes. (**a**), Physical map of a 25-kb region of *N. lactamdurans* DNA carrying all genes related to cephamycin C biosynthesis. *lat* = gene encoding lysine-6-aminotransferase; *pcbAB* = ACV synthetase; *pcbC* = isopenicillin N synthetase (cyclase); *cefD* = isopenicillin N epimerase; *cefE* = deacetoxycephalosporin C synthetase (expandase); *cefF* = deacetylcephalosporin C synthetase (hydroxylase); *cefH* or *cmcH* = *O*-carbamoyltransferase; *cefI* or *cmcI* = cephamycin hydroxylase; *cefJ* or *cmcJ* = cephamycin methyltransferase (17–20). (**b**), Physical map of the clusters of the cephalosporin C biosynthetic genes of *A. chrysogenum*. *cefEF* = expandase/hydroxylase bifunctional enzyme; *cefG* = acetyltransferase (17). The direction of arrows indicates the transcriptional direction of a gene.

Protoplast Fusion

Protoplast fusion has been explored as a means of combining the advantageous characters of different culture lineages (e.g., high titer and fast growth). Mycelia are treated with dithiothreitol (DTT), followed by Novozym™ 234 (a multienzyme preparation from the fungus *Trichoderma harzianum* available from Novo Biolabs) in the presence of an osmotic stabilizer, usually 0.7 M NaCl. Polyethylene glycol (PEG) is then used to induce membrane fusions between protoplasts; the fusants are identified by regeneration on selective media. Auxotrophic markers have been used to select for fusants, but auxotrophic mutants often have reduced titers and are therefore not suitable for industrial strain improvement. Strains that have been transformed with positive selective markers such as phleomycin and hygromycin resistance are better candidates for protoplast fusion.

Genetic Engineering

In the past 10 years, the cloning of many of the genes involved in the biosynthetic pathway of cephalosporins has led to attempts to improve strains through genetic engineering. Enzymes that have been identified as rate-limiting in the biosynthesis of cephalosporins or their precursors are promising targets for strain improvement through genetic engineering (23). Transformation of industrial strains with additional copies of the genes coding

for these rate-limiting enzymes can result in alleviation of a metabolic bottleneck and increase antibiotic production. Transformation methods for *A. chrysogenum* have been developed using protoplasts and PEG treatment.

Based on the kinetic information available for the enzymes in the cephalosporin C biosynthetic pathway in *A. chrysogenum* and the cephamycin C pathway in *S. clavuligerus*, models have been developed to predict the flux of intermediates in these pathways. The model developed for *S. clavuligerus* predicted that the amino acid precursors, in particular α-aminoadipate, were limiting. Introduction of additional copies of the lysine ϵ-aminotransferase gene *(lat)*, required for conversion of lysine to α-aminoadipate in *Streptomyces*, resulted in a fivefold increase in cephamycin C production (24).

Skatrud et al. have transformed industrial strains of *A. chrysogenum* with a recombinant plasmid containing the hygromycin resistance gene and the *cefEF* gene encoding the expandase–hydroxylase bifunctional enzyme. At the shake flask scale, a 39% increase in cephalosporin C titer was observed, with a significant reduction in the levels of penicillin N and deacetoxycephalosporin C produced. The improvement in cephalosporin C titer at the 150-L pilot plant scale was 15%. Enzyme assays indicated that the expandase–hydroxylase activity in the transformant was twofold higher than in the host strain, and Southern blot analysis revealed a single chromosomal integration at a heterologous position (25). Interestingly, when the *cefG* gene (encoding acetyltransferase) was identified, it was found to be adjacent to the *cefEF* gene and had incidentally been included on the genomic fragment that Skatrud's group had used for transformation. Chiang and Basch also reported that recombinant *A. chrysogenum* strains transformed with a plasmid containing the *cefEF* gene had a 40% reduction of deacetoxycephalosporin C present in the cephalosporin C fermentation broth as compared to the parental strain (26). This process was scaled successfully to production tanks.

CEPHALOSPORIN FERMENTATION

Physiology of Cephalosporin C Fermentation

Cephalosporin C is produced by *A. chrysogenum* as a secondary metabolite, with production of the antibiotic associated with a distinct morphological change. When no nutrient stress is placed on the culture, the organism grows as branched mycelia by extension of the hyphal tips, and little or no cephalosporin C is produced. Under glucose-limiting conditions and in the presence of DL-methionine, the mycelial tips swell and form arthrospores. The mycelial cell walls weaken and fragment, releasing the arthrospores into the media. Throughout the formation of the arthrospores, cephalosporin C is produced, with the swollen hyphae being the most productive morphology.

DL-Methionine addition significantly increases cephalosporin C production. This effect is independent of the methionine role as the sulfur donor for the formation of cysteine. The presence of DL-methionine induces small increases in the enzyme activities of expandase and cyclase and a large increase in the ACV synthetase activity (27). In the presence of high concentrations of glucose or glycerol in fermentation media, the cephalosporin C productivity decreases dramatically. The high concentration of glucose represses the production of expandase, but not of cyclase or ACV synthetase (28).

Large-Scale Fermentation

Cephalosporin C is produced industrially by fed-batch fermentation of *A. chrysogenum*. The pH is maintained between 6.0 and 7.0 in a temperature range of 24 to 28 °C. The media must supply carbon and nitrogen for growth, but must also induce the differentiation of the culture required for antibiotic production. The carbon source may be supplied as separate simple and complex carbohydrates feeds, enabling better control of growth and glucose levels. Monosaccharides, particularly glucose, promote rapid growth of the culture but reduce antibiotic titer. Simple sugars may be batched into the media or fed at higher rates earlier in the fermentation. Galactose and sucrose support slower growth than glucose but a higher rate of specific productivity. As the fermentation progresses, this sugar feed is reduced and a larger proportion of carbon is supplied as soybean or peanut oil. This limits the availability of glucose and allows the formation of arthrospores and cephalosporin C. The oil may also serve as a surfactant to reduce potential foaming of the culture.

The organic nitrogen is usually supplied by some combination of agricultural by-products, such as soybean and cottonseed meals, and supplemented with an inorganic nitrogen source such as ammonium sulfate. Ammonia gas and ammonium hydroxide can also be used to supply inorganic nitrogen and to provide pH control. Corn steep liquor is commonly used in the medium as an inexpensive source of amino acids, trace elements, and vitamins.

DL-Methionine induces the formation of arthrospores in *A. chrysogenum*, which as mentioned earlier is correlated with cephalosporin C production. Swartz et al. examined the growth and productivity of fed-batch cultures of *A. chrysogenum*. Batch addition of methionine at 3 g/L interfered with sucrose utilization of these cultures but did not affect glucose utilization. Methionine was found to be a competitive inhibitor of the invertase enzyme required for the metabolism of sucrose. Optimal productivity was achieved when sucrose and DL-methionine were fed in an exponentially ramped feed. Surprisingly, feeding of DL-methionine increased the productivity of strains that were considered methionine independent, meaning batched methionine had no effect on titer (29).

As with all fungal fermentations, dissolved oxygen is an important physical parameter. It is particularly important in the fermentation of cephalosporin C, because the cyclase and particularly the expandase enzymes in the biosynthetic pathway require oxygen for effective catalysis. If the dissolved oxygen level drops below 20%, penicillin N will accumulate and the output of cephalosporin C will be reduced.

Chemical breakdown of cephalosporin C to 2-(D-4-amino-4-carboxybutyl)-thiazole-4-carboxylic acid (compound X) (Fig. 4) results in the loss of ~40% of the cephalosporin C produced, a significant loss of the biosynthetic

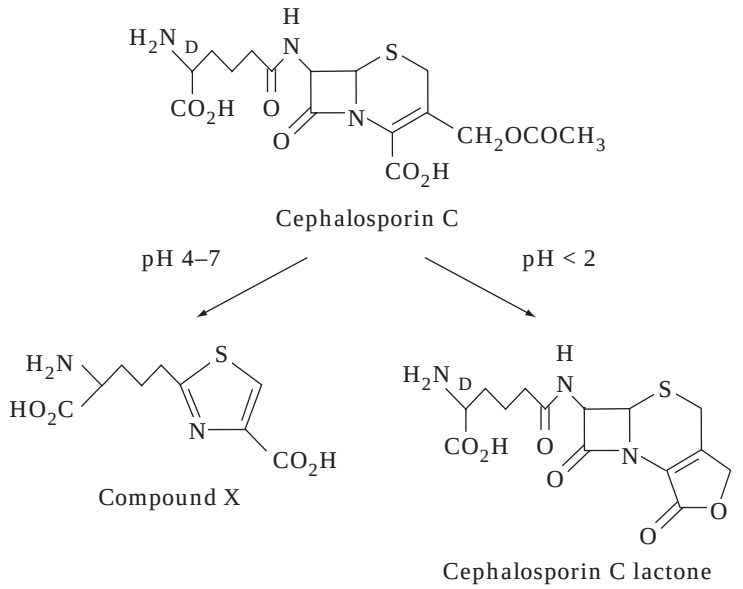

Figure 4. Chemical degradation of cephalosporin C.

potential of the organism (30). Deacetylcephalosporin C, however, is far more stable in the fermentation broth in comparison to cephalosporin C. Addition of an acetyl esterase produced by *Rhodosporidium toruloides* to the fermentation results in the accumulation of deacetylcephalosporin C and an increase in antibiotic yield of ~40% (31).

EXTRACTION OF CEPHALOSPORINS

Cephalosporin C

After the fermentation is complete, the mycelia and insoluble media components are usually removed by filtration or centrifugation. In the fermentation broth, besides cephalosporin C, there is also present small quantities of penicillin N, deacetoxycephalosporin C, and deacetylcephalosporin C. Cephalosporin C must be extracted from the fermentation broth. Under neutral and slightly acidic conditions, a temperature-dependent chemical conversion of cephalosporin C to compound X occurs in the fermentation broth (30). At a pH less than 2, cephalosporin C lactone is formed (32) (Fig. 4). To minimize this degradation, it is important that the cephalosporin C broth be processed rapidly, avoiding extreme pH conditions and keeping the temperature low.

Two main strategies are used for the purification of cephalosporin C. One strategy uses activated carbon column or nonionic resin column to adsorb cephalosporin C from fermentation broth. Because of the high selectivity of activated carbon and nonionic resin, cephalosporin C is preferentially adsorbed over penicillin N, deacetylcephalosporin C, and deacetoxycephalosporin C. A subsequent anion-exchange column gives high purity cephalosporin C product. Alternatively, a combination of anion- and cation-exchange columns arranged in series can be used to purify cephalosporin C directly from the fermentation broth (33).

Because cephalosporin C will be further derivatized to semisynthetic end products, modifications to the cephalosporin C molecule that do not affect the cephalosporin nucleus can be used to facilitate its purification. Therefore, an alternative strategy for the purification of cephalosporin C is substitution of the amine moiety on the α-aminoadipyl side chain of cephalosporin C. Some of the N-substituted derivatives, such as *N*-2,4-dichlorobenzoyl cephalosporin C and tetrabromocarboxybenzoyl cephalosporin C, can be crystallized in acidic aqueous solutions. Alternatively, salts can be formed between the N-substituted derivatives and organic base, such as dicyclohexylamine and dimethylbenzylamine, and they are solvent extractable. Several extraction steps are required to achieve an acceptable purity of the end product, although small amounts of penicillin N, deacetylcephalosporin C, and deacetoxycephalosporin C derivatives are still present (33). N-Substituted cephalosporin C derivatives can be converted to 7-ACA as effectively as cephalosporin C can.

Cephamycin C

The clarified cephamycin C fermentation broth is usually adjusted to pH 2.5 to inactivate most of the penicillin N present. Then, cephamycin C can be isolated with a combination of activated carbon adsorption and anion-exchange resin adsorption. A small amount of deacetoxycephalosporin C and the remaining penicillin N copurifies with cephamycin C. These can be removed by a subsequent silica gel column (34).

PRODUCTION OF THE CEPHALOSPORIN NUCLEUS

Cephalosporin C itself has a relatively low level of antibacterial activity. The semisynthetic cephalosporins with higher antibacterial activity, β-lactamase resistance, and desirable pharmacological properties are derived by modifications of 7-ACA or 7-aminodeacetoxycephalosporanic acid (7-ADCA) (Fig. 1).

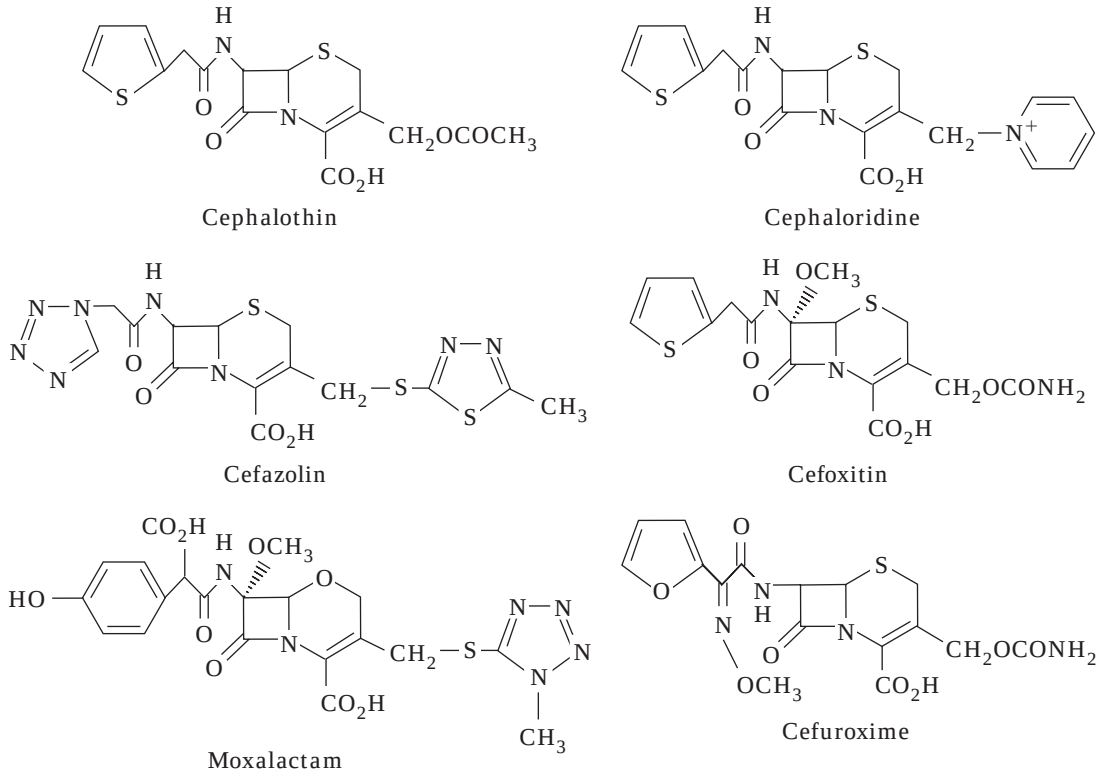

Figure 5. Chemical structure of first- and second-generation cephalosporins.

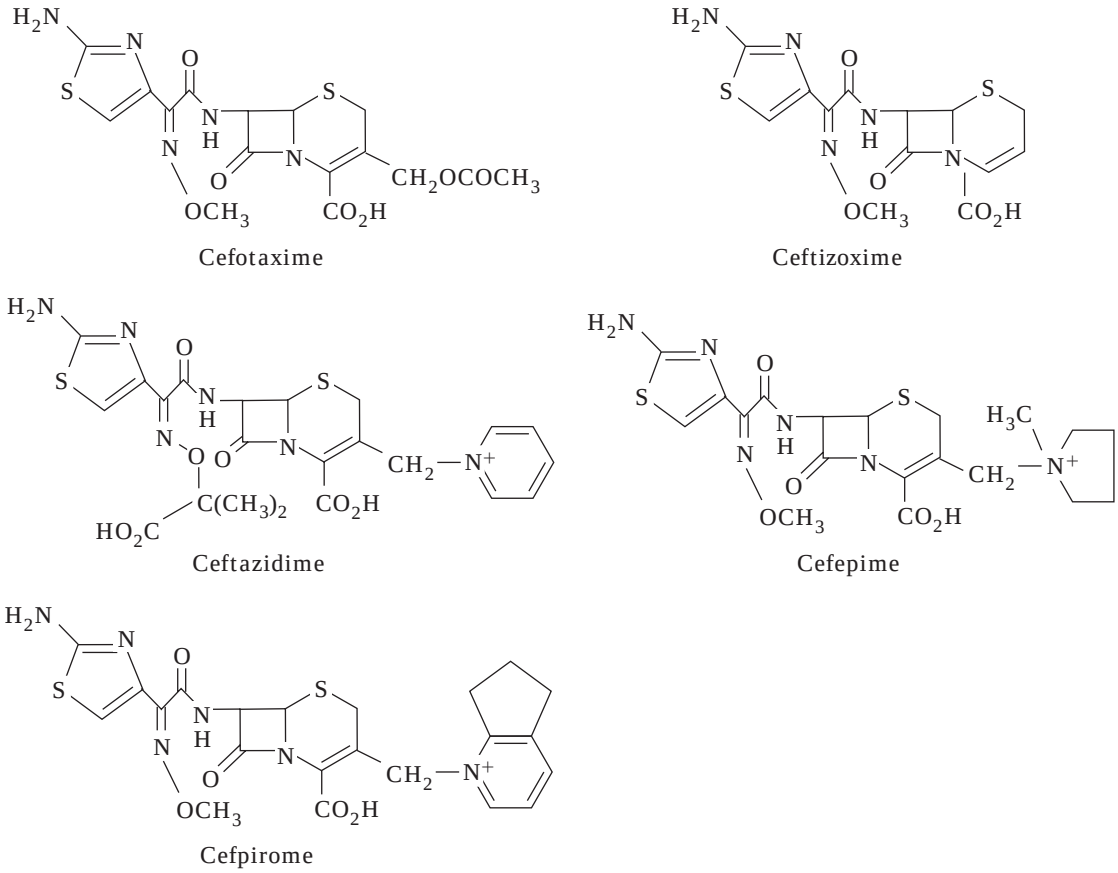

Figure 6. Chemical structure of third- and fourth-generation cephalosporins.

Almost one-third of commercial cephalosporins are derived from 7-ADCA. Because of the lower cost of fermenting penicillins, 7-ADCA is most economically produced from penicillin G by ring expansion of a penicillin sulfoxide ester to yield a cephalosporin ester. The ester group is removed, followed by removal of the phenylacetyl side chain to give 7-ADCA (35). Recently, Merck and Panlabs patented a process for producing 7-ADCA. In this process, *P. chrysogenum* was transformed with the *S. clavuligerus cefE* (expandase) gene. When fed with disodium adipate, this strain produced adipoyl 6-APA, which was then converted by the recombinant expandase to adipoyl 7-ADCA in vivo. The adipoyl side chain was subsequently cleaved in vitro by a *Pseudomonas* adipoyl acylase to produce 7-ADCA (36).

Two-thirds of the commercial cephalosporins are derived from 7-ACA. 7-ACA is produced from cephalosporin C by chemical or enzymatic deacylation. In the chemical process, after protection of the amino and carboxyl groups of cephalosporin C, reaction with PCl_5 in the presence of base yields an iminochloride derivative. Addition of alcohol is used to form the imino ether, which can then be hydrolyzed to form 7-ACA (37).

Alternatively, conversion of cephalosporin C to 7-ACA can be performed enzymatically in two steps. The first step is reaction of the α-aminoadipyl group with D-amino acid oxidase to produce glutaryl-7-ACA. This reaction proceeds through a keto-7-ACA intermediate that undergoes an oxidative decarboxylation in the presence of H_2O_2. Next, a glutaryl acylase is used to remove the glutaryl side chain to produce 7-ACA. An 85% yield of this reaction can be achieved using an immobilized enzyme system (38). Acai et al. coimmobilized the D-amino acid oxidase and the glutaryl acylase enzymes to perform a single-step conversion of cephalosporin C to 7-ACA (39).

SEMISYNTHETIC CEPHALOSPORINS

The outer membrane of gram-negative bacteria is impermeable to penicillins because of their hydrophobicity. Cephalosporins, however, are less hydrophobic, and therefore can pass through the outer membrane to reach their targets. The natural product, cephalosporin C, has low antibacterial activity. Chemical modification at the C-7 position of cephalosporin C yields compounds with a much improved antibacterial activity. Since the development of an efficient method for preparation of 7-ACA, a large number of semisynthetic cephalosporins have been made in the past 30 years. The development of these compounds can be divided into four stages (40).

The first-generation semisynthetic cephalosporins introduced in the mid-1960s include cephalothin, cephaloridine, and cefazoline (Fig. 5). These cephalosporins are modified at the C-3 and C-7 positions. The antibacterial activity of these compounds is still limited because indole-positive *Proteus* species and opportunistic pathogens, such as *Pseudomonas aeruginosa*, are resistant because of the presence of β-lactamases. Since the late 1960s, an enormous effort has been devoted to the development of cephalosporins resistant to β-lactamases.

Out of this research, the second-generation cephalosporins were generated. Among this group, two types of compounds, cephamycins and 7-oximinoacyl cephalosporins, were developed. In 1971, cephamycins were discovered from actinomycetes (10). Cephamycin C has a 3-carbamoyl and a 7α-methoxy group, which confers a remarkable resistance to β-lactamases. Chemical derivation of cephamycin C led to the development of cefoxitin and moxalactam (41) (Fig. 5). The compound developed from 7-oximinoacyl cephalosporin is cefuroxime (41) (Fig. 5). Cefuroxime carries the same 3-carbamoyl-oxymethyl group as cephamycin C does.

In the search for better cephalosporins with broader antibacterial activity and resistance to different β-lactamases, the addition of a hydrophilic aminothiazole group to oximinocephalosporins produced the third-generation cephalosporins, such as cefotaxime, ceftizoxime, and ceftazidime (41) (Fig. 6). Again, the third-gener-

Table 1. U.S. Manufacturers' Trade Names for Semisynthetic Cephalosporins

Semisynthetic cephalosporins	Trade name (manufacturer)
First generation	
Cefadroxil*	Duricef (Bristol-Myers Squibb)
Cefazolin	Ancef (SmithKline Beecham), Kefzol (Lilly)
Cephalexin*	Biocef (International Ethical), Cephalexin (Biocraft, Lederle Standard Products, Novopharm USA, Warner Chilcott), Keflex (Dista), Keftab (Dista)
Cephradine*	Cephradine (Biocraft, Lederle Standard Products, Warner Chilcott)
Second generation	
Cefaclor*	Ceclor (Lilly)
Cefamandole	Mandol (Lilly)
Cefmetazole	Zefazone (Upjohn)
Cefonicid	Monocid (SmithKline Beecham)
Cefotetan	Cefotan (Zeneca)
Cefoxitin	Mefoxin (Merck & Co., Inc.)
Cefprozil*	Cefzil (Bristol-Myers Squibb)
Cefuroxime	Kefurox (Lilly), Zinacef (Glaxo Wellcome)
Cefuroxime axetil*	Ceftin (Glaxo Wellcome)
Third generation	
Cefixime*	Suprax (Lederle)
Cefoperazone	Cefobid (Roerig)
Cefotaxime	Claforan (Hoechst-Roussel)
Cefpodoxime*	Vantin (Upjohn)
Ceftazidime	Ceptaz (Glaxo Wellcome), Fortaz (Glaxo Wellcome), Tazicef (SmithKline Beecham), Tazidime (Lilly)
Ceftrizoxime	Cefizox (Fujisawa)
Ceftriaxone	Rocephin (Roche Laboratories)
Loracarbef*	Lorabid (Lilly)
Four generation	
Cefepime	Maxipime (Bristol-Myers Squibb)

Note: Orally administered cephalosporins are marked with an asterisk. All others are administered by intramuscular or intravenous injection.

ation cephalosporins have been compromised by the rapid emergence of resistant bacterial strains with plasmid-encoded β-lactamases and by their ineffectiveness against strains of *Enterobacter cloacae* and *P. aeruginosa* with constitutively expressed chromosomal β-lactamase.

By the late 1980s, the fourth-generation cephalosporins, cefepime and cefpirome (Fig. 6), had been developed. The new compounds retain the aminothiazole moiety at C-7 with an oxyimino substitution and contain a positively charged quaternary nitrogen at the C-3 position (40). Table 1 summarizes the semisynthetic cephalosporins available in the U.S. market (40,42).

CONCLUSION

Since the discovery of cephalosporin C 50 years ago, rapid progress has been made in the strain improvement and fermentation process development for the production of cephalosporin C. Genetic manipulation of *A. chrysogenum* and *S. clavuligerus* allows the potential for engineering of cephalosporin biosynthetic enzymes with broader substrate specificity for in vivo or in vitro production of new β-lactams. Because of the continuous selection of resistant bacteria carrying newly formed β-lactamases, the development of new semisynthetic cephalosporins remains a constant effort to find new compounds effective against these pathogens.

OUTLINE

INTRODUCTION

Continuously propagatable mammalian cells, in general, and Chinese hamster ovary (CHO) cells, in particular, have become preferred host systems for the production of complex proteins for clinical applications. Nowadays, in pharmaoriented biotech companies, more protein species are being produced in CHO cells than in *E. coli* and in *Saccharomyces*, which were production hosts of first choice during the early years of applied DNA technology. These microbial organisms are capable of producing large amounts of recombinant protein. However, the decision to employ somewhat more complex and costly in-vitro cultures of recombinant mammalian cells has been driven by the need to obtain proteins with superior biological activity and more complex biochemical structures. Biological activity and, last but not least, the pharmacokinetic characteristics of recombinant proteins, when administered in therapy, frequently depend on a number of complex protein modifications, that is, proper folding and disulfide bridge formation, oligomerization, proteolytic processing, phosphorylation, and the addition of specific and complex carbohydrate groups. Most of these and other protein processing steps can be executed with high efficiency by mammalian cells.

CHO cells have become dominant in industry, and not only for historic reasons. Of course, they were chosen as the host substrate for the first recombinant protein from mammalian cells, human tissue plasminogen activator (Activase® tPA) (1), achieving market approval in the United States and other global markets. CHO cells are unique in many ways and exhibit a number of advantages, ranging from ease of introduction of exogenous DNA to the capacity for growth and production at very large scales. This article attempts to summarize and highlight arguments, issues, advantages, questions, and ongoing research, in a cursory way, for the industrial production of high-value proteins derived from CHO cells. In doing so, the development path followed to establish a high-yield process will be followed, from the construction and use of appropriate plasmid vectors to the planning and design of the cell culture manufacturing process. Issues raised and

discussed herein are not meant to be comprehensive, yet it is hoped that the most critical points impacting development efforts will be addressed.

PRINCIPLE OF DNA TRANSFER AND AMPLIFICATION IN CHO CELLS

The following gives a brief introduction into the underlying principles for use of CHO cells as recipients of protein-encoding DNA vectors, and the most popular way to improve productivity with these cells: experimentally induced gene amplification.

A mutant cell line lacking enzyme activity for dihydrofolate reductase, developed by Urlaub and Chasin (2), can be cultivated in the presence of glycine, hypoxanthine, and thymidine (GHT). When these cells are transfected with a functional expression vector for dihydrofolate reductase (DHFR vector), cell lines that have acquired a functional DHFR gene can be selected and expanded in media lacking GHT. A second (or third or more) expression cassette for a product of interest (e.g., a protein with therapeutic value) can be included in the DHFR plasmid or cotransfected as part of one or more additional vectors. Screening a number of "clones," or more correctly, cell lines derived from colonies, will lead to the identification of cells coexpressing the product of interest.

In a second and often time-consuming phase of cell culture work, expression can be augmented by exposing recombinant cells to the drug methotrexate (MTX), a folate derivative that blocks DHFR activity completely and irreversibly. Usually, within a period of 2–3 weeks, from a population of cells a few colonies emerge (while the majority of cells die) that are resistant to the drug due to elevated expression of DHFR. It was found that these cells frequently contain chromosomally integrated plasmid sequences in a higher copy number than observed in cells prior to exposure to MTX. Treatment with stepwise elevated concentrations of MTX can be repeated several times and may result in the isolation of cells that contain dramatically increased copy numbers of the transferred genes.

The same principle for MTX-driven amplification applies to other immortalised cell lines as well (3); however, DHFR-mediated DNA transfer and methotrexate-driven amplification works best with cells that lack an endogenous DHFR gene (activity) prior to transfection.

REGULATORY ISSUES: PRODUCT SAFETY, CELL CHARACTERIZATION, IDENTITY, AND CONSISTENCY FOR PRODUCT FORMATION

CHO cells, originally derived from the ovary of a female Chinese hamster, emerged as a spontaneously immortalized line, more than 40 years ago in the hands of Kao and Puck (4,5). The cells have been the object of many studies since then and are very well characterized with respect to a variety of aspects, including karyotype, chromosome structures, gene mapping, general culture conditions, cell physiology, and media requirements. For the purpose of genetic and physiological studies on the activity of dihydrofolate reductase and its genomic alleles, in the late 1970s, Urlaub and Chasin (2) mutagenized the original cell line with the help of radiation and chemicals. The goal was to create a mutant cell line lacking functional activity of both alleles of the DHFR gene locus. The resulting cell line was called CHO-DUX (sometimes also referred to as CHO-DUKX-B11) and, although not initially intended for this purpose, proved to be an ideal substrate for a number of pioneering gene transfer experiments (6–8).

The "climate" for permission by regulatory agencies, in particular the FDA in the United States, was not favorable in the early 1980s for using "tumor" cell lines, such as immortalized CHO cells, for the production of recombinant proteins. Discussions about risks associated with the use of mammalian cells were controversial, and had been initiated more than two decades earlier (8) when a first generation of "classical" biological products (i.e., vaccines and, later, natural interferons) were developed on the basis of primary monkey kidney cells, human diploid cells, and later, transformed mammalian cells. Manufacturers of recombinant proteins for clinical applications and regulatory agencies were in agreement that it was very important to minimize eventual risks associated with the use of recombinant mammalian cell hosts. Risks were seen in tumor principles, carried by the DNA of the host and in adventitious agents (viruses, mycoplasma, etc.), which could infect the host cell lines. Also, consistency and quality of the recombinant proteins were discussed in the context of risk assessment and risk control. The result of a decade-long discussion was that very stringent manufacturing controls and monitoring procedures were enforced as a prerequisite for manufacture of proteins from such cells. A balance had to be found between the almost assured clinical benefit of some of those first recombinant products and the perceived (real or imaginary) risks associated with the unavoidable necessity to produce them in "tumor" cells.

The first product, recombinant tissue plasminogen activator (Activase® rtPA), proved to be a good candidate to achieve such a balance because the benefit, saving lives of heart-attack patients, outweighed by far anticipated risks, for example, the debated risk of exposing patients to DNA sequences that may transfer a tumor-inducing principle. However, approval was achieved only after a huge amount of data was provided to the regulatory agencies showing that (1) consistently, only a very small quantity of CHO DNA (less then 10 pg/dose recently related to less than 100 pg/dose) was present in the final product, (2) the product itself could be produced with a very high degree of reproducibility, and (3) it was produced with a purity not achieved before in any biological derivation from mammalian cell culture.

Adventitious Agents: Bacterial and Fungal Contamination

Prevention of airborne and other bacterial or fungal infections of cell culture and recovery systems can be assured, to a very high degree of confidence, by the use of a piping and vessel system that maintains absolute containment of the sterile medium fluids. The equipment used must be of a nature that allows cleaning and sterilization by clean-in-place (CIP) and sterilize-in-place (SIP) procedures (usually using high-quality stainless steel). Most cell culture pro-

cesses require complex media containing amino acids, vitamins, protein hormones, and fetal bovine serum. Some of these components cannot be autoclaved. To exclude, therefore, the introduction of bacterial and fungal contamination through these raw materials, prior testing and, in addition, filtration through membranes of 0.2-μm-or even 0.1-μm-pore-size into presterilized containers is employed.

Rigorous testing cell banks (Master Seed Cell Bank, MSCB, Manufacturers Working Cell Bank, MWCB) (for review see Ref. 10), done by analyzing cells of a number of representative cryovials, which represent the bank when frozen in liquid nitrogen, assures that the production cell line itself is not contaminated with viruses, bacteria, mycoplasma, and fungi. Sterility testing of the cell line must be done in appropriate media lacking antibiotic or antifungal compounds, for obvious reasons. Virus testing is done in suitable cell systems that are validated for each of the individual virus species.

Adventitious Agents: BSE

The use of sera or other products derived from bovine sources represents a potential risk of transfer of the causative agent for bovine spongiformous encephalopathy (BSE) to patients receiving recombinant proteins.

Regulatory agencies therefore request detailed information on the origin and processing by the vendor of bovine derived products. For example, sera obtained from countries in which BSE was diagnosed, even in a small number of animals, are considered unacceptable by regulatory agencies. Companies have, in most cases anticipating these regulations, assured their supply of bovine-derived process materials from countries like New Zealand or the United States where BSE has not yet been reported. Recently, due to the high degree of concern raised in Europe, but also in the United States, very stringent process regulations have been discussed. These regulations would restrict to a very large extent, or prevent altogether, the use of bovine-derived process additives, not taking into account the processing of the materials by the vendor or the receiving company. The high degree of concern regarding BSE is based on the possibility that *(1)* a very small proteinaceous compound could be responsible for the disease, *(2)* transfer to the human population as Creutzfeld–Jacob disease has been considered possible, and *(3)* detection of the causative agent is extremely difficult, even with the most sophisticated methods available today. It appears that the complexity of the involved issues will require further discussion in the future and must occur at an international level.

Adventitious Agents: Viral Contaminants

Why were hamster cells chosen as a host for making human recombinant proteins? A strong argument, favoring nonhuman cell lines over human cell lines for the production of proteins, is the fact that certain life-threatening human viruses cannot be propagated, or grow poorly, in nonhuman cell lines. CHO cells have been found to not support the replication of pathogenic viruses such as polio, herpes, hepatitis B, HIV, measles, adenoviruses, rubella, and influenza. Thus, the risk of a viral adventitious agent, belonging to this group of viruses, involuntarily carried along with the product of interest can be considered extremely low. Wiebe et al. tested a total of 44 human pathogenic viruses for replication in CHO cells and found only seven (Reo 1,2,3; mumps; and parainfluenza 1,2,3) that were able to infect these cells (11). Exclusion of these few virus species, as well as some other viruses that can be propagated on CHO cells, such as the minute virus of the mouse (MVM), can be assured to a very high degree of certainty through testing. Tests can be performed with all materials that enter the manufacturing process and would support the viability of the virus in question. Tests are also obligatory with fluids that contain the product of interest and that represent, for example, toward the end of the cell culture production cycle, a manufactured product unit, defined as a "batch."

Sterility filtration of fluids containing a variety of raw materials, some of which may have been exposed to viruses, does not prevent the introduction of viral contaminants into the process of cell culture–based manufacturing of proteins. Only recently have membranes with pore sizes small enough to exclude passage of virus particles become available for industrial-scale operations. However, these membranes cannot be introduced into existing processes without complex consequences on regulatory issues. Testing therefore still appears to be the most efficient method to exclude viruses that may reside within the host cell line itself, or that could be introduced by biologically derived raw materials needed for the cell culture process. Specialized service companies have developed, in close collaboration with the pharmaceutical client companies, batteries of validated test procedures. These utilize cell culture systems in which supernatants or lysates of the production cells are cocultivated with the corresponding virus-sensitive substrates. Because cells in master seed banks and in working cell banks are of the highest importance for the cell culture production process, samples from these are the first to be considered for the rather expensive and time-consuming testing exercise.

Another and complementary approach to virus safety is the design of virus kill and removal steps of the recovery process for the protein of interest. These include physical and chemical principles separating (theoretical) viral contaminants from the product or inactivating them. Again, appropriate testing procedures and the demonstration of inactivation and removal of model viruses, as discussed in the important paper by Wiebe et al. (11) was considered a major provision for the achieved safety of recombinant products from hamster cells.

Product Consistency, Quality, and Purity: DNA, Endotoxin, and Protein Characterization

A very rich collection of methods has become available for the analysis of purified proteins within the last two decades. In addition, most of these methods have been recently optimized and fine-tuned to very high sensitivities and resolution. When employed as routine analytical procedures during the manufacturing process, they can assure high quality and consistency of protein products (12–17). Still, the manufacturer of a pharmaceutical protein has

one major concern: will a product that has demonstrated its efficacy in extensive and expensive clinical trials remain the same in its essential characteristics when employing a defined manufacturing process for its production over many years? It seems surprising, but due to the large size and complexity of proteins under study for clinical use today, their structural features and their functional principles within the human body may not be fully understood by the manufacturer when completing successful clinical trials. This is especially true for the newer generation of pharmaceutical proteins that are larger in size and often contain multiple polypeptides and/or multiple specialized domains exhibiting secondary modifications such as glycosylaton, phosphorylation, and sialylation. Subtle changes, sometimes difficult to detect due to inherent heterogeneities of structures of protein populations, may result in loss or modification of activity and could pose risks to the patient. In order to reduce this possibility, batteries of in-process controls and tests are an inherent part of the production of clinical proteins. In the following section, sensitive and robust techniques and methods are outlined and discussed. The objective is to *(1)* prevent the occurrence of even small changes in the procedures employed to produce the product of interest and *(2)* enable the detection and exclusion from the final vial protein variants differing in a major way from the one tested in clinical trials.

Adherence to GMP Protocol for Manufacturing. The first level of protection against inadvertent changes of the product rests in effective management of the production process over time. The challenge is the same as that of any mature industry: to produce large amounts of material at competitive cost while ensuring that product consistency and quality are maintained. Obviously, manufacturing teams and their supervisors undertake every effort to reproduce the manufacturing process to the utmost detail in every production run. This is achieved by defining and describing each of the various steps in the form of detailed protocols. Almost every aspect of the procedure is documented. These documents establish, in the form of cGMP (current good manufacturing practice) protocols, the basis for the overall procedure. A "sign off" procedure by supervisors represents an integral part, assuring that the operating personnel for the manufacturing process are in fact controlling, assessing, and executing it according to the established protocols. At critical points in the overall process, the signatures are prerequisites allowing the progression of the process to the consecutive steps.

The time period of cell line and process development leading up to the establishment of the manufacturing process is very important for the definition of critical "checkpoints." During this period, knowledge about parameters and steps is acquired that can result in product changes. Once certain limits of variations of process conditions have been identified (within which no change was observed) the cGMP protocol is drafted and finalized. Specific events, defined in precise terms as part of the manufacturing protocols, can trigger a more elaborate investigation. Supervisors and managers can even order an interruption of the manufacturing process. In extreme cases, crude product batches are withheld from further processing and are discarded.

Quality Control for the Detection of Variant Product Forms. Quality control (QC) is an integral part of the manufacturing process of recombinant products. A comprehensive approach, utilizing independently validated techniques, is applied to assess the quality and identity of the product from various angles (for review see also Ref. 18). It is the goal of QC efforts to assure that products made over years of manufacturing will meet the stated specifications in terms of identity, quantity, activity, and purity.

In principle, it is no longer very difficult to produce large quantities of highly purified recombinant proteins. However, methods to produce these proteins are still considered part of a young technology, because its basis is the manipulation of genetic material of various sources in the laboratory. Those manipulations involve the creation of plasmid vectors, based on fragments of genetic information that are linked together as a first step. In a second step, the transfer of such DNA for transgene-dependent protein synthesis to a complex organism such as *E. coli*, yeast, or, as discussed here, into the chromosomes of mammalian cells cultivated in vitro occurs. A major concern has been the fidelity (amino acid sequence identity) of the final product, particularly in view of the high degree of ignorance with respect to gene transfer mechanisms in higher eucaryotes and its consequences. Also, it appears that transfected DNA may have, possibly during the transfer to the host cell, a somewhat elevated propensity for mutation (19). A discussion of issues concerning structure and fate of DNA transferred to mammalian cells will be discussed later.

Nevertheless, based on a history of experience with this technology for more than 10 years, it can be stated that this young technology is in fact a very reliable one. It has been suggested that rigorous and extensive nucleic acid based tests, most notably a complete sequence assessment of the genomically integrated DNA (or transcribed RNA from recombinant cells) should be performed (20,21). It appears that such rather complex, expensive, and time-consuming tests are not necessary. An entire session was devoted to nucleic acid considerations during a conference organized by the International Association of Biological Standardization, held in Annecy, France in 1994. Berthold specifically addressed genetic stability in CHO cells (22). As already pointed out, following the rapid development of techniques allowing manipulation and transfer of DNA molecules to various hosts, powerful and reliable new methods have emerged in analytical protein chemistry. These have increased the capacity to characterize purified protein preparations to an extremely high degree of sensitivity and resolution. These methods represent efficient tools to assess identity (including the amino acid sequence), quantity, potency, and purity of the product at the level where it is most needed—just prior to administration (delivery) to the patient. The results from QC assessments from thousands of lots of approved products are, as far as this author knows very encouraging with respect to (amino acid sequence) identity: no lot has been called into question

based on a QC finding that has indicated a newly emerged mutant gene.

Still, this statement does not negate the possibility that mutants may occasionally emerge. They will, over and over again, within the large population of cells in bioreactors. A 1,000-L reactor usually contains more than 10^{12} cells. However, there is no reason to believe that mutations would occur at a frequency significantly different from the frequency of mutations occurring within the human body (1 bp change in 10^9 bp for each generation) (23). Of course, such mutations will be "scattered," and as individual entities are extremely rare. Therefore, individual and specific variants are not likely to emerge in the population of protein molecules as a sizeable subclass of identical molecules.

A telling example of the power of in-process controls and the associated biochemical assays to identify variants in a population of molecules is given in an article by Sliwkowski and coauthors (24). It describes the detection of an amino acid exchange mutant of a recombinant monoclonal antibody (anti-Her2). This variant was detected early during process-development efforts when using a methotrexate-amplified clone of CHO cells. The variant represented about 10% of the total population of antibody molecules. The origin of this mutant remains mysterious, but it seems it was the result of an early event during the development of the cell line that was used in the process.

MOLECULAR BIOLOGY OF VECTOR DESIGN, TRANSFECTION, AND IDENTIFICATION OF HIGHLY PRODUCTIVE CELL POPULATIONS

DNA Transfer to CHO Cells Using Calcium Phosphate

Graham and van der Eb (25) showed more than 20 years ago that the transfer of DNA into mammalian cells in culture can be achieved by exposing cells to microprecipitates of DNA and calcium phosphate. This simple method (termed calcium phosphate transfection) has become very popular. Typically, a glycerol shock is part of the transfection procedure. The shock is thought to promote the transport of individual DNA–calcium phosphate complexes across the cell membrane, perhaps by inducing endocytosis or phagocytosis. When optimized transfection conditions are used, a high percentage of cells take up DNA. However, in addition to the movement across the outer membrane of the cells, the transport of DNA from the cytoplasm to the nucleus seems to be a significant barrier. In 1982 Loyter et al. reported that only 1–5% of transfected cells have detectable calcium phosphate complexes within the nucleus (26,27). The stable integration of transfected DNA into chromosomes of mammalian cells was first shown by Axel and collaborators (28,29). The number of emerging colonies upon transfection by the calcium phosphate technique has been reported to be low: usually, only between 0.01% and 0.5% of the cells gave rise to recombinant colonies (30). More recent investigations and appropriate improvements of crucial physicochemical parameters of the calcium phosphate transfection methodology in several laboratories have increased transfection efficiencies for stable recombinant cells to about 5–10% (and those of transient transfections to levels of 50% or higher) of the population of cells exposed to exogenous DNA (31–33). Calcium phosphate transfection still seems to be the most frequently used method for the generation of recombinant CHO cells.

Yet, it appears that the transfer of a sufficient quantity of DNA into the nucleus and the integration of at least a few functional plasmid molecules into transcriptionally active regions of the receiving genome is by no means an efficient process. Half a million or more plasmid molecules are usually provided per cell in a typical calcium phosphate transfection, the result of which is stable gene transfer in a small percentage of the exposed cells. It has been shown that the association of the DNA with calcium phosphate protects against nuclease attack during the transport to the nucleus (26). Eventually these complexes become dissociated and nuclear endo- and exonucleases will have access to the "naked" DNA. Moreover, it has been shown that supercoiled plasmid DNA molecules will be converted into relaxed (single-stand cut), open circular, and finally linear molecules (double-strand cut) within the nucleus after 1–2 h (34). This is, of course, an essential step for integration into the linear DNA backbone of a chromosome.

The mechanism by which the DNA is transported across the nuclear membrane (nuclear pores are not large enough for diffusive transport), and finally to the site of chromosomal integration, are not yet known. On the receiving side, at least one strand of the chromosomal DNA must be opened while a linear plasmid molecule is in sufficiently close proximity. Nuclear ligases could then mediate covalent linkages. Very little is known about the mechanism and about the factors affecting site specificity for integration.

Site specificity is a very relevant factor in this context. It is believed that it has influence on the transcription rate of the integrated DNA, even if the DNA carries a powerful (viral) promotor, such as the SV40 early promoter or a CMV promoter. The current assumption is that exogenous DNA will integrate at "random" within the genome, even if the transfection cocktails contain DNA with homology to sequence segments of the receiving genome. This is an observation from numerous gene-targeting experiments in mammalian cells. It was found that only 1 in 1,000 to 1 in 10,000 events would result in targeted integration (35,36). With respect to the actual sites of integration in CHO cells, there is only limited and sporadic data available at present. Only a small proportion of recombinant cell lines should contain the transferred DNA within transcriptionally active regions of chromosomes if integration would truly occur at random subsequent to transfection. In reality, we cannot know whether DNA will end up more frequently than not in transcriptionally inactive regions of the genome. We have no opportunity to analyze cells that did not overcome the selection step. The selection step is, as we know from the low transfection efficiencies in stable transfections, a very significant barrier.

Among the emerging cell lines there is usually extensive heterogeneity in productivity for recombinant proteins. The expression levels from primary CHO clones for proteins like rtPA, a secreted version of the CD4 receptor (rCD4-truncated), and a chimeric TNFR-FC fusion protein had a range of more than two orders of magnitude (37,38), observations which this author believes can be generalized

for all transfections in mammalian cells. As a consequence, the identification of high-producer cell lines is a tedious and labor-intensive exercise and requires the screening of hundreds of individual cell lines. In the author's experience, it is usually necessary to invest 2–4 months of laboratory work into this task. Only then has one enough confidence in having appropriately assessed the upper range of sustainable expression for a novel protein in CHO cells.

Nuclear enzymes such as endo- and exonucleases, but also ligases (39) and possibly recombinogenic enzymes (40,41), acting on the population of plasmid molecules within the nucleus are responsible for the modification of transfected DNA that becomes eventually integrated into the genome. This modification may not only degrade in part the plasmid DNA but is also responsible for creation of larger, that is, more extended DNA complexes. These DNA molecules seem to be created before the integration into the genome. They provide the physical basis for linking the genetic selection marker and the gene(s) of interest in those transfections that utilize separate vectors. It should be noted here that DNA transfer methods, other than the use of calcium phosphate, might deliver different quantities of DNA to the nucleus. This may have profound effects on the structure and copy number of integrated DNA molecules, as will be discussed later.

In discussing the integration loci for transfected DNA in the mammalian genome, it is interesting to note that integration sites for amplified DNA sequences, detectable by fluorescence in situ hybridization (FISH) after selection in methotrexate, did not show a preference for a particular chromosome or chromosomal region. However, in light of recent data on gene amplification mechanisms (42), it is not possible to draw conclusions from these findings toward the identification of the initial (primary) integration site(s).

Additional DNA Transfer Methods

In addition to calcium phosphate transfection (25,31), more recently electroporation (43,44), cationic lipids, and liposome mediated (45–47) transfection techniques have been developed for transfer of DNA into mammalian cells. Most of these techniques have been reported to mediate higher transfection efficiencies as compared with calcium phosphate–mediated DNA transfer. Such claims must be regarded with some caution because all DNA transfer techniques established so far suffer from high variability. Some of the variabilities observed are probably due to technical difficulties in producing reliable and consistently highly efficient carrier systems. The other factors that cause major variations in transfection efficiency are the type of cells used and the condition of the cells prior to transfection.

Because carrier principles for the transfer of DNA to cells can vary widely, one suspects that very different consequences may result within the cell, events over which the person conducting the experiment has no or little control. Just one of the possible consequences should be mentioned here: The technique applied for DNA transfer may affect the copy number average of individual clones, depending on the amount of DNA transferred to the nucleus. It has been proposed that electroporation may result in a smaller copy number of chromosomally integrated DNA than, for example, calcium phosphate–based transfection. In view of the applied selection procedures for the generation of recombinant cell "clones," very different chromosomal structures of integrated plasmid sequences may result.

Another factor to be taken into account for the genomic structure of integrated plasmid sequences is the physical form of the DNA for transfection. Because linearization of plasmid DNA is a prerequisite for integration into any chromosomal site, the structure of the plasmid prior to transfection will affect the final structure when integrated. When circular plasmids are used, as predominant in the past, linearization is dependent on cellular enzyme activity. This will happen most likely at random, and the integrated DNA structure cannot be predicted. Depending on the overall size of the plasmid molecule and the size of the DHFR gene cassette relative to the vector, a significant number of molecules would be linearized within the DHFR sequence, which jeopardizes the functionality of this plasmid. Obviously, molecules whose DHFR expression cassette are interrupted or deleted by the linearization process would be unable to transfer a functional marker gene to the host cells, and such cells would be eliminated through the selection procedure. Therefore, opening the circular plasmid molecule by restriction enzyme digestion with appropriate enzymes prior to transfection has been recommended for improved transfection efficiencies in protocols that aim at integration of plasmid DNA into chromosomal DNA.

We have seen in our laboratory that linearization is, in fact, advantageous in terms of transfection efficiency with stable transfections (32). Linear plasmid molecules are also used routinely in gene transfer experiments that attempt to transfer the desired DNA into specific (homologous) DNA sequences of the receiving genome (gene targeting). In these experiments, linearization is executed in a way that results in cutting the homologous DNA fragment approximately in half. The molecules for DNA transfer then carry DNA sequences that are homologous at their ends (48–50). We have used such an approach in our laboratory by employing (defective) retroviral DNA sequences derived from the CHO genome in expression vector cocktails. They have quite significantly improved the frequency of high-producer cell lines upon transfection (37,38).

CHO CELL ENGINEERING

Use of serum and other more or less undefined and complex media additives for growth of mammalian cells may result in problems of reproducibility in the process, and thus additional costs. To avoid a negative impact on cell growth, testing procedures have to be incorporated prior to use of these additives to identify possible variations from batch to batch. Therefore, the desire to replace some or all of these variable components in cell culture media with well-defined components having high purity and little or no variation in quality has been a priority in the industry for quite some time. Also, use of serum and animal-tissue-derived growth factors (insulin, transferrin) bears

the considerable risk of transmittal of undesired adventitious agents to the production process because these additives frequently cannot be heat sterilized.

Although serum-free and growth-factor-free media may support the growth of mammalian cells, the robustness of the cell culture process, in general, and maximally achievable cell densities in particular may be reduced when using media free of serum- and/or protein growth factors. Therefore, efforts have been undertaken to modify production host cell lines prior to the transfer of expression vector DNA. The hope was to generate hosts for production that would achieve superior growth rates, and so would be more useful for scale-up and higher in productivity. Various oncogenes, cell cycle genes, and/or hormone genes (51–53) have been transferred into the genome of cells, resulting in novel and possibly superior production hosts. In view of actual discussions regarding BSE and other, so far unknown, adventitious agents, which pose the risk of entering production through process additives, the interest in such novel hosts will be very high. It needs to be seen how soon and how frequent these "super CHO" cell lines will be used in the manufacturing of novel products.

METHOTREXATE-MEDIATED VECTOR AMPLIFICATION IN DNFR-TRANSFECTED RECOMBINANT CHO CELLS

Treatment of DHFR-positive CHO cells with incremental concentrations of methotrexate has been used to select for populations and clones of populations of CHO cells with an increased (i.e., amplified) copy number of the integrated DNA within the host genome. The phenomenon of methotrexate-mediated gene amplification had been observed before the use of recombinant DNA technology, most notably in cancer patients who had been treated for extended periods of time with methotrexate (54).

With CHO cells, cell lines containing several hundreds, and sometimes a few thousand, copies of transfected DNA fragments integrated within chromosomes have been established (55,56). Most amplified cells produce more product than unamplified host cells. However, the improvement of specific productivity is highly variable when studying individual clones (57) and also varies from product to product (Wurm, unpublished observation, 1994).

Cytogenetics of Amplified CHO Populations: Long-Term Genetic Stability and Maintenance of Productivity

Subpopulations and clones of methotrexate-treated CHO cells may contain the transfected DNA sequences at very high copy numbers (55,56,58). Studies concerning genetic features of these amplified DNA sequences within the CHO genome have been ambiguous. Whether continued presence of a selective agent (i.e., methotrexate) in long-term cultures of recombinant CHO cells is required for production stability is still controversial. Whereas some studies suggest MTX is required for stable production of recombinant proteins (59), others indicate that continued culture of clonal cell lines in MTX may not be necessary (60). Cytogenetic studies using fluorescence in situ hybridization (FISH) (61) were done in the author's laboratory with clonal and nonclonal recombinant CHO cell lines. They showed that continuous exposure to MTX at the same concentration under which the cell populations were initially established promotes genetic instability at the chromosomal level (62). Cell lines selected at micromolar concentrations frequently show elongated chromosomal structures that hybridize to probes representing the transfected DNA. Some of the chromosomes, containing a large number of more or less tightly arranged bands or regions, differ dramatically from normal CHO chromosomes. This raised questions about cytogenetic stability of such aberrant chromosomes during continuous subcultivation and, in consequence, the production of recombinant proteins based on genes residing within these structures.

The first of our FISH analysis studies was done with cell lines expressing the mouse c-*myc* gene in an inducible manner. The advantage of this system is that the phenomena observed in the genetic context can be attributed solely to the status (expression level, chromosomal location, degree of amplification) of the DHFR selector gene and the inhibitor MTX. The c-*myc* gene is truly silent during regular growth conditions and could not act as a metabolic burden nor result in any selective forces. When these cells are cultivated at 37 °C, the inducible *Drosophila melanogaster* heat shock protein 70 promoter is in "off" status. Even in a cell line containing 1,000–2,000 copies (selected at 320 μM methotrexate) of the transfected DNA, no trace of transcribed c-*myc* RNA and translated c-*myc* protein was observed at 37 °C. However, high-level expression of c-*myc* RNA was induced upon shifting cells to a culture temperature of 43 °C for 1 h.

The continuous exposure of the 320-μM-MTX-selected cell line (c-*myc*) to the drug resulted in about a twofold higher copy number of plasmid DNA as compared with a population of cells that had been cultivated in the absence of any selective pressure for at least 4 weeks. A similar observation, based on a cell line with a constitutive promoter driving tPA expression, was reported by Weidle et al. (59). These authors reported a loss of about 50% in copy number when cells were grown in the absence of methotrexate for about 50 days. This decline in gene number also resulted in a similar drop in productivity. No further copy number and productivity loss was found during the subsequent observation period of up to 100 days.

Following our initial observation of a drop in copy number in cells containing the mouse c-*myc* gene, we extended our studies with this line and also analyzed the chromosomal integration patterns of transfected sequences in two additional CHO cell lines. The three cell lines studied under this program expressed one of the three following proteins: *(1)* human rtPA, *(2)* a truncated version of the human CD4 receptor, and *(3)* the murine c-*myc* protein. The three cell lines had been established by transfecting CHO-DUKX cells using standard calcium phosphate precipitation techniques. Either individual clones or pools of clones were cultivated for extended periods in media containing stepwise increasing concentrations of MTX. In each case, a single individual clone expressing the desired level of recombinant protein was expanded for long-term growth and production. FISH was performed using biotinylated probes complementary to the recombinant sequences. Three dif-

ferent sets of typical integration patterns (site, degree) of amplified sequences were found for lines under study.

FISH signals in the rtPA-expressing cell lines were localized, in the majority of cells, in one of the larger submetacentric chromosomes (probably either chromosome 3 or 4, or the X chromosome). The signals (a bright band of fluorescence) covered most of the length of the short arm and showed weaker fluorescing spots over the center of the chromatids in the long arm. A number of other types of integration patterns (including an elevated percentage of quasi-tetraploid cells) were found in these cells (about 25%) when they were grown in the presence of methotrexate. When methotrexate was omitted, more than 95% of metaphases had the integration described.

In cells expressing c-*myc*, continuous cultivation in media containing high concentrations of MTX was found to be associated with rearrangement and variable amplification of transfected sequences within almost half of the cells (62). Several types of integration patterns were found in these cells: *(1)* chromosomes with highly extended regions of hybridizing sequences, *(2)* cells containing transfected DNA integrated into multiple sites on an individual chromosome, *(3)* cells containing DNA integrated into multiple chromosomes, *(4)* chromosomes joined at amplified regions, *(5)* circular chromosomes, *(6)* cells with small derivative chromosomes or fragments, and *(7)* cells containing a single "normal" integration, exhibiting a bright band of hybridization in the center of the long arm of what we assume is chromosome 2. The last type *(7)* was found in about 40% of cells when grown in the presence of methotrexate. This integration type increased in frequency to 95% when cells were grown in the absence of methotrexate for 3 weeks or more.

Similar results showing quite extensive heterogeneity were observed with yet another recombinant CHO cell line (the fourth studied), producing a chimeric CD4-immunoglobulin protein. When grown in the presence of MTX, CD4-IgG-producing cells showed heterogeneity in both chromosomal location and copy number of amplified sequences coding for CD4-immunoglobulin (CD4IgG) (63).

For the cell line expressing the truncated CD4 molecule, a strong signal was found over the telomeric end of a small acrocentric chromosome (possibly a derivative of chromosome 5, 6, or 7), which covered about one-third of the total length.

In summary, when cultivating these cell lines in the absence of methotrexate, unique and characteristic integrations were found in 95–99% of metaphases. Subsequent to the first analysis, we continued to cultivate these cell lines for extended periods in the absence of methotrexate, and we occasionally performed additional FISH analysis. We found the chromosomal structures described here to be stable within the observation period (a minimum of 60 days and in one case of 160 days). Cytogenetically, these observations indicate a high degree of genetic stability of chromosomally amplified sequences in the absence of methotrexate.

Assessment by Southern Hybridization and FISH of the Chromosomal Status of Amplified DNA Sequences.

Southern hybridization (64) of genomic DNA is a useful tool to acquire insights into the molecular structure of integrated plasmid sequences. Using suitable restriction enzymes it will provide information on the integrity of the expression fragments of interest. Estimates of copy numbers of the chromosomally integrated DNA can be established when, in the same experiment, an appropriate range of quantities of plasmid DNA, restricted with the same enzyme as the one used for restriction of genomic DNA, is used. Also, Southern hybridization may indicate whether one integration locus or more than one exists for the plasmid sequences. However, conclusions on multiplicity of integration must be taken with a degree of caution. Aberrations from the expected signals can be due to postintegration rearrangement in a fraction of the cell population or in the initial cointegration of a few copies of the plasmid sequences that had been subjected to nuclease attack, resulting in the deletion of the restriction enzyme site used for the analysis.

All Southern hybridizations are based on DNA extracted from thousands of individual cells. Even if the cell lines are based on a "cloning" step, one must be aware that none of the so-called clonal cell lines are clonal in the true sense. Mammalian cells, in particular immortalized cells, have an intrinsic genomic fluidity that is most evident when studying chromosome numbers in metaphase spreads (for a review see Ref. 65).

FISH can be used to obtain insights into the extent of chromosomal amplification (not to be confused with copy number estimates) and the location of recombinant DNA within the chromosomal set of cells. In order to provide some useful information, FISH studies must be supplemented by a statistical analysis of identified integration sites (and structures observed). The time point of analysis, with respect to the total period of time (since thaw) for use of these cells, should also be taken into consideration. A reasonable value (from the invested work) may be gained from a FISH study performed shortly after cells have been thawed from a bank of cells stored in liquid nitrogen. Depending on the culture conditions (with or without methotrexate, with or without serum, etc.) and the length of time during which cells have been exposed to in vitro culture, results of FISH analysis may vary considerably. In spite of variability, in the studies discussed we were able to separate without any doubt or difficulty the identity of one recombinant cell line from a second recombinant cell line by using FISH. This was possible because we were able to identify a chromosomal marker containing hybridizing DNA that was present in a large fraction of the individual cells of the populations studied. The identifying chromosomal markers containing recombinant sequences were termed *master integrations*, which we found to be the genetically stable entities in the system.

CHOOSING THE PRODUCTION SYSTEM: ADHERENT CELLS, MICROCARRIERS, AND FREE SUSPENSION ISSUES OF ECONOMY, EXPERTISE, AND TIME FRAME TO CLINIC AND MARKET

Process scientists and their managers must eventually decide which type of production system to choose for the product in question. The choice of a production system is driven

by the anticipated scale of operation for the manufacturing process, as well as by other issues. A number of very successful recombinant products from mammalian cells, such as EPO and GM-CSF, have been administered worldwide to a large number of patients. For these peptide hormones, the applied doses for treatment of patients are relatively small (about 100 μg/patient). Another successful protein therapeutic, recombinant tissue plasminogen activator (hu-rtPA, Activase®) requires a dose of 100 mg/patient, a 1,000-fold difference in dose as compared with erythropoeitin. The number of patients treated per annum with the two categories of products is about the same. It is obvious that such a difference in the annual product requirement would drive very different manufacturing decisions.

In the case of EPO and GM-CSF, a process based on roller bottles appears to be sufficient to supply the market with product. Using roller bottles, a "simple" and robust process can be established with minimal initial investment in hardware.

The Roller Bottle to Roller Bottle Process

Cells thawed from a cell bank can be expanded by subcultivation into a fixed number of roller bottles. This approach is based on cells growing attached to the inner surface of the roller bottle. Standard 2-L roller bottles are usually filled with 300–500 ml of medium. The remaining volume (air) provides the necessary oxygen while the bottles are slowly rolled (at about 1 rpm) in an incubator at 37 °C. The caps on the bottles are closed during the period of incubation. A sufficiently large number of roller bottles containing a healthy cell population represents the starting point for several production cycles. Part of the cell mass in the roller bottles can be immediately used for reproduction of cells in order to initiate the production cycle following the one already initiated. In other words, the bulk of the cell mass will serve as a seed culture to initiate the first production cycle. The remainder will provide, within one or two subcultivations, the basis for the subsequent production cycle.

Media for production are usually rich in nutrient content in order to maintain viability and productivity of the cells for a minimum of 5–7 days. Subsequently, the medium with the secreted product will be harvested, leaving the adherent cells inside the bottle. Sometimes, a refeeding with fresh medium for a second production cycle is possible, on the condition that the product of the first and the second harvest will be similar in composition and quality. Since a standard 2-L roller bottle will have about 300 ml of medium for harvest, 1,000 rollerbottles can provide product from 300 L or 600 L of supernatant, from one or two harvests, respectively. If such a campaign lasts all year long, a manufacturing process based on this principle will deliver 15,000 L (30,000 L) of cell-free culture medium containing the product of interest. Product concentrations in the 10- to 100-mg/L range are possible, resulting in 150 to 1,500 of unpurified product. Of course it must be realized that such a process is very labor intensive, requires the repeated use of trypsin for detachment of cells, and carries with it a considerable risk of contamination with adventitious agents through the handling personnel. However, because subcultivation in plastic cell-culture vessels represents a standard procedure in all laboratories, the scale-up from the lab-scale procedure to the pilot or manufacturing scale is a convenient approach for obtaining considerable (but not large) quantities of recombinant proteins.

The Bioreactor to Roller Bottle Process

The ability to cultivate CHO cells both in suspension and, subsequently, in an attached form allows the roller bottle production process to be streamlined. The seed culture for the roller bottle production phase can be generated in spinners or in bioreactors. The advantage of such a process would be that fewer interactions in terms of subcultivation are needed to generate sufficient cell mass. Being less labor intensive, it also reduces the risk of contamination by adventitious agents of the feed culture.

The Stirred Tank Bioreactor Process

Kilogram-scale production of recombinant proteins from CHO cells was first achieved in stirred bioreactors at very large scale (1,000 L and 10,000 L) with cells synthesizing while floating in free suspension (66). While such adaptation to suspension growth had been, in the early years of CHO technology, a somewhat tedious process, today multiple factors seem to have made this easier. For one, cell culture media have been developed that support the growth of cells in suspension better than those based on formulations such as DMEM and Ham's F12. Also, a number of purposeful genetic modifications (transfection of hormone genes or cell cycle genes, selection of CHO populations, or extended growth of CHO cells in media with little or no fetal calf serum and other modifications) appear to have generated CHO phenotypes that more readily support the transition from adherent growth to suspension growth.

In a bioreactor-based process, the scale-up to very large volumes can occur rather fast. It is usually executed by subcultivations, that is, by diluting the entire volume of one bioreactor into 5–20 volumes of fresh medium, maintained prewarmed in the next larger reactor. Within 10–15 days, therefore, a suspension culture at the 50-L scale could inoculate a 10,000-L reactor. It is major goal of process development work to carefully optimize media for the very last step—the production phase. Such a medium must support good growth in order to achieve the highest cell density possible, and it also must provide the nutritional basis and physiological balance needed to maintain viability and productivity for extended periods. While the termination (i.e., harvest) of such a culture is driven mainly by issues of plant capacity and volumetric productivity, the other important issue to consider is the quality of the derived product. The continuously changing composition of the culture medium during the production phase can affect the quality of earlier synthesized product through degradative activities, such as sialidase activity and proteolytic activity.

BATCH, EXTENDED-BATCH, AND PERFUSION PROCESSES

The batch process is considered a very simple, robust production process for stirred bioreactors. In the step preced-

ing production, cells in a (somewhat smaller) bioreactor are cultivated to maximal cell density and are then transferred, still suspended in the exhausted growth medium, to the production reactor. After addition of fresh medium and eventual adjustments in control of certain process parameters (O_2 supply, pH, temperature, etc.) the production process begins. It ends at a predetermined point in time when synthesis of recombinant protein seizes or slows down due to exhaustion of nutritional components in the medium and/or accumulation of toxic end products of cellular metabolism. For CHO cells the production phase will usually last, depending on the proteins' susceptibility to degradative enzymes and a number of other process-related factors, between 5 and 14 days. The advantage of such a process is obvious. Providing that the inoculating cell mass can be made reproducible and with little variation in biological quality, the resulting production process will show a high degree of reproducibility with respect to cell growth, viability, quantity, and quality of the product being synthesized.

The issue of reproducibility of process parameters and of achievable product quantity and quality is of highest significance, of course. It provides confidence-generating data for the long-term future. Another important point is the obligation to present such data to regulatory agencies that will ultimately give permission to use the process for the generation of the product. For investigational new drug applications (IND) and process licence applications (PLA), rather specific requirements must be met with respect to the minimal number of product batches analyzed. For INDs no less than three product runs are recommended to be presented. Shorter batch processes (5–7 days) have the advantage of generating more data within a given time frame. This can be a very important cost factor because the time period necessary to acquire and evaluate necessary data from the new process will eventually affect the overall time necessary for entering the market.

On the other hand, there are viable arguments that could sway process-development decisions in another direction. The option to prolong the synthetic activities of cells in the production vessel would capitalize on the process investment that allows generation of the necessary cell mass for the production vessel. Therefore, more and more extended-batch or perfused-batch cultures are used. With a longer-lasting production phase in cell culture, feeding additional medium components becomes necessary. Obviously, extending the process for a considerable period of time, (for example, from 7 days to 13 days) makes sense only when the return for this investment in labor and in occupation of the production facility results in a sufficiently high increase in product concentration within the vessel. There are various ways in which medium and medium components can be added to a culture that was initiated a few days earlier in the same tank. This could be done by feeding (batchwise) highly concentrated mixtures of essential amino acids and other medium components, thus not significantly affecting the volume in the tank. Alternatively, a culture may be started in the production vessel at half or so of the working volume, then standard concentration medium could be pumped slowly and continuously, or batchwise, into the tank until the final working volume has been reached. The choice between the modes, or combinations thereof, is in the hands of the process development scientist, who has to carefully evaluate advantages and disadvantages. No matter what principle will be used for extending the production phase, the overall result will always be a tank that contains, in one batch, the entire protein population for subsequent recovery and purification.

A very different philosophy for manufacturing is represented by continuously perfused production processes. Here, the goal is to achieve the highest cell concentrations possible within small tanks. In this process up-front investment for manufacturing equipment is reduced, and product quantities can be quite high. The much improved knowledge base in technology, and in physiology of CHO cells in culture, has made this more-complicated approach to manufacturing attractive. Perfused cultures can be maintained for many weeks and months, with product harvests occurring repeatedly throughout that period. A protein of high interest to the pharmaceutical industry for decades, Factor VIII, is reliably being manufactured using perfusion technology with baby hamster kidney cells, a "cousin" of Chinese hamster ovary cells. While the production of Cognate® Factor VIII (67) has pioneered the use of perfusion technology for recombinant proteins with mammalian cells in a non-CHO cells, other products from CHO cells have recently been approved as well using this technology (68).

Finally, due to the fact that many monoclonal antibodies have been produced at the laboratory scale in perfusion systems for many years by using hollow-fiber technology, the transfer of this technology to the production scale for pharmaceutical manufacturing has been an obvious conclusion for quite a while (69,70). Recently, a diagnostic monoclonal antibody for imaging in patients with prostate cancer (ProstaScint™) was the first FDA-approved product for injection into humans derived from the hollow-fiber perfusion process (71). The application of this and other perfusion technologies, using immobilization of CHO cells on macroporous carriers to produce recombinant antibodies or other proteins, is likely to be yet another option for future manufacturing processes (72).

CONCLUSIONS

The technology of using mammalian cells, and in particular CHO cells, for recombinant protein production is, in spite of significant success stories, still in its infancy. Much has to be done to establish production processes in a more straitforward way and to make them more productive. A data explosion is occurring with DNA sequences from microorganisms, plants, and animals, including the human genome. Subsequently, a tremendous need is arising for more detailed studies and, frequently, the urge to use the translation products of these sequences in many applications. Also, the possibility of designing new proteins, based on concepts provided by nature, will even increase the need for flexible and robust synthetic machinery. Mammalian cells have been used as production hosts in some of the first pioneering experiments for the design of novel pro-

teins (73,74). However, to deliver significant quantities of the desired proteins to analytical chemists, cell biologists, clinical researchers, and so on, takes far too long and is still a very demanding task. Some of the bottlenecks in the knowledge base have been addressed in this article. It is hoped that research efforts will solve some of them in the near future, resulting in more efficient, faster, and less expensive synthesis of recombinant proteins by mammalian cells. It appears that mammalian cells inherently have, due to their large size, the capacity to take up large quantities of foreign DNA without any negative effects, the responsiveness to perform a large number of synthetic tasks, and the capability to meet the challenges of the future.

OUTLINE

INTRODUCTION

Cholesterol oxidase is the enzyme that catalyzes the oxidation of the 3β-hydroxy group of various kinds of steroids. The oxidation is the important step in the catabolism of the sterols. This catalytic property plays an important role in various bioprocesses

The catalytic and structural properties of cholesterol oxidases from microbial origins are described. Further, some applications are described, including cholesterol determination in medical diagnosis, reduction of cholesterol content in the food industry, and pest control (based on its insecticidal activity) in the agriculture industry.

CHOLESTEROL

Cholesterol (cholest-5-en-3β-ol) is principal sterol of higher animals. Cholesterol is practically insoluble in water, but it is soluble in aqueous solutions of bile salts. It is found in all body tissues, especially the brain and spinal cord, and in animal fats or oils.

Cholesterol is considered to be a key intermediate in the biosyntheses of fecal sterols, bile acids, and steroid hormones in animals. Turfitt first demonstrated the formation of 4-cholesten-3-one from cholesterol by *Proactiomyces erythropolis* (*Nocardia erythropolis*) and showed that this oxidation of the 3β-hydroxy group to the keto group of cholesterol was the initial step in the aerobic catabolism of the sterol (1). On the other hand, in the intestinal tract of humans, cholesterol can be anaerobically metabolized by bacterial microflora to coprostanol (65%) and coprostanone (10%) and to a lesser extent to cholestanone and epicoprostanol (2) (Fig. 1).

CHOLESTEROL OXIDASE

Cholesterol oxidase (EC 1.1.3.6) catalyzes the oxidation by dioxygen of the 3β-hydroxyl group of cholesterol and of related steroids (other 3β-hydroxy steroids) to a keto group and catalyzes the successive isomerization of the δ5 double bond to the conjugated position: δ4 (Fig. 2). Thus, in many cholesterol oxidases, both the oxidase and isomerase activities are catalyzed by the single enzyme protein, although the two kinds of enzymes, cholesterol dehydrogenase and δ5-3-ketosteroid isomerase (EC 5.3.3.1) are present in some microorganisms containing *Pseudomonas testosteroni* and *P. putida* (3).

The oxidation is estimated by the following methods.

1. Conjugated enone formation by the increase in UV absorption
2. Monitoring oxygen uptake
3. Hydrogen peroxide production by the oxidative coupling of 4-aminoantipyrine with phenol by peroxidase to give a quinoneimine dye absorbing at 500 nm

Generally, the enzyme is a flavin-dependent oxidase containing one mole of tightly bound flavin adenine dinucleotide (FAD) per mole of protein (4). However, cholesterol oxidases from *Nocardia rhodochrous*, *Streptomyces griseocarneus*, and *Streptomyces violascens* lack FAD or any other cofactor.

The enzyme has been isolated from a number of different soil bacteria that are capable of using cholesterol as the sole source of carbon and energy. They include Gram-positive bacteria such as *Arthrobacter simplex*, *Brevibacterium sterolicum*, *Corynebacterium sterolicum*, and *Rhodococcus equi*; Gram-negative bacteria such as *Pseudomonas* spp., actinomycetes such as *Actinomyces lavendulae*, *N. erythropolis*, *N. rhodochrous*, *Nocardia* spp., *Streptomyces griseocarneus*, and *Streptomyces violascens*; and fungi such as *Schizophyllum commune* (5). There are also two types of enzymes, secreted and membrane bound, according to their localization.

Commercial preparations of cholesterol oxidase can be obtained from the following suppliers: *Streptomyces* spp. (15 units/mg) from Toyobo Co.; *B. sterolicum* ATCC21387 (13 units/mg) from Kyowa Hakko Kogyo Co.; *Pseudomonas* spp. (3 units/mg) from Wako Pure Chemical Industries; *R. erythropolis* (25 units/mg) from Boehringer Mannheim; and *Cellulomonas* spp. (20–60 units/mg) and *Schizophyllum commune* (5 units/mg) from Sigma Chemicals.

The enzymes from *B. sterolicum* (6), *Schizophyllum commune* (7), and *Arthrobacter simplex* (8) are purified, and their enzymatic properties have been examined.

This enzyme can oxidize 3β-hydroxy groups in cholesterols, the biosynthetic precursors such as desmosterol, 17 ketosteroids such as dehydroepiandrosterone, and plant sterols such as stigmasterol, β-sitosterol, and campesterol. Of these, the length of the C17 side chain is especially an important factor in determining the reaction rate. On the other hand, 3α-hydroxysteroids, estrogens, and cholecalciferol do not serve as substrates (9). Further, the relative activities are also dependent on the origin of the enzymes.

Murooka et al. cloned the cholesterol oxidase gene from a *Streptomyces* sp. SA-COO and demonstrated high productivity of the extracellular cholesterol oxidase by using the *Streptomyces lividans* host-vector system (10). Ohta et al. cloned the cholesterol oxidase gene from *B. sterolicum* (11). The gene was also overexpressed into *Streptomyces lividans* (12). Both genes show identities of 64% in nucle-

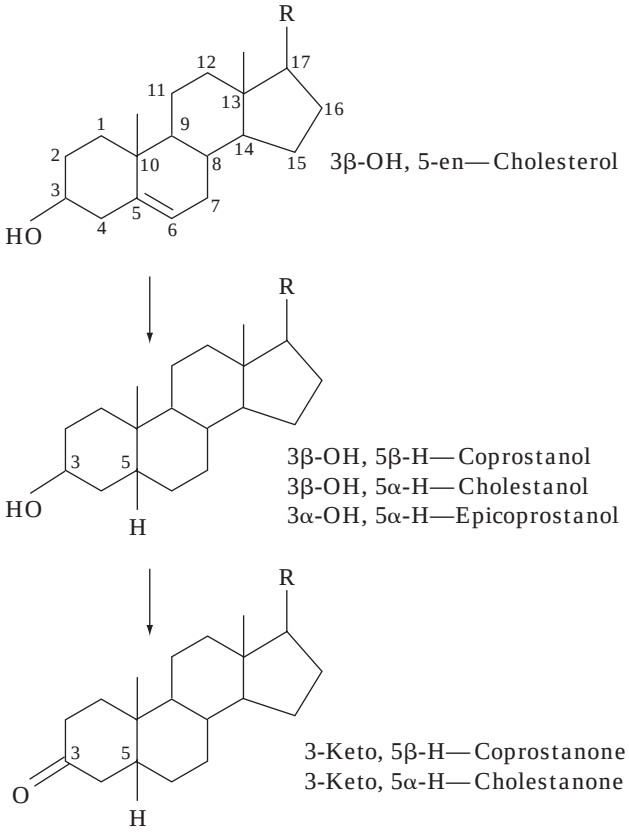

Figure 1. Anaerobic metabolism of cholesterol.

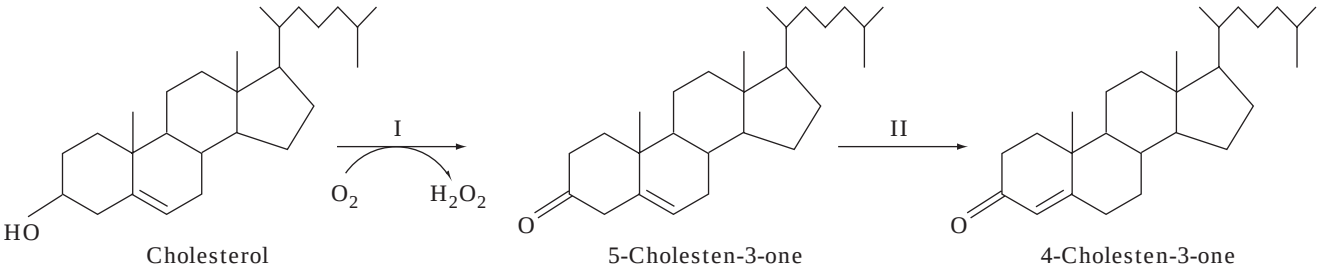

Figure 2. Scheme for the cholesterol oxidase reaction. I, oxidation step; II, isomerization step.

otide sequence level and 58% in amino acid sequence level, respectively. The gene analysis shows that the mature enzyme consists of 503 or 507 amino acids and is preceded by a 42 or 45 amino acid signal sequence for *Streptomyces* sp. or *B. sterolicum*. There are at least six highly conserved regions between the two enzymes, which may play structurally or functionally important roles such as substrate binding or catalysis. The FAD-binding domain in a number of FAD-dependent enzymes contains a pattern of three glycine residues, Gly-X-Gly-X-X-Gly, common to NAD and FAD-binding proteins. This pattern of residues is also found near the N-terminal of the sequences of cholesterol oxidases from *Streptomyces* sp. and *B. sterolicum*.

The crystal structure of the enzyme from *B. sterolicum* has been determined using the method of isomorphous replacement and refined to 1.8-Å resolution (13). The structure is made up of two domains: an FAD-binding domain and a steroid-binding domain. The FAD-binding domain consists of three noncontinuous segments of sequence, including the N-terminal and the C-terminal. The overall topology of this domain is very similar to other FAD-binding proteins. The steroid-binding domain consists of two noncontinuous segments of sequence and contains the roof of the active-site cavity. The active site lies at the interface of the two domains. The FAD lies on the floor of the cavity. The steroid substrate is buried within the internal cavity. The hydroxyl group of the steroid is hydrogen bonded to the flavin ring system of the FAD. The active-site cavity contains one charged residue, Glu361. This residue is appropriately positioned to act as the proton acceptor in the proposed mechanism for the isomerization step.

FAD-dependent cholesterol oxidase shares significant structural homology with another flavoenzyme, glucose oxidase, suggesting that it might also be a member of the glucose-methanol-choline (GMC) oxidoreductase family. A histidine residue is completely conserved in the known sequences of GMC oxidoreductases and may act as the general base in the oxidation reaction.

APPLICATION OF CHOLESTEROL OXIDASE

Diagnosis

Cholesterol oxidase is used in the determination of serum cholesterol concentration for the assessment of arteriosclerosis and other lipid disorders and of the risk of thrombosis.

Richmond (14) and Flegg (15) first showed the possibility of using cholesterol oxidase from microorganisms as a basis for a specific assay for serum cholesterol. In the procedure, 4-cholesten-3-one produced was assayed by its UV absorption after solvent extraction of the reaction mixture. However, their procedures were tedious and time consuming. Allain et al. developed the excellent method in which the hydrogen peroxide produced during the cholesterol oxidase reaction was oxidatively coupled with 4-aminoantipyrine and phenol by peroxidase to form a quinoneimine dye (16). Figure 3 shows the scheme for the enzymatic determination of total cholesterol. First, cholesterol esters are able to be converted to free cholesterol by the action of cholesterol esterase. Then, the liberated cholesterol can be determined by cholesterol oxidase and peroxidase. This enzymatic method is simple and specific under extremely mild conditions. The results with serum samples agreed very well with those obtained by chemical procedures based on the Liebermann-Burchard reaction. This assay system is marketed as a serum cholesterol determination kit; worldwide annual sales amount to $100 to 200 million.

Food Industry

Dietary cholesterol has been implicated as one of the causes of coronary artery disease. Because of this, reducing dietary cholesterol is said to cause a gradual reduction in serum cholesterol and regression of atherosclerotic plaque. The National Cholesterol Education Program coordinating board recommends a daily cholesterol intake in the American diet of 300 mg or less. As a result, reduction of cholesterol in food items relatively rich in cholesterol (dairy foods, eggs) has become a challenging problem.

Some organisms have been shown to degrade cholesterol, as described earlier, but only a few do so without accumulating any steroid intermediates. Watanabe et al. described the degradation of cholesterol in egg yolk and lard by crude cholesterol oxidase in *R. equi* no. 23 and the bacterial cell suspension (17). *R. equi* no. 23 degraded cholesterol with little or no accumulation of steroid intermediates such as 4-cholesten-3-one and 1,4-androstadiene-3,17-dione, which are recognized as key intermediates in a comprehensive pathway of cholesterol degradation.

A biotechnological approach to reducing the cholesterol content of milk involves the genetic engineering of starter culture bacteria (lactococci, lactobacilli, streptococci), leading to the expression of phenotypic traits that are related to cholesterol metabolism. These cultures are then used in

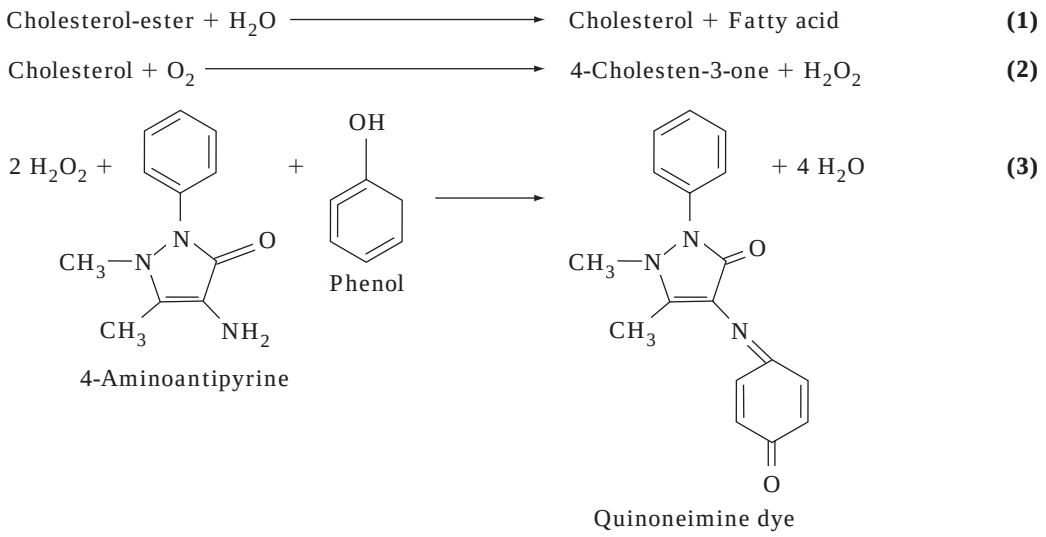

Figure 3. Scheme for the enzymatic determination of total cholesterol. Reactions 1, 2, and 3 are catalyzed by cholesterol esterase, cholesterol oxidase, and peroxidase, respectively.

the production of fermented dairy foods (yogurt and cheeses).

Somkuti et al. have investigated the possibility of introducing the cholesterol oxidase gene from *Streptomyces* sp. SA-COO into a common dairy starter culture bacteria such as *Streptococcus thermophilus* (18) and *Lactobacillus casai* (19). The biosynthesis of a functional cholesterol oxidase in *Streptococcus thermophilus* was confirmed by TLC analysis of reaction products after incubation of sonically disrupted cells with cholesterol. However, unlike *Streptomyces lividans*, *Streptococcus thermophilus* did not secrete cholesterol oxidase into the culture medium.

At present, the use of cholesterol-degrading enzymes in the food industry remains unrealistic because of the lack of toxicological data on enzyme extracts and the intermediate products of cholesterol degradation.

Agriculture

The discovery of novel insecticidal proteins is vital for pest control strategies using transgenic crops. Filtrates from several thousand microbial fermentations were assayed for insecticidal activity against crop-damaging insects. Two *Streptomyces*-culture filtrates killed boll weevil larvae in feeding studies, and the bioactive component was identified as cholesterol oxidase (20). The enzyme was active in a dose-dependent manner, and the LC50 against neonate boll weevil larvae was 20.9 μg/mL after 6 days in diet-incorporation bioassay. *Bacillus thuringensis* subsp. Kurstaki protein has an LC50 of 1 μg/mL against tobacco budworm and 37 μg/mL against European corn borer in similar diet-incorporation bioassay. Thus, cholesterol oxidase is active against the boll weevil in the same concentration range that *B. thuringiensis* protein is active against lepidopterans.

Morphological changes induced by ingestion of cholesterol oxidase suggest that the enzyme has a direct effect on the midgut tissue of boll weevil larvae. Thus, cholesterol oxidase disrupted the midgut epithelium at low doses and lysed the midgut cells at higher doses.

The cholesterol oxidase gene from *Streptomyces* spp. was expressed in tobacco and tomato, and successful control of boll weevil was achieved by the Monsanto company (21).

OUTLINE

INTRODUCTION

Currently, chromatographic purification processes are optimized empirically. Separation media, running conditions, and sequence of purification steps are selected according to the expertise of the responsible scientists.

In biotechnology, computer-aided design is less far advanced than in certain areas of chemical engineering. The lack of expert systems is the reason for the traditional optimization, which is based on trial and error. Mathematical models for description of the chromatographic separation process have been around since the early 1940s (1–4). The common use of computers in the separation laboratory, the need of rapid process development, and the theoretical knowledge accelerated the development of expert systems and software tools. They are considered to be beneficial for design and optimization of purification steps.

The area of computer-aided chromatography design includes the design of experiments, the appropriate interpretation of experimental results (by the aid of mathematical algorithms), the prediction of separation conditions, and the rescaling of unit operations (5).

Four levels of complexity have to be considered for optimization of separation steps. The first level is the general process economics. This level will be influenced by the second level: flow sheeting. The third level is the optimization of particular unit operations. The fourth level is the sectioning of unit operations into their thermodynamical and molecular considerations by the aid of molecular simulation.

Simulated moving bed, countercurrent chromatography, and annular chromatography are not been considered in this chapter, because these modes of chromatography have not been used for bioprocessing to large extent.

BASIC CONSIDERATIONS FOR COMPUTER-AIDED DESIGN OF CHROMATOGRAPHY

Terminology

The word *model* denotes a system of algebraic or differential equations, which are held to be a representation of a physical system. From this general point of view, any relationship between quantities is a model, and the principles of modeling are the principles of chemical engineering science. *Process models*, and here particularly chromatography, can be counted to a chemical process. They are established by application of the three fundamental conservation principles: conservation of mass, momentum, and energy. Because liquid chromatography is carried out under isothermal conditions, the conservation of energy can be neglected in general. The contribution of liberated

or consumed thermal energy during adsorption and desorption is negligibly small. The conservation of mass and momentum and the virtual breakdown of a chromatography system to a small unit, where the adsorption process takes place, are the fundamentals for modeling of chromatography (6).

In principle, there is no difference between *computer models* and other models. Many models are so complex that they can be solved only numerically. In these cases, computers can be used for reasons of convenience, independent of the complexity of the model applied. Further considerations about modeling are given by Vajda and Valkó (7).

We usually assume that the input, initial conditions, and parameters of a model determine the response (result). The *parameters*, which are the different coefficients in mathematical equations, must be evaluated. This process is called parameter estimation. Once a model is established, the performance of a system can be predicted by varying the input and initial conditions. The prediction will yield a correct answer (response) as long as the predictions are carried out within a certain range of validity.

The words *prediction* and *simulation* describe, in this context of modeling, a similar process. The forecast of process conditions, using process parameters acquired at a small scale, is called prediction. Frequently parameters cannot be estimated because of the lack of a determination method or accessibility. Thus, a hypothetical value is used to solve the set of mathematical equations. This process is called simulation.

Depending on the task, some of the *operational variables* may be kept constant or may not be taken into consideration. The most important variables are listed in Table 1. The residence time of a product in a column is a critical factor, when the product undergoes a conformational change or a reaction in the column. Alteration of the residence time in a column can completely change the result of the purification. Reversed-phase chromatography (RPC) and hydrophobic interaction chromatography (HIC) are more susceptible to residence time changes than ion-exchange chromatography or affinity chromatography are.

The *response values* depend on the strategy and the stage where the chromatographic purification is placed. Frequently used response values are:

- *Productivity* (P) is defined as

$$P = \frac{Q_R \cdot C_0 \cdot V_F}{V_t \cdot t_C} \qquad (1)$$

where Q_R is the recovery ratio, C_0 is the sample concentration, V_F is the sample volume, V_t the column volume, and t_C the cycle time, which includes all time periods necessary to start the next cycle (process time). The purity has to be defined before optimization. The productivity in the aforementioned case does not consider the lifetime of a column.

- *Yield* or *recovery* is simply the percentage of recovered material and material present in the feed. Yield is not easily accessable by mathematical models. In most cases, product loss is caused by a very complex event. Unspecific (irreversible) adsorption to stationary phases, aggregation, and denaturation together with enzymatic degradation are responsible for incomplete recovery. These effects are also dependent on age and history of the column. These events are not covered by chromatography models.
- *Dynamic capacity* is the capacity at a certain flow in contrast to the capacity determined by batch experiments. BTC experiments at 5% breakthrough are usually used to determine the dynamic capacity. Originally, the analytical solution of an idealized model, known as the Thomas solution (8), has been used for approximation and prediction of breakthrough curve (BTC). Under conditions applied in preparative chromatography, the BTC deviates significantly from the ideal model. Recently, models have been published that take effects of kinetics under overloaded conditions into consideration (9).
- To minimize the number of purification steps, the highest *purity factor* should be achieved at each step. The regulations for production of pharmaceuticals by recombinant DNA technologies require very high purity standards. The standards can only be met when a purification power of each step is used to the optimal extent. Other factors, such as design of a plant, quality of the materials and buffers, operator training, etc., must also be obeyed. The optimization of the

chromatographic process is only one piece of the puzzle.

- A high *concentration factor* leads to a smaller volume for the next step, which has to be handled and the product becomes more stable. Also, an upper limit in the concentration can be of consideration, because the solubility of the product is exceeded. The concentration factor (CF) can be defined as:

$$\mathrm{CF} = \frac{C_R \cdot V_R}{C_0 \cdot V_F} \tag{2}$$

where C_0 is the initial (feed) concentration, V_F is the feed volume, C_R is the recovered concentration, and V_R is the recovered volume.

- The *process time* may be limited by the stability of the product. Economical considerations also come into play, such as shift time and batches, which have to be produced by a certain time period. The process time includes the optimization of the gradient, flow rate, etc. Process time has to be optimized with regard to total process time. Cleaning, regeneration, and, if necessary, repacking have to be included.

General Criteria of Mathematical Models

Today, broadening of scientific and technological knowledge is based on three cornerstones: theory, experiments, and computer simulation. Reliable computer simulation needs an appropriate mathematical model. Without a valid mathematical model that reflects the real physical situation, the most sophisticated computer algorithm will fail. A model will never be as good as the physical reality, because the complexity has to be reduced to a certain formalism. A fictional model of the complexity of the reality would be as slow and laborious as the reality.

Vajada and Valkó (7) compiled a list of criteria for establishing a model in chemical engineering. These rules also apply for the chromatography of proteins.

- First, scientific curiosity is a strong motivation for establishing a model. A priori curious-appearing models may be of considerable value, when they are integrated with the appropriate objective. This requires the innovative selection of parameters and design of experiments to determine those parameters.
- The second reason for using models is the reduction information and indirect measurements. The most common information reduction in chromatography peak is the approximation of a peak by its first and second moment, instead of using the information from the entire peak curve. Using these information reduction processes, the appropriate model (10–14) must be selected to describe the peak area, width, and the asymmetric shape.
- The ability to design and optimize a separation scheme quickly and effectively is also a motivation for developing a model. To minimize process time and determine optimal column size and optimal gradient shape, loading and sequence of the different process steps (equilibration, loading, washing, elution, and regeneration) are necessary.
- The design of optimal particle properties is also an important goal for manufacturers of resins and for engineers selecting a resin. Modeling of packing provides a directive on the pressure drop and performance loss caused by irregularities (15).
- Control and simulation for validation purposes will become an important issue in modeling of chromatography. The ability to calculate acceptance criteria for scale-up or scale-down will allow rapid, accurate validation of tasks, such as virus clearance. The correct column dimensions, gradient shapes, limits of operation parameters, and rapid diagnosis of separation deficiencies are also added benefits. Scale-up of the production of a biologic is often considered a major change of the process, requiring additional clinical trials that are time consuming and costly. However, if the appropriate scale-up process can be performed with the generation of the same product exhibiting identical qualities, no additional clinical trial would be required. Computer-assisted optimization evaluates the influence of the process change. It would save significant manufacturing costs if the altered scheme were not considered a major change.

The existing models for simulating chromatography are based on different core assumptions. Depending on these assumptions, different levels of complexity are handled. At each level of complexity, different simplifications are made in order to make the mathematical treatment accessible.

According to van Deemter et al. (16) the following assumptions are made:

- The equilibrium concentrations in the two phases are proportional (linear chromatography).
- The exchange process is thermodynamically reversible, that is, the equilibrium between particle and fluid is immediate; the mass transfer coefficient is infinitely high; and longitudinal diffusion and other processes with similar effects can also be ignored. The latter processes are considered ideal chromatography.

From these assumptions one can categorize chromatography into four cases (Table 2). Although the cases 1, 2, and 3 are of great value for understanding chromatography, only case 4 reflects the real situation in preparative chromatography.

Table 2. Modes of Complexity in Chromatography Modeling

	Ideal chromatography	Nonideal chromatography
Linear isotherm	1	2
Nonlinear isotherm	3	4

Source: van Deetmer et al. (Ref. 16).

Differences in Analytical Chromatography

Besides the size and the shape of the separation column, the difference between analytical and preparative chromatography is the intended use (Table 3). In analytical chromatography, the components are separated and identified according to their retention times. In some cases, a component-specific detector is used for the identification. Generally, a small volume (mass) is applied onto the column. Therefore, the separation is carried out under linear isothermal conditions. Frequently, the chromatography can be described as case (Table 2). Preparative chromatography is intended for isolation of a compound. In contrast to analytical chromatography, the separation is carried out in the nonlinear regime. Peak-broadening effects resulting from the nonlinearity of the isotherm must be taken into consideration. The sample is applied as a high concentrated solution or in a large volume as a very dilute solution. The Dirac δ function can no longer be used for describing the sample volume and concentration. The Dirac δ function is a hypothetical approximation for an infinitesimal small volume containing one mass unit.

The whole system is designed so that extra-column effects cannot be neglected. When the performance of a chromatographic separation should be predicted from small scale to large scale, those effects must not be neglected. Special emphasis is put on this problem, because the successful application of computer-assisted optimization is strongly dependent on the extrapolation from small scale to large scale. The extra-column effects can dominate a preparative separation in small scale. In the mathematical description of an analytical column, various mass–transfer problems can be handled by using fine adsorbent particles at a high flow rate. However in a large-scale column, fine particles introduce hydrodynamical problems such as high pressure drop, channeling, and fingering of flow. Consequently, in large chromatography, larger particles are used and mass–transfer resistencies are more pronounced.

Objectives for Computer-Assisted Optimization

The general objective for computer-assisted optimization of chromatography is the reduction of the number of experiments required to identify an optimum. The optimization is accomplished by an iterative process. Frequently, optimal running conditions must be identified. Optimal running conditions can be defined as best buffer for loading, washing, and elution while maintaining highest resolution. The same can be valid for the best throughput (productivity) under highest resolution (17). The latter require chemical parameters (i.e., buffer composition) physical and engineering parameters (i.e., flow rate, height equivalent to theoretical plate). In other words, selectivity, efficiency, and productivity (throughput) must be optimized. Depending on the task, one must rate selectivity, efficiency, and throughput in different ways. Selectivity is mainly achieved by the chromatography sorbent and buffer composition and to some extent by engineering parameters. Efficiency depends on the physical characteristics of the sorbent, the overall setup of the chromatography system, and the chemistry of the mobile phases used. Throughput is influenced by the dynamic capacity of the sorbent, which depends on the composition of the sorbent and the buffers used. All three important characteristics of preparative chromatography are interconnected. Changing one parameter influences the others. Traditionally, after selection of a particular sorbent, one can identify the appropriate separation conditions by seeking the appropriate buffer conditions. Then the throughput is maximized by overloading and increasing the flow rate (18).

Another very important objective in preparative chromatography is the extrapolation from small-scale data to the performance of large scale (scale-up) and the extrapolation from a large scale to small scale (scale-down). When a process is translated from a laboratory scale to a pilot and industrial scale, very often the linear gradient elution must be changed to stepwise elution, because this elution mode is more simple (19,20).

After optimization, the single steps in the sequence of steps have to be optimized, and thus flow sheeting comes into play. In flow sheeting, the performance of the different steps is interconnected, and a strong reciprocal action is observed. However, multiple interconnected experiments must be carried out. The more steps and performance characteristics that are simulated, the fewer experiments needed and thus the faster an optimal separation process is identified.

What are the prerequisites for computer-assisted optimization of preparative chromatography? Because experiments have to be performed in order to have access to parameters for simulation, the experiments should be carried out at the smallest applicable scale. This is not only a heuristic for computer-assisted optimization, but is also valid for all kind of optimization. Whenever possible, the experiments should be carried out with equipment that allows a high degree of automation (21). Electronic data acquisition of a chromatogram is essential for mathematical treatment. The predicted data should be valid for a broad range of flow rates, column sizes, and loading conditions. The main parameters influencing the performance (including the extra-column parameters) should be known. Once the extra-column peak broadening can be discriminated from the parameters of the column, the simulation is fed with this information (22). During scale-up, the contribution of extra columns and column band broadening

Table 3. Differences between Analytical and Preparative Chromatography Other than the Intended Use of the Technique

Analytical	Preparative
Identification by retention or selective detection	Separation coupled with collection of separated proteins
High efficiency	High capacity
Small particles	Large particles
Small loading of columns	Overloading of columns
Linear adsorption isotherms	Nonlinear adsorption isotherms
Sample volume negligible	Sample volume not negligible, (Dirac δ function not applicable) Extracolumn space not negligible

changes. Observing these facts improves the accuracy of the prediction of chromatography from small scale to large scale.

Objectives for Computer-Aided Design

The objective in computer-aided design is the proper selection and order of chromatography steps in a purification process. Based on a primary knowledge on the properties (e.g., isoelectric point, molecular weight, surface hydrophobicity, biospecificity) of the protein of interest and its impurities, expert systems can assist in setting up a prospective purification design.

In parallel, these systems have to consider some basic rules for the separation sequence consisting of capture, purification, and polishing (23):

- Choose separation steps based on different properties.
- Separate the largest impurity first.
- Choose steps that use differences in the properties of the product and the impurities best.
- Use a high-resolution step as soon as possible.
- Set the most laborious step last.

After characterizing the chosen steps experimentally, economic considerations concerning productivity, capital, or production costs must be evaluated. Using computer-aided design routines, several characteristics of the product (amount required in a calculation period, purity required, recovery), resin (cost per liter, lifetime), labor constraints (labor costs, number of operators required), and production constraints (column dimensions available, costs of waste disposal, costs of overheads) can be evaluated to find the optimal scale of an individual purification step.

MATHEMATICAL DESCRIPTION OF THE SEPARATION PROCESS

Chromatographic theories have been applied for description of band broadening and retention of a solute while migrating through the column. In liquid chromatography, the column geometry can be described by the radius (r) and the length (z) of the column. Independently of the model applied, some basic assumptions are made in preparative chromatography of biomolecules:

- The column is considered to be homogeneous in radial direction. The applied protein is distributed homogeneously over the cross-sectional area of the column. As a consequence, the r dimension can be disregarded, and the effective parameter for the column geometry is z.
- The mobile phase is incompressible, and the mobile phase velocity is constant along the column.
- There is no influence of thermal effects. The adsorption process is considered to be isothermal, although this is not consistent with regard to rigorous thermodynamic treatment. The temperature is constant during the experiment, independent of position and time.
- Mass exchanges between mobile and stationary phase are infinitely fast, and the two phases are permanently in composition equilibrium. The need of this assumption is circumvented by kinetic models.
- The ratio between the mobile and stationary phase volume is constant during the experiment, independent of position and time. It is also independent of the mobile phase concentrations of protein and salt.

Depending on the type of chromatography and the intended use, these basic assumptions can heavily deviate from the real conditions.

Plate Models

Using these models, the column is divided into identical theoretical plates, and for each of these plates a mass balance is established. Originally, a linear isotherm was assumed, and in each plate mobile and stationary phase concentrations were in equilibrium. These models introduce the concept of the height equivalent of a theoretical plate (HETP). For a column of length (L) with N theoretical plates, HETP is

$$\mathrm{HETP} = \frac{L}{N} \tag{3}$$

Comparison of HETP of different columns or different conditions is a well-accepted measure for the performance of a column. HETP is not a constant value for a sorbent species, it depends on the column length (24), packing quality, flow rate, solute used for determination, and calculation method (25).

Martin and Synge Plate Model. This model (2) considers the column as a series of stages, and an infinitesimal fraction of the mobile phase volume passes from one stage to the next (Fig. 1). Because an infinitesimal small fraction of volume is transferred from one stage to the next, this model is denominated a continuous plate model. The ratios between mobile and stationary phase volume in each vessel are identical and constant. The mass balance for the jth vessel can be written as

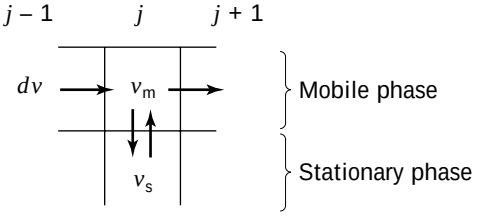

Figure 1. Schematic diagram of the distribution in a Martin and Synge plate model. The infinitesimal small fraction of the mobile phase volume (dv) enters stage j while the identical volume fraction leaves the stage. The distribution between the mobile and stationary phases occurs immediately and infinitely fast.

$$C_{\mathrm{m},j-1} \cdot dv = C_{\mathrm{m,j}} \cdot dv + v_{\mathrm{m}} \cdot dC_{\mathrm{m,j}} + v_{\mathrm{s}} \cdot dC_{\mathrm{s,j}} \quad (4)$$

when $\boldsymbol{dv}$ denotes the movement of the mobile phase volume, v_{m} and v_{s} are the mobile and stationary phase volume of a stage and C is the concentration of the species under consideration. Martin and Synge introduced one mass unit into the first stage. Solving equation 4 with respect to a linear isotherm and sample only in the first stage gives a Poisson distribution.

$$C_{\mathrm{N}} = C_1^0 \cdot \exp\left(-\frac{\mathrm{v}}{v_{\mathrm{m}} + K \cdot \mathrm{v_s}}\right) \cdot \frac{\left(\frac{v}{v_{\mathrm{m}} + K \cdot v_{\mathrm{s}}}\right)^{N-1}}{(N-1)!} \quad (5)$$

which can be approximated by a Gaussian distribution for high plate numbers. In equation 5, C_{N} is the concentration of the Nth stage, C_1^0 is the initial concentration of the first stage, and v is the volume of mobile phase that has left stage N from the start.

Craig Plate Model. Analogously to the Martin and Synge model, this model (26) divides the column into a series of discrete stages (plates), and each stage contains the same volume of stationary and mobile phase. But in contrast to the previous model, the flow is not continuous. It is assumed that the whole amount of mobile phase moves to the next stage after equilibrium is attained (Fig. 2). Then again, the distribution between stationary and mobile phase takes place immediately. Hence, the Craig model is a discontinuous plate model. The mass balance for the jth plate can be written as

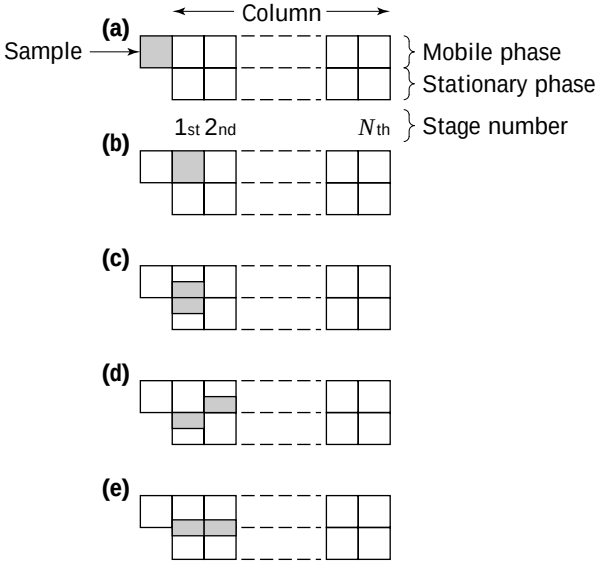

Figure 2. Schematic diagram of a Craig machine for N stages and a constant distribution coefficient. (**a**) A sample segment is arriving at the first stage. (**b**) The segment arrives in the mobile phase of the first stage. (**c**) The sample is distributed between mobile and stationary phases according to the distribution coefficient. (**d**) The mobile phase volumes are moving one stage further. (**e**) Mobile and stationary phases are distributed again.

$$v_{\mathrm{m}} \cdot C_{\mathrm{m},j,t} + v_{\mathrm{s}} \cdot C_{\mathrm{s},j,t} = v_{\mathrm{m}} \cdot C_{\mathrm{m},j-1,t-1} + v_{\mathrm{s}} \cdot C_{\mathrm{s},j-1} \quad (6)$$

The indexes t and $t-1$ denote for the actual and the previous time increment. For a linear isotherm and sample only in the first plate, this model gives a binomial distribution that also can be approximated by a Gaussian distribution for large plate numbers.

In the Craig model, peak dispersion is smaller than in the Martin and Synge model (27). This difference can be related by

$$N_{\mathrm{C}} = N_{\mathrm{M,S}} \cdot \frac{k_0'}{1 + k_0'} \quad (7)$$

when N_{C} is the number of plates of the Craig model, $N_{\mathrm{M,S}}$ is the number of plates of the Martin and Synge model, and k_0' is the retention factor

$$k_0' = \frac{t_{\mathrm{R}} - t_0}{t_0} \quad (8)$$

at infinite dilution. Here, t_{R} is the retention time at the conditions of interest and t_0 is the void time, that is, the retention time assuming nonbinding conditions.

Other Plate Models. The plate models described in this section are extended to kinetic models by introduction of mixing in the stages. Hence, the equilibrium in the stages is no longer instantaneous. The finite time for adsorption and transport kinetics between the phases are compensated by mixing kinetics within the stages. The sectional model is an extension of the Craig model (28). At the end of each time, increment the whole content of the liquid phase of each stage is transferred to the next stage. Therefore, the flow of the mobile phase is discontinuous.

The tanks-in-series model is an extension of the Martin and Synge model (29). The flow of the mobile phase is continuous, and the column is considered as an array of well-mixed cells.

Rate Theory

Although the plate theory was originally developed for linear chromatography with the intention to describe the nonideal effects, this theory was, in the early works, focused on ideal nonlinear chromatography.

The Ideal Model. The mass balance equation was derived independently by Wicke (30) and Wilson (1). In their mass balance equations, axial dispersion was disregarded. DeVault (4) introduced the influence of the pore volume, and Weiss (3) discussed Wilson's approach for several types of adsorption isotherms. The mass balance equation of this ideal model is

$$\frac{\partial C_{\mathrm{m},i}}{\partial t} + H \cdot \frac{\partial C_{\mathrm{s},i}}{\partial t} + u \cdot \frac{\partial C_{\mathrm{m},i}}{\partial z} = 0 \quad (9)$$

Here, C_{m} and C_{s} denote for the protein concentration of species i in the mobile and stationary phase, respectively. H is the phase ratio, t is time, z is column length and u is

the mobile phase velocity. This model is of interest only for nonlinear isotherms. In the case of a linear isotherm and a column of infinite efficiency, the sample pulse travels through the column without any change (31).

Equilibrium-Dispersive Model. According to Van Deemter et al. (16), Giddings (13), and Haarhoff and van der Linde (32), equation 9 can be replaced by

$$\frac{\partial C_{\mathrm{m},i}}{\partial t} + H \cdot \frac{\partial C\mathrm{s},_i}{{}_\partial t} + u \cdot \frac{\partial C_{\mathrm{m},i}}{\partial z} = D_{\mathrm{a},i} \cdot \frac{\partial^2 C_{\mathrm{m},i}}{\partial z^2} \qquad (10)$$

when the mass transfer is not infinitely fast. Here, $D_{\mathrm{a},t}$ is the apparent dispersion coefficient that lumps together axial dispersion and nonequilibrium from adsorption and desorption.

$$D_{\mathrm{a},i} = \frac{\mathrm{HETP} \cdot u}{2} \qquad (11)$$

It is assumed that the mobile and stationary phases are instantaneously in equilibrium. Assuming a column of infinite length, a Dirac $\delta(z)$ pulse as an injection profile, and a linear isotherm, the solution of this equation is a Gaussian distribution (33).

Lumped Kinetic Model. In this model, the dispersion coefficient D_{L} accounts only for the axial dispersion and is not lumped to the influence of nonequilibrium effects.

$$\frac{\partial C_{\mathrm{m},i}}{\partial t} + H \cdot \frac{\partial C\mathrm{s},_i}{{}_\partial t} + u \cdot \frac{\partial C_{\mathrm{m},i}}{\partial z} = D_{\mathrm{L},i} \cdot \frac{\partial^2 C_{\mathrm{m},i}}{\partial z^2} \qquad (12)$$

Depending on the assumptions, different models can be distinguished. If the influence of the mass transfer resistance is negligible and only the kinetics of adsorption and desorption are taken into account, the model is called reaction-dispersive. For a linear isotherm, the kinetic equation is

$$\frac{\partial C_{\mathrm{s}}}{\partial t} = k_{\mathrm{a}} \cdot C_{\mathrm{m}} - k_{\mathrm{d}} \cdot C_{\mathrm{s}} \qquad (13)$$

when k_{a} and k_{d} are the rate constants of adsorption and desorption, respectively. When a Langmuir-type isotherm is assumed, the Langmuir kinetic model is obtained (8).

$$\frac{\partial C_{\mathrm{s}}}{\partial t} = k_{\mathrm{a}} \cdot (C_{\mathrm{s,max}} - C_{\mathrm{s}}) C_{\mathrm{m}} - k_{\mathrm{d}} \cdot C_{\mathrm{s}} \qquad (14)$$

If we assume the adsorption-desorption kinetics as infinitely fast but not the mass transfer kinetics, the model is called transport-dispersive. Then, the kinetic equation for C_{s} is

$$\frac{\partial C_{\mathrm{s}}}{\partial t} = k_{\mathrm{m}} \cdot (C_{\mathrm{m}} - C_{\mathrm{s}}) \qquad (15)$$

when k_{m} is the apparent mass transfer coefficient.

Assuming a Dirac $\delta(z)$ pulse as an injection profile, a linear isotherm, and that mass transfer kinetics in the transport-dispersive model and adsorption-desorption kinetics in the reaction-dispersive model are fast, the solution of these equations is a Gaussian distribution (16). The general rate model consists of two partial differential equations for each component, one for the mobile phase in the interparticle area of the column and one for the fluid in the intraparticle area. It was used by Kucera (34) for linear isotherms and by Lee et al. (35) and Yu and Wang (36) for nonlinear isotherms.

For numerical solutions of these equations several different approaches can be used. The techniques generally applied are finite-difference and finite-element methods. The direct calculation of numerical solutions of the mass balance equations by finite-difference models leads to stability problems of the calculations (37). A method applied extensively replaces the axial dispersion by introducing a numerical dispersion. In this case, a solution for the ideal model is looked for that gives a first-order error equivalent to the axial dispersion. The numerical dispersion can be adjusted by changing the space increment (z) or time increment (τ) of the iteration. The basis for all calculations is a modified form of equation 10

$$\frac{\partial C_{\mathrm{m}}}{\partial z} + \frac{\partial \left[\frac{1}{u} \cdot (C_{\mathrm{m}} + H \cdot C_{\mathrm{s}})\right]}{\partial t} = \frac{D_{\mathrm{a}}}{u} \cdot \frac{\partial^2 C_{\mathrm{m}}}{\partial z^2} \qquad (16)$$

which is identical with

$$\frac{\partial C_{\mathrm{m}}}{\partial z} + \frac{\partial G(C_{\mathrm{m}})}{\partial t} = \frac{D_{\mathrm{a}}}{u} \cdot \frac{\partial^2 C_{\mathrm{m}}}{\partial z^2} \qquad (17)$$

For the ideal model this equation simplifies to

$$\frac{\partial C_{\mathrm{m}}}{\partial z} + \frac{\partial G(C_{\mathrm{m}})}{\partial t} = 0 \qquad (18)$$

Replacing the first term by the backward finite difference and the second by the forward finite difference (backward-forward differences), this equation for the $j + 1$ at the position n is

$$\frac{C^j_{\mathrm{m},\mathbf{n}} - C^{j}_{\mathrm{m},\,-\mathbf{1}}}{h} + \frac{G^{j+1}_n - G^j_n}{\tau} = 0 \qquad (19)$$

This calculation scheme is identical to the Craig model if the ratio of the calculation intervals h/τ equals u. This Craig model was widely used by several authors (38–42). In contrast to a forward-backward scheme (43), which is put to use for isocratic conditions (44,45), it can be applied to calculate gradient elution chromatography (Fig. 3).

More exact calculations with respect to the estimation of the axial dispersion effects are possible using finite-element methods. In chromatography, the method of orthogonal collocation on fixed elements is preferred to the method of moving elements (36,46,47). Arve and Liapis (48–50) call this approach the finite bath method instead of finite element. All these methods are limited to isocratic

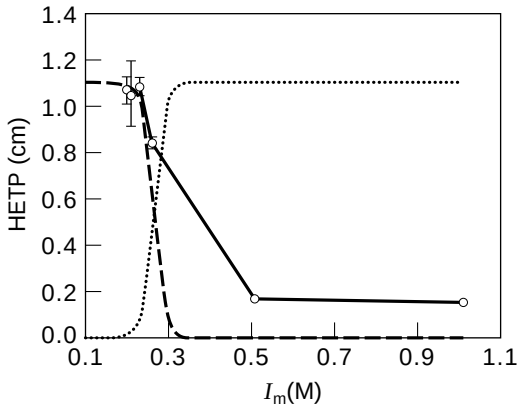

Figure 3. Dependence of HETP on I_m measured by BSA pulses applied to an anion exchanger (Q-HyperD). The column was equilibrated with elution buffers containing various amounts of NaCl. u = 3,006 cm/h; i.d. × h = 5 mm × 5.2 cm. The *dashed line* is a calculation of HETP values according to a Craig model. The *dotted line* occurs when using forward-backward calculation of finite differences.

conditions by means of numerical stability of the calculations (31).

Recently, a fast algorithm based on the assumption of elution as a collocation of point masses migrating with a velocity dependent on the local concentration and the flow rate was presented (51). This model gives comparable results to a Craig model, but the computation time is two orders of magnitude smaller.

Stochastic Theory

A statistical approach developed by Giddings and Eyring (52) has been used for a stochastic model to describe migration and broadening of a sample in a chromatographic column. They considered the migration of a solute in a column as a Poisson distribution process and ignored the axial dispersion. They obtained following probability distribution:

$$P = \frac{k_a \cdot k_d \cdot t_0}{2 \cdot \sqrt{\pi} \cdot (t - t_0)^{0.75}} \cdot \exp[-(\sqrt{k_d \cdot (t - t_0)} - \sqrt{k_a \cdot t_0})^2] \tag{20}$$

This model was extended to more complex situations accounting for axial dispersion and mass transfer resistances (53). For an increasing number of entries of a molecule into the stationary phase and a linear adsorption isotherm, this probability distribution tends to a Gaussian distribution.

Extra-Column Broadening

To be able to describe the behavior of a protein sample in different scales of chromatographic systems, the influence of the extra-column space on the band broadening must be distinguished from the broadening occurring in the column. A comprehensive description of the extra-column effects on gas chromatography is given by Sternberg (54). Most of the explanations are also valid for liquid chromatography (55).

Contributions to Extra-Column Broadening. The extra-column effects can be subdivided into dispersion in tubes, contributions of dead volumes, finite detector volume, and dynamic behavior of transducers and electronics. According to Taylor (56), tubes introduce a symmetrical Gaussian-type broadening (σ_t^2) to the sample. The band spreads under the combined action of molecular diffusion and the parabolic axial flow velocity profile. This broadening can be described by

$$\sigma_t^2 = \frac{t_R \cdot r^2}{24 \cdot D_M} \tag{21}$$

where t_R is the retention time, r is the radius of the tube, and D_M is the molecular diffusion coefficient. Dead volumes create a type of washout kinetic (57). Therefore, they introduce an exponential contribution to the band broadening. This exponential contribution (τ_{dead}) is a function of the dead volume (V_{dead}) and the flow rate (F)

$$\tau_{dead} = \frac{V_{dead}}{F} \tag{22}$$

It was also shown by Sternberg (54) that the finite sensing volume of a detector introduces an additional symmetrical, rectangular broadening. This broadening (σ_d) depends on the sensitive detector volume (V_d) and the flow rate. According to Cram and Glenn (57) it can be described by

$$\sigma_d^2 = \frac{V_d^2}{12 \cdot F^2} \tag{23}$$

An exponential contribution to the band broadening is introduced by the finite response rate of the electronical amplifier and recorder. This contribution (τ_{el}) is independent of the flow rate (57,58).

Mathematical Treatment. Assuming additivity of the variances, the total extra-column broadening can be written as

$$\sigma_{ex}^2 = \sigma_s^2 + \sigma_t^2 + \sigma_d^2 + \tau_{dead}^2 + \tau_{el}^2 \tag{24}$$

where σ_{ex}^2 is the lumped extra column dispersion and σ_s^2 is the variance of the initial theoretical injection profile. Assuming that in liquid chromatography the variances introduced by the electronics and the detector volume are negligibly small compared to the other variances, equation 24 simplifies to

$$\sigma_{ex}^2 = \sigma_s^2 + \sigma_t^2 + \tau_{dead}^2 \tag{25}$$

Lumping together the F-independent variances (σ_A^2) and the F-dependent variances (σ_B^2), the extra-column broadening (σ_{ex}^2) is (59)

$$\sigma_{ex}^2 = \sigma_A^2 + \frac{\sigma_B^2}{F^2} \tag{26}$$

An equation for the prediction of the extra-column contribution to the total broadening can be derived based on the definition of the plate number N of a system

$$N = \frac{V_P^2}{\sigma_{c.i.}^2} \tag{27}$$

If the total broadening (σ_{total}^2) is considered as the sum of the column internal broadening ($\sigma_{c.i.}^2$) and the extra-column broadening (σ_{ex}^2)

$$\sigma_{total}^2 = \sigma_{c.i.}^2 + \sigma_{ex}^2 \tag{28}$$

and N is replaced according to equation 3, the following relationship can be obtained

$$\sigma_{total}^2 = \frac{HETP}{L} \cdot V_R^2 + \sigma_{ex}^2 \tag{29}$$

This equation was derived for analytical chromatography by Huber and Rizzi (60) and has also been applied for preparative chromatography (22). Using this relationship it is possible to exhibit a quantitative picture of the contribution of extra-column broadening on the total broadening (Fig. 4).

ACADEMIC AND COMMERCIAL AVAILABLE COMPUTER PROGRAMS

Computer-aided tools have been developed to different levels of complexity. Programs have been written for prediction of peak profiles, breakthrough curves, gradient shapes, and optimization of resolution (61). On the other hand, expert systems have been created for development of chromatographic separations (62), by using the prediction of peak profiles as tools for optimization.

Expert Systems

An expert system applies heuristic rules for the solution of a problem by using a knowledge base and an interference engine. The knowledge base is a collection of rules and facts gathered from practical experience. The interference engine applies domain knowledge to draw conclusions for the problem under consideration (Fig. 5).

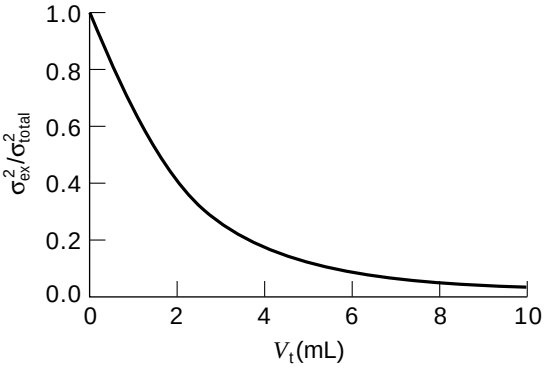

Figure 4. Contribution of extra-column band broadening to total broadening as a function of total column volume (V_t) (22). Original data from experiments using a 0.5-cm i.d. column.

Although the usefulness of expert systems was shown in the late 1960s for chemical applications with the expert system DENDRAL (64), expert systems for chromatography were not introduced until the early 1980s. The expert system ECAT (Expert Chromatographic Assistance Team) (65) provides information for column packing and geometry, and known analyte properties determine the type of chromatographic mode (reversed phase, ion exchange, etc.). Optimizations based on the linear solvent strength model (LSS), assuming a linear relationship between the log k' and the mobile phase modifier concentration, Φ, (66) are offered. A linear relationship between the log k' and the solvent strength of the mobile phase modifier is assumed

$$\log k' = \log k_0' - S\Phi \tag{30}$$

where k' is the capacity factor (normalized retention time in respect to the dead time) defined as

$$k' = \frac{t_R - t_0}{t_0} \tag{31}$$

and φ is the volume fraction of the mobile phase modifier. S reflects the dependency of k' on φ, and k_O' is the capacity factor without the mobile phase modifier.

The expert system expert system for chromatography (ESC) (67) was generated for method development in gas chromatography and HPLC. A set of about 500 chromatograms from the literature constitutes the basis for optimization. Peaks can be simulated, and mobile and stationary phases can be selected. For the peak identification, a curve-fitting tool based on the exponential modified Gaussian function is implemented. Fell et al. (68) developed an expert system to optimize the mobile phase composition in RPC. Therefore, they applied simplex optimization and iterative regression techniques based on experimentally determined retention times.

The European project ESCA (Expert Systems for Chemical Analysis) provided three complex expert systems for method development in chromatography. The first deals with method ruggedness (69); the second, with method (70), and the third, with method development from initial method selection to optimization (71).

The expert system HPLC Doctor (72) and a similar system developed by Tsuji and Jenkins (73) promise help when specific problems with HPLC arise.

Numerous expert systems were developed for RPC (74–76).

A comprehensive description of expert systems in chromatography is given by Hamoir and Massart (62). Presently, for preparative chromatography expert systems are not available. The starting material is very complex, and the purification is generally not completed in one cycle. Expert systems on downstream processing of fermentation products have been developed by Leser and Asenjo (63). These systems comprise optimal flow sheeting of the possible unit operation suited for recovery of bioproducts.

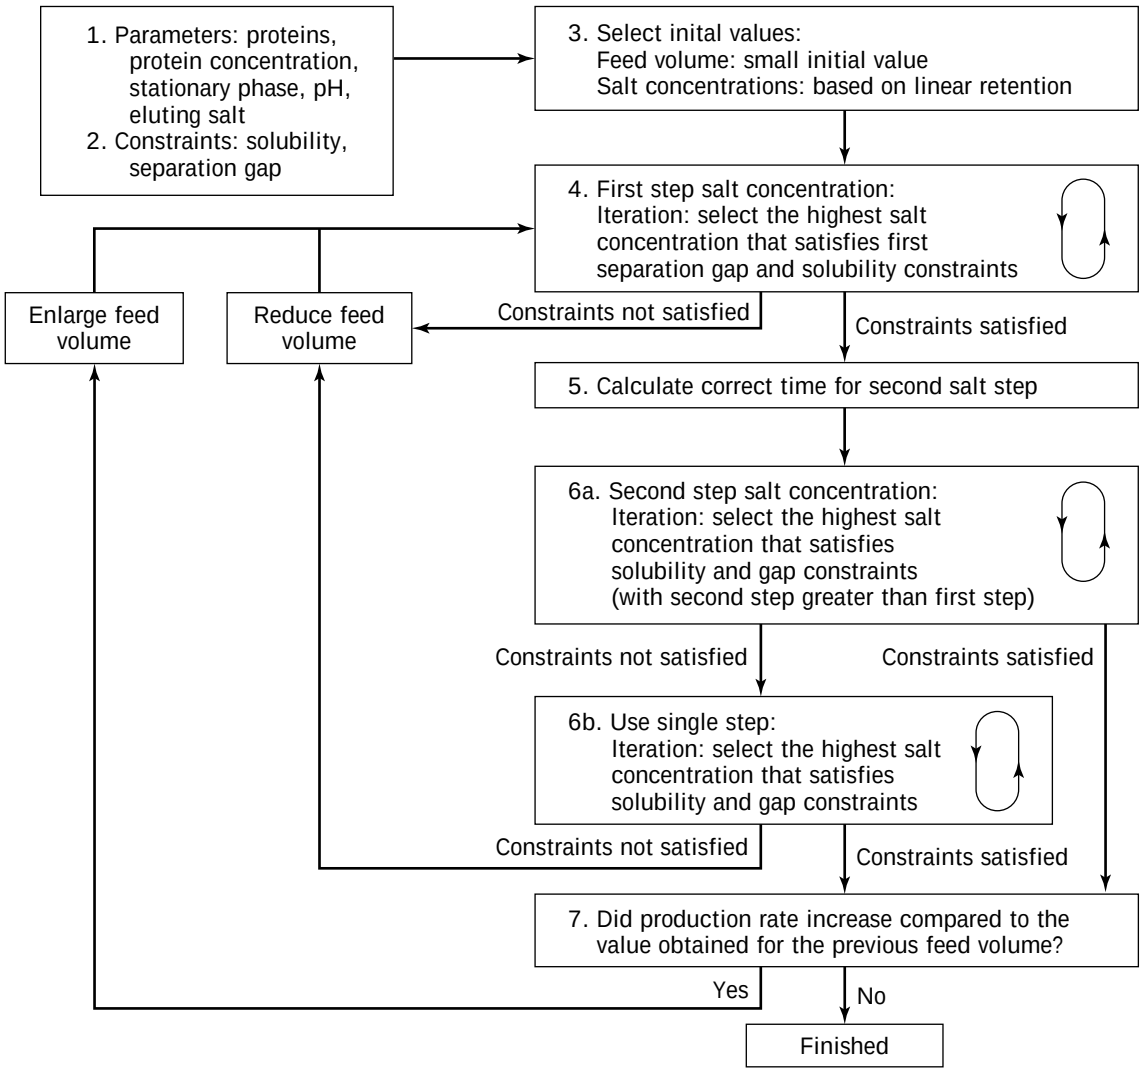

Figure 5. Architecture of the expert system and the links with external databases and algorithms. *Source*: Leser and Asenjo (63).

Leser et al. built an expert system for selecting the sequence of processes for downstream processes, using a commercially available shell (77). The knowledge base contains around 600 logical rules, methods, and structures that emulate the expert's reasoning in selecting downstream processes. The creation of the rationale for the selection of a sequence of high-resolution purification steps must be based on heuristic rules because the existing models for chromatographic separations are not adequate for solving questions of selecting processes, they relate more to the mechanisms of interaction between proteins and matrixes. The heuristic rules are similar to those used to guide the selection of processes for multicomponent mixtures in chemical engineering (Table 4). The rationale for selection of high-resolution purification operations uses the theoretical concept of separation coefficients (23,80).

Simulation Programs

Since the early 1980s, several computer programs for simulating chromatographic behavior have been developed. Most of the programs are only of academic applicability because the experimental accessibility of model parameters is very cumbersome.

Smit et al. (81,82) describe a discrete mathematical model for nonlinear, nonideal chromatography. The nonlinearity can be represented by several different isotherms (linear, Langmuir, Freundlich, sigmoidal). The nonideality is represented by a lumped parameter reflecting axial molecular diffusion, Eddy diffusion, and different sample shapes. No dispersion occurs in the stationary phase. The conservation of mass is used to set up a mass balance. The resulting differential equations are solved by a fourth order Runge-Kutta method.

Phillips et al. (83) use a probabilistic approach for the simulation of a chromatographic separation process, called discrete event simulation. All molecules are executed with the same adsorption–desorption mechanism. Each molecule undergoes a certain number of events (adsorption and desorption). The program can only simulate isocratic conditions and was originally developed for gas chromatog-

Table 4. Classification of Heuristics

Type	Applications and examples
Method heuristics	Specify choice between different unit operations. Describe conditions for preference of microfiltration over centrifugation.
Design heuristics	Specify order or sequence of process steps. Perform low-resolution step before high-resolution step. Use large particles at the beginning of a purification sequences.
Species heuristics	Specify based on the properties of the components. Choose separation method based on the greatest difference in properties of product and impurities. This rule tells us to use always affinity chromatography. There are certain other limitations.
Composition heuristics	Specify feed composition based on separation costs. This rule tells us that affinity chromatography may be too expensive.

Source: Wheelright (78), Nadgir and Liu (79).

raphy. Nonlinear isotherms are also taken into account by applying a molecular density map. The probability of adsorption is related to the accessible (free) binding sites.

Whitley et al. (84) established a very advanced computer program for simulation of peak profiles named VERSEC-LC. The calculation is based on an highly evolved rate model, where the column is virtually divided into different stages (vessels). This model treats the column as a series of N equal volume stages (equivalent to plates or series of vessels or transfer units). The mobile phase flows through these stages at a given rate. Each stage is divided into three fractions: the bulk solution, pore solution, and the solid phase. A gradient between the bulk solute concentration and pore solute concentration results from the combined effects of film and pore diffusion mass transfer resistances. Equilibrium assumed between the solute in the pore solution and the solute on the solid phase is described by nonlinear isotherms. The program can simulate gradients, different loading concentrations, and volumes using different pore structures and diffusion coefficients.

Several computer programs (e.g. Dry-Lab®) use the linear solvent strength theory (LSS) for the calculation of peak positions (27,85). A column is calibrated by two runs, and the optimal gradient shape can be calculated by using a resolution map. The program is mainly suited for RPC, because ion-exchange chromatography (IEC) does not follow the LSS theory (86). The program is intended for optimization of analytical chromatography.

Gallant et al. developed a computer model based on the stochastic mass action (SMA) formalism. SMA is a further improvement of the stoichiometric displacement model (87). The SMA formalism represents the chromatographic adsorption process as a stoichiometric exchange of mobile phase protein and bound counterions. Furthermore, a fraction of counterions is shielded by the adsorbed protein. The accessible sites are corrected by a so-called shielding factor, which is proportional to the stationary phase concentration of protein. For acquisition of the parameters, describing the protein adsorption at different salt concentrations, the LSS formalism is applied, although this formalism is not completely valid for IEC (86). Prediction of protein zone migration and broadening is carried out by a single lumped dispersion model (which is described by equation 10). Gallant et al. (88) propose an optimization routine using simulation of chromatography by the aforementioned models. The optimization runs through different stages. Initially, modeling parameters have to be acquired, and protein constraints (e.g., solubility, resolution) have to be defined. These constraints meet actual requirements of large-scale protein production (Fig. 6).

The program Simulus uses a similar approach as described by Whitley et al. (84), and diffusional resistances and a surface reaction resistance were included. The fundamentals for this program were published by Cowan et al. (29). Furthermore, they have integrated moving grids for calculation of the peak profiles of Wiblin et al. (89). The program is marketed by BIOSEP, AEA Technology (Harwell, U.K.).

ProSys™ Simulation, distributed by BioSepra Inc. (Marlborough, Mass.) is a computer package using the simple Craig simulation (5,90). The computer package is connected to hardware that allows automated determination of the parameters required for optimization of preparative chromatography (ProSys™ Workstation). Currently, it is the only commercially available integrated package of parameter acquisition and simulation software. For IEC, distribution coefficient values as functions of salt concentrations are predicted by linear gradient experiments as proposed by Yamamoto et al. (19). The calculation of simulation parameters can be carried out semiautomatically, assisted by the software. Validation of the simulated peak profiles can easily be accomplished because the software does not discriminate between experimental and simulated runs. So, comparison and superposition are simple. The software package implemented in the ProSys™ Workstation also contains a tool for economical evaluation of chromatographic unit operations (ProSys™ Scale-Up).

All the aforementioned computer programs do not take into account the extra-column band spreading. This mechanism may become very important when it comes to scale-down and parameter acquisition at very small scale (22).

The authors of this chapter have developed a computer program that is an extended version of the simulation program used in the commercial system ProSys. This extended version allows the prediction of peak profiles using a big variety of different adsorption isotherms (90). Furthermore, the influence of extra-column inlet and outlet can be simulated. The modifications of gradient profiles by the mixing device is also part of the simulation (91). Rescaling and influence of the setup can be virtually studied. The simulation program can also be used for validation of chromatographic conditions.

Artificial Neural Networks

Artificial neural networks have been recently applied for chromatographic peak classification (92). Neural networks are specialized computer systems having processing capabilities similar to the human brain. They are distinct from conventional computer systems, because they process entire patterns, rather than successive individual items of data. They are trained by example to carry out their tasks, instead of being explicitly programmed. The processing patterns and learning capabilities displayed by human brains are difficult to mirror using conventional computer programming. Nevertheless, a neural network is, ultimately, a particular kind of computer program, far removed in its theory or implementation from any biological system.

Modern digital computers built with traditional designs have a fundamental limitation, the so-called von Neumann bottleneck. Traditional computation requires a problem to be broken down to a set of operations that are performed in serial fashion, that is, one instruction at a time. Typically, each instruction must be completed before the next instruction is executed. Artificial neural networks represent a fundamentally different approach to computation. They are explicitly designed to mimic the basic organizational features of biological nervous systems: parallel, distributed processing. Artificial neural networks consist of a large number of simple interconnected processing elements, where the processing elements are simplified models of neurons and the interconnections between the processing elements are simplified models of the synapses. The processing of information in such networks therefore occurs in parallel and is distributed throughout each unit composing the network.

Neural networks are particularly appropriate for a defined class of tasks, which may be characterized as follows:

- Pattern recognition, rather than sequential data processing
- tasks demanding nonlinear capabilities in producing their classification, which can be a problem for other techniques
- technically ill-defined tasks, even though the decision may be obvious
- tasks with sufficient examples of the target data available to allow a learning system to be considered

Peak-shape classification is a pattern recognition task that is pertinent to chromatography. The automated determination of the peak profiles in a chromatogram gives an objective answer when two chromatograms are identical or different. It may be a valuable contribution to validation for a purification sequence or validation of scale-up.

APPLICATIONS AND LIMITATIONS OF MODELING

For a conventional software, exact definition of the conditions leading to the optimum is necessary. Mathematical algorithms (explicit equations or differential equations) must be available to calculate the optimum. The major obstacle in preparative chromatography is the complexity of the variables, the problem to estimate the parameters, and the response value. It may be also possible that an optimum is not found within the investigated range of variables.

In Figure 7a and b, a system with a distinct optimum is described. Independently from the starting point (initial pair of variables 1 and 2), an optimum will be found. Systems, where the variable and the response value are related by a peak function or where the variable consists of several variables lumped together, produce a surface with a unique maximum of the response value. The lumped variables or reciprocal action with other variables should be carefully investigated. Minor changes in the experimental conditions may cause a big variation in the optimal response value.

The optimum obtained in a system shown in Figure 7c and d depends on the starting point. Several optima and even local minima are present. Such a system can be characterized by carrying out an optimization strategy with starting points over the whole area in small increments of the considered variables and comparing the reached min-

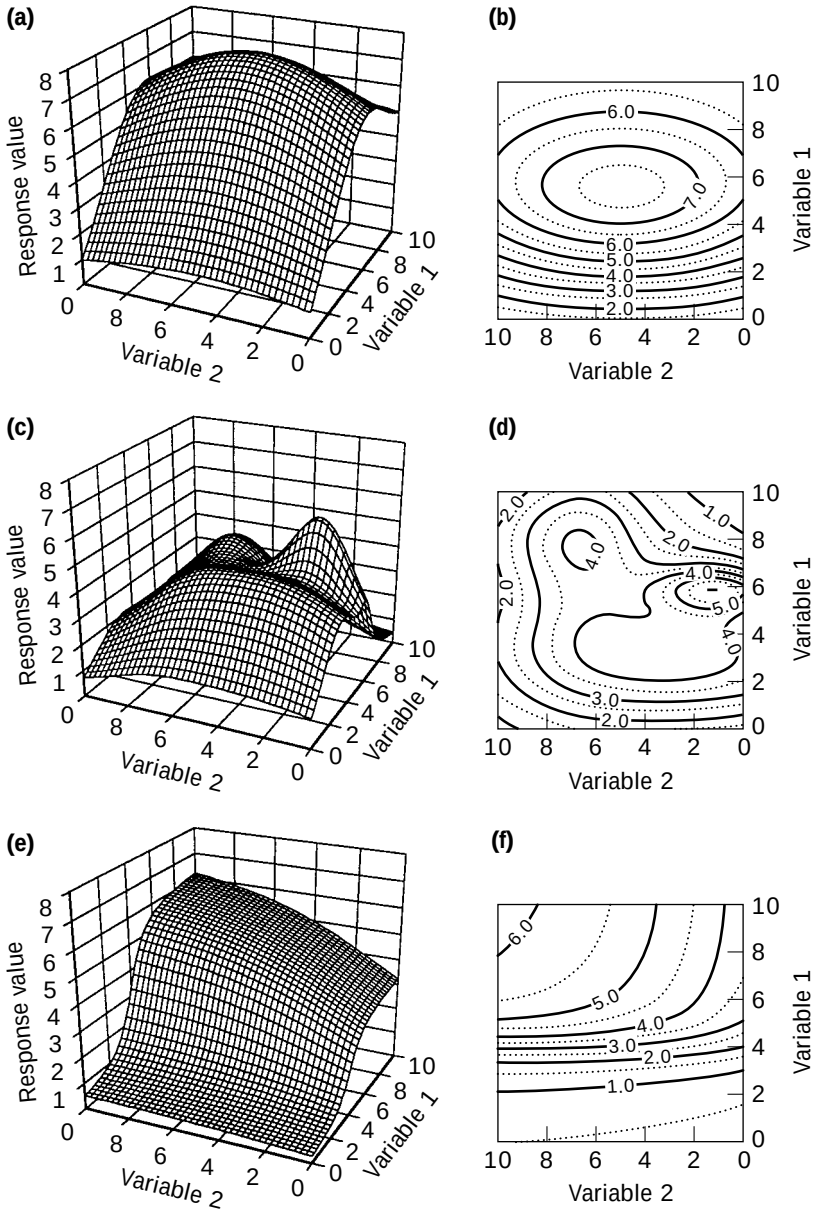

Figure 7. (**a** to **d**) Evaluation of optimum with two variables and one response value. (**e** and **f**) An optimal response value is not found in the considered range. In chromatography, the variable can be, for example, flow rate or loading, and the response value can be, for example, resolution, productivity, or purity.

ima and maxima. Figure 7e and f shows a system where the optimum cannot be reached within the allowed range of variables. This situation is often observed, when the productivity of a chromatographic separation is optimized in respect to flow rate and loading. When the separation is not sensitive to resolution, the system is hypothetically only constrained by the range of the variables. The performance of chromatography is influenced by far more variables than two, but it is very complicated to plot a function with more than two variables in a nonconfusing manner. One way is the overlay of contour plots, as shown in Figure 7b, d, and f and in Figure 8.

Let us assume that a chromatographic separation depends on two variables, such as flow rate and loading. The hypothetical task is to find the optimal response value, such as productivity. Using experimental and simulated results, the optimal response values are searched. A certain purity is presumed. Then the productivity and the purity are plotted versus flow rate and loading. Both contour plots are superimposed. The area, where the presumed purity is reached, indicates the optimal range of operational variables. This approach was used by Mao et al. (93).

Sometimes the conditions are constrained by pragmatic issues, such as availability of equipment (commercially available columns with a certain diameter, costs of a buffer) or by the physicochemical characteristics of the product. Many proteins have limited stability and solubility. There are conditions where the protein may be inactivated. These conditions are not easily transferred into mathematical equations. Sadana (94) summarized possible causes for inactivation of biological macromolecules during separation. During the adsorption and desorption process, proteins may undergo a conformational change. Proteins can associate or they can precipitate on the surface (95–

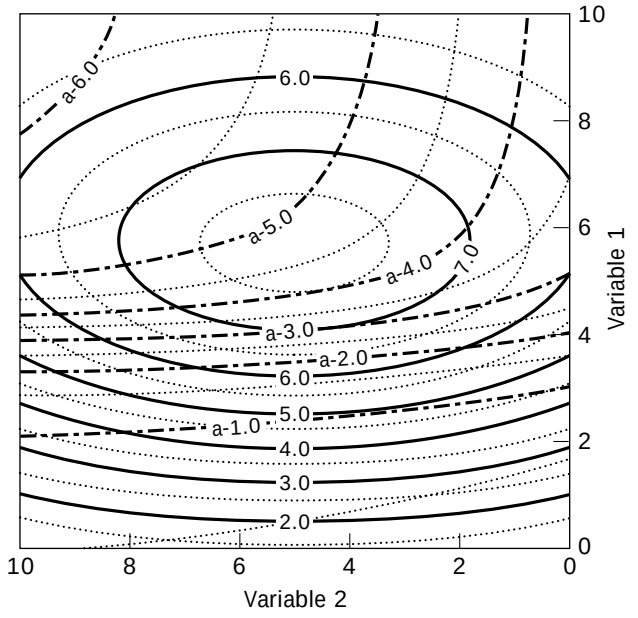

Figure 8. Evaluation of an optimal operational range, when two different response values are related to the two variables. A hypothetical system represented by the graphs **a** and **b** and **e** and **f** in Figure 7 are used to describe the strategy. The contour plots in Figure 7**b** and **f** are superimposed. The intersecting plane formed by the contours with the lower limits of the response values (e.g., a.5.5 and 7.0) yield the optimal range.

97). Self-association was modeled by Lemque et al. (98). They could derive quantitative information on cooperativity effects from the adsorption isotherms. From their model, they showed that protein–protein interaction exists in the adsorbed state and led to an increase in protein self-adsorption. Considering a crude protein sample from a clarified fermentation broth, many proteins and other biological macromolecules are present in this solution. Changing the concentration or pH will affect the self-association. On the other hand, one can also expect the formation of hetero di- and oligomeric protein complexes. Protein-DNA complexes can also occur. The capacity and the lifetime of a column are affected by the aforementioned aggregation phenomenon. This short discussion of protein interaction shows a very important aspect in optimization of chromatography, and complications arise when they have to be translated into a mathematical formulation. One possible way to circumvent these obstacles is the standardization of the sample as far as possible.

Conventional Optimization Methods

Conventionally, resolution has been optimized, because the major activities in computer-assisted optimizations have been carried out in analytical applications. Though some rules may also be applied for optimization of preparative chromatography, in analytical chromatography resolution (R_S) is defined as:

$$R_S = \frac{2 \cdot (t_2 - t_2)}{w_1 + w_2} \tag{32}$$

where t_2 and t_1 are the retention time of the separated substance, and w_1 and w_2 are the peak width at the base. A resolution map is the response value of the optimization. A resolution higher than 1 should be achieved throughout the whole chromatogram. A high resolution is not desired, because it increases the analysis time. The optimization of the running conditions (mobile-phase modifier composition, gradient shape, flow rate, etc.) can be carried out by factorial design, simplex optimization, and others.

Simplex Optimization. Although there are many variants of the simplex procedure (99), they are all based on the basic procedure of Spendley et al. (100). A simplex is defined as a geometric figure having one more point (vertex) than the number of variables being optimized. Thus, for two variables, a simplex is a triangle and for three variables the simplex is a tetrahedron. Although it is difficult to visualize a simplex for more than three variables, the mathematics does not become significantly more complex and the procedure is easily handled by manual or digital computation. Figure 9 shows a two-variable (dimension) simplex as it moves, with constant step sizes, across a response surface. The optimization proceeds by rejection of the vertex, which has the worst experimental response, and by reflecting its coordinates through the midpoint of the hyperplane.

Unfortunately, this original, fixed-step size procedure suffers from several severe limitations. In particular, progress across the response surface is made at a constant rate because the step size is fixed; this fixed size also means that the optimum may not be precisely located because the simplex will be forced (in two dimensions at

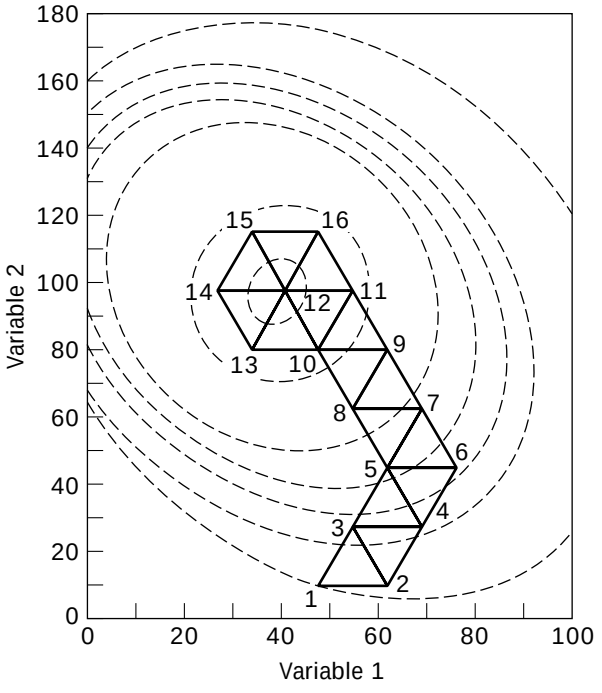

Figure 9. Fixed-step-size simplex optimization of two variables. Initial simplex is 123 and the optimum region is at vertex 10, 11, 12. *Source*: Reproduced with kind permission of Berridge (101).

least) to circle around it. Additionally, the fixed-step size simplex is prone to failure on a surface ridge, in that it will become stranded and not make progress toward the optimum. These limitations have been largely overcome in the modified procedure of Nelder and Mead (102). They introduced two new operations to the fixed-step size procedure, expansion and contraction. The latter operations allow the simplexes to expand and thus accelerate toward the optimum region. When they have approximately located the optimum region, the simplexes contract and reduce the search region until the optimum is precisely located. Figure 10 shows a variable-step size simplex on the same response surface as in Figure 9.

Berridge (101) reviewed the chromatography response functions (CRF) used in analytical chromatography. These functions can be also applied to preparative chromatography (103). The functions successfully used to date for simplex optimization are in general based on sums of terms, usually reflecting resolution and analysis time. The CRF are derived for the separation of a small number of components from a complex sample. A few response functions will be discussed as examples. A comprehensive treatment of the CRF used in analytical chromatography would exceed the scope of this chapter.

For isocratic separations, Berridge (104) developed a function to provide greater flexibility in meeting the needs of fully automated optimization:

$$\mathrm{CRF} = \sum R_i + n^a - |t_m - t_n| - c(t_0 - t_1) \quad (33)$$

where R_i is the actual resolution, n is the number of detected peaks, t_m is the desired retention time, t_n is the retention time of the last peak, t_0 is the dead time, t_1 is the retention time of the first elute peak, and a is a selectable weighting parameter.

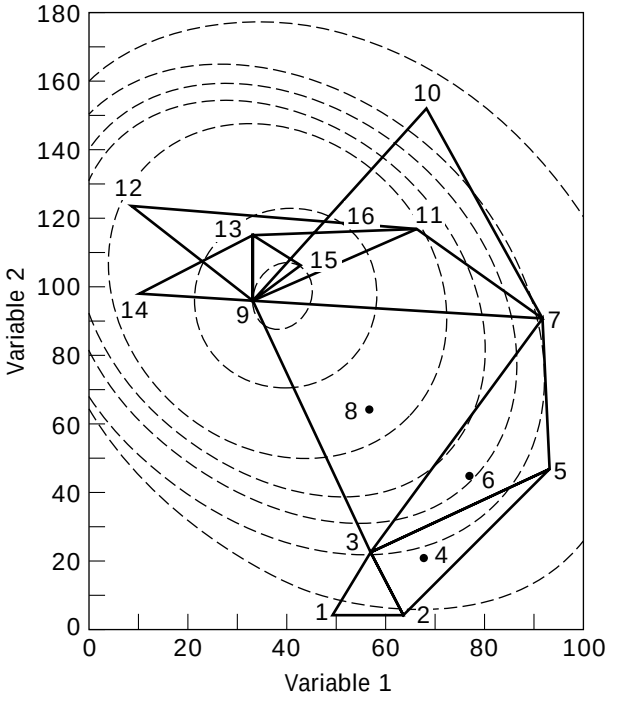

Figure 10. Variable-step simplex. *Source*: Reproduced by kind permission from Berridge (101).

To overcome some of the anomalies generated by using a multicriterion CRF in simplex optimization, Wright et al. (105) simplified the CRF (equation 33) to

$$\mathrm{CFR} = \sum R_i + n - (t_m - t_n) \quad (34)$$

with $t_m - t_n > 1$. The time constraint for the first eluted peak is deleted and that for the last peak is considered only if the difference between the retention time and the target retention time is greater than 1 min. The term for the number of peaks (n) is not raised to a power to ensure that when the term is included, it has a significant influence on the CRF value.

Isocronal Analysis. Atamna and Grushka (106) describe the concept of optimization by isochronal analysis, formerly known as the time normalization for HPLC. Briefly, in this mode of optimization, two experimental conditions are changed simultaneously. One is altered to improve resolution, whereas the other is changed to maintain the analysis time constant. The constant analysis time means:

$$t_{R1} = t_{R2} \quad (35)$$

where the subscripts 1 and 2 indicate two different experimental conditions. From equation 36, the following conditions can be derived:

$$\frac{Z_1(1 + k_1')}{u_1} = \frac{Z_2(1 + k_2')}{u_2} \quad (36)$$

where Z is the column length, u is the linear velocity, and k' is the capacity factor. The need to change two experimental conditions simultaneously is clearly seen from equation 36. The most practical pairs of experimental conditions that can be exploited in isochronal analysis are mobile phase velocity and composition, mobile phase velocity and column temperature, or mobile phase composition and column temperature. When the residence time of a product is of concern, this type of optimization may have some value also for preparative chromatography.

Flow Sheeting

Flow sheeting in bioprocessing is a very complex task. A process for purification of a protein consists of several steps. Usually there is a link between the performance of each step and the performances of the previous step and the subsequent steps. The complexity of the problem is obvious when considering a tree structure, assuming a three-step purification with only two possibilities at each step (Fig. 11). Even in this simplified case we end up with eight different purification schemes. Additionally, an economical evaluation of the individual arrangement is hard because the steps of one sequence are influencing each other.

The use of expert systems is suggested for the rational selection of purification processes starting from different

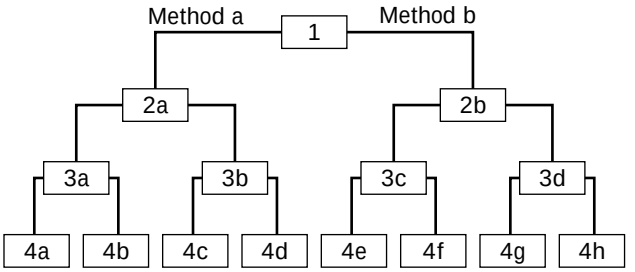

Figure 11. Tree structure of an idealized three-step purification. Each step offers only two possibilities.

microbial sources, such as harvesting, preconditioning, concentrating, purification, and polishing (77,107).

Artificial neural networks are suited to improve the quality of expert systems for flow sheeting. The numerical certainty for defined steps can be fine tuned by feedback with existing results. A successful application has not yet been shown today. However, the large number of software tools for artificial neural networks will promote this application.

The Biopro Designer is a computer program allowing the economical evaluation of each separation step. As in real life, chromatography is limited to other separation steps, such as ultrafiltration, precipitation, etc.

OUTLINE

INTRODUCTION

Hydrophobic interaction chromatography (HIC) is an important chromatography technique used for the separation of biomolecules. The interaction is based on physicochemical characteristics of the molecules other than the charge, as in ion-exchange chromatography (IEC), or the size, as in gel filtration. Although its importance is increasing in industrial applications, the start has been slow. The technique is certainly very powerful when the optimal conditions for a certain separation are determined, but to achieve this has often been far from easy. One reason is that the mechanism of the interaction is complex, depending on several properties of the separation medium as well as of the separated substances, and not yet fully understood. There are a number of hypotheses that approach the phenomenon of hydrophobic interaction from different points of view, but the practitioner will still find that there is no simple theory that will always facilitate the optimization of a separation, as is the case when using other chromatography techniques. Hydrophobic interaction is favored by high salt concentration and is thus a logical purification step after salt precipitation or IEC, where the environment has a high ionic strength.

HIC has been used as a group separation method, rapidly separating what retards on the column from what is not interacting, and as a powerful high resolution technique with gradients of descending salt concentration.

In addition to what is usually designated as HIC, there are several related chromatography techniques based entirely or partly on hydrophobic interaction. Reversed-phase chromatography (RPC) is the most important, working with strong hydrophobic interaction that is often achieved by high substitution with long aliphatic chains. The principal difference between HIC and RPC is methodological in nature. In HIC, the interaction is increased by salt in order to retard the sample on the column and, basically, a return to native conditions will elute the compounds, whereas in RPC the sample is retarded on the column and eluted by addition of organic solvents. The methods based on what are described as salt-mediated and thiophilic interactions gain in importance, whether they should be considered as HIC techniques is perhaps a matter of semantics. Moreover, the binding in affinity chromatography and to dye–ligand matrixes often have significant elements of hydrophobic interaction.

HYDROPHOBIC INTERACTION

Basic Theory

There are several approaches to theoretically elucidate the nature of hydrophobic interaction, ranging from thermodynamics over surface tension to van der Waals forces (1,2). From different angles they all try to explain the observed influence on hydrophobic interaction by ions with salting-out effect, chaotropic ions, type of salt, temperature, pH, and additives. No single theory, however, manages to fully cover the mechanisms of interaction. In HIC the added complexity, contributed by matrixes, spacers, ligands, and the effects of buffer environment on different species of biomolecules, implicates that, apart from very general recommendations, the design of a HIC procedure still has to be founded on careful practical and empirical studies.

Salting Out and Hydrophobic Interaction

There is definitely a relationship between the salting out process used for the precipitation of proteins and hydrophobic interaction as used in chromatography. The Hofmeister series list anions and cations according to decreasing ability to precipitate and increasing ability to dissolve proteins, and the combinations (salts) from the beginning of the list are well known to promote hydrophobic interaction (3–6) (Fig. 1). Probably precipitation by salting-out and HIC are based on the same phenomenon, the principal difference being that in precipitation the hydrophobic interaction has to take place between molecules of the same kind or others that happen to be present in the solution, whereas in chromatography a well-defined counterpart is hydrophobic enough to bind some of the passing compounds, preferably at lower salt concentration than is needed for precipitation.

Thermodynamic Theory

The main and very elegant theory of hydrophobic interaction (7) refers directly to the Gibbs free energy equation (equation 1), which describes the change in energy when a chemical system is transferred from one state to another:

$$\Delta G = \Delta H - T\Delta S \qquad (1)$$

where ΔG is the change in Gibbs free energy, ΔH is the change in enthalpy or heat content, T is the temperature in Kelvin, and ΔS is the change in entropy or disorder of the system. If ΔG is negative, the second state has a lower energy and the system will adapt to it, provided that there are no energy barriers. In hydrophobic interaction, the entropy change is of greatest importance (8). If hydrophobic molecules such as aliphatic carbon chains are immersed in water, the monolayer of water molecules in contact with a carbon chain will be in higher order than those in the bulk of the water. If two or more hydrophobic structures come together, the surface that has to be covered by ordered water molecules decreases, some water molecules join the less-ordered bulk water, and the entire system gains in entropy and thus, according to equation 1, decreases its free energy (Fig. 2). This state will be favorable for energetic reasons and thus promoted. If some of the hydrophobic molecules are attached to a chromatographic matrix as ligands, the setup for HIC is obvious (Fig. 3).

The phenomenon of increased interaction in the presence of salting out ions is explained by a higher gain in entropy when water is transferred from the surface of a nonpolar molecule to the bulk of water. Whether this is achieved because the surface water in the presence of salt is initially more ordered or the bulk water less ordered or both is not quite clear.

Equation 1 reveals that at a higher temperature an increase in entropy will give a higher energy gain because the entropy factor of the equation will be multiplied by a higher number. Consequently, if the binding to a medium has been shown to increase with the temperature, this has been taken as an indication that the interaction is really hydrophobic.

Surface Tension, van der Waals Forces

Another theory (3) suggests that the surface tension of the water surrounding a nonpolar structure and the tendency to minimize it are responsible for the interaction. If salt is added to the water, it has been shown that the surface tension increases. As a consequence, the energy gain in minimizing the surface exposed to the hydrophobic molecules is larger and thus the interaction is stronger. Some salts that influence the surface tension are listed in order of decreasing effect in Fig. 1. Although the salts that increase the surface tension most are among those that should promote hydrophobic interaction according to the Hofmeister series, the order is not quite the same.

A third theory suggests that van der Waals forces (4) are responsible for the hydrophobic interaction in HIC. This is supported by the fact that these forces should be increased as the order of water increases in the presence of salt. Probably the theories mentioned here all describe one part of the complicated interaction, and a combination of them is more relevant to describe the phenomenon of hydrophobic interaction.

Figure 1. The Hofmeister series of anions (**a**) and cations (**b**). The *arrows* indicate increasing salting-out effect and chaotropic effect, respectively. Salts with high ability to promote hydrophobic interaction are combinations of ions found to the left in the series. The same salts are found early in the series of salts listed in order of decreasing ability to promote the surface tension of water (**c**). This indicates the relationship between hydrophobic interaction and surface tension. Which salt to chose depends on the solubility and the production cost of the salt as well as the cost of preventing pollution of the environment by waste buffers.

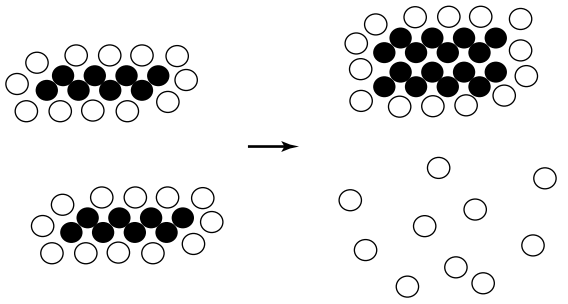

Figure 2. Hydrophobic interaction. Two aliphatic carbon chains (*black circles*) are immersed in water. Only the water molecules (*white circles*) with high order in the monolayer adjacent to the nonpolar molecules are indicated. When two chains are in contact, the surface area that is covered with ordered water molecules is decreased and some water is in a state of less order in the bulk of the water. The free energy of the system decreases, and thus the binding together of the two molecules is favored.

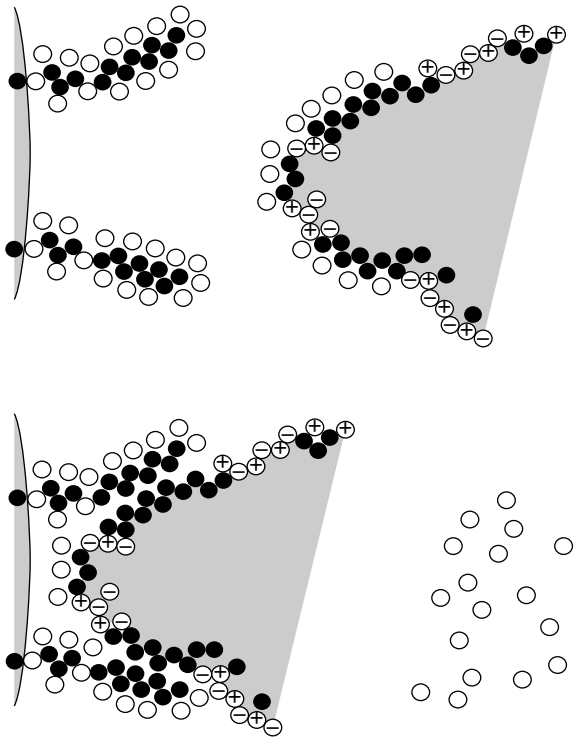

Figure 3. Hydrophobic interaction used for chromatography. Two octyl chains are coupled to a chromatographic medium. An energy gain, equivalent to that described in Figure 1, is achieved by the interaction of the octyl chains with nonpolar moieties on a protein. The carbon atoms of the hydrophobic parts of the protein are indicated with *black circles*, the oxygen atoms of the water with *white circles*, and charged atoms or groups of the protein with *white circles* containing plus or minus signs. The *hatched area* indicates the interior part of the protein.

HYDROPHOBIC INTERACTION CHROMATOGRAPHY

Development of the Technique

As early as 1948 Tiselius presented what he called Adsorption separation by salting out (9), but not until the beginning of the 1970s were reports on the synthesis of media published. Some researchers were working with a mixed mode because of their medias' content of charges (10–13), but charge-free hydrophobic media were also synthesized (5,14,15), and the first commercially available products were presented some years later (16). At present, a wide range of products, including HIC-media for HPLC, are available but phenyl, octyl, butyl, and alkyl ligands are still by far the most common (17,18).

Factors Influencing HIC

In addition to the environmental parameters, including ionic strength, temperature, and pH that influence the hydrophobic interaction as such, there are several factors that have to be controlled to use the hydrophobic interaction for chromatographic purposes. The chromatographic medium is constructed by coupling hydrophobic ligands to a chromatographic matrix, often by use of a short spacer to enhance the sterical possibilities of interaction with large molecules. The type of ligand and the ligand density affect the characteristics of the medium. The choice of buffer ions has been found to change the interaction pattern more profoundly than generally anticipated. The optional use of organic solvents and detergents have to be taken into consideration. The molecules themselves have certain characteristics and will often change chromatographic interaction behavior with the buffer salts in an individual manner (19). Finally, the choice of dimensions of the chromatographic column and the mode of elution will depend on the size range of biomolecules that are subject to processing and the desired throughput of the separation step. One approach, to describe the complex interaction of HIC from a practical point of view, has been to characterize a HIC medium by the interaction pattern of a significant set of protein molecules and to evaluate the result by the use of principal component analysis (20). As described in later sections, the media can be classified by this approach, and the importance of different characteristics of the proteins can be correlated to the interaction of different media.

The Matrix

Agarose-based matrixes with varying degrees of cross-linking are most commonly used for HIC, but organic resins and silica-based media are also used, especially in HPLC applications. All common chromatographic matrixes, such as cross-linked agarose (21,22), organic polymers (23), and silica (24), can be derivatized with hydrophobic groups to give HIC media. Normally, the influence of the by-design hydrophilic chromatographic matrix will just add slightly, if at all, to the performance of the medium, but it is a well-known fact that unsubstituted agaroses intended for gel filtration will expose what can only be characterized as hydrophobic interaction at extremely high salt concentrations (25–27). This allows for using HIC

even for rather hydrophobic proteins that would stick irreversibly to conventional hydrophobic gels. It has to be noted, though, that under normal salt concentrations (e.g., those used in gel filtration) no hydrophobic interaction will be taking place because the gels were successfully designed to be as hydrophilic as possible.

The Ligands

Alkyl, butyl, phenyl, and octyl groups are the most common ligands in commercially available HIC media (Fig. 4). They are listed in what is commonly considered as in order of increasing hydrophobicity, but as mentioned earlier there is no linear or single dimension relationship between their interaction with different species or sets of molecules. It is obvious that the aromatic part of the phenyl group can bind with π-to-π binding as well thus adding to the complexity of the interaction. Other ligands of interest include mercapto derivates, which have yet another spectrum of interaction. They have been claimed to work partly with a special thiophilic interaction, but there is some doubt whether their content of sulfur is really responsible for their interaction pattern or whether they are just another type of hydrophobic medium among the others and working by a combination of the same mechanisms as other hydrophobic media.

The Coupling Reactions

Glycidyl ether is the coupling agent used most often to immobilize hydrophobic ligands (18), but in principle all the common coupling procedures can be used to attach the ligands to the chromatographic matrix. An extensive review of coupling methods is presented in the work by Carlsson et al. (28). The coupling procedure will almost inevitably result in the ligands being attached via an often very short spacer, which is an advantage because conformational restrictions when large protein molecules bind are decreased. On the other hand, the choice of coupling chemistry will always influence the performance of the chromatographic medium by introducing hydrophobic or charged moieties, and the selectivity and the capacity may be very different even if the coupled ligand happens to be the same.

Binding Capacity

The binding capacity of an HIC medium depends partly on the ligand density (11,21,29,30), but it is important to remember that any figures given will always be related to the specific protein that was used to determine the capacity and to the conditions under which the determination was performed. The capacity can be determined as total capacity, with the protein exposed to the medium without flow, or as dynamic capacity, where the linear flow and the residence time of the molecules in the column will influence the result. There may well be a difference of magnitude of 10 to 20 between the capacities for different proteins, a fact that has to be considered when choosing a medium from a catalog where the dynamic capacity is often determined using serum proteins like albumin.

The capacity that can be used is dependent on the contamination picture as well and whether the main part of the impurities are more or less hydrophobic than the desired substance, so in practice it is necessary to determine the dynamic capacity in every specific application; this should be seen as a normal part of an optimization process.

Much work is being done to optimize the dynamic capacity of media, both by suppliers and by users at research sites, but the question is whether the most convenient and uncostly way of increasing the capacity of a column is to increase the amount of gel!

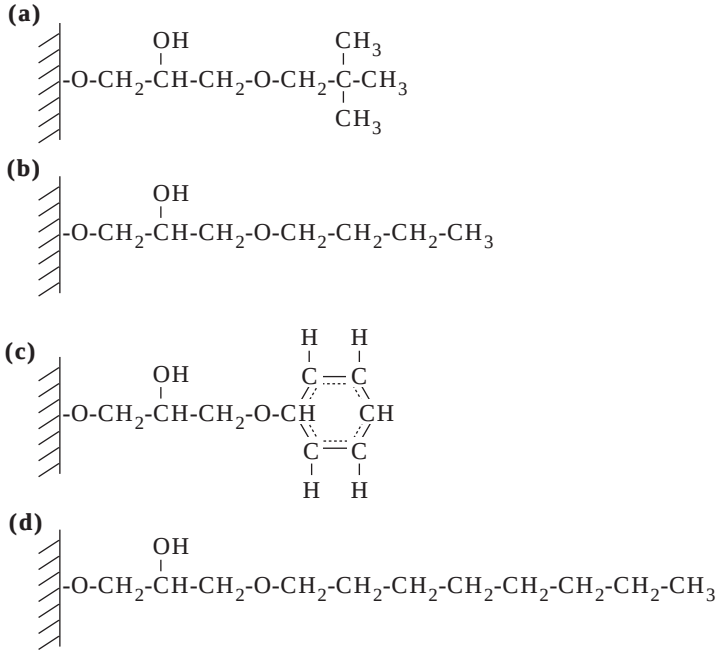

Figure 4. Common hydrophobic ligands. Alkyl (**a**), butyl (**b**) phenyl (**c**), and octyl (**d**) ligands coupled to a chromatographic matrix by glycidyl ether.

HIC and RPC and Column Design

HIC and RPC are both based on hydrophobic interaction, and the borderline between the techniques is more defined by difference in methodology and the type of sample than by the interaction as such.

In RPC the hydrophobicity of the media is higher because the ligands are more hydrophobic and the ligand density is higher. When the sample is run through an RPC column at conditions in the range of physiological pH and salt concentrations, most compounds are retarded on the column. Elution has to be achieved by using increasing gradients of organic solvents. Commonly used solvents are, in order of increasing elution ability, methanol, isopropyl alcohol, and acetonitrile.

In contrast, in HIC very little of the sample is retarded at physiological conditions. The ionic strength of the sample has to be increased to promote attraction, and the elution is normally done by decreasing salt gradients. If some components are still attached to the matrix in weak buffer, a mild organic solvent such as ethylene glycol will be used to wash them out.

As a consequence, HIC is more often used for protein separation where the task often is to retain the tertiary conformation and the biological activity of the separated molecules, whereas RPC is often used for smaller molecules, such as peptides, which lack tertiary structure and subsequently will withstand the elution conditions without denaturation.

Historically, RPC was developed as an HPLC technique to separate small molecules using mainly silica and organic polymer-based matrixes, and HIC was developed as a technique for the separation of proteins, as an alternative to IEC and gel filtration and using the common agarose matrixes as carriers of the hydrophobic ligands. The difference in molecular size range of the molecules to be separated leads to several important differences in the methodologies of the two techniques (31). The differences in behavior between small and large molecules are important in all attraction techniques, such as IEC, HIC, and RPC. But because of the restrictions to expose large molecules to organic solvents, the borderline between separation of small and large molecules happens to coincide more or less with the borderline between the two hydrophobic techniques. But there are other technical reasons behind the difference of methodology based on molecular size (31).

Small molecules interact with the matrix by single point attachment. A molecule is bound to the gel for a certain fraction of the time and is free to move with the buffer the rest of the time. Another way to express the same fact is that at a certain time one fraction of the molecules attach to the column while the rest are moving with the flow. Even if the equilibrium is shifted far toward binding, the macroscopic effect will be that small substances move down the column at some rate in a broad range of salt concentrations, although the speed may be rather low. In a mixture of substances, the rates of movement down the column will be different, as described by the individual equilibrium constants, and a separation will take place. To allow for the molecules to separate, a long path length is needed, and thus long columns and keeping the separating zones sharp are essential for high effectivity. This fact has led to a hunt for high plate numbers, a feature that can be achieved by using small matrix particles. This in turn will cause a high backpressure and the need to work under HPLC conditions. The full utilization of the selectivity of the column will be achieved by elution under isocratic conditions or by shallow gradients. The resulting extremely resolving techniques have been very successful and impressive and have been used for peptide fingerprinting and other types of qualified analysis of small organic molecules.

Proteins, on the other hand, interact with the matrix by multipoint attachment. Even if at some salt concentration, some of the interacting parts of the large molecules may be unbound, there are often several points of interaction left that keep the protein attached to the column. Not until a certain elution condition is reached, such as higher ionic strength in IEC or lower salt concentration in HIC, where all binding sites of the protein are simultaneously unbound, will the protein move down the column. The range between when the protein is not moving at all and moving at full speed is very narrow compared to when small molecules are separated. Isocratic elution is not possible because at constant buffer concentration some proteins will move without retardation and some will hardly move at all. A gradient is needed to elute the proteins in order. Because the resolution is not very dependent on the effectivity of the column, an HIC step where proteins are separated should be performed in short columns, and the linear flow should be kept low by increasing the diameter of the column. In large scale, the use of short and wide columns in protein separation based on IEC and HIC opens up the possibility to run with a high total flow and throughput and still keep the linear flow low enough to allow for the adsorption and desorption to take place without being too far from equilibrium.

CLASSIFYING HIC MEDIA BY MULTIVARIATE ANALYSIS

The performance of HIC media can be monitored by multivariate analysis, using a set or probe of protein molecules with different hydrophobic properties. The interactions of the molecule set with the HIC media could be correlated to molecular weight, isoelectric point, fraction of hydrophobic amino acids, surface charge, and several hydrophobicity indexes (20) without the need for detailed knowledge about the parameters or the mechanisms involved. Instead, the different combinations of media and chromatography conditions can be fingerprinted by their performance in practice and easily compared. As well as artificial mixtures of proteins, serums with 15 to 20 of the proteins identified have been used as probes to determine adsorption patterns (32).

Inversely, biomolecules can be classified by their hydrophobic characteristics as measured by their interactions with a standard set of different hydrophobic media. Molecules with similar adsorption patterns over the media should have similarities on a molecular level.

The results hint that in the tested buffer system, there are at least two main mechanisms that have an impact on HIC (20,33). One mode of interaction was typical on highly

hydrophobic media, for example, with an octyl chain as ligand, where the binding seems to be entirely correlated to the fraction of hydrophobic amino acids and to the hydrophobicity index of the protein molecule. An explanation may be that a higher content of hydrophobic amino acids automatically leads to more hydrophobic amino acids being exposed on the surface of the protein. But because the fraction of exposed hydrophobic areas of proteins is always in the vicinity of 40 to 50% (34,35), another possible explanation takes into consideration that proteins are not rigid bodies with rigid surfaces but that the conformation should be considered as a statistical mean around which the molecule must have the property to breath or change the microconformation, thus allowing a long hydrophobic chain to come in contact with hydrophobic structures that statistically are not always exposed at the surface.

An interesting finding is that the binding to the octyl medium is highly correlated with the molecular weight as well. This phenomenon is logical, though, taking into consideration that larger protein molecules generally have to have a higher fraction of hydrophobic amino acids to keep the tertiary structure.

The other mode of action does not correlate with the content of hydrophobic amino acids of the proteins at all, but instead correlates inversely with the surface charge of the molecules as found in biochemical handbooks. This interaction was displayed on weakly hydrophobic matrixes with short alkyl chains but also with some thiophilic media. An explanation is that charged groups will mask the type of hydrophobic interaction taking place on these gels under the tested conditions. Probably this interaction will be influenced significantly by altering pH.

Very commonly used HIC media, based on phenyl groups and butyl groups as ligands, were shown to work with a mixed mode, that is, combination of the two pure mechanisms. This fact adds to the explanation of the difficulty, especially using these HIC media, to find simple rules after which the separation should be optimized.

It should also be noted that the performance of a HIC medium will always be the result of the combination of ligand, spacer, and matrix. Phenyl gels from different manufacturers have quite different patterns of interaction if tested by a set of proteins as described earlier. This has to be remembered when, after the optimization in laboratory scale, alternative media are tested before scaling-up of a HIC procedure. This optimization is only valid for the medium used. There is thus a risk that competing media, which might be advantageous, will be tested under nonoptimal conditions and rejected under false premises.

THE CHROMATOGRAPHY CONDITIONS

Ionic Strength

A high ionic strength is needed by definition to attach biomolecules to the column. Very often, 1.5 to 1.7 M ammonium sulphate is used as initial buffer concentration without further trials to optimize. Another common approach is to equilibrate the column in weak tris-buffer to preserve the pH and increase the ionic strength by the addition of sodium chloride to a concentration of up to 3 M. It has to be noted, though, that ammonium sulphate, at a certain concentration, is between three and four times as effective in promoting the hydrophobic interaction compared to sodium chloride, so if the substances in question need a stronger interaction to be retarded on the column than can be achieved by almost saturated sodium chloride, ammonium sulphate is a natural choice. Using ammonium sulphate extends the range of HIC to be used for the separation of less hydrophobic molecules.

In production-scale operations, the use of ammonium sulphate has been questioned because of the effect the nitrogen of used buffers may have on the environment by increasing the overnutrition. The choice between overnutrition and possible toxic effects of substitute buffers such as sodium sulphate may not be easy, and all the factors, from the conveniency of the separation procedure to the cost of purifying the sewage, will have to be considered.

Buffer Ions

Recently, it has been shown that the choice of buffer ions greatly influences the function of an HIC medium (32,36). The overall behavior of a buffer-ligand-spacer-matrix system could be switched in a wide range, such as from typical phenyl-like to typical butyl-like or vice versa, by just changing the buffer ions. Optimization work by testing different buffers might then be more beneficial than usually anticipated but, as with pH, the task still includes much work based on trial and error.

pH

It has been shown that hydrophobic interaction between proteins and an octyl gel generally increases with lowered pH and most often decreases with high pH, but the pH dependence in this case is not very profound from pH 6 to pH 8.5. For some proteins, though, the interaction increases with an increase in pH (21). One reason for the different results might be that sodium sulphate was used above pH 8.5 and ammonium sulphate buffer was used below pH 8.5. According to Oscarsson and Kårsnäs (32), the adsorption behavior of serum proteins on octyl gel is quite different in the two environments. The reason for this complexity again has certainly to do with the multimechanism nature of HIC, with irregularities implied by different kinds of interactions between buffer ions and protein surfaces (18) and thus, secondarily, interaction with the HIC matrix.

In practice, changes in pH to get a desired separation can be very powerful because it may alter the entire adsorption spectrum, but, because of the trial-and-error nature of the task, pH is not the primary parameter to use for an optimization.

Temperature

High temperature promotes the binding, and HIC is preferably run at room temperature if the compounds to be separated can withstand this condition without losing activity (4,7,37,38). In room temperature, slightly lower buffer concentrations can be used than if the separation is made in a cold room. Elution of hardly bound substances

may also be facilitated by performing the elution step at cold room temperature. In practice, however, the increase of temperature at the reequilibration of the column in room temperature inevitably produces air bubbles that will destroy the packing of the column, so if a two-temperature scheme is chosen, repacking of the column will most certainly have to be included in the separation cycle.

Flow, Residence Time

Hydrophobic interaction shows signs of being a slower process compared to other interactive chromatography techniques. The desorption of compounds from the column is often run under nonequilibrium conditions, resulting in long tailing peaks that seriously damage the resolution.

It is also generally found that the adsorption of molecules sometimes seems to be a two-step reaction, where the initial binding is weaker and more readily broken under the elution conditions. After some time the bound molecules seem to adapt themselves to the column, possibly involving conformational changes (39). More harsh conditions may have to be introduced for the elution, and there is a risk that the recovery will decrease. On the other hand, there are reports showing that an elution pattern can be quite reproducible even when the bound substances have been immobilized on the column for a long time (21), and HIC is generally considered a high-recovery technique (40).

Elution

Generally, elution of substances bound to an HIC column can be achieved by altering one of the parameters that promote binding. It is possible to elute by increasing pH, if the adsorption was performed at low pH, or by lowering the temperature, although the effect of this may be too small. But most commonly, elution is performed by a descending salt gradient or, in large scale, by stepwise lowering of the salt concentration (5,14).

If substances remain on the column at very low buffer concentration, an organic additive such as ethylene glycol or a detergent can be used for the elution. The ethylene glycol will alter the water structure and weaken the hydrophobic interaction, and the detergent will act by competing with and displacing the protein on the chromatographic medium.

REGENERATION AND CLEANING-IN-PLACE

For process economy, the regeneration of the HIC column is essential. Fouling of the column and irreversible binding of contaminants to the column are common obstacles in HIC. There are three degrees of regeneration: removal of strongly bound or precipitated proteins, removal of hydrophobic substances like lipids and lipoproteins, and sanitation, which means removal or deactivation of microorganisms. Preferably, the regeneration is performed as a cleaning-in-place (CIP) procedure without costly and cumbersome repacking of the column. All washing steps should be performed with reversed flow to give the contaminants the shortest distance out of the column and avoid secondary interaction with the rest of the column. First, all conditions that will decrease possible hydrophobic interaction can be used for the regeneration. Detergents that will compete with the attached substances and ethanol and isopropyl alcohol, buffers normally used in RPC, are obvious choices NaOH, 0.5 to 1 M, has been shown to almost universally sanitize the column and has a good cleaning ability as well. It is important to note that washing with narrow zones of the washing solution is often more effective in removing the column contaminants than exposing the medium for a constant concentration of the washing agent for an extended time. It is not unusual when cleaning HIC media that material will be washed out both in the beginning and at the end of a washing zone where the concentration is increasing and decreasing, respectively. Probably, a lot of equilibria are present, including hydrophobic interaction and interactions involving charges, and if one type of binding is minimized another may be enhanced and keep the contaminants on the column. By wobbling the concentration, the differences of reaction velocities are probably utilized, with elution as the result.

OPTIMIZATION PROCEDURES

Although all the parameters mentioned above can be used to optimize a hydrophobic interaction chromatography step, for many of them the effect of a change is not easy to predict because it will also be dependent on the individual properties of the proteins subject to separation. Thus, a pH change may alter the entire elution pattern or just influence the binding of a single component. Other parameters that may change the entire interaction picture are the buffer ions and the chosen chromatography medium.

Choice of Medium

Ideally, it is preferable that the desired components attach to the medium under moderate salt concentrations (e.g., up to 1 M ammonium sulphate), and a screening of the most common commercially available media is always advisable. This screening is easily performed in small scale and should include a test of whether elution with a high recovery is possible with water or weak buffer. If a lower salt concentration is sufficient on a certain gel, this is a preferable choice for economical and environmental reasons provided that the resolution obtained is still acceptable.

Determination of the Starting Buffer Concentration

An HIC run is normally performed by equilibrating the column in a starting buffer, applying the sample, and eluting with a stepwise descending ionic strength or a descending continuous gradient.

Optimizing the starting concentration, or the concentration at which the proteins are adsorbed to the column, is important to really utilize the HIC step (Fig. 5). In laboratory scale and analytical experiments, where the resolution can be achieved by gradient elution, the ionic strength should be high enough to retard the desired component and to let it elute somewhere in the middle of the

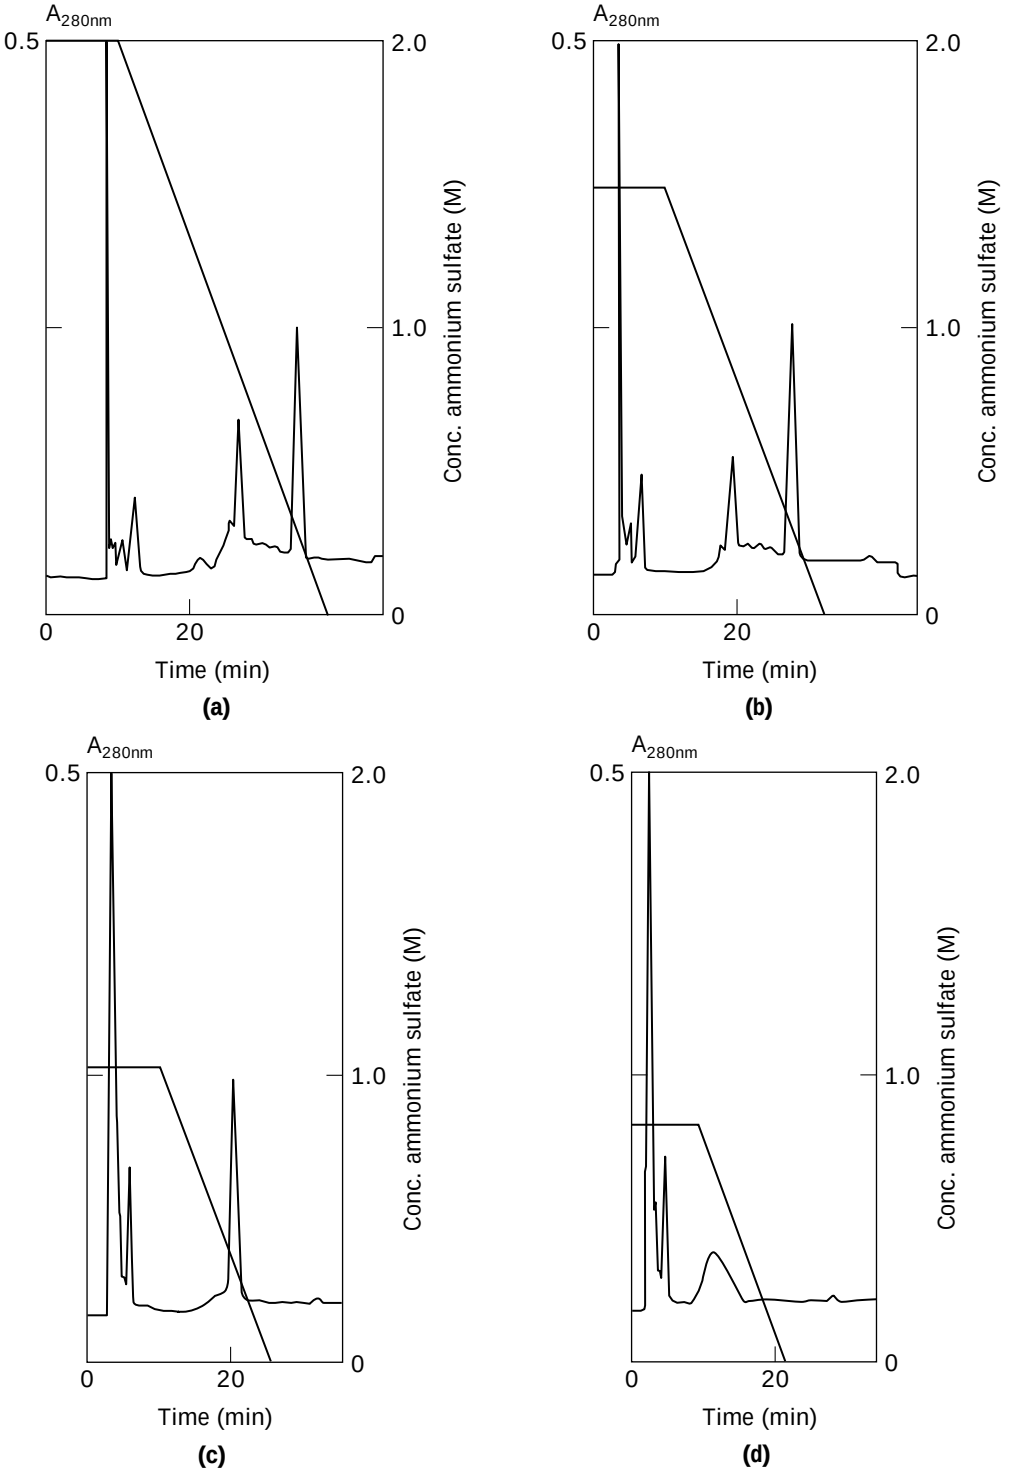

Figure 5. The effect of starting concentration. 100 μL anti-CEA MAB (−IgG1) from mouse ascites fluid, in 0.8 M $(NH_4)_2SO_4$ (AS), applied to an Alkyl Superose HR 5/5 column with a flow rate of 2.5 cm/min. The different concentrations of AS in the initial buffer were mixed in 0.1 M sodium phosphate, pH 7. (**a**) The sample is applied in 2 M AS. Both albumin and IgG are accumulated on the column. (**b**) The sample is applied in 1.5 M AS. Less albumin is bound, which indicates a weaker interaction and less binding capacity. (**c**) In 1 M AS only IgG is binding, and (**d**) in 0.8 M AS the IgG is still retarded but eluted in a broad peak. *Source*: Figure reprinted from ref. 17 by kind permission of Pharmacia Biotech, Uppsala, Sweden.

descending gradient. In this way, the combination of the capacity for the component of interest and the resolution will be favorable. In large-scale runs, well-defined and reproducible gradients are more difficult to achieve, so the elution is preferably done by stepwise decrease of the ionic strength. In some cases, it will work beautifully to chose an ionic strength that is just enough to retard the substance of interest, but in other cases, the peak containing the desired substance will broaden unacceptably at this condition, and the salt concentration will have to be increased (Fig. 5).

Gradient Volume

A gradient volume between 5- and 10-column volumes will give enough resolution in most cases. By increasing the gradient volume, the resolution will increase, but the components will be eluted in a larger volume.

Selectivity of the On and Off Reactions

It is often found that the reaction of binding to the column is rather rapid and selective, whereas the elution of a compound from the column is slower. As a result of this, tailing of zones at elution is very often experienced and the resolution of substances is jeopardized. A way of optimizing a method fully, utilizing the selectivity of the adsorption, is to use the following scheme:

1. Equilibrate the column with a starting buffer that has a lower concentration than is needed to retard the desired substance, adjust the sample accordingly, and run it through the column.
2. Elute everything that was retarded on the column with water or low salt. Check for activity.
3. Add some salt to the buffer and the sample and repeat steps 1 to 3 the desired substance is eluted from the column. To speed up the procedure, a prerun with a gradient starting at high salt concentration will hint at a proper initial concentration when step 1 is run the first time.

An optimized separation scheme includes as its first step running the column in a salt concentration just below the one where the desired substance was found to be retarded. All impurities that bind harder than the desired substance attach to the column and should be eluted. The next step is to bind the desired substance using a slightly higher salt concentration. If this is done carefully, very few contaminants will bind, and subsequently the desired substance can be eluted in high yield by a steep descending gradient, if any contaminating substances were retarded as well, or by a step of very diluted buffer. The described method is advantageous not only because the selectivity of the interaction is fully utilized but also because of the simplicity to recondition sample and buffers by just adding salt. Moreover, the capacity of the column is utilized to bind mostly the compound of interest and very little contaminants. A drawback may be that the capacity of the column for the substance of interest might be lower be-

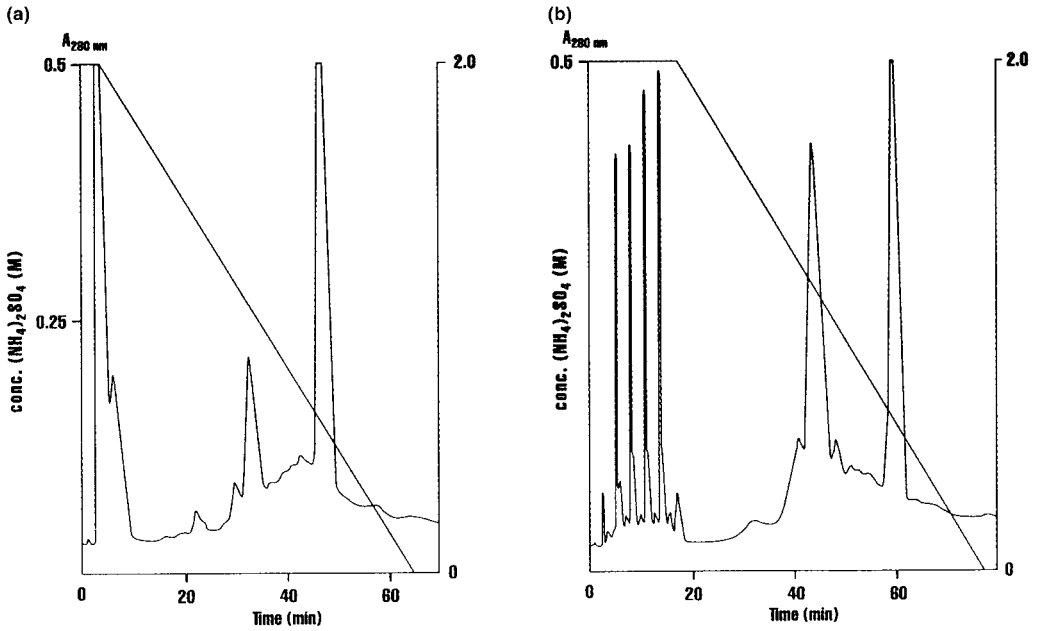

Figure 6. The effect of the suggested method of injecting the sample in diluted aliquots intermissioned by zones of concentrated buffer. In (**a**) 500 μL anti-CEA MAB (−IgG1) from mouse ascites fluid, in 0.9 M $(NH_4)_2SO_4$ (AS), was injected on a column equilibrated in 2 M AS in 0.1 M sodium phosphate, pH 7. In (**b**) the same sample was injected in 100 μL aliquots. 1.3 mL of 2 M AS were injected between every injection of sample. The capacity of the column was fully utilized without the risk of precipitating the sample in tubings and adapters. *Source*: Figure reprinted from ref. 17 by kind permission of Pharmacia Biotech, Uppsala, Sweden.

cause the binding is taking place near the elution concentration.

Equilibration of the Column and Sample Application

There is always a risk that the high salt concentration needed to attach the sample to the column will cause precipitation in tubings, pumps, columns, and detectors. This may be prevented by the following scheme: The column should be equilibrated with the proper buffer concentration but the sample with slightly lower salt concentration. This is easily accomplished by dilution of the sample. Instead of injecting the whole sample volume at one time, the injection should be done in aliquots divided by zones of the equilibration buffer. If the volume of the aliquots is kept less than 10% of the column volume and the volume of the intermediate zones with full buffer concentration exceeds 10% of the column volume, the sample condition will adapt to that of the equilibrated column. In this way, the precipitation in wrong places is avoided and the interaction with the column is still taking place in the correct environment (Fig. 6).

Scaling-Up

To get a similar result in large scale as in laboratory scale, it is important to keep some parameters constant. The column length, the linear flow, and the ratio between gradient and column volumes belong to this category. A constant column length leads to the fact that the desired capacity will be proportional to the cross-sectional area of the column and actually decide it, because the same proportion of the column length should be occupied by the sample in both scales.

Because of the relationship between the volumetric flow, the linear flow, and the cross-sectional area of the column on one side and the gradient-to-column-volume ratio on the other side, the gradient volume will be decided when the diameter of the column is set. In principle, a gradient elution in process scale will then take the same time as in laboratory scale. In practice, a decrease in resolution caused by a more ineffective solvent distribution system at the inlet of a process scale column will sometimes have to be compensated for by a lower flow.

APPLICATIONS

HIC has been used for the purification of serum proteins (41,42), nuclear proteins (43), membrane-bound proteins (44), and viruses and cells (45), and recombinant proteins (46) and insulin receptors (47) have been successfully prepared. Interesting applications include the use of HIC media as biochemical reactors by coupling enzymes by hydrophobic interaction (48) and a method for the exchange of detergents bound to membrane proteins (18).

For further applications and more discussion about large-scale processing using HIC, the works by Pharmacia Biotech and Eriksson (17,18) are recommended.

Preparative chromatography

OUTLINE

INTRODUCTION

Preparative ion exchange chromatography is a technique for separating biomolecules based primarily on their electrostatic interactions with charged stationary phase materials. This technique is the most widely employed chromatographic separation technique in the biotechnology industry today. It is used for both capture and high-resolution separations. The last decade has seen dramatic advances in the state of the art of chromatographic bioprocessing with ion exchange materials. This article presents recent advances in resin materials, modes of operation, and modeling.

BACKGROUND

Ion exchange chromatography (IEC) is the most widely employed chromatographic separation technique in the biotechnology industry today. It is based on the principle of electrostatic interactions between charged surfaces. In IEC, one employs a charged stationary phase material to separate oppositely charged solutes. Cation exchange employs a negatively charged surface to separate positively charged solutes, and anion exchange employs a positively charged surface to separate negatively charged solutes. The binding of solutes to ion exchangers may be viewed as an exchange process in which the solutes compete for binding with salt counterions and other charged components in the mobile phase.

This article focus on preparative protein separations in ion exchange systems, beginning with a brief discussion of various factors that affect protein retention (e.g., pH, ionic strength, mobile phase modifiers). A detailed treatment of the state of the art of stationary phase materials is then presented. A description of different modes of preparative IEC is given, along with separation examples from the literature. Finally, the modeling of preparative ion exchange is addressed.

Factors Affecting the Ion Exchange of Proteins

pH of the Mobile Phase. Proteins are ampholytes, possessing both negative and positive surface charges. In fact, the zwitterionic nature of proteins is what makes ion exchange such a powerful tool for these separations. The charges on the proteins arise because of the presence of acidic and basic amino acid residues on the protein surface as well as the amino and carboxyl termini of the protein.

Thus, the net charge on a protein is a strong function of the pH of the solution. Under acidic conditions, the basic side chains are charged, under basic conditions, the acidic residues will be charged. At the isoelectric point (pI), the net charge on the protein will be zero. In general, when the pH of the mobile phase is greater than the pI of the protein, the protein will have a net negative charge and will be retained on an anion exchanger. On the other hand, when the pH of the mobile phase is less than the pI of the protein, the protein will have a net positive charge and will be retained on a cation exchanger. It turns out that the net charge of the protein is not the sole determinant of its retention (1). The distribution of charges on the surface of the protein is also important. The protein may have patches of positively or negatively charged residues that may interact with the stationary phase even when its net charge is zero. Furthermore, the microenvironment pH often can differ slightly in the resin and bulk solutions. Thus, a protein may be retained even at its pI. In addition, it is important to consider protein solubility constraints in the development of an ion exchange separation, since proteins are sparingly soluble near their isoelectric point. In practice, to prevent protein denaturation, the operating pH in IEC is limited to the range 2–9.

The choice of buffer to establish the operating pH is of paramount interest in ion-exchange chromatography. It is desirable to employ a buffering agent that has the same charge as the stationary phase material or is neutral. This precludes the binding of these ions onto the stationary phase and thus prevents pH shifts within the column. Hence, it is desirable to use cationic buffers (e.g., alkylamines, Tris, aminoethyl alcohol) in anion exchange chromatography and anionic buffers (e.g., phosphate, acetate, citrate, barbiturate) in cation exchange chromatography.

Ionic Strength. The chromatographic retention of proteins is modulated by the ionic strength of the mobile phase. In cation exchange systems, the relative strength of cations is as follows (2): $Ba^{2+} > Pb^{2+} > Sr^{2+} > Ca^{2+} > Ni^{2+} > Cd^{2+} > Cu^{2+} > Co^{2+} > Zn^{2+} > Mg^{2+} > Ti^{2+} > Ag^{+} > Cs^{+} > Rb^{+} > K^{+} > NH_4^{+} > Na^{+} > H^{+} > Li^{+}$. In anion exchange, the relative strength of anions is citrate > sulfate > oxalate > I^{-} > nitrate > CrO_4^{2-} > Br^{-} > SCN^{-} > Cl^{-} > formate > acetate > OH^{-}.

Thus, Br^{-} will bind stronger than Cl^{-} in an anion exchange column. In cation exchange, an equivalent solution of KCl would elute a protein faster than NaCl. Continuous and step gradients of ionic strength are often employed to effect protein separations. While protein retention is generally reduced as the ionic strength is increased, at very high ionic strength (>1 M), hydrophobic interactions can become pronounced.

Mobile Phase Modifiers. Addition of modifiers to the mobile phase can often influence the selectivity of a given separation. Recently, Gagnon *et al.* (3) reported an enhancement of the selectivity of proteins on the addition of poly(ethylene glycol) to the mobile phase. Other additives include chelating agents such as EDTA (to protect enzymes against metal impurities), reducing agents (e.g., dithiothreitol) to retard oxidation, and surfactants and chaotropic agents (e.g., urea) to solubilize membrane proteins (4).

Temperature. There are conflicting reports in the literature on the effect of temperature on resolution and band broadening. Increasing the temperature may reduce the viscosity of the mobile phase and increase the kinetics of the adsorption process. This may result in more efficient separations. However, changes in the temperature may also induce conformational changes in the protein. This may denature the protein or expose more hydrophobic patches to the stationary phase, enhancing nonspecific interactions and causing dramatic increases in protein retention (5). In general, the practice in industry is to employ either room temperature or low temperatures (4 °C) to minimize protease activity and to ensure protein stability.

STATIONARY-PHASE MATERIALS

The stationary phase is of paramount importance in IEC. Ideally, the stationary phase should be rigid enough to withstand high flow rates, provide sufficient selectivity and capacity for the problem at hand, and not denature the protein of interest. Furthermore, it should be stable over a wide range of operating conditions (pH, solvents, etc.) and amenable to rigorous cleaning-in-place with acid or alkali. The choice of the manufacturer is also important (6). The manufacturer should be able to ensure a regular supply with little lot-to-lot variation. Finally, the resin should not leach materials into the process stream.

Selectivity in ion exchange materials is affected by the ligand density, spacer arm chemistry, and the backbone resin material. Unfortunately, state-of-the-art chromatographic modeling cannot a priori predict the selectivity of different resin materials for various classes of separation problem. Thus, selection of an ion exchange resin is problem specific and requires the screening of a large variety of materials for a given separation. In bioprocessing applications, IEC is used for both capture and high-resolution separations. Capture applications demand that the resin possess sufficient dynamic capacity and be rigid enough to allow operations at high flow rates. On the other hand, selectivity is paramount for high-resolution separations.

Particle Size

While reversed-phase chromatography often employs materials of relatively small particle diameter for preparative applications, stationary-phase materials of 30- to 200-μm diameter are typically employed for preparative IEC. Higher resolutions can be achieved with smaller particles at the cost of increased backpressure. Finally, the size of the particle can also influence the mode of packing (7).

Ion Exchange Functional Groups

The stationary phase of an ion exchanger consists of a base matrix that is functionalized with basic (anion exchange) or acidic (cation exchange) groups. The charge on the stationary phase is pH dependent. This pH dependency allows one to categorize ion exchange stationary phases into

strong and weak exchangers. Strong ion exchangers retain their charge over a very wide range of pH, whereas weak ones do so over a narrower range of pH. Thus, the capacity of weak ion exchangers is a function of the pH. Typically, strong exchangers have functional groups with very low pK_a (sulfopropyl in cation exchange) or very high pK_a (quaternary amino–type anion exchangers). Table 1 lists some of the functional groups commonly employed in ion exchange stationary phases and their corresponding pK_a values (8,9).

Capacity and Porosity

The capacity of the ion exchanger can be measured as both the total number of charges per unit stationary-phase volume or the mass of protein adsorbed per unit volume. When one is determining protein-binding capacity, it is important to ensure that the activity of the adsorbed protein is not compromised. The capacity expressed in terms of adsorbed protein is the effective capacity of the column. It is dependent on both the specific protein and the operating conditions (pH, ionic strength). It is also dependent on the pore size and the porosity of the particles. If the particle is pellicular (i.e., not porous), the surface area is relatively low, resulting in reduced capacity. On the other hand, if the particle is highly porous, the capacity increases, but the resistance to mass transfer also increases. Pores that are too small may be inaccessible to the proteins. The pore size distribution is usually unavailable, and a nominal pore size is supplied by the manufacturer.

Conventional ion exchange media have nominal pore sizes between 100 and 1,500 Å. At times, the pore size is also specified as the molecular weight of the largest globular protein that can be accommodated in the material.

Novel and Traditional Matrices

Table 2 lists representative resins available in the market today along with their manufacturers and trade names. As seen in the table, the resins can be roughly divided into five categories. Polysaccharide gels have been in existence since the 1950s (10). These matrices are inert toward proteins, can be easily derivatized, have very high capacities, and are stable over a wide range of pH values. Polysaccharide gels based on weakly cross-linked agarose, dextran, or cellulose have weak mechanical properties and are limited to low-pressure regimes. In contrast, Sepharose® Fast Flow ion exchangers (Pharmacia) are composed of a higher degree of cross-linked agarose, which increases their mechanical stability. High-performance polysaccharide materials (Pharmacia) are also available in relatively small particle diameter (34 μm) and have been shown to be particularly useful for difficult high resolution separations. These polysaccharide-based resins are currently the most widely employed chromatographic materials in the biopharmaceutical industry.

Although silica-based ion exchangers have good mechanical properties, they are not as widely used for bioprocessing because their instability under alkaline conditions precludes alkaline cleaning. Furthermore, surface silanol and siloxane groups can have adverse effects on proteins (11). To overcome this problem, silica supports have been coated with a polymeric layer (12).

Resins based on porous particles of zirconium oxide have been synthesized and characterized for biochromatography (13). Zirconia possesses all the mechanical advantages offered by silica. In addition, it has good thermal and chemical stability. Unfortunately, this backbone material tends to bind proteins, which necessitates coating with a biocompatible layer. Clausen and Carr (14) recently employed a phosphonate analog of EDTA for the modification of zirconia supports to provide a biocompatible stationary phase. As described shortly (see "Dynamic Capacity"), a potential advantage of zirconium is its relatively high density, which has been shown to have potential for expanded-bed applications (15).

The polymer-based matrices (16) have good mechanical properties and are stable over a wide pH range. Furthermore, they have a relatively high loading capacity because of their macroporous structure. The hydrophobic polymer matrices are typically coated with a hydrophilic polymer to reduce nonspecific interactions. Polymeric supports are being used increasingly in the preparation of ion exchangers for bioprocessing (17). In addition, many of the novel materials described below are based on polymeric supports.

The penultimate category of particulate ion exchangers in Table 2 is entitled "Novel" media. Each of the stationary phases in this category possesses unique features that distinguish it from more traditional materials. The POROS® supports are synthesized by a suspension polymerization process. These chromatographic materials consist of a rigid polystyrene–divinylbenzene base matrix covered with a polyhydroxyl layer that can be further derivatized to produce various functional groups (18). This type of resin belongs to the class of particles termed "perfusive" (19,20). Such particles have a bimodal pore distribution containing macropores (6,000–8,000 Å) that transect the particle and interconnecting "diffusive" micropores (500–1,500 Å). The macropores facilitate mass transport, while the diffusive pores increase the available surface area. Their permeability has been shown to be independent of

the particle size (21). The solute breakthrough curves for the POROS media have been shown to be relatively unaffected by the flow rate in contrast to conventional ion exchangers (20). Gerstner et al. (22) have demonstrated that displacement chromatography of proteins can be carried out on these particles at very high linear velocities. The SOURCE™ materials have also been shown to exhibit chromatographic behavior that is independent of flow rate. In addition, the SOURCE™ resins have relatively high efficiency owing to their monodisperse particle size distribution. Recently, the development of agarose-based perfusive materials has also been reported (23).

Hyper-D® materials are composite stationary phases composed of a rigid macroporous support filled with a weakly cross-linked ion exchange gel. The rigid particle provides the necessary mechanical strength for high flow rate operations, while the soft gel provides high binding capacity. The equilibrium uptake of model proteins and the mass transfer rates in Q-Hyper-D® has been studied by Fernandez and Carta (24,25). These materials have a very high binding capacity even at elevated flow rates. In fact, it has recently been shown (26) that large-particle-diameter Hyper-D® materials (200 μm) also exhibit high binding capacities even at elevated linear velocities. It has been proposed that the mass transport mechanism in these materials is surface diffusion due to the high concentrations obtained in the gel (25).

The "tentacular" stationary phases comprise another novel sorbent (27). These chromatographic materials have polyelectrolyte chains (typically 5–50 monomers long)

grafted onto porous matrices. In contradistinction to the supports mentioned thus far, the charge moieties in tentacular phases are attached to the matrix via relatively long, flexible spacer arms. This results in reduced nonspecific interactions between the proteins and the base matrix. Furthermore, since the ligands are able to move relatively freely in space, they can explore the steric distribution of charges on a protein in a more efficient manner. This can potentially result in higher-resolution separations. Tentacular ion exchangers have been employed to differentiate between native and deamidated recombinant human DNAse which differ in a single surface charge (Fig. 1) (28).

Dynamic Capacity

The dynamic capacity of the column is the effective capacity determined from the breakthrough curve (i.e., when the effluent concentration reaches 10–50% of the inlet protein concentration). Table 3 lists the dynamic capacities of several anion exchange media obtained at low linear velocities; these capacities are seen to range from 30 to 165 mg/mL. The cellulosic anion exchangers such as Sepharose® Fast Flow have high dynamic capacities under these conditions. Importantly, dynamic capacities can be strongly affected by the flow rate. In Figure 2, which compares the flow rate dependence of the dynamic capacities of five Q exchangers, the dynamic capacities of the tentacular (Frac-

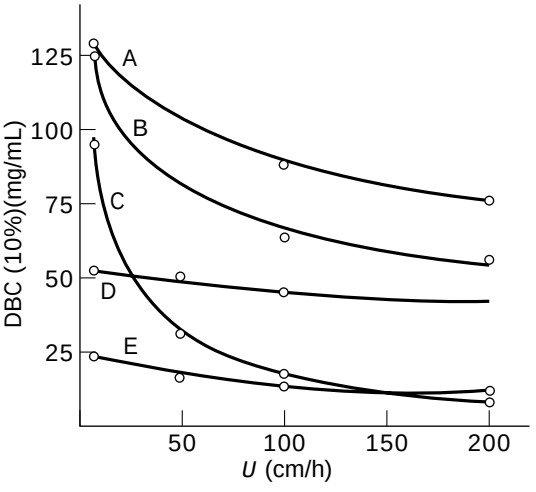

Figure 2. Variation of dynamic binding capacity (DBC) as a function of the flow rate (*U*) for Q anion exchangers. Determination of DBC were performed using breakthrough curves (10%) with a column of 1 cm i.d. containing 4 mL of sorbent. Protein solution was bovine serum albumin at 5 mg/mL in 50 mM Tris–HCl buffer (pH 8.6): A, Q HyperD F; B, Super Q; C, Q Sepharose Fast Flow; D, Q Fractogel EMD; E, Q POROS. *Source*: Reproduced with permission from Ref. 8.

togel EMD) and perfusive (POROS®) resins are relatively low at low flow rates, but their dependence on the flow rate is rather weak. On the other hand, the dynamic capacity of the Sepharose® FF resin exhibits a stronger dependence on the flow rate. The Hyper D® and the Super materials exhibit a moderate flow rate dependence. However, the Hyper D® material has a capacity substantially higher than those of the other materials at elevated flow rates. An important caveat to this discussion on dynamic capacity is that it is often desirable to use low operating pressures in a bioprocessing environment. This practice may affect the linear velocities that can be employed under actual operating conditions and may make performance at elevated velocities less important.

An important recent advance in the state of the art of chromatographic bioprocessing is the development of expanded-bed systems, in which the bed expands during the loading phase, enabling it to directly process unclarified feedstock. This can potentially obviate the need for membrane or centrifugal processing prior to the ion exchange capture step. A schematic of the basic principles of expanded bed adsorption is shown in Figure 3. The Streamline adsorbent, which has a mean particle size of approximately 200 μm, is a specially designed stationary phase for expanded-bed chromatography. It is stable over a wide pH range but unstable in solutions containing oxidizing agents. Accordingly, in situ sterilization may be a problem with these sorbents. Streamline forms a stable expanded bed without the need for external magnetic fields. Its capacities are lower than those of typical commercial adsorbents such as Sepharose FF and Spherodex (29,30). This may be due to the presence of the quartz core, which provides the necessary particle density but reduces the available surface area. The performance of this sorbent has been shown to be similar in packed-bed and expanded-bed modes (29), indicating that the expanded-bed mode behaves like a packed bed with increased voidage.

In addition to the commercially available Streamline material, several other expanded-bed supports are in development. Flickinger and Carr (15) are exploring the potential of zirconia stationary phases for expanded-bed applications. These materials have the desirable property of having sufficient density without further modification. Gilchrist et al. (30) synthesized a polysaccharide–ceramic composite sorbent for use in expanded-bed chromatography. Thommes et al. (31) derivatized Bioran (controlled pore glass) with sulfonic acid residues. These particles compared well with Streamline media in initial evaluations.

Principles of expanded-bed operation: **1**, sedimentation of adsorbent, **2**, upward flow of equilibration buffer resulting in a stable expanded bed, **3** application of unclarified feed by upward flow, and **4**, downward flow of the eluent to elute the bound protein of interest. *Source*: Adapted from Pharmacia catalog.

Membrane Adsorbers

In contrast to all the chromatographic supports discussed thus far, an alternative approach to ion exchange is the use of charged membrane systems. Mass transfer in membrane exchangers is typically dominated by convection, which enables these systems to be operated at relatively fast linear velocities resulting in high throughputs. The typical configuration of membrane ion exchangers is the "pancake" configuration, which has a large width-to-length aspect ratio that provides higher surface areas and lower backpressures. The principal disadvantage of these configurations is the difficulty of achieving a uniform inlet flow distribution and collection of the eluate with minimal backmixing.

Monoclonal antibodies and human recombinant antithrombin III were subjected to preparative purification on Sepharose® FF columns and Sartobind units (32). The membrane exchanger yielded higher throughputs (>13-fold in the case of monoclonal antibodies) and comparable or higher recoveries. However, higher concentration factors were achieved on the Sepharose columns. An extensive review of the state of the art of membrane chromatography can be found in Ref. 33.

Regeneration, Cleaning-in-Place, and Sanitization

A critical issue in ion exchange bioprocessing is the ability to clean the column. This includes column regeneration (between each separation cycle), cleaning-in-place operations (after every 1–10 cycles), and sanitization (between batches). Any commercial ion exchange material must be stable enough to withstand high pH as well as oxidizing conditions.

Column regeneration and cleaning-in-place operations are important for establishing long-term use of ion exchange columns. The conditions are usually determined empirically and are strongly affected by the feed composition. Typical conditions include high salt (1 M NaCl) and/or 1 M NaOH. A complete list of regeneration protocols can be found in Ref. 34. The monograph by Sofer and Nystrom (35) offers a more detailed discussion of column maintenance procedures.

In situ sanitization of the column is necessary to prevent microbial contamination between batches. Formalin, peracetic acid, and sodium hypochlorite are effective chemical disinfectants. Alkaline solutions of ethanol are effective for spore destruction. Clearly, the stability of the resin must be kept in mind when the sanitization conditions are chosen. A recommended validation protocol for the in situ sanitization of an ion exchanger is outlined in Ref. 34.

Relative Efficacy of Resin Materials

In process chromatography, it is important to distinguish between initial capture (recovery) and high-resolution or polishing steps. For product recovery, the capacity and production rate are paramount. In addition, it is often necessary to process large volumes of relatively dilute feedstock, which often contain particulates. It is precisely this challenge that has catalyzed the development of many of the "novel" materials described above. The advantage of perfusive-type materials (e.g., POROS®) and membrane chromatography is that they can be operated at high linear velocities. However, these materials often have relatively low capacities. While the problem can be overcome by carrying out many column cycles for a given batch, this approach has not been widely adopted by the industry. Composite stationary phases (e.g., Hyper-D®) possess high binding capacities and can be operated at reasonably high flow rates without a drastic loss of dynamic capacity or increased backpressure. This makes their use for capture operations potentially very attractive. Expanded-bed sorbents are particularly attractive for capture operations because they combine clarification, concentration, and capture into a single step. It turns out that the stability of expanded beds is quite sensitive to such factors as the solids content, pH, ionic strength, and viscosity of the feed (36). Since the effect of these factors has not been fully elucidated, the choice of the mobile phase conditions in expanded-bed applications will be highly problem specific. Nevertheless, expanded-bed chromatography has generated tremendous interest from the industry.

As mentioned in the beginning of this section, the effect of stationary phase chemistry on selectivity is still unpredictable, and the selection of an ion exchange resin is problem specific. Recently, Levison et al. (37) evaluated the functional and physical performance of a range of ion exchange media based on polysaccharide and polymeric or composite materials. Although the data suggest significant differences in the performance of various media for a common set of criteria, the selection of an ion exchanger remains problem specific. Thus, until the state of the art of chromatographic modeling is further improved, the biochromatographic engineer is left with the daunting task of screening a large variety of materials for a given separation. Fortunately, there are several automated chromatographic workstations that can readily screen a large number of resins in a relatively short period of time. Once the resin with the optimal selectivity has been identified, the task remains to develop an efficient, high-throughput chromatographic process. This requires the selection of the appropriate mode of operation.

MODES OF COLUMN OPERATION

Preparative ion exchange can be carried out by means of a variety of resin materials, column configurations, and modes of operation. While the selection and development of resin materials often receives significant attention, the choice of the proper mode of operation is often given less attention. In fact, the selection of the optimal mode of operation for a given bioseparation problem can have a profound effect on the production rate, yield, and purity for that separation. To date, linear gradient or step gradient modes have been used to carry out most industrial chromatographic bioprocessing. This section briefly describes these gradient modes and presents examples from the recent literature. In addition, the displacement and chromatofocusing modes of operation are discussed.

Step Gradient

Step gradient is often employed for initial capture or recovery operations where the primary objective is to recover and to concentrate the bioproduct of interest. This operation is usually carried out in short, large-diameter columns packed with relatively large-particle diameter stationary-phase materials (>90 μm). This mode of chromatography consists of first loading the column with a large volume of low ionic strength feed solution, followed by a wash step, and finally an elution step based on an elevated salt and/or modified pH eluent. This type of chromatography can be characterized as essentially an on/off operation. The most important stationary-phase characteristic in preparative step gradient chromatography is the dynamic capacity of the resin. Thus, these separations do not require very efficient columns and can be readily carried out in short "pancake"-type columns. These capture steps can be carried out by means of conventional packed-bed columns or with "expanded-bed"-type configurations. As described earlier, it is important to screen a wide variety of ion exchange resins to identify a material that has sufficient selectivity and capacity for a given separation. Several examples of step gradient ion exchange chromatography are now presented.

The use of an expanded bed in the pilot-scale recovery of the anticoagulant recombinant Annexin V from unclarified *E. coli* homogenate has been reported (36). The optimal binding and elution conditions for Annexin V were determined in a 1.6 cm × 20 cm packed bed of Streamline DEAE adsorbent using clarified homogenate. Then 1.7 L of unclarified homogenate was applied to the laboratory-scale Streamline 50 column (5 cm × 100 cm, Streamline DEAE adsorbent) under the mobile phase conditions established with the small packed bed. The protein was eluted using a 250-mM step gradient of NaCl. The elution was carried out in the sedimented mode at a mobile phase velocity of 100 cm/h. The results were very similar to those obtained with the small packed bed. The presence of cell debris did not seem to affect the process. The biomass dry weight and the viscosity of the homogenate were 3.6% and 10 mPa/s, respectively.

Finally, the process was scaled up to a pilot-scale expanded bed: Streamline 200 (20 cm × 95 cm, Streamline DEAE adsorbent). The adsorbent volume, feed volume, and flow rate were scaled up by a factor of 16 to account for the increased diameter of the column, resulting in a feed load of 26.5 L. The rest of the conditions were kept the same. Figure 4 shows the chromatogram from the pilot-scale recovery of the protein. Yields greater than 95% were obtained with both the Streamline 50 and Streamline 200 columns. The expanded bed was cleaned after each run using 0.5 M NaOH with 1 M NaCl followed by distilled

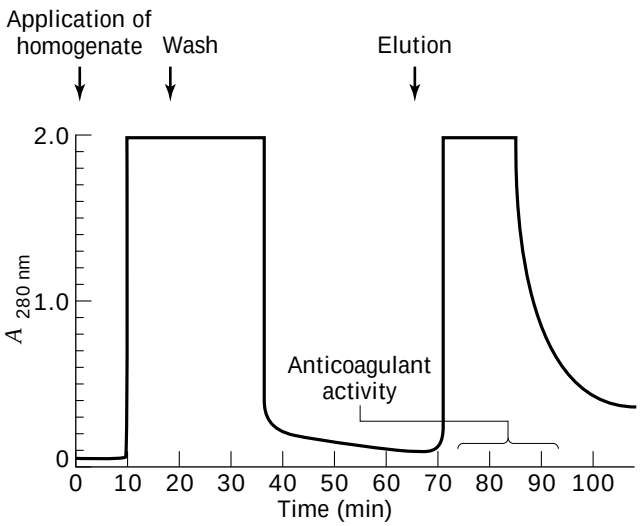

Figure 4. Chromatogram from pilot-scale, expanded-bed recovery of recombinant Annexin V from unclarified *E. coli* homogenate: feed, 26.5 L of unclarified *E. coli* homogenate in 30 mM ammonium acetate (pH 5.5); column, Streamline 200 with Streamline DEAE adsorbent; elution with 30 mM ammonium acetate (pH 5.5) containing 250 mM NaCl; flow rate: upward flow at 300 cm/h during application and wash and downward flow at 100 cm/h during elution. *Source*: Reproduced with permission from Ref. 36.

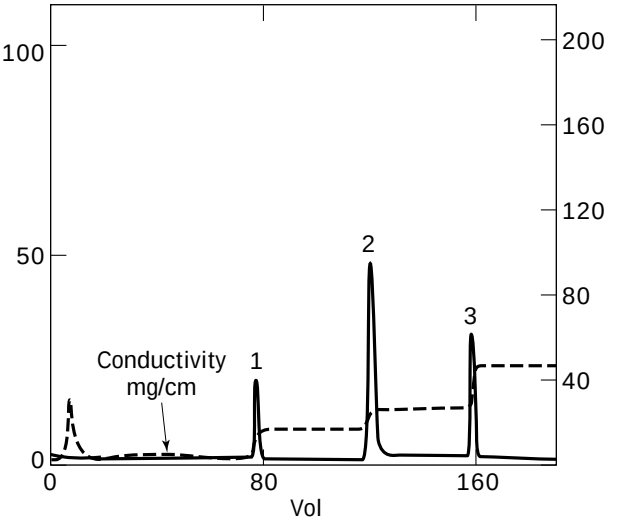

Figure 5. Purification of *Pseudomonas aeruginosa* exotoxin A on Q Sepharose HP (10 cm × 10 cm i.d.): buffer, 20-mM Tris, 1-mM EDTA (pH 7.4). Gradient program, first step salt concentration, 0.15 M NaCl (5 column volumes); second step salt concentration, 0.25 M NaCl (5 column volumes); final step salt concentration, 0.5 M NaCl (5 column volumes). *Source*: Reproduced with permission from Ref. 38.

water, 30% isopropanol, and 25% acetic acid. This example illustrates the potential of expanded-bed chromatography for ion exchange step gradient chromatography.

The use of step gradient in the production and purification of *Pseudomonas aeruginosa* exotoxin A (PE) from *E. coli* has been reported (38). The initial recovery of this protein from the fermentation broth involved cell lysis and centrifugation. Purification was achieved in three steps: weak anion exchange followed by hydrophobic interaction and a strong anion exchange step. The weak anion exchange step was carried out by means of a DEAE Sepharose® Fast Flow column in the flowthrough mode to remove DNA and pyrogens. In flowthrough column operations the impurities are retained on the column, but the product is not. Thus, this type of operation is quite simple to operate and can result in a rapid reduction of impurities from the feedstock. This flowthrough step resulted in a 10-fold reduction in DNA and a protein purity of approximately 25%. In fact, it is quite common to add a flowthrough anion exchange step in a process for DNA clearance.

The final anion exchange operation was carried out on a Q Sepharose high-performance (10 cm × 10 cm) column using multiple step gradients (Fig. 5). The protein of interest was eluted with the second step, resulting in the purification of 0.3 g of protein at a purity of greater than 99%. Since the column loading was relatively low, multiple cycles were necessary to produce sufficient amount of material. The ion exchange columns were cleaned and regenerated between runs with 1 M NaOH and 3 M NaCl. This example illustrates how step gradient chromatography can sometimes be employed for high-resolution separations for systems exhibiting sufficient separation factors. However, as shown in this example, these operations are often limited by relatively low column loading.

Step gradient has many advantages, namely, ease of operation, no need for complicated gradient pumping apparatus, and concentration of the bioproduct. When the separation problem is more difficult, however, a higher-resolution mode of operation is often required.

Linear Gradient

For high-resolution separations, linear gradient chromatography is often employed. This operation is usually carried out in large-diameter columns using a range of column lengths and particle diameters. It turns out that depending on the difficulty of the separation, it may be necessary to employ longer columns and/or materials of smaller particle diameter for these separations. This mode of chromatography is typically carried out by first loading the column with a relatively large volume of low-ionic-strength feed solution, followed by a continuous linear gradient of increasing ionic strength. This type of chromatography cannot be characterized as an on/off operation and is thus dependent on the length of the column and the column efficiency. The most important stationary-phase attribute in preparative linear gradient chromatography is the selectivity of the resin for the given separation. Accordingly, it is again essential that a wide variety of resin materials be screened to identify the material with the highest selectivity. In addition to the selectivity, the dynamic capacity of the stationary phase is also important for preparative linear gradient separations and must be considered when selecting a resin. The major advantage of linear gradient is its ability to resolve difficult separation problems. Several examples of linear gradient ion exchange chromatography are now presented.

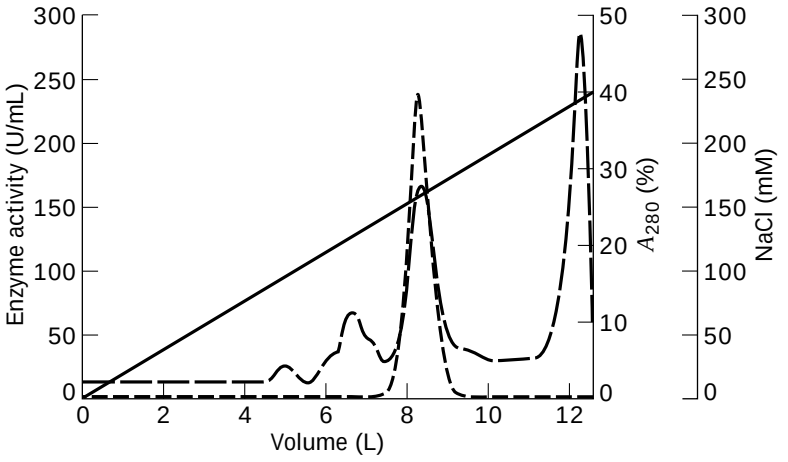

Figure 6. Cation exchange of L-asparaginase on a CM-Sepharose column (24 cm × 11.3 cm i.d.): buffer, 5 mM succinic acid–NaOH (pH 6); feed, dilute solution of cell extract with a conductivity of less than 2 mS; flow rate, 24 cm/h; gradient, 0–300 mM NaCl in 16 L of buffer. Curves: solid, NaCl; dotted, enzyme, dashed, protein. *Source*: Reproduced with permission from Ref. 39.

The use of linear gradients in the purification of L-asparaginase from *Vibrio (Wolinella) succinogenes* has been reported (39). The purification of this enzyme was achieved through a cation exchange step followed by an anion exchange polishing step. Approximately 13 g of protein (184,000 units) was loaded onto a 11.3 cm × 24 cm CM Sepharose cation exchanger at a mobile phase velocity of 24 cm/h. Upon elution of the enzyme by means of a linear gradient of 0–300 mM NaCl, the chromatogram shown in Figure 6 was obtained. This gradient resulted in the recovery of 91% of the enzyme and a 28-fold purification. An anion exchange polishing step followed. Approximately 0.4 g of protein (167,000 units) was loaded onto a 5 cm × 10.2 cm Q Sepharose® FF column at a mobile phase velocity of 15 cm/h. A linear gradient of 0–200 mM NaCl was used to elute the enzyme. This separation scheme resulted in an 87% recovery and a 47-fold purification of the enzyme. These separations required quite low mobile-phase velocities. In addition, the high-resolution step was limited to a column loading of 2g/L, which is typical of high-resolution linear gradient separations.

Often, the purification scheme for a protein involves both step and linear gradient operations. The purification of factor VIII (FVIII) and von Willebrand factor (vWF) from human plasma (40) illustrates the use of both step and linear gradients in the purification protocol. The FVIII–vWF complex is a complicated system in which the two proteins are highly glycosylated, have low pIs, and exhibit strong binding even under conditions of relatively high ionic strength. Furthermore, FVIII is prone to proteolytic degradation without its carrier protein vWF. The naturally adhesive vWF exhibits strong nonspecific interactions with organic, hydrophobic supports.

A wide variety of stationary-phase materials were evaluated for this separation. Silica-based supports could not be used in the purification scheme because they tended to activate FVIII. Supports such as cellulose and poly(styrene–divinylbenzene) were unable to effect the separation owing to the strong nonspecific interactions of vWF. Columns packed with traditional media such as Toyopearl® DEAE, MonoQ, MonoP, and TSK® DEAE 5PW were subject to fouling. On the other hand, tentacular supports gave good results for this separation, possibly because their extended tentacular arms prevent the protein from interacting with the base matrix.

The purification scheme for this complex involved three anion exchange steps and two virus inactivation steps. All the anion exchange steps involved the use of tentacular supports. Weak Fractogel® EMD-DEAE supports were used in the step gradient mode for the first two steps, and strong Fractogel® TMAE in the linear gradient mode was employed for the final purification. The FVIII–vWF complex was strongly retained on the DEAE support, enabling the use of step gradient chromatography to remove a variety of contaminating proteins, solvents, detergents, and stabilizers (employed during viral inactivation steps).

The FVIII–vWF complex was dissociated and separated in the final step by means of a linear gradient. Calcium ions were added to the buffer to cause the dissociation of the complex. Figure 7, which illustrates the separation achieved with the strong tentacular exchanger, indicates that this difficult separation was complicated by the heterogeneity of the protein glycosylation and incomplete dissociation. This example illustrates how linear gradient ion exchange with highly selective resins can be employed for

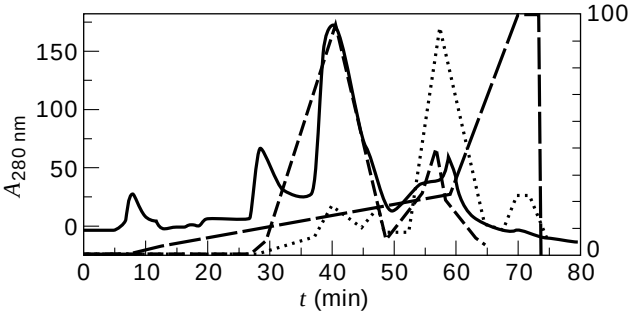

Figure 7. Dissociation and separation of FVIII and vWF from their complex in the presence of 50 mM calcium: buffer, 20 mM Tris–HCl (pH 7.4): feed, 300 units of FVIII in buffer; column, Fractogel® EMD TMAE (20–40 μm, 120 mm × 16 mm i.d.); flow rate, 3 mL/min; gradient, 0–200 mM NaCl. Curves: short dashes, vWF activity; dots, FVIII activity; long dashes, % B (IM NaCl) *Source*: Reproduced with permission from Ref. 40.

very difficult separations. This process resulted in a purification factor of 8,000 with an overall yield of approximately 20%.

According to the conventional wisdom, the more difficult the separation, the lower the column loading that can generally be processed by linear gradient. Thus, linear gradient is often limited to lower column loadings. In addition, linear gradient requires more complicated gradient pumping apparatus. In contrast, displacement chromatography is able to carry out high-resolution separations at very high column loadings, using the simple pumping systems employed for step gradient chromatography.

Displacement

The displacement mode of chromatography, first identified in the 1940s by Tiselius (41), combines the high throughput and concentrating power of step gradient chromatography with the high resolving power of linear gradient chromatography. Although displacement chromatography has been shown to hold significant promise for high-resolution preparative separations, a major impediment to the implementation of displacement chromatography has been the lack of suitable displacer compounds. Recent advances in this field have generated significant interest in displacement technology.

Operationally, displacement chromatography is performed in a manner similar to step gradient chromatography, where the column is subjected to sequential step changes in the inlet conditions. The column is initially equilibrated with a carrier buffer of relatively low ionic strength. The feed mixture is then introduced into the column, followed by a constant infusion of the displacer solution. The displacer is selected such that it has a higher affinity for the stationary phase than any of the feed components. Under appropriate conditions, the displacer induces the feed components to develop into adjacent "square-wave" zones of highly concentrated pure material. After the breakthrough of the displacer from the column effluent, the column is regenerated and reequilibrated with the carrier buffer.

The separation of oligonucleotides from their failure sequences presents a significant challenge to chromatographic engineers. The failure sequences are typically very closely related to the main product. Furthermore, there is considerable conformational heterogeneity of both the product and the failure sequences. Displacement chromatography has been successfully employed for resolving oligonucleotide mixtures characterized by low separation factors. For example, 1.2 g of a 24-mer phosphorothioate oligonucleotide was purified on a POROS® HQ/M column using dextran sulfate as the displacer (42) (Fig. 8). The separation yielded 70% of the product at a purity of about 96%. Methanol was added to the mobile phase to eliminate hydrophobic interactions between the oligonucleotide and the stationary phase and to improve the recovery. The column was regenerated with 3 M NaCl in 0.5 M NaOH. On a semipreparative scale, the entire separation (equilibration + loading + displacement + regeneration) could be accomplished in approximately 32 mins.

An important recent advance in the state of the art of displacement chromatography has been the discovery that low molecular weight displacers can be successfully employed for protein purification in ion exchange systems (43). Pentaerythritol-based dendritic polyelectrolytes ranging in molecular weight from 480 to 5,100 Da have been shown to be effective displacers for protein purification (44). In addition, protected amino acids (45), antibiotics (46), and a variety of anionic displacers have been developed (47–49). Low molecular weight displacers have been successfully employed for very difficult protein separations (50). These novel displacers have significant operational advantages over large polyelectrolyte displacers. First and foremost, if there is any overlap between the displacer and the protein of interest, the low molecular weight materials can be readily separated from the purified protein during postdisplacement downstream processing involving size-based purification methods (e.g., size exclusion chromatography, ultrafiltration).

The relatively low cost of synthesizing low molecular weight displacers can be expected to significantly improve the economics of displacement chromatography. Furthermore, the salt-dependent adsorption behavior of these low molecular weight displacers greatly facilitates column regeneration. In addition, these displacers can be employed in "selective" displacement chromatography, where the product(s) of interest can be selectively displaced while the low-affinity impurities can be desorbed in the induced salt gradient ahead of the displacement train and the high-affinity impurities either retained or desorbed in the displacer zone (51).

Figure 9 shows an example of a selective displacement separation: a displacement experiment was carried out using a feed mixture of ribonuclease B, bovine heart cytochrome *c*, horse heart cytochrome *c*, and lysozyme with *N*-α-benzoylarginine ethyl ester (BAEE) as the displacer. As seen in the figure, the low-affinity protein ribonuclease B eluted ahead of the displacement train in the induced salt gradient, whereas the two cytochrome *c*'s were well resolved in the displacement train. Thus, in spite of the extreme closeness in their adsorption behavior, displacement chromatography resulted in excellent separation of the two cytochrome-*c* proteins with both high yields and high purity. The highest-affinity protein, lysozyme, remained on the column under the conditions of this experiment. This experiment demonstrates that selective displacement chromatography can result in baseline separation of the product of interest from the low- and the high-affinity impurities, while resolving the target bioproduct from very similar affinity impurities in an isotachic displacement train. Recent results have indicated that displacement chromatography may have significant utility for extremely difficult bioseparations such as protein variants (52) and glycoforms.

Chromatofocusing

In chromatofocusing retained, internal pH gradients are employed to effect the separation of protein mixtures. These pH gradients are produced internally by running a buffer of a particular pH through an ion exchanger equilibrated at a different pH. The focusing effects produced by these pH gradients were originally studied by Sluyterman

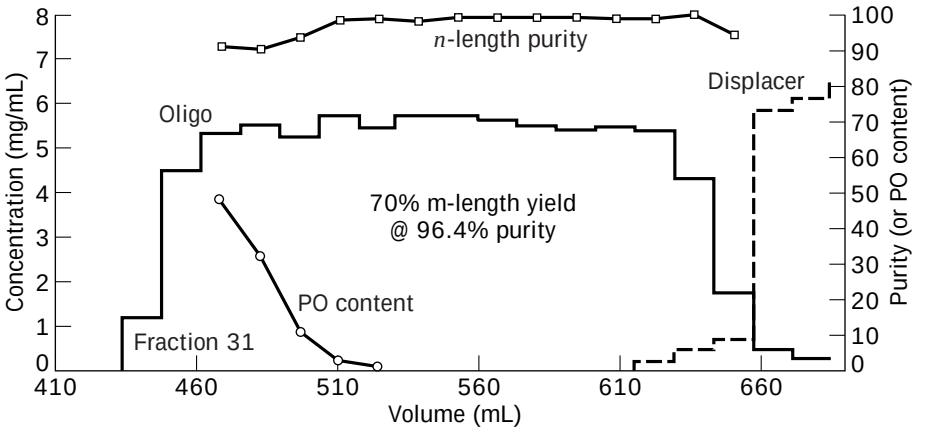

Figure 8. Preparative-scale purification of a 24-mer phosphorothioate oligonucleotide: feed, 1.2 g in 100 mM NaCl, 10 mM NaOH, 5% methanol; displacer, 800 mL of 7 mg/mL dextran sulfate; column, POROS HQ/M (20 μm, 100 mm $\times$ 50 mm i.d.); flow rate, 50 mL/min; fraction size, 14 mL. *Source*: Reproduced with permission from Ref. 42.

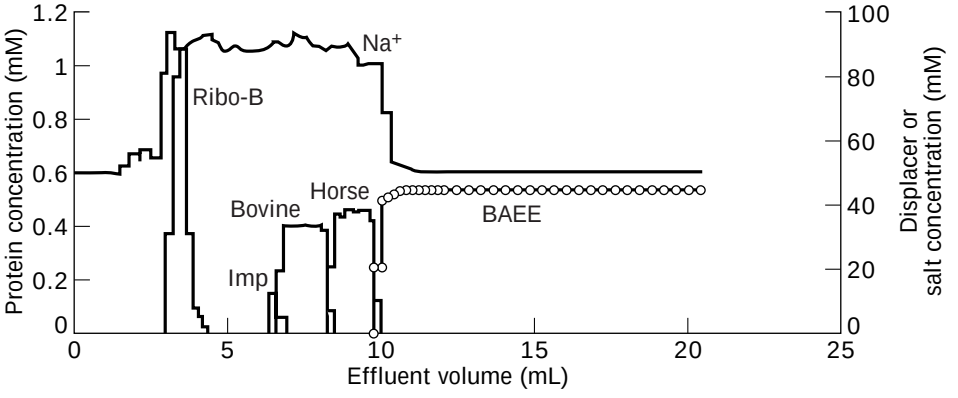

Figure 9. Displacement separation of a four-component protein mixture using BAEE as a displacer-column, 100 mm $\times$ 5 mm i.d. strong cation exchanger (8 μm); buffer, 50 mM sodium phosphate (pH 6.0); feed, 1.6 mL of 0.38 mM ribonuclease B, 0.45 mM horse heart cytochrome *c*, 0.37 mM bovine heart cytochrome *c*, and 0.34 mM lysozyme in buffer; displacer concentration, 45 mM; flow rate, 0.2 mL/min; fraction size, 200 μL. *Source*: Reproduced with permission from Ref. 51.

and coworkers (53,54). Typically, polyampholyte buffers are employed in this mode of chromatography. These buffers are not only expensive but also contain components that can associate with proteins (55). However, Hearn and Lyttle (56) and Frey et al. (57) demonstrated the efficacy of employing multicomponent mixtures of common buffer systems to produce internal pH gradients in ion exchange columns. Recently, Strong and Frey (58) demonstrated the chromatofocusing of model proteins under trace- and volume-overloaded feed conditions using mixtures of common buffers. The ability to carry out chromatofocusing with inexpensive, commonly employed buffers offers new opportunities for this high-resolution technology.

MODELS

Methods development for chromatographic bioprocessing typically involves an evaluation of the linear chromatographic behavior followed by empirical scale-up. Mathematical models are not widely employed for methods development and optimization of chromatography in the biopharmaceutical industry. Thus a significant amount of time is needed for methods development, as well as for the implementation of nonoptimal processes. As a result, there is increasing interest in the use of mathematical models for the development of efficient preparative ion exchange processes.

The classical view of protein retention in ion exchange columns involves the stoichiometric exchange of proteins and mobile-phase counterions (1,59–61). This is referred to as the stoichiometric displacement model (SDM). In this model, the retention of proteins on ion exchange stationary phases is described as follows (for a 1:1 salt, e.g., NaCl)

$$C_{pb} + \nu Q_m \Leftrightarrow Q_p + \nu C_m + \nu C_b \qquad (1)$$

where p is the protein molecule, ν is the ratio of the characteristic charge of the protein to the valence of the counterion, b is the co-ion (the ion with the same charge as the stationary phase) associated with the protein, m is the mobile-phase counterion (ion with the opposite charge of the stationary phase), C denotes the concentrations in the mobile phase, and Q denotes the concentrations on the stationary phase. The characteristic charge of the protein is a statistical average of the electrostatic interactions of the protein with the stationary phase as it travels down the column.

Some of the counterions remain bound to the protein on adsorption, while the rest make way for the interaction of the protein with the stationary phase. Drager and Regnier (60) argued that the equilibrium between the protein and the co-ion can be neglected. This results in the simplified equilibrium reaction

$$C_p + \nu Q_m \Leftrightarrow \nu C_m + Q_b \quad (2)$$

The SDM predicts that the retention of the protein under isocratic, linear conditions (low solute concentrations) is related to the counterion concentration as follows:

$$\log(k) = -\nu \log(C_m) + \text{const} \quad (3)$$

where k is the retention factor under isocratic linear conditions, and C_m is the concentration of the counterion in the mobile phase. This relationship has been experimentally demonstrated (60,62,63) under conditions usually employed in the IEC of proteins. Equation 3 forms the basis for the quantification of the effect of the ionic strength on the selectivity of linear separations.

Linear Chromatography

In linear chromatography, the various solutes migrate down the column independent of each other. The retention is characterized by a linear isotherm and an absence of intersolute competition for the adsorption sites. The plate model (64) is used extensively to characterize the efficiencies and resolutions obtained in these systems. In the plate model, all the nonidealities of the column are lumped into one parameter: N, the number of plates [or, alternatively, in height equivalent to one theoretical plate, HETP = (length of column)/N]. The HETP is widely used for the comparison of different sorbents and the validation of packing procedures. It is usually determined from the effluent profiles of isocratic pulse injections of a tracer. For a gaussian effluent peak, the HETP can be determined from the following equation

$$\text{HETP} = \left(\frac{w_h}{t_r}\right)^2 \frac{L}{5.545} \quad (4)$$

where w_h is the peak width at half-height, t_r is the retention time of the peak, and L is the length of the column. In ion exchange systems, the HETP measurement is affected by the salt in the background. It is recommended that pulse injections be made in a relatively high salt background to reduce Donnan exclusion (65).

The HETP is also a function of the flow rate. For conventional, macroporous sorbents, the plot of HETP versus flow rate (termed a Van Deemter or Knox plot) exhibits a minimum, indicating the presence of an optimum flow rate for operation. The HETP can be viewed as a sum of all the mass transfer, kinetic, and diffusional resistances in the column (66,67).

Yamamoto and coworkers have employed a continuous-flow plate model to characterize and scale up linear gradient and step gradient operations (68). Graphical techniques have been developed for scaling up linear gradient elution in linear chromatography. In this approach, the ionic strength at which the peak will elute in a large column is obtained directly from a plot of GH (gradient slope times the stationary phase volume) versus I_r (ionic strength at the elution time of the peak), which is established with the use of a relatively small column (69). The dimensionless retention time and the peak width in the large column can then be determined from analytical expressions (68). These methods have been applied to the scale-up of β-galactosidase purification in a 30-L column based on linear gradient data obtained with a 23-mL column (69).

Although the foregoing approach appears to work well for linear gradient scale-up of single solutes and multicomponent separations with baseline resolution, an alternative method (70) is required for general multicomponent linear separations. The resolution R_s is related to the operating conditions and the column dimensions as follows (70):

$$R_s \propto \left(\frac{L}{G\ \text{HETP}}\right)^{1/2} = \left(\frac{D_m I_a L}{GHud_p^2}\right)^{1/2} \quad (5)$$

where D_m is the molecular diffusivity, u is the mobile-phase velocity, d_p is the particle size, L is the length of the column, G is the gradient slope times the column dead volume, and I_a is a constant, introduced to dedimensionalize the right-hand side.

The HETP in equation 5 is the HETP in linear gradient elution. An algorithm to estimate the HETP from a set of linear gradient experiments at various flow rates has been developed (71). Thus, for scale-up,

$$\left(\frac{L}{G\ \text{HETP}}\right)_{\text{small column}} = \left(\frac{L}{G\ \text{HETP}}\right)_{\text{large column}} \quad (6)$$

While these approaches have proved useful for the scale-up of linear chromatography, the production rate in these ion exchange systems can be dramatically enhanced by operating these columns under nonlinear conditions. To model various modes of operation under nonlinear (high loading) conditions, an alternative approach must be employed.

Nonlinear Chromatography

To study the effects of nonlinear chromatography, one needs a suitable isotherm that accurately describes nonlinear protein adsorption. Guiochon et al. (72) have employed the Langmuir isotherm extensively to study the nonlinear chromatographic behavior of both small molecules and macromolecules. Berninger et al. (73) have developed the VERSE-LC model, which solves the complete mass transfer equations in conjunction with the Langmuir or modulator-modified Langmuir isotherms to describe nonlinear chromatography. While the Langmuir isotherm has many advantages, it is inadequate for describing protein adsorption in ion exchange systems. Protein adsorption is multipointed in nature (74) and is affected by the presence of mobile-phase modifiers (75–77). The Langmuir isotherm is unable to accurately describe these features.

The multivalent ion exchange model (75,78) incorporates both the multipointedness of the adsorption process and the effect of the mobile phase modifier on the process. It is derived from the SDM in conjunction with the law of mass action. Thus the multivalent ion exchange formalism predicts an isotherm of the form

$$Q_p = K_{eq} C_p \left(\frac{\bar{Q}_1}{C_1}\right)^{\nu_p} \quad (7)$$

where $\bar{Q}_1$ is the number of sites available for the adsorption of proteins, C_1 is the mobile-phase concentration of the counterions, K_{eq} is the equilibrium constant for the exchange process, and the subscript p denotes the protein.

The effect of the size of the protein molecules and lateral interactions on the adsorption process can be considerable (76,79–81). Furthermore, the adsorption of a protein molecule will result in the steric shielding of a number of stationary phase sites underneath the molecule. Brooks and Cramer (76) have defined a steric factor, σ, to account for such steric hindrance and have used the postulate that the steric hindrance will be proportional to the concentration of proteins on the surface (79). A steric mass action (SMA) model was developed that essentially employs equation 7 in concert with the following electroneutrality condition for single component equilibrium (76):

$$\Lambda = \bar{Q}_1 + (\nu_p + \sigma_p) Q_p \quad (8)$$

The parameters for the SMA model (K_{eq}, ν, and σ) can be readily obtained using standard chromatographic techniques. The equilibrium constant K_{eq} and the characteristic charge (for a monovalent counterion) ν are obtained from either isocratic or linear gradient elution chromatography (62). The steric factor can be obtained from nonlinear frontal chromatography. Knowledge of the bed capacity and the protein parameters allows the generation of nonlinear isotherms at any salt concentration.

The SMA formalism can be extended to multicomponent mixtures. In this case, the electroneutrality condition becomes

$$\Lambda = \bar{Q}_1 + \sum_{i=2}^{N} (\nu_i + \sigma_i) K_{eq,i} \left(\frac{\bar{Q}_1}{C_1}\right)^{\nu_i} C_i \quad (9)$$

where N is the total number of components (including the mobile phase counterion) in the system. Equations 7 and 9 then describe multicomponent nonlinear protein equilibria at various salt concentrations.

The SMA model accurately predicts a variety of nonlinear ion exchange behavior in different modes of chromatography. Two distinct approaches have been employed to date. The first involves the development of graphical techniques based on the method of characteristics for the prediction of single solute peaks in nonlinear isocratic and gradient chromatography (77,82). The second approach has employed the SMA formalism in concert with appropriate mass transport equations to describe multicomponent separations. As seen in Figures 10 and 11, the SMA model can accurately predict separations in multistep gradient and linear gradient separations, respectively. In addition, the model can predict sample displacement effects, which can have a profound effect on linear gradient separations under high loading conditions (Fig. 11). This model has also been shown to accurately predict the behavior of complex displacement systems (83). Furthermore, the SMA formalism has been used along with iterative optimization techniques to develop optimal step (84) and linear gradient (85) separations. Finally, the SMA model has been employed to describe the dynamic affinity of low molecular weight displacers in displacement systems, resulting in a simple approach to methods development in displacement chromatography (86).

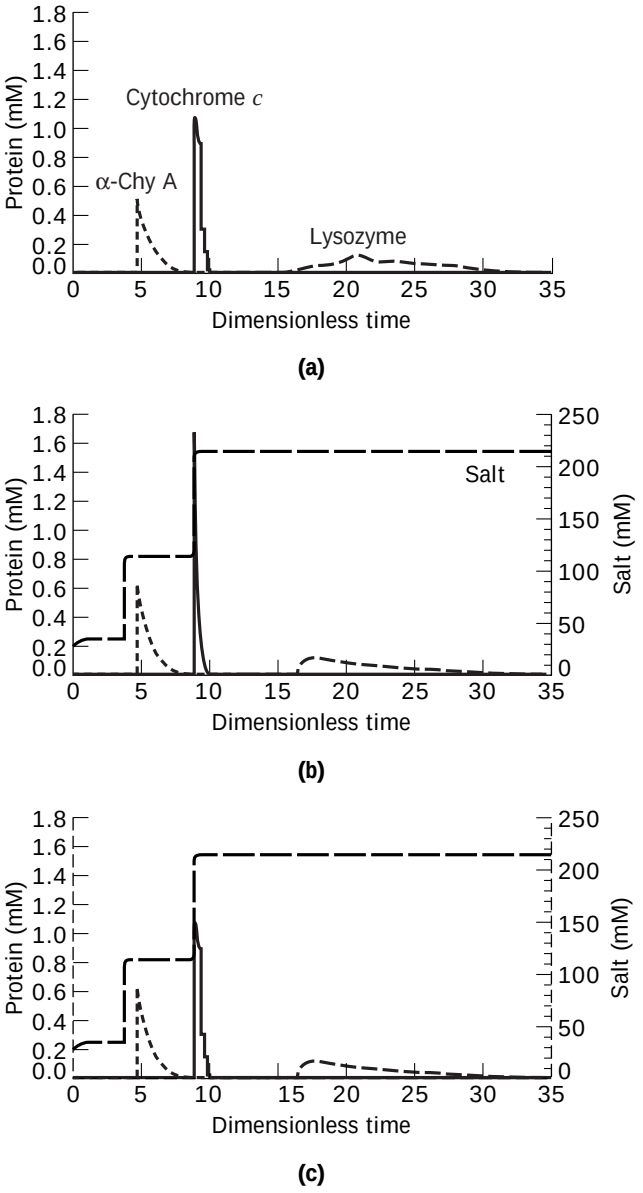

Figure 10. Comparison of step gradient chromatograms: (**a**) experimental, (**b**) simulated (using SMA), and (**c**) simulated (using SMA with fraction collection. Feed 2.8 column dead volumes of 0.19 mM α-chymotrypsinogen A, 0.19 mM cytochrome *c*, and 0.21 mM lysozyme in 30 mM sodium phosphate (pH 6). Gradient program: first step salt concentration, 112 mM, second step salt concentration, 213 mM; delay of 5.1 column dead volumes; flow rate, 0.4 mL/min; column, Waters SP (8 μm, 50 mm $\times$ 5 mm i.d.); fraction size, 147 μL (before 11 column dead volumes) and 413 μL (after 11 column dead volumes). *Source*: Reproduced with permission from Ref. 84.

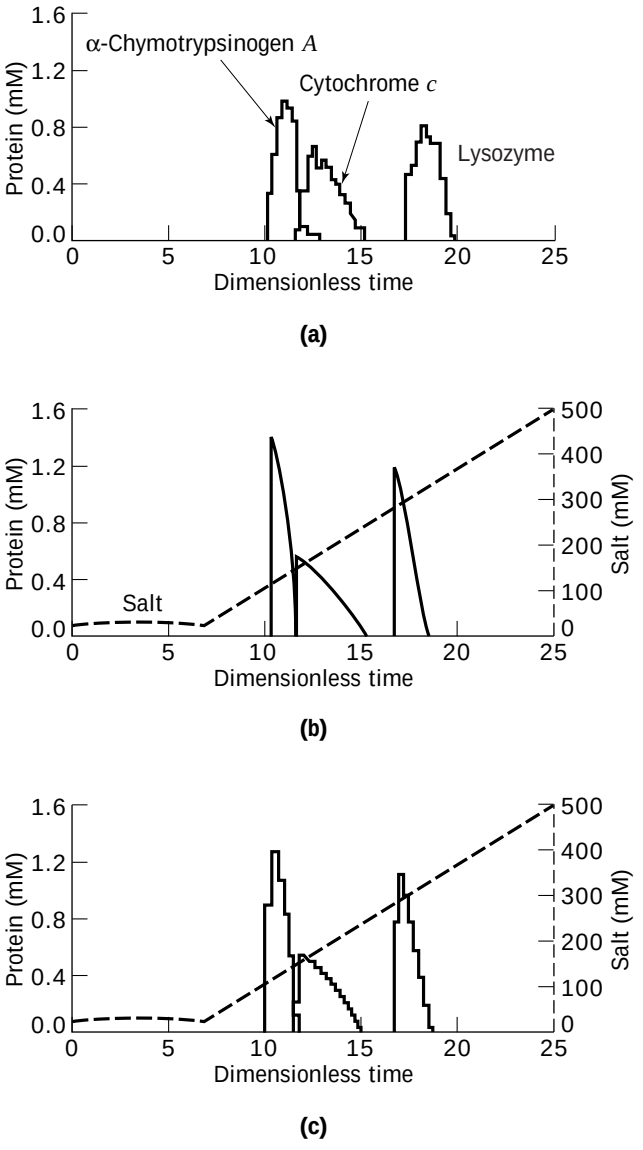

Figure 11. Comparison of linear gradient chromatograms: (**a**) experimental, (**b**) simulated (using SMA), and (**c**) simulated (using SMA with fraction collection). Feed, 6 column dead volumes of 0.2 mM α-chymotrypsinogen A, 0.2 mM cytochrome *c* and 0.2 mM lysozyme in 30 mM sodium phosphate (pH 6); gradient slope, 25 mM Na^+ per column dead volume; flow rate, 0.5 mL/min; column: strong cation exchanger (15 μm, 54 mm $\times$ 5 mm i.d.); fraction size, 200 μL. *Source*: Reproduced with permission from Ref. 85.

Nonstoichiometric Models

Though the SMA model is capable of accurately describing the behavior of nonlinear ion exchange chromatographic systems, it assumes that the individual charges on the protein molecule interact with the discrete charges on the ion exchange surface. In reality, the retention in ion exchange is more complex and is primarily due to the interaction of the *electrostatic fields* of the protein molecules and the chromatographic surface. Haggerty and Lenhoff (87) demonstrated a correlation between the retention of various proteins with their surface potential. Stahlberg and coworkers have developed the electrostatic interaction model (EIM), which treats the retention process as a coulombic interaction between two charged flat plates (88,89). Roth and Lenhoff (90) employ van der Waals forces in concert with electrostatic interactions to quantify the adsorption of proteins onto charged stationary phases. Recently, a mechanistic model has been developed that incorporates stationary-phase properties such as the surface charge density and short-range interaction energies to predict retention on various stationary phases (91). The drawback with the nonstoichiometric approaches reported thus far is that they are limited to describing retention in the linear mode of chromatography.

CONCLUSIONS

The last decade has seen dramatic advances in the state of the art of chromatographic bioprocessing with ion exchange materials. This article has presented recent advances in resin materials, modes of operation, and mathematical modeling. The need to process large volumes of relatively dilute feedstock has catalyzed the development of an array of "novel" chromatographic materials. While many novel materials have been developed, the effect of stationary-phase chemistry on selectivity is still essentially unknown, and thus the selection of an ion exchange resin requires significant column screening. Once a resin with sufficient selectivity has been identified, the task remains to develop an efficient, high-throughput chromatographic process. This requires the selection of an appropriate mode of operation. In fact, the selection of the optimal mode of operation for a given bioseparation problem can have a profound effect on the production rate, yield, and purity for that ion exchange step. Finally, the development of mathematical models capable of predicting scale-up and nonlinear protein chromatography now make it possible to employ modeling for bioprocess methods development.

NOMENCLATURE

C	mobile phase concentration (mM)
d_p	Particle size (cm)
D_m	Molecular diffusivity (cm^2/s)
G	Gradient slope times column dead volume (mM)
H	Column phase ratio (dimensionless)
I_r	Ionic strength at peak elution
k	Retention factor (dimensionless)
K_{eq}	Equilibrium constant (dimensionless)
L	Length of column (cm)
Q	Stationary phase concentration (mM)
$\bar{Q}_1$	Concentration of sites available for protein adsorption (mM)
R_s	Resolution (dimensionless)
t_r	Retention time (min)
u	linear velocity (cm/min)
w_h	Peak width at half-height (min)

Subscripts

i	solute index ($i = 1$ for salt counterion)
p	Protein
m	mobile-phase counterion

Greek

β	Phase ratio (dimensionless)
ν	Characteristic charge (dimensionless)
σ	Steric factor (dimensionless)
Λ	Bed capacity (mM)

OUTLINE

INTRODUCTION

The production of a modern biotechnology product, typically a recombinant protein, requires a multistage downstream process. Such a process usually centers on two or more liquid chromatography steps. As production scales escalate, the columns used become larger and more expensive. It is not uncommon to have bed volumes reaching hundreds of liters at industrial scales.

Radial flow columns were first used for gas–solid catalytic reactions in large packed beds. They were designed to increase gas flow rate and reduce pressure by increasing the cross-sectional flow area. Radial flow chromatography (RFC) columns first entered the commercial biotechnology market in the mid-1980s (1). RFC was intended as an alternative to the conventional axial flow chromatography (AFC) for preparative- and large-scale applications. In a radial flow chromatography column (Fig. 1), the mobile phase flows in the radial direction, not in the axial direction. The mobile enters from the outside tube and merges into the center tube (Fig. 2). In comparison to a slim AFC column, an RFC column provides a relatively larger flow area and a shorter flow path. It allows a higher volumetric flow rate with a lower bed pressure. The effect is equivalent to using a short pancakelike AFC column (Fig. 3). Pancakelike AFC columns are quite common in industrial applications. They are available from most major commercial column vendors. In scale-up to accommodate large feed loads, it is impractical to increase the column height of AFC columns by too much because excessive bed pressure drop will result. This is especially troublesome when soft gels are used. Thus, pancakelike AFC columns are used.

This article is devoted to the discussion of the applications of RFC columns in bioseparations and RFC modeling and scale-up issues. Applications examples will be provided based on existing literature. A general rate model will be presented for the modeling of RFC. Experimental and theoretical comparisons between AFC and RFC will be discussed.

RADIAL FLOW COLUMN CONFIGURATIONS

In 1947, Hopf (2) described a radial chromatography device. The device had a feed pipe in the center. The outward liquid flow in the radial direction was forced by the centrifugal force when the device was rotated. He called this device a chromatofuge. Such a device was obviously too complex and expensive for large-scale industrial application, and thus it was not adopted in biotechnology.

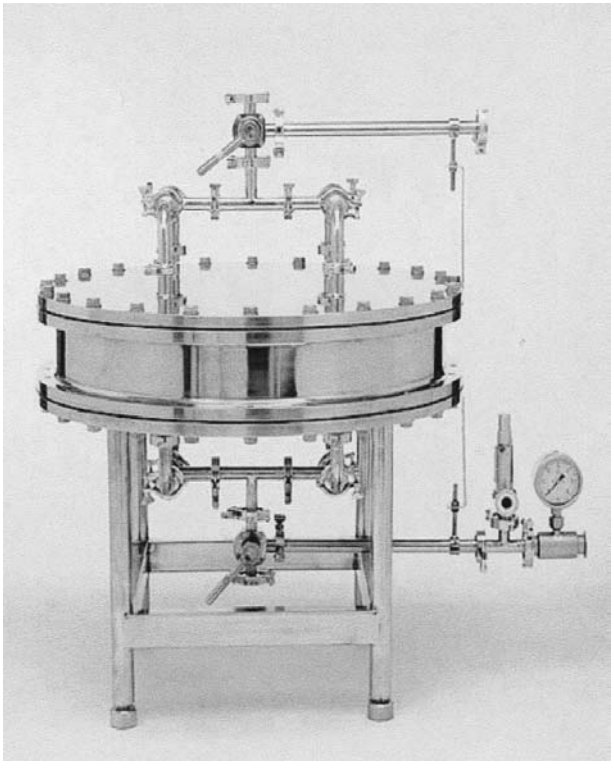

Figure 3. A large-scale pancakelike axial flow column. Courtesy of Pharmacia Biotech, Inc.

To date, two commercial companies have marketed RFC columns. The first one is CUNO, Inc., in Connecticut. They marketed the Zetaffinity series of preparative-scale radial flow cartridges, which looked like a spiral-wound filtration cartridge (Fig. 4). Such a design obviously was rooted in the fact the CUNO is a major manufacturer of industrial filtration systems. The packing for CUNO's RFC cartridges

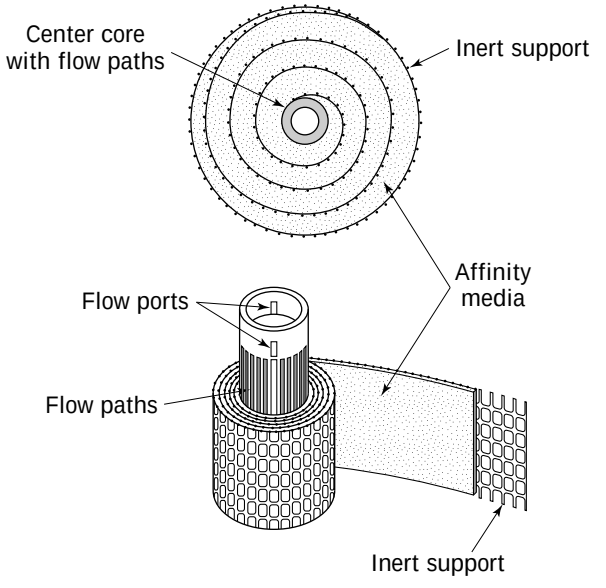

Figure 4. Structure of a Zetaffinity® cartridge.

was based on modified cellulose (3). These cartridges were used for affinity chromatography, hence the trade name Zetaffinity. CUNO discontinued its Zetaffinity product line in 1991.

The second vendor and manufacturer of RFC columns is Sepragen Corporation in Hayward, California. Their RFC product line carries the trade name Superflo®. Sepragen markets unpacked RFC columns ranging from 50 mL to 200 L. Figure 5 shows several Superflo columns with a similar diameter but different column heights. Superflo columns come in stainless steel, acrylic, polycarbonate, and polyethylene. They can sustain a pH range of 2 to 12 and a maximum pressure of 50 psi. They are used by major biopharmaceutical companies at production scales. Sepragen's president owns a U.S. patent (4) on the design of unpacked RFC columns. Figure 1 shows an acrylic RFC column with inward radial flow. The feedstream enters from a center input port at the top. It is then distributed through several flow channels to the outer shell and subsequently enters the packing media in the radial direction toward a center collection tube. The effluent exits the tube through an outlet port at the bottom. The two ports next to the center input port at the top in Figure 1 are packing ports used during media packing. A bubble trap with a pressure gauge sits on the edge of the column's top lid. Figure 2 is an anatomical view of a Superflo column. Superflo columns usually use inward flow instead of outward flow because it is more difficult to distribute outward flow without increasing flow distortion caused by gravity. The other reason for not using outward flow is because inward flow provides slightly sharper peaks than outward flow based on computer simulation (5). Outward flow is usually used for the packing or regeneration of a RFC column.

PACKING PROCEDURES FOR RFC COLUMNS

Because of their structure, CUNO's Zetaffinity cartridges do not require special packing procedures. Sepragen's Superflo columns are packed by first displacing air using outward flow with a buffer solution. Packing slurry is then pumped into the column through the two packing ports on the column top surface (Fig. 1). Excess buffer is squeezed out of the column through the input port on the column top surface. After that, the column is ready for use.

PRESSURE DROPS OF RFC COLUMNS

Because of a short flow path and a low pressure drop, both CUNO's and Sepragen's RFC devices exhibit a highly linear relationship between bed pressure drop versus flow rate. Figure 6 shows a linear relationship between bed pressure and flow rate for an 800-mL Zetaffinity cartridge studied by Huang et al. (3).

Figure 7 shows the pressure drops for a Superflo 20 L column and a Superflo 50 L column packed with several different soft-gel chromatographic media (6). It indicates that the pressure drops are quite low at relatively high flow rates. At lower flow rates, the pressure drop curve is linear. This behavior is similar to that of short pancakelike AFC columns.

COMPARISON OF RADIAL FLOW AND AXIAL FLOW COLUMNS

Saxena and Weil (7) did an experimental case study of the comparison of RFC and AFC. They used a 100-mL axial flow glass column (Econocolumn®) with 2.5-cm i.d. from BioRad Laboratories (Richmond, Calif.) and a Superflo-100 RFC column from Sepragen with a bed volume of 100 mL. Both columns were packed with QAE cellulose with the following procedures. The Superflo column was packed using a 25% slurry (with 0.5 M NaCl) that was pumped in through the two packing ports at a flow rate of 30 mL/min. The final QAE cellulose density after packing was 6 mL per dry gram. The Superflo column was packed in about 20 min. The AFC column was packed using 50% slurry added from the top of the column. After the liquid was drained and the bed was settled, additional slurry was added. This process was repeated until the same amount of QAE cellulose was packed into the AFC column. The two columns were used to separate two 10-mL ascites fluid samples. The samples were pretreated by dialyzing the ascites fluid with 10 mM phosphate buffer of pH 8.0 for 2 days with three changes. Precipitates and debris were then removed by centrifugation. Stepwise salt gradients were used. Figure 8 shows the comparison between the 100-mL

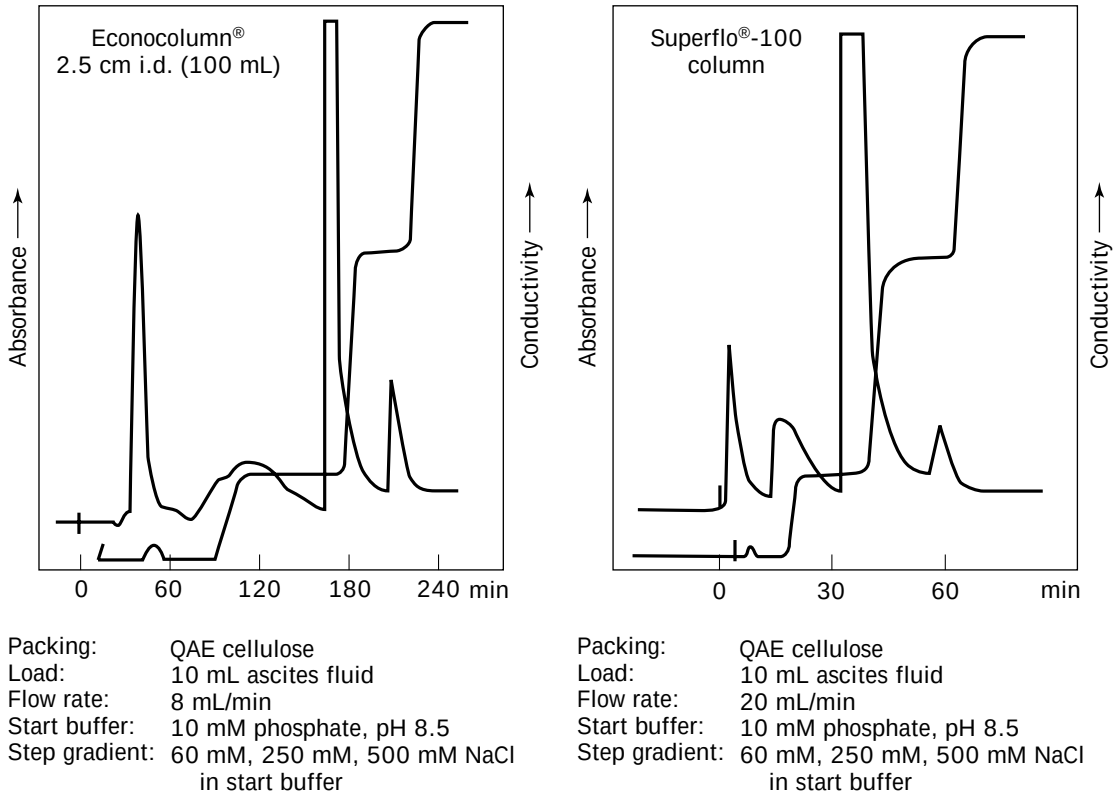

Figure 8. Comparison of AFC and RFC columns. *Source*: Courtesy of Sepragen Corp.

AFC column and the 100-mL Superflo-100 RFC column. From Figure 8, it can seen that the RFC column achieved similar separation results with much less time. In this case, the two columns were equivalent only in bed volume. A stricter comparison should use a pancakelike, short AFC column with its bed height about the same as the packing's thickness in radial direction for the RFC column, and both columns should have equal bed volume. The case study discussed next is close to satisfying these conditions.

Tharakan and Belizaire (8,9) used a 50-mL RFC column with a bed height of 0.95 cm and packing thickness of 3.0 cm in the radial direction and a 50-mL AFC column with a bed height of 2.8 cm. Both columns were packed with Sepharose CL2B resin-containing monoclonal antibody from Pharmacia (Piscataway, N.J.). They studied the purification of a protein called factor IX. Their experimental results indicated that the two columns gave similar purification results. This was expected because the AFC column was pancakelike. Tharakan and Belizaire (8) also packed the same column with S-200 Sephacryl size-exclusion gel from Sigma Chemical Co. (St. Louis). The protein band was more diffused using RFC than AFC.

Lane et al. (10) compared the performance of a Superflo-100 RFC column and a 6.6 $\times$ 4.4 cm i.d. AFC column for the separation of egg-white proteins. Both columns had a nominal bed volume of 100 mL. They were packed with the same media for comparison. Two anion-exchange cellulose media were tested, Whatman DE52 and QA52 from Whatman Specialty Products Division (Maidstone, U.K.). Egg whites were first separated from fresh hen eggs and then treated with a buffer. After treatment with a cell debris remover, egg-white suspensions were filtered using filter paper. The samples for chromatography had a protein concentration of 14 mg/mL. Sample load volume was 40 mL. After sample loading, the column was washed with a buffer. Elution was carried out using a linear gradient of 0 to 0.5 M NaCl in 0.025 M tris/HCl buffer at pH 7.5. Various flow rates were tested, ranging from 5 to 50 mL/min for the AFC column and 5 to 150 mL/min for the RFC column. Figures 9 and 10 represent typical results obtained by Lane et al. (10). They indicate that the AFC column gave slightly sharper peaks and faster elution times for both DE52 and QA52 media at a flow rate of 25 mL/min.

PROS AND CONS OF RADIAL FLOW COLUMNS

RFC columns provide a short flow path and a large cross-sectional area. This has the same effect as short pancakelike AFC columns. However, RFC columns occupy considerably less floor space. Both RFC and pancakelike AFC columns face flow distribution problems. According to Sepragen, its Superflo columns have better flow distribution than typical large pancakelike columns.

Compared to long AFC columns, RFC columns produce smaller pressure drops, thus enabling larger volumetric flow rates. If soft gels are used as separation media, the low pressure drop of RFC columns helps prevent bed compression (11,12). RFC is especially suitable for affinity chromatography using soft gels. In affinity chromato-

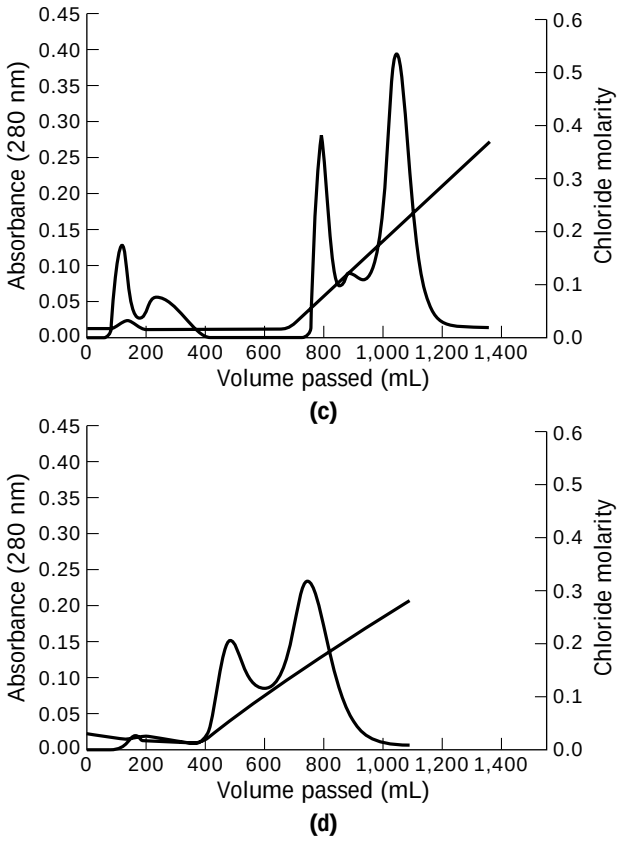

Figure 10. Same as Figure 9, but the columns were packed with QA52.

graphic operations, dilute feeds are typically used. Because of the extremely high affinity between the product and the gel matrix, very high flow rates are permitted without sacrificing column resolution. RFC is also a good choice for strong reversed phase, hydrophobic interaction and ion-exchange media.

Scale-up of RFC columns are relatively more straightforward because it is usually done by increasing the column height. To a certain extent, this does not seems to increase flow distortion problems in practice. If an AFC column is scaled up by increasing diameter, the flow distribution behaves quite differently from a small AFC column for which plug flow is easy to achieve. Thus, predicting actual performance of a large pancakelike AFC column from a small one is difficult.

The disadvantage of the RFC column is primarily its limited resolution caused by a short flow path. If the flow path is increased to a large extent, there will be flow distribution problems in the radial direction because of gravity. High resolution for more demanding separations can only come from using AFC columns with sufficiently large column length. This is precisely the reason why RFC has no use in analytical HPLC. RFC is not suitable for separations in which solute-stationary interactions are weak. For example, RFC is not a suitable choice for size-exclusion chromatography (SEC), because SEC depends strongly on the length of flow path for its resolution. RFC's short flow length cannot meet the demand. It is also expected that RFC is not suitable for other chromatography with weak solute-stationary phase interactions.

If mechanically strong packing materials, such as silica-based particles, are used, a longer column flow path can be used because the bed can sustain a much higher pressure. If a relatively high resolution is desired, RFC would be at a disadvantage compared to AFC since RFC is limited by its short flow path.

APPLICATION EXAMPLES

Applications Using Zetaffinity Cartridges

Huang et al. (3) studied several Zetaffinity cartridges from CUNO that contained modified cellulose-based affinity media. Table 1 lists the dimensions of three Zetaffinity cartridges tested by Huang et al. Figure 11 shows a chromatogram for the removal of proteases from human plasma using an 800-mL Zetaffinity cartridge with a flow rate of 100 mL/min (3). The cartridge contained modified cellulose with para-aminobenzamidine (PAB) as ligand. A 70% efficiency of protease removal was achieved in a single pass. The treated plasma was expected to have a three-fold increase in stability. The same type of 800-mL Zetaf-

Table 1. Dimensions of CUNO Radial Flow Cartridges Tested by Huang et al. (3)

Parameter	Small	Medium	Large
Nominal size	250 mL	800 mL	3200 mL
Bed volume	210 mL	810 mL	3020 mL
Outer diameter	7.0 cm	12.7 cm	12.7 cm
Inner diameter	0.6 cm	0.9 cm	0.9 cm
Height	6.4 cm	6.4 cm	23.8 cm

finity cartridge loaded with 1,260 mg PAB ligand was also used to purify crude trypsin purchased from Sigma Chemical. The data in Figure 12 were obtained by Huang et al. (3) using a flow rate of 295 mL/min.

Planques et al. (13) used a 250-mL Zetaffinity cartridge from CUNO packed with modified cellulose as chromatography media. They first chemically treated the cartridge to couple the media with L-lysine. This affinity chromatography media was able to bind with a human plasminogen protein. After centrifugation and microfiltration, human plasma was diluted with a buffer and then applied to the cartridge at a flow rate of 20 mL/min. After washing and elution, a 85% recovery yield and an increase of 110-fold in specific activity were achieved.

Applications Examples Using Sepragen's Superflo Columns

Akoum et al. (14) used a Superflo-400 RFC column packed with histidyl-Sepharose gel for the purification of myxalin, a glycopeptide with anticoagulant property. The feed for the column was obtained from a fermentation broth with the microorganism *Myxococcus xanthus*. Before the feed was applied to the column, it was clarified and concentrated using centrifugation, microfiltration, and reverse osmosis. A relative short processing time was achieved.

Strætkvern et al. (15) used a 60-mL, 2.2-cm i.d. AFC column, a Superflo-250 column (250 mL in bed volume), and a 2,500-mL AFC column for the separation of DNase from the extracts of cod pyloric cacca. The packing medium was Q-Sepharose Fast Flow anion exchange gel from Pharmacia. Column dimensions and operating conditions are listed in Table 2. Table 3 is a summary of their experimental results. Their results indicate that the RFC column required much less time and achieved higher productivity. The superior performance in this case should not be inter-

Productivity ($mg \cdot h^{-1} \cdot mL^{-1}$ gel)	0.13	0.70	0.1

preted as a fixed rule here because the AFC columns they used were not equivalent pancakelike columns.

Weaver et al. (16) used a 10-L Superflo RFC column packed with Q-Sepharose Fast Flow medium from Pharmacia for the separation of uridine phosphorylase from total crude extracts of *Escherichia coli*. After fermentation, 375 L of broth was concentrated to 10 L. It was then washed with 50 L of 20 mM K_3PO_4 buffer containing 1 mM $MgCl_2$. After adding 20 μg lysozyme per milliliter of broth, 100 mg of DNase, and 100 mg of RNase, the cells were homogenized using a bead mill. The supernatant was diluted to 30 L and then applied to the 10-L RFC column. The feed was recirculated back to the column at a flow rate of 1.3 L/min for 3 h and then discharged. The column was washed with three different buffer solutions to remove bound lipid and hydrophobic proteins. Elution was then carried out using a buffer containing 0.225 mM NaCl. The collected effluent was 50 L. The final product after dialysis had a purity of 85% and a recovery yield of 82%.

McCartney (17) used two Superflo-100 RFC columns packed with S-Sepharose FF (Pharmacia) ion-exchange media in tandem for the purification of an undisclosed recombinant protein from *E. coli*. The system was able to process 4 L feed in less than 2 h with a concentration factor of 64 times.

Saxena et al. (12) applied a Superflo-1500 column (1,500 mL in bed volume) packed with immobilized Protein-A Sepharose in the purification of an antimelanoma IgG2A antibody from ascites fluids. Sample was loaded with a flow rate of 104 mL/min. After loading, the column was washed with a buffer using a flow rate of 170 mL/min. Elution was carried out with a flow rate of 92 mL/min. An actual recovery of 3.1 g of the antibody with a product purity greater than 97% was achieved in 3.5 h. A Superflo-1500 packed with riboflavin immobilized on a Sepharose-4B matrix via an epoxy linkage was used by the same researchers to obtain a crude preparation of a riboflavin-binding protein (12). The entire run was carried out using a flow rate of 350 mL/min. They also used a Superflo-200 column packed with antiricin B-chain antibody immobilized on cross-link agarose (12). The flow rate used was 45 mL/min. A 100% yield was achieved with a product amount of 2.1 g and a purity of 100%.

MATHEMATICAL MODELING OF RADIAL FLOW CHROMATOGRAPHY

In 1950, Lapidus and Amundson (18) proposed a simplified theoretical model for RFC. Their model ignores radial diffusion in the bulk-fluid phase and intraparticle diffusion. It is similar to that used by Rachinskii (19). Inchin and Rachinskii (20) subsequently included molecular diffusion in the bulk-fluid phase. Lee et al. (21) proposed several single component rate models for the comparison of statistical moments for RFC and AFC. They included radial dispersion, intraparticle diffusion, and external mass transfer effects. Kalinichev and Zolotarev (22) performed an analytical study on moments for single component RFC in which they treated the radial dispersion coefficient as a variable.

A rate model for nonlinear single component RFC was solved numerically by Lee (23) by using the finite difference and orthogonal collocation methods. His model considered radial dispersion, intraparticle diffusion, external mass transfer, and nonlinear isotherms. It used averaged radial dispersion and mass transfer coefficients instead of treating them as variables. A nonlinear model of this kind of complexity has no analytical solution and must be solved numerically.

Realistic modeling of RFC should treat the radial dispersion and external mass transfer coefficients as variables rather than constants because the linear flow velocity (v) in the RFC column changes continuously along the radial coordinate of the column. Without this distinctive important feature the curvature in the flow path is lost, and thus the column can be imaginatively cut and spread out to become exactly like a pancakelike AFC column.

General Rate Model for Multicomponent RFC

Gu et al. (24,25) presented a general rate model for RFC in which radial dispersion and external mass transfer coefficients are treated as variables rather than constants. The model was solved numerically using finite element and the collocation methods for discretizations of the bulk-fluid phase and the particle phase governing partial differential equations (PDEs), respectively. Figure 13 is an anatomy of a RFC column for the purpose of modeling. The following basic assumptions are made in order to formulate a general rate model for RFC.

1. The column is isothermal.
2. The porous particles in the bed can be treated as spherical and uniform in diameter.
3. The concentration gradients in the axial direction are negligible. This means that the maldistribution of radial flow is ignored.
4. The fluid inside particle macropores is stagnant, that is, there is no convective flow inside macropores.
5. An instantaneous local equilibrium exists between the macropore surfaces and the stagnant fluid in the macropores.
6. The film mass transfer theory can be used to describe the interfacial mass transfer between the bulk-fluid and particle phases.
7. The diffusional and mass transfer coefficients are constant and independent of the mixing effects of the components involved.

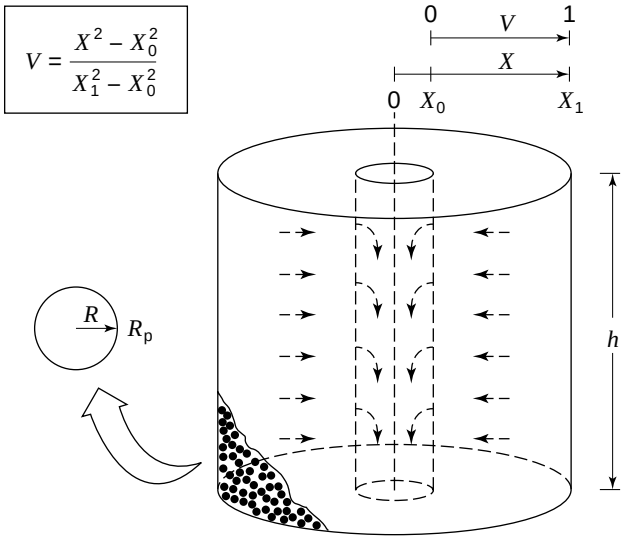

Figure 13. Anatomy of an inward-flow RFC column.

Based on these basic assumptions, equations 1 and 2 are formulated from the differential mass balance for each component in the bulk-fluid and particle phases. In equation 1, the plus sign represents outward flow, and −v is inward flow.

$$-\frac{\partial}{\partial X}\left(D_{bi}X\frac{\partial C_{bi}}{\partial X}\right) \pm v\frac{\partial C_{bi}}{\partial X} + \frac{\partial C_{bi}}{\partial t} + \frac{3k_i(1-\epsilon_b)}{\epsilon_b R_p}(C_{bi} - C_{pi,R=R_p}) = 0 \quad (1)$$

$$(1-\epsilon_p)\frac{\partial C_{pi}^*}{\partial t} + \epsilon_p\frac{\partial C_{pi}}{\partial t} - \epsilon_p D_{pi}\left[\frac{1}{R^2}\frac{\partial}{\partial R}\left(R^2\frac{\partial C_{pi}}{\partial R}\right)\right] = 0 \quad (2)$$

in which C_{pi}^* is related to C_{pi} via isotherm (24).

The initial conditions for the PDE system are at

$$t = 0,\ C_{bi} = C_{bi}(0, X) \quad (3)$$

and

$$C_{pi} = C_{pi} = C_{pi}(0, R, X) \quad (4)$$

The boundary conditions are at the inlet X position

$$\partial C_{bi}/\partial X = (v/D_{bi})[C_{bi} - C_{fi}(t)] \quad (5)$$

and at the outlet X position

$$\partial C_{bi}/\partial X = 0 \quad (6)$$

Equations 1 and 2 can be written in dimensionless forms as follows.

$$-\frac{\partial}{\partial V}\left(\frac{\alpha}{Pe_i}\frac{\partial c_{bi}}{\partial V}\right) \pm \frac{\partial c_{bi}}{\partial V} + \frac{\partial c_{bi}}{\partial \tau} + \chi_i(c_{bi} - c_{pi,r=1}) = 0 \quad (7)$$

$$\frac{\partial}{\partial \tau}[(1-\epsilon_p)c_{pi}^* + \epsilon_p c_{pi}] - \eta_i\left[\frac{1}{r^2}\frac{\partial}{\partial r}\left(r^2\frac{\partial c_{bi}}{\partial r}\right)\right] = 0 \quad (8)$$

In equations 1 to 7, the dimensionless variable, $V = (X^2 - X_0^2)/(X_1^2 - X_0^2) \in [0, 1]$, is based on the local volume averaging method [24]. $\alpha = 2\sqrt{V + V_0}(\sqrt{1 + V_0} - \sqrt{V_0})$ is a function of V.

The dimensionless initial conditions are at

$$\tau = 0,\ c_{bi} = c_{bi}(0, V) \quad (9)$$

and

$$c_{pi} = c_{pi}(0, r, V) \quad (10)$$

The dimensionless boundary conditions are

$$\partial c_{bi}/\partial V = Pe_i[c_{bi} - C_{fi}(\tau)/C_{0i}] \quad (11)$$

At the inlet V position, for frontal adsorption, $C_{fi}(\tau)/C_{0i} = 1$. For elution,

$$C_{\mathrm{fi}}(\tau)/C_{0\mathrm{i}} = \begin{cases} 1 & 0 < \tau < \tau_{\mathrm{imp}} \\ 0 & \text{otherwise} \end{cases}$$

After the introduction of a sample in the form of a rectangular pulse, it component I is displaced, $C_{\mathrm{fi}}(\tau)/C_{0\mathrm{i}} = 0$. If component I is a displacer, $C_{\mathrm{fi}}(\tau)/C_{0\mathrm{i}} = 1$. At the outlet V position, $\partial c_{\mathrm{bi}}/\partial V = 0$. For the particle phase governing equation, the boundary conditions are at r = 0

$$\partial c_{\mathrm{pi}}/\partial \mathrm{r} = 0 \tag{12}$$

and at r = 1

$$\partial c_{\mathrm{pi}}/\partial r = Bi_{\mathrm{i}}(c_{\mathrm{bi}} - c_{\mathrm{pi,r=1}}) \tag{13}$$

Note that all the dimensionless concentrations are based on $C_{0\mathrm{i}}$, that is, the maximum of the feed profile $C_{\mathrm{fi}}(\tau)$ for each component.

The radial dispersion coefficient (D_{bi}) depends on the linear velocity (v). In liquid chromatography, it can be assumed (5,22,25) that $D_{\mathrm{bi}} \propto v$. Thus, $Pe_{\mathrm{i}} = v\,(X_1 - X_0)/D_{\mathrm{bi}}$ can be considered constant in liquid RFC. The variation of Bi_{i} values observes the following relationship:

$$Bi_{\mathrm{i}} \propto k_{\mathrm{i}} \propto v^{1/3} \propto (1/X)^{1/3} \propto (V + V_0)^{-1/6} \tag{14}$$

If $Bi_{\mathrm{i,V=1}}$ values are known, Bi_{i} values anywhere else can be obtained from equation 15.

$$Bi_{\mathrm{i,V}} = [(1 + V_0)/(V + V_0)]^{1/6} Bi_{\mathrm{i,V=1}} \tag{15}$$

χ_{i} can be calculated from Bi_{i} using its definition $\chi_{\mathrm{i}} = 3Bi_{\mathrm{i}}\eta_{\mathrm{i}}(1 - \epsilon_{\mathrm{b}})/\epsilon_{\mathrm{b}}$.

Numerical Solution

The PDE system of the governing equations is first discretized. The finite element and orthogonal collocation methods are used to discretize the bulk-fluid phase and the particle phase governing equations, respectively. The resulting ordinary differential equation (ODE) system is then solved using the public domain ODE solver called DVODE written by Brown et al. (26). The compiled Fortran program is free to academic researchers. Both DOS and Windows 95 versions are available. Information on the software is available at *http://www.ent.ohiou.edu/~guting/CHROM/*.

A study of the effects of treating D_{bi} and k_{i} as variables compared to treating them as constants was carried out by Gu et al. (5,25). The comparison between RFC and AFC was also studied through computer simulation. Figure 14 shows that outward flow gives slightly sharper concentration profile (5). The figure also shows that RFC gives similar concentration profiles as AFC with equivalent physical parameters. These theoretical results support the experimental results obtained by Tharakan and Belizaire (8).

SCALE-UP OF RFC COLUMNS

One of the advantages of RFC columns is the relative ease for scale-up. In Sepragen's Superflo column series, increasing the column height is a rather safe way to accommodate an increase of sample size to a certain degree. However, one must keep in mind that maldistribution in radial flow may deteriorate slightly. If the bed thickness in the radial direction is increased, bed pressure usually increases proportionally. The performance prediction will be less reliable if the column diameter is increased. Figure 15 shows that a 15-fold increase of sample load and bed column produced very similar performances when DEAE cellulose is used to separate an ascites fluid (27,28). Figure 16 is an example with a 50-fold increase of sample load and bed column (27). These two examples are very successful examples.

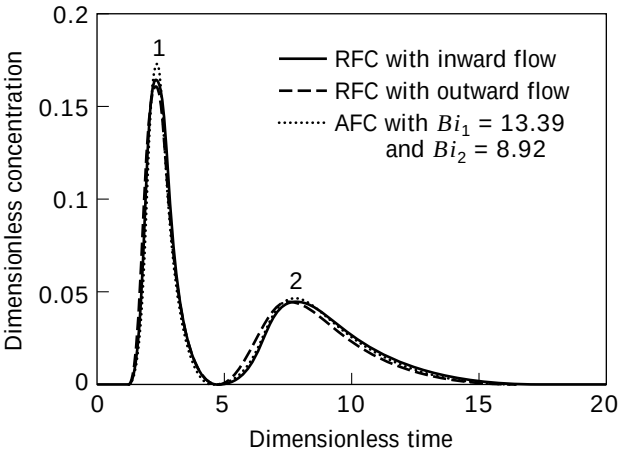

Figure 14. Simulated comparison for inward- and outward-flow RFC and AFC.

The mathematical model introduced above can be used to help the scale-up process. Before a column is bought, its performance can be predicted using computer simulation. Isotherm data must be obtained experimentally or be supplied by the vendor of the packing material. Mass transfer parameters can be estimated by using existing correlations (24).

CONCLUSIONS

RFC columns have a short flow path and a large flow area, resulting in a small bed pressure. They are especially suitable when soft-gels are used. Because of its limited resolution, RFC should be used in chromatographic separations involving strong solute–stationary phase interactions, such as affinity chromatography, strong anion or cation exchange, strong reversed phase, and strong hydrophobic interaction chromatography. RFC is not suitable for SEC and other chromatography with weak solute–stationary phase interactions. RFC is an attractive alternative to AFC in preparative- and large-scale separations. Both experimental and theoretical modeling indicate that to a large extent an RFC column behaves much like a pancake-style AFC column with the same packing volume and with its bed height about the same as the packing's radial thickness in RFC column. However, RFC has a much

smaller footprint, and it seems to handle flow distribution better than very wide pancakelike columns.

NOMENCLATURE

Bi_i	Biot number of mass transfer for component i, $k_i R_p(\epsilon_p D_{pi})$
C_{0i}	Concentration used for nondimensionalization, $\max\{C_{fi}(t)\}$
C_{bi}	Bulk-fluid phase concentration of component i
C_{fi}	Feed concentration profile of component i, a time-dependent variable
C_{pi}	Concentration of component i in the stagnant fluid phase inside particle macropores
C^*_{pi}	Concentration of component i in the solid phase of particle (based on unit volume of particle skeleton)
c_{bi}	$= C_{bi}/C_{0i}$
c_{pi}	$= C_{pi}/C_{0i}$
c^*_{pi}	$= C^*_{pi}/C_{Oi}$
D_{bi}	Axial or radial dispersion coefficient of component i
D_{pi}	Effective diffusivity of component i, porosity not included
k_i	Film mass transfer coefficient of component i
Pe_i	Peclet number of radial dispersion for component i, $v(X_1 - X_0)/D_{bi}$
R	Radial coordinate for particle
R_p	Particle radius
r	$= R/R_p$
t	Dimensional time ($t = 0$ is the moment a sample enters a column)
v	Interstitial velocity
V_0	Dimensionless constant corresponding to X_0
V	Dimensionless volumetric coordinate
X	Coordinate in the radial direction for a RFC column.

Greek Letters

α	$= 2\sqrt{V + V_0}(\sqrt{1 + V_0} - \sqrt{V_0})$ for RFC
ϵ_b	Bed void volume fraction
ϵ_p	Particle porosity
η_i	Dimensionless constant, $\epsilon_p D_{pi} L/(R_p^2 v)$
χ_i	Dimensionless constant for component i, $3Bi_i\eta_i(1 - \epsilon_b)/\epsilon_b$
τ	Dimensionless time, vt/L
τ_{imp}	Dimensionless time duration for a rectangular pulse of the sample

OUTLINE

INTRODUCTION

Size-exclusion chromatography (SEC) is a widely used means for separation of macromolecules of different sizes. Porath and Flodin in 1959 first demonstrated the use of SEC, or gel filtration chromatography, for separations by resolving glucose from two size fractions of dextrans (1). In addition, they applied the technique to desalting of serum proteins. Remarkably, these two applications—crude separations and desalting—remain the primary uses of SEC today. A wide range of materials, including sugars, proteins, and nucleic acids, have been analyzed or separated using this technique. In addition, SEC is used extensively in the characterization of polymers. However, in this article, the emphases are on analysis and on separations involving biological macromolecules.

Basic Principle

The essential principle of size exclusion chromatography is partitioning of species on the basis of preferential sieving into the pores of support particles. Sample is applied to the top of a bed packed with porous stationary phase particles. Elution results from flow of a fixed composition buffer through the bed (isocratic elution), in contrast with other modes of chromatography in which the buffer composition is varied (gradient elution). Molecules that are larger than the pores of the support access only the interstitial space between particles and therefore pass through the column quickly, whereas smaller particles access the volume within the pores and are retained for a longer time by the column (Fig. 1). Therefore, a support must be selected with a pore size distribution so that there exists a differential partitioning of the molecules to be separated.

Lexicon

In any chromatographic process, sample is injected into the column and eluted by continuous flow of a buffer through the column. The time between injection and the peak of any eluted solute is termed its retention time (t_R). An equivalent measure of retention is the retention volume (V_R), which, for the usual case of constant flow rate, is merely the product of the flow rate and retention time. The terms *elution time* and *elution volume* are used interchangeably with *retention time* and *retention volume*. For solute molecules larger than the size of the pores, the elution volume represents the volume of the column between the support particles plus that of extracolumn tubing between the injection loop and the column and from the column to the detector. This is known as the void volume (V_0), and it is frequently estimated using large, inert tracer solutes. The pore volume (V_p) is the volume within the particles occupied by fluid and, in principle, accessed entirely by very small particles, for which the retention volume is maximized:

$$V_{R,max} = V_0 + V_p \quad (1)$$

In general, the elution volume is intermediate between the void volume and the sum of the void and pore volumes and thus defines a distribution coefficient (K_d) through the relation

$$V_R = V_0 + K_d V_p \quad (2)$$

By definition, the distribution coefficient assumes values only between zero and unity. The other relevant volume is that of the support particles or chromatographic matrix (V_m). In principle, one can calculate the pore volume based on the amount and density of the support through the relation

$$V_p = \frac{W_r \rho_{gel}}{1 + W_r \rho_{H_2O}} (V_t - V_0) \quad (3)$$

where V_t is the total volume (sum of void, pore, and matrix volumes, the first corrected for the volume of extracolumn tubing), ρ represents mass density, and W_r is the water

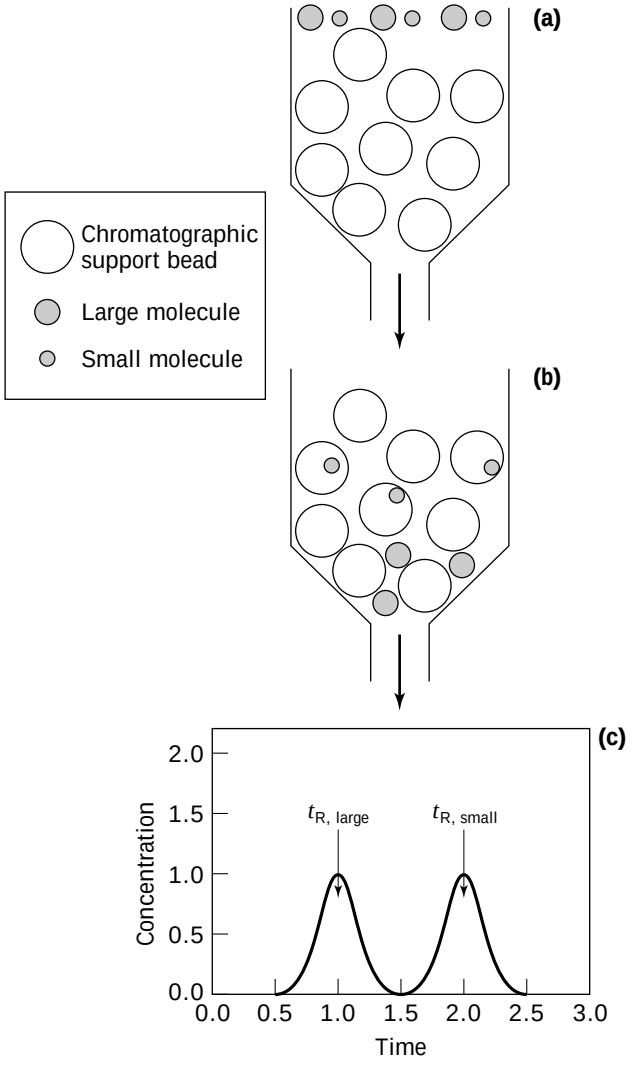

Figure 1. Principle of SEC. (**a**) A mixture of large and small particles is introduced together into the top of the column. (**b**) As the particles move down the column, the small particles are able to access the volume within the pores of the particles. Therefore, the larger particles are eluted from the column before the smaller ones. (**c**) Schematic chromatogram showing the elution profiles of the large and small particles.

regain of gel (grams of water per gram of dry gel divided by the density of water). Experimentally, V_p can be measured as the retention volume of a small molecule that does not interact with the support. With determination of V_0 and V_p, the distribution coefficient of any solute can be determined from its retention and equation 2; conversely, the retention time of a solute could be predicted from a model for its distribution coefficient (see "Process Variables") and from the column parameters.

The typical chromatographic peak is Gaussian in shape. The quality of separation of two (or more) species in SEC is characterized by differences in their retention times and by certain measures of the distribution of material in each peak about the mean. The resolution (R_s) is a measure of separation of two bands, defined by

$$R_s = \frac{t_{R2} - t_{R1}}{\frac{1}{2}(w_2 - w_1)} \quad (4)$$

where w_i is the baseline width of peak i, related to the standard deviation of the Gaussian peak through $w_i = 4\sigma_i$, and t_{Ri} is the retention time of the ith peak. Another measure of separation is the selectivity, α, between two bands. It is defined by

$$\alpha = \frac{k'_2}{k'_1} \quad (5)$$

where k′ of species i is its retention factor (or capacity factor). The retention factor is a relative retention time defined as

$$k' = \frac{t_R - t_0}{t_0} = \frac{V_R - V_0}{V_0} \quad (6)$$

For non-Gaussian bands, t_R and σ can be determined via statistical analysis of the chromatogram from the first and second moments, respectively, of a trace.

MATERIALS

Equipment

A typical laboratory setup for SEC is depicted in Figure 2. The equipment required includes solvent and reservoir, valves and tubing, pump, packed column, detector, fraction collector, and recording device. For the most part, this equipment is universal to the various modes of chromatography. The precolumn setup for SEC, especially at low pressure, is relatively straightforward. Solvent delivery is simpler in SEC than for other modes of chromatography because there is no need for gradient formation and the only pump requirement is for stable flow. Peristaltic pumps are adequate for low-pressure work, whereas piston or diaphragm pumps are used for high pressures (2).

The most important aspect of the equipment is the column packing. The gel must be packed uniformly throughout the column to avoid channeling or other heterogeneous effects that act to blur separation of the solutes. Frequently, the gel is supplied as a powder or as a suspension in a storage solvent. In the latter case, this solvent is filtered off, and in both cases the gel is then suspended in a packing solvent, which is usually an aqueous buffer with some NaCl added. A stable, uniform packing is attained by degassing the gel slurry before packing, pouring it at once, and then packing at a flow rate greater than used in normal operation.

Detection of proteins and nucleic acids is most commonly accomplished with UV absorbance detectors, although more sensitive techniques such as light-scattering and mass spectrometry are also possible (3). The detection limit (C^*) is dictated by the absorbance sensitivity (A^*) of the instrument, the extinction coefficient (ϵ) of the solute, and the path length (L) of the detector, according to

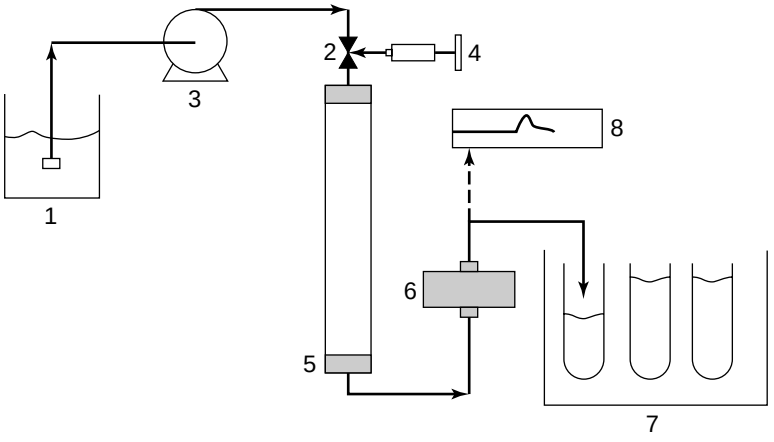

Figure 2. Laboratory SEC setup. Solvent (*1*) is pumped through a three-way valve (*2*) by a peristaltic pump (*3*). The desired volume of sample is introduced by syringe (*4*) through one port of the valve while the solvent flow is temporarily blocked. The valve is repositioned to allow elution of the sample though the packed column (*5*). The eluting solution is monitored by a detector (*6*) and collected in a fraction collector (*7*). A permanent record of the chromatogram is obtained from a recorder (*8*) or computer.

$$C^* > \frac{A^*}{\epsilon l} \tag{7}$$

The sensitivity of absorbance detectors is usually about 5×10^{-4}, and their path lengths can be up to 1 cm. Typical proteins have extinction coefficients on the order of 1 cm^2/mg; therefore, the detection limit is on the order of 1 μg/mL. Nucleic acids exhibit strong absorbance, peaking around 260 nm, with extinction coefficients on the order of 25 to 50 cm^2/mg; consequently, lower concentrations down to 20 ng/mL may be detected. Carbohydrates, on the other hand, exhibit no significant absorbance in UV or visible light; refractive index detectors are often used for their quantitation.

Packing Materials

A wide variety of packing materials are available for use in SEC. The choice of gel for a particular application depends on a number of factors, including materials compatibility, operating conditions, and particularly the sizes of the molecules to be separated. Manufacturers typically provide a good deal of information about their packing materials, including fractionation range, maximum flow rate or pressure drop, and stable operating ranges of pH and temperature.

Properties. The key feature of the packing material with respect to a particular separation is the pore size distribution, because this determines the range of particles that may be fractionated. Very small pores are required for desalting applications, so that all macromolecules are excluded and low molecular weight species are retained. Materials possessing much larger pores are used for analysis and purification of biological macromolecules. Because the pore sizes are normally inferred from the sieving of test solutes, the useful molecular weight fractionation range, rather than the actual pore size, is generally reported. It is important to note that different types of molecules exhibit different fractionation ranges; therefore, a fractionation range reported using protein standards will not be identical to that of, for example, nucleic acids. Some manufacturers report two fractionation ranges: one using protein standards and another using nucleic acids or dextrans. Usually, these two values will be sufficient to at least select an appropriate gel for the application of interest.

Once a fractionation range is determined, a material appropriate for the solutes of interest must be identified. Although the gel materials used in SEC have been developed to exhibit minimal adsorption, biological macromolecules inevitably interact to some extent with these materials. Proteins in particular will adsorb to a variety of surface functionalities. A general rule is that the gel material should be hydrophilic and uncharged. However, most hydrophilic materials exhibit at least a weak charge. Undesirable electrostatic interactions caused by this charge can be minimized by eluting with a buffer of moderate ionic strength, 0.3 to 0.5 M. In addition, the column must be operated under conditions at which the material is stable. Packing materials can deteriorate when subjected to extremes of pH, ionic strength, flow rate, and temperature. For some materials, enzymatic degradation is also possible in the event of bacterial contamination.

The size of the particles and their degree of compressibility determine the pressure drop across a bed and limit the flow rate that may be used. Particles ranging from 5 to 600 μm are available (4,5). Some SEC media, particularly cross-linked materials, are rigid over their normal operating range (Table 1). For these rigid materials, the pressure drop (Δp) across a gel of length (L) is inversely proportional to the square of the particle diameter (d_p) and proportional to velocity (v_0) (flow rate divided by cross-sectional column area), in accordance with Darcy's law:

$$\Delta p = \frac{\mu v_0 L}{k d_p^2} \tag{8}$$

where k is a constant and μ is the fluid viscosity. However, as the particles compress, the pressure drop increases dramatically, effectively setting an upper limit on the maximum attainable velocity. From the standpoint of materials selection, manufacturers supply information regarding particle size, fraction range, and maximum allowable flow.

Available Materials. Materials comprised of dextran, agarose, acrylamide, or combinations have traditionally been the workhorses of SEC. However, novel polymeric materials and polymer-coated silica media have been de-

veloped. Silica possesses excellent mechanical strength, but it is prone to adsorption of biomolecules. Materials are available from a number of manufacturers, and many are summarized in Table 1. Although this list is not exhaustive, it represents many of the commonly used materials, and it is notable that these have not changed significantly over the past 15 years (5–7).

Dextrans are used in a wide variety of protein and nucleic acid separations. They are polysaccharides that are made into a porous gel by cross-linking with epichlorohydrin (8). These materials are quite stable for pH $>$ 2 and for temperatures up to at least 120 °C and can be used with either aqueous or organic solvents. Dextran gels with small pore sizes exhibit low compressibility, but versions with larger pore sizes are quite compressible (9). As a result, some dextran gels are limited to flow rates that can be less than 1 mL/min. Because dextrans are polysaccharides, they are susceptible to bacterial degradation; however, because of their thermal stability, they can be autoclaved. A variation of the traditional dextran gel is provided by cross-linking dextran with *N,N′*-methylenebisacrylamide. This provides a material that is substantially more rigid but has a smaller stable pH range and is more susceptible to adsorption of proteins. The latter obstacle can often be overcome by eluting with a higher ionic strength solvent.

Acrylamide gels are formed by cross-linking acrylamide monomer with *N,N′*-methylenebisacrylamide. The resulting matrix is quite stable over the pH range from 2 to 10 and to high temperatures and is not prone to bacterial degradation. It is less adsorptive than the corresponding dextran material. Consequently, polyacrylamide gels are commonly used for protein separations. Their main disadvantage is that they are incompatible with organic solvents.

A copolymer of D-galactose and 3,6-anhydro-L-galactose is used to form an agarose gel. The composition and degree of cross-linking have a profound effect on the properties of agarose-based media. With less cross-linking, the gels are typically stable only in the pH range of 4 to 9, are compressible at flow rates as low as 1 mL/min, and must be sterilized chemically, but they exhibit little adsorption of macromolecules and broad fractionation ranges that make them much more suitable than acrylamide or dextran for the separation of large proteins and nucleic acids. With a higher degree of cross-linking, the material is stable over a wider range of pH and flow rate, and it can be autoclaved; however hydrophobic interactions may occur between proteins and the support, and the available fractionation range is reduced.

A number of variations on traditional materials have been established. Generally, these are produced to combine the desirable sieving properties of one material with the mechanical or chemical stability of another. The three most commonly used materials—dextran, acrylamide, and agarose—have been combined in all possible pairs. The dextran–bisacrylamide material (Sephacryl) mentioned earlier is one such example. Another is a composite of dextran and cross-linked agarose, covalently bound together to form a material (Superdex, [9]) that has the fractionation range of a dextran support with the rigidity of agarose. The resulting material is autoclavable and stable in the range 3 $<$ pH $<$ 12 and to a variety of strong solvents. Acrylamide has also been entrapped in an agarose gel to form the commercial Ultrogel matrix (7).

Other supports, based on materials such as silica and hydrophilic polymers, have been produced for SEC (5). Although porous silica is inherently rigid and can be manufactured in a variety of pore sizes, it exhibits marked ad-

sorption of proteins and is unstable at basic pH. Other polymer gels exist commercially, such as Toyopearl and Spheron, which are based on polyethers and poly(2-hydroxyethylmethacrylate), respectively. The latter is a material approved by the Food and Drug Administration and can thus be used to produce biocompatible supports.

APPLICATIONS

A number of applications exist for SEC in the research laboratory and in industrial processes. These can be divided into the two categories of sample analysis and purification. The former is most often performed on small columns with high resolution, and the latter is a bulk operation in which the separations are usually fairly crude. A summary of some examples of SEC applications is provided in Table 2.

Analysis

At the analytical level, SEC is used as a tool in characterizing the size, shape, and interactions of biological macromolecules. For example, SEC has been used to study the kinetics and equilibrium dimerization of proteins (10,11). Likewise, it can be used to study the hybridization of nucleic acids (12). Similar applications have been made to reversible interactions between macromolecules and low molecular weight species (13,14). It has also been used to identify and characterize molten globule states in studies of protein unfolding (15). In addition, it is an excellent tool for identification and separation of small molecules that are conjugated to biomolecules, such as probes attached to antibodies or drugs conjugated to targeting molecules (16–18).

SEC is often used for molecular weight determination, although this is an approximate method. Molecules that are similar to the solute of interest but with known molecular weight are used to create a calibration curve of retention time versus molecular weight. The unknown molecular weight of the solute is then estimated from its retention time. The degree of success of this approach is highly dependent on how similar the unknown solute is to the molecular weight standards. That is, a calibration curve prepared with globular proteins will give an inaccurate molecular weight for an oligonucleotide or even for a glycoprotein. Nonetheless, for similar molecules, molecular weights can be successfully estimated. For example, the retention times of a number of globular proteins correlate well with log(MW), as shown in Figure 3. Under the conditions of Figure 3, the retention time of α_1-acid glycoprotein is 8.70, from which an apparent molecular weight of 57 kDa is calculated, significantly greater than its actual molecular weight of 40 kDa.

For molecules of similar chemistry, such as globular proteins, the deviation of the observed elution volume from the calibration curve can be an indication of molecular shape. Deviation from spherical to ellipsoidal shape results in increased molecular friction, and thus the molecule sieves as if its apparent molecular weight is greater than its actual value. Although exact molecular weight determination is complicated by the shape and chemical nature of different protein molecules, changes in a particular structure can be discerned with high resolution. For instance, the extent of modification of a protein by a dye or other ligand can be monitored by the relatively small decrease in retention time if the same column, buffer, and operating conditions are used (16).

Separations

By design, SEC separates molecules based on their size, so it is not possible to achieve well-resolved separations of biomolecules from a mixture of similar species using this technique. Although fair discrimination of molecules according to molecular weight was seen in the previous section, small differences in retention time are insufficient for resolution in purification (see "Dependence of Separation Parameters on Operating Variables"). Nonetheless, crude fractionation of a particular size range is possible with

Table 2. Examples of SEC Applications

Analysis
Molecular weight estimation
Identification and analysis of protein dimers
Analysis of reversible protein–small molecule interactions
Studies of protein unfolding
Identification of products in molecular conjugates
Evaluation of the stability of macromolecular complexes
Separations
Desalting
Crude protein separations
Purification of molecular conjugates
Removal of endotoxins and viruses from pharmaceutical formulations

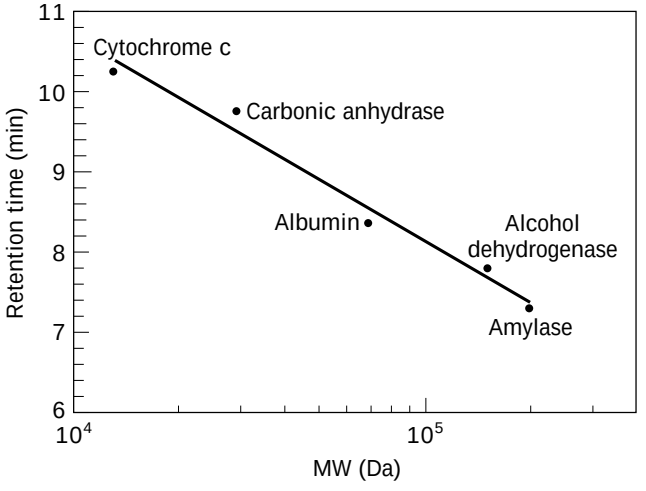

Figure 3. Calibration curve of an analytical SEC column. The elution volumes of several globular proteins were determined on a TSK-GEL G3000SW$_{XL}$ column, 7.8 mm i.d. and 30 cm length. Twenty microliter aliquots (concentration approx. 1 mg/mL) were injected and elution was performed in a buffer of 0.1 M KH_2PO_4 + 0.1 M Na_2SO_4, pH 7. The eluate was monitored by UV absorbance detection at 280 nm.

SEC. Thus, it is best suited either for purification of one molecule of interest from a small set of dissimilar contaminants in the laboratory or as an early or late step in conjunction with other steps in an industrial process.

SEC finds many laboratory applications in manipulations of biological molecules. For example, unreacted species in molecular conjugates are often removed via SEC (18). Cleanup of materials involved in the synthesis of peptides and oligonucleotides is also performed frequently via SEC (19). It is also used for removal of aggregates resulting from a variety of biochemical preparations. For example, an intermediate or final step in purification of a monoclonal antibody is often removal of dimers and aggregates that have been generated as a result of prior processing. In the production of recombinant proteins, a certain fraction may be clipped by proteolysis; these smaller molecules can be separated by SEC (20).

The most common application of SEC at both laboratory and process scales is desalting or buffer exchange. Many processing steps (e.g., extraction, crystallization, other modes of chromatography) involve the use of a solvent that is undesired for future processing or formulation steps. Very small pore SEC columns are used to replace the undesired buffer by the desired one. Usually, a wide disparity in molecular sizes exists between the biological solute and the buffer salts, so short columns can be used, limiting the dilution to twofold or less (21).

PROCESS VARIABLES

Selection of a support material for an application of interest is only the first step in performing an analysis or separation. The amount of sample to be analyzed or purified must be considered. The column length and total amount of material to be injected into the column must be determined. Finally, a flow rate must be found that will provide adequate throughput and resolution. In the process of designing a configuration, convective dispersion, transport of the solutes to and within the particles, and partitioning of the solutes between the mobile and gel phases must all be considered. For these reasons, a substantial body of literature has been devoted to the engineering issues associated with SEC. The most general and applicable models are discussed in this section.

Plate Theory

An operational description of chromatography can be obtained from plate theory, which is a phenomenological description of zone spreading in chromatography, first proposed by Martin and Synge in 1941 (22). The essential concept is that as the solute traverses the column, it undergoes repeated equilibration with the stationary phase, so that each equilibration defines one stage, or plate. The column length over which equilibration occurs is known as the height of an equivalent theoretical plate (HETP), or simply plate height. The development of a solute peak zone is shown schematically in Figure 4. In each stage, fluid in the mobile phase is mixed, and partitioning occurs between the stationary and mobile phases. A mass balance on a particular stage takes the form

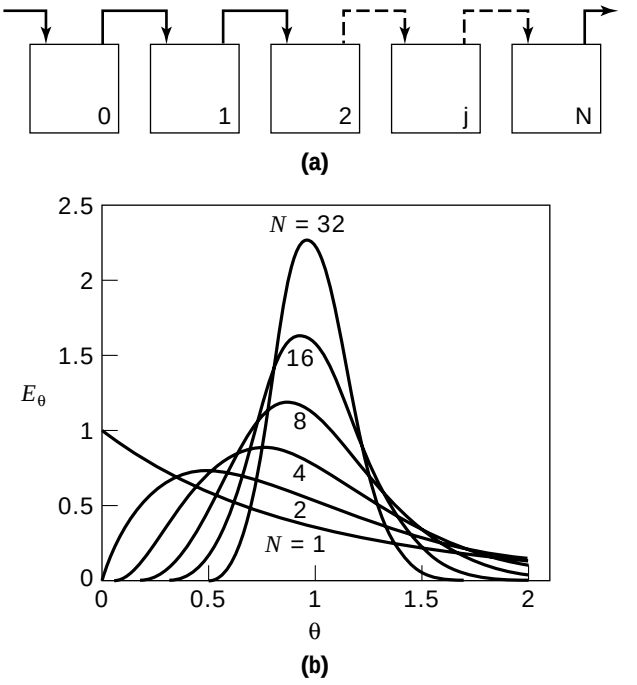

Figure 4. (**a**) Plate theory. The progression of solute through the column can be viewed as passing through a number of stages. In each stage, fluid in the mobile phase is mixed and partitioning occurs between the stationary and mobile phases. (**b**) Residence time distribution from N successive plates. The residence time distribution E, which is the output from a pulse input, in terms of the dimensionless variable $\theta = t/\tau$, is shown as a function of θ for various numbers of plates (N). It can be seen that as the number of plates exceeds approximately 10, the residence time distribution begins to assume a Gaussian shape, which is enhanced as N increases further.

$$Q(C_{j-1} - C_j) = v_m \frac{dC_j}{dt} + v_p \frac{d\bar{C}_{p,j}}{dt}, \qquad (9)$$

where Q is the flow rate, C_j is the concentration of solute in the jth stage, v_m is the mobile phase volume per stage, v_p is the pore volume per stage, and $\bar{C}_{p,j}$ is the average pore concentration in the jth stage. For linear chromatography, the average pore concentration is proportional to the bulk concentration, and equation 9 becomes directly analogous to the mass balance on stirred tanks in series (23).

The input to a chromatography column is essentially a pulse; consequently, the output from a series of N stages is analogous to the residence time distribution (E) from N tanks in series. The output from a single stage is an exponential distribution, but, as the number of plates increases, the residence time distribution takes on a Gaussian shape, as shown in Figure 4. It can be shown that the variance σ^2 of the output peak is dependent only on the retention time and number of stages through

$$\sigma^2 = t_R^2/N \qquad (10)$$

Therefore, the number of plates (N) in chromatography is defined as

$$N = t_R^2/\sigma^2 \quad (11)$$

and the plate height (H) as the length of the column (L) divided by the number of plates

$$H = L/N = L\sigma^2/t_R^2 \quad (12)$$

Relation of Size to Sieving

Because the purpose of SEC is to separate molecules on the basis of their size, interest developed from the time of its introduction to understand quantitatively the relationship between the size of a solute molecule and its retention volume. This is of importance in the use of SEC for molecular weight determination, in its interpretation for applications involving monitoring changes in molecular structure, and in the selection of SEC media and operating conditions to perform a separation.

Volume Exclusion. The primary mechanism of sieving is based on the excluded volume of particles in the pores. At equilibrium, the solute molecules will attain a concentration within the pore based on the volume accessible to the center of the molecule. When the pore size is of the same order as the solute molecular size, the accessible volume becomes significantly less than the pore volume (Fig. 5). As a result of the excluded volume effect, even a monodisperse pore size distribution will produce a continuum of distribution coefficients with increasing molecular size.

To develop this concept into a quantitative model, a geometry is usually assumed. An early result was that of Laurent and Killander (24), who used the expression of Ogston (25) for the available volume in a network of rigid rods to develop an expression for the distribution coefficient:

$$K_d = \exp[-\pi L(r_s + r_r)^2] \quad (13)$$

where L is the total length of rods per volume, r_s is the radius of the (assumed) spherical particles, and r_r is the radius of the rods. The parameters L and r_r are generally not known and must be fit to experimental data. Other expressions were derived for cylindrical, conical, and slit-like pores (26). The problem of ascribing a particular pore geometry was circumvented by Ackers (27), who represented a pore by the maximum characteristic radius particle that could pass through it and postulated that the distribution of pore sizes is distributed normally. For this model, the distribution coefficient takes the form

$$K_d = \text{erfc}\left[\frac{a - a_0}{b_0}\right] \quad (14)$$

where a is the radius of the solute particle, a_0 is effectively an average pore radius, and b_0 is a measure of the variance of the distribution. These parameters must still be determined for each gel from sieving experiments on at least two (preferably more) solutes.

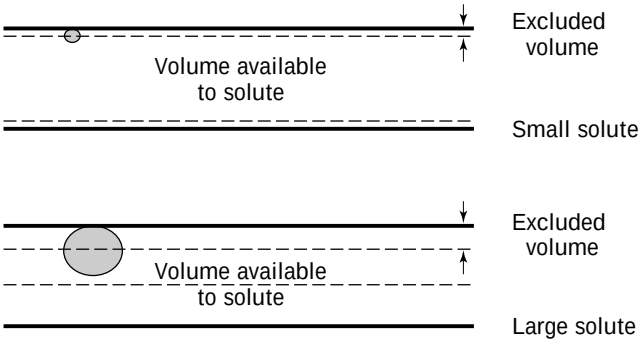

Figure 5. Volume exclusion of solutes in pores. Solutes assume concentrations within pores of varying sizes according to the volumes accessible by the centers of its molecules.

Rates of Pore Diffusion. The models based on volume exclusion (see previous section) are entirely thermodynamic; that is, they do not include any transport limitations and do not predict a dependence of distribution coefficient on flow rate. In practice, a slight dependence is observed, which led to the development of theories that account for transport of solute molecules into the pores. An approach to accounting for diffusion is to model the distribution of molecules between the mobile and gel phases using the one-dimensional (1-D) unsteady-state diffusion equation (28), which has the solution

$$C_g = C_m \text{ erfc}\left[\frac{x}{2(Dt_d)}^{1/2}\right] \quad (15)$$

where C_g and C_m are concentrations in the gel and mobile phases, respectively, x is distance into the 1-D gel phase, t_d is the diffusion time, and D is the diffusion coefficient of the solute. With t_d inversely proportional to the mobile phase velocity (v_0) and b representing the power to which diffusion coefficient is inversely proportional to molecular weight (M), the distribution coefficient can be determined to be (28)

$$K_d = \frac{k}{(\pi v_0 M^b)^{1/2}}(1 - e^{-v_0 M^b/k^2}) + \text{erfc}\left[\frac{(v_0 M^b)^{1/2}}{k}\right] \quad (16)$$

where k is a grouping of constants fit to experimental data.

Purely Empirical Correlations. The equations initially used to correlate SEC data were essentially empirical. The most commonly used forms are

$$V_R = A - B \log(M) \quad (17)$$

and

$$\log(V_R) = A' - B' \log(M) \quad (18)$$

where M is the molecular weight of the solute and A, B, A', and B' are empirical constants for the particular column configuration. As shown in Figure 3 and discussed in "Analysis", very good correlations of data for similar species are possible, but a priori prediction or extrapolation beyond the measured range of molecular weights or to mol-

ecules of different chemistry is problematic. Note that the more sophisticated theoretical models discussed earlier also make use of essentially empirical constants that require calibration of the column using proteins (or other molecules) of known molecular weight. Calibration of the column must be repeated if the pH, ionic strength, or temperature is changed significantly or if the column is repacked. Furthermore, the calibration standards must be well characterized and of a similar nature to the solutes of interest. Nonetheless, the use of theoretical models attaches a physical significance to the parameter's fit from experimental data and provides some insight into the relative contributions of the volume-exclusion versus pore-diffusion mechanisms (28).

Transport Issues

The previous section dealt with the retention time, which mostly results from the equilibrium partitioning of species into the gel support. For separations, it is necessary to consider that chromatography is conducted in a packed bed, under flow, sometimes at high pressures. The configurational aspects of the chromatography column lead to band broadening, or spreading of the eluted solute band. The main contributions to band broadening are eddy diffusion, axial dispersion, and mass transfer resistance at the surface of the particles and within the pores. Eddy diffusion results from the tortuosity of extraparticle paths that solute particles take from the top to the bottom of the column. Axial dispersion is essentially molecular diffusion along the length of the column. The mass transfer resistance at the surface arises from the boundary layer, or film, through which solute must pass to reach the gel particle, and the mass transfer resistance of the pores is due to diffusion of solute into them and is enhanced by their nonuniformity.

A chromatography column is a packed bed of gel particles and is subject to the same types of scaling analysis as for packed beds in other chemical processes. Most of the resistance to mass transfer is at the level of the particle; consequently, the particle diameter is the characteristic length for scaling. Hence, a reduced velocity or Péclet number, *(Pe)* can be defined in terms of the particle diameter as

$$Pe = \frac{d_p u}{D_0} \tag{19}$$

where u is the interstitial velocity of the fluid and D_0 is the bulk solute diffusion coefficient. Likewise, the reduced plate height (h) is

$$h = \frac{H}{d_p} \tag{20}$$

where H is the plate height defined in equation 12.

The relation of interest is that between plate height and flow rate (or velocity) or, equivalently, between reduced plate height and Péclet number. This is obtained from solution to the governing differential mass balance equations in lesser or greater complexity (29–31).

Dependence of Separation Parameters on Operating Variables

Analysis of mass transport in chromatography columns has made it possible to make quantitative predictions regarding plate heights as a function of flow rate in SEC (32). The original analysis of mass transport was conducted by van Deemter (29). His equation has served as the basis for all subsequent analyses:

$$h = 2\lambda + \frac{2\gamma}{Pe} + CPe \tag{21}$$

where λ, γ, and C are constants accounting for eddy dispersion, axial diffusion, and mass transfer resistance at the particle surface, respectively. This equation predicts a minimum plate height with respect to increasing fluid velocity. More detailed accounting of the mass transfer contributions, including that caused by intraparticle diffusion, have produced alternative expressions for the plate height, for example, the expanded form of Horváth and Lin (33):

$$h = \frac{2\gamma}{Pe} + \frac{2\lambda}{1 + \omega Pe^{-1/3}} + \frac{\kappa k_0^2}{(1 + k_0)^2} Pe^{2/3} + \frac{\theta k_0}{30(1 + k_0)^2} Pe \tag{22}$$

where θ is a geometric factor for a given particle, λ, γ, ω, and κ are parameters dependent on the details of the particular column packing, and k_0 is the ratio of intraparticle to interstitial volumes available to the solute of interest. The third and fourth terms represent mass transfer resistances at the particle surface and within the pores, respectively.

For liquid chromatography involving macromolecules, the contributions from axial dispersion and resistance at the particle surface are small, and the largest contribution is from pore diffusion. Consequently, the minimum observed by van Deemter for GLC (29) is typically not observed in SEC of biomolecules, and the plate height is roughly proportional to velocity (32,34,35). Plate height also depends on particle size:

$$H \sim \frac{u d_P^2}{D_0} \tag{23}$$

From this approximate equation, two practical points can be inferred. First, because plate height is a measure of zone spreading and should generally be minimized, smaller particles are preferred because of the strong dependence of plate height on diameter. However, pressure drop is inversely proportional to the square of particle diameter, so the mechanical properties of the material limit the extent to which particle size can be reduced. Second, lower velocities, that is, slower flow rates, will result in less zone spreading. This advantage may be offset where the speed of a separation is important. Furthermore, the flow rate cannot be reduced too drastically or the effects of axial diffusion will become limiting.

An important measure of the separation is the resolution between two or more solutes to be separated. The de-

pendence of the resolution on column variables can be determined from the equations already developed. Combining equations 4, 6, and 12 gives an expression for resolution in terms of capacity factors and plate heights (36):

$$R_s = \frac{L^{1/2}}{2} \frac{k_2' - k_1'}{H_2^{1/2}(1 + k_2) + H_1^{1/2}(1 + k_1')} \qquad (24)$$

Employing the approximation that the plate heights of the two solutes are equal, an expression for resolution as a function of retention, selectivity, and column efficiency can be derived by combining the definition of selectivity (equation 5) with equation 24:

$$R_s = \frac{1}{2}\left(\frac{\alpha - 1}{\alpha + 1}\right) \frac{\bar{k}'}{1 + \bar{k}'} \frac{L^{1/2}}{H^{1/2}} \qquad (25)$$

where $\bar{k}' = (k_1' + k_2')/2$ is the average retention time of the solutes.

Equation 25 expresses resolution as a function of three terms representing selectivity, retention, and zone spreading, respectively. Selectivity is the most important determinant of resolution, up to a point. An increase in α from 1.1 to 1.2 results in an 83% increase in resolution, all other factors being equal; however, an increase from 2.1 to 2.2 results in only a 6% further increase in resolution. Selection of a column best suited to fractionate the species of interest is thus critical to obtaining high resolution. Because the capacity factor is greater than or equal to unity, the middle term takes values only between 0.5 and 1; nonetheless, some improvement in resolution is seen to be possible by increasing the retention time. Because of the weak dependence of resolution on length, significant increases in column length are often required to effect a modest improvement in resolution. The inverse relationship between resolution and plate height suggests that minimizing zone spreading by the methods discussed earlier—reducing particle diameter or flow rate—will concomitantly improve resolution. This is true, subject to the same limitations on flow rate and pressure drop. Furthermore, if speed of separation is important, a trade-off exists.

In addition to the particle size and composition, column length, and operating flow rate, the SEC practitioner must choose column diameter, sample volume, and buffer composition. Column diameter does not appear explicitly in the equations describing resolution, but they are derived with the assumption of a uniform packing, which is increasingly difficult to achieve as the diameter-to-length ratio increases. Therefore, columns used for fractionation are prepared with a length-to-diameter ratio of about 10:1. But in industrial scale desalting applications, where the selectivity is great and resolution not an issue, much wider columns can be used. Sample volumes are usually chosen to be less than 5% of the total column volume, because values greater than a couple of percent tend to produce significant increases in zone spreading. In principle, the solute molecules should not interact with the stationary phase in SEC, but in practice biological molecules exhibit some interaction with a variety of materials, including gels used for SEC (37). Variation of buffer composition can be used to modulate adsorptive interactions. For example, adsorption is often mediated by charge interactions between solute and sorbent and can be reduced by increasing the ionic strength of the buffer, which provides double-layer screening of the electrostatic interactions.

CONSIDERATIONS FOR LARGE SCALE

SEC is used in large-scale industrial processes for the production of proteins for agricultural and pharmaceutical use. At this scale, economic considerations become imperative, and in particular it is important for the chromatographic operation to achieve a high level of productivity and throughput while maintaining high resolution.

General Strategies

For large-scale operation, the throughput required necessitates reuse of chromatography columns in a repeated-batch operation. Usually, the primary goal is to maximize productivity, which is defined as the amount of purified material per column area per time. This can be achieved by maximizing flow rate and minimizing the amount of time during which the column is not actively performing a separation. From a productivity standpoint, the time between elution of the valuable solute and all others is wasted time. One route to improving productivity is to reduce the resolution of the solutes to the minimum necessary (Fig. 6). Likewise, the time after elution of all solutes before the next injection can be used more efficiently by applying the next sample before the column volume of the present run is finished (21). These general guidelines govern both desalting and fractionation; further optimization depends on the particular application.

Another strategy to maximize throughput is to maximize the sample size. However, dispersion effects are enhanced for large sample volumes. Consequently, for fractionation applications, it is advisable to use sample sizes less than 3% of the total column volume (38). Although it is often desirable to have highly concentrated samples, higher concentrations result in higher viscosities, which result in slower diffusion into and equilibration with the gel. The requirement of sample equilibration with the gel also limits the flow rate that may be applied.

For desalting, on the other hand, larger sample volumes can be applied, because the sample elutes in the void volume and the salts are retained in the pore. Because of this large discrepancy in elution volumes, the increased dispersion resulting from large sample sizes is not much of an issue, and sample sizes as great as 25 to 30% of the column volume may be used. Furthermore, small molecules (e.g., ions) equilibrate quickly with the pores because of their small excluded volume and high diffusion coefficients, and macromolecules are completely excluded, so high flow rates may be used without compromising the separation.

Scale-Up Guidelines

The principle of scale-up is to determine the values of new process variables that will allow a desired change in one

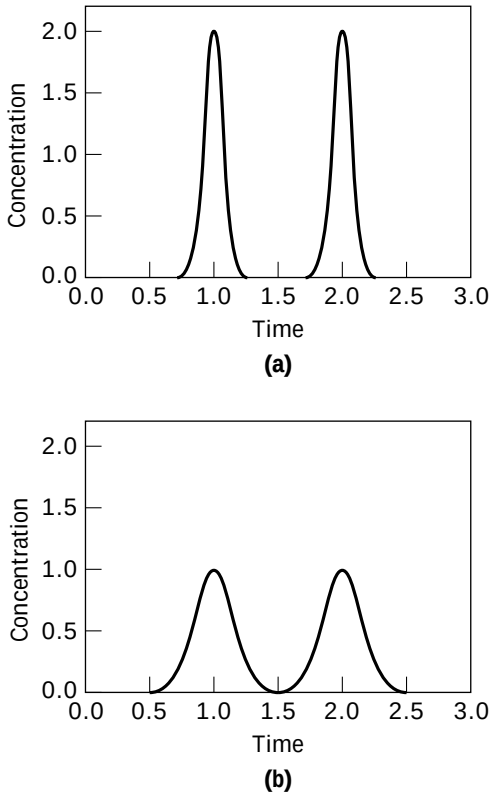

Figure 6. Optimization of resolution for large-scale SEC. (**a**) A small injection of solutes at low flow rate results in well-resolved bands. (**b**) The productivity is increased by increasing flow rate, increasing sample size, or decreasing column length to the point where the solutes are just resolved.

process variable while keeping others constant. Generally, it is desired to increase the throughput while maintaining the same resolution, but sometimes it is necessary to change resolution while keeping throughput constant. In any case, the key is to have a description of the relationship among process variables. It is here that the analysis of the preceding section is most useful.

Scaling rules for isocratic elution chromatography, which includes both SEC and adsorption chromatography, have been described by Wankat and Koo (36). The starting point is the definition of scaling parameters describing the ratios of process variables in the new and old designs, that is,

$$\delta = \frac{d_{p,new}}{d_{p,old}}$$
$$\lambda = \frac{L_{new}}{L_{old}}$$
$$\rho = \frac{D_{new}}{D_{old}}$$
$$\pi = \frac{\Delta p_{new}}{\Delta p_{old}}$$
$$\theta = \frac{Q_{new}}{Q_{old}} \qquad (26)$$

where D is the column diameter and Q is the buffer flow rate. The capacity factor in SEC is a thermodynamic quantity representing the partitioning of solutes in the pores of the support particles and therefore should not vary with column configuration or process variables. Therefore, the description of column resolution in equation 24 can be used for both the new and old designs to define a ratio of design resolutions, Ψ (36):

$$\Psi \equiv \frac{R_{s,new}}{R_{s,old}} = \left(\frac{L_{new}}{L_{old}}\right)^{1/2} \frac{[H_2^{1/2}(1 + k_2') + H_1^{1/2}(1 + k_1')]_{old}}{[H_2^{1/2}(1 + k_2') + H_1^{1/2}(1 + k_1')]_{new}} \qquad (27)$$

The difference between plate heights of the different solutes is usually ignored (see equation 25) and equation 27 is greatly simplified, that is,

$$\Psi = \lambda^{1/2}\left(\frac{H_{old}}{H_{new}}\right)^{1/2} \qquad (28)$$

As discussed in "Dependence of Separation Parameters on Operating Variables", transport resistances at the particle surface and within the pores usually dominate, with the result that the plate height can be represented by a scaling of the form equation 21. Substituting in equation 28 gives a simple design equation:

$$\Psi = \left(\frac{\lambda}{\theta}\right)^{1/2} \frac{\rho}{\delta} \qquad (29)$$

Note that more complete plate height expressions (derived from either theoretical or empirical correlations) may be substituted into equation 28 to develop more sophisticated design equations.

Equations such as equation 29 can be used to derive new sizes and operating conditions for a given change in any of the others. As a simple example, suppose that a design involving a reduction in particle size is desired, while maintaining constant column dimensions and throughput. In this case, λ, ρ, and θ are equal to unity, and the resolution is inversely proportional to the particle size

$$\Psi = \frac{1}{\delta} \qquad (30)$$

Alternatively, the objective of reducing particle size may be to allow a greater flow rate while maintaining constant resolution. In this case, Ψ, ρ, and λ are equal to unity, and the flow rate scales as the inverse square of particle diameter

$$\theta = \frac{1}{\delta^2} \qquad (31)$$

However, this is only valid in the regime where the particles are rigid, and it may not be feasible because of the large increase in pressure drop that would result.

The application of scaling rules to the interrelationship of process variables in equation 24 is an idealization that is subject to a number of constraints. Arbitrary column diameters and lengths are not possible, and certain length-

to-diameter ratios (on the order of 10:1) are desirable to achieve a uniform packing. Also, only certain particle sizes are available, and the range in which they are manufactured is dependent to a large degree on their resistance to flow (i.e., pressure drop). As discussed in "Packing Materials", many packings are rigid only within a certain range of pressure drops. If a new column design takes the pressure drop out of this range, the performance may be drastically altered. For rigid particles, the pressure drop is described by equation 8; therefore, its scaling is

$$\pi = \frac{\theta\lambda}{\rho^2\delta^2} \tag{32}$$

For compressible particles, the same procedure may be used with a correlation that describes the relationship between pressure drop and flow rate (39).

SUMMARY

SEC has been applied extensively to biological macromolecules in the laboratory and has found utility as a step in the production of proteins at large scale as well. Further growth of the biotechnology industry and the ease and applicability of the technique ensure that SEC will be used widely in the future as well. Many packing materials have been developed to enable the chromatographer to perform an analysis or separation quickly, efficiently, and unambiguously through improvements in the inertness and mechanical stability of the support. Engineering analysis has enabled quantitative descriptions to be made regarding the influence of mass transfer resistances to the efficiency (plate height) of the column. These can be incorporated into simple design equations for the development and optimization of column configurations and operating conditions for a number of industrially important separations.

OUTLINE

INTRODUCTION

Citric acid ($C_6H_8O_7$) is a white or translucent solid with a molecular weight of 192.12. It occurs as a natural constituent in citron, lemon, lime, pineapple, pear, peach, and similar fruits (Table 1). It is also found in animal tissues. The popular forms of citric acid are the anhydrous forms, the monohydrate and sodium salts of the acid.

Table 1. Citric Acid Contents of Various Fruits and Vegetables

Fruit/vegetable	Citric acid (wt %)
Lemon	4.0–8.0
Grape	1.2–2.1
Tangerine	0.9–1.2
Orange	0.6–1.0
Currant	
Black	1.5–3.0
Red	0.7–1.3
Raspberry	1.0–1.3
Strawberry	0.6–0.8
Apple	0.008
Tomato	0.25
Potato	0.35–0.5
Asparagus	0.08–0.2
Turnip	0.05–1.1
Pea	0.05
Corn	0.02
Lettuce	0.16
Eggplant	0.01

Citric acid was first isolated by Scheele in 1784 when he crystallized it from lemon juice. It was later synthesized (via symmetrical dicholoroacetone) from glycerol by Grimocex and Adam in 1880. It was first made in crystallized form from lemon juice. Calcium citrate was precipitated through the reaction of hot lemon juice with calcium carbonate, followed by decomposition of the product with sulphuric acid. Two hundred years later, this process is still being used. However, raw material is the principal limiting factor for production on a large scale. Thirty tons of lemon are needed to produce 1 ton of citric acid. The first commercial citric acid was prepared in 1860 in England from calcium citrate imported from Italy and Sicily. By 1880, France, Germany, and the United States had begun manufacturing citric acid using similar methods. In 1913, recovery of citric acid from calcium citrate began in Italy, and by 1922, Italy produced 90% of the world's supply.

MICROBIAL PRODUCTION

In 1893, Wehmer recognized citric acid as a microbial metabolite (1) (Table 2). Although his attempt to develop a commercial fermentation process with a species of *Penicillium* was unsuccessful, he established the basis for the subsequent complete reorganization of the citric acid industry. It was later confirmed that the use of *Aspergillus niger* (Fig. 1) favors sucrose fermentation to citric acid.

In 1923, a plant was started in New York to make citric acid by a fungal fermentation technique developed by Currie (2). This production effectively broke the power of the Italian cartel. In this process, *A. niger* was grown on the surface of a shallow pan of sugar medium. This surface fermentation process was subsequently used in England, The Netherlands, Belgium, Germany, Switzerland, Argentina, and the former Soviet Union.

A new fungal fermentation process was introduced successfully in the United States in 1952. In this process,

Table 2. Chronology of Events in Citric Acid Production

Authors (ref.)	Investigation/remarks
Wehmer 1893 (cited in 1)	Demonstrated citric acid to be a metabolic product of certain molds.
Currie 1917 (2)	First chose *Aspergillus niger* for deriving citric acid.
Doelger & Prescott 1934 (3)	Fermentation above 30 °C decreased citric acid yield and increased accumulation of oxalic acid.
Cahn 1935 (4)	First to describe solid-state fermentation for production of citric acid.
Mazzadroli 1938 (5)	Potassium ferrocyanide could be added to eliminate excess Fe^{2+}.
Szucs 1944 (6)	Citric acid synthesis took place only after total assimilation of phosphates.
Moyer 1953 (7)	Suggested use of methanol as stimulant for increasing acid yield.
Usami & Takatomi 1958 (1)	Spores produced under submerged fermentation were poor, and spores from surface culture were better acid formers.
Usami et al. 1960 (9)	Increase in aeration resulted in higher yields and reduction in cycle time.
Kovats 1960 (10)	Demonstrated lower concentration of sugar leads to lower yields of citric acid and accumulation of oxalic acid.
Schweiger 1961 (11)	Iron concentration above 0.2 ppm affected yield of acid. However, addition of copper 0.1 to 500 ppm at the time of inoculation or during the first 50 h of fermentation countered the deleterious effect of iron.
Naguchi & Bando 1960 (12)	Concentration of ammonium nitrate greater than 0.25% lead to accumulation of oxalic acid.
Sanchez-Marroquin et al. 1963 (13)	Higher yields of citric acid occurred in a simple medium rather than a complex medium.
Clark 1962 (14)	Ferrocyanide addition on the acid yield 10–200 μg/mL was tolerated during growth. But less than 20 μg/mL helped acid production.
Millis et al. 1963 (15)	Addition of vegetable oils, fatty acids, etc., increased acid yield.
Czech. Acad. Sci. 1964 (16)	Mycelial digests from *A. terreus* or *A. Niger* stimulated acid production by 60–70% when added to the medium.
Leopold 1965 (17)	Addition of pressed baker's yeasts to culture medium increased acid yield from 61.5 to 72.1%.
Bruchmann 1966 (18)	Addition of mild oxidizing agents stimulated acid production.
Sussman & Halvorson 1966 (19)	Spore viability varies with age.
Wendel 1967 (20)	In the initial stages, citric acid diffused into the medium, which leads to a stratification on the mycelium. This stratification inhibited fungal metabolism, leading to decreased acid yields. This stratification can be eliminated by stirring.
Tabuchi et al. 1969 (21)	Production of citric acid from *n*-paraffin using yeast, (*Candida*) medium composition. Hydrocarbon, 40–60 gs; NH_4Cl_2, 2 gs; KH_2PO_4, 0.5 g; $MgSO_4$, 0.5 g; cornsteep liquor, 1 g; $CaCo_3$, 30 g/L.
Khan et al. 1970 (22)	Phosphates promoted more growth at less acid yields.
Fedoseev et al. 1970 (23)	Copper sulfate at 4.7 mg/100 g molasses resulted in better conversion of sugar to citric acid.
Kyowa Fermentation Industry 1970 (24)	Citric acid production from dodecane (or) C_{12}–C_{14}. Using arthrobacterium in aqueous medium, inoculum 5% air at 3 vvm[a] at 28 °C, yielded 28 mg/mL.
Sanchez-Marroquin et al. 1970 (25)	The use of ion-exchange resin for reduction of metal content was better than chemical treatment.
Fukuda et al. 1970 (26)	Use of *Corynebacterium* on *n*-paraffins; yield 41.4 mg/mL; culture period 64 h, 32 °C.
Leopold 1971 (17)	Glycerol addition increased acid yield by 30%.
Dhankar et al. 1972 (27)	Acid yield improved by addition of peanut oil to molasses medium.
Kumamoto & Okamura 1972 (28)	Mn^{2+}, Ba^{2+}, Al^{3+} had an effect on fungal morphology.
Sardinas 1972 (29)	Patented a process for citric acid production involving *B. licheniformis*.
Chaudhary et al. 1972 (30)	A low pH in molasses medium was inhibitory to growth.
Ohmori & Ikeno 1973 (31)	Bacterial production of citric acid from media containing isocitric acid.
Dhankar et al. 1974 (32)	Sodium nitrate at a concentration of 0.4% was superior to ammonium nitrate.
Zhuravskii, 1974 (33)	Patented continuous multistage process for citric acid production.
Halama 1974 (34)	Chemicals such as pentachloralphenolate, semicarbozone, tetracycline, etc., used for control of bacterial growth.
Ohtsuka et al. 1975 (35)	Addition of malic hydrazide increased yield from 30 to 70%.
Wold & Suzuki 1973 (36)	The rate of acid production increased when AMP was added to the culture medium.
Wold & Suzuki 1976 (37)	Zn^{2+} regulated growth and production.
Brezhnoi et al. 1976 (38)	Continuous production of citric acid from molasses.
Choudhary 1978 (39)	A 3-day-old slant culture was as good as 7- to 8-day-old spore.
Krishnan & Natarajan 1987 (40)	Liquid–liquid extraction of citric acid.
Krishnan & Annadurai 1992 (41)	Precipitation of citric acid.
Krishnan et al. 1996 (42)	Reduction in cycle time for citric acid production.

[a] vvm, volume air per volume medium per minute.

A. niger was allowed to grow in the entire volume of the culture solution in large deep tanks. This process was introduced in Mexico in 1959 and in Israel in 1961.

The earliest attempt to produce citric acid by the submerged growth technique was that by Amelung, who aerated the culture by bubbling air through the solution. Numerous studies, subsequent to the work of Amelung, resulted in the development of two approaches to the control of citric acid production in submerged cultures. In the first approach, Perquin produced citric acid by inducing the establishment of a deficiency of one of the major nutrients, such as phosphate. In another approach, Johnson et al. studied the effect of manganese and iron and related the concentration of these to the amount of inhibition of citric acid accumulation.

Further development of methods for the control of iron and manganese levels in the culture solution led to the popularity of the submerged fermentation process, now used in the United States, Mexico, and Israel. Excess iron may be precipitated by ferrocyanide. The removal of iron and the presence of specific enzyme inhibitors that control the destruction of citric acid form the basis for the successful submerged fermentation process. Other mineral nutrients required for the submerged fermentation are the same as those for surface fermentation.

The most interesting change in citric acid manufacture was done by Miles Laboratories. They changed the raw materials from molasses to glucose, doubling the production. The company patented a process in which starchy material is first converted to sugar by enzymatic action and then used as the raw material for citric acid production. They also claim that with the addition of various phenols and other compounds to check the growth of *A. niger*, it is possible to use less highly purified starting material. This is similar to the use of the lower alcohols, which has been known for many years and is being investigated now as an additive to blackstrap molasses.

STORAGE OF CITRIC ACID

The popular forms of citric acid are the anhydrous forms, the monohydrate form and sodium salts of the acid. Both citric acid and citric monohydrate are available in variety of sieve sizes. They are conventionally available as granular, fine granular, and powder forms.

Crystalline anhydrous citric acid can be stored in dry form without difficulty, although highly humid conditions and elevated temperatures should be avoided to prevent caking. The product should be stored in tight containers to prevent exposure to moist air. Several granulations are commercially available with larger particle sizes having less tendency toward caking. Materials packed with desiccants are also available. Solutions of citric acid are corrosive to normal concrete, aluminium, carbon steel, copper alloys and should not be used with nylon, polycarbonates, polyamides, polyimides, or acrylics. Recommended materials of construction for pipes, tanks, and pumps handling citric acid solutions are 316 stainless steel, fiberglass-reinforced polyester, polyethylene, polypropylene, and polyvinyl chloride. Sodium and potassium citrates are not as corrosive as citric acid but they should be handled in the same type of equipment as citric acid.

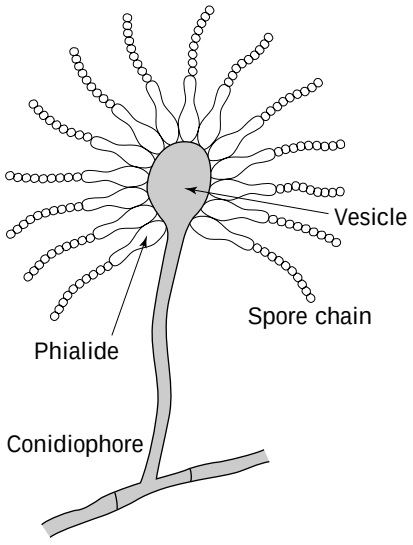

Figure 1. *Aspergillus niger*.

PRODUCT APPLICATIONS

The food and pharmaceutical industries use citric acid extensively because of its high solubility, pleasant sour taste, very low toxicity, and ready assimilability (Table 3). Citric acid also finds application in some cosmetic preparations, metal cleaning, electropickling, copper plating, secondary oil recovery, and other industrial uses (Table 4).

Foods and Beverages

Citric acid is widely used in foods, beverages, and jams and jellies owing to its ability

Table 3. Global Production Pattern of Citric Acid

Others	2

1. To maintain desired pH levels
2. To impart refreshing and tingling taste
3. To act as a flavor-enhancing agent
4. To act as a color stabilizer

In candy manufacture, citric acid helps to enhance the flavor and taste of berries and other ingredients. As a very dependable agent for maintenance of pH, citric acid finds wide application in the production of jams, jellies, preserves, soft drinks, syrup, and soft drink tablets. For pH control and color stabilization, citric acid is used in fruit and vegetable juices. The pH prevents juice spoilage, and natural taste and flavor are greatly enhanced. Lowering of pH inactivates certain oxidative enzymes, thus improving the keeping qualities of frozen fruits, peaches, apricots, plums, pears, and cherries against flavor or color spoilage. Citric acid also combines with trace metals, helping avoid the undesirable oxidation changes.

Pharmaceuticals

Citric acid's wide application in the manufacture of drugs and pharmaceuticals is for enhancing the taste and flavor. It is used as an anticoagulant for blood. Powders and tablets owe their effervescent property to citric acid. The free acid and its sodium and potassium salts are used as mild acidulants in astringent preparations. Several salts of citric acid are used in the manufacture of antianemic tonics, vitamins, liver tonics, antipyretic agents, cough syrups, antidysentery, and antidiarrheal agents. It is also used in inducing fertility.

Cosmetics

Hair rinses and hair setting agents derive benefit from citric acid. It is also used in astringent lotions, bleaching lotions, and others.

Metallurgy

Citric acid finds extensive use in metallurgical application and as a sequestering agent for such metals as iron, copper, zinc, nickel, cobalt, chromium, and manganese. The acid and ammonium salts are added for scale removal in boilers; cleaning of reactors could be done very well using the acid. Citric acid is widely used in electropickling of copper and its alloys and in copper coating. Any iron plugging in the oil-flow line could be removed by the acid. Tanning liquors, bottle washing compounds, and diazo printing paper all contain citric acid.

Industrial Uses

It is used in the manufacture of several esters, linoleum, inks, silvering compounds, and fabric dyes (Table 5). Citric acid enjoys a superior status above phosphates in the manufacturing of detergents.

Other Applications

Some of the algicides, pesticides, fish preservation, chemicals, and insecticides are based on citric acid. Preservation of latex from certain natural plants involves the use of citric acid.

Vogelbusch GmbH, Austria

THE TECHNOLOGY OF CITRIC ACID PRODUCTION

Citric acid production centers around one strain, *Aspergillus niger*, which is still extensively used. In the late 1970s, processes involving *Candida* yeast became commercial. *Candida guillermondi* has unique benefits over *A. niger* in that trace metal removal is not essential. It can also tolerate higher pHs (3.5 to 5) and sugar concentrations for acid production. The rate of acid production is also faster. As in the case of *A. niger*, nitrogen limitation triggers acid production. Certain bacteria also produce citric acid on a variety of substrates.

Citric acid can be manufactured commercially by three methods:

1. Surface culture technique
2. Submerged culture technique
3. Solid substrate technique

Commercially used substrates are citrus fruits (not adapted presently because the fruits are costly and seasonal), sucrose, glucose, molasses cane juice, and certain petroleum fractions.

Shallow pan reactors, stirred tank fermenters, and airlift fermenters are commonly used depending on the process requirements. Fermenters work in a semibatch mode or a continuous mode. It will be of interest to state here that yields of product vary with the pretreatment to which the media are subjected. For example, yields for pretreatment with suitable exchange resins is 98% in the case of sucrose and 75% for molasses; ferrocyanide-treated molasses yields 68% as contrasted to the untreated molasses, for which the yield is 62%.

Citrus Fruits and Pineapples

Lemon peels and the white layer are removed and separated for the recovery of oil and pectin, respectively. The remaining portion is pulped and filtered. The filtrate is likely to contain pectin and albumin, which are removed by spontaneous fermentation. In the case of pineapples, the waste and low quality fruits are crushed and filtered. The lemon juice and the pineapple juice, recovered separately, could contain 4% and 0.75% citric acid, respectively. Calcium carbonate or hydroxide is added to the individual juice to the required amount, and the temperature is maintained between 55 and 95 °C. Any oxalate present is filtered preferentially before citric acid. The calcium citrate cake obtained is washed and reacted with a small amount of sulfuric acid. The resultant slurry is filtered to recover citric acid solution from the precipitated calcium sulfate. The clear filtrate is subjected to decolorization before recovering the citric acid crystals by evaporation. This process is on the decline, as stated earlier.

Cane Molasses and Beet Molasses

Blackstrap molasses, about 40 °Bé with a sugar content of 52 to 57% sugar, or beet molasses, 41 °Bé containing 48 to 52% sugar, could be used for citric acid production (Table 6). However, cane molasses should be purified before subjecting it to fermentation. Alternate methods for molasses purification are discussed below:

1. *Sulfuric acid treatment*. The pH of the molasses (10% total reducing sugar) is adjusted to 3.0 by adding 0.1 N sulphuric acid. This is allowed to stand for 1.5 h and then centrifuged at 3,000 rpm for 15 min. The supernatant is collected and used.
2. *Potassium ferrocyanide treatment*. The molasses (10% TRS) is heated to 85 °C for 30 minutes and centrifuged at 3,000 rpm for 15 min; 100 mL of the supernatant is collected, and 0.5 mL of K_4 $Fe(CN)_6$ (10% solution) is added. The pH is adjusted to 6.5.
3. *Tricalcium phosphate treatment*. The pH of the molasses (10% TRS) was adjusted to 7.0 by the addition of 0.1 N NaOH and treated with 2% (w/v) tricalcium phosphate followed by heating at 105 °C for 5 minutes. The mixture was cooled and centrifuged at 3,000 rpm for 15 minutes. The supernatant was used.
4. *Tricalcium phosphate with hydrochloric acid treatment*. The TCP-treated liquor was adjusted to pH 2.0 by the addition of 0.1 N Hcl followed by vigorous shaking. The mixture was allowed to stand for 6 h. The supernatant was used after centrifugation at 3,000 rpm for 20 min.
5. *Bentonite treatment*. The pH of molasses (10% TRS) was adjusted to 7.0. Bentonite 2% (w/v) was added and kept in a boiling water bath for 30 min. The solution was then centrifuged at 3,000 rpm for 15 min. The supernatant was collected and used.

Table 6. Analyses of Cane and Sugar Beet Molasses

Component	Beet (%)	Cane (%)
Water	20.0	16.5
Sugar	62.0	53.0
Nonsugars	10.0	19.0
Ash	8.0	11.5

Molasses Medium

Beet molasses is the most widely used raw material in the United States and Europe. Latin American and Caribbean plants use sugar as raw material (3 tons of sucrose per ton of citric acid). Smaller plants in the Caribbean use citric wastes from citrus fruits. The production rates are Argentina, 2,000 tons per annum, Mexico, 1,000 tons per annum; and Uruguay, 500 tons per annum.

The beet molasses or pretreated cane molasses is taken in a mixing vessel where dilute sulphuric acid is added to register a pH of 5.5 of 6.5. Phosphorous, potassium, and nitrogen are added as nutrients to the required amount for growth and citric acid production. This mixture is sterilized with live steam. After this, a requisite amount of sterile water is added to give a sugar percentage of 15 to 20%. The feed is admitted into shallow aluminium pans arranged in convenient stacks in a sterile room. Each tray is shallow (about 75-mm deep) but big enough to hold solutions up to 500 L. The temperature (28 to 32 °C) and humidity (40 to 60%) are controlled for maximum yield. This sugar medium is inoculated with the spores of a selected strain of *A. niger*. In about 8 to 10 days, the fermentation process is over (pH being about 2). The acid might be contaminated with oxalic acid and gluconic acid. The tray contents are sent out for recovery of the acid, and the trays and the chamber are sterilized with steam. Dilute formic acid or sulfur dioxide could also be used for positive sterilization.

The recovery consists of adding hydrated lime (1 part of lime to every 2 parts of liquor) to the fermenter broth kept at 95 °C. The precipitated calcium citrate could be reacted with enough dilute sulfuric acid when citric acid remains in solution, leaving behind calcium sulfate. Based on the sugar content of the raw materials, the yield could be 35 to 65% by weight of sugar. In this process, pH maintenance is difficult.

Submerged Fermentation

The majority of industries have adopted this process. Conventionally, the growth phase and the production phase are two distinct regions. Two different media are used, one for growth and the other for production (Table 7). After 3 to 4 days of lush growth, the mycelia are separated from the growth medium and added to the production fermenter under stirred conditions. In the production fermenter, the pH and temperature are maintained around 3 and 30 °C, respectively. Air is sparged without interruption into the solution at about 1 to 1.2 volume air per volume medium per minute (vvm). In about 4 to 5 days, the production becomes nearly complete with about 65 to 70% of sugar being converted to the final product.

The submerged process is admirably suited for a flexible operation. It is possible to introduce certain process accel-

Table 7. Medium for Citric Acid

Component	Sporulation (g/L)	Production (g/L)
Sucrose	140	140
Bactoagar	20	0.0
Ammonium nitrate	2.5	2.5
Potassium hydrogen phosphate	1.0	2.5
Magnesium sulphate heptahydrate	0.25	0.25
Copper ion	0.0048	0.00006
Zinc ion	0.0038	0.00025
Ferrous ion	0.0022	0.0013
Manganous ion	0.001	0.001

erators or nutrients at desired and convenient time intervals; activated carbon or ascorbic acid could be used as the accelerator. The flexibility of such a fermenter is so good that sugar concentration and pH could be maintained at desired values. The acid recovery is through the calcium citrate process. For every ton of citric acid produced, one needs about 3,650 kg of molasses, 5 to 14 kgs of nutrient, 650 kg of sulfuric acid, and 450 kg of lime. Although one might use several organisms (*A. niger* is still the most sought after), the yield depends mainly on the nutrient used, presence of trace metals, and above all, the pH and air supply.

In the new process by Miles Laboratories mentioned previously, sucrose has been replaced with glucose for acid production. Starch is converted to sugar through enzymatic reaction, and the resulting sugar is the raw material for acid production. Specific chemicals control the growth of the mold at the expense of citrate production. An interesting point is that their starting material is not of high purity. They use very large fermentation vats into which sucrose solution is pumped, and fungal spores are added to help the growth and production cycles. After the cycle is over, the vats are charged with fresh medium.

Solid-Substrate Fermentation

In the solid-substrate fermentation process, the mold *A. niger* ferments molasses or sucrose adsorbed on beet or cane pulp. Carriers such as beet or cane pulp offer large areas for microbial contact with the medium and ensure good aeration. Bagasse is preferred over beet pulp because of its larger surface area and lower cost. In addition, bagasse can be used several times over. Bagasse is broken down into fine pieces, 1 to 2 mm long, sterilized, and soaked in molasses or sucrose solution before being inoculated with the selected strain. The citric acid yields are about 45% of the sugar content of molasses and 55% of sucrose. This process is labor intensive and needs more floor space, plus there is the likelihood of contamination. It is difficult to maintain pH. The process requires good aeration with controlled humidities.

Relative Merits between Submerged and Surface Fermentation

The starting sugar cane concentration and the yield percentage are more or less the same for submerged and surface fermentation. However, the surface process is highly labor intensive and not easily amenable for pH or tem-

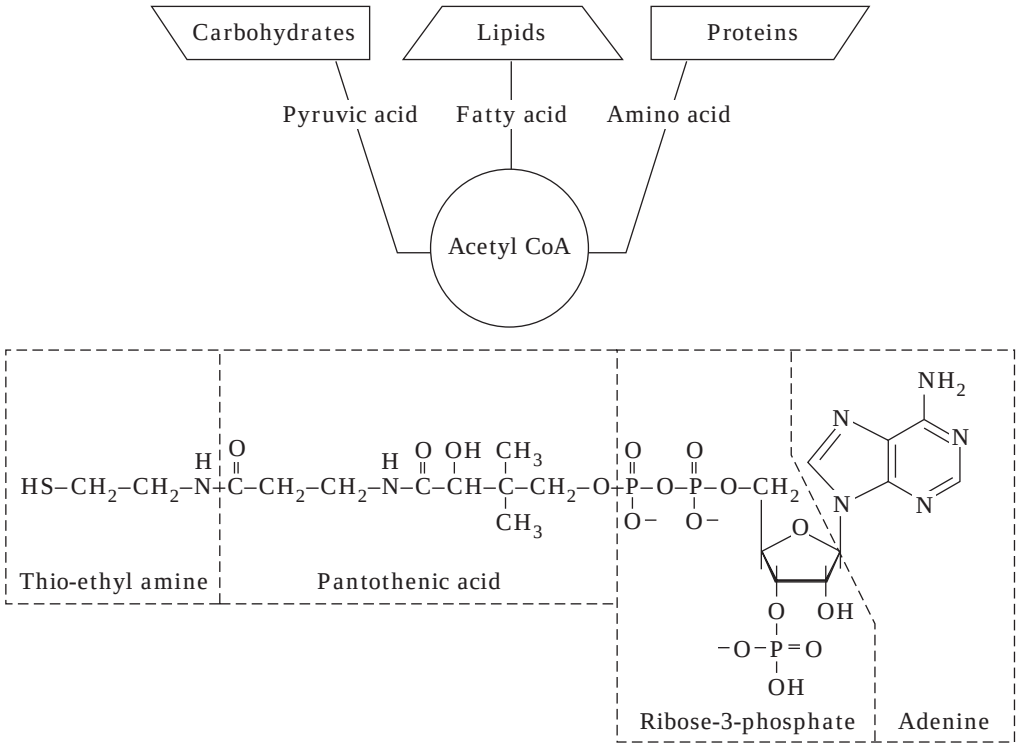

Figure 2. Enzyme CoA.

perature control. Flexibility of operation is higher in the submerged process because addition or removal of chemicals is easier. The risk of contamination is less in the submerged process. The surface process needs a larger working area, and the chance of pollution (caused by spores) is also high. Oxalic acid formation is higher in surface fermentation.

One advantage of the surface process is that it is less energy intensive. Although automation of the submerged process may be easier, in the event of contamination, the losses suffered will be enormous.

BIOCHEMISTRY OF CITRIC ACID PRODUCTION

Successful production of citric acid depends on several factors. External factors can be controlled directly, and biochemical factors, the various biological reactions that go

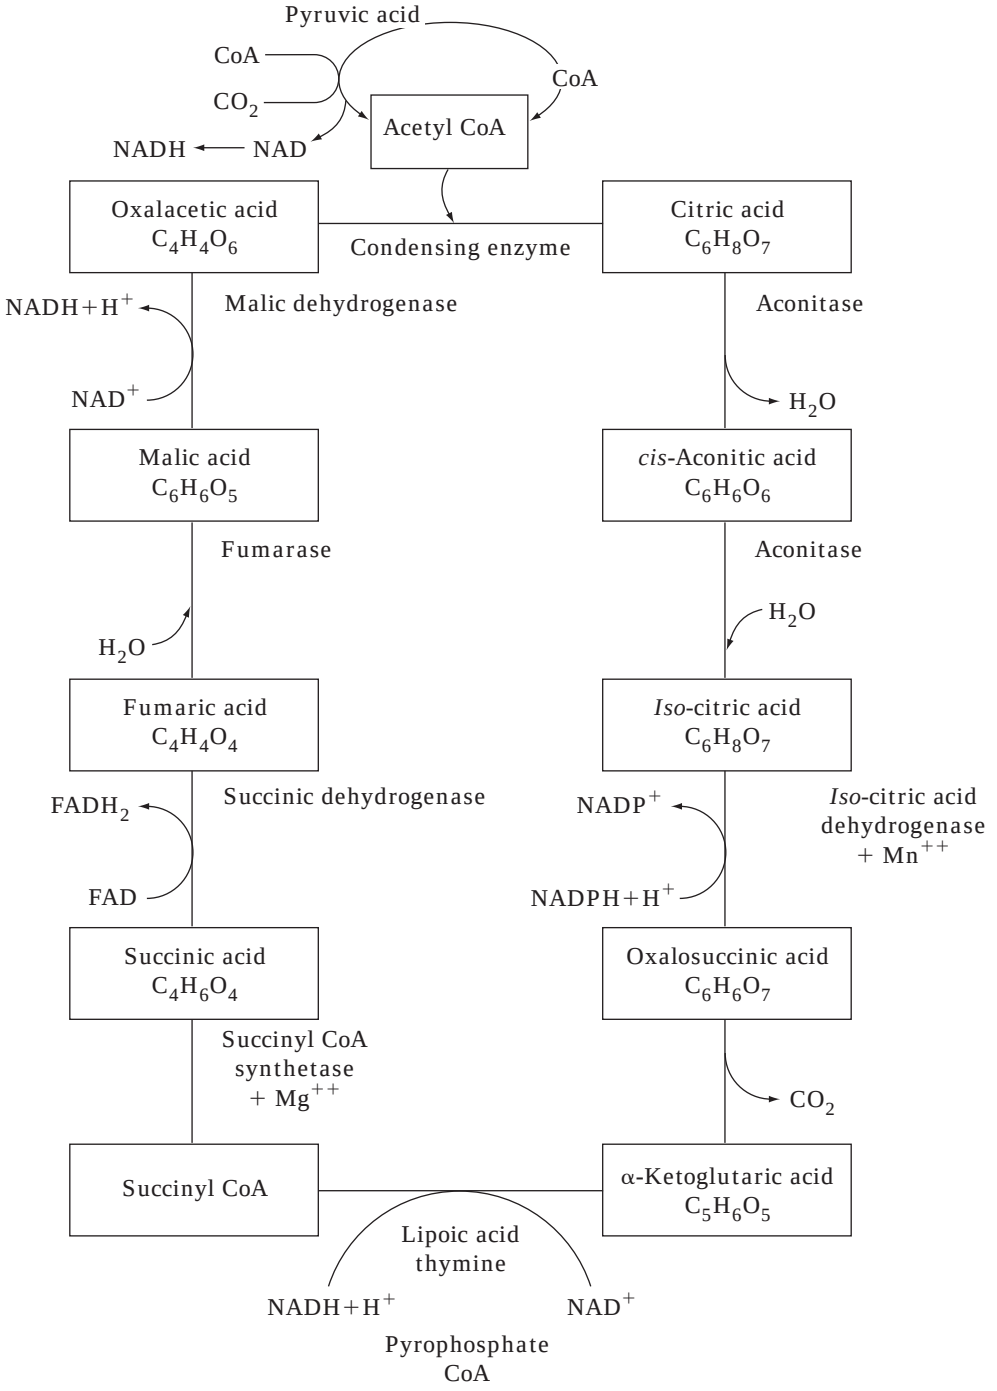

Figure 3. Tricarboxylic acid-cycle.

on inside the cell, can be controlled indirectly by controlling the external factors.

External Factors

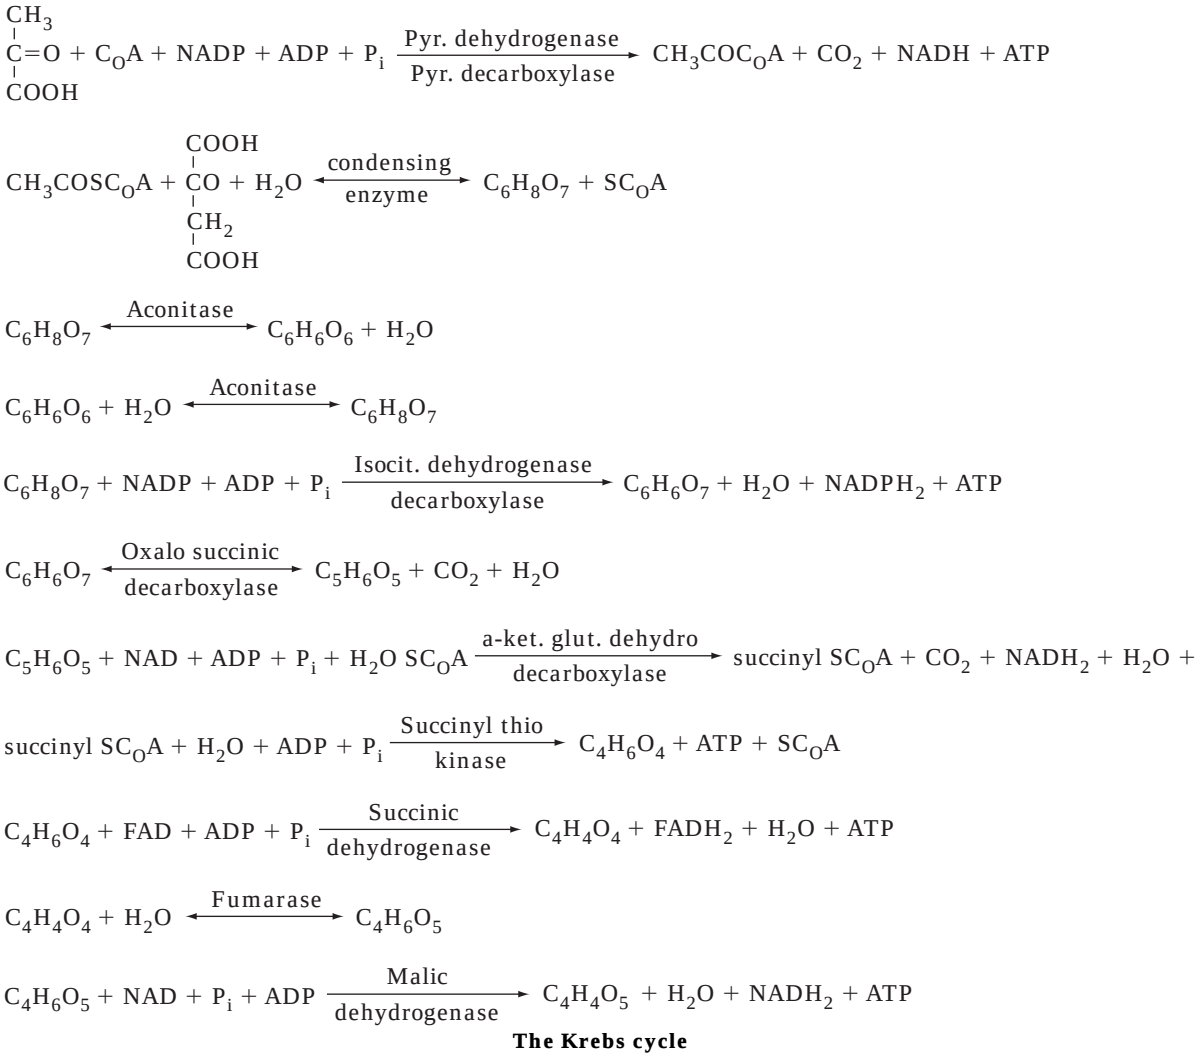
- The type of sugar used and sugar levels
- The pH in the milieu
- The temperature of production
- The presence or absence of trace metals such as Fe, Cu, Zn, Mn
- The presence or absence of phosphates and nitrates in the medium
- The oxygen concentration in the environment

Biochemical Factors

- Breakdown of sugars to pyruvic acid and acetyl CoA (Fig. 2)
- Formation of oxalacetic acid from pyruvic acid and carbon dioxide
- Promotion of the enzymatic reaction necessary for citric acid accumulation
- Suppression of the enzymatic reaction that represses citric acid production
- Oxygen concentration in the medium and cell (citric acid production needs a copious supply of oxygen)
- Favoring citric acid accumulation at the expense of cell growth

Based on the external and biochemical factors, one could draw the following conclusions:

1. Glycolytic and pyruvate enzymes should be activated for the citrate synthesis by maintenance of high sugar levels.
2. Repression of enzymes in the tricarboxylic acid (TCA) cycle would inhibit citrate production.
3. Manganese deficiency should be ensured for NH_4^{2+} generation, which would counter the inhibition of phosphofructokinase by citrate.
4. A copious oxygen supply will overcome possible cell starvation, even under emergent conditions.
5. Ideal pH maintenance encourages citrate production rather than oxalic or gluconic acid formation.



The Krebs cycle

In most cells, catabolism of simple sugar is the major source of energy. It starts with the glycolytic pathway. Glucose is broken down into two molecules of three-carbon compounds called pyruvic acid. The cell gains two ATP molecules for each molecule of glucose entering the glycolytic pathway. The ATP molecules are storehouses of energy, releasing energy necessary for cell work. The catabolic reaction also gives rise to NADH, which is useful for several anabolic reactions.

Depending on the type of cell and availability of oxygen, the pyruvic acid produced earlier can undergo two different types of reactions. When anaerobic conditions prevail, pyruvic acid is converted to lactic acid or ethyl alcohol. Under aerobic conditions, the pyruvic acid is converted to carbon dioxide and acetyl CoA (Fig. 2). This acetyl CoA is further degraded in the (Fig. 3) TCA cycle or election transport system to produce energy for cell work. Several other substrates exist that can give rise to acetyl CoA. For example, proteins and lipids can be degraded to provide acetyl CoA. Thus, cells can degrade several chemical compounds to acetyl CoA and subject them to the TCA cycle and electron transport chain for obtaining energy.

The TCA cycle together with the electron transport system constitutes the cells' primary metabolic furnace. These two combine to burn acetyl CoA in oxygen to liberate carbon dioxide, water, and useful energy. This energy from the TCA cycle and electron transport chain is captured and taken up in ATP for storage of energy.

During oxidation of one molecule of acetyl CoA (by 0the TCA cycle occurring in the mitochondrial matrix), one molecule of flavoprotein (FP or FAB) and three molecules of nicotinamide adenine dinucleotide (NAD) are reduced. These reduced coenzymes are oxidized by molecular oxygen by way of a system of enzymes and coenzymes called the respiratory chain or electron transport system, occurring in the inner mitochondrial membrane. During this oxidation process, enormous amounts of energy are released, some of which is utilized by the inner membrane subunits.

The TCA cycle occurs in the following ways:

- The pyruvic acid is decarboxylated; the acetyl group combines with CoA to give acetyl CoA. The H and NAD combine to give NADH. Energy transfer occurs, yielding ATP.
- Active acetyl combines with oxalacetic acid to form citric acid. The released SCoA can now combine with more CH_3CO.
- Citric acid looses water to give rise to aconitic acid.
- Isocitric acid results as *cis*-aconitic acid gets rehydrated.
- Isocitric acid loses hydrogen to yield oxalosuccinic acid. The H combines with NADP to form NADPH. Energy transport takes place, yielding ATP. Loss of CO_2 also occurs.
- Decarboxylation of oxalosuccinic acid takes place to yield α-ketoglutaric acid. Hydrogen reacts with NAD to form $NADH_2$. Energy is released to convert ADP to ATP.
- SCoA combines with the succinyl group of α-ketoglutaric acid and gets converted to succinic acid, yielding SCoA and ATP.
- Dehydrogenation of succinic acid leads to fumaric acid. Hydrogen joins FAD to form $FADH_2$ and energy. This leads to formation of ATP.
- Malic acid is formed as fumaric acid gets hydrated.
- Malic acid is dehydrogenated to form oxalacetic acid. Oxalacetic acid combines with active acetyl to form citric acid and the cycle continues. The released hydrogen forms $NADH_2$ from NAD and energy released gives rise to ATP.

Several yeasts and bacteria can produce citric acid from specific substrates:

Citric Acid Production by Yeasts

Candida lipolytica
Candida tropicalis
Candida zylenoides
Candida fibrae
Candida intermedia
Candida parpsilosis
Candida petrophylum
Candida subtropicalis
Candida oleophila
Candida hitachinica
Candida citra
Candida guillermondi
Candida sucrosa

A variety of substrates can be utilized by the *Candida* species. They could utilize glucose, acetic acid, calcium acetate, hydrocarbons, molasses, alcohols, fatty acids, and natural oils (such as coconut oil). For example, *Candida* can utilize glucose or molasses as indicated in the list. *C. lipolytica* can use *n*-paraffins, n-alkanes, and alkenes.

From Glucose	From Molasses
Glucose, 10–18%	Sugar cane/beet molasses, 5–250 g/L
NH_4Cl	$(NH_4)_2 SO_4$, NH_4Cl, NH_4NO_3
KH_2PO_4	0.3–1.5 VVM, 6 days
$MgSO_4 \cdot 7H_2O$	5.5–6.50 pH for growth
22–30 °C, 3–6 days	2.8–4 pH for production
	3,154 kg sugar → 1,119 kg monocitrate

Citric Acid Production by Bacteria

Certain bacteria are preferred for producing citric acid because of their low doubling time. Examples include:

Bacillus licheniformis *Bacillus subtilis* *Brevibacterium flavum*	They utilize glucose or isocitric acid or hydrocarbons
Arthrobacter paraffinens can utilize dodecane (C_{12}–C_{14}) at 28 °C over a period of 72 h; yield 28 mg/mL	*Bacillus licheniformis* can utilize glucose medium: 30–37 °C 36–120 h; pH 7; nitrogen salts act as nutrients; yield 42 g/L

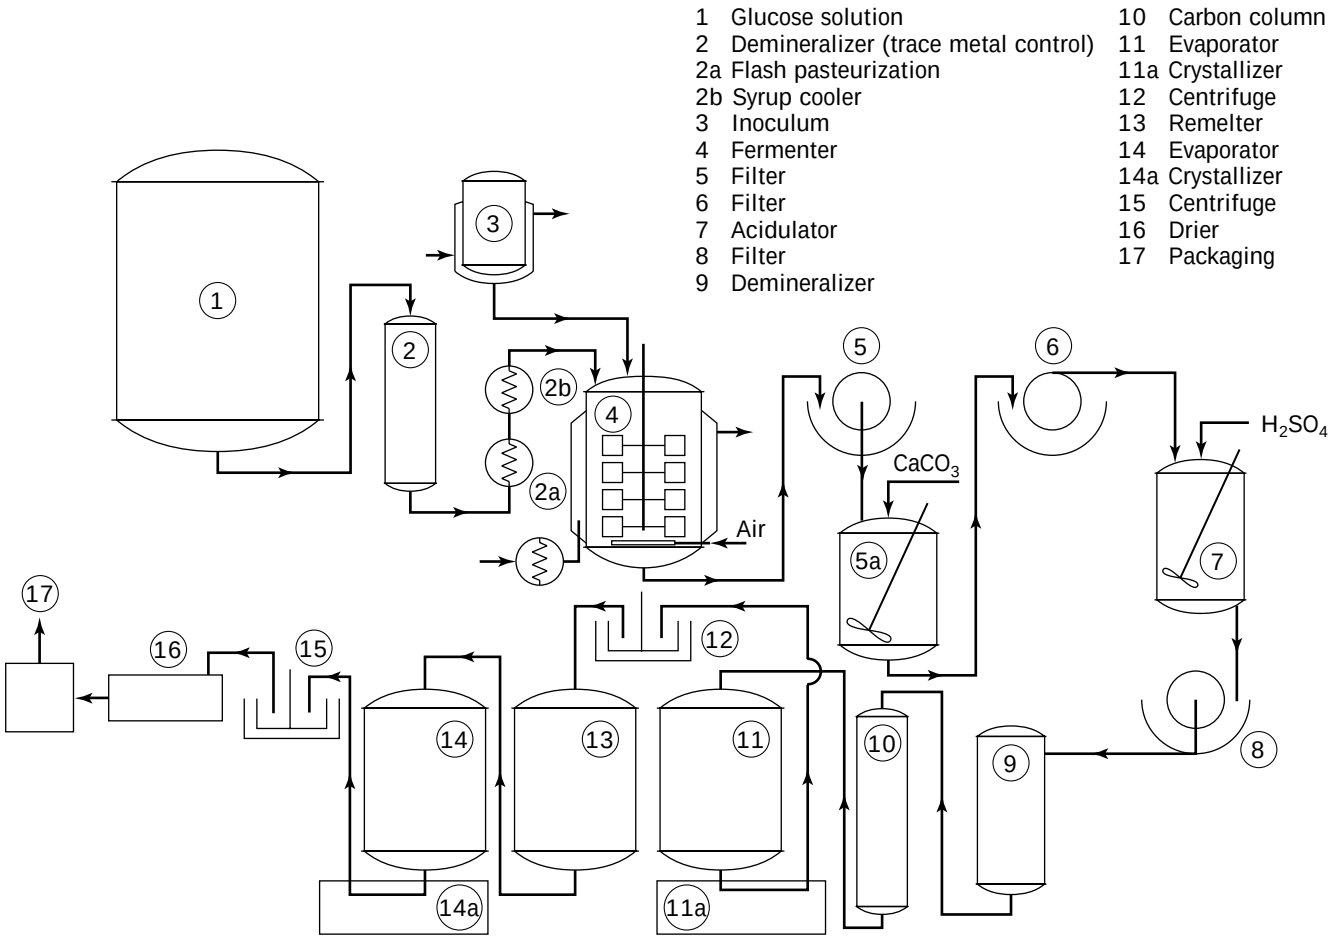


Figure 4. Citric acid production and separation flowsheet.

Recovery of Citric Acid

Two important routes are followed. One is the precipitation as calcium citrate (Fig. 4). The second is the liquid–liquid extraction technique as discussed by Krishnan and Natarajan (40). Solvents such as esters, ketones, amines, and alcohols have been successfully used for the recovery, as outlined by Rieger and Kioustelidis (43).

CONCLUSIONS

Citric acid enjoys a unique place in several important everyday applications. The capabilities of *A. niger* have been almost totally exploited by using several strains of its culture and their mutants. The application of *A. niger* for citric acid production has been stretched nearly to the limit. It is the wishful thinking of the author that some more work could be undertaken in producing such stains that could utilize unclarified raw materials in shorter periods. No effort should be spared in developing newer and cheaper chemicals (promoters) that could accelerate the production rate.

Care has been taken to cover the entire world literature on citric acid production. However, some references might have been missed more because of specific constraints rather than because of oversight or willful omissions. I should like to end by saying that some more work on the application of bacterial culture would be rewarding. It may not be right to say that the last word has been spoken on citric acid production.

Dissolve away difficulties,
Filter out gloom
And from the mother liquor of life
Gather crystals of (citric acid) joy.

Adapted from Krishnan.

OUTLINE

INTRODUCTION

The importance of adequate cleaning in a biological process cannot be overemphasized. The required stringency of cleaning and cleaning validation is best evaluated by performing a risk analysis. The risks associated with the use of improperly cleaned equipment and materials (such as filters and chromatography media) vary with the product source, intended use of end product, the position of the equipment and materials in the processing train, the phase of development of the process, and the type of unit operation. A further consideration is whether the equipment or facility is used for more than one product. Robust cleaning methods, suitable cleaning agents, and cleaning validation ensure that a product with the desired properties is manufactured without contamination from processing additives, well-defined impurities, unexpected contaminants, and previously run product.

PRODUCT SOURCES

For certain complex product sources such as plasma, the potential safety risk from inadequate cleaning is clearly very high. The impurities in the source material are not fully characterized, making evaluation of cleaning efficiency more difficult. For other products, such as secreted products from a mammalian cell culture such as chinese hamster ovary (CHO) cells, the impurities are clearly defined, cleaning efficacy is more readily assessed, and the risks are fewer than with products derived from multiple sources such as blood donors. Robust cleaning procedures are also required for synthetic processes such as those used to produce oligonucleotides used for antisense therapy and synthetic peptides, but the cleaning methods and assessment of their efficacy may be even simpler.

INTENDED USE OF PRODUCT

If the end product is intended for use as a therapeutic agent delivered in a large dose for an extended time in a healthy individual, the criticality of cleaning is obvious. For a product intended for in vitro diagnostic use, the potential contamination that can arise from inadequate cleaning can result in an incorrect diagnosis and even result in a dangerous treatment for a patient. For industrial enzymes, contamination from previously run product may or may not have a detrimental effect on product performance, but even in this case the limits of cleanliness should be defined.

POSITION IN PROCESSING TRAIN

A typical processing scheme will consist of several unit operations (Table 1). The closer one gets to final product, the more critical the cleaning becomes. For example, it has been suggested by some regulators during oral presentations that firms using contract manufacturers for formulation and filling consider supplying their own dedicated equipment to ensure no risk of contamination from other products caused by insufficient cleaning. But even upstream in fermentation or synthetic processes, the lack of adequate cleaning can lead to contamination of the next batch with unknown impurities that adulterate the product in such a way that its safety, potency, and efficacy are compromised.

PHASE OF PRODUCT DEVELOPMENT

From research to full-scale manufacturing, proper cleaning is essential for reproducible processes. Not surprisingly, there is a great rush to get a product into the clinic to demonstrate efficacy. In this rush, cleaning is sometimes overlooked, resulting in laboratory data that are unreliable. For example, when a researcher uses a chromatography column for developing a purification process and fails to adequately clean precipitated impurities, the purification process in the next run is likely to yield a product that does not represent what is intended. Good manufacturing practices (GMP) are required for all clinical trials (1). This requirement is also applied in many nations other than the United States. Although cleaning validation might not be complete at this stage, routine cleaning is essential, and it is advantageous to have a cleaning validation plan.

Cleaning and cleaning validation are essential in the manufacture of marketed products and are part of good manufacturing practices. For therapeutics, the legal requirements are given in the U.S. Code of Federal Regulations in the form of general guidance (21 CFR 211.67 and 21 CFR 600.11).

MULTIPRODUCT VERSUS DEDICATED EQUIPMENT AND FACILITIES

In the past, most facilities used for manufacturing therapeutics were dedicated to one product or a family of products from the same source. For complex biologicals, such as plasma products and traditional vaccines, this is still the case. For these biologics, starting materials, and even the final products, may not be sufficiently well defined to evaluate the effectiveness of the cleaning regimes in removing all traces of previously run product and processing materials. Advances in analytical technologies, however, are allowing firms to better assess cleaning effectiveness, especially for well-characterized products. Products that are considered well characterized include therapeutic DNA plasmids, therapeutic synthetic peptides of 40 or fewer amino acids, monoclonal antibodies for in vivo use, and therapeutic recombinant DNA-derived products (2).

Today, there is a trend to reduce processing costs by employing contract manufacturers to produce clinical trial

materials, thereby avoiding the construction of costly facilities for products that may not ultimately obtain regulatory approval. There are also many firms that campaign products (produce one at a time) to fully utilize space, equipment, and personnel. Regulators carefully scrutinize cleaning and cleaning validation in such facilities to ensure that there is no cross-contamination of products. Cleaning validation using sensitive, specific, and nonspecific analytical methods is essential for such operations (see "Methods for Evaluating Cleanliness").

UNIT OPERATIONS

General Considerations

Each unit operation has somewhat different cleaning requirements, which as previously stated are dependent on the nature of the product source and its intended use, its position in the process train, and whether it is used for more than one product. Cleaning is not an issue to be addressed after a process is finalized; it should be designed into the process. In fact, the selection of the most suitable equipment and materials may be dependent on their ability to be cleaned. Records kept during research and development may be valuable in the design of a cleaning process. For example, a researcher may find that a standard cleaning procedure recommended by an equipment vendor is not sufficiently harsh for a particular product feedstream.

Although each feedstream and each unit operation have unique features that must be considered before the most efficient cleaning protocol can be designed, there are many commonalities that can used to minimize development time. References such as regulatory guidelines and PDA's book on cleaning should be consulted (3). Keeping up with the latest technical and regulatory publications and comments at meetings and workshops is essential.

In the design of the cleaning regime for each unit operation, critical factors to consider include the type of cleaning method, compatibility, and detection methods. Cleaning may be automated or manual. Automated cleaning can provide more consistent results. Manual cleaning, on the other hand, is clearly much more difficult to validate, and operators must be certified to perform the task. Cleaning-in-place (CIP) is preferred, but for some components, cleaning-out-of-place (COP) is necessary. Cleaning may be accomplished by chemical or physical methods, or, most likely, by a combination of both.

Chemical Methods

When chemical methods are used, the contact time, temperature, and cleaning agent concentration must be specified. The order of adding cleaning agents and rinsing agents may be critical. Additionally, if the chemical agent is flowing through the equipment, then flow must be specified. It is essential to ensure that the cleaning agent is compatible not only with the specified equipment, but also with any ancillary components that might be exposed to the agent. The nature of the soil must also be considered. Whereas hot alkali and detergents might work for one unit operation, for another they may actually exacerbate the cleaning problem by causing deterioration of the equipment or aggregation of impurities. Organic solvents used for removal of lipids may extract potentially harmful chemicals from some equipment components in a given unit operation. If a packed chromatography column containing a soluble hydrophobic protein is cleaned by treatment with a salt solution, the protein is likely to precipitate and actually leave behind a larger residue. For filters and chromatography media, compatibility with the cleaning agent is of particular concern. For example, when incompatible cleaning conditions are used, an immunoadsorbent might leach significant amounts of antibody, leading to reduced capacity and hence inconsistent results in the next batch. Table 2 shows some common cleaning agents and their mechanisms.

Physical Methods

Physical methods include high velocity flow, jet sprays, and agitation. If physical methods are used, it is essential to ensure compatibility with the equipment. Physical methods commonly used for cleaning tanks and fermentation vessels (e.g., spray balls) are clearly not suitable for any packed chromatography columns or thin piping.

Combining Methods

A combination of physical and chemical methods is usually used. Mechanical forces remove gross soils and deliver cleaning solutions to large areas, but chemicals (such as alkali, acid, and detergents) are generally required as well. According to Rohsner and Serve, cleaning processes require energy as well as chemical and physical reactions (4). Cleaning mechanisms are further addressed by LeBlanc et al. (5).

Some development work is necessary to put into place the most efficient and cost-effective cleaning methods for each unit operation. It is important to recognize that the nature of the soil may change somewhat upon scale-up of a process, necessitating a modification of the cleaning procedure. This is most common in the earlier processing steps such as fermentation. Ranges of acceptable conditions should be established and validated to accommodate the worst-case soil.

Fermentation and Cell Culture. At this early step in the process, the nature of the soil to be cleaned is not well defined, but it may contain substances such as lipids; soluble and precipitated proteins; endotoxins (if Gram-negative bacterial fermentation is used); small, soluble

Table 2. Common Cleaning Mechanisms and Cleaning Agents

Mechanism	Agent
Dissolve	Water, alkali, acid
Saponify	Alkali
Degradation of proteins	Alkali, acid
Wetting	Surfactants
Emulsification, suspension	Phosphates, surfactants
Sequester	Chelating agents

highly charged molecules; large DNA; particulate cell debris; and even whole cells. The amount of each substance to be removed depends on the fermentation or cell culture process. Filamentous fungi generally require harsh cleaning, vessels used for yeasts and bacteria are more easily cleaned, and animal cell cultures in which the products are secreted require even less stringent conditions. Assessing the cleanliness at this early stage requires the use of nonspecific assays such as total organic carbon, and in some cases specific assays are also used (see "Methods for Evaluating Cleanliness").

If the product is secreted and very few cells die during the process, the substances to be removed from the bioreactor may be limited, and relatively mild cleaning procedures might be very effective. However, if the cells die and lyse at unknown rates in a process that is not well controlled, there will be more debris and released cellular components to remove. The heat used to kill cells may also cause aggregation and precipitation, making the cleaning more difficult. The type of cell culture media (i.e., serum, serum-free, defined) must also be considered.

In addition to designing the cleaning procedure to accommodate the type of cells or microorganisms, it is necessary to evaluate the bioreactor design and ensure that the CIP mechanisms are suitable. CIP system design and operation for bioreactors have been addressed by Chisti and Moo-Young (6).

Cell Removal and Clarification. Cell removal and clarification most commonly use filtration and centrifugation operations. Techniques such as expanded bed absorption, two-phase separations, and precipitation are also used. Each one of these methods may require its own unique cleaning procedures. Cleaning must ensure removal of cells, cell membranes, cell walls, nucleic acids, proteins, lipids, etc.

Filtration. In filtration operations, one must consider the membranes as well as the hardware. Chemical cleaning is most common, and the cleaning agents must be compatible with both the membrane and the wetted components of the hardware. Filter housing designs that should be considered for ease of cleaning are discussed in Ref. 3. In addition to the piping and membranes, wetted components may include spacers, gaskets, valves, and seals. Adhesives may also be present. The cleaning agent should not damage any of these over time. Some membranes are incompatible with cleaning agents such as sodium hydroxide; some may be cleaned with mild detergents and then sanitized with bleach. Furthermore, some filter materials have pressure and temperature requirements that must be considered when designing the cleaning protocol. And as with other unit operations, the number of uses of wetted components may need to be defined to ensure that with extended exposure to cleaning agents extractables are not released and that the membrane performance is not changed.

The stringency of cleaning required is dependent on the level of gel polarization and membrane fouling. Brose and Waibel have addressed the adsorption of proteins to microfiltration capsules (7).

The cleanliness of tangential flow membranes is often determined by measuring the flux of clean water through the system at a standard transmembrane pressure. Guidance and cautions for performing this measurement have been described by Michaels (8). Other methods of assessing cleanliness include total organic carbon, physical inspection, and comparing the specifications of a water-for-injection (WFI) rinse.

Centrifugation. Because centrifuges represent a significant capital cost, they are frequently used for more than one product. Cleaning validation is essential to prevent cross-contamination. Although continuous desludging disk centrifuges can be designed so that they can be cleaned in place, those that do not desludge continuously cannot. The bowl in tubular bowl centrifuges must usually be cleaned out of place after disassembly (3). Aerosols generated during centrifugation may require further evaluation of the equipment area to be cleaned. For low-volume products, cleaning can be minimized by using disposable self-contained tubes. This approach may be preferable, for example, when centrifugation is used to prepare multiple products over a relatively short period of time, such as for monoclonal antibodies used for in vitro diagnostics.

Phase Partitioning and Precipitation. With the exception of aerosol generation, phase partitioning and precipitation present the same general cleaning issues as found in tanks and centrifuges. Equipment design plays a major role in determining how well these pieces of equipment can be cleaned.

Expanded Bed Adsorption and Big Beads. Expanded bed adsorption and the use of large (on the order of 300 μm) beads are two techniques in which product isolation is achieved by binding to chromatographic media. Unlike standard chromatography (see next section), particulates and even whole cells are applied to the chromatography media. Cleaning is essential to ensure that the equipment does not retain soils from previous runs and that media can be reused. Chromatography media, whether used for isolation or purification, have a high degree of surface area that allows for adsorption and even entrapment of impurities. Even though chromatography media are dedicated to one product, cleaning must address the specific feedstream—both impurities and product—and its interaction with the media. Furthermore, the equipment must be designed to ensure that cleaning procedures will remove all traces of previously run product and that no residual live organisms remain.

In a study to evaluate the effectiveness of a cleaning and sanitizing method, a challenge test was performed by adding an *Escherichia coli* homogenate containing approximately 10^9 colony forming units (cfu) per milliliter to two STREAMLINE expanded bed columns. One column contained 250 mL of STREAMLINE SP and the other 250 mL of STREAMLINE DEAE. Sodium chloride cleaning solutions of increasing concentrations from 0.1 to 0.5 M were added, and the reduction of living microorganisms measured. As seen in Figure 1, the relative reduction in living cells is approximately 10^5. The increase in the number of cells in the eluate from the DEAE illustrates the necessity to understand the nature of the impurity to be removed and its interaction with the component being cleaned. In this case, the increase occurs when the increased sodium

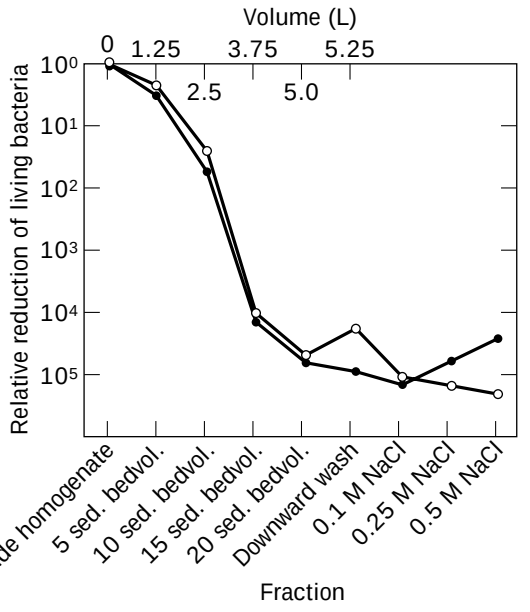

Figure 1. Relative reduction of living *E. coli* cells for STREAMLINE DEAE (●) and SP (○) in relation to the volume of the washing solution. *Source*: With kind permission from Kluwer; Ref. 9.

chloride concentration releases negatively charged *E. coli* cells from the positively charged DEAE (9).

Chromatography. A robust chromatographic process provides the purity required for proteins, peptides, oligonucleotides, plasmids, viral vectors, etc. But it is essential to select equipment and media that can be cleaned in place.

Most of today's chromatographic media can tolerate rather harsh conditions, such as exposure to sodium hydroxide. In affinity chromatography, the ligand usually determines the cleaning solutions that can be used. Protein A, for example, has been shown to withstand even sodium hydroxide (10). On the other hand, with immobilized monoclonal antibodies, it is often necessary to protect the column by using only clarified, partially purified feed. The cost of preparing a monoclonal antibody for use as an immunoadsorbent used in the purification of a therapeutic product is extraordinarily high, because the immobilized antibody must have the same purity as the therapeutic itself (11). One example of the highly successful use of such a column is described by Feldman et al. for the purification of factor VIII from human plasma (12).

As with other unit operations, specific impurities must be addressed in designing the cleaning regimes to ensure that there is no residue carried over from batch to batch of product. Clearly, efficient cleaning is even more important the closer one gets to final product purity. All cleaning procedures, contact time, and temperature must be specified. To maintain column lifetime, the least harsh method that provides a safety window should be implemented.

From a typical bacterial fermentation, one might have to remove soluble and precipitated proteins, hydrophobic proteins and lipids, nucleic acids, viruses, and endotoxins.

Proteins and lipids. Soluble proteins are the easiest to remove. For ion exchange, gel filtration, and most affinity chromatography media, a high salt wash (e.g., 1 to 2 M NaCl) is most common. For hydrophobic interaction chromatography (HIC), low-ionic-strength buffers or water are usually sufficient. In some cases, a detergent must be used, but this approach is more costly and requires validation of detergent removal.

Precipitated proteins frequently require up to 1 M sodium hydroxide or 1 M acetic acid. This is often followed by a water rinse and then a salt wash (except for HIC). Like precipitated proteins, hydrophobic proteins usually require sodium hydroxide. Other approaches include the use of ethanol, detergents, and a combination of cleaning agents. For example, ethanol (20%) in 1 M sodium hydroxide has been used at 40 °C for 30 to 60 minutes to remove host cell proteins from an ion exchanger.

For lipids, very little information is available. Commonly used solubilizing agents may destroy some chromatography media. Detergents and organic solvents (i.e., ethanol and acetonitrile) have been used with some success, but it is necessary to be aware that explosion-proof areas may be required for organic solvents. For those already working in such an area, this does not present a problem, but for firms used to working only in aqueous conditions, this may increase costs significantly. Furthermore, solvent disposal or recycling must be implemented. Removal of lipids before chromatography is strongly recommended to alleviate these concerns and added expenses.

Nucleic Acids. Nucleic acids bind tightly to anion exchangers. Some earlier work to evaluate their removal was performed by loading radiolabeled calf thymus DNA onto a DEAE Sepharose® Fast Flow column. Combinations of sodium chloride and sodium hydroxide were insufficient to totally remove all of the DNA. More recently, the ability of different cleaning agents to remove nucleic acids from a quaternary amine anion exchanger was tested using three different samples (13). The data from two of the samples are shown in Table 3 and 4. It is interesting to observe that for the monoclonal antibody (Table 4), DNase was required to thoroughly remove all traces of nucleic acids.

Viruses. Regulatory agencies have expressed concern about the retention of viruses on columns. As stated at the International Conference on Harmonization Guideline on Viral Safety, "Assurance should be provided that any virus potentially retained by the production system would be adequately destroyed or removed prior to reuse of the system. For example, such evidence may be provided by demon-

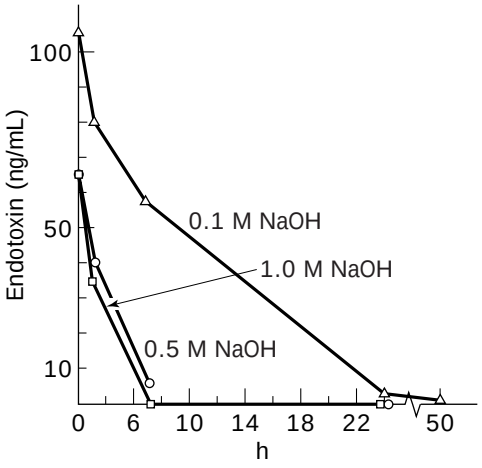

Figure 2. Inactivation of *E. coli* endotoxin by sodium hydroxide.

strating that the cleaning and regeneration procedures do inactivate or remove virus" (14). Table 5 shows work from Q-One Biotech summarizing the inactivation of eight different viruses by 0.1 M and 0.5 M NaOH. The kinetics of inactivation, which must be taken into account for specifying contact time, are also shown.

Endotoxins. Like nucleic acids, endotoxins are highly negatively charged and may bind tenaciously to anion exchangers. Sodium hydroxide has been shown to be very effective in inactivating endotoxins. Figure 2 shows the inactivation of *E. coli* endotoxin in solution at room temperature. Although a contact time of up to 5 hours with 1 M NaOH is indicated here to inactivate endotoxin, the added action of flow may enhance removal. In a study on a chromatography system challenged with a solution containing 1,200 endotoxin units (EU) per milliliter, it was found that circulating 1 M NaOH for 60 minutes was sufficient to inactivate endotoxin in the both the system and the packed column of a quaternary amine anion exchanger that was placed in line. In addition to the *Limulus* amebocyte lysate (LAL) test for endotoxin, a total organic carbon assay was used to analyze the rinse fluids for any carbon-containing residues remaining from the endotoxin. No residue was detected (15).

Combining Cleaning and Sanitization Methods. The ability to remove microorganisms from chromatography media is an issue that should be addressed in development. Depending on the microorganisms, they may produce endotoxins, enterotoxins, spores, and proteases—all of which could adulterate a product. Sanitization of chromatography columns is readily accomplished with sodium hydroxide (16). Combining cleaning and sanitization is the most cost-effective approach. In many cases, addition of sodium chloride to a sodium hydroxide solution provides an efficient, simple method that is easy to validate for removal of bioburden (tested by routine monitoring) and impurities from the feedstream. The importance of compatibility of the wetted materials with such combinations should be considered at the design phase.

Formulation and Final Filling. Cleaning issues in formulation and filling operations are addressed in depth elsewhere. Some relevant texts include those by Olson and Groves (17) and Cole (18). A recent publication that ad-

Notes: Virus titers expressed in $TCID_{50}$ units for all viruses except BHV and MLV (expressed in pfu). Italicized titers: No virus was detected in these samples and values listed are theoretical minimum detectable titers.

HIV = human immunodeficiency virus; BVDA = bovine viral diarrhea virus; CPV = canine parvovirus; BHV = bovine herpes virus; POL = poliovirus; SV-40 = simian virus-40; MLV = murine leukemia virus; ADV = adenovirus.

dresses reducing pyrogens in cleanroom wiping materials provides valuable information on cleaning (19).

METHODS FOR EVALUATING CLEANLINESS

Several methods for evaluating cleanliness were discussed previously in conjunction with the different unit operations. There are three basic methods to evaluate cleanliness: visual inspection, assaying rinse water, and assaying surfaces by swabbing. The nature of the unit operation and equipment design frequently determine which method will be most appropriate. A combination of methods is usually necessary for validation. Visual inspection may be quite useful as a qualitative assessment of cleanliness for equipment such as tanks. As noted by several regulators, "you can always see the ring around the bathtub." However, more sensitive, quantitative methods are also required. For multiproduct facilities, it is absolutely necessary to use product-specific assays. Product-specific assays are also used for dedicated facilities.

Rinse water can be collected after cleaning and examined for residues. In many cases, the quality of the rinse water is compared to WFI that has not been run through the component being tested. Other tests commonly run on rinse water (3) include LAL for endotoxin, total organic carbon (TOC) (20,21), protein assays, sodium dodecylsulfate–polyacrylamide gel electrophoresis (SDS-PAGE), spectrophotometric analysis, and product-specific assays such as ELISAs.

Swabbing is performed by using non-carbon-containing materials that do not interfere with subsequent testing but from which swabbed soils can be extracted. The swabs themselves should not generate particles, background carbon, or nonvolatile residues. Swabbing of surfaces allows evaluation of the cleanliness of areas in which non-water-soluble residues might remain. However, there may be components or areas of systems that are hard to reach by swabbing. In this case, a soil can be applied to pieces of the equipment, called coupons, that are cut out or provided by a vendor. The soil is allowed to dry, and then the coupon is swabbed after cleaning. Coupons can be useful in designing the cleaning protocol. The coupon can be placed inside equipment and cleaned during a normal cleaning cycle. Sometimes, the coupon and the soil are heated to simulate a difficult cleaning problem. Cleaning methods can be tested on the baked-on soil. After the swabbing is performed, the swab is extracted, and the extract is analyzed by assays such as TOC, HPLC, and ELISA.

A survey of five U.S. biotechnology companies revealed which assays are commonly performed and how they are used at different stages of manufacturing (22). The report presents the purpose of each test, detection limits, acceptance criteria, and methodology in a concise tabular form.

SETTING LIMITS

How clean is clean? As analytical methods become more sensitive, the likelihood of finding something is increased. Attempts to define acceptance limits of cleanliness have been made by Fourman and Mullen (23) and Zeller (24) and discussed in Reference 3. Fourman and Mullen suggested that "No more than 10 ppm of any product should appear in another product" and "No more than 0.001 dose of any product will appear in the maximum daily dose of another product." But clearly, a risk analysis should be performed to assess the potential hazard for each product.

Whereas for some therapeutics these low levels suggested by Fourman and Mullen may be accepted by regulatory authorities, for many multiproduct facilities, "not detectable" may be required. On the other hand, for diagnostic products, the real issue should be whether the product is consistent and whether the carryover affects its accuracy.

The acceptance criteria for upstream unit operations such as fermentation may not be as stringent as those for final purification and processing steps. Typical acceptance criteria for CIP of fermenters has been discussed by Naglak et al. (25).

In addition to setting specifications for residual impurities derived from the product feedstream and final product, it is necessary to consider the removal of cleaning agents. Analytical strategies for organic cleaning agent residues have been addressed by Gavlick et al. (26). The questions: "What is the level of detergent residue that would be acceptable to the Food and Drug Administration (FDA)? What is the basis for arriving at this level, if any?" were answered by the FDA's Office of Compliance as follows: "FDA has repeatedly stated that it is the firm's responsibility to establish acceptance limits and be prepared to provide the basis for those limits to FDA. Thus, there is no fixed standard for levels of detergent residue. Any residues must not adversely alter drug product safety, efficacy, quality, or stability" (27).

CLEANING VALIDATION

Although it is not a regulatory requirement, a master plan for cleaning validation can be quite valuable. The master plan will provide a time frame for performing the work, prioritizing tasks, designating responsibilities, describing protocols, and listing all facility, equipment, and process validation requirements. Although the time frame will most likely change, the plan will ultimately save time and may prevent regulatory delays by ensuring that no critical items are overlooked. A final validation report should be signed by management.

Agalloco described a series of questions that provide insight into cleaning validation (28): What items are being removed? How are samples taken? What analytical tests are utilized? When shall cleaning validation be performed? Which physical parameters shall be evaluated? How much residual will be permitted? These questions should be addressed during the preparation of the master plan.

Two cleaning validation guides written by the U.S. FDA are very useful (29,30). Although the intent of these guides is to provide FDA investigators with information that results in consistency in inspections, there are many relevant points that should be considered by any firm that has to perform cleaning validation. For example, in the mid-

Atlantic version, it is stated that operators performing cleaning operations should be aware of problems and have special training, and the length of time between the end of processing and each cleaning step should be controlled. The documents further address issues such as equipment design, documentation, analytical methods, sampling, and establishment of limits. Although no one approach is required, the guidance provided in these documents should be followed or a reason why it was not adhered to provided.

One of the more difficult techniques to validate is swabbing. Some of the variables include operator swabbing technique, extraction efficiency from the swab, and recovery of residue from different wetted materials. In spite of its difficulties, this technique provides valuable information that cannot be obtained from visual inspection and rinse water analysis. Total protein analysis and total carbon analysis of swab samples for the cleaning validation of bioprocess equipment have been addressed by Strege et al. (31,32). Use of this technique for validating detergent residues has also been presented (33).

Most cleaning validation is performed at pilot or full scale, but for certain unit operations such as chromatography, the parameters that are to be validated can often be established with scaled-down models using production feedstream. Seely et al. scaled down a chromatography system and used cleaning conditions that were harsher than those used in normal production to determine if residues remained on the packed column (34). At the same time, production columns were also evaluated for cleaning efficacy by collecting relevant product fractions from blank runs and assaying them for UV280 absorbing material and endotoxin. In addition, reversed-phase HPLC, ELISA, and silver-stained SDS-PAGE assays were performed. No endotoxin or UV280 absorbing material was found. A trace amount of the product was found, but the level (about 0.3% of the amount normally collected) was thought not to represent a significant cycle-to-cycle carryover risk to the final product. Furthermore, the eluate after storage was evaluated by TOC for evidence of further cleaning effects of the storage solution.

Once cleaning is validated, it is much more convenient to monitor key process conditions such as cleaning agent concentration, pH, conductivity, temperature, contact time, and flow if applicable. Revalidation of cleaning may have to be performed when there is a change in a process or equipment, after maintenance or shutdown periods, or after area contamination. Each firm should establish the frequency of cleaning revalidation.

CASE STUDIES

Some case studies further illustrate the critical issues in cleaning and cleaning validation.

Validation of CIP of a Bioreactor

In a 1994 paper, Geigert et al. presented a case study on the CIP of a bioreactor (35). They addressed five key questions: What components need to be cleaned from the bioreactor? What is a scientifically sound and appropriate sampling plan? How will the test samples be handled prior to analysis? Are the test methods chosen scientifically sound and appropriate for the intended purpose? What is clean?

The components to be cleaned included active protein, host cell components, media ingredients, and cleaning agents. The sampling plan included swabbing of a few select surface sites, performing a worst-case cleaning challenge using artificial soil or reducing cleaning parameters, and evaluating liquid from the rinse. Both final rinse and earlier rinse samples were taken to show that the cleaning process was effective. Samples were evaluated for their stability during storage and handling. As an example, it was noted that hydrophobic proteins may adhere to certain plastic storage containers.

Several assays, both specific and nonspecific, were evaluated. Three assays were selected: SDS-PAGE, a bioassay, and pH. TOC was not yet set up at the facility; SDS-PAGE and the bioassay had already been validated by quality control and only needed to be further validated for the limit of detection for the cleaning studies. The absence of cleaning agent was determined by pH, and the absence of final product by the bioassay. Four protein products were analyzed by SDS-PAGE with silver staining. The limit of detection varied from 1 ppm to 10 ppm. The bioassay was performed for the three products that might be campaigned in a single bioreactor. Two products were from yeast; one was from *E. coli*. The two yeast products could be detected at levels as low as 4 ppb, but the *E. coli* product, which was very hydrophobic, aggregated. This study illustrates that the test procedures to evaluate cleanliness are critical in supporting the validation work. By using validated test methods, the firm was able to provide a high degree of assurance that a 1,600-L bioreactor could be cleaned sufficiently between product campaigns, thereby avoiding the additional costs of purchasing costly dedicated equipment.

Changeover of Equipment from Development to a Dedicated Unit

In this example, a firm had used a pilot-scale chromatography unit for development work in the purification of monoclonal antibodies (IgA and IgM) (36). To avoid the expense of purchasing a new unit, the firm decided to use this system for the manufacture of clinical trial material. This required extensive cleaning validation. Because the unit contained tubings and threaded fittings, it was decided that replacing low-cost wetted components was less expensive than validating their cleaning. After the new components were installed, the cleaning of the system was validated by demonstrating absence of carryover on previously exposed sites and by using new surface sites to establish a baseline for future cleaning validation. Samples were taken by swabbing and collecting rinse water, and samples were analyzed by both TOC and ELISAs. The IgM ELISA has a limit of detection of 25 ng/mL, and the IgA ELISA has a limit of 4 ng/mL. The results showed that the 16 used surfaces sampled were below the detection levels of the ELISAs.

CIP Validation in a Multiproduct Facility

A multiproduct biopharmaceutical contract manufactur-

ing facility must address cleaning and cleaning validation to satisfy its own requirements as well as the requirements of their customers and regulators. Sherwood has presented a description of CIP experiences in such a facility (37). The facility manufacturers monoclonal antibodies and recombinant proteins by mammalian cell culture. The author points out that "Each company must determine their own cleaning policies and acceptance criteria based upon knowledge of the equipment and processes employed."

Visual inspection, final rinse water, and swabbing of surface samples were used to evaluate CIP of fermenters and purification holding vessels. Because visual inspection is subjective, two observers are always used. For the rinse water samples, sample containers are single use, and sample storage temperatures and duration were validated. The following tests were performed on rinse water: pH and conductivity, nitrate and protein concentration, bioburden, TOC, endotoxin, and an enzyme immunoassay (EIA). The EIA was only performed for the purification holding vessels. In general, nonspecific assays are used for screening both product and manufacturing materials in fermentation, whereas in the purification area more specific assays are used. For the swab samples, TOC and protein concentration were performed for the fermentation, and in the purification area, the EIA was added.

Acceptance criteria are more difficult to establish in such a facility because the final product dose is not known. Acceptance limits have to be based on analytical method performance criteria, pharmacopeial requirements, and historical data.

The usefulness of performing cleaning validation was illustrated by the performance qualification of the CIP of the fermenter vessel. In one run, a sight glass swab showed a high TOC result. After investigation, a manual cleaning of the sight glass was implemented.

For the initial performance qualification, three consecutive CIP runs were monitored and found to meet acceptance criteria. On an annual basis, one CIP run is fully monitored. The author noted that ongoing monitoring in such a contract manufacturing facility may also require final rinse and swab sampling.

SUMMARY

Cleaning and cleaning validation require sound scientific judgment. Cleaning is not just an afterthought, but should be designed into a process. Today there is a trend to use contract manufacturing, and most of these facilities will manufacture more than one product. Cleaning validation is particularly critical for such facilities. Regulatory agencies are spending more time investigating cleaning and cleaning validation. Ultimately, adequate cleaning leads to enhanced product quality, fewer batch failures, and hence better profitability.

OUTLINE

INTRODUCTION

The general biology of the genus *Clostridium* has been treated recently in detail by Hippe et al. (1). More than 100 species of bacteria fall into this group, probably because only four simple criteria need be met for membership: *(1)* ability to form heat-resistant endospores, *(2)* obligate requirement for anaerobic energy metabolism; *(3)* inability to reduce sulfate as a final electron acceptor, and *(4)* a gram-positive type of cell wall. The extreme heterogeneity of this huge "genus" has become more and more evident over the past 20 years. First, the GC content of the DNA of more than 100 species of *Clostridium* ranges between 21 and 54 mol %. Second, the 16S rRNA gene sequences have been determined for most of these species together with their close relatives. A recent analysis of these data indicates that the genus *Clostridium* is in fact mixed in with some of the closely related bacteria to form several very divergent "clusters", providing a strong basis for a taxonomic revision (2).

The largest rRNA homology group, which is newly designated cluster I (2), contains all the butanol-producing species of *Clostridium* (Table 1) (2–7). Fifty-five strains classified as *Clostridium acetobutylicum* in national collections were recently examined by means of DNA–DNA hybridization (3) and a combination of DNA fingerprinting and 16S RNA gene sequence analysis (4). The results show that these strains fall into four taxonomic groups. These taxa, or species, are listed in Table 1, together with three other butanol-producing species. Also listed in Table 1 are five ethanol-producing clostridia, which are considered important because of their potential to produce ethanol from fermentation of specific substrates such as crystalline cellulose or at a high temperature. Reclassification suggests that these "clostridia" fall into three or four distinct phylogenetic clusters (2). *C. thermocellum* is the most thoroughly studied ethanol-producing cellulolytic clostridial species. It is grouped with seven other cellulolytic species in cluster III (2) or group E (5). *C. thermohydrosulfuricum* strains have recently been divided into two groups and reclassified as *Thermoanaerobacter thermohydrosulfuricus* or *T. ethanolicus* (6) and placed in cluster V (2) or group A (5). *C. thermosaccharolyticum* most likely belongs in the new genus *Thermoanaerobacterium* (6) in cluster VII (2) or group C (5). The phylogenetic position of *C. saccharolyticum* has not been determined (7). Table 1 also includes strain numbers and culture collection numbers that appear most frequently in the literature dealing with solvent production by these clostridia.

The major role of the solvent- and acid-forming saccharolytic clostridia in nature is the degradation of organic materials, namely the biopolymers starch, cellulose, hemicelluloses, and proteins. Utilization of these polymers requires that these bacteria produce and secrete enzymes such as amylases, cellulases, proteinases, and xylanases. Some of these enzymes are of potential importance to commercial processes (8). The anaerobic fermentation of sug-

Table 1. Clostridial Species Important for Solventogenic Fermentations

Former name(s)	Proposed (new) name	Ref.

[a]All butanol-producing species fall into cluster I(2).

ars from digestion of polymers or other sources is called a saccharolytic fermentation. The major products that accumulate are organic acids, neutral solvents, CO_2, and H_2. The solvents and acids are listed in Table 2 for typical fermentations by 11 solvent-producing *Clostridium* species (9–19). Production of CO_2 and H_2 gases is always high in these fermentations (see Table 2 note *a*); however, the exact amount produced is not listed for each species. In a natural setting these clostridia occur in conjunction with a consortium of other anaerobic bacteria, which utilize these fermentation products as rapidly as they are formed for their own energy and growth needs. In this way most of the organic starting materials are mineralized. Only a few isolated strains of *Clostridium* produce significant amounts of solvents and hence are potential candidates for industrial fermentations.

The reason for the high level of interest in basic research and development of fermentation technology for solvent production by the clostridia is straightforward. First, although there is no immediate threat that the world's petroleum reserves will be used up, a severe dwindling of these nonrenewable resources, which serve as the major source of fuels and chemicals, will most likely occur in the mid-twenty-first century (20). Second, it is now technologically possible to produce essentially all commodity chemicals from renewable biomass feedstocks such as starch and cellulose. Third, from about 1915 until the mid-1940s, fermentations employing *Clostridium acetobutylicum* made a significant impact on the commercial solvents industry. Typically, more than 1000 kg of butanol, 500 kg of acetone, and 175 kg of ethanol plus other utilizable byproducts were produced in 90,000-L fermentors in North America and elsewhere (21).

From about 1925 to 1980 research on the physiology and biochemistry of the clostridial fermentations was centered on the unraveling of the metabolic pathways essential to our current understanding of the biology of solvent formation (8). Over the past 10 years, basic research on clostridial solventogenesis has made great strides in the following areas: development of genetic methods applied to the solventogenic *Clostridium* species, regulation of pathways of solvent production, degradation and use of biopolymers, and relation of solvent production to developmental processes such as sporulation. This summary treatment of the biology of the solventogenic clostridia will emphasize our current understanding of the clostridial fermentation strategies, physiologic control and genetic mechanisms regulating solvent production, and future directions for development of new solvent-producing strains. The advantages and problems inherent in the biology of these bacteria relevant to their use in commercial solvent production also are presented.

Table 2. Ethanol and Butanol Fermentations by *Clostridium* Species

Organism	Substrates utilized	
	Complex polymers	Sugars
	Ethanol fermentations	
C. thermocellum	Cellulose, xylan	Cellobiose, few hexoses and pentoses
C. thermohydrosulfuricum (T. ethanolicus)	Starch, pectin, salicin, xylan	Many dissacharides, hexoses, pentoses, etc.
C. thermosaccharolyticum	Starch, xylan	Dissacharides, hexoses, and pentoses
C. saccharolyticum		Dissacharides, hexoses, and pentoses
	Butanol fermentations	
C. acetobutylicum taxon I (corn-starch-utilizing strains)	Starch, xylan	Cellobiose, lactose, some hexoses and pentoses
C. acetobutylicum taxon II		
C. saccharoperbutylacetonicum taxon III (molasses-utilizing strains)	Starch	Sucrose, cellobiose, some hexoses and pentoses
C. beijerinckii taxon IV	Starch	Sucrose, cellobiose, some hexoses and pentoses
C. aurantibutyricum	Starch	Sucrose, hexoses, and pentoses
C. puniceum	Starch, pectin	Hexoses, pentoses
C. tetanomorphum		Cellobiose, some hexoses and pentoses

[a]The gases CO_2 and H_2 are also produced in these fermentations. Production per 100 mmol of hexose CO_2, 150–220 mmol; H_2, 50–100 mmol.
[b]N, not reported.
[c]Amount of butyrate is variable depending on conditions.
[d]Acetone only is produced.
[e]Either isopropanol or acetone is produced, depending on the strain.
[f]Both isopropanol and acetone are produced.

PHYSIOLOGY AND BIOCHEMISTRY OF THE SOLVENT FERMENTATIONS

Clostridium's General Fermentation Strategy

Thauer et al. (22) outlined the general energy metabolism of the chemotrophic anaerobic bacteria, which include the clostridia. The clostridia depend almost exclusively on the fructose biphosphate pathway (Embden–Meyerhof pathway) for conversion of one hexose to two pyruvates with the net production of two ATPs and two NADHs (Fig. 1, pathway 1). In the fermentation of pentoses, the intermediates from 3 mol of pentose-5-phosphate, are one glyceraldehyde 3-phosphate and two fructose 6-phosphates. A combination of the enzymes transaldolase and transketolase is used (Fig. 1, pathway 6). The sugar-phosphates enter the fructose biphosphate pathway and have the capability of producing five ATPs and five NADHs per 3 mol of pentose fermented. The phosphorolytic 3-2 cleavage of xylulose-phosphate yielding acetyl-phosphate is not found in the clostridia or in other obligate anaerobes. Also, the clostridia do not have the enzyme pathway for oxidation of glucose 6-phosphate to NADPH, pentose 5-phosphate, and CO_2. However, high activities of glucose 6-phosphate dehydrogenase and of 6-phosphogluconate dehydrogenase were found to be induced in sporulating cells of *C. thermosaccharolyticum* (12). Possibly this pathway (Fig. 1, pathway 7) is induced during sporulation to provide extra NADPH for biosynthesis and has been overlooked in other clostridia. Yet, NADPH–ferredoxin oxidoreductase (Fig. 1, reaction 4), which is ubiquitous in all clostridia investigated (23), probably provides the NADPH for biosynthesis during both vegetative growth and sporulation. Most pyruvate produced from sugars during the clostridial fermentation is cleaved by pyruvate–ferredoxin oxidoreductase in a coenzyme A (CoA) dependent reaction yielding CO_2, acetyl CoA, and reduced ferredoxin (Fd_{red}), as shown in Figure 1, reaction 2. Acetyl CoA is central to all clostridial fermentations. The thioester bond of acetyl CoA is a very high energy bond; thus it is an important source of ATP in most clostridial fermentations, because for every mole of butyrate or acetate produced, a mole of ATP is formed (Fig. 2, reactions 2 and 6). Acetyl CoA is also the most important precursor of all alcohols and organic acids synthesized by these organisms: it thus serves as a major intermediate in these fermentations (Fig. 1). The NADH, which is formed during oxidation of glucose, is thus reoxidized and recycled so that the fermentation can continue.

The second key element in the clostridial fermentation strategy is the system that manages electron flux diagrammed in Figure 1, reactions 3–5. This system consists of ferredoxin and/or other iron–sulfur proteins that can accept or donate electrons at a very low potential ($E^{0\prime} = -0.41$ V) close to the hydrogen electrode; a ferredoxin–NADH oxidoreductase for passing electrons between NADH and Fd; a ferredoxin–NADPH oxidoreductase for controlled production of NADPH needed for biosynthesis of bacterial mass; and one or more hydrogenases permitting the use of protons as final electron acceptors, producing hydrogen gas, typical of most clostridial fermentations.

The electron distribution system functions in coordination with the branched fermentation pathways typical of clostridia, which eventually yield from two to five major acids and solvents (Table 2). The amounts of reduced versus neutral and oxidized products always are balanced with the amounts of H_2 and ATP produced, and there is a

great deal of natural variation dependent on species and fermentation conditions (24). Figure 2 diagrams an example of this principle, in which *C. acetobutylicum* produces five organic fermentation products from acetyl CoA by utilizing three branch points in the fermentation pathways. Certainly, this variety of pathways available to the clostridia provides physiologic versatility and thus adaptability to different growth conditions. Presently, research is focused on elucidating the physiologic signals and details of molecular sensor and responder systems that control the direction of flow toward specific products in these fermentations (see "Regulation of Solvent Production"). The usefulness of these organisms will depend on directing these fermentations toward one or perhaps two major products. Another consequence of the biology of *Clostridium* (and perhaps all solvent-forming microbes) is that the yield of

Figure 2. The butanol fermentations. organic solvents and acids formed is limited to only two-thirds of the substrate sugars fermented. As diagrammed in Figures 2 and 3, all fermented hexoses are funneled into CO_2, which is expelled, and acetyl CoA, which is the precursor of solvents and organic acids. Thus, only two-thirds of the substrate carbon is recovered as useful organic products. Exceptions to this one-third loss of productivity are the fermentations of sugars to produce two lactic acids by *C. thermolacticum* and the fermentation of sugars to produce three acetic acids by *C. thermoaceticum* (25).

Ethanol Fermentations

Tables 1 and 2 list three thermophilic clostridia, *C. thermohydrosulfuricum*, *C. thermocellum*, and *C. thermosaccharolyticum*, that produce significant amounts of ethanol together with acetate and some lactate during growth at 55–70 °C (26). *C. saccharolyticum*, first described in 1982, is a mesophile (37 °C optimum for growth) that grows on 20 different sugars and sugar alcohols including cellobiose, but it does not utilize starch or cellulose (7). In contrast,

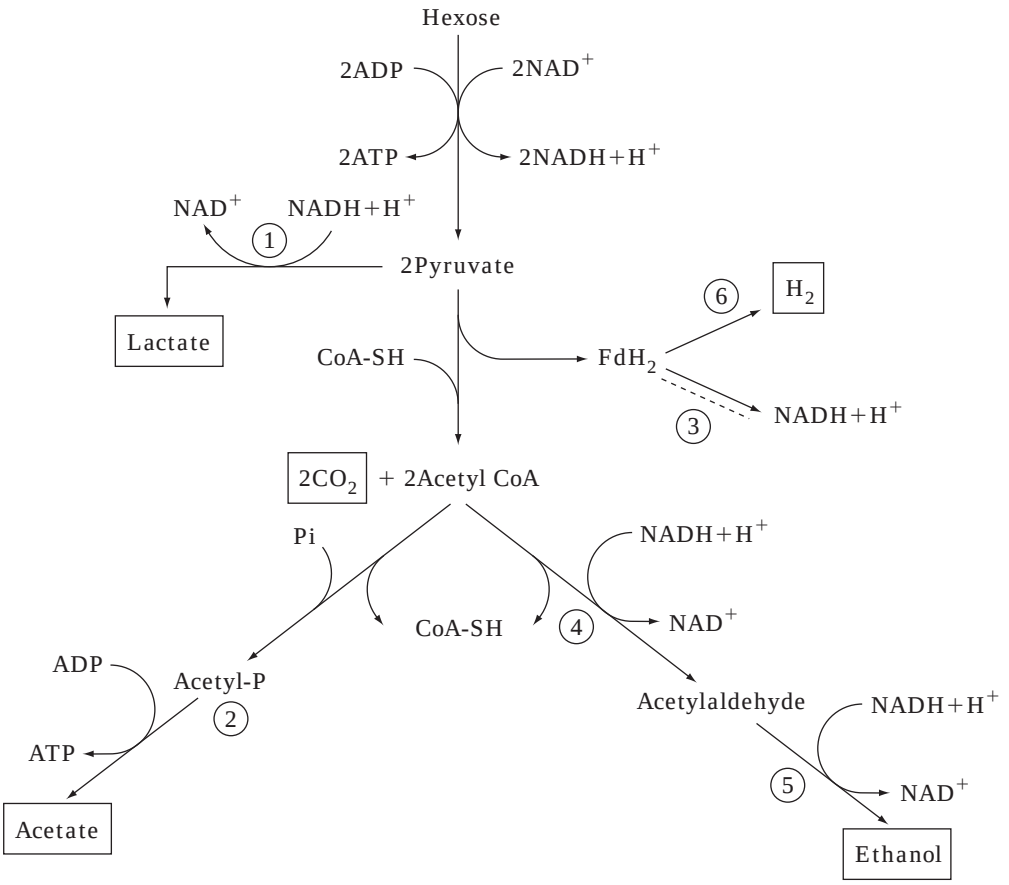

Figure 3. Clostridial ethanol fermentations. Numbers indicate enzymes as follows: 1, lactate dehydrogenase; 2, phosphotransacetylase + acetate kinase; 3, NADH: ferredoxin oxidoreductase and ferredoxin: NAD oxidoreductase; 4, acetaldehyde dehydrogenase; 5, ethanol dehydrogenase, and 6, hydrogenase. *Source*: Reproduced with permission from Ref. 25, p. 35.

C. thermocellum, which will utilize crystalline cellulose and hemicelluloses as feedstocks, is an excellent candidate for future bioconversion of cellulosic biomass to solvents. All these thermophilic clostridia utilize starch but are more limited in their ability to ferment sugars than is *C. saccharolyticum*. During the ethanolic fermentation of hexoses, the bulk of the pyruvate is converted to acetyl CoA, reduced ferredoxin (FdH_2) and CO_2 (Fig. 3). Depending on fermentation conditions, some of the pyruvate is diverted to lactate by lactate dehydrogenase. In one branch of the major fermentation pathway, acetyl CoA is reduced to acetaldehyde and then to ethanol by means of two NAD^+-linked dehydrogenases (Fig. 3, reactions 4 and 5). Acetate is formed via a second branch yielding a stoichiometric amount of ATP as in other clostridial fermentations (Fig. 3, reaction 2). Using this three-branched pathway, *C. thermocellum* produces about 0.6–1.0 mol ethanol/mol hexose, whereas the *C. thermohydrosulfuricum* and *C. saccharolyticum* fermentations yield 1.8–1.9 mol ethanol/mol hexose, which makes the latter two species attractive ethanol production organisms (Table 2).

The biochemical basis for the different product ratios produced by different species using the same branched pathway (Fig. 3) remains unknown, although the problem has been studied indirectly. Batch cultures of *C. thermosaccharolyticum* subjected to slow feeding of glucose show restricted growth, producing excess ethanol (1.0 mol/mol glucose) and little acetate or butyrate. On the other hand, rapidly growing cultures of this bacterium produce mostly acetate, lactate, and butyrate (12). Batch fermentation of cellulose by *C. thermocellum* yielded ethanol as the major product for the first two days, while lactate and acetate accumulated from days 2–5. Maintaining the pH at 7.2 rather than 6.5 favored a high ethanol/lactate ratio (9). Thus, in batch fermentation, the amount of ethanol observed depends on the pH and the time of sampling. Referring to Figure 3, it is clear that when these clostridia produce more than 1 mol of ethanol/mol of hexose fermented, a significant transfer of electrons must occur from FdH_2 to NAD^+ catalyzed by Fd:NAD^+ oxidoreductase. The role of this electron-balancing function was made clear when strain LQRI of *C. thermocellum*, which produced exactly 1:1 ethanol–acetate from cellobiose, was found to be devoid of Fd:NAD^+ oxidoreductase (27). Both strain AS39 of *C. thermocellum* and *Thermoanaerobacter brockii* contained this enzyme and could produce excess ethanol and low H_2 in experimental fermentations. Because *T. brockii* is in the same genus as *C. thermohydrosulfuricum* (5,6), it

is likely that the high ethanol production by this clostridium is a result of the same electron-balancing pathways (see Table 2).

Because of the effective degradation of various crystalline cellulose sources by *C. thermocellum*, the cellulose enzyme complex has been extensively studied, as discussed later in "Biology of Substrate Utilization." To take advantage of this capability, the approach has been to develop mutants or devise both batch and continuous culture fermentation conditions that will increase the relative yield of ethanol to other products and increase tolerance of the organism to produce ethanol at 15 g/L rather than the normal 5 g/L (9). A second approach, which uses the principle of symbiotic coculture, is also available. Coculture fermentations have been developed at the experimental level to exploit the advantageous properties of two thermophilic clostridia to produce ethanol from biomass (26,28). A metabolic explanation for a stable communal coculture of *C. thermocellum* and *C. thermohydrosulfuricum* fermenting cellulose to ethanol has been presented. *C. thermohydrosulfuricum* depends on the products cellobiose and glucose formed from degradation of cellulose by *C. thermocellum*. Glucose utilization by *C. thermocellum* is inhibited by cellobiose, and both glucose and cellobiose are more rapidly utilized by *C. thermohydrosulfuricum*, which then allows some growth of *C. thermocellum*; however, the major fermentation, which is carried out by *C. thermohydrosulfuricum*, yields a high ratio of ethanol to acetate plus some lactate. Recent example cocultures of strains of these two bacteria fermenting 10 g of cellulose per liter yielded an end-product ethanol to acetate ratio of 10.5 to 4.3 in 19 hours (28). Since the thermophilic clostridia also secrete potent amylases and pullulunases, starch biomass is clearly an important feedstock for ethanol production catalyzed by these organisms, as discussed later (see "Development of New Solvent-Producing Strains").

Recently, 10 or more mesophilic cellulose-fermenting clostridia have been isolated, which degrade cellulose and ferment cellobiose to a mixture of acetate, ethanol, and other products (29). *C. saccharolyticum*, which was originally isolated from a cellulose-enriched sewage sludge, has been grown on cellulose in stable coculture with "*Bacteroides cellosolvens*" (30). Since *C. saccharolyticum* ferments cellobiose primarily to ethanol at 25 °C (Table 2), cellulose fermentation employing this strain in coculture with a mesophilic cellulolytic clostridium may form the future basis for direct bioconversion of cellulose to ethanol.

Butanol Fermentations

Very few species of the butyric acid clostridia are capable of producing significant amounts of butanol. The seven organisms listed in Table 1 have quite distinctive properties. *C. acetobutylicum*, taxon I, is the amylolytic type strain, ATCC 824^T or DMS 792; and phylogenetically it is only distantly related to the saccharolytic strains belonging to taxonomic groups II, III, and IV (4). *C. acetobutylicum*, taxon II (strains NCP 262 or NRRLB 643), contain a very small genome of 2.9 Mbp (versus 4.0 Mbp for strain ATCC 824 or 6.5 Mbp for a strain of *C. beijerinckii*, strain NCIMB 8052T) (31). Taxonomic group III, *C. saccharoperbutylacetonicum*, strain N1-4, is closely related to the other saccharolytic strains (4). In addition to *n*-butanol, all four of these strains produce butyrate, acetate, ethanol, and acetone (Table 2). Alternatively, some *C. beijerinckii* strains typically produce isopropanol instead of acetone. Even though these four organisms carry out basically the same fermentation, they are quite distinct biologically as to rapid growth and fermentation with a high butanol yield on different substrates in industrial-scale batches. The taxonomic group I strains utilize maize or potato starch effectively, whereas organisms of taxa II and III were selected to carry out a saccharolytic fermentation with a molasses substrate. *C. puniceum* carries out the same amylolytic fermentation, producing mostly butanol under the proper conditions (18). *C. puniceum* has the added ability to produce pectinolytic enzymes, which would increase access to plant starch important for some starting substrates. Taxonomic group IV, *C. beijerinckii* (NRRL B592) and *C. aurantibutyricum*, which ferment starch and a variety of sugars to butanol, ethanol, and isopropanol, have been the subjects of research but not commercial fermentations. *C. tetanomorphum* differs from the other organisms in that, during a saccharolytic fermentation, it produces equal amounts of butanol and ethanol but not acetone or isopropanol. Both the more recently described strains, *C. tetanomorphum* and *C. puniceum*, differ from the other five organisms in that they produce significant butanol and ethanol throughout exponential growth rather than only during the later stages of batch fermentations (18,19).

The earlier studies up to 1988 on the biochemistry, genetics, and development of butanol fermentation by the clostridia have been reviewed (24,32,33). Recent advances in the molecular biology, regulation of the fermentation, and other new developments are reviewed by Rogers and Gottschalk (25) and in a review of a meeting on solventogenic clostridia (34). The major enzymatic pathways for the products of butanol fermentation are now known, and the physiologic controls of the switch from an acidogenic to a solventogenic fermentation observed in some of the organisms have been identified. Figure 2 depicts the five major pathways of this fermentation. A characteristic shift in the fermentation pattern was known for some time by microbiologists running industrial fermentations employing strains of "*C. acetobutylicum*" (21,24). In a typical experimental batch culture fermenting glucose, there is an early accumulation of acids (acidogenic phase) followed by butanol formation (solventogenic phase) and a reutilization of butyrate and acetate (Fig. 4). *C. acetobutylicum* growing exponentially on sugars or starch at a pH 5.6 or greater produces butyrate, acetate, CO_2, and H_2 as major fermentation products (Fig. 2, thick gray arrows). During this acidogenic fermentation phase, the bacteria are running a basic butyrate–acetate fermentation. To maintain electron balance, for every mole of acetate formed, an extra mole of H_2 is formed, similar to the case of ethanolic fermentation. Therefore, about 2.4 mol of H_2 is produced from a fermentation of 1 mol of hexose that produces 0.4 mol of acetate and 0.8 mol of butyrate. The extra 0.4 mol of H_2 comes from transfer of electrons from NADH through NADH:Fd oxidoreductase and hydrogenase to H_2 (Fig. 2, reaction 1).

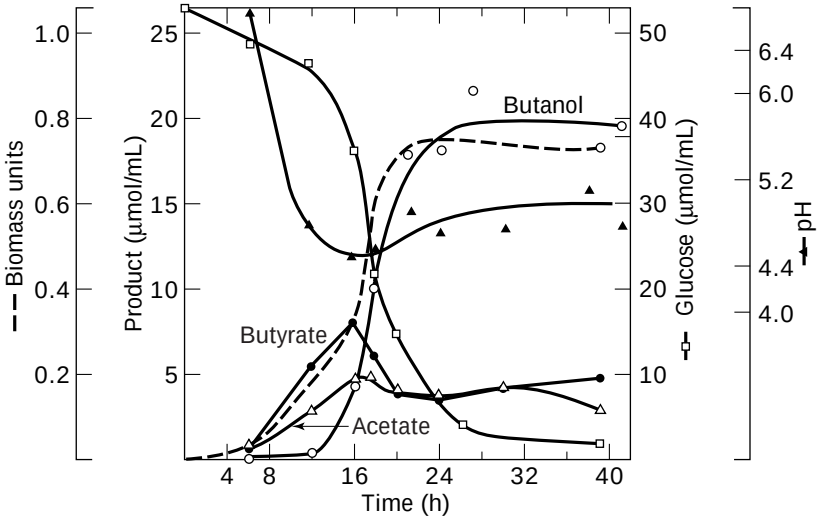

Figure 4. The switch from acidogenic to solventogenic fermentation by *C. acetobutylicum*, strain NRRL B643, in batch culture. *C. acetobutylicum* was grown in a yeast extract, amino acid medium at 37 °C with glucose as an energy source. Samples withdrawn at times shown were analyzed for biomass (dashed line), glucose (open squares), and pH (solid triangles); products in the broth were determined using gas chromatography: acetate (open triangles), butyrate (solid circles), and butanol (open circles). Acetone and ethanol determinations are omitted. *Source*: Reproduced with permission from Ref. 24, p. 6.

With accumulation of acids in a batch culture, the pH drops to pH 4.0–4.5 (depending on the strain), the growth becomes linear, then stops, and the classical switch in the fermentation occurs. The triggering of solvent formation requires the induction of new enzyme pathways in the cells (Fig. 2, thick black arrows) catalyzing formation of butanol, acetone, and ethanol. The connection among the processes of organic acid accumulation, drop in pH, slowing of growth, and induction of solvent-forming enzymes is addressed in the next section. During this phase, there is a net uptake of butyrate and acetate from the fermentation beers back into the cells (Fig. 4) and their recycling and conversion to butanol or ethanol (Fig. 2, arrow, reaction 9). Finally, acetone or isopropanol is produced as a result of decarboxylation of acetoacetate (Fig. 2, reactions 10 and 11).

Depending on the clostridial strain, one or two CoA-dependent aldehyde dehydrogenases and two or three alcohol dehydrogenases are needed for butanol, ethanol, and isopropanol formation, and some of these enzymes are induced 40 to 200-fold at the shift (Fig. 2, reactions 3, 7, 8, and 11). Three additional changes occur as a result of the shift from acidogenesis to solventogenesis:

- There is a lower ATP yield per mol of glucose fermented because net accumulation of acetate and butyrate allows additional production from acetyl phosphate and butyryl phosphate during exponential growth (Fig. 2, reactions 2 and 6).
- Operation of the alcohol pathways requires 2 mol additional NADH per mol of alcohol produced.
- The amount of H_2 made is reduced to about 1.4 mol of H_2 per mol of glucose fermented, since electrons must be shunted from FdH_2 to NADH (Fig. 2, reaction 1).

These changes in electron flux may be involved in regulatory signals for promoting the induction of the shift. This is discussed later ("Regulation of Solvent Production").

Acetone and eventually isopropanol production requires two enzymes: acetoacetyl–CoA transferase (ACT) and acetoacetate decarboxylase (Fig. 2, reactions 9 and 10). In *C. acetobutylicum* and *C. beijerinckii* strains, these enzymes are induced 50- to 100-fold during the shift to solventogenesis. The production of acetone by many of the solvent-forming clostridia is biologically interesting because the pathway neither produces extra ATP nor acts as an electron sink. Even a reduction of acetone to isopropanol by *C. beijerinckii* strains is oddly inefficient, requiring only one NADH, while reduction of acetoacetyl CoA to butyryl CoA recycles two NADHs (Fig. 2, cf. pathways 9–11 and 5). The best guess is that the physiologic role of this pathway is recycling of accumulated organic acids for detoxification and pH control. Thus, after induction of these enzymes, acetate and butyrate are taken up by the bacteria, the ACT enzyme transfers CoA from acetoacetyl–CoA to these acids to form their acyl–CoA intermediates (Fig. 2, reaction 9), and then they are funneled through the alcohol pathways to butanol and ethanol. The decarboxylase pulls the reaction, forming CO_2 and acetone (Fig. 2, reaction 10), or is reduced to isopropanol (Fig. 2, reaction 11) and excreted. During the solvent production phase, reduction in concentration of acids in the medium occurs early, while acetone continues to accumulate long after, when there is no net increase in acids. It appears that in these clostridia, acid production and acid recycling occur throughout solvent formation. High levels of the butyrate pathway enzymes are present during this period, and added [^{14}C]butyrate is rapidly recycled to [^{14}C]butanol continuously. In contrast, *C. tetanomorphum*, which produces both butanol and butyrate simultaneously throughout the fermentation of sugars, contains no ACT enzyme, produces no acetone, and does not recycle [^{14}C]butyrate to [^{14}C]butanol at any time (25).

Other Solvent Products

The butanol-fermenting clostridia can be forced to produce several alternative solvents by growth under special conditions with specific carbon sources. For example, growth of *C. beijerinckii* in a chemostat culture at pH 6.5–6 with glycerol as a carbon source yielded 61% conversion to 1,3-propanediol (35). Glycerol fermentation by 17 of 21 solvent-producing clostridia produced 1,3-propanediol. *C.*

acetobutylicum and *C. beijerinckii* grown in defined media with rhamnose, with a gas phase (CO_2) plus 0.2% $NaHCO_3$, yielded 1,2-propanediol, propionic acid, and propanol as major fermentation products. Three strains of *C. thermosaccharolyticum* ferment glucose yielding up to 7.9 g/L of *R*(–)-1,2-propanediol with a best yield ratio of 0.27 g per gram of glucose. *C. sphenoides* normally produces lactate, acetate, and ethanol from fermentation of glucose. During phosphate limitation, this organism yields up to 34 mM D(–)-1,2-propanediol per 100 mM glucose fermented. New fermentation pathways are probably induced under these conditions. However, the biochemistry has not been carefully studied (see Ref. 25 for specific references).

Another strategy for unusual solvent production uses the principle of enzyme recruitment. It has been demonstrated that *C. acetobutylicum*, grown until it has shifted into the solventogenic phase, can convert several organic acids to their analogous alcohols when added to the growth medium through the recycle mechanism outlined earlier. For example, propionate, valerate, and 4-hydroxybutyrate are taken up by this bacterium and converted to *n*-propanol, *n*-pentanol, and 1,4-butanediol, respectively (25).

REGULATION OF SOLVENT PRODUCTION

Physiology of Control of Solvent Formation

To obtain a high yield of a specific product in a fermentation for solvents, it is often necessary simply to adjust the growth medium, carbon source, and other conditions that will ensure maximum amounts of the desired solvent and minimize production of other products. However, research on the cellular regulatory mechanisms that govern the fermentation not only will allow more effective control of culture conditions but will open the door to development of new highly productive strains. Because many clostridial fermentations typically depend on branched fermentation pathways, analysis of the control elements becomes particularly important. Because most of the recent research is centered on the *C. acetobutylicum* butanol fermentation, this work is emphasized here, although a few observations from the clostridial ethanol fermentations are mentioned. The pathways, products, and characteristics of the acidogenic and the solventogenic fermentations of *C. acetobutylicum* were presented in the preceding section. The culture conditions that promote the shift away from acid production and favor optimal butanol and acetone production are listed in Table 3. These conditions are about the same for batch or continuous cultures of *C. acetobutylicum* (24,32,33) and of *C. puniceum* (18). The conditions that favor butanol and ethanol production without acetone (the alcoholic fermentation) by continuous cultures of *C. acetobutylicum* (36) are also listed in Table 3. The internal status of the bacterium has been measured for each of the three different fermentations (36–38). During the acidogenic fermentation in batch or continuous cultures, the following conditions are required: adequate glucose, a pH_o greater than pH 6.0; and a low level of organic acids. The intracellular pH (about pH_i 6.8) is maintained close to neutral either by excretion of H_2 through the action of hydrogenase or by hydrolysis of ATP and pumping H^+ out of the cell. At a pH_i 6.8 the cell maintains a low positive ΔpH and a very low level of undissociated butyric acid. ATP is produced and utilized at a high rate in this fermentation. The low NADH/NAD ratio is probably a result of the high NADH:Fd oxidoreductase activity, whereby excess electrons are dumped onto FdH_2 and exit through hydrogenase as molecular hydrogen. H_2 is produced in excess in the acidogenic fermentation (Table 3 and Fig. 2, reaction 1, gray arrow).

The shift to a solventogenic fermentation requires an adequate carbon source (glucose), an acid pH_o (pH 4.8–4.4), and high concentrations of butyrate and acetate in batch cultures. Continuous chemostat cultures limited for PO_4 or nitrogen source can be forced to carry out a solventogenic fermentation either by adding a high concentration of organic acids or by setting the pH_o to pH 4.8–4.3, depending on the strain of clostridium (36,37). The intracellular pH (pH_i 5.9) is more acid and results in a greater than 10-fold higher concentration of undissociated butyric and acetic acids in the cell. Also a very high positive ΔpH of 1.1–1.5 is maintained by these cells. Curiously, this high ΔpH persists even when solvent-producing cells are treated with *N*,*N*′-dicyclohexylcarbodiimide (an ATPase inhibitor) or after CO gassing (a hydrogenase inhibitor) (36). A high concentration of ATP is maintained, and turnover of ATP is slowed in the cells, because growth is slower during solvent production. The NADH/NAD ratio is maintained similar to acidogenic cells, even though production of butanol results in new sites for oxidation of NADH. This is due to a net transfer of electrons from FdH_2 as mentioned earlier. This physiologic state is somehow essential for the induction of the enzymes required for solvent fermentation (Fig. 2, reactions 7–10).

The alcoholic fermentation, in which high amounts of butanol and ethanol are produced without acetone, has been studied only recently (36). The alcoholic fermentation in continuous cultures requires high glycerol and limited glucose, at a neutral pH. Table 3 lists three inhibitors of hydrogenase activity that, when added to continuous cultures with adequate glucose, also force cells to produce butanol, butyrate, and ethanol, but no acetone (37). These conditions cause an overload of NADH in the cell, resulting in a high NADH/NAD ratio and various levels of ATP (Table 3). The high level of NADH leading to butanol and ethanol formation is accompanied by increased activities of NADH-dependent alcohol and aldehyde dehydrogenases, which differ from the NADPH-dependent dehydrogenases that are expressed at high levels during solventogenesis in the bacterium. For example, the NADH-dependent butyraldehyde dehydrogenase activity is 100-fold higher in alcohologenic cells, while the NADPH-dependent enzyme activity is induced in solventogenic cells. This suggests that different sets of genes are expressed in these three fermentation conditions (36). The inversion of the transmembrane pH gradient ($-\Delta$pH 0.3) observed during the alcoholic fermentation at neutral pH (Table 3) is apparently due to the low rate of H_2 production. But this inversion does not seem to create an energy crisis for the bacteria, since a similar proton motive force (pmf) was measured for both alcohologenic and acidogenic cells (36). An increase in the electrical potential ($\Delta\Psi$) compensates for the low chem-

Table 3. Conditions for Three Fermentations by *Clostridium acetobutylicum*

	Acidogenic	Solventogenic	Alcoholic
Intracellular status			
$[H^+]$	pH_i 6.8 ΔpH 0.3–0.6	pH_i 5.9 ΔpH 1.1–1.5	pH_i 6.2 ΔpH − 0.3
Undissociated butyrate, acetate	Low concentration	High concentration	Low concentration
ATP (μmol/g cell mass)[a]	Low (0.62), High turnover	High (1.6), Slow turnover	Variable (0.3–1.3), slow turnover
NADH/NAD (ratio)[a]	Low (0.14)	Low (0.1–0.2)	High (0.5–0.8)
Enzymes	Acid pathways (2 and 6 in Fig. 2) NADH:Fd oxidoreductase very high (gray arrow at 1, Fig. 2)	Solvent pathways, induced: butanol (7 and 8 in Fig. 2), acetone (9 and 10 in Fig. 2)	Alcohol pathways, induced: NADH-dependent alcohol and aldehyde dehydrogenases, Fd:NAD $(P)^+$ reductases
Major products	Butyrate, acetate, excess H_2	Butanol, acetone, low H_2	Butanol, ethanol, very low H_2
Fermentation conditions	Adequate glucose: pH_o 6.5–6.2; low $[organic\ acid]_o$	Adequate glucose: (1) pH_o 4.8–4.4, high $[organic\ acids]_o$; (2) Limited PO_4 either neutral pH at high $[organic\ acids]_o$ or pH 4.3 at low $[organic\ acids]_o$	(1) Glycerol and low glucose, pH_o 6.5; (2) Adequate glucose, pH_o 6.5–5.6 + neutral red (1 μM) or + CO gassing or + methyl viologen (4 μM) or limited Fe

[a]Data from Ref. 21.

ical potential (ΔpH). This may be related to the distribution of K^+ across the membrane.

Thus, in *C. acetobutylicum* each of the three fermentation conditions produces a distinct intracellular state, which in turn causes the bacterium to develop the enzyme network needed for each type of fermentation. The current view of physiologic control of *C. acetobutylicum* metabolism is a dual signal model in which a high internal ATP and/or butyric acid level generates one signal and a high NADH level provides the other (37). But how these internal physiologic signals are sensed by molecular sensors in the cell and transferred to molecular responders that specifically regulate gene expression by *C. acetobutylicum* is still unknown.

Genetics of Solvent Formation

Mutations That Affect Solvent Production and Its Regulation. Isolation and characterization of mutants of the solventogenic clostridia has provided valuable information on gene function and regulation of the solvent-producing pathways and of the linkage of this process with developmental changes in the bacterial cell (39). During industrial production of acetone and butanol by *C. acetobutylicum*, the early brewmasters recognized that high solvent-producing strains produced a high percentage of spores. Thus, the high solvent-producing strains were selected by subjecting cultures to cycles of sporulation, heat activation, and outgrowth (32). Mutants that fail to sporulate often also fail to produce solvents. These mutant cells tend to accumulate when *C. acetobutylicum* and related clostridia are repeatedly subcultured in batch cultures or grown in continuous culture, rather than starting cultures from fresh heat-activated spores. When the culture loses the capacity to produce solvents and form spores, this change is called "strain degeneration." Some strains, such as *C. beijerinckii* (NCIMB 8052), tend to degenerate more rapidly than others. In contrast, *C. acetobutylicum* (ATCC 824) will often give rise to asporogenous cells that continue to form acids or solvents (40). Recent studies on the phenomenon of clostridial strain degeneration have been reviewed (41). No satisfactory molecular explanation for the permanent degeneration of clostridial cells was available until just recently. In *C. acetobutylicum*, strains ATCC 824 and ATCC 4259, a large 210-kb plasmid (pWEIZ or pSOL-1) has been demonstrated that carries four solvent-forming genes of the *sol* operon, *ctfA*, *ctfB*, *adc*, and *aad* (see Fig. 5) (42). Degenerate strains that produce no butanol or acetone have lost the pSOL-1 plasmid. Since degenerate strains lacking pSOL-1 are also unable to sporulate or carry out any of the coordinate developmental functions, it is likely that major regulatory genes controlling development are located on this plasmid as well. A similar link between the induction of endospore formation and a fermentation shift occurs in *C. thermosaccharolyticum*. Exponentially growing cells produce acetate, butyrate, and lactate. A change in culture conditions produces elongate forms that ferment sugars to primarily ethanol, CO_2, and H_2 before the cells proceed to sporulate. Asporogenous mutants were selected that remained in the intermediate stage and continued to produce ethanol (43).

Mutants of solvent-forming clostridia that have defects in the pathways leading to acid production have been isolated to bias the carbon flow toward solvent production. Following mutagenesis, pathway mutants are often selected through the use of suicide substrates, which are toxic analogs of normal end products formed during the fermentation. For example, allyl alcohol acts as a suicide substrate when oxidized to the toxic aldehyde, acrolein, by the activity of alcohol dehydrogenases. Members of one set of allyl alcohol resistant mutants of *C. acetobutylicum* are

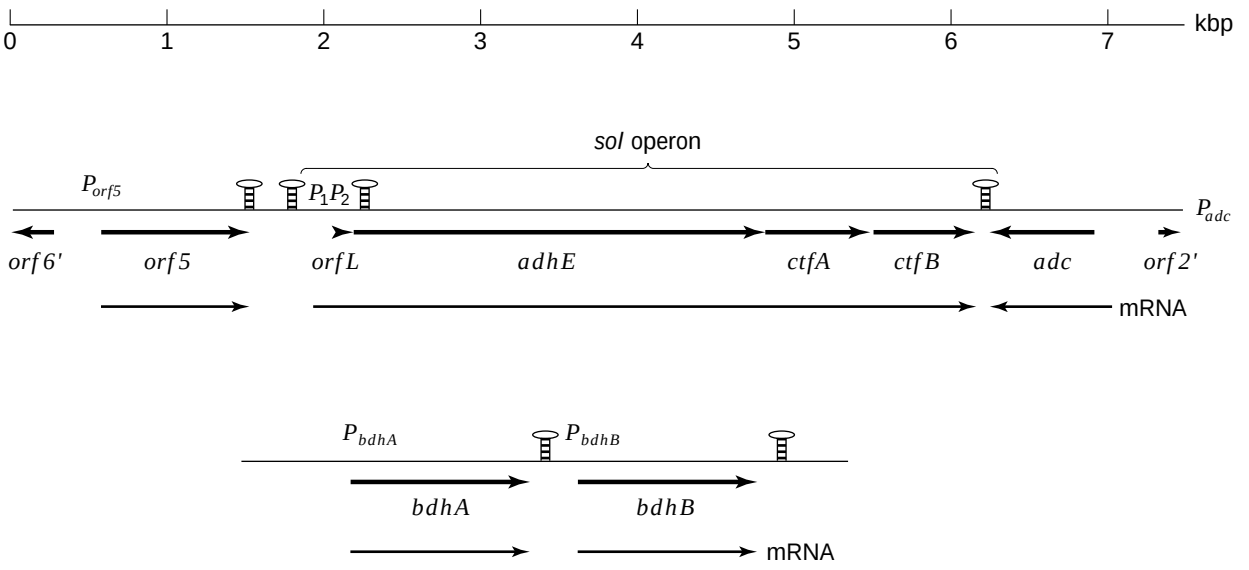

Figure 5. Organization of chromosomal gene regions encoding solventogenic enzymes in *C. acetobutylicum*, strains DSM 792 and ATTC 824. Arrows and arrowheads represent lengths, locations, and orientation of genes; lines with arrows indicate primary mRNA transcripts. The *sol* operon is marked off by a dashed line. A prime at the end of an open reading frame (ORF) indicates that the ORF is truncated. Promoter positions are indicated by P_{adc}, P_1, P_2, P_{bdhA}, P_{bdhB}, and P_{orf5}; possible stem–loop structures are indicated by hairpin symbols. *Source*: Reproduced with permission from Ref. 51, p. 253.

defective in butanol and ethanol production because of altered alcohol dehydrogenase enzymes. However, these mutants contain normal butyraldehyde dehydrogenase activity and produce significant amounts of butyraldehyde (15) (see Fig. 2, reactions 7 and 8). Fluoroacetate-resistant mutants of *C. thermosaccharolyticum* were found to be deficient in acetate kinase or phosphotransacetylase enzyme activities and thus produce less acetate and more ethanol than the parental strains (see Fig. 3, reaction 2) (44). An asporogenous ethanol-tolerant mutant of *C. thermocellum* (LD 1) was selected by means of fluoropyruvate. When fermenting cellobiose, this mutant strain produced a high ratio of ethanol to acetic acid, in contrast to the parental strains, which produce mostly lactic acid and acetic acid (9). Mutants of *C. acetobutylicum* (B643) and *C. beijerinckii* (NCIMB 8052) that produce excess butanol and acetone and more importantly also recycle virtually all acetate and butyrate have been isolated (15,16). These super recycling strains may be used in future production methods covered in a later section "Development of New Solvent-Producing Strains").

Conjugative Transposons and Transfer of Plasmid Vectors. Conjugative transposons are a class of mobile genetic elements usually found as residents in the chromosomes or plasmids of gram-positive bacteria (see reviews, Refs. 45,46). Originally discovered in *Enterococcus faecalis*, these elements have a broad host range and are important tools for genetic analysis. These mobile elements can integrate almost at random into the chromosome of the recipient bacterium, therewith creating an insertion that disrupts the sequence of the DNA information in a specific gene. Thus, the transposon mutagenesis differs from mutagenesis due to physical or chemical means in that only one specific alteration in the host cell DNA occurs, rather than a possibility of two or more random changes in the DNA that obscure the alteration in the phenotype and gene under study. Genetic techniques ensure that only one copy of the transposon has been integrated into the cell for each mutational event. The gram-positive bacterium *Enterococcus faecalis* is the usual donor in matings with *Clostridium*, yielding a transfer frequency of 10^{-3} to 10^{-4} per recipient. The transferred transposon, Tn916 (16.4 kbp), Tn925 (14.5 kbp), or Tn1545 (23.5 kbp), carries an antibiotic resistance marker such as tetracycline resistance (*tetM*) that allows selection of the transconjugants. Because the genes required for the conjugation and DNA transfer are located within the transposon, a transposon carried either on a plasmid or on the chromosome of the donor will be transferred. A number of specific Tn916-induced mutants have been identified in *C. acetobutylicum*. Both structural gene mutants in the fermentation pathway and regulatory mutants preventing solventogenesis, sporulation, and granulose formation have been selected (45,46).

Development of methods for transfer of plasmid vectors into *Clostridium* is vital to the application of genetics to further our understanding of the molecular basis of regulation of solvent formation. A summary of these transformation methods and the clostridial cloning vectors used with *C. perfringens* and *C. acetobutylicum* is available (48). There are two effective methods of transformation of *C. acetobutylicum*. Transformation of protoplasts requires conversion of cells to wall-less protoplasts followed by uptake of plasmid or bacteriophage DNA induced by polyethylene glycol (PEG), regeneration back to rod-shaped cells,

and selection of transformed cells. Using this procedure with strain N1-4 of *C. saccharoperbutylacetonicum*, 10^4–10^5 transformants per microgram of plasmid or phage DNA are obtained. Transformation of whole cells requires suspension of washed cells together with plasmid DNA, electroporation in a cuvette at high voltage (5.0 kV/cm) using a BioRad Gene Pulser, and, after a recovery period of 2–4 hours, selection for transformants. When *C. beijerinckii* (NCIMB 8052) is used, about 10^2–10^4 transformants are obtained per microgram of DNA. Basically, the short pulse of electric current punches temporary holes in the cell membrane, permitting the plasmid DNA to enter the cell. To be useful and identifiable, the plasmid DNA must be able to survive and replicate along with cell division of the host bacterium. In addition, there must be selectable markers such as the *ermC* gene, for antibiotic (erythromycin) resistance, so that colonies of transformed cells can be identified.

Vectors for *C. acetobutylicum* are chimeric cloning vectors that contain an origin of replication that operates in *Clostridium* and a second origin of replication that permits the plasmid to replicate in *E. coli*. Thus, specific pieces of *Clostridium* DNA can be ligated (cloned) into specific sites of this vector, replicated and multiplied in *E. coli*, extracted, and then transferred to mutant *Clostridium* cells to study their effects on the physiology of the host cell. This technique has permitted identification of the roles of suspected regulatory genes and overexpression of specific fermentation pathways in *Clostridium acetobutylicum* (49).

Unfortunately, the successful transformation process is strain specific, as is plasmid survival. Originally, transformation procedures were successful only when *Clostridium* strains in taxa III and IV (see Table 1) were used. Later, electroporative transformation of *C. acetobutylicum* (ATCC 824, taxon I) with plasmid pIM13 from *Bacillus subtilis* was successful. But when a shuttle plasmid was prepared by ligating pIM13 together with *E. coli* plasmids, no transformants were seen. It was discovered that strain ATCC 824 contains a restriction endonuclease (*Cac* 824 I) that cut these shuttle vectors in more than 40 sites, thus destroying the plasmid in the cell. The strain 8052 (taxon IV) does not carry this restriction endonuclease, which explains why the same shuttle plasmids survive in these bacteria (49). The clever solution to survival of these shuttle vectors in the *C. acetobutylicum* (ATCC 824) host requires replication of the shuttle plasmid in *E. coli* in the presence of a second plasmid that expresses a specific transmethylase. This Φ3TI transmethylase adds a methyl group to a cytosine base in the sensitive sites of the shuttle vector DNA. This protects the plasmid DNA, and when extracted and electrotransferred into *C. acetobutylicum* (ATCC 824), the methylated plasmid survives at a high frequency (10^5 transformants/μg DNA) and replicates (49). To date, the important production strains of *C. acetobutylicum*, NRRL B643 or NCP 262 (taxon II), have not been successfully transformed by means of the methods and vectors available. Perhaps there are additional restriction endonucleases that act as barriers to vector survival in these strains.

Cloning, Genetic Organization, and Expression of Solvent and Acid Pathway Genes. Application of molecular genetic techniques together with basic enzymology to the steps in the *C. acetobutylicum* fermentation pathway has revealed a great deal about how this network is organized and regulated. Most of the genes coding for the enzymes involved in acid and solvent fermentation have been cloned in *E. coli*, since this organism expresses many foreign proteins from plasmid-borne genes on specially constructed expression vectors (50). Sequencing of the DNA regions coding for the solvent genes together with the adjacent upstream promoter regions has revealed the basic organization of these genes (Fig. 5, Ref. 51). In strains ATCC 824 and DMS 792, acetoacetate decarboxylase is encoded by a gene (*adc*) in a single operon. Adjacent is the convergently transcribed *sol* operon, which encodes an aldehyde/alcohol dehydrogenase (*adhE*), and the two subunits of acyl CoA transferase (*ctfA* and *ctfB*). The promoters P, P_2, and P*adc*, all have high homology to typical gram-negative and gram-positive bacterial promoter sequences and control expression of these genes. A typical terminator sequence (Fig. 5, hairpin symbols) between the two regions stops transcription from both directions. This entire region of the DNA that includes the *sol* operon and other linked genes such as *adc* is carried on the 210 kbp plasmid (pSOL-1) in *C. acetobutylicum* (ATCC 824), along with other yet undetermined regulatory genes. The remaining genes coding for solvent- and acid-forming enzymes appear to be carried on the chromosome in this strain.

At present, the distribution of the solvent genes in the other six groups of butanol-producing clostridia is not known. The DNA sequences reveal that these solvent genes as well as the genes encoding for butyrate production are transcribed by the RNA polymerase with sigma H (σ^H) that carries out expression of many housekeeping genes in gram-positive bacteria. Alternative sigma factors do not appear to play a role in regulation of solventogenesis in *C. acetobutylicum* (51).

The expression of a synthetic acetone operon carried on a shuttle plasmid (pFNK6) and transferred back into *C. acetobutylicum* (ATCC 824) reveals some additional properties of regulation of solvent production (49). The synthetic acetone operon was constructed from the *adc*, *ctfa*, and *ctfb* genes arranged to transcribe in the same direction from the P*adc* promoter (see Fig. 5). In cell extracts from strain ATCC 824 (pFNK6), the activities of the two acetone enzymes were more than fourfold higher than in cell extracts of strain ATCC 824. The course of the batch fermentation by ATCC 824 (pFNK6) differed from ATCC 824, with almost double the yield of both butanol and acetone and the complete disappearance of butyrate and acetate from the broth by 20 h (Fig. 6). The increase in butanol is consistent with the view that diversion of acetoacetyl CoA to acetone formation and away from butyryl CoA might cause a temporary high rise in NADH/NAD ratio and trigger early induction of the enzymes for butanol synthesis (see Fig. 2, reactions 5, 9, and 10, and 7 and 8). Two "degenerate" mutants of ATCC 824, namely M5 and DG1, which had lost the pSOL plasmid and produce none of the enzymes encoded by the *sol* operon, were transformed with plasmid pCAAD containing the *adcE* gene or with pFNK6 containing the synthetic acetone operon D (42). The degenerate mutants with pCAAD produced significant butanol and butyric acid but no acetone. The same degenerate mutants with pFNK6 produced butyric acid and acetone but

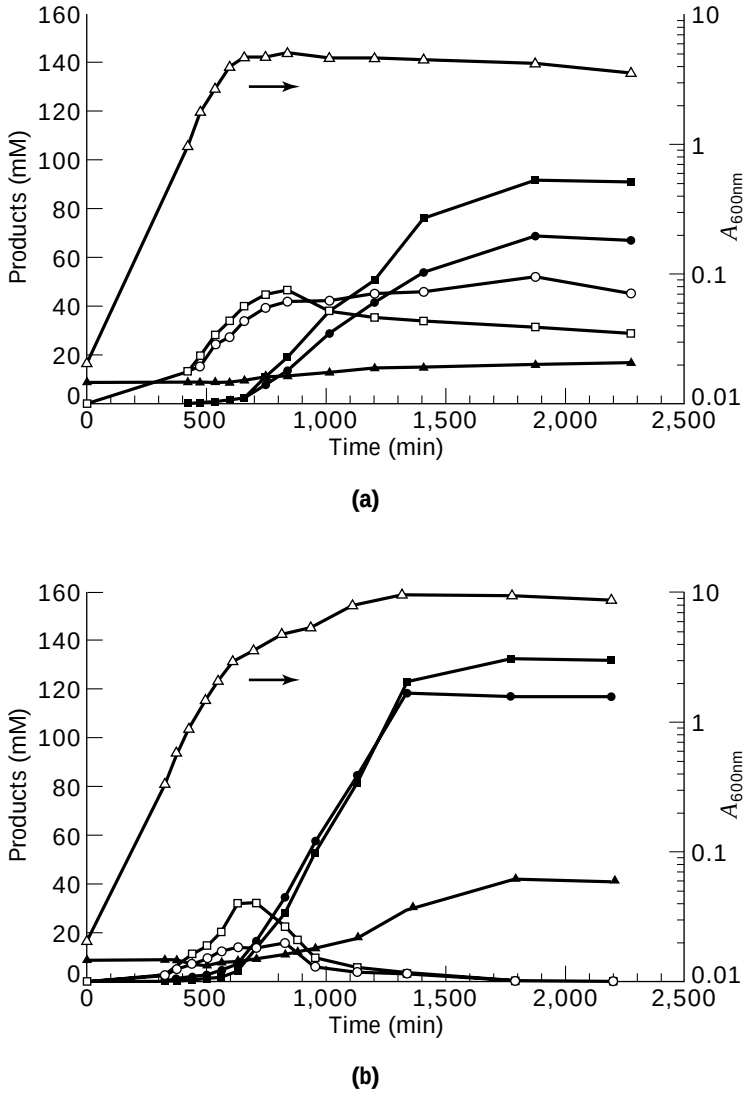

Figure 6. Optical density and product profiles in pH 4.5 batch fermentations for *C. acetobutylicum* strains: (**a**) ATCC 824 and (**b**) ATCC 824 (pFNK6). Open triangles, optical density at 600 nm; solid squares, butanol; solid circles, acetone; solid triangles, ethanol; open squares, butyrate; open circles, acetate. *Source*: Reproduced with permission from Ref. 49, p. 62.

no butanol. The butyraldehyde dehydrogenase (BYDH) activity was produced only in late growth phases in M5 (pCAAD), as is typical for strain 824 (50). M5 cells alone produced no butanol or BYDH activity. Thus the regulatory signals for the *sol* operon must operate "in trans" and be able to control multiple copies of the plasmid-borne genes for solvent production.

Chromosome Mapping and Gene Sequencing. When gene transfer methods and a number of cloned genes became available, construction of a genetic map of the *C. beijerinckii* chromosome was begun to expand genetic analysis of a solventogenic clostridia. About 32 genes have been positioned relative to one another on the 6.5-Mbp circular chromosome map (31). The process of mapping depended on preparation of the genomic DNA by lysis of cells within agar blocks, treatment with exonucleases that cut this DNA in just a few places, and then pulsed-field gel electrophoresis. The large chromosome pieces displayed on the gel are than probed with cloned genes to position each gene. As indicated earlier ("Butanol Fermentations"), this method has revealed wide divergence in strains of *C. acetobutylicum* (4). Other differences in arrangement of solvent genes and regulatory genes may emerge later.

The complete genomic DNA sequences of a number of Eubacteria and of Archaea, such as *Methanococcus jannaschii* are now available (52). The complete DNA sequences of the genome and the pSOL-1 plasmid of *C. acetobutylicum* (ATCC 824) are currently being determined (53). These sequences should provide valuable information on the genetic basis for expressing the proteins and regulatory networks essential for cellular vegetative and developmental changes carried out by this organism. Future successful strain development employing *Clostridium* will depend on complete analysis of the genetic potential of these organisms.

Insertional Mutagenesis with Integrational Plasmids. Recently, it has been possible to develop gene transfer involving homologous recombination in the solvent-producing strains *C. beijerinckii* and *C. acetobutylicum* (ATCC 824). Conjugation procedures with *C. beijerinckii* and electro-

transformation with *C. acetobutylicum* were used to obtain transconjugants or transformed cells at high efficiency, leading to the detection of the integration of plasmids that lack a replication function active in *Clostridium* (Rep^-). Transformants or transconjugants arise by a Campbell-type recombination event between the chromosomal segment in the plasmid and the same region in the bacterial chromosome (31). This insertional event results in an altered or inactivated gene. Nonreplicative (R^-) plasmid constructs containing parts of the acetate kinase gene (*ack*) or butyrate kinase (*buk*) gene fragments were integrated into normal regions of the chromosome of *C. acetobutylicum*. The altered strains produced more butanol during fermentation of sugars (54).

Is Solvent Production a Cellular Stress Response?

Endospore Formation and Solventogenesis. The ultimate response of a number of bacteria to physical or chemical stress or starvation is formation of stress-resistant, metabolically inactive resting cells. Species of the gram-positive *Bacillus* and *Clostridium* differentiate into highly resistant endospores. The biology of endospore formation, including the molecular events that take place during this developmental process, has been studied primarily in *B. subtilis* by many microbiologists over the past 30 years (55). The physiologic changes inside the cell that signal the shift of *C. acetobutylicum* to solventogenesis are most likely either a shift in the redox state of elements in the electron transfer system, such as NADH or reduced Fd, or an increase in the concentration of butyric acid or H^+, or maybe both, as suggested earlier (see "Physiology of Control of Solvent Formation"). In this bacterium, the shift to solventogenesis is associated with other rather massive changes, which include induction of endospore formation and must involve the induction and activation of complex regulatory networks, proteins, and pathways (25). What are the molecules that receive the physiologic signals, and how are all these events triggered in this bacterium? As mutant studies cited earlier ("Genetics of Solvent Formation") indicate, initiation of solvent production and sporulation are tightly coupled, although clearly solventogenesis is not a prerequisite to sporulation in *C. acetobutylicum*, *C. beijerinckii*, and *C. thermosaccharolyticum*. Hence there must be both separate and common control mechanisms. Two lines of recent research support the view that these bacteria are regulated by two classes of the molecular signaling systems that normally operate in bacteria for stress control and adaptation to environmental change.

First, in many bacteria, coordinate transcription of sets of genes is regulated by alternative sigma factors that confer new promoter specificities on RNA polymerase. Examples are heat shock, or stationary phase in *E. coli*, sporulation in *Bacillus* and streptomycetes, and flagella synthesis in many bacteria. Development of endospores in *Bacillus* requires a temporal sequencing of gene expression regulated by four sigma factors (σ^F, σ^E, σ^G, and σ^K) and a protease (*spo* II GA) that activates the σ^E protein. All the genes encoding these sigma factors and the protease have been identified in *C. acetobutylicum* by cloning and sequencing (56). Thus, even though the physiologic signals for sporulation in *Bacillus* (nutrient starvation) are different from those for *Clostridium* (blocking of growth in the presence of excess nutrients), they utilize the same general regulatory features for development. As pointed out above, σ^H the sigma factor that directs RNA polymerase to general cellular promoters in *C. acetobutylicum*, similar to σ^A in other bacteria, apparently also directs the expression of solvent and acid enzyme genes in this bacterium. Therefore, it is clear that the genes concerned with solventogenesis (*sol* genes) are not part of the sporulation cascade. Indeed, a different mechanism coordinates sporulation and solventogenesis, along with other key physiological and morphological changes that occur during the metabolic "switch."

The second major signal system required for endospore formation is the phosphorelay pathway essential for initiation of sporulation (57). In *B. subtilis* a number of response regulator proteins respond to environmental, cell cycle, and metabolic signals, resulting in the phosphorylation of the SpoOA transcription factor. The SpoOA~P controls the transcription of numerous genes by activating or inhibiting the levels of other transcription regulators, which in turn regulate transcription of proteins such as sigma factors required to enter the sporulation cycle. The SpoOA protein acts as a transcriptional regulator both as a repressor of transcription and as an activator by binding to DNA sequences called the "OA boxes" (5-TGNCGAA-3) (57). Only the phosphorylated form, SpoOA~P, is active. PCR primers of portions of SpoAO averaged from sequences of four bacilli, were used to isolate SpoOA segments from the DNA of 11 other species of *Clostridium* and *Bacillus* including *C. acetobutylicum*, *C. beijerinckii*, and *C. pasteuranium*. The complete sequence of the *spoOA* gene from *C. beijerinckii* has been determined and, as in the case of two *Bacillus* strains, the promoter region of the gene has a σ^H promoter with an OA box (58). This is consistent with the autoregulation of *spoOA* by SpoOA~P, first shown in *B. subtilis*. Further, possible "OA box motifs" were found in all the promoter regions for the solvent genes *adc*, *ctfAB*, *adhE*, *bdhA*, and *bdhB* (see Fig. 5) and for the genes *ptb-butk* of *C. acetobutylicum* (31). Expression of these genes is either activated or repressed during the switch to solventogenesis.

Thus, in *C. acetobutylicum* (ATCC 824), direct control by SpoOA is likely. This view was tested in *C. beijerinckii* (NCIMB 8052) by means of the insertional mutagenesis technique described earlier ("Genetics of Solvent Formation"). An R^- (unable to replicate) integrational plasmid containing a DNA segment in the *spoOA* coding region was prepared and transferred into the cell. Recombination occurred by the Campbell-type mechanism, yielding an insert of the plasmid with its antibiotic resistance marker (Em^R) within the chromosomal *spoOA* gene inactivating its expression. The $SpoOA^-$ strain was asporogenic, unable to produce granulose, and unable to produce solvents (31). This indicates that all three of these "switch" responses are most certainly regulated by the phosphorelay system.

Heat Shock Response System in Clostridium. Exposure to a heat shock of all organisms, from bacteria to humans, results in the rapid burst of synthesis of from 15 to 40

proteins. This transient upshift in synthesis of this set of heat shock proteins is also triggered by exposure to toxic chemicals, virus infection, ethanol, and other agents. The major proteins induced include two important categories. First to be induced are the chaperone proteins such as GroES, GroEL, DnaK, DnaJ, and GrpE, which are required for folding newly synthesized proteins and preventing aggregation of denatured proteins destined to be renatured or digested by proteases. Second, a series of ATP-dependent proteases (e.g., Lon, ClpP, ClpX) is induced, since such enzymes must play a role in protein processing or in digesting damaged proteins. There are also a number of sigma factors and other proteins induced. These heat shock proteins function as well in cells growing in normal conditions by "chaperoning" the proper folding of many proteins and digesting abnormal or denatured proteins. Thus the general function of this stress-induced family of proteins is to ensure a high yield of correctly folded proteins even in the presence of protein-denaturing physical and chemical shocks (for general review, see Ref. 59).

Since solvent production in *C. acetobutylicum* and other clostridia is often enhanced by stress conditions such as accumulation of toxic acids that inhibit growth as outlined earlier, it is important to ask how regulation of this heat shock system is related to induction of solventogenesis. The two major chaperon families (the GroE and the Dna K-J groups), as well as 10 or so other heat shock proteins, are transiently induced when *C. acetobutylicum* is upshifted from 30 °C to 42 °C for 5 min. (60). When the same organism shifts to solvent production by a drop in pH at a high butyric acid concentration, the same transient induction of heat shock proteins occurs. Thus, this stress response is coordinated with the induction of the expression of genes encoding solvent-forming enzymes. In the case of *E. coli*, the expression of the heat shock genes depends on a special sigma factor, σ^{32}, which forces cellular RNA polymerase to recognize specific promoter sequences of the heat shock gene family. However, the regulatory mechanism for heat shock gene expression in *C. acetobutylicum* appears to be different. No evidence for an alternative sigma factor has been found, and the promoter sequences of the *groE* and *dnaK* operons conform to the common promoter region for gram-positive bacteria. However, in both *C. acetobutylicum* and *B. subtilis* there is a conserved inverted repeat (IR) of 9 bp separated by a 9-bp spacer within the promoter region of the *dnaK* and *groE* operons. This IR has been identified in 27 bacterial species (both gram-negative and gram-positive), always occurring only before the *dnaK* and *groE* operons. There is evidence in *B. subtilis* that this IR is a site that interacts with a regulatory protein (ORF 39) that may act alternatively as an activator and a repressor (61). A similar protein (ORF A) identified in *C. acetobutylicum* is a candidate for the same regulatory function.

How the mechanisms regulating heat shock and general stress response in the clostridia may be connected with the *SpoOA* phosphorelay system involved in the initiation of endospore formation and solventogenesis is still not known. In any case, the stress response in gram-positive bacteria is designed to combat a variety of stress situations. In summary, the overall stress response of the solvent-forming *C. acetobutylicum* and perhaps other solvent-producing clostridia appears to involve three response systems. First, heat shock genes are induced, expressing a 10- to 20-fold increase in chaperone proteins protecting vital cellular enzymes and other proteins against denaturing effects of internal butyric acid. Second, solvent genes are induced, expressing a 40- to 100-fold increase in butanol and acetone pathway enzymes and resulting in recycling of butyric and acetic acids, thus detoxifying the environment. Finally, the first two stress responses permit the cell time to induce the complex machinery required for differentiation to endosporulation, which is the ultimate stress response available to all the clostridia.

DEVELOPMENT OF NEW SOLVENT-PRODUCING STRAINS

The Product Tolerance Problem

When a *Clostridium*-based fermentation is contemplated for a commercial solvent production system, the factors such as rate and efficiency of substrate conversion to solvents must be considered. But the major problem to be faced for all clostridial fermentations is extraction of low concentrations of solvents from water. It has been calculated that when distillation is used in the recovery of ethanol at less than 6–8%, or *n*-butanol at less than 2–3% from fermentation beers, the energy required exceeds the net energy recovery in the final products obtained in the commercial process. Yeasts and strains of *Zymomonas mobilis* convert sugars to an ethanol concentration high enough (10–20%) to permit separation of the solvent from the fermentation beer on an energy budget sufficiently low to allow profitable industrial production. In contrast, cocultures of *C. thermocellum* and *C. thermohydrosulfuricum* fermenting liquefied wood to ethanol produce a low final yield of 2% ethanol, a concentration above which growth of both these bacteria is inhibited. Likewise, the butanol–acetone fermentation by *C. acetobutylicum* stops when only 2% (w/v) solvents is reached, primarily owing to the toxicity of butanol.

There has been only limited research on the biological basis of low tolerance of clostridia to solvents involving strains of three organisms: *C. thermocellum*, *C. thermohydrosulfuricum*, and *C. acetobutylicum* (24). Growth of *C. thermocellum* at low concentration of ethanol results in an increase in the ratio of unsaturated/saturated fatty acids in the cytoplasmic membrane consistent with work with other bacteria. A mutant strain, C9, adapted to growth at higher levels of ethanol (2%) exhibited even greater increase in the amount of unsaturated fatty acids. The view is that ethanol enters the cell, causing a decrease in membrane fluidity, and the bacteria adapt by altering the fatty acid content to increase fluidity. The low ethanol tolerance of *C. thermocellum* (5 g/L) has been ascribed to specific inhibition of a number of enzymes required for glycolysis. Glucose fermentation by *C. thermohydrosulfuricum* (strain 39E) was inhibited by 0.5–2% ethanol. A mutant strain (39EA) grew in 8% ethanol at 45 °C and 3.3% ethanol at 68 °C. Unfortunately, the mutant strain produced a 1:1 ratio of ethanol to lactate, while the parent strain (39E) pro-

duces an ethanol-to-lactate ratio of 8:1. The ethanol-tolerant mutant also, incomprehensibly, lost the ability to utilize starch for growth (see review, Ref. 24).

The studies with *C. acetobutylicum* on product tolerance reveal that the effect of butanol appears to be opposite of ethanol in that butanol increases the cell membrane fluidity (24). Growth of *C. acetobutylicum* in 1% butanol increases the ratio of saturated to unsaturated fatty acids in the membrane. Thus, this adaptation is similar to fatty acid changes in mesophilic bacteria in response to maximum growth temperatures. Growth of this organism is inhibited at 11, 51, and 43 g/L of acetone, ethanol, and butanol, respectively, while as little as 6–8 g/L of butyrate and acetate inhibit growth. Thus, the view that the metabolic shift of these clostridia from an acidogenic to a solventogenic metabolism with recycling of organic acids is a detoxification stratagem is consistent with these observations. However, the fermentation is finally restricted by a low concentration of the major solvent, butanol.

Preliminary experimental approaches to improving butanol tolerance have been reported. Physiologic replacement of normal membrane fatty acids with long-chain fatty acids such as oleic acid (C_{18}) and elaidic acid (C_{20}) in cell membranes of *C. acetobutylicum* has been partially successful. Adding oleic acid or elaidic acid to growing cells in a biotin-free medium results in bacteria twice as tolerant to butanol inhibition. Butanol-resistant mutants selected from *C. acetobutylicum* (ATCC 824) will ferment corn starch to yield 7.9 g per liter of butanol (24). These butanol-tolerant mutants yielded 14 g per liter of butanol during fermentation and tolerated 16 g per liter of butanol. Autolysin-resistant mutants of strain NCP 262 are somewhat more butanol tolerant but produce only 20 g per liter of total solvents during fermentation. Clearly, the mechanism of solvent tolerance has not been elucidated. Thus, the low solvent yields characteristic of all *Clostridium* fermentations remain a major stumbling block for commercialization.

Biochemical engineers have developed new designs for continuous fermentation combined with product recovery technologies to cope with solvent intolerance inherent in clostridial fermentations. Application of these techniques for the acetone–butanol fermentation was reviewed by Maddox et al. (62). A combination of the new separation technologies and specialized mutant strains may be the best approach for future solvent production systems. For example, a pervaporation technology was combined with a fed-batch fermentation employing the superrecycling mutant B18 of *C. acetobutylicum* (NRRL 643) (15). Continuous removal of acetone and butanol through silicone tubing maintained the level of butanol in the broth below 4.5 g/L while hourly glucose consumption was held at about 2 g/L for 80 h. There was little accumulation of organic acids, and a high solvent yield (63). A long-term (2,000 h) continuous cultivation of *C. beijerinckii* (NRRLB 592) in a two-stage chemostat with on-line solvent removal by membrane evaporation produced solvents at a rate of 9.27 g/L/h without degeneration (64). The substitution of the high solvent, superrecycling *C. beijerinckii* strain BA101 should improve yield and productivity (16). The combined application of either mutant or genetically altered clostridia with integrated fermentation and product recovery technologies may successfully sidestep the low product tolerance characteristic of the clostridia.

Biology of Substrate Utilization

Solventogenic clostridia have the potential for converting carbohydrate substrates from excess agricultural crops or forest and agricultural wastes into solvents and fuels. The carbohydrate feedstocks for these fermentations are primarily starch, cellulose, xylans (or hemicelluloses), and lactose. Three recent reviews present the details of the enzymology, and genetics of utilization of these carbohydrates by the clostridia (62,65,66). Most of the solvent-producing saccharolytic clostridia utilize starch as a carbon source, reflecting their synthesis of extracellular and cell-bound amylolytic enzymes. Each species carries an array of three or four of the following enzymes: α-amylase, which hydrolyzes α-1,4-glucosidic linkages of amylose at random; β-amylase, which hydrolyzes α-1,4-glucosidic linkages from the ends of amalose, releasing disaccharides; glucoamylase, a hydrolyzer like β-amylase, but one releasing glucose; and pullulanase, which hydrolyzes α-1,6-glucosidic linkages or branch points of amylopectin. Some thermophilic clostridia, such as *C. thermohydrosulfuricum*, produce a novel double-headed amylopullulanase that has both α-amylase and pullulanase activity. Strain development for utilizing specific starch-containing feedstocks will require selection of strains that contain the best array of these enzymes for the effective utilization of the selected carbon source. In addition, *C. puniceum* produces pectinolytic enzymes that seem to aid in exposing the starch feedstock to the amylolytic enzymes (8). Because most of the genes involved in expressing the enzymes for starch utilization have been cloned, it is now possible to genetically engineer solventogenic clostridial strains for each starch source.

The thermophilic *C. thermocellum* has been the central object of research on bacterial utilization of cellulose as a carbon source for solvent production (66). There are also seven or so mesophilic cellulolytic clostridia that are closely related but with distinctly different arrangements of cellulases (29). Although as noted earlier ("Ethanol Fermentation"), *C. thermocellum* has major drawbacks as a candidate for commercial production of ethanol, extensive study of the genetics and biochemistry of the extracellular cellulose complex indicates that it may play a role in new strain development. During batch growth of *C. thermocellum* in media with insoluble cellulose, most of the cellulose activity is located in large-cell-associated multiprotein aggregates (cellulosomes) that also bind to cellulose fibers. Clusters of cellulosomes are observed, and the basic subunit in *C. thermocellum* strain YS as a 2.1-MDa complex including 14 different polypeptides. In other strains, cellulosomes up to 3.5 MDa consisting of 50 polypeptides have been described. Multiple forms of β-1,4-endogluconases and exogluconases plus a 210-kDa scaffolding protein are organized in the cellulosome structure.

Other separate components in *C. thermocellum* include two xylanases and two β-glucosidases. Many of the genes for these proteins have been cloned, partially sequenced,

and also expressed in *E. coli*. Thus, in future strain development, many or all of the component parts of the cellulosome from *C. thermocellum* could be genetically transferred and expressed in other solventogenic clostridia such as *C. acetobutylicum*. This later organism already produces xylanases and can grow slowly on xylans as a source of fermentable sugars. Six different strains of *C. acetobutylicum* contain both extracellular and cell bound β-1,4-exogluconases; but cannot utilize cellulose as a carbon source (65). The genetic technology is now available to develop a cellulolytic *C. acetobutylicum* that will convert cellulose to acetone and butanol.

Metabolic Pathway Inactivation and Amplification

As noted earlier ("Genetics of Solvent Formation"), the genetic methods for DNA transfer and insertional mutagenesis now available for some of the clostridial strains that produce solvents together with recent advances in cloning and sequencing of many of the important genes encoding solventogenesis and pathways of substrate utilization promise a new era of strain development. The best experimental examples for changing the ratios of fermentation products come from studies with *C. acetobutylicum*. Normally, the bacteria carrying out this fermentation produce five different organic products (as well as H_2 and CO_2) in different amounts, depending on growth conditions (see earlier: "Butanol Fermentations" and "Physiology of Control of Solvent Formation"). Ideally, during solvent production, a mutant that produced only acetone, ethanol, and butanol, with no residual organic acids, would be desirable. By transferring a plasmid carrying the three genes required for acetone production to a normal *C. acetobutylicum* (ATCC 824), one can produce an excess of the two acetone enzymes in the cell (49). This amplifies the capability to recycle the organic acids and produce a high yield of both butanol and acetone (see Fig. 6). The same result is obtained with a mutant strain, B18, of strain NRRL 643, selected for low acid production following mutagenesis (15).

The second approach to directing the flow of carbon into specific products in the *C. acetobutylicum* fermentation is "gene knockout" by insertional mutagenesis. Recent experiments indicate that inactivation of acetyl kinase or of butyrate kinase prevents acetate or butyrate production, respectively, and permits an earlier and increasing flux toward butanol. Since autolysin, an enzyme produced by *C. acetobutylicum*, causes a late growth phase self-lysis, inactivation of this enzyme might also prolong solvent production. Autolysin-deficient mutants of *C. acetobutylicum* strain P262 show increased cell stability and a higher butanol tolerance.

Another problem facing the use of *C. acetobutylicum* for a continuous fermentation is the natural coupling of solventogenesis with development of endospores. The normal biology of the organism has coordinated these and other processes to adapt to organic acid stress and other stress situations. In *C. acetobutylicum* (ATCC 824), the loss of the large 210-kb pSOL-1 plasmid causes loss of the *sol* operon as well as certain unknown genes required for sporulation and granulose formation (42). Thus, in strain ATTC 824, loss of the pSOL-1 plasmid may serve as an advantage for development of a continuously fermenting, solvent-producing strain. By transferring the genes of the *sol* operon and the *adc* gene on a plasmid back into a pSol-1-negative strain, it is possible to induce solvent formation uncoupled from spore formation (42). In a number of strains of *Clostridium* as well as the butanol-producing strains, the initiation of sporulation and solvent formation is controlled by a complex phosphorelay mechanism as in *B. subtilis*, as noted earlier ("Is Solvent Production a Cellular Response?"). Further study of this regulatory network in the clostridia may reveal ways to upregulate solvent formation and also block initiation of endospore formation.

Since microbiologists estimate that only about 0.1% or less of all the bacteria in nature have ever been successfully isolated, there must be a large untapped natural pool of uncharacterized clostridia with valuable capabilities worthy of the attention of industrial microbiologists. For instance, in 1979 only five clostridial thermophilic bacteria were known. By 1995 more than 16 clostridial thermophiles had been purified (26). Recent reclassification demonstrates that *Thermoanerobium* sp. and *Thermoanaerobacter* sp. are close relatives to the clostridia, which expands the number of candidates for new strain development to more than 25. Thus, just considering growth temperatures in the range of 55–70 °C as a desirable property, many natural species are only recently isolated from nature. Perhaps a program of genetic engineering should be preceded by the application of new enrichment techniques to a search for natural species with new pathways, increased solvent production, or increased tolerance to chemical or physical stress.

ACKNOWLEDGMENT

OUTLINE

INTRODUCTION

For the past 40 years, therapeutic preparations of plasma coagulation factors have been derived from plasma. The plasma fractionation industry developed during and after the second World War and was often a partnership between a governmental or not-for-profit organization that obtained the blood from volunteer donors and the nascent commercial plasma industry. Since the beginning of blood banking and the production of plasma products, the regulatory oversight has been done by the national organizations responsible for biologics control. The authority and the procedures of these organizations are different than those for pharmaceutical regulation.

Regulation of the plasma products in the United States was based on the Public Health Service Act of 1902. This act was promulgated to regulate the production of vaccines and therapeutic serums. The latter phrase was construed to include blood and plasma products when this industry developed later on. Compliance was monitored by the Public Health Service Laboratories, later to become the National Institutes of Health. In 1972, the regulation of U.S. biologics was moved to the Food and Drug Administration (FDA).

One of the major efforts in any of the biological control agencies was the development of standards and assays for impure and poorly characterized natural products. This major component of biologics regulation is seen in the name of the former U.S. control organization, Division of Biologics Standards at NIH, and in the U.K., the National Institute of Biological Standards and Control (NIBSC).

Although regulation has properly belonged to national regulatory bodies, there are other inputs to the regulatory process from supranational organizations, such as the European Community and the International Conference on Harmonisation (ICH). In the United States, the FDA requires that an advisory committee votes for approval of licensure. These committees include representatives of advocacy groups that have voting membership in the FDA blood product advisory committee (BPAC). The recommendations of professional organizations are also quoted in regulatory documents or regulatory decisions. The Scientific and Standardization Committee of the International Society of Thrombosis and Haemostasis has provided recommendations for the hemophilias and thrombotic disease. In addition, civil liability law has an impact on all therapeutic producers, particularly in the United States.

Regulatory documents of the FDA are published in the Code of Federal Regulations (CFR), and updated guidance documents can be obtained from the FDA World Wide Web site (*http://www.fda.gov*). European documents are found in the European Pharmacopeia, and guidance documents are obtained from the Committee on Proprietary Medicinal Products (CPMP).

Blood Coagulation

Blood coagulation results from a series of proteolytic reactions that first activate a procoagulant protein, and then the resulting coagulant is inactivated either proteolytically or by interaction with an inhibitor (1) (Fig. 1). Although presented as the coagulation cascade (Fig. 2), implying amplification, the complexity results in many points where there is sensitive biochemical control. Individual components are identified by roman numerals, and the activated form is indicated by a lowercase "a."

Factor IX, the defective protein in hemophilia B, is the proenzyme of a serine protease that is cleaved to activated factor IX (IXa). Factor VIII, the defective or deficient pro-

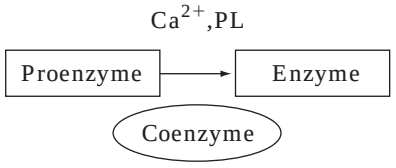

Figure 1. Prototype coagulation step.

tein in hemophilia A, is a protein cofactor that circulates bound to a large polymeric protein, von Willebrand's factor, which is defective in von Willebrand's disease. In the bound state the factor VIII remains in the plasma; in the presence of small amounts of thrombin, it is released from the von Willebrand factor and activated. In the presence of factors IXa and VIIIa there is activation of the downstream enzymes in the coagulation cascade (Fig. 2). Absence or defects of either factor IX or factor VIII leads to inability to form fibrin clots. Absence of the carrier protein, von Willebrand's factor, leads to low circulating levels of factor VIII as well as decreased recruitment of platelets to damaged endothelium and leads to a hemorrhagic state.

The factor VIII gene product is ~250,000 kDa derived from a gene of 186 kb in 26 exons. The gene product is glycosylated intracellularly, and the tyrosine at position 1680 must be sulfated. During passage through the Golgi apparatus there is excision of much of the central portion of the protein (B-domain), resulting in a heavy and light chain held together by Ca^{2+}. This is the form found in the circulation.

Genetic Hemorrhagic Disorders

Hemophilia A and hemophilia B are the result of mutation of genes located on the X chromosome. As such they are sex-linked, and sons of carrier mothers have a 50% likelihood of carrying the defective gene and presenting with the clinical phenotype of abnormal hemorrhage. This leads to crippling and death in those severely afflicted.

Treatment of these diseases began with plasma and evolved to more purified and concentrated plasma products (2). Adequate treatment for those with severe hemophilia involves lifetime intravenous administration given approximately weekly. Although the treatment is effective, there are two major safety issues with plasma products: blood-borne viral infections and the development of antibodies that inhibit the therapeutic effect. Hemophilia A and B were one of the early targets of the biotechnology industry.

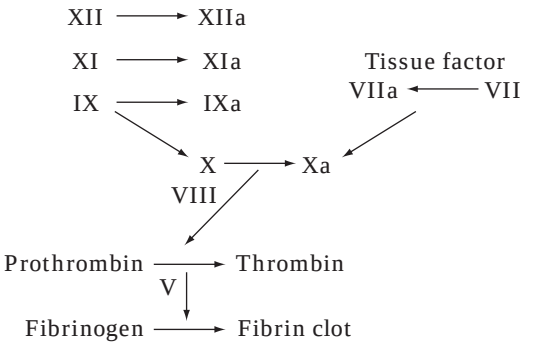

Figure 2. Coagulation sequence.

The patient population is small, with 16,000 patients with hemophilia A (deficiency of factor VIII) and hemophilia B (deficiency of coagulation factor IX) in the United States. Of these, about 8,000 have severe disease and need frequent treatment. Treatment with plasma products temporarily improved the well-being of this patient population until the HIV epidemic; 6,600 U.S. patients were infected (3). Patients with severe hemophilia A need frequent and lifelong treatment; this group uses ~50,000 to 100,000 factor VIII units annually.

Viral infection from plasma products has been the major problem in the treatment of the congenital bleeding disorders. Infection with most blood-borne viruses has been minimized during the past 10 years by viral inactivation. The most common procedure is the destruction of the lipid-coated viruses (HIV, hepatitis B and C) by extraction with a solvent-detergent mixture. Another procedure is the use of heating either in solution or in the dry state. Many regulatory authorities are demanding two viral inactivation and removal steps for recombinant and plasma-derived factor VIII and factor IX.

The second problem for the treatment of hemophilia A is that 15% of patients will develop inhibiting antibodies to factor VIII and become refractory to standard treatment. Although most patients who develop antibodies may be genetically predisposed, in other cases this is because of neoantigenicity induced in the factor VIII during production and viral inactivation (4).

A third hemorrhagic disease, von Willebrand's disease, is the result of heterogeneous mutations of the gene for a polymeric carrier protein of factor VIII, von Willebrand's factor.

REGULATORY ISSUES FOR RECOMBINANT COAGULATION FACTORS

Statutory drug law is based on the principles of safety and efficacy. Regulatory oversight of pharmaceutical production is done in large part through good manufacturing practices (GMPs) and good laboratory practices (GLPs). This is a body of regulation and policy that can change rapidly. In addition, in the regulation of biologics there is a need for product consistency whether the product is derived from animals or from cells. The particular origin of biologics leads to special needs in the control of the starting materials, including cells, genes, etc. This is best exemplified in the regulations for the establishment of intensively characterized master cell banks for cell-derived products (5). This cell bank will be expanded in number under standard conditions to produce a consistent product over decades.

The advent of the biotechnology products for coagulation deficiencies (i.e., cell-derived rather than plasma-derived coagulation factors) raised few unique regulatory issues. Traditional biologics regulation had already dealt with cell-derived products, including the potentially dangerous live virus vaccines. A regulatory framework for the characterization and control of cell lines had already been

constructed, and in 1984, a workshop sponsored by the Bureau of Biologics dealt with many of the residual issues. This was followed by a WHO report in 1987 (6,7). This was followed by the development of *Points-to Consider* for products derived from mammalian cells (8) and the EEC equivalent (9). The *Points-to-Consider* are not legal regulatory documents, but they inform those who are dealing with the agency of the current views of the regulatory authority. There is an effort to have as much commonality as possible between the international regulatory agencies, and extensive efforts to harmonize the guidelines are ongoing by the ICH (10). Of particular concern originally was the quality and quantity of residual DNA in the final product (11); a fear that has diminished with time.

The FDA does not produce specific documents on coagulation or fibrinolytic products. In contrast, the European Community has specific and detailed regulatory documents for the coagulation products (12). The basis for regulation of recombinant coagulation factors is similar to plasma-derived coagulation factors: the assessment of safety, efficacy and consistency. More particularly, there is intensive and extensive evaluation of the cell production systems, the control and standardization of the final product, and clinical effectiveness and safety. The main point of the original regulation for cell-derived coagulation factors was that the products should be identical with plasma-derived products. More recently, products with similar but not identical structures have been received by regulatory authorities with little additional concern.

The GLPs and GMPs are in principle identical around the world; however, there can be significant differences in detail. There has been rapid change in pharmaceutical science during the past decade, including filling procedures, air and water systems, and analytical methods. Approved production facilities of today may not meet GMPs in 5 years. In addition, regulatory policy can change without any formal notification or publication. For these reasons, it is important that the manufacturer maintain constant communication with the regulatory agency from inception to final approval.

Many facilities for recombinant products will be designed and maintained as single product manufacturing areas. This will include raw materials, cell lines, expansion of cell lines, fermenters, purification equipment, and the filling line. It will only be for the postfilling operations that there will be contact with other products. Some useful products may have such small demand that a few lots will meet needs for several years. Such a case may be recombinant activated factor VII (VIIa) for use in hemophilics with inhibitors not responsive to other modes of therapy. In this case, the plant must have a validated procedure for producing a different product.

Cellular Issues in Recombinant Coagulation Products

All cells used for the production of recombinant coagulation factors must either meet the *Points-to-Consider* documents by the FDA or have information indicating that there is no compromise to the safety and efficacy of the product if some of the points are modified. The relevant *Points-to-Consider* are those involved with production of the master cell banks (5) and the *Points-to-Consider* for products derived from mammalian cells (8). The European equivalents are CPMP *Note for Guidance: Production and Quality Control for Medicinal Products Derived by Recombinant DNA Technology* (9) and the ICH documents on the analysis of the expression construct (10).

The cells must not only synthesize the desired protein, but efforts must be made to simplify the purification process and minimize the presence of adventitious infectious agents by simplification of the growth medium. In particular, the use of fetal calf serum is avoided if at all possible to minimize a significant source of microbial and antigenic contamination. It is likely that regulatory agencies in the future will require more effort to develop culture systems free of serum or other animal protein.

During the production time, there must be no evidence of either microbial contamination or of change in the cell or the cell product. Both the U.S. and European documents require characterization of the vector to demonstrate the stability of the inserted gene over the time of a production run or longer. The development of PCR technology has allowed the characterization of cDNA and RNA. Frequent sampling and testing of the conditioned media during production and the final purified product are a requirement.

The cells must be capable of appropriate post-translational modifications. In the case of factor IX, there must be carboxylation of the 10 to 11 glutamic acids so that the molecule has full function. This has been accomplished by inclusion of a gene for a protease to remove the propeptide and allow carboxylation of the glutamic acids at the NH_2 terminal of the factor IX molecule. Other significant post-translation modifications include the formation of a β-OH aspartate residue, sulfation, phosphorylation, and glycosylation. In addition, there must not be the production of any protease that will degrade or activate factor IX.

A similar constraint is true for cells producing factor VIII. This is a heavily glycosylated molecule, and each production system could yield different products, some of which might be immunogenic. Although this is a concern, no such immunogenic derivatives have been found as yet in factor VIII produced by recombinant technology.

Von Willebrand's factor must be produced in cells allowing polymerization of the monomer and secretion of these virus-sized protein molecules into the media. The cell culture system must also be able to sulfate a specific tyrosine residue to allow binding to factor VIII and thrombin activation of the factor VIII.

Purification Issues in Recombinant Coagulation Products

Purification of coagulation products revolves around three issues: the removal of foreign allergens, the removal of DNA, and the removal of adventitious agents originating from the host cell and the media. The issue of allergens is of importance because the recipients need lifelong therapy. In contrast to the older plasma products, the purification process using mouse immunoglobulin affinity columns may be a new hazard, and at this time, monoclonal antibody purification is the universal purification method for factor VIII. The monoclonal antibodies do not have to meet the full requirements for a therapeutic monoclonal antibody but must have been examined for murine viruses.

There are no absolute requirements or regulations for protein purity within the U.S. or European regulations.

However, the manufacturer is obligated to have satisfactory test systems to detect nontherapeutic proteins derived either from the cell source or the purification procedure (e.g., leached monoclonal antibodies). The ultimate test will be in recipients of the product (see "Clinical Trials").

The factor IX product being developed not only is grown in media without protein but the purification steps do not involve monoclonal antibodies. This strategy simplifies the purification process and is also deemed desirable in terms of the introduction of viruses either in tissue culture or in the final product (13). Although this is apparently the first coagulation product from cells grown in the absence of protein in the media and purified without the use of monoclonal antibodies, it may set a new standard.

The same procedures for the removal and inactivation of viruses that are required for cell-derived products are required for the plasma products. Although the use of cell-derived products in contrast to plasma-derived products will only rarely contain viruses transmissible to humans, the newer knowledge of virology and the public perception demands extreme measures. The manufacturer must show that the purification methodology has the capability to remove or inactivate viruses of different types. However, the European guidelines are much more specific than the comparable U.S. documents (14).

One of the first issues for cell derived products was the establishment of limits for DNA. This was set at 10 pg/dose for all products in the original FDA documents (10), but the current WHO level of 100 pg/dose (7) seems to be the actual figure used by the FDA. Products used for the treatment of hemophilias are infused 1,000 times in a lifetime; however, there is no change in the dosage for products used a few times as opposed to 1,000 times in a lifetime. The requirements for DNA removal revolve around the theoretical ability of cell-derived DNA to be incorporated into somatic cells in the recipient (11).

Final Product

The structure of the gene product must be extensively studied. This will include extensive peptide mapping, molecular weight analysis by electrophoretic assessment, and perhaps mass spectrometry. In some cases such as factor IX, the complete amino acid structure is feasible, whereas for factor VIII the total amino acid sequence is more onerous than useful in the light of the established gene structure. Disulfide bonding should be characterized and shown to be identical to plasma-derived coagulants. As noted earlier, there are specific post-translational modifications for given products important for their function, such as glutamyl carboxylation of factor IX, that should be characterized.

The final product will include degradation products of the gene product. These should be identified, analyzed for their sequence, and discriminated from other protein contaminants.

A specific issue for the coagulation factors is that they are in the appropriate state (i.e., nonactivated for factor VIII or IX). For von Willebrand's factor, the polymeric forms must be functional. As noted earlier, the circulating form of the coagulant proteins should be the proenzyme; factor IXa can induce thrombus formation. In the case of the cofactor, factor VIII, the uncleaved, nonactivated form is necessary; the presence of the activated form yields inaccurate potency measurements and is rapidly cleared. Thus, the purification system should remove the activated forms and be done in a manner that does not produce these forms.

Preclinical Testing

In general, the preclinical testing of recombinant products is similar to plasma-derived products and includes routine pyrogen, safety, and potency testing. Specific and accurate potency measurements for labeling and dosing must be available.

Potency Measurement

The assumed efficacy of the final product is assessed by the potency assay, the results of which yield the labeled value for treatment. The standard assay is a bioassay with intrinsic variability (2,15). The unit definition for coagulation products is the functional activity found in 1 mL of normal plasma containing a 10th volume of anticoagulant. This operational definition is translated into WHO standards for coagulants by the preparation of plasma or plasma fractions that originally were compared to normal plasmas. All WHO coagulation standards have been prepared by the NIBSC in the United Kingdom. These are calibrated in multicenter studies organized by the Scientific and Standardization Committee of the International Society on Thrombosis and Haemostasis. New standards are compared to previous WHO standards and also to plasma standards. As both factor VIII and factor IX therapeutic products become more purified, there are inconsistencies with older standards (15). A further complication is the development of what are apparently more accurate quantitative potency tests based on better biochemical knowledge but that can show very substantial differences with the standard reference tests (16–18). The European Pharmacopia designates a reference methodology for the measurement of coagulation factors. In general, this seems to be the assay used by the control laboratory rather than that with which there is the most experience. At this writing, the reference methodology for factor VIII in the European Pharmacopiea is the chromogenic assay. In contrast, the FDA has no designated reference method for coagulation factors but does distribute national references. There is a consistent difference in the pharmacokinetics when assessed by different methods (17,18).

The development of variant proteins such as the B-domain deleted factor VIII aggravates the difference seen between the different methods of measuring potency. The specific activity of the B-domainless variant is reported as being substantially higher than plasma-derived factor VIII (17). The in vitro potency assays are approximately equivalent on a molar basis. Whether they are the same therapeutic quantity must be answered.

A recombinant von Willebrand factor is in development (19). Von Willebrand's factor has several different functional attributes of importance to its efficacy. These include the support of platelet aggregation, binding to collagen, and the binding to factor VIII. At this time there is no

consensus as to the appropriate potency test for a therapeutic product to treat von Willebrand's disease. The WHO standard for von Willebrand's factor is plasma and not a purified preparation.

Animal Models

Animal models add useful information before clinical testing of the products. A dog model of hemophilia A has been used extensively in the preclinical testing of factor VIII. One of the most immediate questions was the comparison of the pharmacokinetics of recombinant factor VIII with the plasma product. If the proposed product was more rapidly removed from the circulation than the plasma product, this would raise serious doubts about the efficacy of the product. Experiments in the dog hemophilia model showed normal pharmacokinetics and rapid binding of factor VIII to canine von Willebrand's factor (20). Various approaches have been and are being assessed to determine abnormal immunogenicity with animal models: induction of immune tolerance in newborn animals in addition to laboratory comparison of the epitopes of the plasma and recombinant product (21).

Thrombogenicity of the factor IX preparations has been assessed by both laboratory testing and assessment of the ability to form clots in animals (22). Although this concern arises from thrombosis associated with the use of older, less-purified products, there is still concern that even the purified products and recombinant factor IX can produce thrombosis. Animal pharmacokinetics comparing plasma-derived and recombinant factor IX are a necessary prelude to clinical studies. Dog models of hemophilia B are available, but the animal pharmacokinetic studies are generally performed in smaller laboratory animals. Because there is endogenous factor IX coagulant activity in the samples, the plasmas are assayed for the quantity of human factor IX antigen present over time (23).

Animal models for coagulation factors have been developed over the years for specific known adverse effects. In addition, animal testing is of value for identifying unsuspected effects.

Clinical Trial Information

Clinical trials are the final step in the assessment of the efficacy and safety of a new therapeutic product. The FDA regulations outline the information needed to begin human studies and the type of studies needed to establish safety and efficacy (24). European regulations are similar. Efficacy of treatment of the hemophilias has never been established in a placebo-controlled study because observational studies coupled with historical data clearly established the effectiveness originally of both factor VIII and factor IX replacement therapy for preventing or treating hemorrhagic episodes. This type of data was acceptable to the regulatory authorities around the world in the mid-60s and was consistent with the biologics definition of efficacy (25) based on the pharmacologic and pharmacokinetic studies. Current policy would, however, require comparison with an approved efficacious product for the factor VIII and factor IX products. The FDA does not prescribe an exact protocol but describes the general types of clinical trials that could give efficacy data (26). In contrast, the EEC guidelines describe in detail the clinical trials to be undertaken (12). Many of these details are derived from articles promulgated by a nonregulatory professional organization, the International Society on Thrombosis and Haemostasis (ISTH) (27,28).

In addition to establishing efficacy, clinical trials are designed to detect adverse events. The most common concern is for known or unknown infectious agents. Recommendations of the ISTH serve as guidelines for some of the European community policies.

The original protocols for recombinant factor VIII started with pharmacokinetic trials in older patients with frequent need for treatment. The strategy was to keep these patients solely on recombinant factor VIII for several years. This would give ample opportunity to test any abnormal immunogenicity of the product. In addition, there would be interim pharmacokinetic studies as the most accurate way of assessing low-level inhibitors. A trial was also done in previously untreated patients (PUPs) independent of any request from a regulatory agency (29). This study yielded valuable results on the treatment of hemophilia in very young patients without the confounding of immunologic or viral infection by other products. This set a precedent for the evaluation of all future recombinant products and has been incorporated into the EEC requirements for all recombinant factor VIII and factor IX. This will probably also be required by the FDA in the future. Although the immunogenicity of recombinant factor VIII and plasma factor VIII is a major concern, it is not clear what information comes from the routine PUP studies, because any excess immunogenicity should be observed in older patients. There are no specific European clinical guidelines for recombinant coagulation factors. There are the general clinical guidelines (12) for the coagulation products, which specifically exclude recombinant products (6,8). Based on the historical knowledge and precedent, there is no requirement for a blinded efficacy trial. Efficacy assessment is based on the comparison of pharmacokinetics with an approved product. For factor VIII, the requirements are to study 12 pretreated (PTP) subjects over 1.5 days with eight sampling times. A minimum of three lots are to studied. These subjects should be maintained solely on the experimental product for a further 3 to 6 months and then have a repeat pharmacokinetic study. Before approval, a study of pharmacokinetics in 20 PUPs must be started using the same protocol as in the other patients. There is a requirement for at least 10 surgical procedures in a minimum of 5 patients and clinical assessment of 30 immunocompetent patients after licensure.

In addition, information should be submitted on 30 patients who have been treated on at least 10 days with at least 6 months of follow-up. The factor VIII inhibitor titer must be repeated every 3 months. After approval, there is a periodic update on the laboratory parameters of at least 50 patients treated for at least 2 years.

With plasma-derived factor IX, the major adverse event other than viral disease transmission was thrombosis associated mostly with the earlier less-purified plasma fractions containing large amounts of the other vitamin K coagulants. The clinical trials for a recombinant factor IX

must test for evidence of in vivo coagulation with currently available tests for thrombin–antithrombin complex and prothrombin fragment 1.2. In addition, there will probably be required testing for the enzymatically active form of factor IX (IXa). Although the FDA does not specifically deal with this issue, this still must be addressed for U.S. licensure. The European guidance documents call for tests for in vivo activation of coagulation.

PUP studies will be required by the FDA and by the European Community for factor VIII and factor IX products. The European community requirements for plasma-derived factor IX require pharmacokinetic studies in 10 subjects with 10 sampling times. Treatment with the same product should be maintained for 6 months, and repeat pharmacokinetic studies should be performed in 3 to 6 months. Current published clinical experience with recombinant factor IX are limited to abstracts indicating pharmacokinetics and clinical effectiveness similar to plasma-derived factor IX (30). These studies are not inconsistent with the European guidelines and were accepted by the BPAC (December 19, 1996).

Von Willebrand's factor is a new molecule to deal with, and there are no national regulatory comments addressing the therapeutic use of this particular protein. Although the pharmacokinetic analysis of the clearance of the coagulation activity of factors VIII and IX is accepted throughout the world, there is no accepted or validated functional assay for von Willebrand's factor. Should the functional assay be based on the ristocetin cofactor activity or the ability to bind to platelets or the content of multimers or the content of intact monomers or the ability to bind factor VIII?

One can anticipate that the regulatory agencies will use the SSC/ISTH guidelines for appropriate clinical studies (31). The current FDA policy is to request comparative clinical data with another product, but there is no product licensed in the United States for the treatment of von Willebrand's disease.

Although von Willebrand's disease is a common genetic deficiency, the clinical phenotype is extremely variable, and for the most part, the hemorrhages are less severe and less frequent than in hemophilia A or B. This leads to difficulty in recruiting patients into a structured protocol. Heretofore, the clinical trials of von Willebrand's factor have been uncontrolled, and current treatment strategies are based on overall experience. The surrogate markers that have been used traditionally are the level of factor VIII, the shortening of the bleeding time, and the functional level of the von Willebrand factor as assessed by the ability to support platelet aggregation in the presence of ristocetin. Inhibitor development is an issue in von Willebrand's disease, and this will have to be assessed. With recombinant von Willebrand's factor, the factor VIII level will be endogenously regulated and will increase to peak levels 10 to 20 hours after infusion. This is in contrast to the current practice of infusing patients with plasma products containing von Willebrand's factor and factor VIII with instantaneous increase in the factor VIII level.

Two recombinant factor VIII products have been licensed in the United States and in Europe. Recombinant factor IX is in clinical trials and the license was submitted to the FDA in 1996. Recombinant factor VIIa, a product proposed for use in factor VIII and IX patients with inhibitors, is being reviewed by the FDA (1997) and has been licensed in Europe and Canada for the treatment of patients who acquire inhibitors to factor VIII. A recombinant von Willebrand factor is undergoing preclinical development.

Tissue Plasminogen Activator (Alteplase)—Regulatory Issues

The in vivo formation of blood clots is usually a process limited in time and space. The formation of thrombi, pathologic blood clots, are the result of subacute or chronic disease processes resulting in blockage of blood vessels. The development of fibrinolytic agents, enzyme that digest fibrin clots, was the first major advance in the treatment of thrombotic diseases in 50 years. The biologics used for this purpose are activators of the endogenous proenzyme, plasminogen. Tissue plasminogen activator (tPA) (alteplase) was the first fibrinolytic agent produced by recombinant technology.

The regulatory issues for the licensure of tPA are documented in contemporary news reports (31) and in a recent book by Beebe and Murano (32).

Production of tPA

One technical issue was emphasized: the effect on product of altering culture conditions. Early production of tPA in roller bottles was used for the initial clinical investigation, including the initial pharmacokinetic studies. When there was change to fluid-phase culture, there was a significant decrease in the pharmacokinetics, leading to the need for an increase in the clinical dosage. It was originally proposed that this was due to the chain structure of the tPA but that has been ruled out (33). Despite investigation of the carbohydrates and other possible structural changes, the post-translational change resulting in the pharmacokinetic change is still a mystery.

CLINICAL TRIALS

Gene Therapy in Hemorrhagic Diseases

Gene therapy is the procedure in which a new gene is transplanted into the body of a host to improve its health. Recombinant proteins are produced by placing the desired gene in a cell system and producing the desired gene product in vitro. Ex vivo gene therapy is accomplished by transplanting cells containing the desired gene into the host; these cells will then propagate and produce the desired biologic effect. In vivo gene therapy injects a gene construct that will enter the cell of the host and produce the desired protein.

Hemophilias A and B are prime targets for gene therapy. The ideal of a one-time or infrequent treatment as opposed to weekly intravenous injections is attractive, but despite substantial advances there are many hurdles to overcome (34,35). Gene therapy procedures are changing rapidly, and this is noted in the regulatory documents with the suggestion that there be constant contact between the regulators and developers of any product proposed for gene therapy (36,37). Many of the molecular biology issues are

covered by the regulatory documents on recombinant products (5,7–10).

Vectors

Vectors and gene product are characterized in the same manner as for cells producing rDNA proteins (8–10). For smaller viral vectors this would include sequencing the entire viral sequence; for larger viral vectors this may not be feasible. The gene product should be completely characterized, however, because the vectors used for in vivo gene transfer will not be expressed in the same cell, and many of the post-translational changes may differ. As with other cell-derived products, the development and characterization of master cell banks will be required (5,7). In addition, there must be establishment of a vector bank, that is, the final product for most of the proposed vectors is the result of the interaction of a cell and the vector. The vector bank should be tested for the presence of adventitious agents. Stability of the host cell–vector system must be established.

The most promising vectors under study for treatment of the hemophilias include replication of defective retroviral and adenoviral vectors, adeno-associated virus, and nonviral vectors. Retrovirus vectors have promise for in vitro exchange with a variety of cells, including fibroblasts, endothelium, and myoblasts. The nonviral vectors would seem to raise fewer issues albeit much lower in vivo expression. The strategy issues to be resolved include choice of vector and in vitro or in vivo gene transfer.

Production Issues

There are different regulatory issues and pathways for the licensure of vectors used in vitro and in vivo. Products for in vivo transduction will be produced purified and packaged in the final form for administration to the patients in a facility meeting all the standards for biologics production (38). For vectors where the transduction will be done in vitro, the producing institution will be responsible for the production of the vector and will have to meet all GMPs; however, the actual product administered will be done after expansion of the patient's transduced cells and will be a service for an individual patient similar to treatment with blood.

Current standards for the production of pharmaceutical products encourage the development of single product production facilities. However, the target group for gene therapy in the hemophilias is small, and only a few production runs may be needed if the hope of long-lasting or permanent effectiveness is achieved. This would lead to a multiuse production area with stringent validation of the facility after changeover from one product to another to prevent cross-contamination.

There are no specific guidelines as yet for the degree of purification for a gene therapy product; rather, it is left to the producer to show adequate purification and justify the adequateness of the procedure. The consistency of the purification method must be demonstrated. Published purification methods for viral vectors involves density gradient ultracentrifugation; it is unlikely that this will be implemented as a production method. Published purification procedures give little information on the degree of purity achieved. Because the desired outcome with gene therapy would be one-time or infrequent exposure to the agent, the presence of small amounts of cell-derived or process-derived protein is less of an issue than for recombinant proteins administered frequently.

The fidelity of reproduction of the vector is an issue because an error in replication could yield a toxic gene product. Where possible the correct nucleotide sequence should be verified.

Lot release testing suggested by the FDA includes (35):

1. Test for RNA or DNA content
2. Test for homogeneity of size and structure of RNA/DNA
3. Test for contamination with RNA or host DNA
4. Test for noninfectious viruses
5. Tests for toxic materials
6. Identity tests by restriction enzyme mapping
7. Sterility including testing for adventitious agents and replication competent viruses
8. Potency

The only test that would be unique for the coagulation products would be the potency test. It will be the responsibility of the manufacturer to design and validate a potency test during the development phase. It is likely that the standard coagulation tests of conditioned media produced by cells treated with a given amount of vector would be adequate for the validation of a lot. Whole animal methods could be developed but could be anticipated to be less quantitative and too time consuming to be useful for lot release.

Possible Adverse Effects

Viral mutagenesis and tumorigenicity are of concern even in replication of incompetent vectors because the genes could be inserted into chromosomes and disrupt growth regulation genes. Identification of the insertion mode and testing for replication competent viruses is recommended for the master cell bank, the working cell bank, and lot release testing on the adenoviral vector products.

The FDA and EEC guidelines (36,37) specifically are concerned with the ability of replication-incompetent viral genomes to form recombinants with cellular viral components. Strategies suggested include separation of the structural and enzymatic genes, removal of complementary viral sequences from the packaging cell lines, and prevention of infection of the packaging cell line with wild-type viruses that could lead to the formation of replication-competent recombinant viruses.

Specific issues with viral vectors are the pathology induced by the viral components. As many pathologic viral sequences as possible should be removed. The induction of virus antibodies preventing retreatment is an issue that can be modulated by minimization of the viral structure and perhaps regulation of the administered dose.

Animal Studies

Preclinical animal testing will be of importance not just for determining efficacy but for supporting safety and study-

ing tissue distribution. All viral vectors will have to be examined by appropriate routes of administration and dose effects in the most sensitive animal models. Species will depend on sensitivity to particular viral toxicity. There is no requirement or indication that regulatory authorities will require primate studies.

Studies are mandated of the vector distribution in animals. A specific issue will be whether there is uptake into germ-line cells. Although this can be studied in animals by study of ovarian and testicular cells, it is not clear whether this will be a reliable indicator of human cell or organ location. Although there is public and political concern about germ-line modification, the FDA does not have any specific prohibition of a product with germ-line modification. The organ of synthesis for both factor VIII and IX is the liver, and this is the site of uptake of the majority of adenoviral vectors administered intravenously.

The cell or organ location is of importance to the final gene product; post-translation modification will be affected by the cell type transduced. There is at this time, however, no set experimental protocol for such studies, and the manufacturer will be expected to use all appropriate tools and develop specific tools as necessary for a given product.

Retroviral transduction and implantation of the ex vivo transduced cells should give an identifiable localized expression of the gene product. There may, however, be specific cell–cell interactions.

Presence of functional clotting should ensure adequate in vivo function. Human factor IX and factor VIII have been maintained in the therapeutic range for up to a half a year in various animal models with various vectors (35). The most promising are the ex vivo retrovirus-transformed fibroblasts or muscle cells and the adenovirus vectors with in vivo transfer.

As noted above, measurable shifts in clearance occur with recombinant products. Although the steady-state levels are measurable in both animals and humans, it will be difficult to measure clearance in patients, although this might be a regulatory issue.

A particular problem with factor VIII may be the need to have the gene product secrete directly into the plasma compartment. In the absence of the stabilizing effect of von Willebrand's factor, it is possible that factor VIII will be proteolyzed to an inactive form before reaching the plasma compartment where it functions.

Persistence of the transgene depends on absence of antibody to the vector-infected cell or the gene product. The antibody response to the vector and the toxicity of the vector can be limited by introducing lower quantities of the viral DNA. More recent experience indicates that immunity to the adenovirus may be circumvented.

Adverse effects of the vector and the implanted gene may be detected before patient exposure only in animal models, and at this time there have been no unexpected events. As expected, there are reports of liver damage with the use of adenoviral vectors, which can be minimized by dose adjustment (39). Adverse effects of the vector and the implanted gene may not be detected in an animal model.

Clinical Trial Issues

The initial decision to attempt gene therapy in hemophilia will be difficult and controversial and will be reviewed by regulatory groups, patient advocates, lawyers, and politicians. In the United States, any clinical use directly or indirectly involved with government funding formerly was approved by the NIH's Recombinant DNA Advisory Committee (RAC) and subsequently by the Office of Recombinant DNA Activities after approval of the the originating institution's internal review board. The results of these reviews were placed in the public domain, and it was understood that all adverse effects would be open information. In addition, the RAC and the FDA often had parallel review processes for other projects. In 1996, the role of the RAC was made more limited, and the FDA assumed all regulatory review and approval responsibility.

Certain principles in regard to informed consent have already been established by the RAC and the FDA. These include many of the usual points such as the trial goal and known risks. In addition, there must be clear discussion of the methodology and the duration of the therapy and of follow-up. One specific point mentioned is the provision for autopsy. The patient must have a commitment and understanding of the trial and the importance of each patient's value to the study as well as the advantages he or she may achieve.

The hemophilia patient who would benefit most would be the patient without access to adequate means of alternative treatment. Because 80% of the hemophilic population in the world does not have access to treatment, one can argue that this is a potential target group. Outside the United States, there has been an effort to treat human factor IX deficiency by gene therapy in China (40).

A second group to be considered for early treatment with gene therapy might be patients with inhibitors (antibodies) to factor VIII. These patients are already undergoing frequent exposure to induce tolerance. Treatment with gene therapy would simply be a modification of tolerance therapy, which could have great benefit for patients with inhibitors. Assessment of therapy would be more difficult if there is no measurable plasma factor VIII. Alternatives could be evidence of a decrease in the inhibitor titer, similar to that seen in classic tolerance regimens, or evidence that there is long-term production of gene product or mRNA. A third group would be those without adequate venous access for administration of current products.

The group that might benefit the most would be the very young or newborn hemophiliacs who, in principle, would not have any of the damage caused by lack of factor VIII or factor IX. It can be anticipated that gene therapy treatment of this group will not be approved in the absence of substantial long-term safety data from older patients.

There will be a regulatory requirement for long-term follow-up: how long and for what are not discussed in the *Points-to-Consider*. The obvious points are evidence of functional expression, unusual immunologic outcomes, viral shedding if a viral vector is used, and cell trafficking. Semen samples will be collected to assess germ-line effects. The patients currently undergoing gene therapy have been informed of the importance of autopsy information.

It is easy to state that the clinical trial must be designed to assess clinical safety and efficacy; it is far more difficult at this time to anticipate with precision the scientific or regulatory requirements, such as the number of patients

to be included, the duration before licensure by a regulatory agency, and the statistical design and the number of patients in a monogenic disease where the assessment of bleeding reduction can be done with retrospective data.

The first major effectiveness issue will be the expression level. Clinical efficacy initially will be a plasma level deemed sufficient to minimize hemorrhage, 5 to 10% of the normal plasma level. The need for other replacement therapy will be the ultimate test of efficacy. The initial trials will begin with a dosage based on the animal data or some fraction thereof, and there may well need to be adjustment. Expression should be seen in days to weeks; duration of expression must be monitored frequently. There are no historical data to support toxicity of supranormal levels of factor VIII in the patient with hemophilia. However, nonhemophiliac subjects with supranormal levels of factor VIII have increased incidence of venous thrombosis (40,41).

The immunologic issues, inhibitor formation, and immune complex disease will have to be studied. The worst possible outcome would be the induction of chronic immune complex disease, which has never been reported in the 30-year history of the treatment of hemophilia despite studies indicating increased levels of immune complexes. The other side of the issue is that for years large daily doses of factor VIII have been used to develop immune tolerance in patients with factor VIII inhibitors, and no chronic immune complex disease has been reported. If recipients of gene therapy do develop immune complex disease, it would be observed within days to months and perhaps should be part of the normal treatment protocol as well as play a role in the investigative use of gene therapy in hemophilia.

Although hemophilia patients with inhibitors are routinely treated with factor VIII, these are patients with no intrinsic synthesis of the factor VIII. A concern raised by the FDA is that the cells producing the gene product could be destroyed by an immune cytolysis. This potential outcome would argue against the use of known inhibitor patients for the initial trials. Patients without hemophilia A who develop antibodies to factor VIII have not been reported to have any organ damage despite the presence of cells producing normal amounts of factor VIII.

The development of inhibitors usually occurs with the first 20 treatments, but the current European guidelines request prolonged inhibitor follow-up, and it is likely that long-term follow-up will be requested in gene therapy. Follow-up for the development of antibodies to the vector may also be suggested. If therapy is by a modified viral vector, there may be limited antibody formation. Methods should be developed to detect antibodies to this vector in the presence of wild-type virus infection.

Surveillance of the impact of the vector will be mandatory. The older hemophilia patient population is infected with a variety of chronic viral diseases, and many already have liver disease. Adenoviral vectors targeted to the liver will at least temporarily induce some inflammatory reaction. Other unknown adverse effects resulting from the vector may occur with this novel and dramatic therapeutic approach.

Gene therapy science is moving rapidly, and as old problems are solved, new areas of concern arise. The developers of any such product must be aware of all the issues. Preclinical and clinical studies must be rigorous; at this time, the regulatory guidelines are appropriately rigorous. The best updated source of information on the regulatory issues may be found at the FDA's Center for Biologics Evaluation and Review (CBER) internet site (*www.CBER.FDA.gov*).

TRANSGENIC ANIMAL PRODUCTS

The term *transgenic animal* is used for animals with either somatic cell DNA alterations or germ-line alterations. The potential value of transgenic animals for the production of therapeutic proteins would involve the production of animal strains with germ-line DNA alterations, a regulatory base exists both in the United States and Europe (42,43). The use of transgenic animals to produce proteins secreted into milk is an attractive alternative to the large investment in a sophisticated plant to produce therapeutic proteins. At this time, there is little evidence of commercial interest in this approach. Many coagulation proteins have been produced in the milk of transgenic animals (44).

The regulation in the United States of transgenic products would involve not only the FDA drug or biologics regulatory groups but in addition the veterinary medicine and food regulators of the FDA in addition to the Department of Agriculture. The FDA regulatory issues are spelled out in Reference 42.

Many of the issues of blood-derived products would be involved, including screening for viruses, assessing the health of the donor, etc. The possibility of adapting unknown animal viruses to a human host will not be a trivial issue and will have to be addressed by the producer.

The actual gene and the regulatory element characterization are covered by the *Points-to-Consider* for cell-derived products (8). The regulatory elements are of particular interest, and extensive characterization of the enhancers, promoters, suppressors, and presence of dominant control regions should be reported.

There must be a full record of all the procedures in obtaining the ova, methods for in vitro fertilization, and introduction of the altered DNA. After homologous recombination, it is important to show loss of function of the wild-type gene.

Both the history of the donors of the gametes and the recipient (foster parent) animals need to be documented in detail. Intensive veterinary evaluation of health with particular emphasis on diseases related to the species and the breed will be required.

The founder animal must be studied for the presence of the introduced gene and for the expression of the gene product in addition to the absence of functional product from the inactivated wild-type gene. The characterization of the gene expression should be evaluated as a function of age, season, etc. The acceptable range for the gene product should be established to allow for all the systematic variations. Anatomical localization and function of the transgene should be evaluated, and that the transgene is at the desired location must be verified. There is particular concern about the post-translational modifications in a species and at a tissue site different from the normal human prod-

uct, which could lead to functional and immulogic problems.

The maintenance of a given transgenic line is presumed desirable, and methods similar to the master working cell bank for cell-derived products is suggested.

In addition to study of the transgene in the founder, there must be extensive study of the transgene stability in the succeeding generations until stability of the gene and the gene expression are demonstrated. In the founder, there may well be multiple gene copies inserted which over succeeding generations will be rearranged or deleted. It is desirable to demonstrate at the founder stage that there is integration at a single chromosomal site. If this is not possible, studies of the chromosomal integration must be done in the later generations. In addition, the RNA transcript should be examined for quality and quantity and identification of the tissues or cells producing the transcript.

The animals must be kept isolated from sources of known and unknown infections during their productive life. Animals would only be acceptable in the absence of disease and with a consistent level of production of the gene product.

ACKNOWLEDGMENTS

The author gratefully acknowledges the helpful guidance and education on gene therapy and international regulatory insights and issues by Terry Snape, Sheila Connelly, Milt Mozen, and Arthur Thompson.

OUTLINE

INTRODUCTION

Today, there are about 3500 known enzymes (1), of which about 70% are cofactor dependent and about 15% are commercially available. Cofactors such as adenosine triphosphate (ATP), nicotinamide adenine dinucleotide (NADPH), acyl coenzyme A, *S*-adenosylmethionine (SAM), sugar nucleotides, and 3′-phosphoadenosine-5′-phosphosulfate (PAPS) are involved in stoichiometric amounts in cofactor-dependent enzymatic reactions (2). The very high cost of these cofactors prohibits their use as stoichiometric reagents. For economic reasons, regeneration of the cofactors from their reaction products is an essential requirement in making use of cofactor-dependent enzymes in preparative synthesis of organic compounds.

Using coenzyme recycling, the expensive cofactor is needed only in catalytic amount, so there is a drastic reduction in cost of the respective reactions. Additionally, coenzyme regeneration can accomplish three major objectives. First, it can influence the position of equilibrium of a reaction. A thermodynamically unfavorable reaction can be driven by coupling with a favorable cofactor-regeneration reaction. Second, regeneration affords only catalytic amounts of coenzyme, preventing the accumulation of cofactor by-product, which may inhibit the reaction of interest. Third, coenzyme regeneration can simplify the downstream processing of the reaction mixture.

The following chapter deals with methods for the regeneration of nicotinamide coenzymes, because this type of cofactor is the most significant. Hitherto, more than 650 oxidoreductases are known (3), of which about 90 are commercially available. For the majority of these redox enzymes, about 80% and 10% require nicotinamide adenine dinucleotide (NADH) or its respective phosphate (NADPH) respectively.

REGENERATION OF NICOTINAMIDE COENZYMES

Introduction

Nicotinamide adenine dinucleotide (NAD) and the analogous 2′-phosphate (NADP) are involved in redox reactions catalyzed by alcohol dehydrogenases. Two electrons and a proton (hydride) are transferred from the reduced coenzyme NADPH to the carbonyl compound in a stoichiometric reaction. Using coenzyme recycling, the expensive cofactor is needed only in catalytic amounts, leading to a drastic reduction in the cost of dehydrogenase-catalyzed reactions. This chapter discusses methods for regeneration of nicotinamide coenzymes.

Cost of Coenzymes. Nicotinamide adenine dinucleotides (NADH, NADPH) are expensive compounds. In Table 1 the actual prices per mole are listed and compared with the costs in the year 1976. If these coenzymes were used in stoichiometric amounts, enzymatic reductions with dehydrogenases would be prohibitively expensive. Therefore, the application of dehydrogenases on the industrial scale requires effective methods for coenzyme regeneration. The economic barrier to large-scale reactions posed by cofactor costs has been recognized for many years. A range of publications address this topic (2,5,6).

The turnover number (TN) is defined as the number of moles of product formed per mole of cofactor or enzyme per unit time. This number is indicative of the productivity of

Table 1. Prices of Nicotinamide Coenzymes

Coenzymes	Price in dollars per mole (depending on purity, 1976)[a]	Price in dollars per mole (mean catalog prices, 1998)
NAD^+	1.722 to 49.550	710
NADH	6.030 to 52.766	3
$NADP^+$	20.667 to 168.604	25
NADPH	177.032 to 535.197	215

[a]from Ref. 4.

the process. The total turnover number (TTN) is defined as the total number of moles of product formed per mole of coenzyme or enzyme during the course of the entire reaction. Hence, the TTN reflects the loss of coenzyme and enzyme throughout the process, and thus it is a useful estimate of the operational cost of the coenzyme or the enzyme. In order to overcome economic limitations, total turnover numbers of greater than 100 are desirable. For a batch synthesis, the cost of the coenzyme or enzyme is calculated on the basis of its initial cost. In contrast, for a continuous process, the cost may be calculated on the basis of the activity loss over the entire process time. When estimating the cost of a given reaction per unit time, the rate of the reaction must also be considered. The regeneration cost is defined as the cost of the components (enzymes, reagents, and coenzymes) required to regenerate one mole of coenzyme per unit time (7).

The highest TTN can be achieved as follows:

- The substrate concentration is as high as possible, determined by the substrate solubility, product inhibition, and enzyme stability.
- The concentration of coenzyme and enzyme to achieve acceptable reaction rates is as low as possible.
- The coenzymes and enzymes are highly stable.

Thus, both the initial costs of the cofactor and the enzyme, and the efficiency of their regeneration and utilization, determine their contribution to the cost of the product.

Origin of Coenzymes. Nicotinamide adenine dinucleotide (NAD) is presently isolated from yeast (8), and its 2′-phosphate NADP is normally synthesized by enzymatic phosphorylation of NAD using NAD-kinase (EC 2.7.1.23) and ATP (9,10). NADPH can be prepared from NADP by three different methods: chemical (11), enzymatical (12,13), or microbial reduction (14). Additionally, a combined chemical and enzymatic route for the synthesis of NADP has been developed that may be useful for the preparation of NADP analogs (15–17).

Requirements of an Economical Coenzyme Regeneration System. Chenault and Whitesides (4) compiled the following criteria for an ideal coenzyme regeneration system:

- Compatibility with the synthetic reaction
- Commercial availability of inexpensive and stable enzymes with high specific activity
- Simple and cheap auxiliary substrates; the corresponding products should not interfere with the isolation of the product of interest. They should not influence the stability of enzymes and coenzymes.
- High turnover numbers (TN) and total turnover numbers (TTN).
- The equilibrium constants of the coupled coenzyme regeneration system should be as high as possible.
- The analysis of the yield should not be effected by the substrates or products of the coenzyme regeneration.

As a rule of thumb, 10^3–10^4 cycles are sufficient for laboratory-scale redox reactions, whereas at least 10^5–10^6 cycles are desirable for industrial-scale synthesis. The exact turnover number required depends on the initial cost of the coenzyme and the value of the product of interest. A high turnover number requires a high selectivity for the formation of enzymatically active coenzyme. 1,4-dihydro-NAD^+, or $NADP^+$, is the only enzymatically active form; 1,2- and 1,6-dihydro species are not active. For instance, if 50% of the original coenzyme activity is to remain after 1,000 cycles, the regeneration reaction must be 99.3% regioselective. In the case of industrial applications of dehydrogenases, 10^6 turnovers are desired, resulting in a requirement for the regioselectivity of 99.99993%. Chemical, electrochemical, photochemical, or enzymatic methods (see later) show different selectivities in the formation of 1,4-dihydro $NADP^+$. Electro- and photochemical methods especially suffer from poor regioselectivities. Thus, the requirement for very high regioselectivity necessitates enzymatic catalysis, particularly in the recycling of NADH and NADPH (2,6,18).

Stability of Nicotinamide Coenzymes. *Nicotinamide coenzymes contain three labile bonds that may be the target of general or specific acid-or base-catalyzed hydrolysis*:

- the N-glycosidic bond between nicotinamide and ribose
- The phosphodiester bond between the two riboses
- The bond between ribose and phosphate (NADP)

Oppenheimer (19) and Chenault and Whitesides (6) compiled data on the influence of different buffers on the stability, and the possible products from the hydrolysis of NADPH. Under basic conditions, the reduced nicotinamide coenzymes are stable; under acidic conditions, they are unstable. In contrast, the oxidized coenzymes are stable under acidic conditions, and labile under basic conditions (19,20). As a compromise, NAD and NADH are used at pH 7–7.5, whereas NADP and NADPH are used at pH 8–8.5. The mechanisms of the decomposition of NADPH were studied in great detail (20–22). The N-glycosidic bond between nicotinamide and ribose is the most labile bond of the molecule. Base-catalyzed hydrolysis of this bond results in the removal of the nicotinamide ring and, thus, the coenzymatic activity is destroyed. On the other hand, the general acid-catalyzed protonation of the nicotinamide ring at position C_5 is followed by a rapid rearrangement to a cyclic ether product. Additionally, the 2′-phosphate group

of NADPH catalyzes this decomposition intramolecularly. The half lifes for NADH and NADPH in 0.1 M phosphate (pH 7, 25 °C) are 27 h and 13 h, respectively (20). Organic buffers such as imidazole, Tris, Hepes, and triethanolamine, partially stabilize reduced coenzymes, resulting in a half life that is three times as long. The major pathway for the decomposition of $NADP^+$ is nucleophilic addition at C_4 of the nicotinamide ring, yielding a 1,4-dihydropyridine structure (23–25). In Tris-buffered solution at pH 7–8, $NADP^+$ is stable over at least 14 days (Peters, unpublished data). There is a strong dependence of the stability of the oxidized coenzymes on the concentration of the buffer (Peters, unpublished data). At low molarity (50 mM), the half-life in Tris buffer is lower compared with the half-life in buffer of high molarity (500 mM). Poly(ethylene)-glycol-coupled $NADP^+$ is very stable at pH 8 in Tris buffer of any molarity. Half-lifes of more than 240 days have been reported (Peters, unpublished data).

Principles for the Regeneration of Nicotinamide Coenzymes

Nonenzymatic Regeneration. Nonenzymatic methods for coenzyme regeneration can be divided in chemical, electrochemical, and photochemical methods. Chemical reduction of $NADP^+$ using a reducing agent like sodium dithionite ($Na_2S_2O_4$) suffers from very low total turnover number of less than 100 (26). Moreover, this agent can deactivate enzymes, presumably by modification of thiol groups in the protein (27). The major disadvantages of most electrochemical and photochemical regeneration methods (28–31) are low regioselectivity, leading to coenzyme inactivation (as already discussed) occurrence of side reactions, and low total turnover numbers of less than 1,000 (2,6). However, Simon and coworkers (32) stated that electro- and photochemical methods should not be underestimated. Schummer and coworkers (33) reported the synthesis of polyfunctional (*R*)-2-hydroxycarbonic acids on the preparative scale with resting cells of *Proteus vulgaris* by using electrochemical regeneration. Several groups (34–37) reported on the electrochemical regeneration of NADPH by using a bipyridine rhodium-(I) complex as an electron-transfer agent and formate as an electron donor. The bipyridine-rhodium complex can be coupled to poly(ethylene) glycol and thereby retained in an enzyme-membrane reactor. Dicosimo and coworkers (38) described the electrochemical regeneration of NADPH using the dye methyl viologen and flavoenzymes. However, enzyme denaturation on the surface of the electrode or enzyme deactivation by redox agents may occur.

In summary, enzymatic methods meet most of the requirements for an ideal coenzyme regeneration system as described earlier. The difficulties encountered with enzymatic coenzyme regeneration are mainly competitive or mixed inhibition by the substrate or product (39,40). In the following sections, the two general concepts for coenzyme regeneration using enzymes are presented (18). Focus will then turn to the most attractive methods for the recycling of reduced and oxidized nicotinamide coenzymes.

Substrate-Coupled Regeneration. In the substrate-coupled approach, both the main reaction and the regeneration of the coenzyme are catalyzed by a single enzyme (Fig. 1). The auxiliary substrate (S'_{red}) of the coenzyme regeneration reaction serves as the hydride donor. In order to shift the equilibrium of the reaction to the desired position, the hydride donor, usually a low-cost alcohol, is applied in large excess. However, yield of the system is limited by equilibrium of the coupled system. For the reduction of acetophenone using 2-propanol as auxiliary substrate, the equilibrium was reached at 60% yield (41).

In the case of the reduction of 2-acetyl-naphthaline using 2-propanol as hydride donor, the equilibrium could be shifted by the use of cyclodextrins, and thereby the total yield was increased to 93% of 1-(2-naphthyl)-ethanol (42). In the continuous synthesis, yields of more than 80% were obtained, and total turnover numbers for the coenzyme were in the range of 10^4. In this application the native coenzyme was not recovered from the product solution but was directly used in substoichiometric amounts. The total turnover number for the enzyme was greater than 10^6, and the productivity was 2.5 times as high as the comparable system with enzyme-coupled cofactor regeneration (formate dehydrogenase system). This demonstrates the potential of substrate-coupled systems for coenzyme regeneration.

Due to the lack of a well-established method for NADPH regeneration, the substrate-coupling method is mainly used for this purpose. However, there are some drawbacks of this method:

- The auxiliary substrate has to be present in a large excess, which may lead to complications in product recovery, or which may cause enzyme deactivation or inhibition.
- Enzyme deactivation may also occur as the result of the accumulation of highly reactive carbonyl species like acetaldehyde or cyclohexenone.

A special enzyme reactor employing a membrane that is only permeable to gases (comparable to Gore-Tex) may avoid most of these drawbacks. This type of reactor was successfully applied to improve cofactor recycling via the yeast alcohol dehydrogenase–ethanol system in the stereoselective reduction catalyzed by lactate dehydrogenase (43). The reaction scheme is shown in Figure 2.

Enzyme-Coupled Regeneration. In the case of the enzyme-coupled approach to NAD regeneration (Fig. 3), the reduction of the main substrate and the coenzyme re-

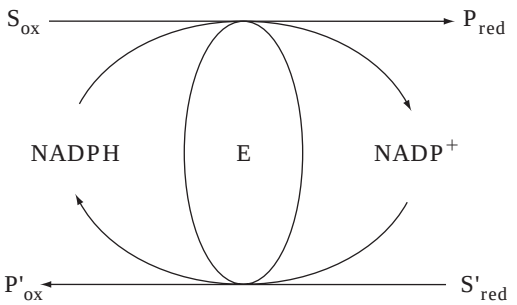

Figure 1.

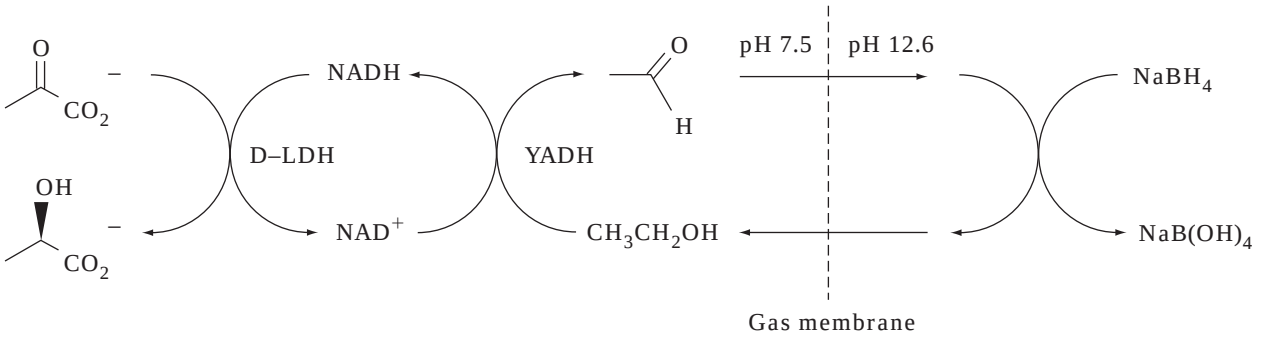

Figure 2.

generation reaction are catalyzed by two different enzymes (44). The enzymes employed should have sufficiently different substrate specificities to avoid interferences. The enzyme-coupled cofactor recycling has the following major advantages:

- The position of the equilibrium of a redox reaction can be influenced. Thermodynamically unfavorable reactions can be driven by coupling with a favorable cofactor regeneration reaction.
- High turnover numbers can be achieved: >600,000 (45).
- The activity ratio has to be optimized for each pair of enzymes to ensure neither lack nor excess of reduction equivalents (46).

However, there are also some disadvantages to this type of cofactor-recycling method:

- Cross inhibition between the main substrate and the coenzyme regeneration system may occur (46).
- A second enzyme must be used, generating additional costs.
- The characteristics of the second enzyme, such as pH and temperature optimum, must be compatible with the main reaction.

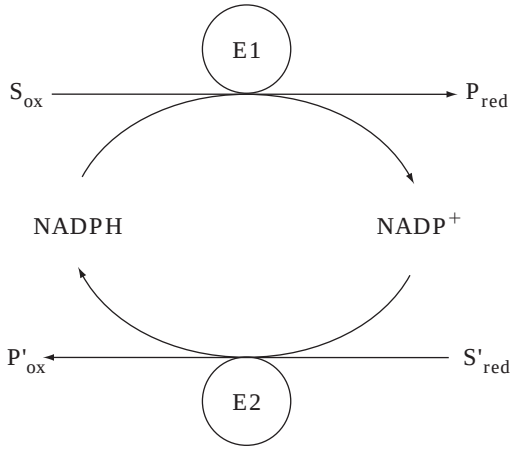

Figure 3.

Survey of Coenzyme Regeneration Methods and Their Assessment

Different methods for the regeneration of NADPH have been discussed in great detail by several authors (2,6,7,18,20,32,47–52). In this chapter, only the most useful methods are discussed and assessed with respect to their applicability in batch and continuous synthesis. Furthermore, recently developed new methods for nicotinamide coenzyme recycling are highlighted.

Regeneration of NADPH. In Table 2, the major disadvantages of a selection of available cofactor-recycling systems are listed, and each method is assessed with respect to its applicability in batch or continuous processes.

For the regeneration of native and poly(ethylene) glycol-bound NADH (PEG-NADH), the formate dehydrogenase (FDH) from *Candida boidinii* (53) has been widely and successfully applied (45,54–57). This enzyme catalyzes the oxidation of inexpensive formate (HCOOH) to carbon dioxide (CO_2). The reverse reaction is hardly detectable (53). Therefore, the FDH reaction can shift the equilibrium of unfavorable reactions to the product side. Both the auxiliary substrate and the coproduct are innocuous to enzymes and are easily removed from the reaction. Therefore, product isolation is easy. FDH has a broad pH optimum for activity, so it can be easily implemented in coupled enzymatic synthesis. The major disadvantages are the low specific activity of 4 U/mg and product inhibition by NADH. However, these drawbacks can be circumvented or minimized: the former by using immobilized or membrane-retained systems (54,58); the latter by adjusting the optimal ratio of enzymatic activities for the main reaction and the coenzyme-recycling reaction (46). Overall, the formate–FDH system is the most economical method for regeneration of NADH for batch and continuous processes. The total turnover numbers (TTN) range typically from 10^3 to 10^5 (45,56,58). Unfortunately, the *C. boidinii* formate dehydrogenase does not accept $NADP^+$.

Although several NADP-dependent formate dehydrogenases have been discovered (59–63), only the recently described mutant formate dehydrogenase from *Pseudomonas* sp. 101 (64,65), using $NADP^+$ as coenzyme, was applied in batch and continuous synthesis. Acetophenone was reduced by the NADPH-dependent alcohol dehydrogenase from *Lactobacillus* sp. (EC 1.1.1.99) with this enzyme for the regeneration of NADPH, at a space–time yield

Table 2. Methods for In Situ Regeneration of NADPH

Methods	Major disadvantages	Assessment
Glucose/glucose dehydrogenase	Not applicable in the enzyme-membrane reactor K_m value for PEG-NADP$^+$ 1,000 times that of native NADP$^+$ Complication of product isolation caused by gluconate High amounts of K^+ or Na^+ necessary to stabilize enzyme	Useful only for lab-scale reactions in batch reactors with native NADH or NADPH, but not for PEG-NAD(P)H
Glucose-6-P/glucose-6P dehydrogenase	High costs for glucose-6-phosphate (~5.500 $/mol) Coenzyme deactivation by 6-phosphogluconate No efficient usage of the coenzyme Complication of product recovery caused by 6-phosphogluconate	Useful only for lab-scale reactions, regeneration of NADH and NADPH
Glucose-6-sulfate/glucose-6-P dehydrogenase	Complication of product recovery caused by 6-sulfogluconate Substrate is accepted only by glucose-6-phosphate dehydrogenase from yeast	Circumvents some limitations of the former method; useful for preparative applications in continuous reactors; regeneration of NADH and NADPH
Ethanol/alcohol and aldehyde dehydrogenase	Relatively complicate and unstable multienzyme system with low TTN Oxygen sensitivity of alcohol and aldehyde dehydrogenases Low reactivity of the aldehyde dehydrogenase with NADP$^+$ Only activated carbonyl substrates are reduced at good yields, which may cause enzyme deactivation	Useful only for lab-scale reactions; regeneration of NADH and NADPH
Formate/formate: NAD$^+$ dehydrogenase	Low specific activity (3 U/mg) Deactivated by autooxidation Product inhibition caused by PEG-NADH	Simple and stable system for regeneration of PEG-NADH in batch or continuous mode of operation up to the process scale; very good compatibility with other enzymes
Formate/formate: NADP$^+$ dehydrogenase	Enzyme not commercially available yet	Simple and stable system for regeneration of NADPH in batch or continuous mode of operation; very good compatibility with other enzymes
Sec. alcohol/*Th. brockii* alcohol dehydrogenase	Deactivation by autooxidation possible Relatively expensive enzyme (58 cents/unit)	Simple and stable system for regeneration of PEG-NADPH in batch or continuous mode of operation; very good compatibility with other enzymes

of 8 g/(L day) and a conversion rate of 90–95% (66,67). The new FDH is quite stable, showing no loss in activity over one year at 4 °C (67). Unfortunately, this enzyme is not yet commercially available. A further disadvantage is the relatively high K_m value of the mutant FDH for NADP (320 μM). Additional work is required to engineer FDH mutants with improved kinetic properties. In conclusion, the new formate–NADP dehydrogenase (EC 1.2.1.2) has a large potential for use as a regeneration system for NADPH.

The secondary alcohol dehydrogenases from *Thermoanaerobium brockii* (TBADH) accept a broad range of secondary alcohols and NADP$^+$ as coenzyme (68). The enzyme is commercially available and contains a very low NADP-2′-phosphatase activity (Peters, unpublished data) (NADP(H) is hydrolyzed at the 2′-ribose phosphate bond at a rate of 0.1% per day in the continuous synthesis of NADPH (69).) This enzyme has been applied in the reduction of numerous carbonyl compounds using the substrate-coupled approach for coenzyme recycling (70–75). Since this enzyme tolerates up to 30% isopropanol, the substrate-coupled regeneration of NADPH is highly favorable. The TBADH-enzyme family is also an excellent system for the regeneration of native and poly(ethylene) glycol-bound NADPH (Peters, unpublished data; 69). In a model system, glutamate dehydrogenase (GluDH) was employed for the synthesis of glutamate from α-ketoglutarate. A complete set of kinetic data was recorded and the effectivity of the regeneration of PEG-NADPH by the TBADH was studied in a batch reactor. The optimal activity ratio of GluDH/(GluDH + TBADH) was 0.6. At this ratio, 95% of the total coenzyme is reduced. The conversion of α-ketoglutarate is affected negatively only at a TBADH portion of less than 20%. For comparison, in the leucine dehydrogenase–FDH system studied by Wichmann and coworkers (55), only 10% PEG-NADH is present at the optimal activity ratio of 1:1. The reason for this different behavior is the product inhibition of FDH by PEG-NADH. In contrast, TBADH shows only slight product inhibitions by 2-butanone and PEG-NADPH. The loss of coenzyme in the enzyme-membrane reactor is a function of the absolute coenzyme concentration (76) and, therefore should be as low as possible. The K_m value of the TBADH for native and

PEG-bound NADPH is 10 μM. Hence, only 0.2–0.3 mM NADPH is usually sufficient to ensure a maximum usage of the catalytic activities in the reactor.

Overall, the TBADH is recommended for the recycling of NADPH for the following reasons. First, the enzyme is commercially available and is stable in a polypropylene enzyme-membrane reactor. Second, the specific activity is almost 10 times as high as that of formate dehydrogenase. Favorably, the K_m values for native and PEG-bound NADPH are low (10 μM), and the product inhibitions by 2-butanone and PEG-NADPH are also low. Third, the TBADH is compatible with high amounts of organic solvent (e.g., 30% isopropanol) and is stable at elevated temperatures.

Regeneration of NADP$^+$. Oxidized nicotinamide coenzymes are used for the synthesis of carbonyl compounds from the corresponding racemic hydroxy compounds. For their regeneration, both enzymatic and nonenzymatic methods have been reported (for review see Ref. 7). Enzymatic methods seem to be preferred because of their compatibility with biological systems and their simplicity. The regeneration of oxidized nicotinamide coenzymes is somewhat problematic due to thermodynamics that are often unfavorable. Additionally, product inhibition by the reduced coenzyme may cause problems (see later).

In Table 3, the major disadvantages of various available cofactor-recycling systems are listed, and each method is assessed with respect to its applicability in batch or continuous processes. The alcohol dehydrogenase from *Pseudomonas* sp. which is not yet commercially available, has potential for the recycling of NAD$^+$ (77,78). A range of simple ketones can be used as hydrogen acceptors, which are reduced at high velocity (up to 270 U/mg). However, the kinetic limitations of this enzyme must be explored in more detail.

For recycling of NADP$^+$, the secondary alcohol dehydrogenase from *Thermoanaerobium brockii* (TBADH) is problematic due to the low product-inhibition constant K_{ip} for NADP$^+$ of 50 μM (Peters, unpublished data; 69). The K_m value of NADPH is 10 μM. Therefore, the oxidation of alcohols producing the reduced coenzyme is the favorable reaction.

Acetaldehyde and the commercially available alcohol dehydrogenase from baker's yeast (YADH) have also been used to regenerate NAD$^+$ from NADH (79). The total turnover numbers were 10^3 to 10^4. However, deactivation of the enzyme by the highly reactive acetaldehyde and the self-condensation of acetaldehyde outweigh the advantages of the inexpensive enzyme and the volatility of the reagents involved.

The most widely applied method for regeneration of oxidized nicotinamide coenzymes involves glutamate dehydrogenase (GluDH), which catalyzes the thermodynamically favorable reductive amination of inexpensive α-ketoglutarate to L-glutamate (40,80). Both the substrate and the product are innocuous to enzymes. The commercially available and inexpensive GluDH accepts NADH, NADPH, and their respective poly(ethylene) glycol-bound coenzymes (Peters, unpublished data) and has a reasonably high specific activity of 40 U/mg protein. The products of the reductive amination of α-ketoglutarate, PEG-NADP$^+$ and L-glutamate, do not strongly inhibit the reaction (Peters, unpublished data). The ratio of the product inhibition constant to the Michaelis–Menten constant (K_{ip}/K_m) will determine the efficacy of the reaction (40). At a K_{ip}/K_m ratio greater than 1, the reaction may proceed to acceptable conversions. If this ratio is less than 1, the reaction can never proceed efficiently. The K_{ip}/K_m ratio for the substrate and product of the reductive amination of α-ketoglutarate to L-glutamate is 10.5. For the PEG-NADPH and PEG-NADP$^+$, the K_{ip}/K_m ratio is about 30 (Peters, unpublished data). Hence, product inhibition by L-glutamate and PEG-NADP$^+$ does not play a significant role in the efficacy of the regeneration reaction. The disadvantage of this regeneration method is that L-glutamate may complicate product isolation from the reaction mixture. This must be addressed case by case.

Pyruvate and commercially available and inexpensive lactate dehydrogenase (LDH) have been used for recycling of NAD$^+$ (6,81). The LDH is stable and has a high specific activity of about 1,000 U/mg protein. However, the redox potential is less favorable and, in contrast to GluDH, LDH does not accept NADPH. A further disadvantage is that pyruvate tends to polymerize in solution and reacts with NAD$^+$ in a process catalyzed by LDH. Despite these draw-

Table 3. Methods for In Situ Regeneration of NADP$^+$

Methods	Major disadvantages	Assessment
Alcohol/*Pseudomonas* sp. alcohol dehydrogenase	Enzyme not commercially available	
Sec. alcohol/*Thermoanaerobium brockii* dehydrogenase	Strong product inhibition by PEG-NADP$^+$; K_{ip} (NADP), 50 μM; K_m (NADPH), 10 μM	Not useful due to the severe product inhibition by PEG-NADP$^+$
Acetaldehyde/yeast alcohol dehydrogenase	Self-condensation of acetaldehyde Enzyme deactivation by highly reactive acetaldehyde	Not useful for the regeneration of NAD$^+$ due to side reactions and deactivation by acetaldehyde
α-Ketoglutarate glutamate dehydrogenase	Glutamate may complicate product isolation	Simple and stable system for regeneration of PEG-NADPH, good compatibility with other enzymes
Pyruvate/lactate dehydrogenase	Pyruvate tends to polymerize in solution and reacts with NAD$^+$ in a process catalyzed by lactate dehydrogenase	Simple and stable system for regeneration of NAD$^+$; side reactions may happen

backs, the pyruvate–LDH system has been applied in enzymatic oxidation reactions of 10–100 mmol of material.

Immobilized Coenzymes and Reactor Concepts

Enzyme-catalyzed reactions are often accompanied by the following disadvantages:

- Enzymes may not be sufficiently stable under the reaction conditions employed. Some lose their catalytic activity due to autooxidation, others due to self-digestion and/or denaturation by the solvent, and others due to mechanical shear forces.
- Isolated enzymes are water soluble and must be used repeatedly due to the economics of the processes for which they are used (82). They must be separated from the reaction mixture without destroying their catalytic activity.
- The productivity, expressed as the space–time yield, is often low due to the limited tolerance of enzymes to high concentrations of substrate(s) and product(s).

Some of these problems may be overcome by "immobilization" of the enzyme. However, a special problem is encountered with NADPH-dependent dehydrogenases because the coenzyme has to associate and dissociate freely to and from the active site(s) of the enzyme(s). Therefore, coimmobilization of the dehydrogenase and the cofactor is necessary to make the system practical (83). Either dehydrogenase, coenzyme, or both may decompose, leading to the replacement of the immobilized system.

If the K_m value for the coenzyme is in the micromolar range and the substrate-coupled approach for coenzyme regeneration is employed (as discussed earlier), a column reactor can be used with a small amount of free coenzyme dissolved in the mobile phase (72). This situation is particularly efficient if the reaction mechanism is an ordered bi-bi- or Theorell–Chance mechanism where the coenzyme is bound first to the active site, followed by the substrate. These mechanisms were found for a broad range of alcohol dehydrogenases.

The immobilization techniques most widely used for coenzyme-dependent dehydrogenases are shown in Figure 4. Immobilization techniques for coenzymes may be divided into coupling and entrapment methods.

Coupling Methods. For dehydrogenases, coupling methods can be further divided into methods for coupling the coenzyme on cross-linked enzymes or methods for coupling the enzyme and coenzyme on a carrier.

Coupling of the Coenzyme to Cross-Linked Enzymes. Enzymes can be attached to each other by covalent bonds, termed *cross-linking*. Bifunctional reagents such as glutardialdehyde, dimethyl adipimidate and dimethyl suberimidate can be used. The coenzyme can be bound to cross-linked enzymes using a spacer long enough so that the coenzyme has access to the active sites of both enzymes, thereby transferring the hydride. These requirements are very difficult to meet in practice. Lortie and coworkers (84) reported on the coimmobilization of horse liver alcohol dehydrogenase (HLADH), albumin, and NAD^+ using glutaraldehyde as the cross-linking agent. Long-chain aldehydes were prepared using this immobilized HLADH/NAD^+ system in a packed-bed reactor (glass column). The conversions were performed in organic solvent (hexane) saturated with buffer. Because proteins and coenzymes are insoluble in the water immiscible hexane, they remained in the aqueous phase. The long-chain alcohols (substrate) diffused into the aqueous phase, underwent enzymatic conversion, and the product (aldehyde) finally diffused back into the organic phase. This system was limited by the mass transfer between the organic phase and the water-containing porous particles. Lortie and coworkers (84) generalized this result to all types of fixed-bed enzyme reactors in biphasic systems. Importantly, the regeneration of the coenzyme was not a rate-limiting step.

Coupling of the Coenzyme on a Carrier. Another option for immobilizing coenzymes is to bind both the dehydrogenase(s) and the coenzyme to an insoluble carrier such as cellulose, dextrans, starch, chitin, agarose, or synthetic copolymers (85,86). The activation of the hydroxyl groups of polysaccharides is usually done by reaction with cyanogen bromide, leading to the formation of reactive imidocarbonates. Synthetic polymers can be activated using partial hydrolysis of the acetate groups followed by activation with epichlorhydrin. A range of preactivated polysaccharides and synthetic polymers (Biosynth, Eupergit, etc.) may be obtained from commercial sources. The enzyme is coupled via its amino groups. Also, in this case, a spacer long enough to allow the coenzyme to have access to the active sites of the enzyme(s) must be used. Horse liver alcohol dehydrogenase (HLADH) and an NADH analogue, N^6-[(6-aminohexyl)carbamoyl-methyl]-NADH, have been successfully coimmobilized to Sepharose 4B (83). It was shown that the coenzyme could be regenerated at a cycling rate of 3,400 cycles/h using the substrate-coupled approach. Both thermal and storage stability of the HLADH were increased substantially. It was not necessary to add soluble coenzyme to the substrate solution to maintain activity.

Entrapment Methods. Polymer-linked coenzyme derivatives are often introduced in enzyme reactors with coenzyme-dependent processes, because they can be retained upon ultrafiltration or dialysis and are recycled (Fig. 5) (35,39,45,47,56,57,76,87–93). Small substrate and product molecules can freely pass through the membrane (e.g., polyamide, polyethersulfone), but large enzymes and the polymer-linked coenzyme cannot. Synthetic membranes of defined pore size covering the range between 500 and 300,000 Da are commercially available at a reasonable cost. Additionally, a variety of synthetic membrane shapes, such as membrane discs or hollow fibers, are on the market. A simple form of a membrane reactor that does not require any special equipment is also shown in Figure 4. In this simple technique, termed *membrane-enclosed enzymatic catalysis* (MEEC), the enzymes and polymer-bound coenzyme are entrapped in a dialysis bag, which is mounted on a gently rotating magnetic stirring bar (81).

One modification of the enzyme membrane-reactor concept makes use of charged ultrafiltration membranes in order to retain the native coenzyme in the reactor (94–97). The application of charged ultrafiltration membranes in membrane reactors is limited to the production of non-charged products. In contrast, nanofiltration membranes

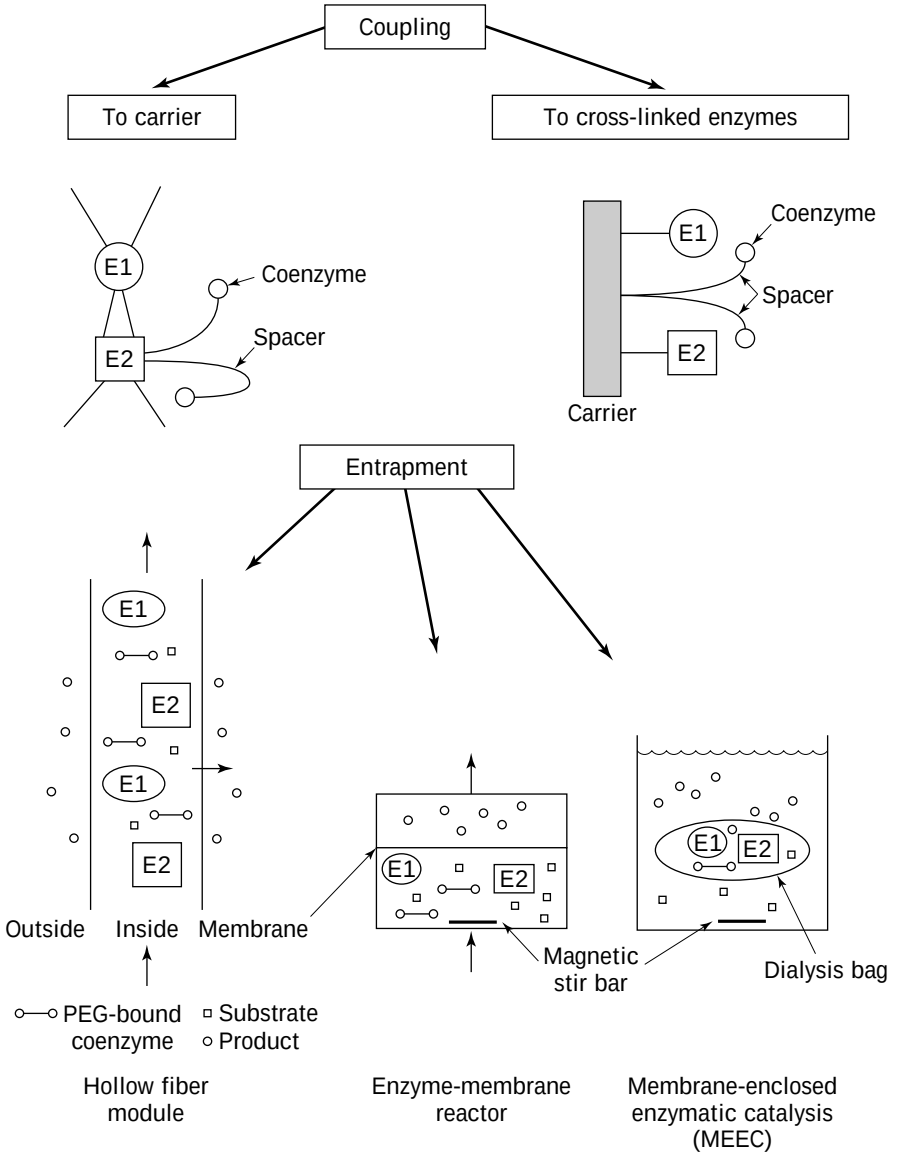

Figure 4.

can be used to retain the coenzyme in the reactor, whereas the reaction product(s) may freely pass the membrane (98). The separation of coenzyme and reaction product is due to the differences in the molecular weight, without a negative net charge of the membrane. For a recent overview of the applications of dehydrogenases using the enzyme membrane reactor technology, the reader is referred to Ref. 99.

Many reports on the preparation of polymer-linked coenzyme derivatives are available (100–109). The dextran-bound coenzymes have been demonstrated to the serious problem of protein leakage, due to the instability of the isourea linkage between coenzyme derivatives and dextran (110). However, more stable dextran derivatives can be synthesized by using bromohydroxypropyl derivatives of dextrans (111). These derivatives are used mostly in enzyme electrodes or as stationary phases in affinity chromatography (112).

The polyethyleneimine and polylysine derivatives of coenzymes (109) have the disadvantage of having electrostatic interactions between the multicharged polymers and enzymes, thus interfering with their effectiveness as active coenzymes. The relative reaction rates compared to native NAD^+ were 2–25% (polyethyleneimine) and 2–60% (polylysine), depending on the enzyme tested. The synthesis of polyacryl copolymers has the advantage that parameters like solubility, charge and the functional group can be varied just by exchange of the monomer (106). However, polyacryl-bound NAD^+ showed only 30% of the V_{max} value of the native coenzyme (113).

Another approach was established by Bückmann and coworkers using poly(ethylene) glycol derivatives with molecular weights of 3,000 to 20,000 kDa and modified coenzymes. The yield of the coupling of *N*(1)-(2-aminoethyl)-NAD^+ with the carboxy-PEG derivative was 90% (103). The alkylation of NADPH with 1,4-bis-(2,3-epoxypropoxy)-butane was investigated by Stein (114). This method allows the direct alkylation of NADPH in a one-step reaction, whereas all other described alkylation methods are mul-

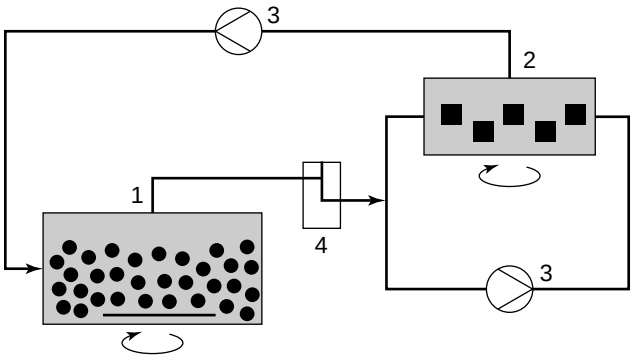

Figure 5.

tistep reactions starting from the oxidized coenzymes. Moreover, the coenzymatic activities of the NADPH derivatives were almost identical to the native coenzymes. The NADPH derivatives carry a hydrophilic spacer and a terminal epoxy group, which can be coupled easily to PEG-NH_2, resulting in a stable, covalent bond between PEG and the coenzyme derivative. For most of the enzymes tested, the coenzymatic activity of PEG-NADH is comparable to the native coenzyme (88,103,115). However, there are also exceptions (105). The PEG–coenzyme derivatives have been successfully applied in the abovementioned enzyme membrane reactor (35,39,45,56, 57,76,87–93). PEG-NADH, as well as other PEG-derivatives, are commercially available from spin-offs of German research centers in Braunschweig and Jülich (ASA Spezialenzyme GmbH; Jülich Enzyme Products).

Modern reactor concepts for the application of dehydrogenases and native coenzymes in organic solvents have been worked out by several groups (89,116–118). These concepts circumvent the immobilization of the coenzyme by using hydrophobic microfiltration membranes and two-phase systems, an emulsion membrane reactor or a differential circulation reactor with continuous extraction, respectively.

Conclusions

Enzymatic reductions catalyzed by NADP-dependent dehydrogenases require stoichiometric amounts of nicotinamide coenzymes, which are very expensive compounds. The application of dehydrogenases on a preparative scale therefore requires effective methods for the regeneration of these coenzymes.

Today, coenzyme regeneration of both NADH and NADPH are very straightforward and the cofactor is no longer the dominant cost in preparative reductions. Nicotinamide coenzymes are labile compounds, but if they are used under optimal conditions, the half-life can be extended to more than 14 days. Coupling of NADPH to poly(ethylene) glycols stabilizes the coenzymes, by which means the half-life can be extended to more than 240 days. Enzymatic methods for coenzyme regeneration are preferable to nonenzymatic methods because they meet most of the requirements for an ideal recycling system. Two different principles can be distinguished: the substrate-coupled and the enzyme-coupled approaches. The enzyme-coupled method is advantageous because even unfavorable reactions can be driven to the product side by coupling with a favorable cofactor-regeneration reaction.

The most economical method for PEG-NADH recycling is the formate–formate dehydrogenase system, which has been applied up to the commercial-scale process.

For the regeneration of (PEG-NADPH, the alcohol–alcohol dehydrogenase from the *Thermoanaerobium brockii* system or the formate–formate:NADP dehydrogenase system are recommended.

The α-ketoglutarate–glutamate dehydrogenase system catalyzes the thermodynamically favorable reductive amination of α-ketoglutarate. Both NAD^+ and $NADP^+$, as well as PEG-$NAD(P)^+$, can be regenerated effectively.

The use of the enzyme membrane reactor technology in conjunction with poly(ethylene) glycol-linked coenzymes made possible the scale-up of enzymatic processes to preparative scale (91,119,120). Among others, this technology was successfully applied for the synthesis of different L-amino acids and a range of chiral hydroxy compounds of high value.

OUTLINE

INTRODUCTION

Transport properties of electrolyte solutions (i.e., *conductance, diffusion, viscosity, thermal diffusion*, etc.) play a relevant role in basic and applied researches because they control most processes occurring in many fields of pure and applied science, such as chemistry, biology, medicine, colloids science, engineering, and materials science. In this article, electrolytic conductance will be emphasized, considering in particular the physical phenomena on which this quantity is based, the experimental apparatus used for its measurement, and some of the theories proposed to explain the variation of conductance with the electrolyte concentration. It will also be shown that conductance is a macroscopic property yielding both kinetic information in the form of ionic mobilities and thermodynamic information in the form of thermodynamic equilibrium constants for the formation of ion pairs. Conductance behavior also yields information on electrolytic systems at the microscopic level when the experimental data are analyzed with the theoretical equations based on models in which ion–solvent and ion–ion interactions are included.

CONDUCTION OF ELECTRICITY THROUGH MATTER

The transport of electricity through matter is effected by the movement of charge carriers. Depending on the nature of the charge carriers involved in the process, two basic classes of conductors can be distinguished. In the first class (*electronic conductors*), electricity is carried by electrons; in the second class (*electrolytic conductors*), electric current is carried by ions. Electronic conductors include metals and semiconductors.

The properties of the electronic conductors follow solid-state band theory. The rigorous treatment of electronic conductors is beyond the scope of this article, but to provide some background information for the reader, the mechanism of electrical conduction in metals can be summarized as follows. The energy levels of isolated atoms have discrete values. The filling of these energy levels by electrons is governed by the laws of quantum mechanics. As atoms approach one another to form a crystal lattice, the original energy levels combine to form energy bands. In metals, the conductivity bands correspond to the highest, partially occupied, energy levels of the metal atom in the ground state and contain a sufficient number of loosely bound electrons in random motion. Under the influence of an external electric field, the original random motions of electrons become oriented, and an electron flux (*electrical current*) runs along the conductor.

Quite different is the mechanism of conduction in electrolytic conductors. In electrolyte solutions, ions and solvent molecules are in rapid thermal motion, and any net ionic migration is essentially a small perturbation along the direction of the electric field superimposed on the former. Because ionic velocities are only of the order of 10^{-6} s^{-1} for an electrical field of unity (1 V/cm^{-1}), the solvent is usually approximated as a continuum in which the ions are assumed to move at a constant velocity, which is the time average equal to the sum of their components of motion in the direction of the applied field divided by the time of observation. Electrolytic conductance is, in last analysis, a measure of the steady-state flux achieved between the effects of an external electrical force and those of the internal hydrodynamic resistance to ionic motion. As such, it is an important research tool with which molecular interactions may be conveniently investigated.

In many technological processes (i.e., *electrodialysis, ion-selective electrode production, environmental and waste applications*, etc.) as well as in some biological processes (i.e., *permeation of ions through cellular membrane*), an artificial or natural membrane is interposed between two electrolyte solutions. From a physical point of view, the *membrane* is a potential barrier for the ionic flux; thus, the mechanism of conduction in these systems differs from that occurring in the simple electrolytic systems. Membranes can be divided in two main types: membranes that have a preferential permeability for a particular ion and membranes that are totally unpermeable to any kind of ions. The membranes of the first type are used in the technological applications where ion selectivity is the main factor of the process. The ionic conduction in these electrolyte membrane systems is only allowed for a particular ionic species. Quite different is the conduction mechanism for the systems containing a membrane of the second type. In these systems, the flux of ions (*hydrophilic*) is hindered by the hydrophobic character of the membrane (e.g., *lipidic bilayers*). To overcome this handicap, two alternative mechanisms are possible (*carrier and channel mechanisms*). Ionic transport mediated by carrier is obtained by using macrocyclic compounds (1,2) (e.g., natural antibiotics such as valinomycin and enniatin B or synthetic macrocyclic compounds such as crown ethers, cryptands, etc.). These carrier compounds form intrusion complexes with alkali metal ions. In these complexes, the central hydrophilic ion is hosted into a cavity containing oxygen atoms, and the exterior of the complex is hydrophobic. Such a feature, decreasing the energy barrier imposed by the membrane to the ionic flux, allows for the transport of the hosted ionic species across the hydrophobic membrane. It has been observed that the conductance of lipidic bilayers (10^{-10} S/cm) linearly increases with the carrier concentration. Such a result suggests that current-carrying species are 1:1 complexes between alkali metal cation and macrocyclic molecules. A transport mechanism consistent with the experimental results is depicted in Figure 1. According to this mechanism, the ionic transport across the membrane occurs in four distinct steps: (*1*) Association of ion M^+ and carrier S in the interface electrolyte solution–membrane (rate constant K_R); (*2*) Translocation of the complex M^+S to the opposite side of the membrane (rate con-

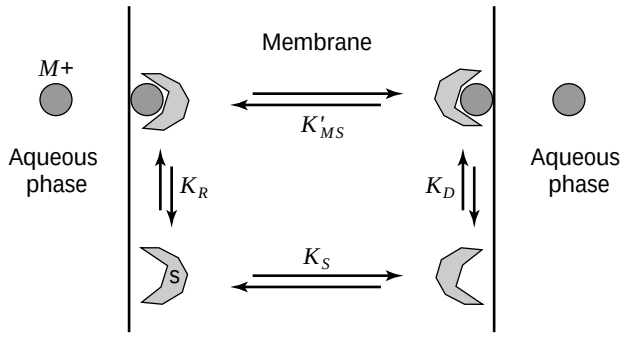

Figure 1. Carrier mechanism.

stant K'_{MS}); (*3*) Release of the ion to the solution (rate constant K_D); and (*4*) Back transport of the unloaded carrier (rate constant K_S). The kinetics of this carrier mechanism for a given system can be analyzed by studying the electric conductance behavior (3).

Different from the ionic transport mediated by carrier compounds is the channel mechanism. A channel consists of one or several binding sites arranged in a transmembrane sequence, and it is accessible from both sides at the same time. A number of simple *molecules* (e.g., the linear pentadecapeptide gramicidin A [4]) introduced into a biological or artificial membrane form channels permeable to cations. A detailed model of the gramicidin A channel was proposed by Urry (5). Information on the mechanism of ion transport through channels has been obtained in experiments (3) in which small amounts of gramicidin A were added to a planar bilayer membrane. Under this condition, the membrane current under a constant applied voltage shows discrete fluctuations with more or less the same amplitude. The experiment has been explained assuming that the single current fluctuation results from the formation and disappearance of a single channel permeable to ions.

In addition to electronic and electrolytic conductors, there is a special class of *solid-state polymer electrolytes* (6) that have recently attracted considerable worldwide interest for their prospective applications in batteries, sensors, and other practical devices. Polymer electrolytes are simply formed by dissolving an inorganic salt in suitable polymeric hosts. These host polymers contain electronegative heteroatoms (*oxygen*, *nitrogen*, *sulfur*, or *phosphorus*) that interact with cations by donor–acceptor bonds to form polymer–cation complexes. Poly(ethylene oxide) (PEO) and poly(propylene oxide) (PPO) are the most-used polymers that form solid-state polymer electrolytes.

PEO: -CH-CH-O-

PPO: -CH-CH-O-
|
CH

The mechanism of ionic transport in such systems was initially attributed to ion hopping between fixed coordination sites of polymer. Recently, the percolation theory (7) formally describes these ion conductors as a random mixture of conductive islands interconnected by a nonconductive matrix in terms of ion size, charge, and interactions with other ions and the host matrix.

As stated before for the electronic conductors, a detailed description of the conductivity properties of polymer electrolytes and the transmembrane ionic transport is beyond the scope of this article, which focuses mainly on electrolyte conductance, namely, *conductance in liquid electrolyte solutions*.

ELECTROLYTIC CONDUCTANCE

In an electrolytic conductor, the relationship between the steady-state flux (J) of ions and the driving forces of the electric field (X) can be represented by the power series

$$J = A + BX + CX^2 + DX^3 + \ldots \quad (1)$$

where A, B, C, and so forth are constants, and the units of J and X are $cm^3/s/K$ and volt/cm, respectively. For small applied fields, the terms containing the powers of X greater than unity can be neglected, and equation 1 therefore becomes

$$J = A + BX \quad (2)$$

The constant A in equation 2 must be zero because the ionic flux vanishes when $X = 0$. Hence, for small electric fields, the ionic flux is linearly related to the driving force

$$J = BX \quad (3)$$

where B is a constant specific of the system under investigation. The ionic flux J, representing the number of moles of ions crossing a unit area per second, can be easily converted into the charge flux or the current density i (number of electrical charge crossing unit area per second) by the relationship

$$i = JzF = zFBX \quad (4)$$

In the preceding equation, z is the charge number, i has units of ampere (A) per cm^{-2}, and F is the faraday equal to $F = eN$ (e is the electron charge equal to $e = 1.602177 \times 10^{-19}$ coulomb, and N is the Avogadro's number equal to $N = 6.02214 \times 10^{23}$ mol^{-1}). For a given electrolytic system, zFB is constant. Setting this constant equal to χ, equation 4 becomes

$$i = \chi X \quad (5)$$

that can be rearranged in the form

$$\chi = i/X \quad (6)$$

where χ is the *electrolytic conductance* as of a solution of known concentration (also referred to as the *specific conductance* in older literature) and has units of siemen (S) cm^{-1}. Table 1 compares representative values of the specific conductance of electrolytic solutions with those of metallic conductors and nonelectrolytic systems.

Table 1. Representative Values of Electrolytic Conductance at 25 °C

Substance	Type of conductor	Electrolytic conductance (S/cm)
Acetonitrile	Nonelectrolyte	1×10^{-8}
Water	Nonelectrolyte	2×10^{-7}
0.1 M KCl	Electrolytic	1×10^{-2}
4 M H_2SO_4	Electrolytic	8×10^{-1}
Iron	Metallic	1×10^{5}
Copper	Metallic	6×10^{5}

By definition, the electric field X is the ratio of the potential difference ΔV between two regions of the electrolyte and the distance l between them.

$$X = \Delta V/l \tag{7}$$

On the other hand, the density current (i) is the ratio of the total current (I) and the area (A) of the electrodes

$$i = I/A \tag{8}$$

Thus, combining equations 7 and 8 with equation 6 one has

$$\Delta V = I(l/\chi A) \tag{9}$$

According to Ohm's law, the quantity $(l/\chi A)$ must be a resistance, that is,

$$R = (1/\chi)(l/A) \tag{10}$$

The modern units for resistance is reciprocal siemen (S^{-1}), and the older unit of ohm (Ω) is no longer used. Equation 10 indicates that electrolytic conductors, like metallic conductors are ohmic conductors (i.e., they obey the Ohm's laws) and can therefore be represented in an electrical circuit as a resistor.

Measurements of Electrolytic Conductance

In conductance experiments, the electrolyte is placed in a conductivity cell of controlled geometry, and the resistances (R) of solutions of known concentration are measured. The cells are generally constructed in Pyrex glass with sealed platinum electrodes. Other noble or passive metals, such as gold, silver, titanium, stainless steel, and tungsten, as well as graphite can be used as electrodes for technical applications of conductivity (i.e., routine or in situ industrial measurements). Cells designs are available for a variety of research and industrial applications. The different types of conductance cells have in common an electrode compartment, shown schematically in Figure 2. The geometry factor, l/A (cm^{-1}), known as the cell constant, κ, is generally determined by calibrating the cell with a solution of known conductivity. Aqueous potassium chloride solutions are usually used for this purpose (8) because the specific conductance of this electrolyte at different concentrations and temperatures has been determined with a very high degree of accuracy. Cells are designed

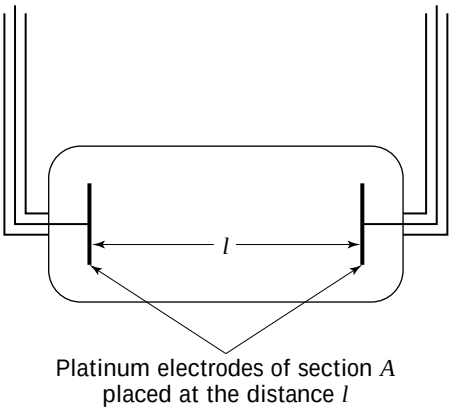

Figure 2. Schematic representation of conductometric cell.

with various cell constants so that the resistance of different electrolytic systems ranges between 1,000 and 30,000 S^{-1} in order to avoid errors arising from high density current and insulation linkage. Table 2 summarizes recommended cell constants for various conductance ranges.

The electrical resistance of electrolyte solutions cannot be measured with a traditional bridge circuit (e.g., a Wheatstone bridge) operating with direct current (dc) because this would give rise to polarization at the electrodes and in some cases to the electrolysis of the solution. Polarization produces undesirable changes in the electrolyte concentration during measurements that must be avoided because the resistance of the electrolytic system depends on ionic concentration. The simplest way to achieve this requirement is to use alternating current (ac) in the frequency range between 500 and 20,000 Hz. This rapid reversible change in applied potential effectively eliminates polarization effects.

The theory and design of ac bridges suitable for electrolyte conductance measurements were discussed by Jones and Josephs (9) and by Shedlovsky (10). A crude representation of the different ac bridges commercially available can be made in reference to the Kohlraush's bridge circuit, schematically depicted in Figure 3. The conductivity cell forms one arm of the bridge and a standard variable resistance box (R) forms another arm of the bridge. The other two arms of the bridge consist of two closely equal resistances, R_a and R_b. With ac bridge impedances are determined. The impedance Z is defined by the relation

$$Z = (R + X_R)^{1/2} \tag{11}$$

where R is the resistance and X_R the reactance given by

Table 2. Recommended Cell Constants for Various Conductance Ranges

Conductance Range (S cm)	Cell constant (cm^{-1})
$(0.5–20) \times 10^{-6}$	0.01
$(0.1–20) \times 10^{-5}$	0.1
$(0.2–20) \times 10^{-4}$	1.0
$(0.1–20) \times 10^{-3}$	10.0
$(0.1–20) \times 10^{-2}$	50.0

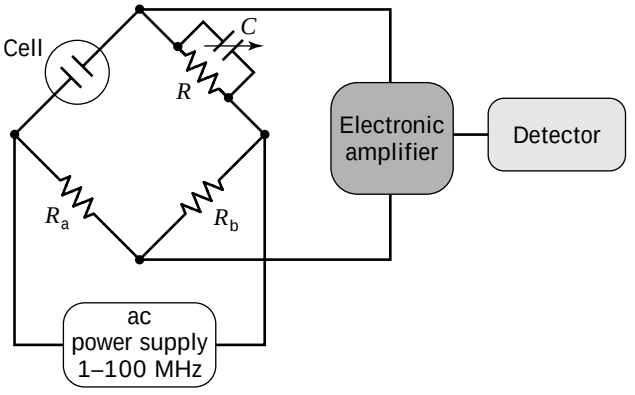

Figure 3. Schematic representation of a conductance apparatus based on Kohlraush's bridge circuit.

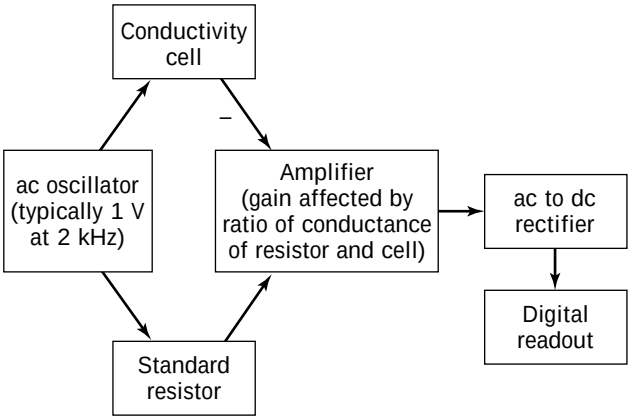

Figure 4. Block diagram of a typical digital conductivity meter.

$$X_R = X_L - X_C \tag{12}$$

where $X_L = 2\pi fL$ is the inductive reactance and $X_C = 1/(2\pi fC)$ is the capacitive reactance. In the preceding equations, R, X_L, and X_C are in reciprocal siemen (S^{-1}), f is the frequency in hertz, L is the inductance in henry, and C is the capacitance in faraday. Because the resistances used in the bridges for conductometric measurements are generally noninductance, capacities and resistances are the variables determined by balancing the bridge. Thus, only a standard variable condenser box (C) needs to be placed in parallel to the resistance box (R). For the measurement, both C and R are adjusted until zero signal from the electronic amplifier is detected. For this null condition, the following relations for the reactance capacities $X_C = 1/(2\pi fC)$ as well as for the resistances (R) can be written

$$\begin{aligned} [1/(2\pi fC)]_{cell}/[1/(2\pi fC)]_a &= [1/(2\pi fC)]/[1/(2\pi fC)]_b \\ &= [1/C)]_{cell}/[1/C)]_a \\ &= [1/C)]/[1/C]_b \\ R_{cell}/R_a &= R/R_b \end{aligned} \tag{13}$$

Because $[1/C)]_a = [1/C]_b$ and $R_a = R_b$, one obtains

$$\begin{aligned} C_{cell} &= C \\ R_{cell} &= R \end{aligned} \tag{14}$$

The ac bridge circuit is, in other words, a simple RC circuit allowing us to measure the individual impedance contributions from the resistance and the capacitance reactance. The block diagram for typical digital instruments used for routine resistance measurements is shown in Figure 4.

The conductance of electrolytic solutions changes by as much as 2% per degree Kelvin (Fig. 5). Thus, it is very important to have accurate temperature control within ± 0.001 K for high-precision measurements. Although the thermostatic bath may have any convenient and appropriate design, mineral oil rather than water is recommended for use in the bath. This is because the high dielectric constant and conductivity of water compared with mineral oil may result in leakage of electrical energy from the cell sufficient to introduce errors of appreciable magnitude. For routine or industrial applications such as in situ conductivity measurements, temperature control need not be very precise, and temperature regulation within ± 0.1 K is sufficient in most cases. Cells are available with built-in temperature sensors and associated instrumentation that automatically convert conductance values to a reference temperature, generally 25 °C. This feature on commercial bridges is referred to as automatic temperature compensation of conductivity.

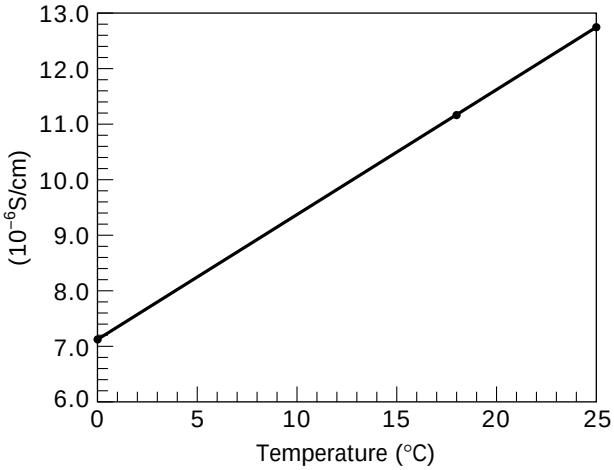

Figure 5. Dependence of the specific conductance of aqueous KCl solution (0.1 mol/L) with temperature.

For high-precision and high-accuracy conductivity measurements of dilute electrolyte solutions, the conductance of the solvent, χ_o, must be subtracted from the *apparent* (i.e., *experimental*) conductance, χ_a, as measured in the cell to obtain the real conductance, χ, of ionic species in solution.

$$\chi = \chi_a - \chi_o \tag{15}$$

The electrolytic conductance of commonly studied solvents is summarized in Table 3. Because conductivity measurements can be extremely accurate, by comparing measured

Table 3. Specific Conductance of Common Solvents at 25 °C

Solvent	Specific conductance (χ_0[S/cm])
Water	$1–2 \times 10^{-7}$
Methanol	$1–2 \times 10^{-8}$
Glycerol	$1–3 \times 10^{-8}$
Ethylene glycol	$6–8 \times 10^{-8}$
Acetonitrile	$3–4 \times 10^{-8}$
Propylene carbonate	$1–2 \times 10^{-6}$
Nitromethane	$1–3 \times 10^{-8}$
N-*N*-Dimethylformamide	$2–4 \times 10^{-8}$

conductances to those determined for highly purified solvents (see Table 3) the purities of solvents can be easily determined.

Molar, Equivalent, and Ionic Conductivity

The current density (i) across unit area per second can be expressed in terms of ionic velocity (v_i) by

$$i = F\Sigma_i c_i z_i v_i \tag{16}$$

where c_i, z_i, and v_i are the number of moles per cubic centimeter, the charge number, and the velocity in cm/s of the nth ionic species. Dividing equation 16 for the strength of electrical field (X) gives

$$i/X = (F/X)\Sigma_i c_i z_i v_i \tag{17}$$

Substituting equation 6 in equation 17 and setting the mobility of the nth ions $U_i = (v_i/X)$ one obtains

$$\chi = F\Sigma_i c_i z_i U_i \tag{18}$$

Restricting the treatment to 1:1 symmetrical electrolytes for which $z^+ = z^- = z$ and $c^+ = c^- = c$, equation 18 becomes

$$\chi = Fzc(U^+ + U^-) \tag{19}$$

Equation 19 shows that, contrary to electronic conductors, the specific conductance of electrolyte solutions depends on the ionic concentration. Thus, in order to normalize the electrolytic conductance for the concentration, a new quantity, the molar conductivity (Λ_m) is defined as

$$\Lambda_m = 10^3\chi/c_m \tag{20}$$

where c_m is the concentration (mol dm^{-3} units) of the electrolyte. The units of Λ_m are S cm^2 mol^{-1}. Molar conductivities taking into account only the molar concentration of the electrolyte do not always normalize the conductance, as in the cases where multiply charged ions are involved. To account for unsymmetrical electrolytes, such as $MgCl_2$, normalization is achieved by considering equivalent concentrations, $c = c_m/z$. In terms of equivalent concentrations, the normalized quantity is the *equivalent conductance* Λ (S cm^2 eq^{-1}), defined similarly to equation 20 by

$$\Lambda = 10^3\chi/c \tag{21}$$

Figure 6 shows that the equivalent conductance for a typical electrolyte (KCl in water) decreases as the ionic concentration increases. Thus, for meaningful comparisons of conductivity differences for different electrolytes, it is necessary to define a common reference state for equivalent conductances. The reference state is that of infinite dilution where the equivalent conductance at zero electrolyte concentration is referred to as the *limiting molar conductivity* and given the symbol Λ_o. As will be shown in the next section, the dependence of conductance on ionic concentration results from interionic interactions. Because at infinite dilution such interactions are negligible, only ionic velocity is affected by the external electrical field. Under these circumstances, Λ_o represents the conductivity of the electrolyte solution in its ideal state.

Substituting equation 21 in equation 19 gives

$$\Lambda = F(U^+ + U^-) = \lambda^+ + \lambda^- \tag{22}$$

where λ^+ and λ^- are the ionic equivalent conductance of the cation and anion at the given concentration. At infinite dilution, equation 22 for the limiting equivalent conductance becomes

$$\Lambda_o = \lambda_o^+ + \lambda_o^- \tag{23}$$

An important implication of this equation is that at infinite dilution, molar conductivities are *additive*. This property, discovered by Kohlrausch, is known as the *Kohlrausch law of independent ionic conductivity*. Thus, the limiting equivalent conductance for any electrolytic system can be obtained from the sum of the contributions of the individual ions. Limiting equivalent conductivity for a large variety of ionic species in different solvents as a function of temperature has been measured by many researchers. Table

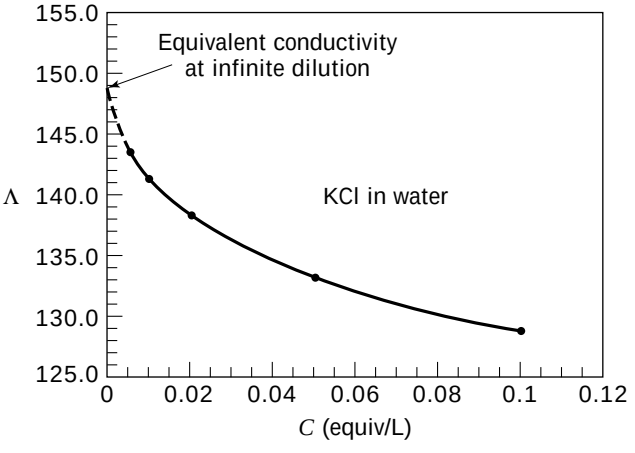

Figure 6. Dependence of Λ(S cm^2 equiv^{-1}) with electrolyte concentration C (equiv/L).

4 reports individual ionic λ_o values for selected ions in water at 25 °C.

THEORIES OF ELECTROLYTIC CONDUCTANCE

The search for a mathematical expression able to theoretically predict the concentration dependence of the molar conductivity has been the object of numerous scientists since the time of Arrhenius (1883). An ideal theory of conductance would predict Λ from fused salt systems (*solute mole fraction equal to unity*) to infinite dilution (*solvent mole fraction equal to unity*). In spite of this intense effort, the different conductance equations so far proposed take into account only the influence of the ion–ion and ion–solvent interactions on the ionic mobility and the concentration of free ionic species in solution. Thus, they are limited to concentrations up to where the effect of short range three-ion interactions (i.e., *triple ions formation*) becomes significant.

Debye–Onsager–Fuoss Theory

Because of the electrical charge on the ions, the ionic distribution in an electrolyte solution is modulated by the ion–ion interaction field superimposed to the ionic thermal motion. In order to quantitatively express the contribution of electrostatic interactions on ionic distribution, it is necessary to choose a model to represent the system. Although the model must include all the relevant properties of solute and solvent, the problem is to select a sufficiently simple model that is amenable to available mathematical treatments. All models for conductance behavior, though different in some details, are essentially based on the *primitive model* proposed by Debye and Hückel (11) in which

1. The electrolyte is completely dissociated at all the concentrations.
2. The solution is considered to be a collection of point charges (ions) in a homogeneous medium of viscosity (η) and relative permittivity (ϵ) (hydrodynamic continuum).
3. The Coulombic field surrounding the ions has spherical symmetry.
4. Only ion–ion long-range electrostatic interactions are considered.
5. The electrostatic potential energy of each ion is smaller than the thermal energy, that is, $|z_i e\psi| \ll kT$.

Table 4. Equivalent Ionic Conductivity of Selected Ions at Infinite Dilution in Water at 25 °C

Cations	λ_0^+(S cm^2 equiv^{-1})	Anions	λ_0^-(S cm^2 equiv^{-1})
H^+	349.8	OH^-	198.30
Li^+	38.7	Cl^-	76.4
Na^+	50.1	I^-	76.8
K^+	73.5	Br^-	78.1
Rb^+	77.8	NO_3^-	71.4
Cs^+	77.3	ClO_4^-	67.3
Ag^+	61.9	ClO_3^-	64.0
NH_4^+	73.5	HCO_3^-	44.5

Fe^{3+}	68.0	$Co(CN)_6^{3-}$	98.9
$Co(NH_3)_6^{3+}$	102.3	$Fe(CN)_6^{4-}$	110.5

In the Debye–Hückel theory, the central ion is considered, from a time-averaged point of view, at rest. The ion is surrounded by a symmetrical ionic cloud localized at the distance (*Debye distance*) given by

$$x^{-1} = [(\varepsilon T/\Sigma z_i c_i)(1{,}000\ \kappa/8\pi e^2 N]^{1/2} \qquad (24)$$

where z_i and c_i are the charge number and the concentration of the nth ion, respectively, ϵ is the static dielectric constant of the solvent, T is the temperature (Kelvin), κ is the Boltzman constant ($1.38\ 10^{-6}$ erg/degree), e is the electron charge ($4.80\ 10^{-10}$ absolute electrostatic unity [e.s.u.]), and N is the Avogadro's number. To the extent that one seeks to interpret the equilibrium properties of electrolytic solutions (i.e., *activity coefficients*), this picture of a static central ion surrounded by a ionic cloud with spherical symmetry is quite reasonable. Ionic interactions yielding the formation of spherically symmetrical ion clouds in the absence of external fields change from spherical to axial symmetry (*egg shape*) when a uniform external field (i.e., electric field as in the conductance or chemical potential field as in the diffusion) is applied to the electrolyte solution (Fig. 7).

Onsager (12) accounts for this asymmetrical distribution by considering the mutual interactions between an ion and its asymmetrical cloud. In the mathematical treatment of the migration of ions, he assumed that the drift velocity of an ion, besides the electric force arising from the externally applied field, is also determined by two other extra forces (i.e., *relaxation* and *electrophoretic forces*). The basic conductivity equation obtained by Onsager is

$$\Lambda = \Lambda_{0^\circ} - S\sqrt{c} \qquad (25)$$

where Λ_0 is the limiting conductance due to the unper-

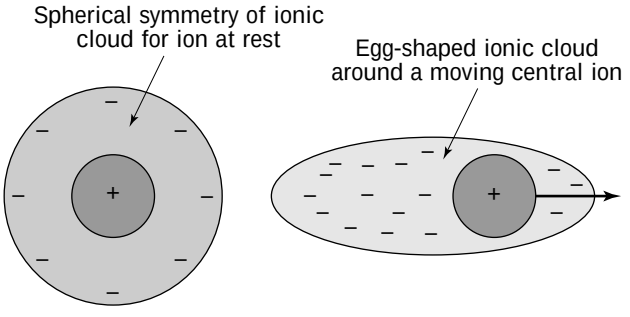

Figure 7. Ionic cloud for central ion at rest and in movement.

turbed ion movement in the external field at infinite dilution, and S is a constant that depends on absolute temperature, valence type of solute, dielectric constant, and viscosity of solvent. S includes the relaxation and the electrophoretic effect calculated via two particle correlation functions, assuming ions to be point charges and truncating series terms at the term $c^{1/2}$. It is important to realize that the constant S (and the constant E to be described in the next paragraph) does not account for finite size of ions and their solvation shells. For solvents of high dielectric constants ($\varepsilon > 45$), equation 25 can be considered an acceptable extrapolation formula, and we refer to it as the *limiting law*. However, for solvents of lower dielectric constant, deviations from equation 25 become large even in the case of completely dissociated electrolytes. The reasons for this drastic limitation arises from the crude assumption of the Debye–Hückel physical model, which represents the ions as point charges.

A further development of the conductance theory was made by Fuoss and Onsager (13), who treated the ions as finite-size particles. The resulting conductance equation derived by Fuoss and Onsager is

$$\Lambda = \Lambda^{o} - S\sqrt{c} + Ec \log c + J_a c \qquad (26)$$

where Λ_0 and S have the same meaning as in equation 25, E is a new constant dependent on the same variables as S, and J_a is a parameter that according to the new model depends on the cation–anion distance a, which can be used as a variable in fitting data to equation 26 or simply estimated as the sum of crystal radii of cation and anion; a is therefore referred to as the *distance of closest approach*. The logarithmic term in equation 26 derives from the integration of the higher terms of the continuity equation. Although Equation 26 is based on a more realistic model (*rigid charged spheres in a continuum*) it does have limitations because it often fails to accurately describe conductance behavior in many solvents, particularly solvents with low dielectric constants. However, for solutions containing salts with large ions, such as tetraalchylammoniun salts in high dielectric constant solvents, equation 26 does in fact reproduce the experimental data with acceptable accuracy. The problems encountered with equation 26 arise when electrolytes with small ions in solvents of moderate dielectric constants are involved, and where ion pair formation (Fig. 8) becomes significant. Ion pairs behaving as a dipole in the external electric field do not contribute to the conductance current.

In 1926, J. Bjerrum (14) developed a theory of ionic association. This theory was based on the observation that for certain systems the ratio of measured activity coefficients to the stoichiometric concentration was less than the activity coefficients calculated by the Debye–Hückel theory. To account for such discrepancies, Bjerrum postulated that some ions associated to ion pairs that as dipoles are no longer included in the ionic atmosphere. In order to obtain the degree of association of ions into neutral ion pairs, Bjerrum calculated the probability function [$W(r)$] of finding an anion in the spherical shell surrounding the reference cation. By applying a mathematical treatment analogous to that used by Debye– Hückel in the derivation of the activity coefficients, he found an analytical form for $W(r)$ that after a sharp minimum, diverged to infinity (Fig. 9). In order to mathematically treat this function, Bjerrum arbitrarily cut the integral off at a certain critical distance between the cation and the anion at which the electrostatic attractive force is balanced by the mean force corresponding to the thermal motion. Such a distance, in which the ion is at minimum energy, depends on the valence type (z), electron charge (e), dielectric constant of solvent (ε), Kelvin temperature (T), and Boltzman constant (k). For uniunivalent electrolytes, this critical distance (*Bjerrum distance*) is represented by the equation

$$R = e^2/2\varepsilon kT \qquad (27)$$

Integration of the probability function from the distance of closest approach (a) of the ions to R allows one to calculate the fraction of ions present in solution in the associated state. Thus, the degree of ion-pair association and the ion-pair association constant can be calculated.

Taking ion pair formation into account, Fuoss (15) extended the previous conductivity equation 26 to

$$\Lambda = \Lambda^{o} - S\sqrt{c\gamma} + Ec\gamma \log c\gamma + jc\gamma - K_a c\gamma f_{\pm}^{2}\Lambda \qquad (28)$$

where $f_{\pm}^{2}$ is the mean ionic activity coefficient calculated by the Debye–Hückel theory, and γ is the fraction of the electrolyte that exists as unassociated ions. In terms of γ, the thermodynamic equilibrium constant for the formation of ion pairs is determined by the mass equation

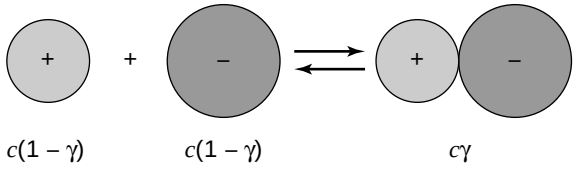

Figure 8. Schematic representation for ion-pair formation.

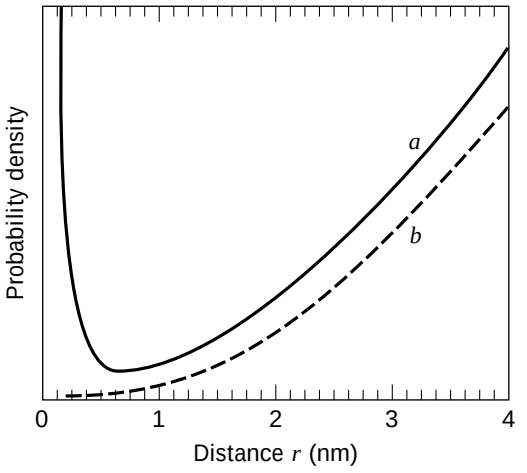

Figure 9. Bjerrum's curves of probability. (**a**) Two ions of opposite charges; (**b**) uncharged particles.

$$K_a = (1 - \gamma)/c\gamma^2 f^2 \quad (29)$$

Subsequently, Quint and Viallard (16) and Lee and Wheaton (17) extended the above equation to mixed electrolytes and for unsymmetrical electrolytes (e.g., $MgCl_2$). After the publication of equation 28, the theoretical treatment of the conductance of electrolyte solutions seemed to be completely solved in term of the electrostatic theory. However, numerous accurate experiments studies during the past 25 years have shown that equation 28 still has severe limitations. In particular, the systematic investigation on the conductivities of electrolytes in different solvents carried out by many researchers confirmed the limitation of equation 28 (or similar conductivity equations derived by Pitts [18], Kraeft [19], and Fuoss et al. [20]). Part of these limitations were eliminated by refining the mathematical treatment of the electrophoretic and relaxation terms [21]. Nevertheless, the most important limitation of the theory was the small concentration range over which equation 28 can be applied.

Several mathematical improvements were made to push the concentration limit of the conductivity equation to higher values. Fuoss and Hsia (22), by a new integration of the equations of continuity and motion with retention of terms of order $c^{3/2}$, presented in 1967 the empirical $\Lambda(c)$ function

$$\Lambda + \Lambda^o - S\sqrt{c} + Ec\gamma \log c + Ac + Bc^{3/2} \quad (30)$$

This equation is valid for 1:1 electrolytes up to the concentration $C_{max} = 3\ 10^{-7}\ \varepsilon^3$ mol dm^3, above which ion pair formation becomes statistically undefinable due to the presence of triple ions (23). Thereafter, Fernandez-Prini (24) expanded the function of the Fuoss–Hsia equation using, as suggested by Justice (25), the Bjerrum radius (R) as the lower limit in the integration instead of the contact distances a. The modified conductivity equation derived by Justice and Fernandez-Prini is

$$\Lambda = \Lambda_o - S\sqrt{c\gamma} + Ec\gamma \log c\gamma + J_1(R)c\gamma + J_2(R)c^{3/2}\gamma^{3/2} - K_a c\gamma f^2_{\pm}\Lambda \quad (31)$$

It turned out that equation 32 was also not free from theoretical and experimental problems. The most serious was the prediction that a given electrolyte in different solvents of the same dielectric constants should have the same association to ion pairs.

Many violations of the failure of this *isodielectric rule* (26) show that the primitive model can be considered an oversimplified physical model adequate to describe the conductometric behavior of electrolytic systems, in which long-range ion–ion interactions play the main role, but it completely ignores additional effects caused by anion–cation, anion–solvent, and cation–solvent short-range interactions. Recently, Fuoss (27) proposed a new model for ions in solution, based on the concept of the Gurney cosphere (28) surrounding each ion. This *chemical model* takes into consideration short-range specific ion–solvent interactions (*solvation*) related to the polarizability, dipole moment, and shape and size of ions and solvent molecules, both of which are explicitly ignored in the primitive model. This new model involves the dual roles played by the ions involved in ion-pair formation. As long as the distance between the two ions is greater than the diameter of the Gurney cosphere, an ion involved in pairing is an anonymous member of an enormous population; once inside the cosphere, the ions behave like particles and move from site to site by interchanges with solvent molecules. Because of this duality, the long-range interactions (*relaxation field* and *electrophoresis*) can be determined by using continuum electrostatic and hydrodynamic theories, whereas short-range interactions can be determined by the thermodynamic changes of the free energy of the pairing process involving both solvent separate ion pairs and contact ion pairs. For symmetrical electrolytes, the conductance equation based on the chemical model can be written in the following symbolic form

$$\Lambda = \gamma\{[\Lambda_o(1 + (\Delta E/E)] + \Delta\Lambda^v + \Delta\Lambda^H + \Delta\Lambda^{el}]\} \quad (32)$$

In this equation, where γ is the fraction of solute that contributes to the conductance current, $(\Delta E/E)$ is the part of the relaxation field generated by purely electrostatic interactions between ions, $\Delta\Lambda^v$ is the part of the relaxation field caused by the change in the electrophoretic current caused by perturbation potential, $\Delta\Lambda^H$ is the Sanding–Feistel (29) hydrodynamic–hydrodynamic interactions term, $\Delta\Lambda^{el}$ is the electrophoretic countercurrent, and Λ_o is the limiting conductance. Starting from this chemical model proposed by Fuoss, Lee and Wheaton, in a series of papers (30), derived a conductivity equation for the general case where any number of ionic species of any valence type may be presented in solutions. Thus, not only 1:1 electrolytes but also asymmetrical and mixed electrolytes can be analyzed.

OUTLINE

INTRODUCTION

In its extensive meaning, biological corrosion, or biodeterioraton, refers to any corrosion caused by biological activity. Indeed, the original meaning of the term *corrosion*, as derived from *rodere*, the Latin root for "act of gnawing," includes biological activity. Microbiological corrosion refers, by definition, to the degradation of metallic structures due to the activity of a wide variety of microorganisms, usually embedded in a gel matrix, the biofilm, attached to the metal surface.

Before further discussion on this subject, a short review of the milestones in its historical development is presented. Evidence of anaerobic corrosion was observed as early as 1840, when Mallet noted sulfide corrosion products typical of anaerobic process on an ancient anchor on the bottom of the Seine River (1).

The phenomenon of microbially influenced corrosion (MIC) was reported by the end of the nineteenth century by Garret (2), who postulated that corrosion of lead in water was caused by metabolites produced by bacterial degradation of organic matter. He suggested that biooxidation of nitrite to nitrate enhanced the corrosive action of water.

Sulfate-reducing bacteria were discovered in 1895 by Beijerinck. In 1910 Gaines (3) indicated that iron bacteria and sulfur bacteria were responsible for the corrosion of buried ferrous metals.

The formation of deposits in waterpipes by iron bacteria (in particular aerobic species *Sphaerotilus natans*, *Caulobacter*, and *Gallionella*) was investigated by Harder (4). In 1921 Grant et al. (5) produced evidence that the rate of pitting of brass was highly increased by ammonia, which could be produced by bacterial activity.

In 1934, Von Wolzogen Kuhr and Van Der Vlugt (6) proposed a theory on the direct role of sulfate-reducing bac-

teria in the corrosion mechanism by their utilization of cathodic hydrogen and stimulation of the anodic dissolution of iron.

In 1953 Uhlig reported on the role of microorganisms, such as slime-forming bacteria, fungi, algae diatoms, and protozoa, attributing their corrosive action to the formation and conservation of differential aeration and concentration cells (7).

Several reviews dealing with MIC have been published since 1971 (8–11), with a particular effort in research during the so-called energy crisis. In fact, marine fouling on offshore platforms and biofouling in industrial cooling systems, as well as the problem of oil and gas reservoir contamination by sulfide, enhanced the need for a deeper insight into the role of, and the mechanism associated with, bacterial corrosion of metal. The adoption of accelerated tests, designed ad hoc according to newly developed measurement techniques, can address the right selection of materials, surface treatments, and welding filler materials, as well as the optimization of chemical and mechanical protective or preventive measures.

MICROORGANISMS IMPLICATED IN BIOLOGICAL CORROSION

To indicate proper defensive means against corrosion of metal materials, an accurate study and a deeper understanding of the mechanisms of action of the microorganisms involved are undoubtedly of the utmost importance. An essential role in the corrosion process is often played by the cell structures, for instance, the capsular material, essentially of a polysaccaridic nature, which has a protective function and allows surface adhesion. It is in this way that microorganisms create stratified deposits under which the cell's metabolic activity takes place. The capsular material contains substances in such concentrations as to actually exert a corrosive action on metals and, further, to ensure suitable conditions for development of some anaerobic microorganisms.

Microorganisms from a wide range of genera and species are involved in corrosion problems. They may be classified in three general groups: bacteria, fungi, and algae.

Bacteria

The bacteria associated with metal corrosion are unicellular, with a rigid cell wall, and divide by binary fission. They can be either autotrophic or heterotrophic, and either aerobic or anaerobic. There are three basic shapes of unicellular bacteria: spherical, rodlike, and curved or spirilloid. They vary considerably in size. Some iron bacteria are filamentous, obtaining the energy for carbon dioxide fixation by oxidation of ferrous ions to ferric ions with the consequent precipitation of ferric hydroxide. They are responsible for the formation of tubercles in potable-water-transmission pipelines. The taxonomy and physiology of these bacteria have been reviewed by Pringsheim (12) and Stokes (13).

The most important bacteria associated with the corrosion process are those whose metabolism is closely related to the well-known sulfur cycle reproduced in Figure 1. Aerobic bacteria of the *Thiobacillus* genus, known as sulfur-oxidizing bacteria, undertake the upper part of the cycle, (i.e., the oxidation of sulfur to sulfuric acid), and the central part of the cycle (i.e., reduction of sulfate to sulfide) is carried out by anaerobic bacteria (*Desulphovibrio* and *Desulfotomaculum* genus), indicated as sulfate-reducing bacteria (SRB). A list of the SRB and their main characteristics can be found in Table 1 (modified from Ref. 14). A list of other bacteria relevant to biological corrosion is found in Table 2.

Fungi

The fungi associated with corroding metal are generally filamentous or yeastlike. Unlike some bacteria, fungi require oxygen for growth, and obtain energy for growth through aerobic oxidation of an organic substrate, which releases organic acid metabolites as the end product, or through anaerobic fermentation. The fungi can utilize hydrocarbons as a source of carbon; they may be active in largely hydrocarbon environments and have proven to be the agents responsible for the corrosion of aluminium aircraft fuel tanks in the presence of condensed water.

Algae

Algae are a heterogeneous group of chlorophyll-containing plants found in seawaters and freshwaters. They are autotrophic organisms, and algae are commonly found in cooling water systems. Their role is similar to that of the

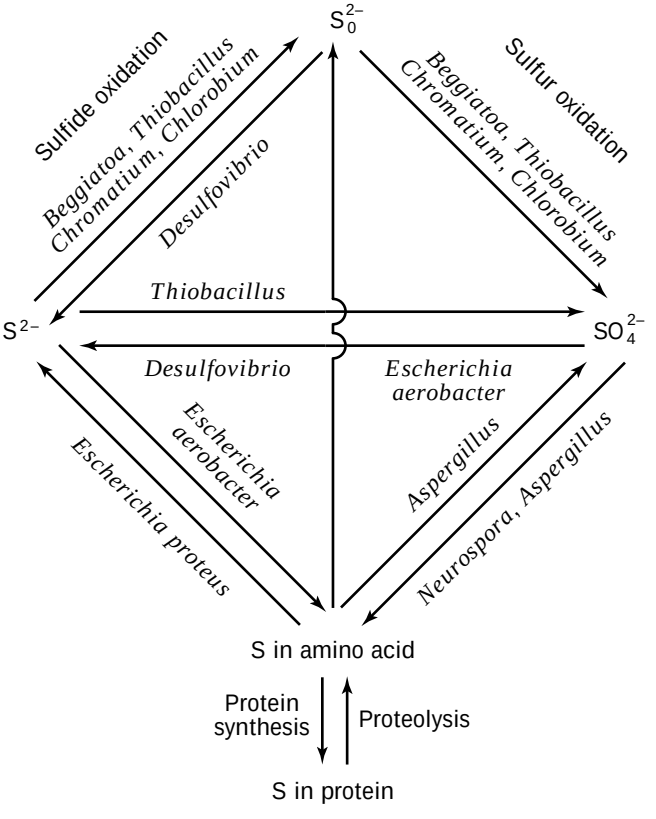

Figure 1. The sulfur cycle and microorganisms involved.

Table 1. List of Sulfate-Reducing Bacteria

Genus or species	pH	Temperature (°C)	Characteristics	Metal influenced	Mechanism
Desulfovibrio	4–8	10–40	Anaerobic	Iron and steel, stainless steel, aluminum, zinc, copper alloys	H_2 utilization to reduce SO_4^{2-} to S^{2-} and H_2S; promotion of sulfide film formation; no spore formation
Dv. desulfphuricans					Growth on pyruvate or choline in sulfate-free media
Dv. vulgaris					
Dv. salexigens					Obligate saltwater species (Cl^-)
Dv. gigas					
Dv. africanus					
Desulfotomaculum	6–8	10–40	Anaerobic	Iron and steel, stainless steel	Reduction of SO_4^{2-} to S^{2-} and H_2S; spore formation
Dt. nigrificans		55 optimum			Hydrogenase activity variable; not coupled to sulfate reduction; growth on pyruvate in sulfate-free media
Dt. orientis		10–40			Hydrogenase apparently absent
Dt. rumnis		10–40			Growth on pyruvate in sulfate-free media
Desulfomonas		10–40	Anaerobic	Iron and steel	Reduction of SO_4^{2-} to S^{2-} and H_2S

Note: From Ref. 15.

fungi: By adhering to the metal surface they encourage the formation of differential aeration and concentrate cells, thereby accelerating already-existing corrosion processes. The corrosive effect of algae attached to metal surfaces was investigated by Terry and Edyvean (15), who demonstrated that microfouling organisms readily attach to unprotected steels, cathodically protected steels, and painted steels within 100 days of exposure, causing alternating pH values night and day and enhancing pitting corrosion. Evidence of siliceous skeletons of diatoms causing defects in electroplated coatings of metals was shown by Ebneth and Ritterskamp (16).

MICROBIOLOGICAL CORROSION FEATURES

Metal corrosion in an aqueous environment is recognised as an electrochemical phenomenon where the anode reaction takes place when part of the substratum (metal) is oxidized and transferred into solution. The balancing cathode reaction consists of the contemporaneous reduction of components in the corrosive environment to fully preserve electroneutrality. Metal ions in solution might subsequently precipitate as free insoluble products, or may firmly adhere to the metal surface, where they can have a protective effect.

In favorable circumstances and under natural conditions, these films may have a protective function; a typical example of this function was seen in archaeological findings consisting of iron handiwork, which is well preserved even though found in corrosive ground. These well-preserved items were covered with a slightly compact, tightly adherent, thin, black film of ferric and ferrous phosphate.

When the metal is submersed in water, wet soil, or any other aqueous system, the initial reaction is metal dissolution to cation, which involves freeing of electrons:

$$Fe \rightarrow Fe^{++} + 2e^-$$

For the corrosion to continue, these electrons need to be consumed by reduction reactions that take place on the same metal on the so-called cathodic sites. Generally, the oxygen reduction to hydroxyl ion is the most common cathode reaction in a neutral environment:

$$O_2 + 2H_2O + 4e^- \rightarrow 4OH^-$$

In a neutral environment, the overall reaction is formation, and possibly subsequent precipitation, of insoluble products by the reaction of the ferrous ions with the hydroxyl ion (and, often, oxygen) in solution. As a rule, reactions occur evenly over the metal surface. Anode sites may be determined by either heterogeneous material (e.g., stress areas, inclusions) or preexisting, unevenly distributed oxide films. The overall corrosion rate may depend on quite a number of factors: Anode and cathode reactions, however, must remain balanced in the process to fully maintain electroneutrality. Lacking oxygen, the cathode reaction that may replace the preceding reaction in aqueous ambient in sustaining the corrosion process is reduction of the ion H^+, as follows:

$$2H^+ + 2e^- \rightarrow H_2$$

The reaction, however, is quickly checked in neutral solutions so that the corrosion process is rapidly stopped. At lower pH values, hydrogen evolution usually prevails, in both the presence and absence of oxygen. Besides these basic reactions, other factors affect the whole process such as, in particular, the metal surface microgeometric characteristics and the ambient oxygen concentration variation that creates differential aeration cells. Cathode sites are, in this case, the highest oxygenation areas. Similar concentrations of cells may occur on metal in the case of con-

Table 2. List of Other Bacteria Relevant to Microbial Corrosion

Genus or species	pH	Temperature (°C)	Characteristics	Metal influenced	Mechanism
Thiobacillus thiooxidans	0.5–8	20–40	Aerobic	Iron and steel, stainless steel	Sulfur and sulfide oxidation to H_2SO_4; protective coating damage
Thiobacillus ferrooxidans	1–7			Iron and steel	Fe^{2+} oxidation to Fe^{3+}
Gallionella	7–10			Iron and steel, stainless steel	Fe^{2+} oxidation to Fe^{3+}; manganous oxidation to manganic; tubercule formation promotion

P. aeruginosa	4–8			Aluminium alloys	

tact with soils or solutions where the concentration of aggressive ions is not homogeneous.

Many articles (10,11,17,18) on this subject have originally assumed that in order to participate in the corrosion process, microorganisms ought to be in a vegetative phase and produce oxydizing agents through their metabolism, or else directly intervene in one or both of the metal's electrochemical reactions. It has always been known that all bacterial colonies (not only the ones consisting of vegetative cells) may be responsible for differential aeration cell formation on metal surfaces. Microhabitats generated by these colonies often create anaerobic conditions that stimulate, in turn, the activity of SRB.

There are several ways of classifying MIC, such as on the basis of the metabolism of implicated microorganisms, as follows (10,11,19):

- Absorption of nutrients by microbial growth in adhesion to the metal surface
- Evolution of corrosive metabolites or end products of fermentative growth
- Sulfuric acid production
- Interference in the cathodic process under anaerobic conditions by obligate anaerobes

Another method of classification is on the basis of the mechanism involved (20):

- Corrosion by SRB
- Corrosion by acid producers
- Corrosion due to heavy microbial growth and deposits
- Corrosion associated with the rupture of protective coatings

Even though such classifications are useful, the mechanism and means of recognition of MIC are discussed, in view of industrial application, with reference to aerobic or anaerobic environmental conditions. Some practical examples are reported as well to provide the reader with the visual appearance of different MIC phenomena and practical ways of identification.

Bacterial Corrosion under Aerobic Conditions

Many aerobic microorganisms are capable of affecting the corrosion process. Some microorganisms are responsible for surface cell-deposit formation (bioscaling phenomena). In a marine environment, the biofouling phenomenon is mostly due to cirripeds, mussels, and so on. The corrosion process, in such cases, consists of formation of a differential-aeration cell due to oxygen assumption by the microbial colonies, tending to exhaust oxygen concentration under such mass. Poorly aerated surfaces behave as anodes, while better aerated surfaces, farther from the deposit, provide the cathode balancing of the reaction. The simple mechanism of aerobic corrosion is schematized in Figure 2 (after Ref. 10).

The formation of an occluded area on a metal surface is a mechanism potentially involved in MIC. It is based on the observation that when microorganisms form colonies on the surface of a metal, they do not constitute uniform layers but local colonization sites related to such metallurgical features as roughness, inclusions, surface charge, and superficial defects. The development of an occluded cell formed by sticky polymers is reproduced in Figure 3; biological and nonbiological (e.g., metals and chloride) species tend to aggregate to the colony site.

Microbiological corrosion on a reactor made of steel, with no addition of particular alloy elements and belonging to the FE33 commercial category, can be so marked under aerobic conditions as to be detectable by simple optical microscopy. A case study, taken from a reactor employed for yeast biomass industrial production and showing uniform generalized corrosion, is shown in Figure 4. The corroded surface, examined under a scanning electron microscope and reproduced in Figure 5, shows how the difference in molar volumes existing between oxide flakes and metal causes the process of spalling. Spalling of the corrosion products and superficial pitting due to the action of localized cellular deposits are shown in Figure 6.

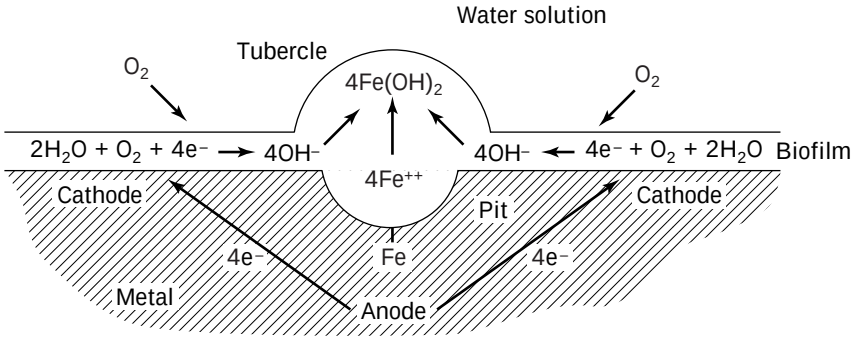

Figure 2. Aerobic corrosion mechanism by differential aeration cell (after Ref. 10)

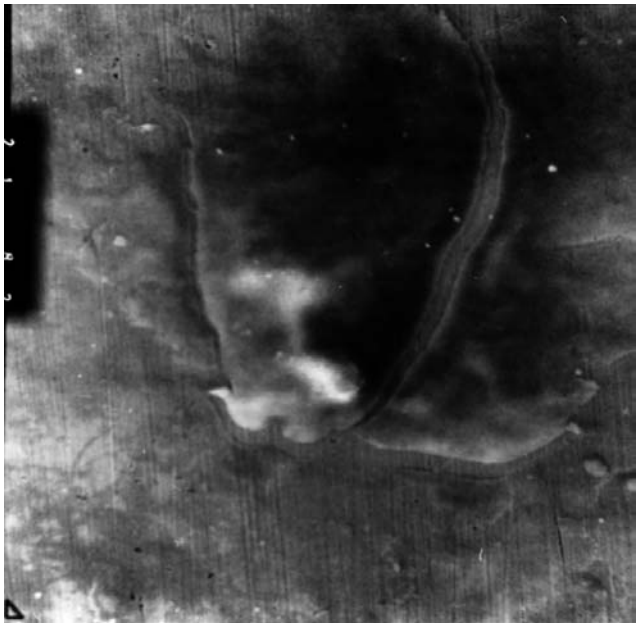

Figure 3. AISI 304 (500×): development of occluded cell under aerobic conditions.

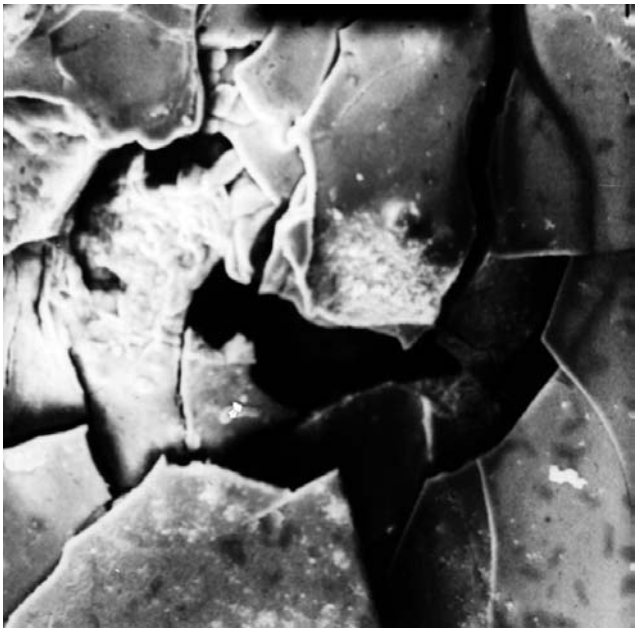

Figure 5. FE33 (500×): morphology of aerobic corrosion products showing spalling phenomenon.

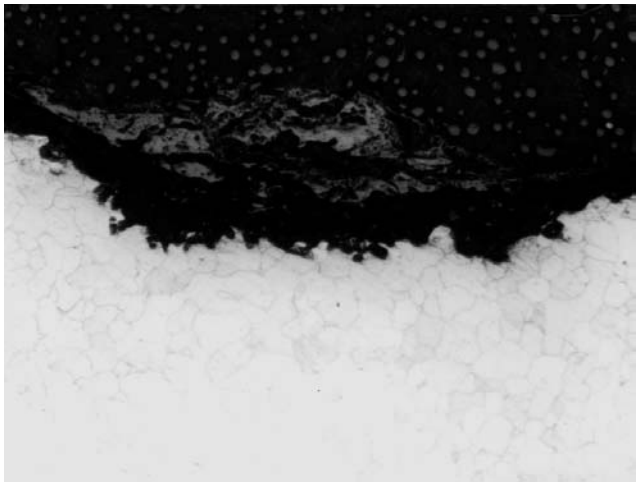

Figure 4. FE33 (120×): uniform generalized aerobic corrosion phenomena.

One particular type of aerobic corrosion is due to microorganisms belonging to the *Thiobacillus* genus. These are chemio-lithotrophic microorganisms that draw the energy needed for their vital processes from oxidation of inorganic substances. The nutrition functioning of these microorganisms, in particular *Thiobacillus ferrooxidans*, was investigated; various models have been proposed, among which one of the most feasible is that iron as a complex is absorbed through the microorganism's cell wall and donates the electron to the respiratory tract. The energy liberated during the subsequent metabolic phases is employed to form ATP, and the ferric iron and water formed are expelled from the cell, forming colloidal ferric hydroxide (21). So little energy is made available through the ferrous iron oxidation reaction (about 6.6 kcal/g-atom) that the organism is compelled to oxidize vast quantities of iron to obtain what it needs to grow.

Another type of microorganism, *Thiobacillus thiooxidans*, is capable of producing sulfuric acid. The relevant

Figure 6. FE33 (300×): spalling of aerobic corrosion products and superficial pitting due to localized cellular deposit.

mechanism has been studied in detail by Booth (22) and Purkiss (23): The generally accepted path involves the following reactions that may depend on the substrate and the environment:

$$2H_2S + 2O_2 \rightarrow H_2S_2O_3 + H_2O$$

$$5Na_2S_2O_3 + 4O_2 + H_2O \rightarrow 5Na_2SO_4 + H_2SO_4 + 4S$$

$$4S + 6O_2 + 4H_2O \rightarrow 4H_2SO_4$$

Bacterial Corrosion under Anaerobic Conditions

According to the previously mentioned considerations concerning electrochemical reactions, a corrosion process involving ferrous metals would seem unlikely in a near pH-neutral, oxygen-deficient environment, because neither of the two common cathode reactions can take place under these conditions at a sustained rate. This, however, is not always true, and when a corrosion phenomenon takes place in such conditions it is much more serious than under aerobic conditions.

The main factor responsible for this problem is the activity of SRB as well as their sulfured metabolic products. Buried metals corroded by this sort of process are one example of the severe economic losses and damage caused by this type of corrosion.

The process of anaerobic corrosion is characterized by a coating on corroding steel consisting of strongly reduced black sulfide–containing corrosion products. Graphitization takes place in cast iron, and little superficial evidence of corrosion can be noticed; the iron migrates from the material, leaving a soft residue, mainly carbon-made. As with bacterial involvement in the corrosion process, the explanation proposed by Wolzogen Kuhr and Van der Vlugt (6) is based on the assumption that cathode hydrogen may be utilized for sulfate reduction; the equations describing the process are as follows:

$$4Fe \rightarrow 4Fe^{2+} + 8e^- \quad \text{anode reaction}$$

$$8H_2O \rightarrow 8H^+ + 8OH^- \quad \text{water dissociation}$$

$$8H^+ + 8e^- \rightarrow 8H \quad \text{cathode reaction (*)}$$

$$SO_4^{2-} + 8H \rightarrow S^{2-} + 4H_2O \quad \text{cathode depolarization (*)}$$

$$Fe^{2+} + S^{2-} \rightarrow FeS \quad \text{corrosion product}$$

$$3Fe^{2+} + 6\,OH^- \rightarrow 3Fe(OH)_2 \quad \text{corrosion product}$$

The overall reaction can be written as

$$4Fe + SO_4^{2-} + 4H_2O \rightarrow 3Fe(OH)_2 + FeS + 2OH^-$$

Through the reactions marked by an asterisk, a biological action develops, bringing about hydrogen activation that, in turn, causes sulfate reduction. Several research projects carried out in recent years seem to support this assumption (24,25); lately, however, some studies point to an alternative process involving sulfide and the iron sulfide film (26,27).

Laboratory studies employing cultures of SRB are unlikely to produce heavily-pitted corrosion, and normal iron oxide and hydroxide corrosion products are nearly always absent. A similar phenomenon also occurs in the presence of elementary sulfur, which often forms, under natural conditions, in the periphery of pitted areas; it very seldom does so under laboratory conditions.

A combination of these and other observations related by King and Miller (27) has led to a more critical approach to the classic theory. In view of the particularly complex problems involved, we find it advisable to analyze the classic theory and cathode depolarization alternative mechanism separately.

Classic Theory. The Classic theory is based on the fact that some SRB strains possess the hydrogenase enzyme, which is capable of catalyzing both the reversible reactions involving hydrogen; that is,

$$H \leftrightarrow 2H \leftrightarrow 2H^+ + 2e^-$$

as well as sulfide reduction using molecular hydrogen, according to following:

$$SO_4^{2-} + 4H_2 \rightarrow S^{2-} + 4H_2O$$

Hydrogenase-positive strains of alophile, thermophile, and mesophile bacteria were shown by Booth and Tiller (28) to be capable of cathode depolarization, whereas hydrogenase-negative bacteria proved completely inactive in this process. Thus, strains such as *Desulphovibrio desulphuricans* and *Desulphovibrio vulgaris*, both hydrogenase positive, use the cathode hydrogen for substrate reduction, whereas hydrogenase-negative strains, such as *Desulfotomaculum orientis*, were found to play no role at all in this mechanism.

Among other hypotheses, a relation has been supposed to exist between the microorganism hydrogenase coefficient and the corrosion rate. In this manner, the steel corrosion rate would be related to hydrogenase activity, even if only in the limited field of experimental conditions. However, subsequent experiments that employed active cell cultures of several different strains of SRB indicated that the corrosion rate did not depend on the hydrogenase activity. And, further, hydrogenase-negative bacteria proved to be at least as aggressive as the *Desulphovibrio* species. This clearly indicates that other factors must be involved.

Cathode Depolarization Alternative Mechanism. Studies on cathode depolarization always refer to the acknowledged property of sulfides, both in solution and in solid state, (for instance, elemental sulfur) to act as corrosive agents. Further, it might be noted that the mild steel corrosion rate increases by up to 230% when in contact with iron sulfide. Serious corrosions in acidic environments were likewise found to be imputable to the presence of sulfured compounds and to elemental sulfur, with the corrosion rate varying from 5.3 mm per annum for iron sulfide to 1,100 mm per annum for sulfur.

Laboratory studies on the influence of ferrous iron on anaerobic mild steel corrosion by active SRB cultures hinted that a protective film was formed on the metal surface at low iron-ion concentration. However, the presence in solution of sufficiently high iron concentrations caused all of the bacterially produced sulfide to precipitate as iron sulfide, so that no protective layer was formed in the medium on the metal and the corrosion rate increased considerably (29). Electrochemical studies showed that substantial and energetic cathode depolarizations took place, even if the ferrous iron concentration was subsequently reduced.

In a previous study (30) associated with bacterial growth in a medium containing 0.5% ferrous iron, the corrosion rate of mild steel was shown to be an approximately linear function of time and independent of the hydrogenase activity of bacteria. The results of further tests clearly showed that the highest contribution to the corrosion process is provided by the ferrous sulfide mechanism. A comparison between mild steel corrosion by means of chemically prepared and biogenic ferrous sulfide indicated that at high ferrous iron concentrations most of the corrosion in bacterial cultures may be ascribed to biogenic ferrous sulfide. King et al. (31) showed that corrosiveness of chemically prepared ferrous sulfide is a stoichiometric function of sulfur, and that stimulation of corrosion due to iron sulfide decreases with time.

High corrosion rates in free bacterial systems may only be obtained by means of a continuous iron sulfide supply. The efficiency decrease of depolarization due to iron sulfide as a function of time without the presence of bacteria is ascribed to the hydrogen atomic bond of the iron sulfide structure. However, the iron sulfide activity may be renewed in the presence of SRB because of their capability of using the hydrogen contained in the film. In this way an explanation can be provided for this alternative mechanism, which is considered responsible for the high corrosion rate observed in the ground.

Under anaerobic conditions, too, the mechanism of formation of occluded areas on the metal surface is often associated with microbiologically induced corrosion. In connection with the development of occluded cells, microorganisms create conditions under the colony very different from those on the surrounding metal, leading to the formation of crevices (as shown in Fig. 7) as well as of ion concentration cells. This hypothesis is supported, in the presented case study, by energy dispersion spectrometer EDAX™ investigation revealing the presence of a series of deposits containing Fe, Cr, Ni, Mo, Ca, and S.

In parallel with the previously mentioned phenomenon, it may be noted that the microbiological community usually remains fixed to the colonization site, thus fixing the anodic site. The resulting pitting corrosion is characterized by the formation of small anodes and corresponding large cathodes, which allow the formation of pits in the metal matrix. Figure 8 shows incipient pitting triggered by microbiological activity on AISI 316. Incipient pitting engendered by microbiological activity on AISI 347 is shown in Figure 9; a detail of pits in the growing phase on the same metal is shown in Figure 10.

An example of intergranular corrosion, usually taking place on the border of uniform corroded areas, is reproduced in Figure 11. EDAX™ investigation (Fig. 12) on the selected corroded point revealed the presence of the following elements (% w/w): S: 1.58, Ca: 0.17, Cr: 34.7, Fe: 48.4, and Ni: 15.15. In the surrounding area the following elements were present (% w/w): Nb: 2.3, Cr: 14.7, Fe: 70.7, and Ni: 12.3.

DETECTION AND MONITORING OF MIC

In the recent past, the most important developments related to MIC research were provided by a multidisciplinary

Figure 7. AISI 304 (1,000×): crevice corrosion due to the formation of occluded area.

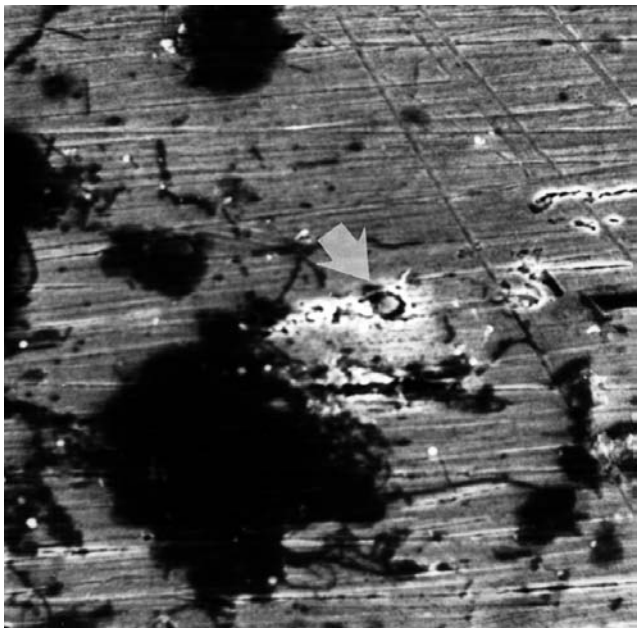

Figure 8. AISI 316 (1,000×): anaerobic incipient localized pitting corrosion.

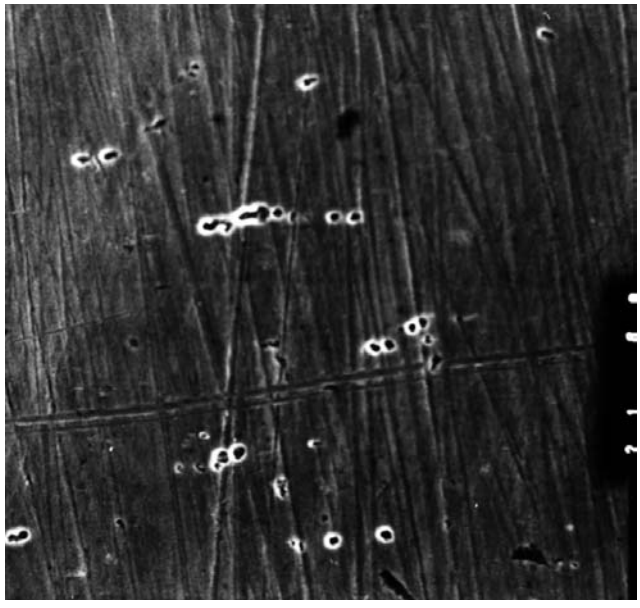

Figure 9. AISI 347 (1,000×): anaerobic incipient pitting corrosion.

approach combining nondestructive analytical and electrochemical investigation methods. Indeed, appropriate techniques for detection and monitoring of the phenomenon are essential to dealing successfully with the nature of mutual interactions and to setting up effective control methods. Evidence of MIC lies in the conspicuous presence of microorganisms in those areas where the integrity of the material has deteriorated markedly. However, the electrochemistry of MIC has not been clearly defined because of the limits of the techniques employed in detection and monitoring (32). Some of the most important developments in MIC research over the past years were the result of a combination of nondestructive analytical and electrochemical methods aimed at characterizing microbial biofilms and corrosion reactions (33). In the following, the main traditional and innovative techniques are briefly presented and discussed.

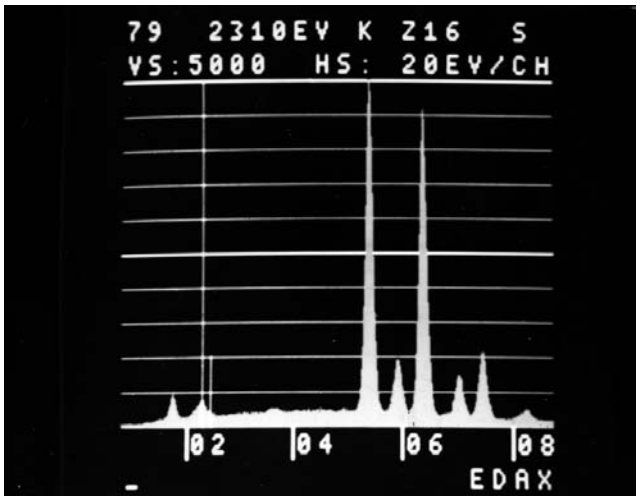

Figure 12. EDAX™ investigation in correspondence to the corroded point shown in Figure 11.

Microscopic Analysis

The identification of bacteria in pitted areas by means of scanning electron microscopy (SEM) was performed by several researchers (34–37), even though microbially induced pitting on stainless steel, the degree of interaction on this material being limited to a few surface monolayers, is not easily revealed. Moreover, it requires large amounts of corrosion products.

Energy-dispersive X-ray spectroscopy is widely applied in analyzing pit composition and is commonly employed for failure analysis of corroded metals. Recently developed (38) atomic force microscopy was applied to investigate sample topography in corroded pipework, allowing the analysis of profiles, depth, and size of pits, even in the presence of a nonconductive sample. In situ biofilm formation occurring under MIC conditions may be monitored by confocal laser microscopy (39); it allows the attainment of three-dimensional biofilm structure and has the potential of becoming an important method in the study of MIC kinetics.

Spectroscopic Analysis

Fourier transform infrared spectroscopy has been applied to monitor copper corrosion under biofilm (40,41), adopting Ge (an IR transparent internal reflection element) as substratum to be coated by a thin Cu film. The technique is severely limited by IR absorption by water, as well as by its inability to distinguish dead cells from live ones. X-ray photoelectron spectroscopy (XPS) and Auger electron spectroscopy (AES) may provide meaningful information about corroded surface composition and chemical states, as binding energies of the photoelectrons and Auger electrons are atom specific and changes in the binding energies of electrons are related to electron distribution around the atom. The limitations of these techniques, recently applied to study MIC (42–44), are connected with the kinetic energies of the Auger electrons and photoelectrons, which permit characterization of only few monolayers of the top surface, as well as with the need for cooling equipment to prevent bioproduct evaporation and decomposition under operative conditions (ultrahigh vacuum $<10^{-9}$ torr). XPS can provide composition and valence states of surface elements, as well as explore the mechanicistic nature of MIC over a relatively large area; Auger electron spectroscopy may be used to analyze smaller areas, obtaining chemical information of pits (31).

Extended X-ray absorption fine structure (EXAFS) may be employed to characterize enzymatic corrosion products created by bacterial consortium on metal surfaces (45,46), exploiting the oscillation of X-ray absorption spectrum in the range of 1 keV above the K-absorption edge (47). Limitations are related to in situ monitoring, as the X-ray energy may be too high.

Electrochemical Techniques

Conventional electrochemical techniques for detection and monitoring of MIC have been used for a long time and include corrosion and pitting potential measurements, linear polarization resistance (48), and electrochemical direct current (DC) methods (49,50); these techniques provide evidence of MIC and partial mechanistic information on loss of corrosion resistance and on electrochemical interactions (51), even if DC techniques require high applied currents and therefore can alter biofilms. Large polarization techniques have limited applications in MIC studies because of the destructive nature of applied currents to microbial biofilms. Consequently, electrochemistry of the biofilm–metal interface can be better investigated by means of techniques requiring small or zero applied potential.

Time-dependent changes in open circuit potential (OCP) were used to prove 316L stainless steel oxidation under a photosynthetic biofilm producing oxygen under illumination (52). Combined OCP and redox potential measurements of the bacterial medium permit accurate estimation of the corrosion tendency of a metal in microbially active environments (53), as well as of changes occurring in the passive films. Time-dependent changes of galvanic current between identical electrodes in dual cells demonstrated the effects of biofilms on induction of corrosion (54,55).

The concentric electrodes system, consisting of a small area anode surrounded by a large-area annular cathode, allowing maintenance of a uniform current profile with reduced overpotential, was successfully applied to monitor pitting commencement and development in SRB-containing anaerobic artificial seawater (56). Because the passive film has a blocking effect on anodic dissolution, this test apparatus, if employed with stainless steel, can result in overpotential to the anode so much higher than the redox potential as to impair bacterial growth.

The scanning electrode technique (SVET) has provided a nondestructive, on-line method to define the magnitude and sign of current densities in solution over freely corroding metals; in particular, it was applied to locate the presence and position of anodic electrochemical activity on the surface of carbon-steel samples by analysis of current maps and OCP (57), demonstrating the possibility of ob-

taining qualitative and quantitative information regarding localized corrosion influenced by bacteria.

Electrochemical impedance spectroscopy (EIS) was used to investigate the impedance of metal specimens exposed to microbial biofilms, in conjunction with biofilm analyses. It consists of the measurement of amplitude and phase shift of sinusoidal currents resulting from the application of small-amplitude sinusoidal signals to metal samples over a large frequency range (10 kHz to 5 mHz) (58). EIS can provide polarization resistance values (inversely proportional to corrosion rate), double-layer capacitance, and solution resistance so as to evaluate localized corrosion and three-dimensional surface deposits (51).

Future studies of MIC electrochemistry will focus on the combined use of different techniques, includings, confocal laser microscopy to characterize biofilm structure, EIS to investigate initiation of pits too small to be observed microscopically, and XPS and AES to analyze the surface chemistry and structure resulting from the corrosive phenomenon.

PROTECTIVE AND PREVENTIVE MEASURES

Replacement costs, maintenance shutdown, and loss of profits caused by microbiologically influenced corrosion of metal structures are problems in many industries. MIC, once recognized, is a question of optimizing prevention measures and minimizing maintenance and countermeasure efforts. Studies of MIC have addressed both understanding the complexities of microbial interactions with metal substrata and setting up protective and preventive measures. In particular, the involvement of microbial biofilms was amply investigated in the corrosion of several metals, including aluminium (58), copper (59), mild steel, and stainless steel (60). No universal approach to prevent MIC, has been developed so far, however, and the problem is tackled more from the corrosion than from the microbiological viewpoint.

Cathodic Protection

Cathodic protection principles and theory have been discussed extensively in the literature (61,62). Two techniques are commonly adopted: sacrificial anodes usually made of magnesium, zinc, or aluminium alloys, which corrode preferentially to provide structure protection, or impressed current from a rectifier via an inert anode. The cathodic protection method is used extensively to protect structures buried in soil or in marine environments.

In the absence of SRB, protection of steel is achieved at a potential depression of -0.85 V versus $Cu/CuSO_4$. In the presence of a soil environment presenting risk of microbial corrosion, a further -0.1-V potential depression is required to ensure the protection of the structure (63,64). The achievement of this value allows the suppression of SRB growth as well, even if, in the case of bare steel in direct contact with soil, the formation of iron sulfide can lead to extraordinary current requirements. On the other hand, far lower potential values must be avoided, because hydrogen cracking and alkaline blistering of protective coatings can occur.

In the presence of cell suspensions of sulfate reducers, a linear relationship between the hydrogenase-enzyme microbial activity and the additional current requirement to maintain different cathodic potential was verified (63). A focal conclusion is that the corrosion rate is enhanced in the case of an incompletely protected sample because of the accelerating effect of bacteria (65).

Protective Coatings

Protective coatings provide a barrier, impermeable to soluble aggressive species, between the metal and the surrounding environment. The range of available protective coatings is wide, and includes products based on coal tar, asphalt bitumens, epoxy resins and coal tar epoxies, thermoplastic polymers, synthetic polymeric coatings, and cementitious materials. Paints are also used as coating materials. Many of these coatings, being of organic nature, may biodeteriorate. Moreover, they usually cannot prevent gas diffusion and, for instance, allow hydrogen sulfide to pass the coating layer and reach the metal.

In marine environments, metallic coatings, especially aluminium and zinc, are often employed. Protection of steel by these metals is partly due to both their action as physical barriers and their anodic effect on the basic material.

In terms of industrial applications, when contamination connected with corrosion products must absolutely be avoided (e.g., in the food and pharmaceutical industries), the inner sides of plant sections or apparatuses should not be lined with coatings or resins (e.g., epoxy resins). In fact, the resulting unevenness (pores, microcrevices, blisters) might cause an extremely nonuniform, seriously corrosive process under the coating, due to an unfavorable relation between anodic and cathodic zones (66). Figure 13, referring to a FE33 steel sample from a reactor employed in yeast-biomass production, clearly demonstrates how crevice or surface unevenness of the protective paint leads to corrosion under the coating—a process detectable only under an optical microscope.

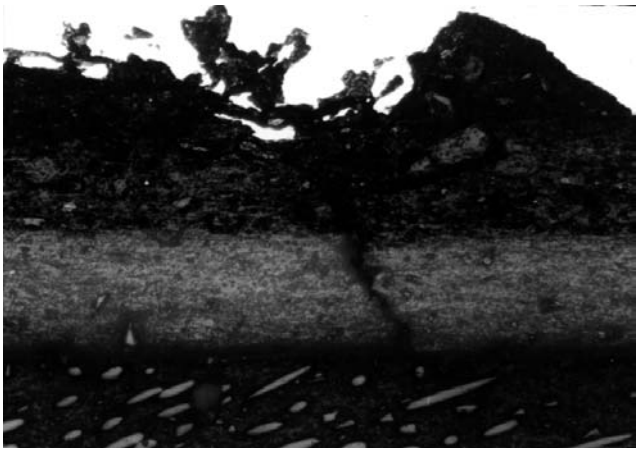

Figure 13. FE33 painted (300×): start of aerobic MIC below the paint due to protective coating unevenness.

Inhibitors and Biocide

In closed systems it is possible to use corrosion inhibitors and biocides to stop or limit the biological activity. The use of such chemicals has limitations because biocides are potential hazards to health and environment. Organic biocides can take part in complex and uncontrolled reactions, and completely unexpected compounds can be formed. Oxidizing biocides, for example, hydrogen peroxide, which cause death of cells by attacking cell enzymes, can be used in cooling systems and drinking water mains. Oxygen-based biocides (e.g., ozone) are used to prevent bacterial hydrogen-sulfide production. Nonoxidizing biocides, which cause cell-wall rupture, blockage of enzyme systems, or denaturation of proteins, include heavy-metal organic compounds, organic copper salts, organic sulfur compounds, amines, chlorinated phenols, and quaternary ammonium salts. The treatment is ineffective if the bacteria have previously formed nodules as their habitat, so in this case a preventive mechanical removal of nodules is necessary.

Careful and well-documentated observations by plant operating engineers have recognized the efficacy of regular scraping in pipeline corrosion control; experimental runs showed that well-established consortia of SRB are deeply disturbed by the mechanical treatment, with reestablishment only after 1–2 weeks (67). On the basis of these remarks, microbial corrosion in pipelines can be effectively prevented or controlled by combining mechanical scraping to remove protective nodules with proper dose treatment using a penetrating biocide (68).

Remedial action in the case of SRB-induced corrosion is usually approached by a combined action consisting of the application of a biocide and a corrosion inhibitor. Compounds such as molybdate show a double effect, inhibiting both SRB and the corrosion (69). It was observed (70) that 18 mM 2-*n*-Heptyl-4-hydroxyquinoline *N*-oxide inhibited respiration in *Hemophilus parainfluenza* by blocking electron transport between cytochromes b and c_1. Inhibition of the periplasmic hydrogenase enzyme in *Desulfovibrio vulgaris* was verified by both carbon monoxide and copper II chloride (71). In case of *Desulfovibrio desulphuricans*, characterized by a cytoplasmatic hydrogenase, only carbon monoxide was found effective in inhibiting the hydrogenase, and copper II chloride had no effect (72). Sodium molybdate evidenced inhibiting action on stainless steel corrosion by making passive the anodic reaction of an active corrosion cell and inhibition of the growth of a culture of *D. vulgaris* and unidentified *Vibrio* sp. (73). The main conclusion is that viable bacteria are necessary only in the early stages of pit formation, and not for the maintenance of galvanic current; in any case, the effective treatment of actively pitting systems requires the adoption of both a corrosion inhibitor and a biocide.

Alternative Materials

Solution of the problem of MIC based on safety considerations (74) may consist of the application of the substitution principle, in which a safer material is used in place of a more hazardous one, thus decreasing the need for added protective equipment and also decreasing plant cost and complexity. The use of common steel should be avoided in the construction of industrial plants for bioleaching of mine drainage. Biologic desulfurization of pit coal and the use of stainless steel, such as AISI 304, is compulsory to avoid safety problems connected with possible metallic structure failures (75). A number of resistant alloys providing adequate corrosion strength are available (e.g., all experimental runs on higher nickel–chromium alloys and titanium highlight their resistance to MIC), although their cost makes their use uneconomical in most situations. Steel and iron will be replaced extensively by nonmetallic materials, such as composite fiber reinforced resin systems, due to the availability of reliable and long-lasting materials. Other plastic materials, such as PVC and polyethylene, must be used with care, because they may contain plasticizers susceptible to biodeterioration, resulting in progressive embrittlement of the polymer. Cement products, including spun concrete and reinforced or prestressed concrete, are widely used for buried piping; however, their selection must be site specific, because they may have problems in some heavily contaminated soils and waters (63,76).

CONCLUSIONS

Microbiological corrosion is an interesting but costly and frustrating problem more widespread than one would expect, and it is often associated with the more common problem of biofouling. Microorganisms play a very complex role, and several mechanisms were suggested to highlight their involvement in the corrosion process. In many instances their role consists of the formation of differential aeration and concentration cells, in the production of aggressive metabolites, or in the acceleration of an existing corrosion process. Microbial involvement in the process can be indicated by localized corrosion associated with tubercles, discolorations, slime, anaerobic metabolism odors, sludges, and underdeposit corrosion phenomena.

The majority of these problems can be ascribed to SRB. The knowledge of aspects of SRB physiology and of their ability to grow on hydrogen, as well as the role of enzyme hydrogenase, has shown the most probable mechanism of corrosion due to these organisms.

From a practical industrial viewpoint, avoidance or minimization of microbial corrosion problems can be faced first by optimal selection of materials and, subsequently, by interposition of barrier systems or modification to the surrounding environment. The combined use of chemical inhibitors and biocides represents the most common solution to dealing with internal problems in process systems.

MIC problems will be positively contained and safely controlled in industrial situations only if designers and plant operators properly consider projects, design features, operating and maintenance procedures, and system monitoring.

OUTLINE

INTRODUCTION

Corynebacteria and brevibacteria are Gram-positive, aerobic actinomycetes. The primary industrial interest in corynebacteria and brevibacteria relates to the production of amino acids by fermentation. In 1956, a researcher at Kyowa Hakko Kogyo Co. in Japan isolated soil bacteria capable of producing large amounts of glutamic acid (1). Until that time, glutamic acid was produced commercially from *konbu* a type of seaweed used in popular Japanese cuisine. The discovery of these bacteria proved to be a major innovation in the industry at the time, and today these bacteria account for worldwide production of more than 800,000 metric tons of glutamic acid (primarily for use as a flavor enhancer) and 330,000 metric tons of lysine (for feed additives) annually.

SPECIES RELATIONSHIPS AMONG GLUTAMIC ACID–PRODUCING CORYNEBACTERIA

When first identified, the species we now call *Corynebacterium glutamicum* was classified as *Micrococcus glutamicus*. Several "species" of glutamic acid–producing bacteria were similarly identified by a number of groups, and classified into genera such as *Brevibacterium*, *Corynebacterium*, *Arthrobacter*, and *Microbacterium*. During the subsequent four decades, considerable effort has been spent on reconciling the phylogeny of these bacteria. Nonetheless, the scientific literature regarding these bacteria is still laden with inconsistencies in the nomenclature, and an opportunity exists to establish conventions for species designation among these bacteria.

Systematics among the glutamic acid–producing bacteria have evolved from the classical morphological and physiological analyses to include molecular genetic characterizations. It can be argued that morphological analyses caused much of the confusion encountered in the literature because corynebacteria and brevibacteria belong to a group of bacteria, frequently called the "coryneform" bacteria, whose common characteristic appears to be pleomorphism. Abe and coworkers (2) identified several characteristics that are useful for distinguishing the corynebacteria and brevibacteria from sister clades. In addition to their prolific glutamate production under aerobic conditions, they require biotin, and individual bacteria are

nonmotile, nonsporulating, and occur as short clubs or rods in V-shaped aggregates of two or more. Chemotaxonomic information has permitted a more methodical classification of these bacteria (3). Based on the presence of relatively short-chain mycolic acids (containing 22–36 carbon atoms) in the cell walls, and the types of lipids that comprise their cell membranes, these bacteria cluster with members of the genera *Rhodococcus, Mycobacterium*, and *Nocardia* into an informal collection known as the CMN group, which includes many medically significant pathogens.

In recent years, molecular systematics have been used to more precisely define the glutamic acid–producing bacteria. Chromosomal DNA of the glutamic acid–producing bacteria comprises approximately 52–56 mol % G + C. Comparison of 16S and 23S ribosomal RNA structures has revealed that many of the glutamic acid–producing species that have traditionally been classified into the different genera *Corynebacterium* and *Brevibacterium* (e.g., *B. divaricatum, B. flavum, B. lactofermentum, C. glutamicum*, and *C. lilium*) may all actually be members of the same species, *Corynebacterium glutamicum* (4). In the same studies, other species within the genus *Brevibacterium* (e.g., *B. linens*) were found to be much more distantly related, containing a higher G + C content in their genomic DNA, showing greater divergence among their ribosomal RNA structures, and lacking the mycolic acids that are characteristic of the CMN group. For this reason, in this article we shall refer to all of the glutamic acid–producing bacteria simply as corynebacteria, with emphasis on the well-characterized *C. glutamicum*.

COMMERCIAL INTERESTS IN CORYNEBACTERIA

The main industrial interest in corynebacteria concerns the production of amino acids. The twenty amino acids can be commercially manufacture and are used in a variety of products including food additives, animal feed supplements, cosmetics, and medicines, as well as some industrial applications. Currently, the highest revenues are from the animal feed industries and human food uses. The overall global market for amino acid animal feed additives is estimated to be worth more than $2 billion, and totals about 700,000 metric tons of material. Lysine and methionine account for an overwhelming majority of the market, which also includes lower-volume products such as threonine (Table 1). The market for monosodium glutamate alone, used in the human food industry as a flavor enhancer, is also estimated to be $2 billion. The worldwide market growth rate is around 8–12% annually for amino acids (5), but individual amino acids could experience different spurts of growth. For example, the price of cysteine doubled during 1996 due to increased demand that sparked a worldwide shortage (6). In 1990, the world production of threonine was 1,000 metric tons per year, but already new projects will give BioKyowa, for example, a total capacity of 10,000 metric tons annually for tryptophan and threonine in 1998 (7).

In 1990, aspartic acid was produced at around 10,000 metric tons per year, mainly for the production of aspartame. Most of the world's aspartic acid still goes into aspartame, but Donlar Corp. and Rohm & Haas believe the emerging application for polyaspartate, a newer specialty polymer with a wide range of applications, will drive new production of aspartic acid (8).

Table 1. Industrial Production of Amino Acids

Amino acid	Worldwide production (ton/year)	Production process
L-Glutamic acid	>800,000	Production by corynebacteria
L-Lysine	330,000	Production by corynebacteria
DL-Methionine	350,000	Chemical synthesis
L-Aspartic acid	10,000[a]	Bioconversion by *E. coli*
L-Phenylalanine	5,000[a]	Production by corynebacteria
L-Threonine	1,000[a]	Production by corynebacteria and *E. coli*

[a]Production data from 1990; all other data from 1997.

Amino acids are produced industrially by four different processes: production in reactors by bacteria (glutamate, lysine, phenylalanine, threonine, tryptophan, valine), bioconversion (aspartic acid), chemical synthesis (methionine), and extraction from natural materials (cysteine). Corynebacteria in particular are involved in the production of the two most important amino acids, glutamic acid and lysine (Table 1).

Corynebacteria are able to accumulate 8–10 times as much intracellular amino acid, such as glutamic acid, as accumulated by Gram-negative bacteria such as *Escherichia coli* (9). In addition, the amino acid biosynthetic pathways in corynebacteria are usually less strongly regulated than those in *E. coli*, for instance (Fig. 1). *E. coli* has three isoenzymes for aspartokinase and as many as five for acetohydroxy acid synthase (AHAS). The abundance of isoenzymes complicates the prospects of using genetic engineering to improve amino acid production in *E. coli*. These observations explain why corynebacteria are preferred for the production of the major amino acids.

Other industrial applications for corynebacteria concern the production of vaccines from *Corynebacterium tetani* and *C. diphtheriae* (10), the production of L-malic acid from fumaric acid by the fumarase of immobilized *Brevibacterium ammoniagenes* (11) and the production of L-ascorbic acid by 2,5-diketo-D-gluconic acid reductase of *Corynebacterium* sp. (11). Corynebacteria may also be used to produce recombinant proteins such as gamma interferon, proteases, and cellulase (12).

Corynebacteria, and specifically *Brevibacterium linens*, are involved in the cheese ripening process. Although the lactic acid bacteria play a key role in cheesemaking by catabolizing nitrogen compounds, the roles of other bacteria, such as brevibacteria, are also important. Possessing powerful and varied enzymatic systems, they contribute to the aging of ripened cheeses by producing unique flavors (13). Flavored compounds produced by these bacteria, including peptides, amino acids, and sulfured compounds, have found applications in the food industry as additives in cheese-flavored products (sauces, crackers, etc.) (14).

Not surprisingly, the *Corynebacterium* strains that are used in industrial fermentations are not the original iso-

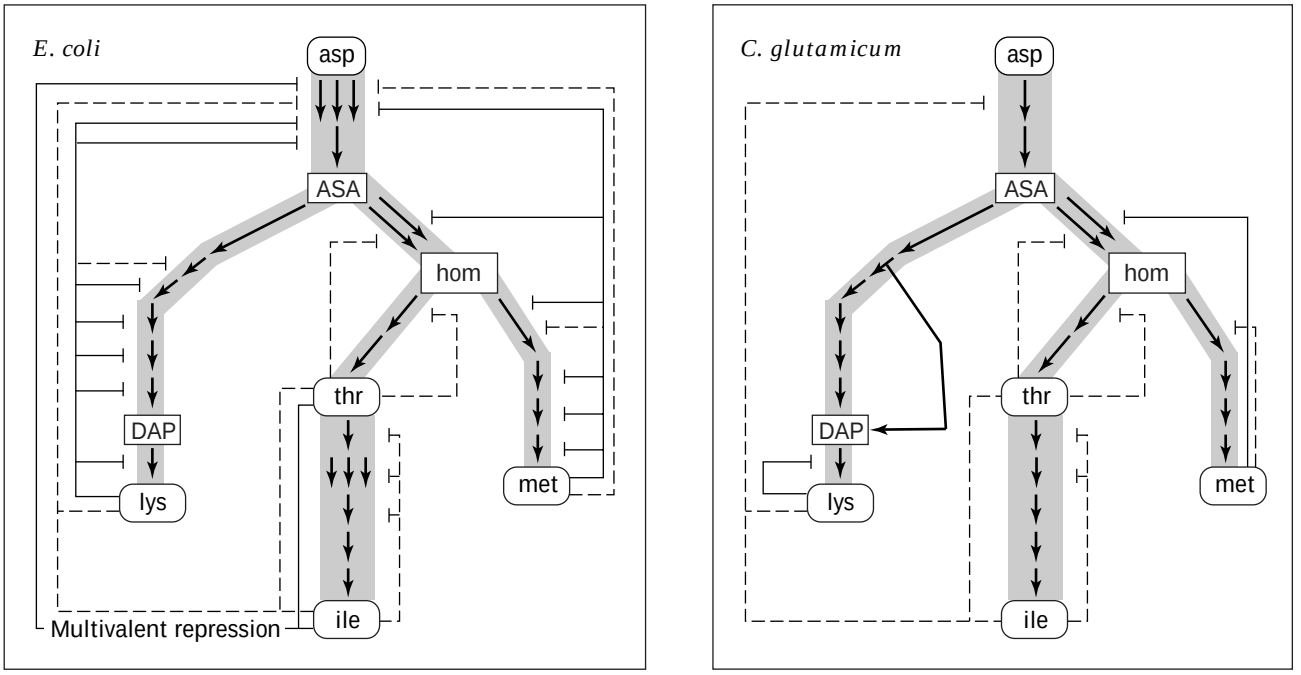

Figure 1. Summary of feedback inhibition and genetic repression operating in pathways for synthesis of aspartate derived amino acids in *E. coli* and *Corynebacterium*. Dashed lines denote feedback inhibition, solid lines denote genetic repression. Arrows indicate individual, enzymatically catalyzed steps. Steps that are catalyzed by multiple isozymes in *E. coli* are indicated by more than one arrow. Note that control of these pathways in *E. coli* is much more complex than that known in *Corynebacterium*. *E. coli* lacks the parallel pathways leading to lysine biosynthesis (described later in the text). More detailed depictions of the enzymes and intermediates involved in these pathways are depicted later in this chapter. ASA, aspartate semialdehyde; hom, homoserine; DAP, *meso*-diaminopimelate.

lates that were identified for their prolific amino acid production. A great deal of research has focused on improving the properties of the production strains. Glutamate excretion from the cells appears to be the major limitation to yield in glutamate production. Because excretion can be enhanced by manipulating the culture conditions, biochemical engineering and reactor design have been the primary routes toward improving glutamate yield. In lysine fermentations, however, the primary bottleneck appears to be in the rate of synthesis of the amino acid. For this reason, improvements in lysine production have come mainly from metabolic engineering. Following, we discuss both aspects, describing first biochemical engineering of the glutamate production process, and second, metabolic engineering of the pathways leading to lysine and other aspartate-derived amino acids.

BIOCHEMICAL ENGINEERING FOR IMPROVED AMINO ACID PRODUCTION

General Characteristics of Industrial Amino Acid Fermentations

Corynebacteria are mainly involved in industrial production of amino acids by fermentation processes. The volume of industrial fermentors for amino acid production may reach up to 100 m^3 in order to support the high demand of the market. Some production facilities produce up to 100,000 metric tons per year of amino acids. These large cultures are usually realized in fed-batch mode, in order to reach the highest productivities. Although continuous cultures also lead to high productivities, they are rarely used in industry due to the higher risks of bacterial contamination. The industrial raw materials are complex media such as cane or beet molasses, corn steep liquor, or starch hydrolysates. The carbon sources are thus mainly sucrose (from beet molasses), or sucrose, glucose, and fructose (from cane molasses). The nitrogen sources are ammonium salts provided by the medium in the first stage of the cultures, and later during the fermentation as ammonium hydroxide, which is used to regulate pH in the reactor.

Glutamic Acid Fermentation

Glutamic acid fermentation provides a good example of the development of a process in order to answer industrial problems. Glutamic acid is produced industrially by fed-batch fermentations of 25–40 h. The final concentration of glutamic acid ranges between 90 and 120 g/L with a biomass production of 15–25 g/L. Depending on the raw materials used, the conversion yields vary between 50 and 60%. Glutamic acid production is an aerobic process. Therefore it is very important to control the dissolved ox-

ygen at its optimal level. Oxygen limitation leads to a drastic decrease in glutamic acid titer, and to significant production of succinic and lactic acids. Moreover, an ammonium limitation with sufficient oxygen supply results in a deviation of the fermentation process to a production of 2-oxoglutarate. In industrial-scale processes, automatic addition of gaseous ammonia avoids ammonium limitation and enables the pH regulation of the broth without the harmful effects of liquid ammonia and the undesirable dilution of the fermentation liquid.

Corynebacteria usually excrete little or no glutamic acid into the medium. Therefore, different processes were developed to increase the excretion of this amino acid. The first industrial process was based on biotin limitation. Takinami et al. (15) reported that in media with high biotin concentrations, *B. lactofermentum* did not produce glutamic acid. But when the biotin concentration was low (<3 μg/L), glutamic acid was excreted in the external medium (Fig. 2). Glutamic acid fermentation by biotin limitation occurs in two phases (Fig. 3). Cultures begin with a relatively high concentration of biotin to permit cell growth. When the biotin becomes limiting, bacterial growth slows down and glutamic acid is excreted. Using biotin limitation to enhance glutamate, industrial production has given glutamate titers up to 90 g/L.

The process of biotin limitation introduces different problems on an industrial scale: it does not allow the use of complex media that often contain high biotin concentrations, and it necessitates a precise and tedious monitoring of the biotin concentration. These problems were partly solved by the use of antibiotics or surfactants. The addition of sublethal concentrations of penicillin to a culture of *C. glutamicum* led to excretion of glutamic acid (16). This process was used in industry but was quickly replaced by a process involving surfactants. Addition of either penicillin or surfactants leads to an excretion of glutamic acid. Current modern production processes are fed-batch fermentations consisting of an initial period of rapid growth of the bacteria followed by a phase of extensive glutamate excretion, which is induced by the addition of surfactants such as amine surfactant (17) or Tween (18) (Fig. 4). Glutamate production via surfactant addition may reach titers of 120 g/L in industrial media.

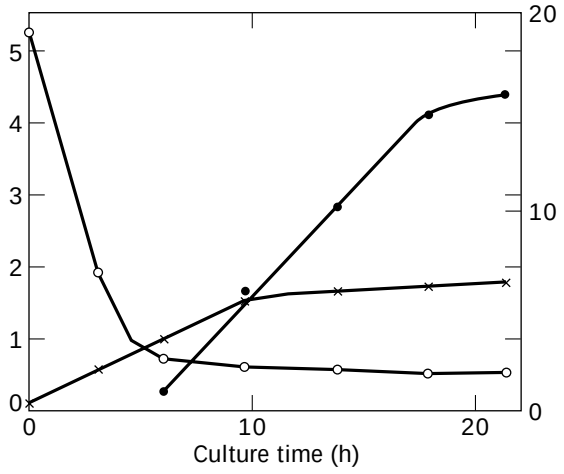

Figure 3. Production of glutamic acid by biotin limitation process. Closed circles, glutamic acid accumulated (g/L); x, dry cell concentration (g/L). *Source*: Adapted from Ref. 15.

The development of the fermentations that rely on penicillin or surfactants led to benefits for the amino acid industries. These processes have the main advantage of allowing the use of cheap, biotin-rich materials, such as molasses. Nevertheless, the monitoring of these fermentations remains delicate due to the sensitivity of the bacteria to surfactants. The ratio of surfactant to biomass concentration, and the physiological state of the cells when the surfactants are added, are critical determinants for production of high levels of glutamic acid (19).

The high levels of glutamic acid reached in industrial processes are usually explained by the fact that the excretion of glutamate leads to a reduction in the internal pool

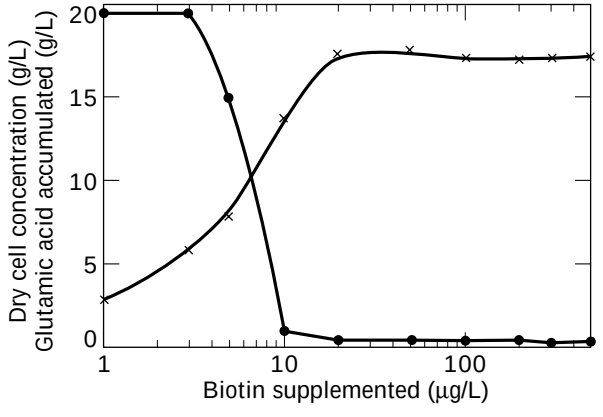

Figure 2. Relationship between the level of external biotin and the accumulation of glutamic acid in *Brevibacterium lactofermentum*. Closed circles, glutamic acid; open circles, dry cell concentration. *Source*: Adapted from Ref. 15.

of this amino acid, which in turn relieves feedback control mechanisms. Regarding the regulatory aspects, 2-oxoglutarate dehydrogenase, which converts 2-oxoglutarate to succinyl-CoA at the branch point where glutamate formation diverges from the TCA cycle, is a key enzyme for glutamic acid biosynthesis (Fig. 5). The properties of the enzyme must be favorable for deviation of the carbon flux towards the glutamic acid pathway in order to prevent further oxidation through the TCA cycle. It has been shown that in overproducing strains, the V_{max} of the glutamate dehydrogenase is 150 times higher than that of 2-oxoglutarate dehydrogenase. Also, the intracellular 2-oxoglutarate concentration is high enough to direct the flux to glutamic acid biosynthesis, even with a 70-fold lower K_m value of 2-oxoglutarate dehydrogenase for 2-oxoglutarate (20). Recently, Kawahara et al. (21) showed that the activity of 2-oxoglutarate dehydrogenase was reduced in cells cultured under glutamate-production conditions (biotin limitation and addition of penicillin or surfactant) as compared to those in glutamate nonproductive conditions. In contrast, glutamate dehydrogenase activity, which draws carbon away from the TCA cycle into glutamate, was unchanged under these conditions. Thus, a high flow of carbon to the TCA cycle could be easily converted to glutamate after exhaustion of biotin, or addition of antibiotic or surfactants.

The second aspect of regulatory mechanisms of glutamic acid biosynthesis concerns the carbon dioxide fixation to form oxaloacetate. The efficiency of glutamic acid biosynthesis depends on the supply of oxaloacetate to the first part of the TCA cycle (Fig. 5). Anaplerotic pathways, such as phosphoenolpyruvate carboxylase and pyruvate carboxylase, may then play an important role in the production of glutamic acid. In the future, increases in carbon dioxide fixation might improve the production yield of the strains.

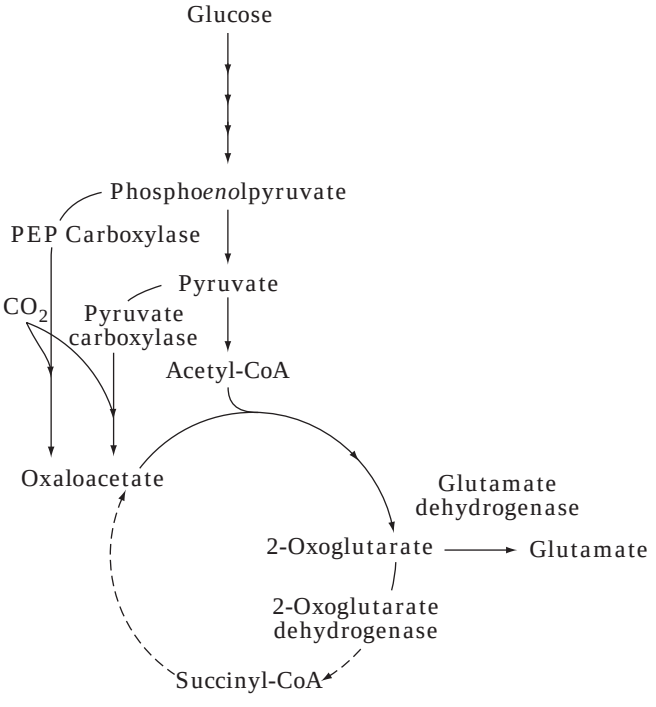

Figure 5. Simplified scheme of glutamic acid biosynthesis pathway through anaplerotic pathways as oxaloacetate generating system.

The mechanism of glutamate excretion into the medium has long been a subject of controversy in the literature. Three different mechanisms have been proposed to describe glutamate efflux. The "leak" model proposes that glutamate is excreted because the cell membrane is physically altered after different treatments, such as biotin limitation, addition of sublethal antibiotic concentration, or addition of surfactants. The second hypothesis is based on a general model for many efflux processes in bacteria, namely, that inversion of the influx system of glutamate is induced by changes in chemical potential or regulation, or by uncoupling due to changes in the membrane structure. Finally, the last hypothesis proposes the existence of a specific glutamate carrier analogous to the recently characterized lysine transport system. These different hypotheses are discussed in a recent review (22).

Momose and Takagi (23) isolated mutant strains of *C. lactofermentum* sensitive to temperature and able to excrete glutamic acid after a thermal upshock from 30 °C to 37 °C in biotin-rich media. One of their mutants produced 20 g/L glutamic acid from molasses. In the future, with such strains it could be possible to produce glutamate from biotin-rich materials without the use of expensive additives, such as antibiotics or surfactants, just by simple control of the temperature.

METABOLIC ENGINEERING OF CORYNEBACTERIA

Through classical mutagenesis and selection, it has been possible to identify *Corynebacterium* mutants that overproduce lysine. By 1958, Kinoshita and colleagues (24) had learned that homoserine auxotrophs secreted higher amounts of lysine than did wild-type strains. Mutants with altered feedback inhibition in the lysine biosynthetic pathway have also been found to overproduce the amino acid. Thus, resistance to the lysine analog 2-aminoethyl-L-cysteine (AEC) has been a hallmark of the lysine overproduction phenotype. Other mutants that overproduce lysine have been found to contain lesions in pathways, such as those for leucine and alanine biosynthesis, which compete for the pyruvate that is required for lysine biosynthesis. Lysine production by *Corynebacterium* strains that are resistant to one or more lysine analogs and that carry auxotrophies for one or more additional amino acids has been described previously (25). The introduction of molecular genetics coupled with a greater understanding of how *Corynebacterium* regulates lysine synthesis has made it possible to enhance lysine productivity even further through metabolic engineering.

Metabolic engineering is an emerging field of research that combines the analysis of complex biochemical networks with biochemistry, enzymology, and molecular biology. Through metabolic engineering it is possible, at least in principle, to identify processes within the cell that limit overall lysine productivity, for example, and introduce spe-

cific changes into the cell to alleviate these limitations. Metabolic engineering requires both a detailed understanding of biosynthetic pathways and their regulation, and the ability to alter specific steps in these pathways. The most direct method for making these alterations is genetic manipulation. In this way, *E. coli* strains, with their well-characterized physiology and wide array of molecular genetic resources, have been engineered to produce large amounts of threonine, valine, or tryptophan. Metabolic engineering in *Corynebacterium*, however, cannot draw on the same diversity of resources, and although the physiology of these bacteria is becoming ever more understood, methods for introducing changes into these strains at the genetic level are not as well developed as they are for *E. coli*.

Genetic Tools for Manipulating *Corynebacterium*

To make the genetic changes necessary for metabolic engineering in *Corynebacterium*, researchers need to be able to identify and clone the genes that are involved in the target pathway. They also need methods for altering these genes to affect the regulation or level of expression of the enzymes they encode, and for subsequently reintroducing the altered genes into *Corynebacterium* to monitor their effects on amino acid biosynthesis. Therefore, metabolic engineers must have at their disposal an array of plasmids that can replicate in both *Corynebacterium* and other, more easily manipulated hosts, such as *E. coli*. Also required are a collection of selectable markers encoding, for example, antibiotic resistance, well-characterized transcriptional promoters that permit regulation of the altered genes, and efficient transformation or conjugation systems that allow the plasmids to be inserted into the target *Corynebacterium* strain.

Plasmids. Several different plasmids have been isolated and developed for the introduction and expression of genes in *Corynebacterium* (26). The majority of these were originally identified as small (3–5 kbp), cryptic plasmids from *C. glutamicum*, *C. callunae*, and *C. lactofermentum*. They fall into four compatibility groups, exemplified by the plasmids pCC1, pBL1, pHM1519, and pGA1. Shuttle vectors, plasmids that are capable of replicating in both *Corynebacterium* and *E. coli*, have been developed from these cryptic plasmids by incorporating elements from known *E. coli* plasmids (particularly the ColE1 origin of replication from pBR322 or pUC18), as well as antibiotic resistance markers. A fifth class of plasmids that is very useful for manipulating *Corynebacterium* is based on pNG2, a plasmid originally isolated from *Corynebacterium diphtheriae* (27). This plasmid and its derivatives replicate efficiently in many species of corynebacteria, as well as in *E. coli*. Since the sole origin of replication in pNG2 (an element of only 1.8 kbp) functions in both the Gram-positive and Gram-negative host, there is no need to add an additional ColE1-type element to it. As a result, pNG2 derivatives (e.g., pEP2) are much smaller than other *Corynebacterium* shuttle vectors and are therefore more easily manipulated.

Selectable Markers. Several genes conferring antibiotic resistance have proven useful for plasmid selection and other recombinant DNA work in corynebacteria. These include the kanamycin resistance determinant from Tn*903*, a hygromycin resistance marker isolated from *Streptomyces hygroscopicus*, a tetracycline resistance gene from *Streptococcus faecalis*, a bleomycin resistance gene from Tn*5*, and a chloramphenicol resistance marker from *Streptomyces acrimycini*. Work in our laboratory has shown that this latter gene does not confer chloramphenicol resistance to *Corynebacterium* unless its native promoter is substituted by a promoter that is known to work in *Corynebacterium*. The β-lactamase gene that is employed in many *E. coli* plasmids such as pBR322 does not confer ampicillin resistance in *Corynebacterium*.

Transformation Systems. Several methods have been devised for introducing foreign DNA into *Corynebacterium*. The earliest method to be employed routinely was based on protocols that had been successful for other Gram-positive species involving incubation of spheroplasts in the presence of DNA and polyethylene glycol (28). While useful, these methods were generally inefficient, often yielding fewer than 10^5 transformants per milligram of DNA. Electroporation of *Corynebacterium* spheroplasts has proven to be a much more efficient and reliable means of transformation. Spheroplasts are generated by growing the cells in rich media containing glycine and/or low concentrations of other inhibitors of cell wall biosynthesis, such as isonicotinic acid hydrazide (isoniazid), ampicillin, penicillin G, or Tween-80. The spheroplasts are then washed in low-salt buffers containing glycerol, concentrated, and mixed with DNA before being subjected to electroporation. Efficiencies as high as 10^7 transformants per microgram of plasmid DNA have been reported with this protocol.

A third method for DNA transfer into corynebacteria involves transconjugation. This method takes advantage of the promiscuity of *E. coli* strains carrying derivatives of the plasmid RP4. In *E. coli*, RP4 encodes many functions that mediate the conjugal transfer of plasmids from the host strain to other recipient strains of *E. coli*, or even to other species. These "*tra* functions" mediate pilus formation and plasmid transfer. RP4 also carries an origin of transfer, *oriT*, a *cis*-acting element that is recognized by the transfer apparatus that allows the plasmid to be conducted through the pilus and into the recipient strain. From this system Simon et al. (29) have developed a useful transconjugation tool that allows the transfer of plasmids from *E. coli* to *Corynebacterium*. They relocated the *tra* functions from RP4 into the *E. coli* chromosome in a strain called S17-1. Plasmids carrying the RP4 *oriT* can be mobilized from S17-1 into other recipients very efficiently. Although this method has proven useful for introducing replicating plasmids into *Corynebacterium*, it has proven even more useful for generating gene disruptions. This is accomplished by introducing a selectable marker into a clone of the *Corynebacterium* gene that is targeted for disruption. This construct is then ligated into an *E. coli* plasmid that carries the RP4 *oriT* but lacks an origin to support replication in *Corynebacterium*. S17-1 carrying this plasmid is then incubated with the recipient strain and the mixture is later transferred to a selective medium. Because the

plasmid that was introduced is unable to replicate in corynebacteria, transconjugants that express the selectable marker are most likely to have undergone a cross-over recombination within the genomic DNA.

Restriction-Deficient Strains. Regardless of the transformation system used, there is clear precedent in the literature that corynebacteria are able to recognize *E. coli*–derived DNA as foreign and will most often degrade it. This ability has been attributed to the *Corynebacterium* restriction and modification system. To overcome this system, some transformation and transconjugation protocols call for briefly heating the recipient strain prior to transformation. The heat treatment presumably inactivates the enzymes responsible for the restriction system, allowing the introduced DNA to become established before the enzymes are turned over. Another strategy for improving the efficiency of DNA transfer has been to isolate *Corynebacterium* mutants that are deficient in the restriction system. These strains will incorporate plasmids that had been propagated in *E. coli* with almost the same efficiency as plasmids that had been propagated in *Corynebacterium*. In an alternate strategy used to circumvent the restriction system in *Corynebacterium*, Leblon and coworkers (30) developed an "integron" system for gene disruption. Integrons are DNA molecules that have the same restriction/modification properties as the target host's DNA, carry DNA that is homologous to a portion of the host genome (i.e., a region of the genome that is to be disrupted), and are unable to replicate in the host cell. A cloned gene from *Corynebacterium* is first interrupted with a selectable marker in a plasmid that is propagated in one *Corynebacterium* strain. This construct is then excised from the corynebacterial plasmid and self-ligated to form a nonreplicating circular molecule. This "integron" is then electroporated into the restrictive host. Modification of the DNA allows the integron to elude the host restriction system, and recombination into the host genome permits expression of the selectable marker.

Promoters. Reliable transcriptional promoters are required for efficient expression of foreign genes in *Corynebacterium*. For certain experiments, there is also a need for regulated promoters whose activity can be induced under specific culture conditions. Promoters such as the *fda*, *thrC*, and *hom* promoters derived from *Corynebacterium* genes have proven useful for heterologous gene expression. Inducible promoters from *E. coli*, such as P_{lac}, P_{tac}, and P_{trc}, which are induced by isopropylthiogalactopyranoside (IPTG) when the *lac* repressor (*lacI*) is present; P_{trp}, which responds to the inducer indole acrylic acid when the *trp* repressor (*trpR*) is present; and lambda P_L, which is repressed in the presence of the temperature-sensitive lambda repressor (cI857), have all been used to modulate gene expression in *Corynebacterium*. There is also intense interest in identifying developmentally regulated promoters from *Corynebacterium*, such as promoters that are activated during late exponential or stationary phases of culture, although this work has proceeded slowly.

Gene Identification. With all other genetic tools in place, there still remains the challenge of identifying relevant genes from *Corynebacterium*. In *E. coli*, some of the resources that have been used to isolate genes are transducing phage, transposable elements, genetic maps of the *E. coli* chromosome from transduction and transconjugation experiments, and more recently, complete physical and sequence maps of the chromosome. To date, the most successful method for identifying and recovering genes from *Corynebacterium* has been to use *Corynebacterium* genomic DNA to complement known auxotrophs of *E. coli*. In this exercise, libraries of plasmids carrying fragments of the *Corynebacterium* genome are introduced into *E. coli* strains that are deficient in a particular enzyme or function. Transformants that no longer display the auxotrophy (e.g., homoserine deficiency) are likely to carry the complementing gene from *Corynebacterium*. This strategy has led to isolation of numerous *Corynebacterium* genes, including several from the pathways responsible for synthesis of aspartate-derived and aromatic amino acids, intermediary metabolism, and other cellular processes. One limitation to this strategy is that not all genes from *Corynebacterium* will be expressed in the *E. coli* host. Thus, although a gene may be represented in the plasmid library, it may be unable to complement the *E. coli* mutation and therefore would not be recovered during selection. Overcoming this limitation, a smaller number of genes have been identified with a similar strategy in which a plasmid library from wild-type *Corynebacterium* was used to directly complement mutations in other *Corynebacterium* strains. Although this strategy avoids the concern of insufficient gene expression in the auxotrophic host, its utility is limited by poor plasmid transformation efficiency in the auxotrophs. Still other genes have been identified by hybridization with nucleic acid probes based upon homologous genes from other species, and direct amplification of genes using the polymerase chain reaction and degenerate oligonucleotide primers.

Transposable Elements. Transposable elements are extremely powerful tools in gene identification because they couple mutagenesis with gene recovery. Unlike classical mutagenesis techniques, which generate point mutations or small deletions within a gene, when transposable elements insert within a gene they form large disruptions, thereby "tagging" the altered gene for easier identification. A number of transposable elements have been found to transpose in *Corynebacterium*. Transposons found in the plasmids pTP10 of *C. xerosis* and pNG2 of *C. diphtheriae* have been shown to transpose in *C. glutamicum* and confer resistance to erythromycin. A group from the Mitsubishi Chemical Company in Japan developed a series of artificial transposons from an insertion sequence, IS*31831*, that they discovered in *C. glutamicum* (31). After inserting a selectable marker between the inverted repeats of IS*31831*, these researchers were able to introduce the resulting transposon into *C. glutamicum* strains on an *E. coli* plasmid (unable to replicate in *Corynebacterium*) via electroporation. They found that the selectable marker had inserted into the genome of the target cell at a frequency of approximately 4×10^4 mutants/μg DNA. The use of such transposons to generate *Corynebacterium* auxotrophs has led to the isolation of several genes responsible for amino

acid biosynthesis, as well as other functions in corynebacteria.

Transducing Phage. Transducing phage have been used in other systems for mapping genetic loci and for isolating genes. In 1976, researchers at Ajinomoto Co. in Japan surveyed 150 strains of characterized and uncharacterized glutamic acid–producing coryneform bacteria to identify phage that might be useful for transduction (32). Of 24 different phage isolates recovered from this screen, only three were able to transduce a *trp* marker from a trp^+ donor to a trp^- recipient with any appreciable frequency, although even this efficiency was only 10^{-7} or less. These researchers were able to improve transduction efficiency slightly by including 4 mM cyclic adenosine monophosphate (cAMP) or 1.2 M magnesium chloride. Several different researchers have attempted to develop reliable transduction methods by isolating corynephages from sources such as contaminated industrial fermentations, soil, and animal waste. Although many phage have been isolated and characterized, few have been associated with transduction, and an opportunity still exists to develop a reliable, high-efficiency transduction system for general use with the glutamic acid–producing bacteria.

Metabolic Engineering for Aspartate-Derived Amino Acids

Classical mutagenesis and selection has given rise to amino acid–overproducing strains that carry mutations that alleviate feedback inhibition in critical regulatory enzymes, eliminate reactions that compete for substrates, alter control of gene expression, or somehow modify other aspects of the cell's physiology. Metabolic engineering of the pathways for the aspartate family of amino acids has followed very similar themes. Aspartate is derived from oxaloacetate, a tricarboxylic acid cycle (TCA) intermediate. All of a cell's lysine, methionine, threonine, and isoleucine are produced from aspartate (Fig. 1). *Corynebacterium* modulates the partitioning of precursors into pathways specific for the individual amino acids in this family at several levels, including feedback sensitivity of several key enzymes, differences in the specific activities of competing enzymes at nodes where the pathways for two amino acids diverge, and genetic repression. Although it is complex, regulation of the aspartate pathways in *Corynebacterium* does not appear to be as complex as that in *E. coli* (Fig. 1).

Lysine. Although there appears to be some level of transcriptional regulation of the operon that encodes diaminopimelate decarboxylase, the enzyme that carries out the final step in lysine biosynthesis (Fig. 6), the main control in lysine biosynthesis in *Corynebacterium* is exercised by aspartokinase (AK), which catalyzes the first common step toward the synthesis of all of the aspartate-derived amino acids. Many AEC-resistant strains of *Corynebacterium* have been shown to produce an aspartokinase that is insensitive to the feedback inhibition by lysine and threonine that is displayed by the wild-type enzyme. Sequence analysis of cloned aspartokinase genes from AEC-resistant *Corynebacterium* strains has revealed the molecular basis

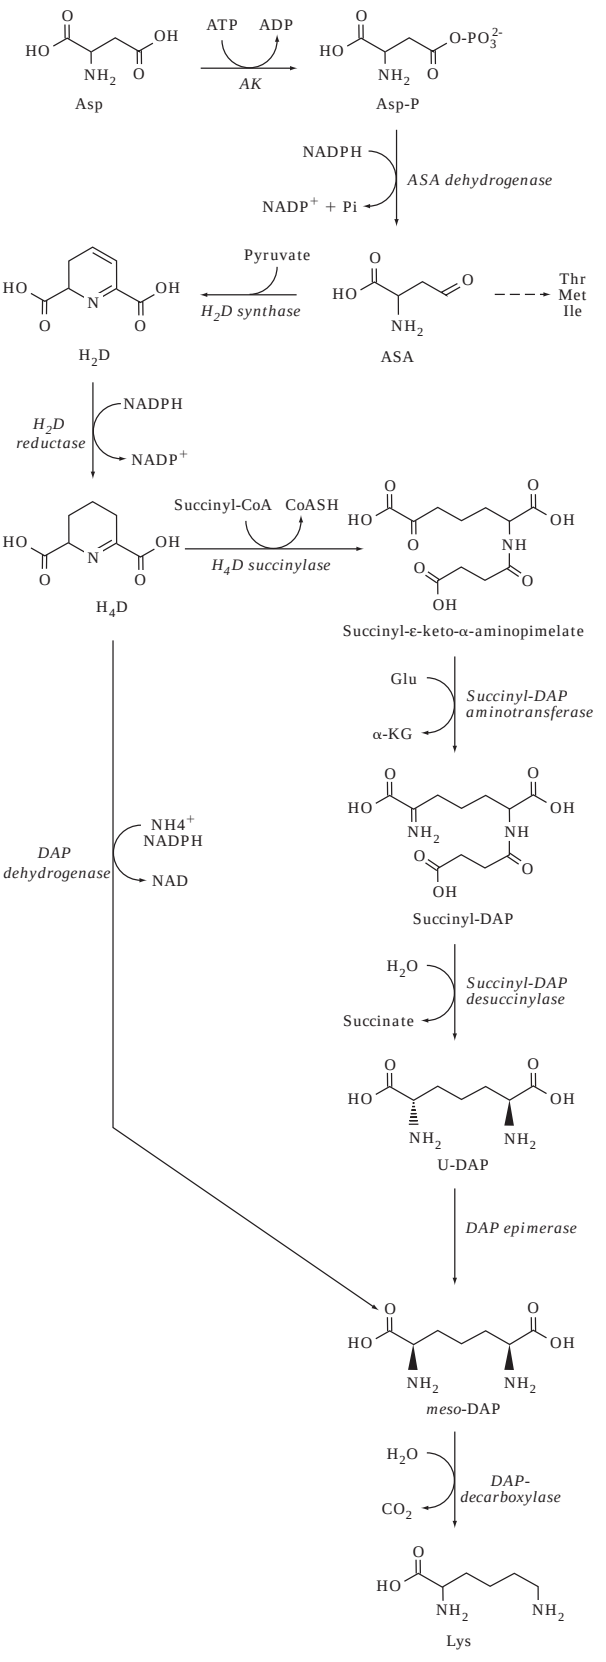

Figure 6. Lysine synthesis in *Corynebacterium glutamicum*. AK, aspartokinase; ASA, aspartate semialdehyde; H_2D, dihydrodipicolinate; H_4D, tetrahydrodipicolinate; DAP, diaminopimelate; α-KG, α-ketoglutarate.

of lysine overproduction in these strains. In *Corynebacterium*, aspartokinase is synthesized as two polypeptides, AKα and AKβ, which are encoded by overlapping reading frames and assemble as an $\alpha_2\beta_2$ heterotetramer. Feedback resistance is due to mutations that lead to amino acid substitutions within the AKβ subunit: specifically, substitution of tyrosine in place of serine at position 301, aspartate in place of glycine at position 345, or glycine in place of arginine at position 349 (22). From this it is postulated that the β-subunit of aspartokinase mediates regulation by lysine and threonine, although it is not clear whether these amino acids are directly involved in binding of either lysine, threonine, or both. Regardless, these mutations alone allow *Corynebacterium* to accumulate and secrete high levels of lysine.

However, it is clear that feedback inhibition of aspartokinase is not the only limitation to lysine overproduction. In AEC-resistant lysine overproducers, amplifying expression of the deregulated aspartokinase gene through recombinant DNA techniques further increases the synthesis of lysine, indicating that the specific activity of this enzyme is also limiting. A further limitation in lysine production, especially at the industrial scale, comes at the point of lysine secretion (33). Wild-type *Corynebacterium* cannot secrete significant amounts of lysine. Many lysine-overproducing strains have been found to possess enhanced lysine export systems in addition to deregulated aspartokinase activity. The lysine export mechanism apparently involves symport of two hydroxyl ions and can proceed against a lysine gradient and against the membrane potential (33). At this time, the molecular basis for increased lysine export during overproduction is not yet fully understood.

Unlike *E. coli*, *C. glutamicum* possesses two biochemical pathways for synthesizing lysine or, more precisely, for synthesizing *meso*-diaminopimelate (*meso*-DAP), the immediate precursor to lysine. The first pathway (the succinylase pathway) is initiated by the enzyme tetrahydrodipicolinate succinylase and involves a total of four enzymatic steps to produce *meso*-DAP. The second pathway (the dehydrogenase pathway) converts tetrahydrodipicolinate to *meso*-DAP in a single step through the action of DAP dehydrogenase. Because these two pathways incorporate nitrogen via different substrates (the succinylase pathway uses glutamate while the dehydrogenase pathway uses ammonium), the operation of these two mechanisms allows *C. glutamicum* to grow in the presence of different nitrogen sources. *meso*-DAP is an important cell wall component in corynebacteria, providing the crosslinking of the peptidoglycan material in this structure. Strains of *C. glutamicum* that are deficient in the succinylase pathway were found to have altered morphology and cell wall rigidity (34). Deficiency in the dehydrogenase pathway reduces productivity during lysine fermentations without significantly altering growth rates (35). The dehydrogenase enzyme has a lower affinity for the common substrate than does the succinylase, and it is constitutively expressed. The succinylase pathway, on the other hand, is energetically more expensive. ^{13}C-nuclear magnetic resonance studies on carbon flux (36) have confirmed that during normal growth the majority of the *meso*-DAP is produced via the succinylase pathway, and that during conditions of high lysine production the dehydrogenase pathway accounts for the bulk of this flux.

Threonine. Aspartate semialdehyde is the last common intermediate in the pathways for the synthesis of lysine and the other aspartate-derived amino acids (Fig. 7). Given

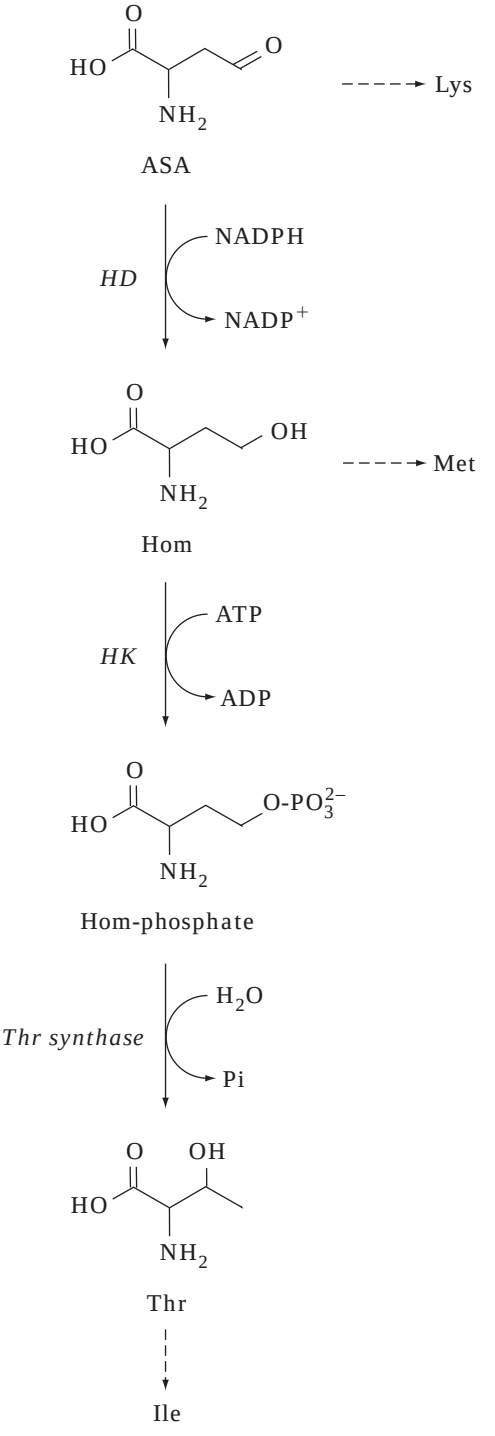

Figure 7. Threonine synthesis in *Corynebacterium glutamicum*. ASA, aspartate semialdehyde; Hom, homoserine; HD, homoserine dehydrogenase; HK, homoserine kinase.

the fact that lysine, methionine, threonine, and isoleucine are all derived from aspartate, it would seem to follow that deregulation of aspartokinase should boost synthesis of these other products along with lysine. The observation that the first committed step toward threonine, methionine, and isoleucine is catalyzed by an enzyme (homoserine dehydrogenase) with a stronger affinity for aspartate semialdehyde than the enzyme (dihydropicolinate synthase) that leads to lysine would seem to support this notion. However, when feedback inhibition of aspartokinase is relieved, the predominant product to accumulate is lysine because, unlike the pathway for lysine biosynthesis, the threonine and methionine biosynthetic pathway contains additional regulatory mechanisms. Homoserine dehydrogenase itself is inhibited by accumulation of threonine, and expression of the homoserine dehydrogenase gene is repressed by methionine. The result is that, even though homoserine dehydrogenase can outcompete dihydrodipicolinate synthase for aspartate semialdehyde, accumulation of the products of this branch in the pathway is quickly squelched. Lysine synthesis, which has almost no subsequent direct regulation, then resumes unhindered.

Because of its strong feedback regulation, homoserine dehydrogenase is an obvious target for metabolic engineering to improve threonine biosynthesis in *Corynebacterium*. Mutations near the carboxy terminus of this enzyme have been found to confer insensitivity to feedback regulation. When the deregulated homoserine dehydrogenase gene, hom^{dr}, and copies of *thrB*, which encodes homoserine kinase (the next enzyme in the pathway toward threonine), were integrated into the genomes of AEC-resistant strains of *Corynebacterium*, threonine accumulated at the expense of lysine (22,23). Inefficient export of the excess threonine in these cells triggered feedback inhibition of homoserine kinase, causing homoserine to accumulate as well. Concomitant overexpression of *thrB* from an inducible promoter was found to partially compensate for the deficiencies in threonine export by allowing more homoserine to be converted to threonine, but this effort led to the discovery that excess threonine was rapidly lost as the degradation products isoleucine and glycine. Disruption of the gene encoding threonine dehydratase, the first enzyme in the pathway from threonine to isoleucine, permitted more threonine to accumulate. However, threonine was still lost as glycine through two additional pathways, the first involving threonine dehydrogenase, and the second involving serine hydroxymethyl transferase, which is also active in serine catabolism (22). The difficulties encountered in development of *Corynebacterium* strains that overproduce threonine illustrates the complex and elegant regulation of this pathway.

Isoleucine. Overproduction of isoleucine has been accomplished by introducing excess threonine dehydratase (encoded by *ilvA*) into threonine production strains (37) (Fig. 8). Thus, combining a deregulated aspartokinase, deregulated homoserine dehydrogenase, overexpressed homoserine kinase, and overexpressed threonine dehydratase will result in abnormally high levels of isoleucine accumulation. Threonine dehydratase is normally feedback-inhibited by isoleucine, so it is not surprising that

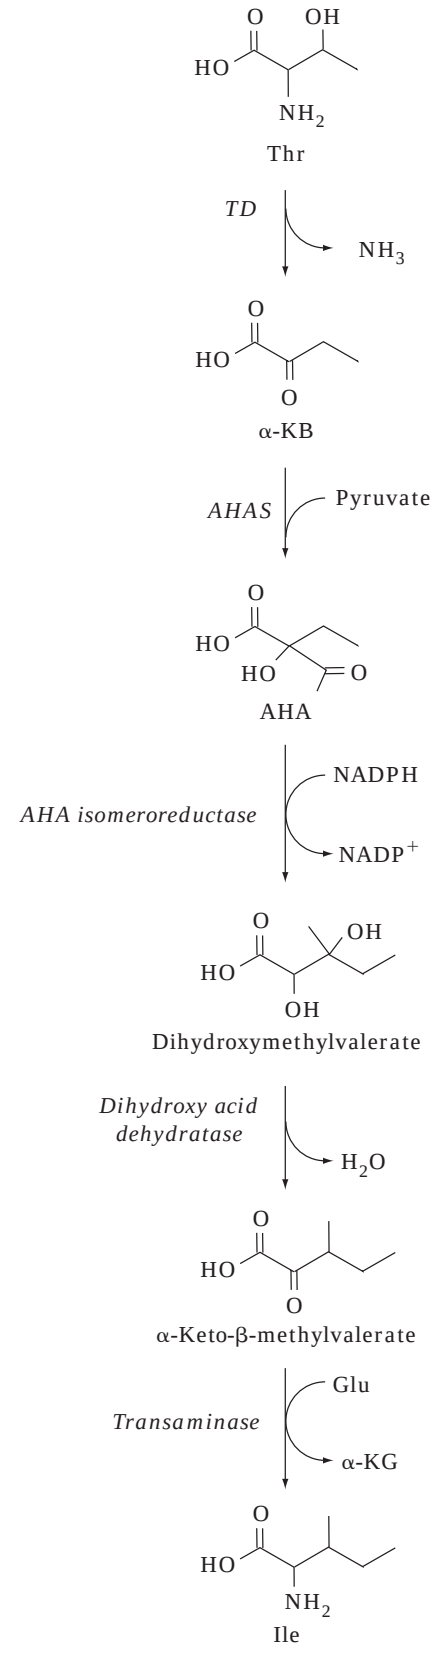

Figure 8. Isoleucine synthesis in *Corynebacterium glutamicum*. TD, threonine dehydratase; α-KB, α-ketobutyrate; AHA, acetohydroxy acid; AHAS, acetohydroxy acid synthase; α-KG, α-ketoglutarate.

mutant derivatives of threonine dehydratase with reduced sensitivity to isoleucine provided an additional dividend in this isoleucine production system (38). Despite these gains, it appears that amino acid export is once again a serious limitation to the effectiveness of amino acid production (33). An increase in threonine dehydratase activity causes α-ketobutyrate to accumulate. This induces the activity of the next enzyme in the isoleucine pathway, acetohydroxy acid synthase (AHAS), which might be expected to promote the conversion of threonine to isoleucine. Indeed, the addition of α-ketobutyrate alone to the medium enhanced flow through the latter parts of this pathway. However, when threonine dehydratase is overexpressed in the threonine production system, α-ketobutyrate is excreted into the medium. AHAS is also involved in valine and leucine synthesis and is itself feedback inhibited by the branched-chain amino acids. It appears that under isoleucine fermentation conditions a concomitant accumulation of valine may inhibit AHAS, thereby overcoming the stimulatory effects of α-ketobutyrate accumulation (37). Observations of intracellular concentrations of isoleucine suggest that isoleucine export is also a major rate-limiting step in isoleucine overproduction (39).

PERSPECTIVES

Considerable progress has been made in the production of amino acids by corynebacteria since the isolation of the first strain of *C. glutamicum*. In only four decades, the field has advanced from classical genetic manipulation of strains with uncharacterized lesions, through elegant biochemical analyses of enzymes from wild-type and overproducing strains, and on to the current molecular approaches. Aided by information gathered from sophisticated metabolic flux analyses and a greater understanding of biochemical pathways and cellular processes, the field has begun to apply a more rational strategy based on metabolic engineering of improved strains. These new strategies, facilitated by the development of improved genetic tools for the manipulation of corynebacteria, should permit the unraveling of complicated regulatory pathways. Using these methods, researchers have overcome many obstacles to amino acid overproduction and gained valuable insights that have benefited the broader scientific community.

Challenges to further enhancements in amino acid production remain in the areas of amino acid transport and global regulatory mechanisms (40), particularly those relating to central carbon metabolism. There is also opportunity for further improvement of large-scale fermentation techniques. The availability of the complete genomic sequence of closely related Gram-positive bacterial strains, including *Mycobacterium tuberculosis* and *M. leprae*, will undoubtedly aid in the isolation of homologous genes from corynebacteria. As the analysis of bacterial genomes and proteomes continues to mature, functional genomics and high-throughput chip-based technologies for the visualization of gene expression and cellular protein content hold out the promise for synthesis of an accurate and detailed picture of cellular metabolism. The study of the glutamic acid–producing corynebacteria will likely lead to continuous gains in productivity while offering new insights into microbial physiology.

OUTLINE

INTRODUCTION

There are three principle areas of modern biotechnology where crystallization plays important roles. These are (*1*) The crystallization of proteins as well as viruses, nucleic acids, and macromolecular complexes for X-ray diffraction analysis; (*2*) the crystallization of specific proteins as a part of their formulation in a therapeutic compound, agricultural chemical, or drug; and (*3*) the crystallization of enzymes, and in some cases other proteins, as a means of purification from bulk processes. Although the objectives in each of these situations may be quite different, with the exception of scale, the underlying principles and approaches are fundamentally the same.

In cases of crystallization for X-ray analysis, one is usually dealing with quite pure, often exceptionally pure molecules, and the goal is to grow only a few large, perfect crystals like those shown in Figure 1. The X-ray analysis is a singular event or study, confined to the research laboratory, and the product is basic scientific knowledge. The crystals themselves have no material or medicinal value, but serve as intermediaries in the crystallography process. They provide X-ray diffraction patterns that in turn serve as raw data allowing the visualization of the macromolecules composing the crystals. Thus, they serve as an essential component in the elucidation of molecular structure.

Macromolecular structure is of formidable value in biotechnology because it is the essential knowledge required to apply the technique of rational drug design in the creation and discovery of new drugs and pharmaceutical products. It is the basis of powerful approaches now being applied in small, emerging biotechnology companies as well as major pharmaceutical companies to identify lead compounds to treat a host of human ailments, veterinary problems, and crop diseases in agriculture. The underlying hypothesis is that if the structure of the active site of a salient enzyme in a metabolic or regulatory pathway is known, then chemical compounds, such as drugs, can be rationally designed to inhibit or otherwise affect the behavior of that enzyme.

A second approach, of equal importance to biotechnology, that also requires X-ray quality crystals is the genetic engineering of proteins. Although recombinant DNA techniques provide the essential synthetic role that permits modification of the proteins, crystallography provides the analytical function. It serves as the structural guide for the introduction of intelligent and purposeful changes, in the place of random and chance amino acid substitutions. Crystallography allows direct visualization of the structural changes introduced and offers new directions for chemical or physical enhancements.

Bulk crystallization, along with the detailed consideration of crystallization processes and products, has long been a staple in the pharmaceutical and chemical industry (1), where it has been applied to conventional small mol-

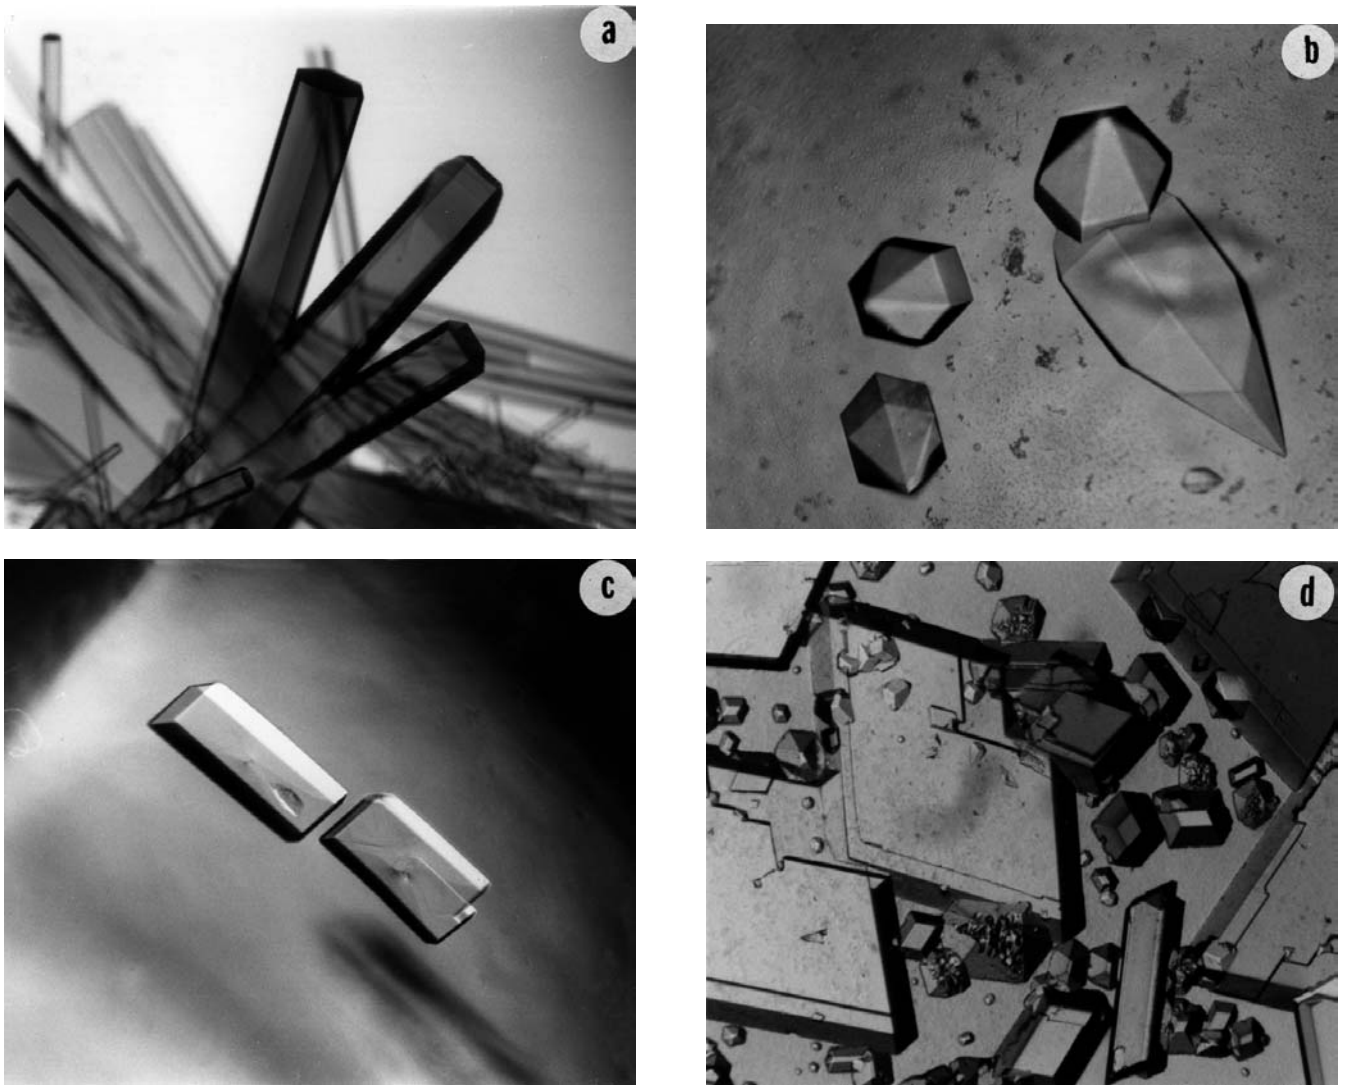

Figure 1. The crystals shown here were grown for X-ray diffraction studies that require a relatively small number of crystals, but of large size and high quality. (**a**) Beef liver catalase, a detoxifying enzyme; (**b**) α_1-acid glycoprotein, a human serum protein; (**c**) Fab fragments of an antiviral mouse antibody; and (**d**) canavalin, the major storage protein from legumes.

ecules and even more complex biological molecules such as glycosides, peptides, and antibiotics. A few examples from the literature where the crystallization procedures are described in some detail are for L-alanine (2), fructosylxyloside from *Scopulariopsis brevicaulis* (3), cephalosporin (4), and a flavanone, hesperidin from orange peels (5). Here, it has long been recognized that manipulation of crystalline formulations could dramatically affect solubility, shelf life, impurity content, thermal stability, release, efficacy, or a host of other commercially significant properties. Much research has, therefore, been devoted to the crystallization of commercially important conventional, small molecules during the past hundred years.

Only more recently has it become evident that crystalline formulations hold substantial promise for the administration and delivery of biological macromolecules as well (6,7). The first major example was that of insulin, a small protein of striking physiological importance to nearly all animals and crucial to the treatment of diabetes. In this instance, it was found that injection of crystalline protein resulted in a more prolonged, slower release of the protein drug and a significant improvement in its efficacy. This timed-delivery feature, first realized for insulin, now appears possible for other protein drugs.

In the coming years, a majority of biotechnology products will likely be proteins, particularly genetically modified proteins designed for introduction into living organisms, including humans. Their delivery and release will be a major problem, and their formulation as crystals will serve a major role in solving those problems. Here, unlike the growth of protein crystals for X-ray diffraction analysis, the crystals are in fact the product, and their produc-

tion must be reproducible. The physical properties of the crystals, such as size, morphology, solubility, and impurity levels will be rigorously specified. They will be produced, under strict regulatory control, as is any drug. Thus, the objectives are quite different than for crystals produced for diffraction analysis.

In terms of pharmaceutically important proteins, natural insulin from animal tissues was certainly the first to be produced in bulk quantities by crystallization (8), and recombinant insulin followed (9). Others, however, are now known, including a large-scale facility for the production of crystalline Fab fragments from monoclonal antibodies (10).

The third area for crystal growth, the downstream processing of proteins produced in large fermentations for the purpose of purification, has associated with it yet another set of objectives and problems. Crystallization is one of the oldest chemical purification technologies and one that has been seriously underutilized to this point in biotechnology. Here, the goal is to promote the crystallization of macromolecules from extremely large volumes, commonly reaching several thousands of liters, of rather impure solutions or culture broths. The ideal is to achieve a very high degree of purification in a single, economical step, and at the same time generate a concentrated, stable, and active product that appeals in its form to a broad customer base. Although certain crystal sizes, morphologies, size distribution, and other features of the crystals may be preferred, these are not the most important parameters. Often crystals such as those shown in Figure 2 are quite acceptable. The major considerations are yield, reproducibility, degree of purification, and the ability to crystallize the material in spite of very high and variable contaminant levels.

Major difficulties accompany the crystallization of proteins in downstream processing and purification that are not seen in X-ray diffraction or formulation crystal growth. For example, processes such as vapor diffusion (discussed later), which is applicable to microliter volumes, are completely inapplicable to thousand liter volumes. Exotic precipitants may not be economical, sensitive procedures such as column chromatography may be out of the question, and speed is often of the essence. Waste product disposal can be a significant consideration. The process must be carefully conceived and developed to be as economical and efficient as possible and still yield the desired crystalline product at the required purity.

There are many examples in the literature of crystallization used for the purification of proteins from bulk fermentations, and these provide useful guides to the design of new procedures for other macromolecules. In one of the earliest reports, Fukumoto et al. (11) reported the purification of lipase from a strain of *Aspergillus niger* by fractionation with ammonium sulfate and its ultimate crystallization from acetone. Tsujisaka et al. (12) in 1973 purified the same enzyme from *Geotrichum candidum* using salt fractionation, DEAE Sephadex, and gel chromotography. The protein was crystallized from its aqueous solution. Buckel et al. (13) in 1981 and Mack et al. (14) describe a scheme based on salt fractionations and chromatography for the production of glutaconate CoA-transferase from *Acidaminococcus fermentans*.

In the 1990s, the appearance of reports of bulk crystallizations accelerated, including those on procedures for protein iminopeptidase from *Bacillus coagulans* (15), chymosin mutants from *Trichoderma reesei* (16), and pyroglutamyl peptidase from *Bacillus amyloliquefaciens* (17). Although only abstracts are currently available, some additional enzymes have also been crystallized for commercial production, these include cellulase (18,19), subtilisin protease and glucose isomerase (18), and alcohol oxidase (20).

THE UNIQUENESS OF MACROMOLECULAR CRYSTALS

Macromolecules, being unique in their properties, both in terms of size and complexity, give rise to crystals that are unique as well (21,22). We cannot, therefore, expect that

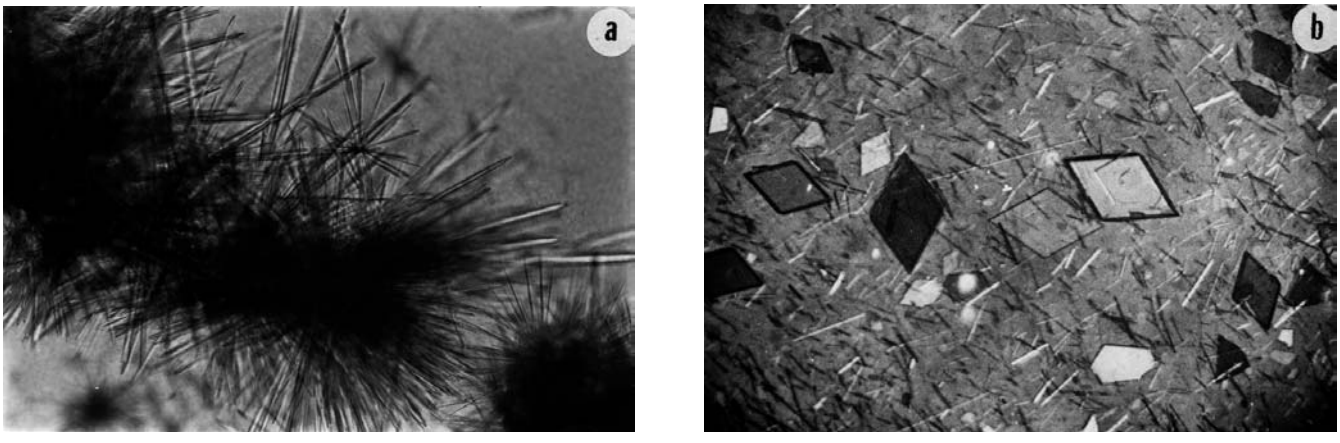

Figure 2. Needle crystals of α-amylase (**a**) and platelike microcrystals and needles of pineapple bromelin (**b**) are entirely suitable for downstream processing of enzymes produced in bulk for industrial purposes but are not of sufficient size nor of useful morphology for analytical studies.

macromolecular crystals will necessarily develop according to precisely the same mechanisms and principles as do conventional crystals (23). Indeed, recent investigations using advanced physical techniques such as inelastic light scattering, interferometry, and atomic force microscopy (22) have yielded evidence of new mechanisms and properties not before encountered with conventional crystals.

Macromolecular crystals are relatively small in comparison with conventional crystals, rarely exceeding 1 mm on an edge and generally smaller. Because only one stereoisomer of a biological macromolecule naturally exists, they do not form crystals possessing inversion symmetry and, therefore, generally exhibit simple shapes that lack the polyhedral character of small molecule crystals. They are extremely fragile, often crushing at the touch; degrade outside a narrow temperature, ionic strength, or pH range; generally exhibit weak optical properties (24); and diffract X-rays to resolutions far short of the theoretical limit (25). The reason for most of these character deficiencies is that macromolecular crystals incorporate large amounts of solvent in their lattices, ranging from about 30% at the lower limit to 90% or more in the most extreme cases (26,27). Proteins also have, as individual molecules, an array of water molecules surrounding them that are relatively tightly bound both in solution and in the crystal (28).

There are two other crucial differences between macromolecular and conventional crystal growth that have important practical consequences. The first is that macromolecular crystals are usually nucleated at extremely high levels of supersaturation, often several hundred to a thousand percent. Small molecule crystals, on the other hand, usually nucleate at only a few percent supersaturation. Virtually every quantitative aspect of crystal growth is a direct function of supersaturation (29). Although high supersaturation may be essential to promote nucleation, it is far from ideal for growth, and the many problems observed for macromolecular crystals attest to this. Furthermore, supersaturated macromolecular solutions, in addition to crystal nuclei, produce alternate solid states that we refer to collectively as amorphous precipitates. Unlike conventional systems, competition exists at both the nucleation and growth stages between crystals and precipitate. This is particularly acute because competition is promoted by high levels of supersaturation. Because amorphous precipitates are kinetically favored, though of less-favored energy states, they tend to dominate the equilibration process and often inhibit or preclude crystal formation.

Given the complexities that beset macromolecules, can we reasonably expect their crystallization to resemble that of conventional molecules? Evidence to this point suggests that the answer is in principle yes, but in practice no. It appears that the fundamental mechanisms and pathways of macromolecular crystal growth are the same as for conventional crystals (30,31) but that the magnitudes of the underlying kinetic and thermodynamic parameters that govern the process differ dramatically.

METHODS FOR GROWTH OF PROTEIN CRYSTALS

The growth of macromolecular crystals has been studied for more than 150 years, initially as a purification tool, and more recently for other purposes. It has been the topic of several texts and reviews and, with the increasing importance of protein crystallography, has become a major factor in the biotechnology industry. Because this body of literature exists, no attempt will be made here to exhaustively review all methods and aspects of macromolecular crystal growth. An effort will be made, however, to describe the underlying principles, present the most commonly employed laboratory approaches, summarized in Table 1, and suggest ways in which the field can be addressed by novice crystal growers.

The strategy used to bring about crystallization (22,32–37) is to direct a macromolecular solution slowly toward a state of supersaturation by modifying the properties of the solvent or the solute. This is generally achieved by altering the concentration of a precipitating agent, such as salt, or by altering some physical property, such as pH. This is illustrated by a version of the classical phase diagram for supersaturation, modified somewhat for the case of proteins in Figure 3.

In concentrated solutions, macromolecules, unlike most conventional molecules, may aggregate as an amorphous precipitate, a result to be avoided. It is usually indicative that supersaturation has proceeded too far or been reached too swiftly. One would like to slowly and marginally exceed the equilibrium point of saturation and thereby allow the macromolecules reasonable opportunity to assemble into a crystalline lattice.

The traditional procedure, illustrated by Figure 4, for inducing proteins to separate from solution as a solid phase is to gradually increase the level of saturation of a salt. Classically, the salt was ammonium sulfate, but others are also in common use (see, for example, Table 2 and the databases described in Refs. 26 and 27). Although the protein may separate as an amorphous precipitate, with appropriate care, manipulation of salt concentration is an effective means for growing protein crystals. This approach has, in fact, probably yielded more varieties of protein crystals than any other (22,26,27).

The accepted explanation for this salting-out phenomenon is that the salt ions and macromolecules compete for chemical interactions, principally hydrogen bonds, with the solvent molecules, that is, water. This occurs because both salt ions and protein molecules depend on hydration layers to maintain solubility. When competition between

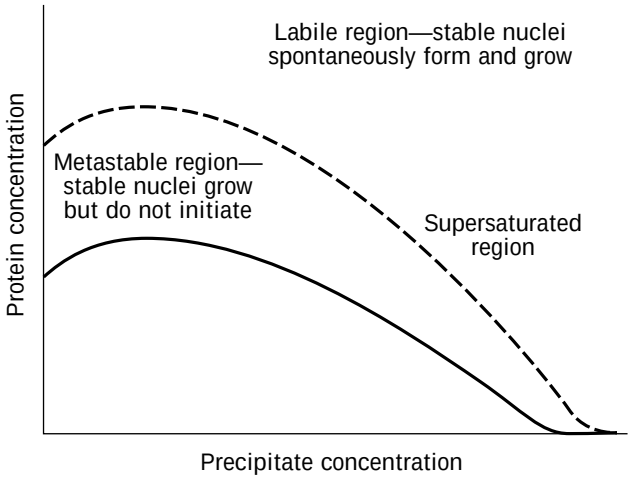

Figure 3. A phase diagram for a hypothetical protein showing its solubility as a function of precipitant concentration. The solid line represents the maximum solubility, or saturation curve, for the protein. Note that the protein is less soluble at very low and very high concentrations of the precipitant, corresponding to the salting-in and salting-out regions, respectively. The supersaturated region lies above the maximum solubility curve, and is, in turn, demarcated by a boundary discriminating the metastable region of supersaturation from the labile region. In the labile region, crystal nuclei can both spontaneously form and grow, whereas in the metastable region they can only grow.

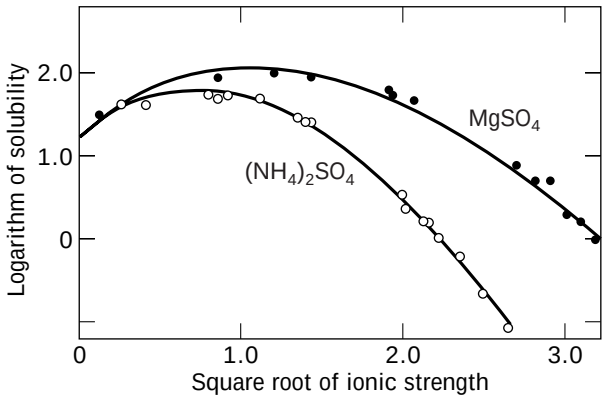

Figure 4. The solubility of the protein enolase at constant pH and temperature as a function of ionic strength produced by two separate salts. The two ends of the curves correspond to the salting-in and the salting-out regions of the solubility diagram.

ions and proteins becomes sufficiently intense, the protein molecules begin to self-associate in order to satisfy, by intermolecular interactions, their electrostatic requirements. Thus, dehydration, or the elimination and perturbation of solvent layers around protein molecules, reduces solubility. For a specific protein, the solubility minima are usually quite dependent on the pH, temperature, chemical composition of the precipitant, and properties of both the protein and the solvent (for more extensive discussions, see Refs. 38–42).

In the low ionic strength range, as seen in Figure 4, a phenomenon known as salting-in occurs in which the solubility of the protein increases as the ionic strength rises from zero. Protein solubility at low ionic strength is diminished by the removal of ions essential for satisfying the electrostatic requirements of the molecules. As ions are removed, and in this region of low ionic strength cations are most important (38–41), the protein molecules again balance their electrostatic requirements by forming interactions among themselves.

The salting-in effect can be applied in the opposite sense, that is, reducing ionic strength can serve as a crystallization tool. In practice, a protein is optimally solubilized at moderate ionic strength and then extensively dialyzed against distilled water. Many proteins, such as catalase, concanavalin B, immunoglobulins, and plant seed proteins, have been crystallized by this means (26,27,32,33).

Proteins may be forced from solution, at constant pH and temperature, by increases in ionic strength, or they can be crystallized or precipitated at constant ionic strength by changes in pH or temperature (38–41). This is illustrated by Figures 5 and 6. Reduction in solubility occurs because the charge distribution on a macromolecule, its surface features, or its conformation may change as a function of these variables (39). By virtue of its ability to inhabit a range of states, a protein may exhibit a number

Table 2. Common Precipitants Used in Macromolecular Crystallization

Salts	Organic solvents	Polymers
Ammonium or sodium sulfate	Ethanol	Poly(ethylene glycol) 1,000, 3,350, 6,000, 20,000
Lithium sulfate	Isopropanol	Jeffamine T
Lithium chloride	1,3-Propanediol	Polyamine
Sodium or ammonium citrate	2-Methyl-2,4-pentanediol	
Sodium or potassium phosphate	Dioxane	
Sodium or potassium or ammonium chloride	Acetone	
Sodium or ammonium acetate	Butanol	
Magnesium or calcium sulfate	Acetonitrile	
Cetyltriethyl ammonium salts	Dimethyl sulfoxide	
Calcium chloride	2,5-Hexandediol	
Ammonium nitrate	Methanol

of environmentally dependent solubility minima, and each of these minima may afford the opportunity for crystal growth.

Similar effects may be achieved as well by the slow addition to the mother liquor of some relatively mild alcohols or other organic solvents such as ethanol, acetone, or methylpentanediol. The only essential requirement for the precipitant is that at the specific temperature and pH of the experiment, the additive not adversely affect the structure and integrity of the protein. This is a stringent requirement and deserves some consideration. An organic solvent will compete, to some extent like salt, for water molecules. It also reduces the dielectric shielding capacity of intervening solvent. Reduction of bulk dielectric increases the effective strength of the electrostatic forces responsible for one protein molecule associating with another.

Polymers such as polyethylene glycol also serve to dehydrate macromolecules in aqueous solution, as do salts, and they furthermore alter the dielectric properties in a manner similar to organic solvents. They produce, however, an additional important effect. Polyethylene glycol perturbs the natural structure of the solvent and creates a more complex network having both water and itself as structural elements. A consequence of this restructuring of solvent is that macromolecules, particularly proteins, tend to be excluded, and phase separation is promoted (43,44). This is illustrated for several proteins in Figure 7.

Combinations of approaches using both precipitating agents, such as those seen in Table 2, and variation of physical parameters are frequently effective in promoting the crystallization of macromolecules. Increasing the concentration of a precipitating agent to a point just below supersaturation and then adjusting the pH or temperature to further reduce the solubility of the protein is a common approach. Modification of pH can be brought about quite well using the vapor diffusion technique (see later section) with volatile acids and bases such as acetic acid and ammonium hydroxide.

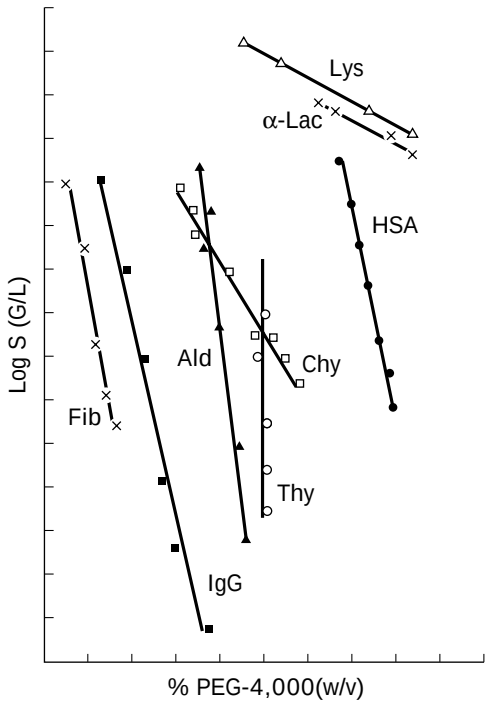

Figure 7. Solubility of various proteins in PEG-4,000. Measurements were made in 0.05 M potassium phosphate, pH 7.0, containing 0.1 M KCl. Human fibrinogen (×), human γ-globulin (■), lysozyme (△), α-lactalbumin (+), chymotrypsin (□), aldolase (▲), thyroglobulin (○), human serum albumin (•).

Because of the complexity of interactions between solute and solvent and the shifting character of the protein (45), the methods of crystallization must usually be applied over a broad set of conditions with the objective of discovering the particular minimum (or minima) that yield crystals. In practice, one determines the precipitation points of the protein at sequential pH values with a given precipitant, repeats the procedure at different temperatures, and then examines the effects of different precipitating agents and their concentrations.

METHODS FOR PROMOTING SUPERSATURATION

The oldest technique used for the crystallization of proteins and nucleic acids (see Table 1), with a history of more than 150 years (46), is what is commonly called batch crystallization (32,33,38,47–49). It is the simplest, most thoroughly tested, and when optimized, the most reliable of all crystallization methods. Lysozyme, for example, is most generally crystallized by the batch method. It relies on the mixing of a protein solution at undersaturated concentration with precipitant components. The latter alter the electrolyte properties of the solution to produce a mother liquor supersaturated with respect to protein. From such a solution the solid state may be expected to eventually form, and if the conditions and physical parameters have been chosen correctly, this solid state will be crystalline rather than amorphous. Alternatively, the physical state of an undersaturated protein solution may be altered by, for example, lowering or raising the temperature. The supersaturated solution produced as a result may yield crystals.

The batch method is attractive because of its inherent simplicity and reproducibility. It requires nothing more than the combination of two or more solutions into one and a period of time until nucleation commences and growth follows. The concept is appealing because it can be carried out with an absolute minimum of human intervention. Because the apparatus is nothing more than a container for a small quantity of fluid, which can be varied as circumstances require from a few microliters to hundreds of milliliters, it is fully amenable to interface with both simple and complex observational systems designed to monitor and record the process of protein crystal growth. Thus, the technique is very useful, for example, for inelastic light scattering studies of nucleation (50–57), or time-lapse photography investigations of protein crystal growth (58,59). It is particularly attractive as well for macromolecular crystallization experiments in space.

Batch crystallization requires no complex device to produce equilibration, either through the liquid or the vapor phase. It relies strictly on the energetics of the system—the activation barriers to nucleation—to regulate the process. Although it has not, in recent years, been extensively used to screen for protein crystallization conditions, this reflects more a prejudice of investigators and the popularity of other methods rather than any deficiency in the batch method itself. Because it was commonly used in the past with fairly large volumes of protein solution, investigators have mistakenly come to believe that it is inappropriate for small samples, which is untrue. It can even be carried out using microliter amounts in glass capillaries or under oil. It can be a useful screening technique as well as a good method for the preparation of large quantities of protein crystals once optimal values for parameters are established.

There are a number of ingenuous devices, procedures, and methods for dynamically altering the degree of saturation of a protein solution. Generally, these rely on the slow increase in concentration of some precipitant such as salt or polyethylene glycol. These same approaches can of course also be used for salting-in, modification of pH, and the introduction of materials that alter protein solubility. These techniques have been extensively reviewed elsewhere (32–36,60–63), and only a selection will be dealt with here.

Dialysis is familiar to nearly all biochemists as a means of modifying the components of a protein solution (32,33). As illustrated in Figure 8, the solution containing the protein is enclosed in a membrane casing or in a container having a semipermeable membrane partition. The membrane selectively allows the passage of small molecules and ions, but pore size prevents passage of the much larger protein molecules. The vessel or dialysis tube containing the protein is submerged in a larger volume of liquid that has the desired properties of pH, ionic strength, ligands, and so forth. With successive changes of the exterior solution and concomitant diffusion of small molecules and ions across the semipermeable membrane, the protein solution gradually acquires defined properties.

The dialysis approach, in some manifestation, has been used to crystallize many proteins (27,33). It was usually applied on a large scale, and only when substantial

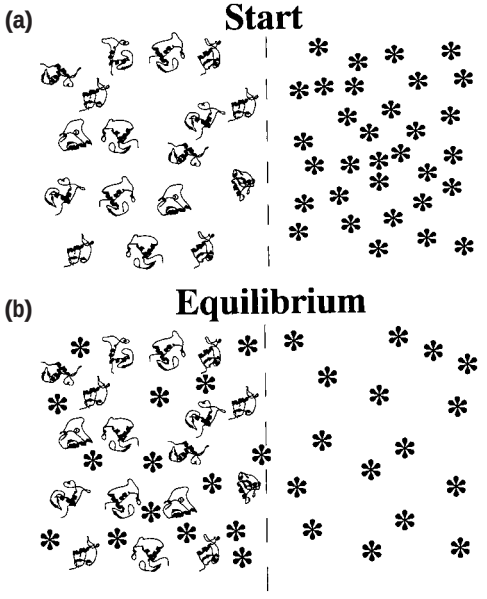

Figure 8. A schematic description of the dialysis process. (top) Protein molecules are separated from conventional small molecules or ions by a semipermeable membrane that prevents the macromolecules from passing. (bottom) The small molecules or ions have passed through the membrane and at equilibrium are equally distributed on its two sides.

amounts of protein were available. It has the advantage that liquid–liquid diffusion through a semipermeable membrane exposes the protein to a continuum of potential crystal-producing conditions without physically perturbing the mother liquor. Diffusion through the membrane is slow and controlled. Because the rate of exchange of substituents in the mother liquor is a function of the concentration gradient across the membrane, the nearer the system to equilibrium, the more slowly it changes.

This method has been adapted to much smaller amounts of protein by crystallographers who use almost exclusively microtechniques. These typically involve no more than 5 to 50 μl of protein solution in each trial. First described by Zeppenzauer et al. and Zeppenzauer (64,65) and subsequently modified and refined by numerous others, the method confines a protein solution within a glass capillary or the microcavity of a small plexiglass button. The cavity of the button or the ends of the microcapillary tube are closed off by a dialysis membrane. The whole arrangement, charged with protein solution, is then submerged in a much larger volume of an exterior liquid that is held within a closed vessel such as a test tube or vial. The microdyalysis method is shown schematically in Figure 9. If the exterior solution is at an ionic strength or pH that induces the mother liquor to become supersaturated, crystals may grow. If not, the exterior solution may be exchanged for another and the experiment repeated.

The dialysis buttons, seen in Figure 10, are particularly ingenious. Not only are they compact and easy to examine with a dissecting microscope, but they have a shallow groove about their waist. A section of moistened dialysis membrane is placed over the mother-liquor-filled cavity, and it is held securely in place by simply slipping a rubber O-ring over the top of the button and seating it in the groove. These buttons are in wide use and have proven quite successful.

The technique of liquid–liquid diffusion (Figs. 11 and 12), also known as free-interface diffusion, for the crystallization of macromolecules (25–27,62,63,66) is in principle and practice simple and straightforward. It relies on the direct interdiffusion of a precipitant solution into a protein solution across their common liquid–liquid interface. When the two solutions are juxtaposed, precipitant gradients form in the region of the interface and produce local supersaturation. This promotes the formation of crystal nuclei and subsequent growth, often to sizes useful for analysis.

The fundamental idea of liquid–liquid diffusion of a solvent or solute into a macromolecular solution is similar to dialysis. The method is particularly applicable in microgravity because the necessity of a membrane is eliminated and the two liquids can be maintained relatively stable with respect to one another for long periods of time. Because the diffusion rate of macromolecules is so much less than that of the small molecules of most precipitants, there is relatively little penetration of protein into the precipitant during the course of most experiments.

The technique of liquid–liquid diffusion has been applied in laboratories on earth to grow macromolecular crystals, and with some success. A search of the National Institute of Standards and Technology (NIST) database (26,27) shows 35 entries using this technique with another 193 ascribed to various kinds of dialysis. Direct liquid diffusion has not, however, been as extensively used in conventional laboratories as have some other techniques, such as batch or vapor diffusion, because of some inherent disadvantages. Significantly, most of these methodological deficiencies are relieved or eliminated in the absence of gravity.

On earth, density-driven convective currents produce immediate and continuous turbulence at the liquid–liquid interface. Transient mixing, if layering of solutions is used, or the necessity of a membrane, as in dialysis, lessens the methods' effectiveness. Sedimentation produces a particularly deleterious effect with the free-interface method because nuclei and small growing crystals, under the influence of gravity, fall from the liquid–liquid interface. Thus, as a crystal forms, gravity increasingly pulls it downward from the region of the solution where growth would most favorably continue. Gravity essentially removes growing crystals from an optimal growth environment and thereby imposes a self-limiting character on the process, in turn restricting crystal size.

Currently, the most widely used method for bringing about supersaturation in microdrops of mother liquid is vapor diffusion (26,27) (Fig. 13). This approach (32,33,35, 60,62,63,67) has provided a diversity of applications and may be divided into those procedures that use a "sitting

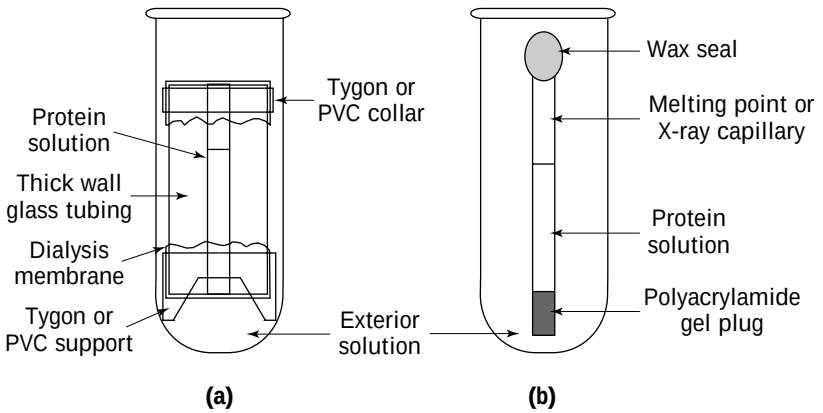

Figure 9. A microdialysis cell (**a**), for crystallization of small protein samples, is closed at one end by a section of dialysis membrane held in place by a Tygon ring that also serves as a support. (**b**) A similar arrangement using a thin glass capillary, but the membrane has been replaced by a polyacrylamide plug that is permeable to small molecules and ions.

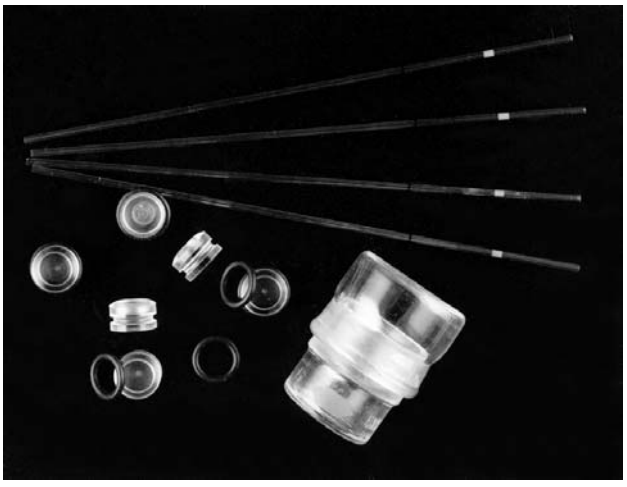

Figure 10. The thin glass capillaries shown here may be used for either batch crystallization or crystallization by dialysis with volumes in the microliter range. The dialysis buttons seen both face on and on edge can be closed by dialysis membrane held in place by the rubber O-rings. Once filled with protein solution they can be submerged in a larger volume of solution contained, for example, in the small weighing bottle.

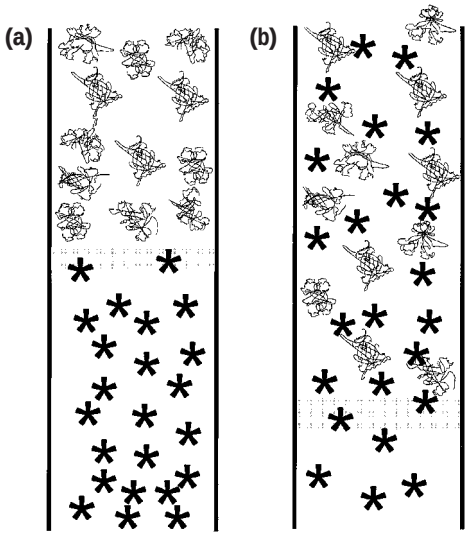

Figure 11. In free-interface diffusion the protein solution is (left) initially layered atop a precipitant solution, such as a highly concentrated salt. Diffusion of the small molecules into the protein solution (right) induces crystallization to occur.

drop" and those that use a "hanging drop." In either form, the method relies on the transport of water or some volatile agent between a microdrop of mother liquor, generally 2 to 25 μL volume, and a much larger reservoir solution of 0.75 to 25 mL in volume. Through the vapor phase, the droplet and reservoir come to equilibrium. Because the reservoir is of much larger volume, the final conditions at equilibrium are essentially those of the initial reservoir state. A variety of devices currently in use for protein crystal growth by vapor diffusion are shown in Figure 14.

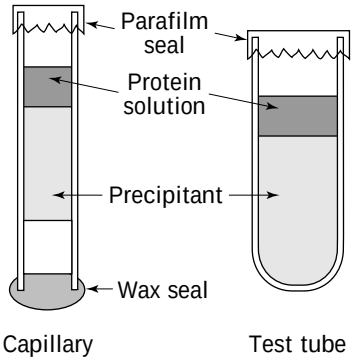

Figure 12. Diagram illustrating the free-interface diffusion technique for the crystallization of microliter amounts of protein solution on the left and milliliter amounts on the right. The method relies on the direct diffusion of precipitant and small molecules across the liquid–liquid interface.

In the vapor phase, water can be removed slowly from droplets of mother liquor, pH may be changed, or volatile components such as ethanol may be gradually introduced. As with those methods already described, the procedure may be carried out to further advantage at a number of different temperatures.

According to one popular procedure (32,33,67) (Fig. 15), droplets of 10 to 20 μL are placed in the nine wells of siliconized glass depression plates. The samples are then sealed in transparent containers, such as Pyrex dishes or plastic boxes that also hold reservoirs of 20 to 50 mL of the precipitating solution. The plates bearing the protein or nucleic acid samples are supported above the reservoirs by the inverted halves of disposable Petri dishes. Through the vapor phase, the concentration of salt or organic solvent in the reservoir equilibrates with that in the sample. In the case of salt precipitation, the droplet of mother liquor must initially contain a level of precipitant lower than the reservoir, and equilibration proceeds by diffusion of water from the droplet into the reservoir. This holds true as well for nonvolatile organic solvents, such as methylpentanediol and for polyethylene glycol. In the case of volatile precipitants, none need be added initially to the microdroplet, because distillation and equilibration proceed in the opposite direction.

The method described here has the advantage that it requires only microliter amounts of material and is well suited for screening large numbers of conditions. A disadvantage is that all the samples in a single container must be equilibrated against the identical reservoir solution. It does, however, permit some flexibility in varying conditions once the samples have been dispensed, by modification of the concentration or pH of precipitants in the reservoir. When clear plastic boxes are used, large numbers of samples can be quickly inspected under a dissecting microscope and conveniently stored.

The disadvantage of identical reservoir conditions throughout a single container was overcome by the introduction of plastic plates specifically designed for protein crystallization. One of these, sponsored by the American

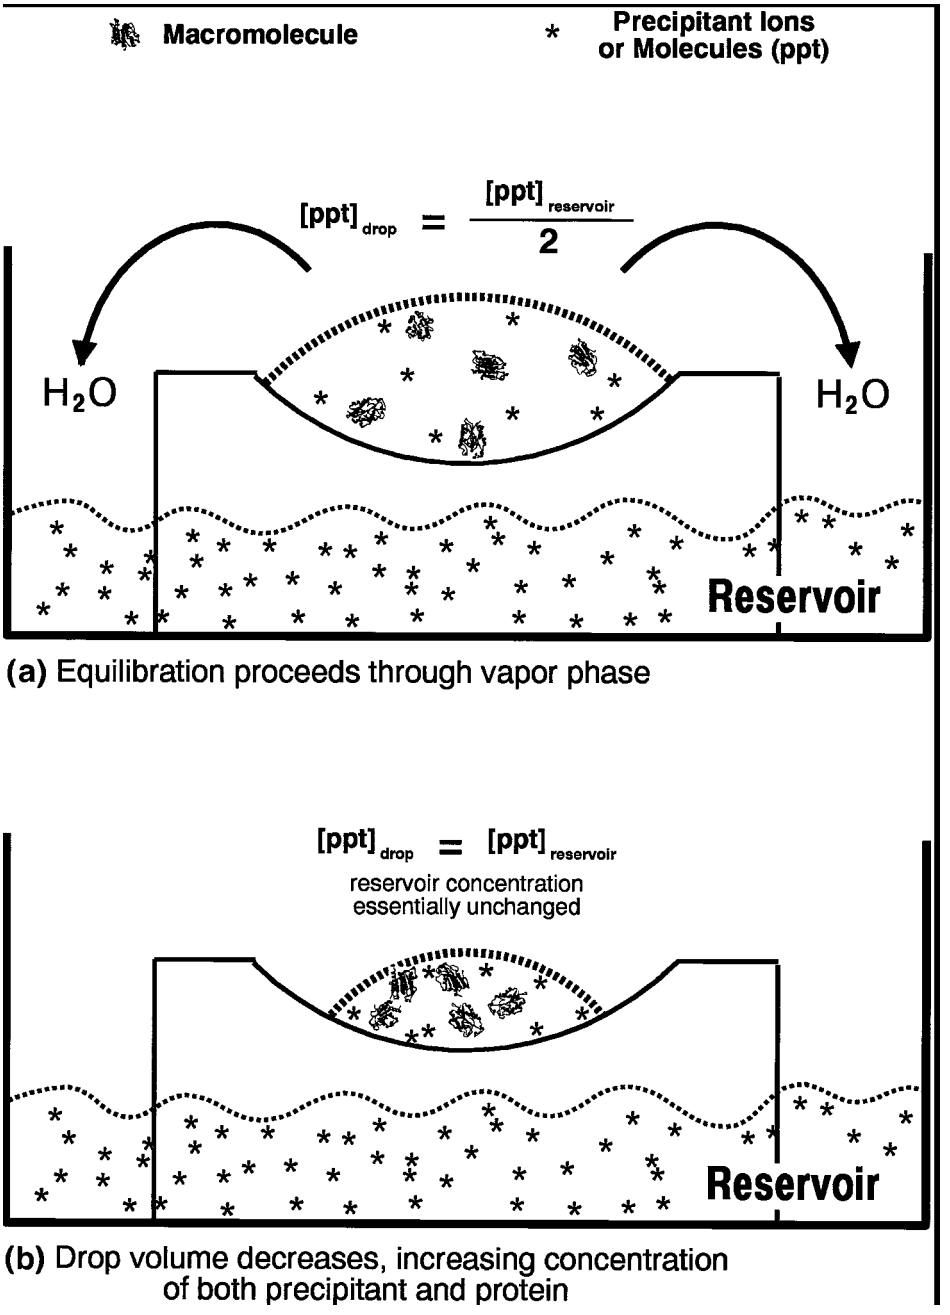

Figure 13. In vapor diffusion, a small drop of mother liquor containing protein and a low concentration of precipitant is, in (**a**), initially exposed to a much larger reservoir solution containing a high concentration of precipitant. At equilibrium in (**b**), through loss of water and reduction in volume, the mother liquor achieves a precipitant concentration approximately equal to that in the reservoir, thereby promoting crystallization of the protein to occur.

Crystallographic Association, is a plastic plate having accommodation for 15 protein samples. Each chamber has a separate reservoir compartment and the mother liquor microdroplet may be either suspended from the underside of a glass cover slip, as in the hanging drop method described later, or sandwiched between two glass cover slips. Sealing of the chambers from air requires silicon grease or oil between cover slips and the plastic rims of the chambers. With these plates, the optical properties are very good but equilibration tends to be slow, and the setup is quite tedious.

A second crystallization plate (68), also seen in Figure 14, is supplied by Charles Supper. With these plates, the drop sits atop a clear support post that protrudes upward from a circular moat containing the reservoir solution. The chambers can be rapidly and conveniently sealed from air by transparent plastic tape pressed over the upper surface of the plate after the reservoirs have been filled and the drops of mother liquor dispensed. Equilibration, as with the other plate, is through the vapor phase. Although the optical properties are less favorable with these devices, they are convenient and compact and can be used for rapid screens of crystallization conditions.

The hanging drop procedure (Fig. 16) also uses vapor phase equilibration, but with this approach a microdroplet of mother liquor (as small as 2 μL) is suspended from the underside of a microscope cover slip, which is then placed over a small well containing a milliliter or less of the pre-

Figure 14. Four examples of trays, plates, or combinations used for crystallization by vapor diffusion. All are commercially available and can be used for either the hanging-drop or the sitting-drop approach.

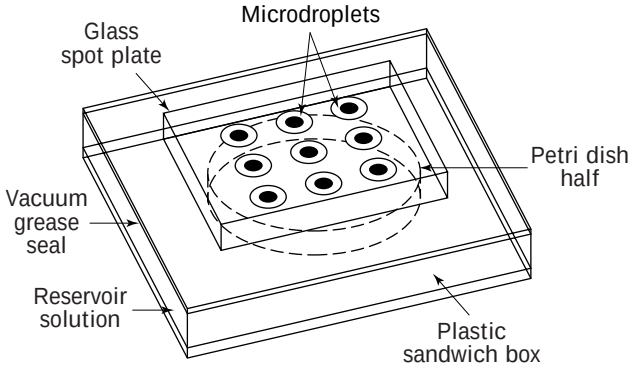

Figure 15. Schematic diagram of a nine-well depression spot plate enclosed in a plastic sandwich box used for the crystallization of macromolecules by the vapor diffusion method. Microdrops of 10 to 25 μL can be placed in the depressions with 25-mL reservoirs of precipitating solution in the bottom of the box. Equilibration proceeds through the vapor phase.

cipitating solution. The wells are most conveniently supplied by disposable plastic tissue culture plates that have 24 wells with rims that permit sealing by application of silicone vacuum grease around the circumference. The hanging drop technique can be used both for the optimization of conditions and for the growth of large single crystals.

Although the principle of equilibration with both the sitting drop and the hanging drop is essentially the same, they frequently do not yield the same results even though the reservoir and protein solutions may be identical. Presumably because of geometrical differences in the apparatus used to achieve equilibration, the path to supersaturation is different, even though the end point may be the same. In some cases there are striking differences in the degree of reproducibility, final crystal size, morphology, or time required for growth. These observations emphasize the point that in crystal growth the route leading to supersaturation and the kinetics of the process may be as

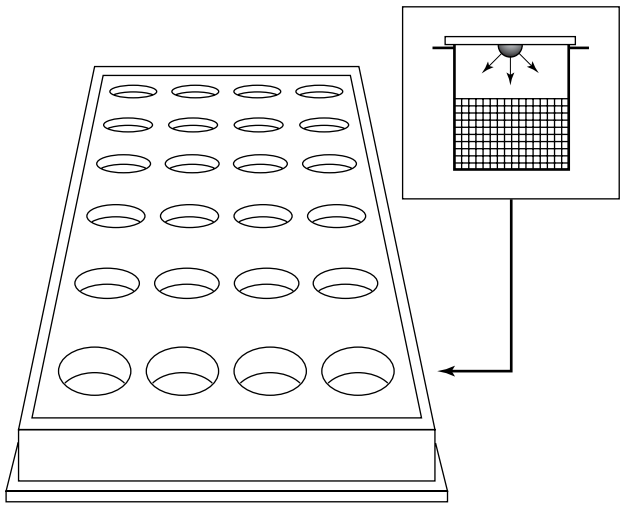

Figure 16. The standard configuration for hanging drop protein crystallization experiments is shown here. A tissue culture plate provides 24 wells for reservoirs of about 0.5 to 0.75 mL. Each well can be covered by a glass slip with a drop of protein solution hanging from its underside. The drop of 2 to 20 μL equilibrates with the reservoir solution over time through the vapor phase, causing precipitant concentrations to increase in the drop and induce crystallization.

important as the end point achieved. There are nearly limitless variations on these themes for liquid–liquid or vapor diffusion, ranging from the very simple to the unnecessarily complex. You need only use a bit of imagination to devise a novel approach for yourself.

With some exceptions, the methodologies used for protein crystallization, most of those described above, have been devised for the growth of crystals from very small volumes of mother liquor. Indeed, reducing the amount of material needed has been a principal objective in X-ray crystallography laboratories for some time. Crystals can now be obtained from only 2 to 4 μL of solution, and entire screening matrixes (see later discussion) can be explored using only 2 to 5 mg of protein or nucleic acid.

Two major applications of protein crystallization, for formulations, and for downstream processing of macromolecules do not, however, benefit from reduction in scale. On the contrary, they profit from very large volumes and high yields of the crystalline product. As a consequence, the microtechniques described earlier may represent model approaches, but they are, in themselves, quite inappropriate to bulk processes.

Large-scale, industrial crystallizations are, at least currently, limited to methods based essentially on batch crystallization in combination with manipulation of pH and temperature. In addition, many chemical compounds that might be used as precipitants or additives in laboratory settings cannot be used in many cases in bulk processes because of expense, hazard, or the creation of unacceptable by-products (7). Although this might appear severely limiting, remarkable success has been achieved using only these simple tools. The large number of biological macromolecules in crystalline form and produced in kilogram (or

larger) amounts available on the commercial market attests to this.

The restriction on techniques is compensated to a great extent in industrial processes by other factors. For example, the objective protein is usually in relatively high concentration and comprises a significant fraction of the total protein present. It is usually produced by genetically engineered or overproducing strains of simple microorganisms; hence, it does not suffer from many of the sources of microheterogeneity, seen in Table 3, that afflict many natural products. In addition, crystals produced in large-scale processes are usually very small crystals of marginal perfection that would be unsuitable for analytical work. Such crystals may, however, be entirely appropriate for the intended purpose of purification and product formulation.

THE CRYSTALLIZATION OF PROTEINS BY VARIATION OF PH OR TEMPERATURE

One of the most useful techniques for producing a supersaturated solution is adjustment of pH to values where the protein is substantially less soluble. This may be done in the presence of a variety of precipitants so that a spectrum of possibilities are created whereby crystals might form. The gradual alteration of pH is particularly subtle because it may be accomplished by a variety of gentle approaches that do not otherwise perturb the system. Although microdialysis is probably equally suitable, more success with pH has been achieved by the vapor diffusion method, using "sitting" microdroplets on spot plates or in one of the plastic plates available for protein crystallization. The ambient salt, effector, or buffer conditions are established before dispensing the microdroplets in the depressions on the plate. The pH is then slowly raised or lowered by adding a small amount of volatile acid or base to the reservoir. Diffusion of the acid or base then occurs from reservoir to sample, just as for a volatile precipitant.

If the pH is to be raised, for example, a small drop of concentrated ammonium hydroxide can be added to the reservoir; a drop of acetic acid may be used to lower it. The pH can also be gradually lowered over a period of days by simply placing a tiny chip of dry ice in the reservoir. The liberated CO_2 diffuses and dissolves in the mother liquor to form weak carbonic acid. When a specific pH end point is required, the mother liquor may be buffered at that point and then moved significantly away by addition of acid or base. The microdroplets of mother liquor may then be returned to the buffer point by addition of an appropriate volatile acid or base to the reservoir.

As shown in Figure 4, individual proteins display distinct solubilities at varying levels of salt concentration and can be selectively separated from solution as amorphous precipitate or crystals. At very low ionic strengths where salting-in occurs, the solubility of the protein increases with the ionic strength because of a decrease in its activity coefficient. The salting-out effect, which Hofmeister (39,41) suggested to be caused by a reduction of the chemical activity of water by salt, occurs as the ionic strength increases. Because ionic strength is a function of the second power of the valence, multivalent ions are most efficient. In the salting-out region of a protein's solubility profile, the logarithm of protein solubility as a function of the ionic strength is linear and can be expressed by

$$\log S = \beta - K_s(I/2)$$

where I is the ionic strength in moles per kilogram of water, S is the solubility of the protein in grams per kilogram of water, and K_s is a constant. K_s serves as a measure of the slope of the solubility extrapolated to zero ionic strength and is the logarithm of the solubility at that point (39).

In principle, the precipitation or crystallization of a protein is effected by manipulating the factors that appear in the above equation. One can crystallize a macromolecule by increasing the ionic strength at constant pH and temperature, a K_s fractionation procedure, or it can be brought about at constant ionic strength by manipulating the pH and temperature, which in most cases strongly influence solubility.

With all techniques, the objective is to produce a supersaturated protein solution by very gradual and nonperturbing adjustment of conditions. An example is shown in Figure 17. In practice, a solubility minimum is determined for the protein at some specific pH, temperature, and ionic strength. The protein solution is set initially at the requisite salt concentration for this solubility minimum, but either the pH or temperature is set initially to maintain protein solubility. The temperature is then slowly relaxed to minimize protein solubility, or the pH is gradually equilibrated via the liquid or vapor phase to an appropriate value.

In the case of temperature shifts, the protein is generally raised to a higher temperature, as, for example, with squash globulin, insulin, or excelsin (41,42,50,52,69,70), a

Table 3. Sources of Microheterogeneity

Presence, absence, or variation in a bound prosthetic group, substrate, coenzyme, inhibitor, or metal ion
Variation in the length or composition of the carbohydrate moiety of a glycoprotein
Proteolytic modification of the protein during the course of isolation or crystallization
Oxidation of sulfhydryl groups during isolation
Reaction with heavy metal ions during isolation or storage
Presence, absence, or variation in post-translational side-chain modifications such as methylation, amidiation, and phosphorylation
Microheterogeneity in the amino or carboxy terminus or modification of termini
Variation in the aggregation or oligomer state of the protein caused by association or dissociation
Conformational instability caused by the dynamic nature of the molecule
Microheterogeneity caused by the dynamic nature of the molecule
Partial denaturation of sample
Genetically different animals, plants, or microorganisms that make up the source of protein preparations
Bound lipid, nucleic acid, or carbohydrate material or substances such as detergents used in the isolation

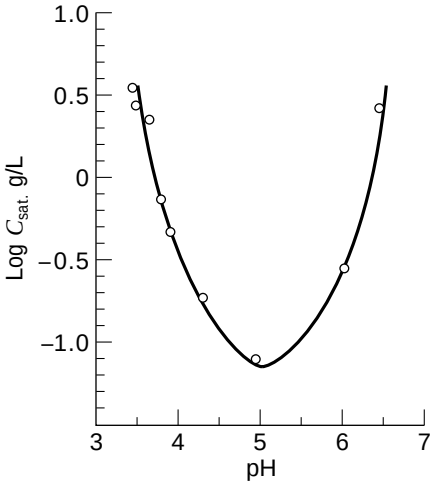

Figure 17. The solubility of insulin falls dramatically in the immediate neighborhood of pH 5, providing a ready means for creation of a supersaturated solution. The protein is simply dissolved to high concentration at pH 7 or higher, and the pH subsequently lowered through addition of H_3O^+ by vapor diffusion or dialysis.

process that increases solubility. The solution is then cooled slowly to where the protein is no longer soluble. This can be achieved by placing the warm solution in an insulated or thermally controlled container or by placing the sample in a Dewar flask. The approach to supersaturation thus occurs at an almost imperceptible rate. Exactly the same technique can be applied if the protein is more soluble at cold than warm temperature. Under these circumstances, the protein solution is cooled under established ionic strength conditions and then allowed to warm slowly. This approach was used, for example, to grow crystals of DNase by Kunitz (71) and is the basis of Jakoby's sequential extraction procedure using decreasing concentrations of ammonium sulfate (72).

The use of pH gradients in space and time has been successful in many investigations (26,27); they can be used in association with direct liquid dialysis or with vapor diffusion methods as well. They can, furthermore, be used in conjunction with a host of different precipitating agents. Temperature can be used in an analogous manner (73).

Proteins and nucleic acids are structurally flexible and are believed to alternate between several conformational states. In particular, they may assume substantially different conformations when they have bound coenzyme, substrate, or some other ligand. As a consequence, a protein with bound effector may exhibit different solubility properties than the nonliganded form. In addition, if multiple conformational states are available, the presence of effector may be used to select for only one of these, thereby imposing a degree of conformity of structure that would otherwise be absent.

The addition of ligands can sometimes be used to induce supersaturation and crystallization in those cases where its binding to the protein produces solubility differences under a given set of ambient conditions. The effector may be slowly and gently combined with the protein, for example, by dialysis, so that a resulting complex becomes supersaturated. The addition of ligands, substrates, and other small molecules has seen widespread use in protein crystallography, because it provides useful alternatives if the apoprotein itself cannot be crystallized.

No matter what the ultimate objective of macromolecular crystallization is, it is first necessary to (*1*) identify a set of physical and chemical conditions that yield some kind of crystals, (*2*) optimize those conditions, and (*3*) reproducibly apply the conditions according to reliable procedures that will consistently produce the requisite crystals. Thus, the initial step consists of screening large numbers of possible precipitants, buffers, effectors, pHs, temperatures, etc. The second is a careful screening using a finely sampled matrix of conditions focused on those that yielded crystals, and the third is on devising reproducible procedures for application. Clearly, the first stage is the greatest hurdle that must be overcome, but it is not necessarily the step demanding the most effort. Table 4 is included here, not to alarm or intimidate the novice, but to alert those interested in macromolecular crystal growth of the complexities and the many factors that may have an impact on a crystal growth investigation. Fortunately, only a few of these factors may be simultaneously operative for a particular problem; the trick is to discover which they are for your specific case.

How does one begin the process, that is, how do you discover those initial conditions that yield crystals and provide starting points? Over the years, a vast number of reports and observations entered the literature, without much form or even clear purpose (46). Attempts were made to sort and classify (48,74); to shape ad hoc experiments into more rational approaches (26,32,34,55,75); to gather,

Viscosity of mother liquor
Heterogeneous or epitaxial nucleating agents

collate, and systematize the experiences of thousands of investigators into rationally constructed databases (27,37); and finally to extract from those bases arrays of conditions most likely to yield protein and nucleic acid crystals.

These sets of conditions form the foundation for the crystal screens (57,76–82), now commercially available (Hampton Research), that have virtually revolutionized the initial search for crystallization conditions. Although some important macromolecules continue to slip through these still imperfect nets, the number of successes is impressive. Improved screening techniques alone are to a great extent responsible for the explosion of new crystals, grown not only by crystallographers, but by the myriad of biochemists and molecular biologists whose need for structure is acute. The search for novel, and perhaps even better, precipitants and conditions for crystal growth continues, and we can reasonably expect even more useful developments in this area.

With arrays of high-probability conditions that need be tested against no more than a few milligrams of protein or nucleic acid, attention has focused on the macromolecules themselves. Three principles have clearly come forward: purity, stability, and solubility. Failure in crystallization can probably be attributed, in general, to one or more of these.

Homogeneity has always been recognized as important, though not always essential. The trick is to recognize when it is the crucial factor and direct one's efforts there. Important advances have been made with regard to purification. Not only are there now more powerful techniques and instruments available (36,83), but crystallography has benefited to an extraordinary degree from the refinements of recombinant DNA technology and the development of high-yield expression systems (84–86). With the introduction of endogenous purification tools such as the histidine tag or glutathione sulfur transferase (GST) chimers (87), even greater availability of ultrapure crystallizable protein seems on the horizon. Recombinant systems provide us not only with pure, native proteins, but a way to introduce mutations and thereby create almost limitless alternatives should the native molecule prove unyielding. They offer systematic approaches as well to the intelligent engineering of solubility properties and stability.

Chemical and conformational stability of the target macromolecule, too, has long been recognized and given serious attention. Ligands are used to lock discrete conformations, disulfides introduced by mutation or chemical modifications are made to reduce mobility (88), proteins and ribosomes from thermophilic organisms are used for their natural stability, and proteolytic or mutational truncations are made to remove naturally flexible domains or elements (36). We are only beginning to understand how to manipulate conformation to enhance crystallization properties (89), and this area also promises much for the future, particularly for challenging topics such as antibodies, multiple domain enzymes, and multimolecular complexes.

Perhaps the principle least recognized but now receiving the most attention is solubility, meaning here not only dissolution of macromolecules in a liquid, but in a disaggregated, monodisperse molecular form. Indeed, we have come to recognize aggregation and polydispersity as a principal reason why many macromolecules cannot be crystallized. This includes not only membrane and lipophilic proteins (90) but macromolecules that have a strong propensity to aggregate, such as antibodies (91), hormone polypeptides, and proteins whose purpose is ordered aggregation, such as those from viral capsids.

Extending observations that nonionic detergents promote the growth of hydrophilic (92) as well as membrane proteins (90,93), light-scattering studies have confirmed the salient importance of monodispersity in macromolecular crystallization (50,53,78,94,95). The current consensus among those involved in crystallization research is that if by some means monodispersity can be ensured, then there is better than an 80% chance that crystals will be obtained. To promote monodispersity, the common approaches are to incorporate detergents in crystallization trials or to crystallize at low protein concentrations, at higher temperatures, or in the presence of chaotropic agents. This is an area that continues to be under active investigation.

Additional factors have emerged from recent crystal growth research and from the empirical results generated by the current revolution in crystallography. Among them are the importance of surfaces and their promotion of heterogeneous nucleation (96–100), the value of unique environments such as microgravity (101–103), gels (104–106), thin capillaries (107), the broad range of polymeric precipitants useful in growing crystals (108,109), and new approaches to solving the problem of persistent microcrystals (110).

OUTLINE

INTRODUCTION

Crystallization is a mass transfer separation process commonly used in many chemical industries. It permits highly selective purification of a material from an impure mixture, and the crystalline state of the final product is frequently advantageous. Whereas bulk crystallization has been applied for the purification of many small organic biological products, including antibiotics and amino and or-

ganic acids, and has played an important role in chiral resolutions of organic materials, until recently it has been applied only rarely to the bulk purification of proteins. It is well known that proteins, despite their large size, can be crystallized. Nevertheless, a survey of the vast protein crystallization literature, almost entirely devoted to producing crystals for X-ray studies, reveals that protein crystallization has been perceived generally to be tedious, difficult, and disrupted by the presence of impurities. These perceptions have perhaps arisen because of the unique requirements of protein X-ray crystallography, which remains the primary method for the determination of protein structure. The requirements for X-ray crystallography and bulk protein crystallization are contrasted in Table 1. The significant differences highlight the fact that many of the well-known issues that bedevil the production of protein crystals for X-ray crystallography are not germane to the bulk crystallization of proteins for manufacturing uses. In fact, the bulk crystallization of many proteins is found to be reasonably straightforward, similar in nature to the crystallization of inorganic molecules (1), and capable of achieving high degrees of purification at good yield and large throughput. This article will focus on existing knowledge relevant to the bulk crystallization of proteins from solution and largely bypass the more specialized field of protein crystallization for X-ray crystallography, for which excellent reviews already exist (2,3). Useful general reference books on bulk crystallization of materials include those by Randolph and Larson (4) and Mullin (5).

THE PROTEIN CRYSTAL

In addition to the beauty of the crystalline form (Fig. 1), protein crystals share many features in common with smaller inorganic and organic molecule crystals. They consist of highly ordered molecular arrays with distinct crystal faces. Proteins usually exhibit polymorphism, leading to several crystallographic forms, depending on various factors including the nature of the precipitant or the temperature (Table 2). Obtaining the most appropriate crystal form is often important for process manufacture, because "chunkier" crystal forms are easier to wash, store, and transport without excessive crystal damage and fragmentation. Needle forms, which are difficult to process, occur commonly in industrial practice. Transition boundaries between different polymorphic forms must be established experimentally and may be affected by many factors, including temperature, pH, and precipitant type and concentration. A common example is the tetragonal-orthorhombic transition for lysozyme, which occurs at about 25 °C (6). Further, the crystals may undergo significant habit change in the presence of impurities or under varying conditions (7) and exhibit dendritic morphologies during very high crystal growth rates.

A significant feature of all protein crystals is their large degree of incorporated solvent, which is typically 50% v/v (8), but varies generally between 30 and 80%. This has the practical result of making protein crystals unstable when exposed to air, resulting in their rapid collapse to an amorphous state. Consequently, protein crystals are usually maintained as a liquid crystal slurry.

SOLUBILITY

Crystallization processes depend on the production of a supersaturated solution that leads to the formation of the crystalline solid phase, consisting primarily of solute. Consequently, an accurate protein solubility data set determined for the conditions chosen for the crystallization process is essential. Two processes are fundamental to crystallization: nucleation and subsequent crystal growth by addition of additional solute to the nucleated crystal. The extent of supersaturation is the primary determinant of both the yield of crystalline solute from the solution and the rate of crystal growth.

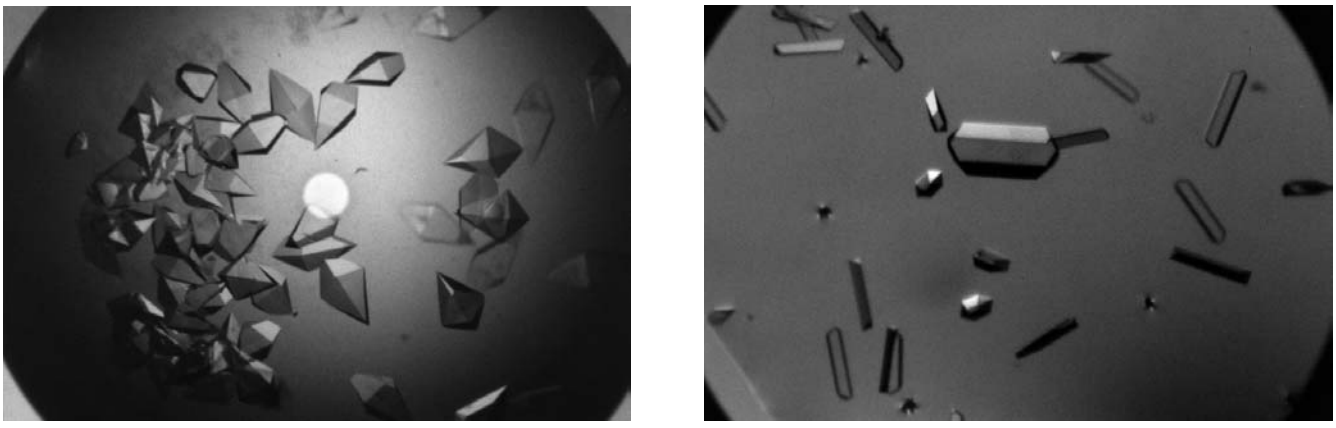
Nucleation

The influence of solubility on the crystallization process is illustrated by Figure 2. Under any set of conditions, there is a unique protein solubility given by the solubility curve. This curve represents the thermodynamic boundary at which there is stable coexistence of solid and dissolved protein forms. Below the solubility line, solution conditions thermodynamically favor the maintenance of a single, homogeneous liquid phase, and protein crystals added to this solution will dissolve. Solution conditions that lie above the solubility curve represent supersaturated conditions under which the formation of a protein-rich solid phase and a saturated liquid phase are favored. The solubility data represent the lower limit of the crystallization process in that once the protein concentration in solution declines to this concentration, the system is at equilibrium and no further crystallization is possible.

Metastable Region. The supersaturation region can be further divided into a metastable region and a nucleation

Table 1. The Conflicting Crystallization Needs of X-ray Crystallographers and Bulk Protein Manufacturers

	X-ray crystallography	Bulk manufacture
Aim of crystallization	Protein structure determination	Protein purification
Protein used	Usually novel	Usually well characterized
Protein quantity available	Usually limited (mg)	Large (grams or more)
Number of crystals desired	One	Unlimited
Crystal size	Generally $>300\ \mu$m	$25\ \mu$m or more
Lattice order	Very highly ordered	Ordered
Solution purity	Preferably free of impurities and protein heterogeneity	Usually contains many impurities



(a) **(b)**

Table 2. Polymorphic Forms of Proteins

Protein	Crystal form	Condition	Reference
Lysozyme	Tetragonal, orthorhombic	Temperature	6
Lysozyme	Monoclinic; triclinic; tetragonal	Nature of salt	9
Cytochrome c_2	Hexagonal; triclinic; tetragonal	Ionic strength, pH	10
Ovalbumin	Monoclinic; triclinic	pH	11

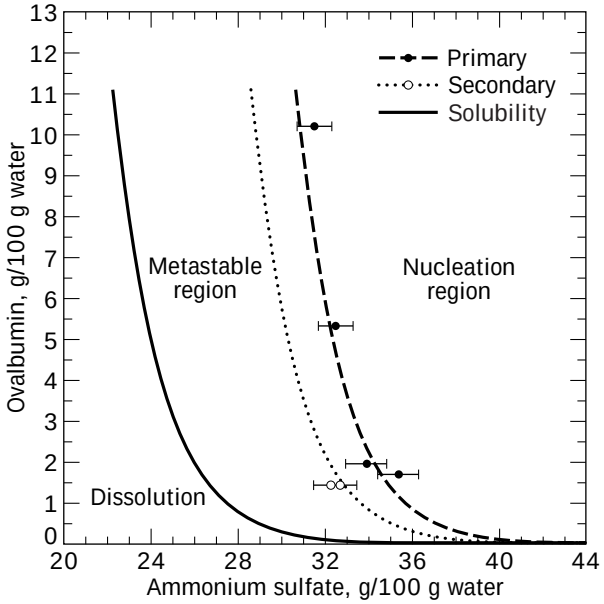

Figure 2. Solubility and nucleation data for ovalbumin at pH 5.2 and 30 °C (11).

region. The metastable region represents a region of low supersaturation in which nucleation does not occur spontaneously within times useful for crystallization processes, despite the existence of supersaturation. However, if crystals are already present, crystal growth will occur. This is the preferred region for the operation of industrial crystallization processes, since it provides the greatest degree of control over the crystal number in the crystallizer and, hence, crystal size distribution and quality. The width of the metastable region is of great significance for crystallization processes and appears to be reasonable generous for proteins (Table 3), although the available data are extremely limited.

When crystallization processes are operated in the metastable region, the crystallization process must be initiated by providing crystal nuclei to the crystallizer (seeding), so that crystallization can begin. The number, mean size, and size distribution of these seeds are variables that permit the quality of the final crystal product and the process crystallization time to be manipulated (Fig. 3).

Nucleation Region. In some crystallization processes, seeding is not preferred, usually because of requirements

Table 3. Typical Size and Metastable Regions for Various Molecular Species

Molecular category	Size of metastable region (c/c*)
Ionic, inorganic salts	≅1.1 or less
Small organics (e.g., sugars)	≅5–30
Proteins	≅1–20
Large proteins (MW > 200 kDa)	≅1.1 or less

Note: c, concentration; c*, concentration at solubility limit under same conditions.

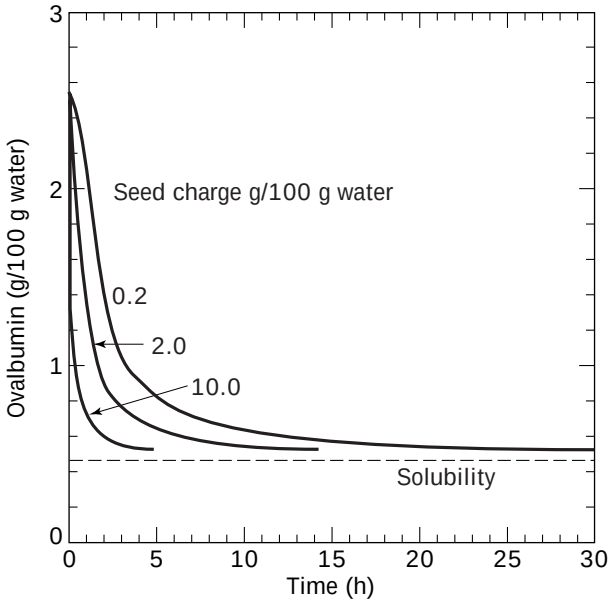

Figure 3. The effect of initial crystal seed charge on the rate of crystallization (given as decrease in ovalbumin concentration in solution) during ovalbumin crystallization from aqueous ammonium sulfate (27% w/v) at pH 4.9 and 30 °C (11).

for aseptic operation (e.g., pharmaceutical preparations) or when a very small (<30 μm diameter) final mean crystal size is desired. In these cases, batch crystallization processes must be initiated in the nucleation region. In this region of higher supersaturation, spontaneous production of large numbers of tiny crystal nuclei will occur after an initial induction time. The control of such processes can be difficult, because rates of crystal nucleation and growth are usually very high at the large supersaturation typical of this region. The nucleation region can be further subdivided into a primary nucleation region, in which nucleation will occur spontaneously from the supersaturated solution (heterogeneous nucleation if active foreign nuclei, such as dust, are present, or homogeneous nucleation if they are not) or secondary region (at lower supersaturation) if crystals are already present. In industrial crystallization, secondary nucleation predominates. However, the threshold between these regions is fuzzy.

Precipitation. At very high supersaturation, conditions will favor the production of a disordered solid phase (precipitation), which usually forms rapidly on nucleation. Such operation generates amorphous protein precipitates, which lack the purity and structural properties of protein crystals. Precipitation processes have been widely used for protein recovery and are covered elsewhere in this encyclopedia. Recent dynamic light scattering (DLS) studies of supersaturated protein solutions have suggested that there is a significant difference in the manner in which homogeneous nucleation occurs for crystallization and precipitation processes (12).

Factors Affecting Protein Solubility

Proteins vary widely in their solubility in aqueous solutions. Most commercially manufactured commodity proteins exhibit high solubilities (40 to 100 mg/mL) in aqueous buffers, but more esoteric proteins can have unusual behavior. For example, some proteins (prolamins) are more soluble in aqueous ethanol than in water (13). Accurate measurement of protein solubility is required for proper design of crystallization processes. This is frequently a tedious process, made difficult by the challenge of obtaining sufficient quantities of pure protein material and the common contamination of the material with heterogeneous forms of the protein, whose effect on the solubility is unclear. For real crystallization processes, the effect of impurities present, often in significant concentration, on protein solubility must not be overlooked. Issues and protocols for protein solubility determination have been discussed by Ries-Kautt and Ducruix (9). Recently, a useful apparatus for the rapid measurement of protein solubility (Fig. 4) using only small quantities of protein has been developed in which solutions near the solubility limit are equilibrated with small volume crystal beds of the protein (14). Protein solubility is affected by many factors, and the major factors are discussed below.

Solution pH. The pH of solution usually has a marked influence on protein solubility. The solubility often exhibits a minimum at the isoelectric point (IEP), with a sharp increase in solubility within small pH changes either side of the IEP (Fig. 5). In concentrated protein solutions, typical of those necessary for protein crystallization, this generalization is fallible. For example, glucose isomerase has an IEP of 4.0, but has minimum solubility in ammonium sulfate at about pH 7 (15).

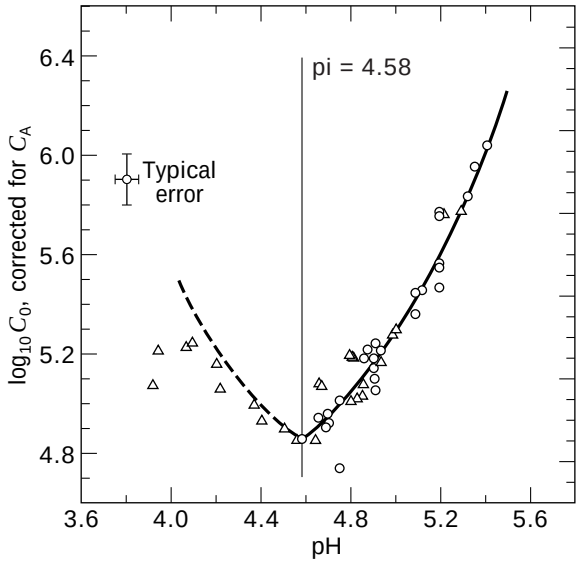

Figure 5. The effect of pH on ovalbumin solubility (C_o) near the isoelectric (pI) point at 18 and 30 °C. *Source*: Reprinted with permission from Ref. 51. Copyright © 1996 American Chemical Society.

Temperature. Proteins exhibit a wide range of solubility responses to temperature. The solubility of some proteins is largely unaffected by temperature; others, such as glucose isomerase (15) and lysozyme (16), show marked increase with temperature; and others exhibit a retrograde response. The effect of temperature and salt concentration on lysozyme solubility is presented in Figure 6. The two common crystal forms of lysozyme have been noted to have a markedly different solubility response to temperature (6).

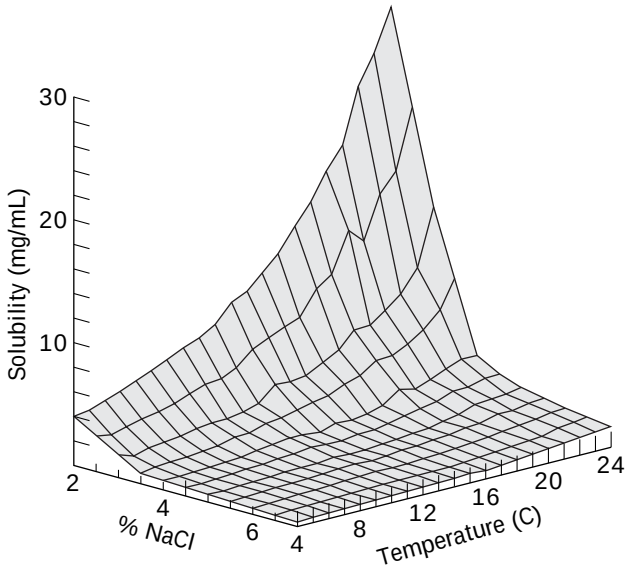

Figure 6. The solubility of tetragonal lysozyme as a function of salt concentration and temperature at pH 4.6 in 0.1 M sodium acetate. *Source*: Reprinted from Ref. 16 with kind permission of Elsevier Science-NL, Amsterdam.

Ionic Strength. Increasing ionic strength decreases globular protein solubility, although diverse effects occur, including regions of low ionic strength ($I < 0.15$ M) at which salting-in phenomena are commonly observed. In some cases, a solubility minimum with concentration has been observed for some protein–salt combinations, particularly for divalent salts (15,17,18). Protein solubility during precipitation processes has often been analyzed by the Cohn plot in which protein solubility is graphed as a logarithmic function of ionic strength. It has been frequently noted, however, that protein solubility in crystal suspensions is lower than for amorphous precipitate suspensions and that the Cohn relationship exhibits poor fit for the former (6,19).

Salt Type. The varying ability of different salts to alter protein solubility is well known and is described by the Hofmeister series (lyotropic series), which ranks ions according to their salting-in or salting-out effect. However, care is needed in applying the series, as shown for lysozyme (20).

Nonelectrolytes. A wide variety of nonelectrolytes can influence protein solubility, usually in a complex manner. Organic solvents (ethanol, acetone), polyethylene glycol (PEG), sugars, and even amino acids have been used to salt-out proteins. Where waste disposal of inorganic salt-rich mother liquors is difficult or expensive, nonelectrolyte nonsolvents may be a good alternative. The complex behavior of these systems is illustrated well by ethanol, which salts-out at low temperatures and low concentrations, but salts-in at all concentrations as temperature rises. These effects do not depend on the dielectric constant (polarity) of the solvent, but on the unusual properties of ethanol and water mixtures (13).

PREDICTING CONDITIONS FOR CRYSTALLIZATION

Obtaining the appropriate conditions for protein crystallization is more challenging than for many small organic and inorganic molecules, because relatively little is known about protein solubilities, often only small quantities of the protein are available early in process development, protein crystallization even under optimal conditions can be slow (days, months), and the use of a precipitant, rather than temperature, to create supersaturation adds an extra degree of freedom in locating conditions for good crystallization. Because X-ray crystallography has until recently been the sole method for protein structure determination, immense effort has been put into the development of protocols for quickly finding suitable conditions for protein crystallization at the microscale. Typical techniques used are well known and include dialysis, vapor diffusion, and batch crystallization methods. Various statistical search strategies, such as sparse matrix screens using commercially available solution kits (21), and robotic technology for repetitive microscale tests (22) are used to reduce the

amount of material and time required and optimize the likelihood of finding a suitable set of conditions.

This body of work exists as an accessible database (23) and serves as an excellent resource for quickly narrowing down suitable systems for the bulk crystallization of proteins. Unfortunately, the transient solution environment typical of microscale systems means that additional tests are required to define crystallization conditions exactly. Process engineering issues can then be applied as an additional set of criteria. Precipitants used for the crystallization will need to be available in bulk at low cost and, for some sites, waste disposal concerns may impose constraints on the use of concentrated salt solutions. In this vein, the use of biodegradable alternative precipitants has been investigated.

Both DLS (12,17) and fluorescence spectroscopy techniques (24,25) have been applied recently to attempts to differentiate conditions leading to precipitation, or crystallization. Although changes in solute structure are seen, the predictive ability of these techniques remains elusive. An alternative approach for predicting optimal solution conditions for protein crystallization is to measure the osmotic second virial coefficient (B_{22}) of the protein in the crystallization mixture, but at dilute (<8 g/L) protein concentrations (26). It was discovered that for the proteins tested (Table 4) there exists a crystallization slot characterized by B_{22} values in the range of -1 to -8×10^{-4} mol/mL/g^2. At more negative values, the solution was found to promote the formation of amorphous protein aggregates, whereas at positive values, the protein preferred to remain in solution. Although independent experimental validation of this approach has not yet been published, subsequent work by Wilson to extend the method to more proteins and by others investigating the application of lattice model (8) or colloidal theory (27) to describe protein interaction in concentrated solutions has supported the validity of this approach. Measurements of B_{22} may provide a faster approach to optimal conditions than do microscale tests, which require several days for the result to be known.

Table 4. Values of B_{22} Corresponding to Crystallization Conditions

Protein	Precipitant and pH conditions[a]	$B_{22} \times 10^{-4}$ mol/mL/g^2
Lysozyme	2% NaCl, pH 4.6	−3.0
Canavalin	0.7% NaCl, pH 7	−0.8
Concanavalin A	1 M $(NH_4)_2SO_4$, pH 7	−2.5
Concanavalin A	0.1 M NaCl, pH 6	−1.9
BSA	52% satd $(NH_4)_2SO_4$, pH 6.2	−2.0
Ovostatin	7.5% PEG 8000, pH 7.5, 20°C	−7.1
Ribonuclease A	50% n-propanol, pH 5, 24°C	−4.1
α-Chymotrypsin	10% PEG 3350, pH 4.6	−8.4
STMV	12.5% SAS, pH 6.5	−1.8
Ovalbumin	43% SAS, pH 5.4	−6.1

Note: BSA = bovine serum albumin; SAS = saturated ammonium sulfate.
[a] −298 K unless stated otherwise; original buffer conditions given in reference. *Source*: Ref. 26.

KINETIC STUDIES

The knowledge of rates of protein crystal growth is of primary importance in industrial crystallization processes, but except for lysozyme, few systematic studies have been published. Most kinetic studies have been performed using static crystal measurements, the most common method of which involves nucleating several crystals in a growth cell located on a microscope and following the increase in crystal dimension with time as supersaturated solution is pumped gently around the crystals (28,29). These are useful for fundamental studies of growth mechanisms, but have a number of disadvantages for process design:

- The growth rate is typically expressed as a face (e.g., two-dimensional increase) growth rate whose applicability to three-dimensional crystal growth in suspended crystal slurries in industrial crystallizers, in which the hydrodynamic conditions may be vastly different, has not been validated.
- Because crystals grow at different rates, a large number of crystals must be followed to obtain a reasonable approximation of mean population growth rates.

Nevertheless, the method has benefits in that data can be obtained on individual crystals. Few kinetic studies of protein crystallization have been performed in bulk crystallizers in which the growth of a large crystal population can be measured under conditions more typical of industrial conditions (11,30).

Factors Affecting Rates of Protein Crystal Growth

Supersaturation. Chief among the factors determining the rate of crystal growth is the degree of supersaturation, which defines the driving force for crystallization. Supersaturation (s) can be defined a number of ways and is typically defined in the manner most convenient for the user. The relative supersation (σ) = s/c^* is commonly used. In industrial practice, it is convenient to express the relationship between the growth rate (G, μm/h) and supersaturation (s) as a power law:

$$G = ks^n$$

where k is the nth-order growth rate constant and n is the kinetics order. From the studies performed on protein growth kinetics, a range of dependencies of growth rate on supersaturation have been reported, but most have revealed a second-order dependence (Table 5). This may be interpreted as surface integration kinetics control of the rate of crystal growth. In isolated cases, a first-order dependence was measured, for example, for concanavalin A (Table 5), which is more indicative of a diffusion-controlled growth mechanism. The growth rates of protein crystals and their dependence on supersaturation are contrasted in Figure 7. Protein crystal growth rate appears to be independent of crystal size (31,32).

In the case of lysozyme, which has been extensively studied, the usual growth rates experienced in static cell studies suggest that about two to three layers of molecule are added to the crystal face every second, amounting to a

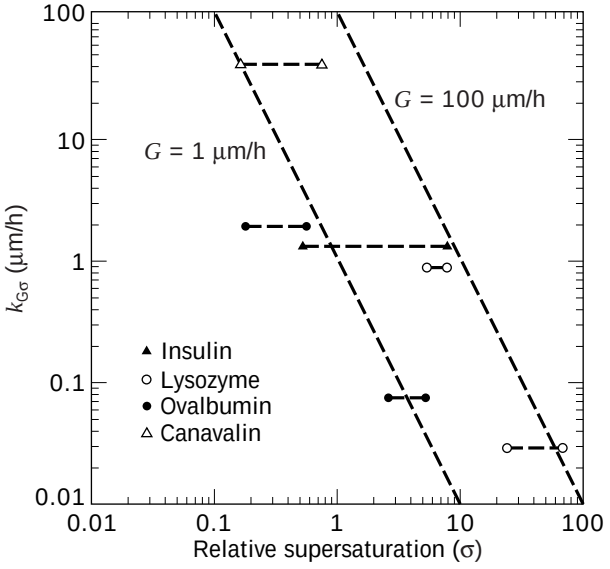

Figure 7. Values of the second-order growth rate constant, $k_{G\sigma}$, against relative supersaturation for various proteins. Most average crystal growth rates, G (expressed on a volume equivalent diameter basis), fall between 1 and 100 μm/h over the range of supersaturation commonly used.

face growth rate of 0.1 to 1 nm/s (0.4–4 μm/h) (34). Recent work has proposed that protein crystal growth occurs by the addition of oligomers of lysozyme into the crystal, rather than by monomer incorporation (35). There is a large body of supporting evidence for this view, both with lysozyme and for other proteins (1,7), although this finding remains controversial (36).

A comparison of protein growth rates with those of other commonly crystallized materials reveals that proteins are slower to crystallize relative to most smaller molecules for a given relative supersaturation (Fig. 8). Nevertheless, known protein crystal growth kinetics are comparable to those of aluminum trihydroxide, which is crystallized industrially on a very large scale. Furthermore, the metastable zone available for protein crystallization (e.g., the values of supersaturation in which it is convenient to operate a crystallizer) is many fold more than that possible in many small molecule crystallizations (Table 3).

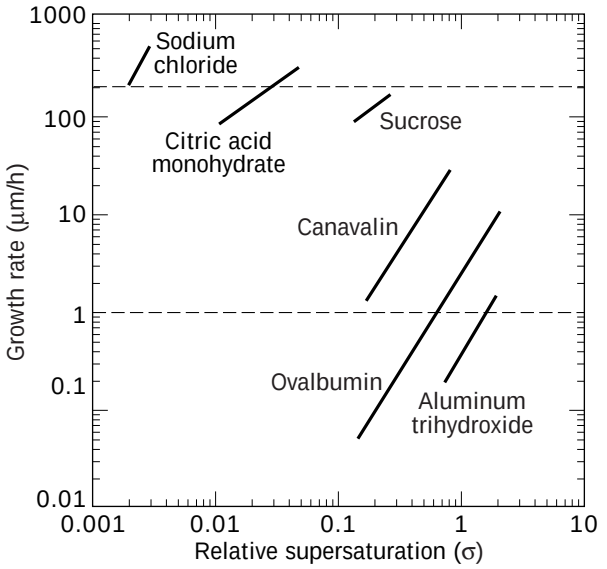

Figure 8. Comparison of average crystal growth rates for various values of supersaturation for industrially crystallized small molecules and the proteins ovalbumin and canavalin.

Most commercial protein crystallization processes are batch operations. During isothermal batch crystallizations, the supersaturation will fall rapidly from an initially high value to much lower values, especially because supersaturation is typically achieved by the addition of precipitant. In these cases, it may be uneconomical to wait for the system to reach equilibrium before terminating the crystallization. Although low supersaturation is undesirable because it will result in long crystallization times, excessive supersaturation is also undesirable and generally results in any of a number of inconvenient features, including greater inclusion of impurities in the crystal lattice, unusual and dendritic crystal forms that are hard to process (Fig. 9), and amorphous precipitation. Where the solubility of the protein being crystallized exhibits sensitivity to pH, temperature, or other factors, the supersatu-

Figure 9. Rosette of α-amylase crystals. *Source*: Courtesy of Richard Bott, Genencor International, Inc.

ration may be maintained at a moderate value by changing these factors as crystallization occurs, provided that there are no deleterious results such as decreased rate, change in crystal form, denaturation, etc. This can only be determined by thorough solubility studies.

Temperature and pH. The effect of temperature and pH on the kinetics of protein crystallization have been little studied. There are frequent comments in the literature that different pH and temperature conditions, or even changes in the primary structure of the protein, altered the rate of crystallization or made crystallization easier. In most cases, there are insufficient data to confirm that the experimental variable (pH, temp, etc.) had a direct influence on the rate of crystallization, rather than an indirect influence through some other effect, such as an altered protein solubility, which in turn would result in increased supersaturation for the same initial protein concentration and hence a faster crystallization rate.

The pH has been observed to have a marked effect on the crystallization rate, independent of its effect on solubility, in the case of ovalbumin (11). An increase in pH at values up to 1 pH unit higher than the isoelectric point (pH 4.6) resulted in an increase in the rate of crystallization of up to 10-fold. Whether this trend continued at larger deviations from the IEP was not studied. Reports on the effect of temperature are rare, but the probable dependence of the rate of protein crystallization on kinetic mechanisms implies that the rate should increase with temperature at a given supersaturation. Although the results above are too limited to generalize to all commercially produced proteins, it is interesting to note that conditions that have been observed to enhance crystallization rate (increased temperature, pH values away from the IEP) also correspond to conditions of greater protein solubility. Consequently, a compromise is necessary between high crystallization rates and the need for high recovery of protein as crystal.

Impurities. The presence of some impurities in a crystallizing solution is known to result in depressed rates of crystal growth for many molecules. In most cases, such poisoning is difficult to prove unequivocally. The impurities likely to be present in protein solutions undergoing crystallization can be arbitrarily divided into three categories:

- Nonprotein impurities
- Protein contaminants not derived from the product protein
- Heterogeneous forms of the product protein

The term *pure* typically means crystals devoid of the latter two categories, because large quantities of the precipitant inevitably will be present in the solvent channels within the protein crystal. In fact, it is exactly this property that makes protein crystals amenable to X-ray crystallography.

Nonprotein Impurities. The rate of protein crystallization appears to be remarkably unaffected by the presence of small compounds, such as salts, precipitants, sugars, and pigments, compared to small molecule crystallization processes (1), although they may have a pronounced effect on solubility of the protein (15). This resilience may be because of the comparatively small number of contact points between adjacent protein molecules in the crystal, which makes disruption of the ordered lattice by small molecules more unlikely compared to the tightly packed lattices of salts and other small molecules. This is convenient for protein bioprocessing. However, polysaccharides derived from microbial cell wall or components of the media are commonly present in fermentation broths and have been implicated as causing difficulties in bulk crystallization processes, particularly affecting the crystal morphology and properties of the final product (37). This problem was resolved by the use of carbohydrate-hydrolyzing enzymes.

Contaminating Proteins. The presence of contaminating proteins has often been considered a primary reason for not adopting crystallization as a protein purification process. In fact, in the few cases studied to date, the presence of contaminating proteins had little or no deleterious effect on the rate of crystallization. The rate of crystallization of ovalbumin was unaffected by the presence of up to 0.22-mol fraction of total protein as lysozyme and conalbumin (11); similarly, the rate of lysozyme crystallization was unaffected by the presence of up to 5% w/w ovalbumin (36). However, the literature on this issue is scarce.

Heterogeneous Forms of the Product Protein. An important issue is the effect of microheterogeneous forms of the product protein on rates of crystallization. There is mounting evidence that even small changes in the primary sequence of a polypeptide may lead to large alterations in its crystallizability. Unfortunately, the term *crystallizability* is vague and may refer to an improved propensity for nucleation, altered solubility under the conditions used for crystallization, or an actual enhancement in the rate of growth of the crystal face for a given supersaturation. Discerning between these effects requires extensive characterization of protein behavior, which typically is not performed. Nevertheless, numerous reports of protein variants that have either improved crystallizability or that inhibit crystallization of the preferred protein exist. Thus, variants of recombinant human insulin were generated by site-directed mutagenesis that exhibited improved crystallizability under physiological conditions (38), whereas for ovalbumin, the subtilisin-treated variant, plakalbumin (which possesses 6 fewer amino acid residues out of the original 385), is reported to exhibit greatly improved crystallizability (39). This opens the possibility of engineering protein variants with improved crystallization characteristics to improve properties germane to their final use or to reduce processing cost. Some forms of heterogeneity, however, may also be responsible for poisoning rates of protein crystallization. This has been reported for lysozyme in mixtures of that protein from different sources (40). This adverse effect of variant forms is more likely, because they would share a high degree of homology with the native protein and might be expected to integrate into the lattice in such a way as to poison or disrupt further growth. The

ability of crystallization process to select for crystals of only one microheterogeneous form of a protein is unclear.

Other Factors. The effect of a number of other operating variables on the rate of protein crystallization have not been investigated. It would be expected that the precipitant used, or its concentration, would alter the rate of crystallization. However, data are scarce. Certainly, the effect of salt concentration (ammonium sulfate) on the rate of ovalbumin crystallization was negligible, independent of its effect on protein solubility, which is large (11). Agitation, or a convective environment, has been argued to have a deleterious effect on crystal growth in small-scale studies performed on microscope cells (29), although other studies have contradicted these findings (41,42). Nevertheless, some agitation is essential in industrial crystallizers to prevent the crystals settling in the vessel. A more serious effect of agitation is crystal breakage. Protein crystals appear to be relatively fragile, probably because of the small density of intermolecular contact points between neighboring molecules in the crystal lattice. Consequently, rough handling of the crystals should be minimized. High pressure (up to 3,000 bar) was reported to increase the crystallization rate of glucose isomerase relative to that of solutions at atmospheric pressure (43); however, it is more likely that the enhanced rates observed were the result of higher rates of nucleation at high pressure, which would generate larger crystal surface areas for growth (44). This latter effect would be advantageous for the production of large numbers of small (<10 μm) protein crystals in the absence of seeding, because induction times for nucleation were also reduced by high pressure.

Growth Dispersion

Growth rate dispersion (GRD) refers to the existence of a population of crystal growth rates under identical crystallization conditions. The primary cause of GRD remains unclear, but it is now accepted that crystals, under conditions of constant supersaturation, will grow at different, but constant, growth rates. The most significant effect of GRD is to broaden the crystal size distribution with time, which is generally undesirable for most industrial applications. The existence of GRD in protein crystallization is largely unstudied, but appears to be small relative to crystallizations that exhibit the effect strongly, such as sugars.

PURIFICATION BY CRYSTALLIZATION

Crystallization is capable of highly selective purification of most compounds from impure mixtures. Protein crystals sought for X-ray crystallography need to be highly pure, because the crystal is required for structure determination. This requirement has commonly led to the comment that protein solutions must be highly pure to attain crystallization. However, for bulk crystallization purposes, this requirement is not relevant. Because of the highly open structure of protein crystals, small impurities, such as salts, sugars, etc., are likely to be present in the final crystals to a similar degree as in solution, although protein crystals appear to exclude the pigments and colorants found routinely in fermentation broths (37). Successful protein crystallization has been routinely obtained in the presence of other contaminating proteins with degrees of purification similar to those achieved by ion exchange. Most of the carryover of contaminating protein is in the liquid adhering to the exterior surface of the crystals. Studies showed that ovalbumin crystals (MW 45,000 Da) produced in bulk crystallization were substantially free of both smaller and larger protein contaminants, which comprised 22 mol % of the total protein initially present in solution (11), after a single wash of the crystals (Fig. 10). Similar results have been observed for lysozyme (36).

PROCESS APPLICATIONS OF PROTEIN CRYSTALLIZATION

Despite the ubiquity of crystallization for the structural determination of proteins, actual process applications of crystallization as a technology for the purification and recovery of proteins remained relatively rare until the last few years. An increasing number of proteins are now produced in multikilogram or multiton quantities by crystallization from clarified fermentation broth. These include insulin, glucose isomerase, asparaginase, subtilisin, lipases, thermolysin, and penicillin acylase (45–47). The first major use of crystallization was in the purification of insulin, which was crystallized as a zinc complex from salt solution. This technology was developed in the 1950s and simulated the natural process found for storage of insulin as zinc hexameric crystalline arrays in the pancreas (30). More recently, the ability of insulin to be crystallized has been used in slow release forms to achieve a more sustained titer of the hormone in the blood (38), due presumably to the regulation of insulin adsorption by slow dissolution kinetics at physiological pH.

The salient features of protein crystallization processes reported in the patent literature are listed in Table 6, al-

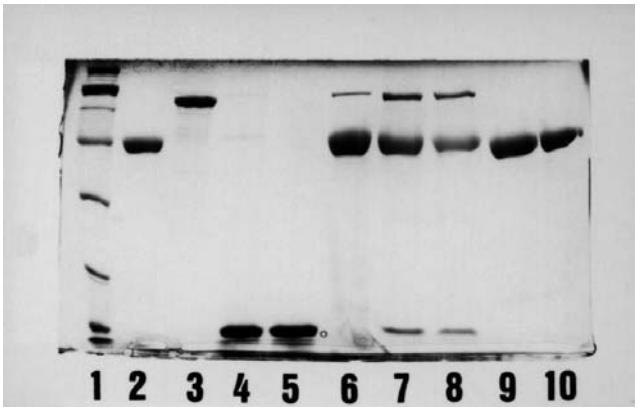

Figure 10. Crystallization of ovalbumin from a solution mixture of ovalbumin (0.784 mol fraction of protein), lysozyme (0.182), and conalbumin (0.034) results in high purity crystals by overloaded SDS-PAGE analysis with Coomassie blue R-250 staining. Lanes: 1, molecular weight; 2, ovalbumin; 3, conalbumin; 4 and 5, lysozyme; 6, initial solution; 7 and 8, final mother liquor; 9 and 10, washed ovalbumin crystals separated from the mother liquor (11).

Table 6. Selected Protein Crystallization Processes from Patent Literature

Protein	Conditions	Yield (%)	Time (h)	Company	Reference
Subtilisin	pH 5.2–5.8; 0.5M NaCl	84	24–48	Genencor	18
Glucose isomerase	1.5% $MgSO_4$	97	3	Stabra AG	47
Peroxidase	pH 4.0; 1.5% $CaCl_2$; 20% PEG 4,000	90	4	Novo-Nordisk	48
Alkaline protease	pH 7.5; 0.5M NaCl	76	4	Solvay	37
Amylase	pH 7.6; 8% NaCl	91.5	24	Solvay	49

though the process may not be used to produce the protein in commercial practice. In the majority of cases, halide salts are preferred for producing the supersaturation needed to obtain crystallization, although a recent report suggests that the use of PEG may greatly enhance the process at lower salt contents (48).

Crystallization is usually performed using clarified fermentation broth that has been concentrated normally by ultrafiltration so that supersaturation is attained on addition of precipitant. The crystallization pH is generally adjusted to values at or near the isoelectric point of the protein to take advantage of the lower solubility at these pH values. Alkaline proteases, such as those from *Bacillus* species (e.g., subtilisin) and lysozyme, are exceptions. These enzymes are typically crystallized at lower pH values to minimize autolysis during the process (46). Process temperatures vary widely. Temperature change plays a minor role compared to precipitant addition for obtaining supersaturation. This is usually the result of the constraints imposed on process temperature by protein stability requirements or the relative insensitivity of protein solubility to temperature, particularly at high salt concentrations. Typically, the crystals produced in commercial crystallization processes are small (30 to 100 μm in diameter) to aid their more rapid dissolution, in either product applications or subsequent purification steps. By the end of the crystallization process, the crystal content of the liquor can be up to 20 to 30% v/v (18).

The crystalline product can be separated from the mother liquor by settling of the denser crystal phase and decantation of the mother liquor from the crystals, or by usual solid–liquid separation technologies such as microfiltration, pressure filtration, or centrifugation. Washing to remove the mother liquor from the crystals improves crystal purity and the overall purification ability of the process. Generally, the crystals must be maintained as a concentrated slurry in a suitable salt solution to avoid redissolution or drying out and reversion to an amorphous state.

A novel approach to protein crystallization, which overcomes the problem of maintaining the crystal form, is the subsequent cross-linking of the crystals by, for example, glutaraldehyde, which renders the crystals insoluble in aqueous solutions. This process has been used to develop mechanically robust and stable enzyme crystals called CLECs (cross-linked enzyme crystals) suitable for repeated use and easy separation from the reaction liquor in organic syntheses (45,50). A photograph of CLECs is given in Figure 11. A further advantage of CLECs is their enhanced stability relative to the noncrystalline form and even to the un-cross-linked crystal form of the enzyme under adverse conditions, such as low water environments, elevated temperatures or the presence of proteases, which makes them of value in the synthesis of many chirally pure drugs and chemical intermediates. A recent example (50) comprising a lipase revealed the half-life of the soluble enzyme to be 5 h compared to more than 13 days for the cross-linked crystal form.

CONCLUSION

In addition to its critical importance for protein structure determination by X-ray crystallography, protein crystallization is now emerging as a useful bulk technology for protein purification. It is particularly well suited to commodity proteins where bioprocessing costs must be contained in the face of demands for improved product quality. Protein crystallization offers potentially high degrees of purification at any scale in reasonable process times and cost. Nevertheless, the gaps in knowledge concerning the application of protein crystallization at process scale remain large, despite its successful use in the production of commercially significant proteins. Protein crystals also offer exciting prospects as novel forms of catalysts in controlled-release formulations and as biomaterials. The sensitivity of protein crystallizability to even single amino acid changes in the polypeptide chain further suggests that fruitful results can be obtained using tools of modern molecular biology and protein engineering, already well established in the production of commodity proteins. Perhaps what is needed most, however, is the realization that crystallization, long overlooked in production processes for

proteins and far more elegant than its wilder sibling—precipitation—deserves to be considered alongside the many other operations commonly selected for protein purification.

ACKNOWLEDGMENTS

I would like to thank Professor Ted White and Dr. Russell Judge for their participation in much of the work described in this article and for their reading of the drafts. I also give my heartfelt thanks to Todd Becker, John Kan, Alfred Gaertner, Rick Bott, and all the team at the California Technology Center of Genencor International, Inc., Palo Alto, Calif., for their hospitality during my stay with them and for their insight on protein crystallization and proteins. Finally, I acknowledge the many useful discussions with researchers in the field, especially Marc Pusey (NASA, Huntsville, Ala.), Bill Wilson (Mississippi State Univ.), Harvey Blanch (Univ of California, Berkeley), Kris Berglund (Michigan State Univ.), Chuck Glatz (Iowa State Univ.), and many others. Thank you.

OUTLINE

INTRODUCTION

The Increased Importance of Microorganisms and Cell Lines

Microorganisms have a significant effect on human life, whether as a result of the diseases or benefits they cause humans or to their food source (plants and animals) and through their effect on the environment (food spoilage, water pollution). In addition, microorganisms and cell lines are used increasingly within biotechnology and are therefore an integral part of the infrastructure of microbiology and fundamental in underpinning scientific research. They are used in crop improvement, food production, pharmaceutical production, and treatment of waste. Industry has the capacity to screen isolates for particular biochemical properties and metabolite production, to evaluate and develop commercial kits and rapid detection kits for microbially produced compounds, and to evaluate organisms' capacity for use in bioremediation and as biocontrol agents.

With the decline in the use of animals in scientific experimentation over recent years, both for economic and ethical reasons, many modern standards and specifications require the use of microorganisms and cell lines in the testing of products and quality control procedures. Culture collections, therefore, supply microorganisms and cell lines for the British, European, and U.S. testing standards, disinfection testing, the assessment of mutagenicity against a range of microorganisms, toxicity testing, NAMAS accreditation, quality accreditation, water and environmental reference strains, and biological and biomedical research.

The supplier is responsible for adequate quality control procedures to ensure the authenticity of these cultures. Failure to do so may result in potential loss incurred as a result of contamination, work on the wrong organism or biochemical product, or invalid manufacturing quality control procedures.

Preservation of Existing Biodiversity

Over recent years, there has been increased concern regarding the conservation of biodiversity and the wealth of genetic information still to be harnessed. This matter has been found to be so important that it has been taken up governmentally at an international level. The Convention on Biological Diversity was signed by the governments of 155 countries and the European Community at the Earth Summit in Rio de Janeiro in 1992. The objectives of the convention were the conservation of biological diversity, the sustainable use of its components, and the fair and equitable sharing of benefits arising from the use of biological resources. The consequences of the introduction of this complex convention has been to generate interest in the scientific aspects of diversity and to begin to establish a number of major programs and projects aimed at increasing knowledge and improving conservation procedures, particularly in situ methodologies.

At a legal level, the common inheritance principle regarding ownership of biological resources has changed to sovereign rights, and access to genetic resources will be controlled by the contracting parties and subject to national legislation. Scientifically, countries are required to establish research and training programs, develop guidelines and procedures for conservation (ex situ and in situ), introduce procedures for assessing and monitoring environmental impact, establish emergency response procedures, and establish partnerships that support capacity building and technology transfer in developing countries.

These regulations are far from being neatly juxtaposed to the Budapest Treaty legislating the patenting of microorganisms used in the industrial microbiology industry because the patent system limits the access to biological re-

sources. The role of the Budapest Treaty is discussed later.

Conservation of microorganisms is obviously a very important component of the biological diversity initiative because they are the most biochemically adaptable organisms on the planet on which they are ubiquitous, occupying every ecological niche. Thus, culture collections have a primary role in conserving microorganisms and cells.

THE DEVELOPMENT OF CULTURE COLLECTIONS AS A RESOURCE

Since Krael established the first culture collection in Prague in 1890 (1), many others have been set up, not only to conserve living examples of microbes (e.g., bacteria, fungi, protozoa, algae, viruses), but also cell lines (human, animal, and plant cells) and DNA probes. Although the preservation of genetic diversity will fundamentally benefit humankind anyway, it is not known which materials may be useful or, indeed, for what purpose they may be required in the future. It is also impossible to predict changes in special habitats or in the general environment, nor what effect such changes may have on the bacterial genome or chromosomal elements. Therefore, some cultures that are of no importance today may be of significance in the future, and it is therefore of fundamental importance to preserve today's biodiversity.

There are three main types of culture collections, the classification of which largely depends on the size of the collection, its documentation, and the service provided. The first type is one where conservation of a small collection is a secondary activity of the laboratory. As such culture collections evolve and increase in size, a second type that is larger and more specialized will arise. These collections often result from specific research programs that are vulnerable when projects come to an end or individual senior scientists retire. Such collections need correct documentation to be a valuable resource and a greater effort to maintain the resource successfully.

The third type of culture collection is the nationally and internationally recognized service-supply culture collections where conservation is the primary function. In order that such service-culture collections can become a recognized international resource, three principal elements must be satisfied. First, the culture collection has to be preserved in a viable state. Second, the history, original source, and properties of the culture must be documented. Third, the cultures must be available to the wider scientific community.

With the increasing demand on such culture collections for authenticated, reliable biological material, the World Federation for Culture Collections (WFCC) has published recommendations for good practice in culture collections so that new and existing collections have guidance and approved standards of operation (2).

Service-supply culture collections exist primarily to maintain and supply on request cataloged, authenticated cultures and to give expert advice on cultivation and preservation to scientists, technologists, industrialists, and teachers. The primary task of the staff therefore is curatorial, thus distinguishing it from secondary collections. Through continuity of work, these culture collections become expert in documentation and preservation techniques and in the knowledge of the behavioral properties of the holdings.

For a service collection to be a truly valuable resource center, it must keep abreast of the developing science it serves. There must be an active accessioning policy, ongoing reassessment of preservation procedures, awareness of taxonomic changes, identification of new requirements, and an original research program. Recently, as a consequence of this, other services have become equally important, including cryopreservation, bulk supply of cultures for screening for products and quality control, patent and safe deposit facilities, identification of cultures, and the delivery of training courses.

OPERATION OF CULTURE COLLECTIONS

It is important that all culture collections operate good practice in all aspects of their function, from microbiology to dispatch of samples. The various activities of culture collections and their successful management are discussed in this section.

Organization, Funding, and Objectives

It is of fundamental importance that the establishment that houses a culture collection realizes its importance, accepts the responsibility inherent in maintaining a public service to appropriate standards, and is committed to its long-term maintenance. In the case of existing collections, this aspect should be continually clarified with the director of the parent institute, its scientific council, senior university officials, governing board, or other appropriate authorities.

Intrinsic to such a commitment is appropriate funding. The operation of such culture collections is a long-term commitment and requires core-funding from the overseeing parent organization. Support solely in the form of short-term contracts is totally inappropriate, because necessary levels of funding need to be guaranteed for the future activities of the culture collection, including the services being planned and the standards users would expect.

All culture collections should have a mission statement and long- and short-term objectives relating to the scope of the holdings and to the range of services that it will offer. If these statements are not agreed upon by the parent institute and other funding bodies, then the culture collection will not be able to operate effectively.

A considerable degree of income generation is possible from culture collection activities, varying from as little as 25% to as much as 85%. This can depend on a mixture of sources of income, culture sales, and contract services.

Holdings

The diversity of microorganisms and cells and their number should be continually addressed by a culture collection because appropriate funding will be needed to maintain the collection. Microorganisms that require particular con-

tainment facilities are those that are potentially pathogenic to humans, animals, or plants or those that are toxic.

When a new culture collection is being established, it often relates to the interests of the parent organization. However, it is advisable to aim to complement existing collections rather than duplicating existing ones. It is necessary, therefore, to have a clearly defined accession policy on which new strains are to be added to the collection. Lack of such a policy will result in many unsolicited strains entering a collection uncritically without due regard to collection objectives, storage capacity, personnel, and financial resources. Conversely, the range of a collection should not be restricted as to limit the effectiveness of the service provided to the scientific community.

New accessions may arise as a result of any of the following: (*1*) From the collection's own research; (*2*) From samples sent to the collection for identification; (*3*) From active solicitation by the collection; (*4*) They may arise unsolicited; (*5*) As a formal patent deposit under the Budapest Treaty.

Staff

The effective curation, management, and staffing of a culture collection is a demanding task. Routine accessions, preservation, maintenance, viability checking, culture supply, and additional services are all extremely time consuming. The staff have to have considerable knowledge not only about the organisms themselves, but also their growth and preservation requirements, properties, and potential applications. Where a culture collection offers other services, such as identification and taxonomic expertise, additional specialized staff are required. Experience in culture collection management in addition to taxonomy is a fundamental prerequisite to expertise, and it is therefore important to attract and retain staff of a high caliber.

Preservation and Maintenance

There are a number of techniques available for the preservation of microorganisms, each of which has particular advantages and disadvantages. In addition, different organisms require special preservation techniques in order to ensure optimal storage and maintain purity. The choice of technique should be determined by relating the features of each method to the needs of the user. A number of considerations must be taken into account when deciding which method is most appropriate.

Purity of samples is of paramount importance, and the preservation method should minimize the chance of contamination. The process of preservation and storage should be fully validated. Because preservation could result in loss of viability and hence cell death, a process causing minimum damage should be chosen. Viability should be ascertained immediately after preservation and reassessed during storage.

Preservation may introduce the possibility of a change in the characteristics of a culture. This can happen either as a result of a significant number of cells dying during the preservation process, thus selecting for a resistant population of surviving cells, or by genetic drift as a result of mutation or, for example, loss of plasmids.

The expense of preserving and storing cultures may also influence the choice of method, and this may be further influenced by the number of cultures and factors, including staffing, equipment, materials, and storage space. The operation time for the preservation and maintenance of a small collection may be too labor intensive for a large collection. The high capital cost for methods such as freeze-drying might be considered unsuitable for a small collection, although once preserved the samples require little maintenance. Storage in liquid nitrogen vapor may be cheaper, but for large collections, a sizeable storage space is required. Considerable attention must therefore be taken when the choice of preservation is being made, particularly with regard to the long-term objectives and size of a collection.

The consequence of loss of a culture is another factor to be considered when choosing a preservation method. Valuable samples should be preserved by methods that minimize loss and should ideally be preserved by more than one technique.

Finally, the choice of preservation technique will depend on the frequency of distribution of a sample. Samples that are regularly distributed should be preserved by a method amenable to bulk storage and that does not put them at risk to loss of viability or contamination as a result of frequent manipulation. Cultures that are to be supplied through the mail should be in a form suitable for packaging and must survive transportation time and temperature in accordance with IATA (1988) Dangerous Goods Regulations for Transport of Infectious Material (3).

There are four main storage methods briefly outlined in the next section. This subject has previously been reviewed in depth, for further information see the work by Kirsop and Doyle (4).

Subculture. Preservation of samples by continued subculture is open to the risk of complete loss on the one hand and contamination on the other. Samples are incubated on a suitable medium, at an appropriate temperature, and for a suitable time. The procedure is repeated at intervals that ensure that a fresh culture is prepared before the old one dies. Samples are therefore continually in danger through loss of viability, particularly because the survival time of a particular microorganism varies considerably. *Staphylococcus* spp. and coliforms will survive for several years, but *Neisseria* spp. require subculture within a few weeks.

The majority of media used for the storage of microorganisms are unenriched and have limited nutrients. Excess carbohydrates should not be included in the medium because the acid produced might kill the culture.

Storage periods can be extended by reducing the metabolic rate of the microorganism. This can be achieved by reducing the storage temperature to 5 °C in many instances. However, exceptions occur; *Neisseria* spp. survive better at 37 °C. Restricting the availability of air with parafilm can also limit metabolism.

Thus, repeated subculturing, together with mislabeling or transposition of cultures, can result in significant contamination of deposits. Genetic drift and instability of characters also increases with each subculture. A large inoculum reduces the risk of selection but increases the risk

of contamination. Therefore, this method is not to be recommended.

Freeze-Drying. Freeze-drying has found popularity with many service culture collections primarily because it is suitable for batch production and distribution. Maintenance of viability requires very little attention, storage being relatively simple and effective and allowing preservation for 50 years for some microorganisms. The capital cost of freeze-drying equipment is initially high, and the preparation of samples is quite labor intensive, but the fact that large batches of samples can be prepared, significantly reducing labor hours per ampule, quickly recoups the initial financial outlay.

The process of freeze-drying is the removal of water from frozen samples by sublimation. Cultures are suspended in a suitable medium (generally mannitol), frozen, and exposed to a vacuum. The water vapor is trapped in phosphorous pentoxide or a refrigerated condenser. The microorganisms are stored in individual ampoules or vials in an inert gas or under vacuum. There are two types of freeze-dryers in general use; however, the centrifugal rather than shelf dryer is more popular and has more advantages.

Although shelf dryers automatically stopper the ampules, the bungs can be naturally permeable to air or water vapor or theromas simply leak. The glass ampoules produced by centrifugal freezing are completely constricted, preventing leakage, and they can be plugged with cotton-wool, eliminating cross-contamination and acting as a filter to prevent scatter of microorganisms into the environment when the ampoules are opened.

Even though freeze-drying has been widely used to preserve a variety of microorganisms, the process always needs refining to optimize preservation in a particular microorganism. Factors that can be adjusted and controlled are composition of medium, growth temperature, growth phase of the culture, rate of freeze-drying, final temperature, duration of drying, and the final moisture content of the culture.

In general, freeze-drying does not cause instability of characteristics and genetic drift.

Drying. Desiccation has been used across a range of microorganisms, although the process is rather a specialized application and there is less information available on the method. Long-term viability appears to be good, when samples are stored between 5 and 10 °C, and contamination is not a major problem, although strain stability is less well documented. The simplicity of the process makes it suitable for storing large numbers of cultures.

L-Drying. The term *L-drying* originates from the term *drying from the liquid state* (5). Suspensions of microorganisms are dried in ampoules under pressure, but the vacuum is adjusted to allow rapid drying without freezing. The method is widely applied and allows a significant reduction in drying time and thus labor costs when a number of microorganisms are preserved. Samples should be stored at 5 °C.

Freezing. Preservation by freezing has been carried out for a variety of different microorganisms over temperatures ranging from −20 °C (refrigerator) to −140 °C (vapor phase nitrogen) to −196 °C (liquid nitrogen). Freezing and thawing can cause injury to cells by the formation of crystals that may damage the cells' integrity or by the concentration of electrolytes through the removal of water as ice. Eutectic mixtures form at −30 °C and above, exposing cells to high salt concentrations. Temperatures of −70 °C and below have been found to be increasingly successful, and storage in the vapor phase of liquid nitrogen is now ubiquitous as a preservation method.

Storage in the liquid phase of nitrogen results in considerable safety problems resulting from nitrogen invading vials that subsequently become explosive (Fig. 1). The freezing and thawing process itself may cause a significant loss in microorganisms. However, once stored, virtually no further loss occurs. The addition of cryoprotectants, the adjustment of growth conditions, the rate of cooling and warming, and freezing methodology can reduce losses (4).

The temperature of samples should be lowered at a controlled rate of 1 to 3 °C/min to −30 °C followed by a more rapid rate of 15 to 30 °C/min to −100 °C or lower. Ideally, this should be carried out using a commercial programmable freezer, which usually operate on a differential thermocouple principle. If such equipment is not available, many microorganisms, including bacteria and fungi, can be successfully frozen by placing the ampules in a dry chest, in a mechanical refrigerator set at below −65 °C, or

Figure 1. Storage of cells in the gaseous phase of liquid nitrogen.

in the top of a liquid nitrogen storage tank for 30 minutes, and then placing the samples at the required temperature.

Preprepared plastic ampoules containing beads and cryopreservant are now commercially available to enhance preservation (Prolab Diagnostics, Microbank). A vial of 25 beads is inoculated and agitated and the microorganisms attach to the beads. Excess cryoprotectant is then removed and the ampoule frozen. Beads can then be removed when a culture is required. The vials are placed in a cryoblock before they are removed from the storage vessel. This ensures that the remaining beads do not thaw out while one bead is removed. Thus, loss of viability does not result from repeated thawing.

The major disadvantage of freezing is refrigerator failure or interruption to the supply of liquid nitrogen. Both will result in the loss of cultures; however, this can largely be overcome by 24-h alarm systems warning of refrigerator failure or loss of liquid nitrogen supply. The initial capital cost is high, but the process is not labor intensive.

Preservation of Cell Lines

It is impractical for most laboratories to maintain cell lines in culture indefinitely; moreover, cell cultures will undergo genetic drift with continuous passage and risk losing their differentiated characteristics. Therefore, it is necessary to store adequate cell stocks for future use. It is recommended practice that a limit is set for the number of passages any cell line should undergo before replacing from cryopreserved stocks. This is of less importance for undifferentiated cell lines having infinite life span, although it still remains a consideration.

Nearly all cell lines can be cryopreserved successfully in liquid nitrogen at -196 °C. A few simple criteria must be adhered to in order to provide sufficient cells for all future needs.

The essentials for efficient cryopreservation are slow freezing (i.e., at a rate between 1 and 3 °C per minute) and fast thawing, which is achieved by placing ampoules in a water bath at the temperature required for growth. The addition of a cryoprotectant, such as glycerol or dimethyl sulphoxide (DMSO), enhances survival. Nevertheless, DMSO does have certain toxic properties. Therefore, care must be taken in handling the cryoprotectant, and some consideration may be necessary as to whether cells should be washed immediately on thawing.

Sample Safety and Security. For security, and in order to minimize the possibility of strains being lost, each culture should be maintained by at least two different procedures. Cryopreservation and lyophilization are the best methods for minimizing the risk of genetic drift, therefore, at least one of these methods should be used. Where only freezing is available, duplicates should be stored with different electrical supply. Duplicates of important or irreplaceable strains should be securely held in different buildings or ideally on a different site. The documentation of samples is equally important because loss owing to natural disaster or fire would make the corresponding cultures meaningless and worthless.

Cell Banking Procedures. When a culture is received in the laboratory, it is important that a strict accessioning scheme be followed (Fig. 2). The method described prevents substantial genetic variation from the original deposit. Starter cultures or ampoules received should be propagated according to the conditions provided by the originator, and a token freeze should be produced (usually up to 5 ampoules). Cultures derived from this token freeze should then be subjected to detailed quality control and characterization. If these results are satisfactory, then a master (or seed) stock should be made. Major authentication of the culture should then be undertaken on the master cells because it is these ampoules that will be used to provide the working or distribution stock.

One ampoule from the master stock is used to produce a working or distribution stock. The number of ampoules in each bank is dependent on how often it will be used. Because the production of these banks is both expensive and time consuming, the numbers required should not be underestimated. For some industrial processes, master banks may contain up to 200 ampoules, and working banks may contain 1,000 ampoules.

Once the working bank is depleted, a fresh one is made from an ampoule from the master bank; similarly, a new master bank is made from the frozen freeze stock. If no more frozen freeze stock remains, then one of the current master bank ampoules should be used.

The level of characterization and quality control that should be carried out at each stage will depend on what it is to be used for and what the necessary regulatory bodies require (Table 1). Quality control implications are obvi-

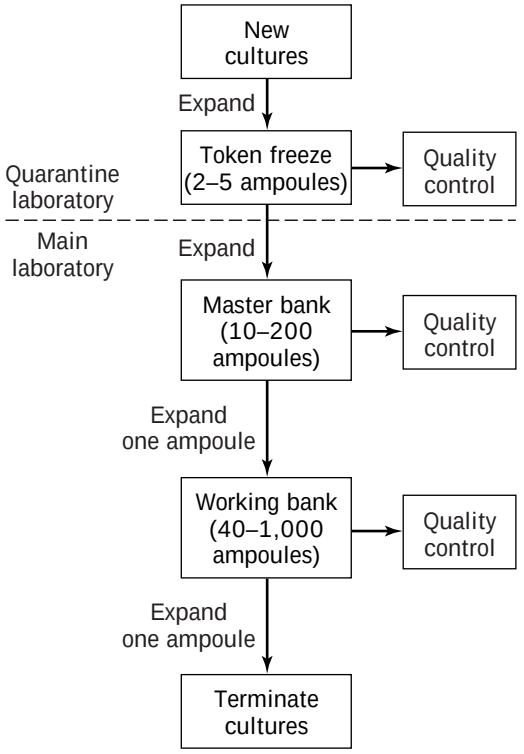

Figure 2. Cell banking procedures.

Table 1. Table of Quality Control Requirements for Cultures within Collections

	Culture type			
Cell lines	Bacteria	Fungi	Protozoa	Algae
Viability	Viability	Viability	Viability	Viability
Purity	Purity	Purity	Purity	Purity
Test for bacteria, yeast, and other fungi				
Test for mycoplasma				
Test for viruses				
Authenticity	Authenticity	Authenticity	Authenticity	Authenticity
Isoenzyme analysis	Gram Stain			
Cytogentic testing	Description of morphology			
DNA fingerprinting				

ously more intense for cultures used in the manufacturing industry.

CULTURE COLLECTION SERVICES

The aim of culture collections is to supply authenticated cultures to bona fide scientists, on request, promptly and without restriction on their ultimate application. The staff of culture collections have expertise and knowledge of the appropriate scientific literature and as such can advise on strain selection. In addition, they provide a range of scientific services, largely in response to the needs of the user. These include safe and patent deposit facilities and identification and preservation services. The expertise gained by culture collections and their staff enables them to run training courses and seminars for other scientists.

Culture Supply and Pricing Policy

Culture collections should be able to readily distribute cultures listed in their catalog on request. Arrangements for culture supply vary according to the financial basis and policies of the legal owner of the collection. Service-supply collections usually levy fees for supplying cultures. This charge should strike a balance between definable measurable costs and those that yield an income that is significant in relation to costs, but that do not result in a declining effective use of the collection.

Consideration should be taken as to the fact that many collections are partly government funded, unit costs would be far too high for what is a reusable commodity (i.e., they can be subcultured), and fees should not discourage the use of the collection. Therefore, culture collections operate on a nonprofit basis. It is often common practice to charge commercial companies higher fees than nonprofit organizations. Further charges may be levied for postage and packaging and any special documentation.

Great care should be given to distribution of pathogenic or toxic cultures. Originators of a request should be able to guarantee that their establishment has stipulated equipment and staff to handle pathogenic or toxic cultures. Dispatch of cultures should be in accordance with IATA (1988) Dangerous Goods Regulations for Transport of Infectious Material (3).

Restrictions to which countries cultures can be distributed also exist. Because the threat exists that microorganisms could be developed for use in biological warfare, cultures can only be issued to countries in the Australia Group of nations. The nations belonging to this group and restricted groups are detailed in *The End-Use Control* (6).

Catalogs

Catalogs are fundamental to the operation of culture collections. They describe the strains available and their salient properties, including literature citations, propagation properties, etc. Stocks are usually arranged alphabetically, in the case of bacteria by genus and species name. Increasingly catalogs are becoming available in computerized form, either on-line or on disk, because, they can can easily be updated whereas paper catalogs cannot. Such catalogs adopt a field structure and definitions that enable the data to be integrated into the international and major regional schemes that are in operation, including the Internet, on which many resource centers are accessable through the World Wide Web, Microbial Strain Data Network (MSDN), World Data Centre on Micro-organisms (WDC), Microbial Information Network Europe (MINE), and more recently CABRI (Common Access to Biotechnological Resources and Information).

CABRI is researching and developing the formation of an integrated resource center service linking databases of different organism type, genetic materials, and other biologicals in Europe so that users worldwide can access these relevant catalogs during one searching session through a common entry point and request or order products to be delivered to their place of work.

Safe Deposits

Safe deposits are held for a variety of reasons, including as a back-up to existing collections and for the retaining of ownership and confidentiality of strains. These collections are not listed in catalogs and their taxonomic status may be unclear. In some cases, the service collection may hold stocks in its collection and market them on behalf of the owner.

Patent Deposits

The rapid advance in genetic manipulation techniques and the allied boom in biotechnology over recent years has led to increased awareness of the enormous industrial poten-

tial of microorganisms. Competition is fierce in the race to exploit this potential, and large sums of money are being risked in commercial development of new microbial processes. In such circumstances, patent protection naturally becomes a major concern of any organization involved in modern industrial microbiology.

An important principle of the patent system is that an invention should be disclosed to the public. Although most kinds of invention can be disclosed simply by means of written description, those involving the use of new microorganisms cannot. No matter how detailed the written description may be, a new microbiological process cannot be tested without a culture of the organism itself. Therefore, in addition to a written disclosure, the patent offices of most industrial countries require the strain used in a microbiological invention to be deposited in a recognized public culture collection, where it will eventually be available to the public.

Patent deposits are now regulated internationally by the Budapest Treaty on the International Recognition of Deposit of Microorganisms for the purpose of patent procedures and patent depository facilities in Europe, under which certain culture collections of a generally acknowledged high scientific standard are officially recognized as international depository authorities (IDAs). The main feature of the treaty is that all countries party to it, and hence their patent offices, must recognize a deposit that is made in any one of these IDAs as being valid for the purposes of their patent procedure. This means that one deposit is all that is needed, regardless of the number of countries in which patent applications citing the strain are filed.

The Budapest Treaty contains detailed provisions on the procedure to be followed by the applicant in making a deposit and by the IDA in accepting, storing, and subsequently making the material available to the public. Broadly speaking, these provisions are designed to ensure that the applicant makes a viable deposit and provides enough information on it to enable the IDA to handle and maintain it safely and correctly. The IDA, for its part, must process the deposit promptly, issue the depositor with a receipt and certificate as proof of deposit and viability, keep the deposit for at least 30 years, and provide cultures to those parties entitled to receive them but most importantly, *to no one else.* Entitled parties in this respect are those who have the depositor's written authorization or who have an official certificate of entitlement from the appropriate patent office. The IDA is also bound by strict rules of secrecy and may not give information about a deposit to anyone not entitled to receive the patent-deposited cultures.

Microorganisms must become available to the public at some stage of the patenting procedure. To date, there are three kinds of systems in operation. In the Netherlands and Japan, patent applications are published twice, first 18 months after the filing date of priority date and before the application has been examined, and second when the application has been accepted. Once the patent office has decided to grant a patent, after the second publication date, the microorganism must be made available. The major advantage of this system to inventors is that their microorganisms do not have to be released until they has an enforceable right. In Japan, the patent owner is given a further measure of protection in that the recipients of cultures must not pass them on to a third party and must use them only for experimental purposes.

In the United States, patent applications are not published until the patent is granted, and any microorganism deposited for patent purposes need not be available until then. Thus, under the U.S. system, inventors again have an enforceable right at the time they are required to make the organism available. Additionally, under the U.S. mechanism an inventor is never put in the position of having to allow access to the organism when no legal protection is available because if a microorganism is not granted a patent, then it need never become available.

The EPC (European Patent Convention) also operates a dual publication system, but stipulates that a microorganism for which a patent is being sought must be made available at the date of first publication, before any enforceable right exists. This mechanism reflects the principle that the microorganism is an integral part of the patent application and should therefore be available at the same time as the written description. Availability at first publication can be restricted to an independant expert acting on behalf of a third party. This expert has to be selected from a list held by the EPC and is not permitted to pass the strain on to anyone else. On second publication, the strain becomes generally available, whereupon the inventor has an enforceable right.

There are 23 IDAs. A full description of these is described by Halluin (7).

Culture Authentication and Identification

Culture collections have a critical responsibility when it comes to the authentication of microorganisms and cells from their initial receipt through preservation procedures and to dispatch to external scientists. Quality control of cultures should be as extensive as possible and have three primary targets; authenticity, purity, and viability. Research using the wrong organism wastes time, is expensive, and leads to publication of invalid results.

The identification of a new accession should be ideally confirmed by a competent specialist (e.g., the depositor) or confirmed by the culture collection itself to ensure that it agrees with published descriptions. Culture collections with specialized expertise in identification can also offer an identification consultancy to the scientific community. The microorganisms identified would not necessarily enter the culture collection.

Documentation and Quality

Increasingly, many culture collections operate using a quality management system such as BS EN ISO 9001. Essentially, these regulations ensure that all procedures have proper protocols that are fully documented, thus allowing all activities to be fully traced if the need arises. All equipment has to have records of calibration and servicing, and all laboratory records, worksheets, and equipment log

books are regularly audited. All staff are trained in these procedures.

In order for a culture collection to run completely successfully, it has to keep good records about the microorganisms and cells it holds, including the following categories of information, place, substrate or host, date of isolation, name or person isolating the strain, depositor, name of person identifying the strain, preservation procedure used, optimal growth media and temperature, any data on biochemical or other characteristics, and any regulatory conditions applying (e.g., contamination level).

Duplicate copies of computer files or paper records of all information should be kept to prevent unexpected loss of information.

Research

It is important that culture collections have an ongoing research program. This ensures that staff are kept abreast of current developments and are aware of the needs of the wider scientific community. Lack of adequate research programs discourages high-caliber staff from joining a culture collection and may encourage the loss of existing quality staff. As well as the obvious research and development into preservation and taxonomy, culture collections have the necessary skills to undertake a diverse spectrum of research, whether by themselves or acting as consultants. As discussed earlier, culture collections have the capacity to screen isolates for particular biochemical properties and metabolite production, evaluate and develop commercial kits and rapid detection kits for microbially produced compounds, evaluate organisms' capacity for use in bioremediation and as biocontrol agents, and select test organisms used in the evaluation of materials, media, culture vessels, and diagnostic reagents.

Safety

It is the responsibility of all culture collections to handle cultures and carry out procedures as safely as possible and within the relevant guidelines. This is particularly important with regard to microorganisms that are pathogenic to man or are genetically manipulated. Within the United Kingdom, all laboratory procedures should be performed in line with COSHH (Classification of Substances Hazardous to Health), and all matters of safety are enforced by the HSE (Health and Safety Executive), which also offers an advisory service.

All culture collections are responsible to their own staff, the delivery services, and receiving laboratories and must therefore address all matters of safety properly. All service collections have regulations for both the deposit and dispatch of cultures that have to be fully abided by before samples can be transported following the IATA (1988) Dangerous Goods Regulations for Transport of Infectious Material (3).

Within the United Kingdom, microorganisms are categorized in accordance with the Advisory Committee on Dangerous Pathogens (1995) Categorization of Pathogens According to Hazard and Categories of Containment. In the United States, a similar categorization has been devised (U.S. Department of Health, Education and Welfare, 1974; American Type Culture Collection, 1986). Both sets of guidelines have been accepted by the WHO, and other countries tend to adopt these systems. Information is given on the degree of containment and protective clothing, which should be applied during handling of such organisms in the laboratory.

The control of genetically manipulated organisms is somewhat more complicated in the United States than it is in the United Kingdom. U.S. researchers must adhere to the policy that research in this field must conform to the requirements of the coordinated framework, such as the National Institutes of Health Recombinant DNA Guidelines. In the United Kingdom, genetic manipulations are the responsibility of the Advisory Committee in Genetic Manipulations. Other countries likewise tend to adopt these systems.

All culture collections must additionally follow the regulations of their own countries and the institutes within which they work.

Training and Publications

Culture collection staff require appropriate training for all techniques and procedures they carry out. If an organization has a quality management system, such as ISO 9000, then this will be performed as a mandatory requirement. Once the staff have become skilled, they are then in an ideal position to train others in techniques relating to culture preservation, growth, and identification given that they have adequate teaching facilities and supervision.

Regular publication relating to culture collection activities and the research activities carried out within an organization is necessary to enhance its activities.

National and International Collaboration

Microbiologists having interests in culture collections have banded and assembled in formal or informal national federations or associations of the culture collections within them, such as UKFCC (U.K. Federation of Culture Collections). These federations tend to be further affiliated with international bodies, such as ECCO (European Culture Collections Organisation), which comprises 54 collections from 21 European countries. This organization itself is affiliated to WFCC (World Federation for Culture Collections). These federations provide excellent opportunities for discussion and exchange of information in all aspects of culture collection curation.

European Culture Collection Organization. ECCO was established in 1981. The aim of the organization is to promote collaboration and trade ideas and information about all aspects of culture collection activity. Membership is open to representatives of any resource centers that provide a professional service on demand and without restriction, that accept cultures for deposit, that provide catalogs, and that are housed in countries with microbiological societies affiliated to the Federation of the European Microbiological Society (FEMS). After 14 years of activity, ECCO comprises 54 members from 21 European countries. The total holdings of the collections are about 300,000 deposits representing a large pool of biodiversity from different sources (from humans, animals, plants, foodstuffs, environmental) as well as various sources of biotechnological interest, including GMO strains and organisms of interest for genetic engineering.

World Federation for Culture Collections. Most of the culture collections organized in national or regional federations are members of the WFCC. This international organization has been set up as a multidisciplinary commission of the International Union of Biological Science and is a federation within the International Union of Microbiological Societies (IUBS). Various committees exist within the WFCC for carrying out specific tasks in the different aspects of culture collection work. These include the publication of books, provision of training courses, collaboration with postal and patent organizations, setting up databases, providing help for endangered culture collections,

and designating quality standards and guidelines for collections. One of the major activities of WFCC is to organize its quadrennial meetings (International Congress of Culture Collections).

The World Data Centre (WDC), now the World Centre on Microorganisms (WDCM), covers a central role in WFCC. Initiated in 1972 by Prof. V.B.D. Skerman and sponsored by UNEP and UNESCO, the database pioneered the organization of microbial culture collections worldwide. Relocated to the RIKEN Institute in Japan in 1986, the WDC, under the directorship of Dr. H. Sugawara, developed into a valuable information resource at the microbial level. Several databases are available as hard copies and are also accessible through the Internet. The core databases, CCINFO and STRAIN, are regularly updated and published as the WDC Directory. CCINFO covers information on nearly 500 microbial resource centers in the world, their organization, the kinds of cultures held, the expertise available, and the services offered. Strain lists all microbial species held by registered collections. The WDCM activity of continual data collection and dissemination plays an important role in the improvement of data quality of collections and for making the resource centers known to the scientific community.

Any individual with an interest in culture collection activities is eligible for membership. Culture collections as institutions may become affiliate members if they meet the standards established by the federation. Individuals or organizations may be accepted as sustaining members on the basis of extraordinary support of the objectives and activities of the Federation. Further information can be obtained from the WFCC (Table 2).

Access to Resources

Hard copy catalogs get out-of-date rapidly; the best and most up-to-date information can be obtained from most resource centers on the World Wide Web. Table 3 gives a comprehensive list of contact information for the major repositories.

OUTLINE

INTRODUCTION

The process of choosing and optimizing a cell culture medium for a large-scale production process shares many biological issues and experimental approaches with the process of optimizing medium for any in vitro model system at the laboratory scale. However, there are some significant differences. The cell culture aspect of any large-scale process should fit in seamlessly with the upstream process of the transfection and selection of the protein of interest in the desired parental cell line, the equipment and scale available and desirable to run the process, and the downstream purification process. Issues surrounding the speed

of development and the cost, safety, and reproducibility of the process are of major importance in developing a commercial process.

The importance of seeing the entire process—from selection of the host cell line through transfection and selection of the production line, to the growth of the seed train cells and the actual production culture, harvest, and purification of the protein—as an integrated whole cannot be overemphasized. Failure to do so will result in an unworkable process, at worst, and missed opportunities for maximizing the reliability and minimizing the cost, at best. If the end goal is kept in mind from the first, many opportunities for trade-offs in various aspects of the process will arise that allow decisions to be made in a timely manner. For example, if two candidate production lines exist, one with high specific productivity but slow doubling time and low saturation density and the other with lower specific productivity but better growth characteristics, the choice between the lines should be made taking into consideration the titer from each line and the total tank and equipment usage (seed train, production, and purification) required to obtain a given final yield of protein. It might be surprising to some how taking this broader view will change decisions made early in the process that are much harder to change later. In another case, one medium formulation was found to increase the stability of a cell line even though the titer was reduced compared to the standard medium formulation. The advantages of the increased stability were seen to far outweigh the minor loss of product in the short term.

This chapter will concentrate on specific aspects of choosing and optimizing the cell culture medium for large-scale processes. However, as will be emphasized again in the section at the end, this cannot be achieved optimally without taking into consideration the product (as well as the cell line) to be secreted and the purification process and equipment to be used. Some of the basic parameters that influence protein yield from a mammalian cell culture process are outlined in Table 1 and are discussed in detail subsequently.

OPTIMIZING CELL GROWTH AND SURVIVAL

The aim of optimizing the growth and survival of cells in production culture is to obtain the maximum average viable cell number per volume of medium over the duration of the culture (viable cell days [VCD]). Characteristics of the cell that will influence the total VCD are listed in Table 2. When selecting the production line to be used for large-scale culture, these parameters and specific productivity should be taken into consideration. A transfected cell line with high specific productivity is useless as a production line if it cannot be grown in the conditions necessary for large-scale culture. For example, a tetraploid line may have a high specific productivity but be too fragile to do well in a fermenter. Or, a low-cell inoculum may be acceptable with a rapidly growing cell line, but not with a slow growing line producing a labile product. Continuous culture systems strive to produce a steady-state situation where the cell number is constant and the growth rate and death rate are balanced. Ideally, one would wish to achieve something like a contact-inhibited G_0-arrested state in which the cells are neither growing or dying. This is based on the as-yet-unproved assumption that suspension cells producing recombinant proteins will have a specific productivity in G_0 equal to or higher than that in log phase growth. In our experience, however, it is difficult to achieve a true G_0 growth arrest state in suspension-cultured cells (1).

Although a great deal is known about the optimal growth conditions for specific types of cells, including Chinese hamster ovary (CHO), baby hamster kidney (BHK), and transformed human embryonic kidney (293) cells, it is still impossible to exactly predict the optimal medium formulation for every cell type in every culture configuration. In addition, the process of obtaining a stably transfected cell line expressing a recombinant protein can change the growth phenotype of the cells. Thus, the empirical approach is still the only method of ensuring that the medium being used is optimal for a particular production line. The optimal medium components or concentrations may vary from one CHO production line to the next. This is not surprising given that these lines are transfected with foreign DNA, selected using rather stringent conditions, and frequently amplified in the presence of a mutagen such as methotrexate. Additionally, the lines are engineered to secrete biologically active molecules that may act on the cell

or the medium components, altering the environment of the culture. Generally speaking, however, two media optimal for the growth of two CHO-derived cell lines will be similar to each other and differ from the medium optimized for the growth of a dissimilar cell line such as a 293-derived line. For this reason, it is best to concentrate on one or a few cell lines for large-scale production efforts. Currently, most recombinant proteins produced commercially in mammalian cells use CHO as the host cell line.

Measuring Viable Cell Number

Accurate measurement of cell viability or characterization of cell death is key to the optimization of any production cell line. Viability can be readily measured by a variety of well-known techniques; however, it has more recently been established that many cell lines grown under batch culture conditions undergo cell death via apoptosis (1,2). Apoptosis is an active programmed cell death that exhibits specific morphological traits, such as nuclear condensation and fragmentation, maintenance of organelle and membrane integrity, and gross cell shrinkage (3). This contrasts with necrotic cell death, which is passive in nature and recognized by the degradation of cellular membranes and organelles and cell swelling (4). These different forms of cell death are distinct in morphology, mechanisms, and the way in which they can be identified. An understanding of such is required for accurate reciprocal viability quantification, because the observation of simple loss of membrane integrity (e.g., using trypan blue exclusion) may be insufficient to account for all cell death caused by apoptosis. This may also be important in the accurate calculation of specific productivity. Finally, if one desires to improve the yield in an industrial process by decreasing cell death in the culture, it is crucial that one understand the mechanism of cell death in the cultures and the extent to which death decreases total VCD.

Viability can be assessed most simply by the exclusion of charged dyes such as trypan blue or propidium iodide (PI) that move freely into dead cells and exhibit minimal uptake into live cells. The extent of cell death can then be quantified by microscopy, or in the case of PI, by flow cytometry (1,5). Loss of plasma membrane integrity also results in the release of intracellular contents into the media that may then be quantified, such as the enzyme lactate dehydrogenase (LDH) (6). LDH content can be assayed in both the cellular and supernatant fractions, allowing relative quantification of cell death.

Apoptotic morphology specifically can be readily identified by staining fixed cells with a fluorescent dye such as acridine orange, which fluoresces green when bound to double-stranded nucleic acids (7). The classic apoptotic morphology of condensed or fragmented nuclear material can then be observed. An assessment of the percent apoptotic CHO cells during the course of a production run in a 2-L fermenter is shown in Figure 1. From day 7 there is an abrupt increase in the percentage of cells that show the characteristics of apoptotic cell death even though the total cell number in the culture does not change appreciably over this time period. However, the percentage of apoptotic cells increased from day 7 to a value of 50% apoptotic cells on day 11. Clearly, this large proportion of apoptotic cells will adversely affect the titers late in the run.

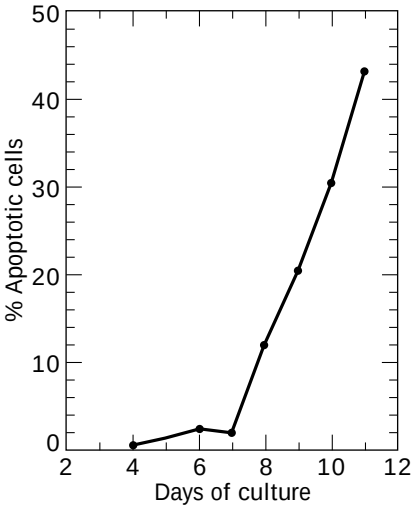

Figure 1. Apoptotic cell death in fermenters. Apoptosis was identified by light microscopy after acridine orange staining. Values are expressed as percent of total cell number that are apoptotic on days 4 to 11 of a 2-L minifermenter run using CHO cells.

An additional characteristic of apoptotic cell death that can be used for quantification is that of DNA strand breaks, which are introduced at the internucleosomal linker sections of DNA in apoptotic cells (8). The ultimate loss of short DNA fragments, coupled with reduced accessibility to intercalating fluorochromes such as PI because of the condensation of chromatin, often results in the congregation of apoptotic cells within a fixed cell population to a hypodiploid peak, when analyzed by flow cytometry (5). The percentage of cells localized to this peak can be quantified if not obscured by excessive amounts of cellular debris.

The free 3′-hydroxyl groups at the ends of the apoptotic DNA strand breaks may also be labeled with a fluorescent nucleotide using terminal deoxynucleotidyl transferase (9) or annexin (10). These techniques allow the fluorescelnation of apoptotic cells with only a low level (or no) labeling of nonapoptotic cells. Cells labeled in such a way may be counterstained with PI, allowing concurrent cell cycle analysis, so that exit from the cell cycle can be tracked by flow cytometry (1). These methods can be used to trace the effects of manipulating the culture parameters on the amount of cell death in the cultures (11). Such experiments are an invaluable adjunct to direct empirical determination of conditions that optimize titer because they can help in deciding which experimental manipulations, among the many possibilities, might yield benefits.

Considerations of Scale

Virtually all industrial productions of recombinant proteins or antibodies in mammalian cell culture are done on a large scale (100 to 12,000 L). The few exceptions may be production of antibodies or proteins for research use only. Although even these small- and intermediate-scale pro-

cesses will benefit from using an optimized medium, any medium optimization will obviously be aimed at use in large-scale processes. We have found that suspension-adapted cells and suspension processes scale well from plates to fermenters. Spinners are actually less predictive, in some cases, than static plate cultures using suspension cells. (Suspension-adapted cells grown in tissue culture plates in medium containing additives such as F-68 frequently will not attach but remain in suspension.) The experiments described in this article can be performed, preferably using the suspension-adapted cells, in plates, including 96-well plates for high throughput screening. However, larger (e.g., 60 mm) plates allow multiple sampling from the same plates over time. The type of careful empirical derivation of optimal process parameters described herein really cannot be performed entirely in fermenters because too many conditions are required. However, these experiments can help narrow the number of parameters to be tested on a larger scale. Figure 2 presents data on yield of identical cells in identical medium cultured in small- and large-scale vessels. The cells in 60-mm plates, roller bottles, and spinners all performed similarly to those in the 1,000-L fermenter. The static shake flask cells that performed very poorly may have been suffering from oxygen deprivation. A few experiments, such as adjustments in medium volume, might allow closer congruence between the small-scale model selected and the performance in large-scale fermenters. All major changes or improvements to a process based on results from small-scale work should be confirmed using fermenters. The use of 2-L minifermenters allows replication of conditions and good statistical analyses of results. If these titers are then confirmed in larger-scale fermenters, one can be confident that a rational approach using small-scale cultures, which allows complete analysis of the interacting variables in the medium, has led to a robust and optimal process.

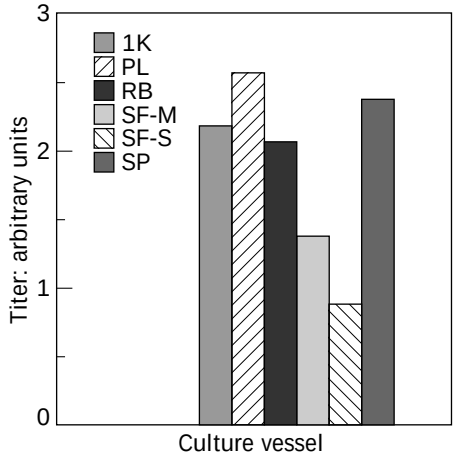

Figure 2. Cells were inoculated into a 1,000-L production fermenter. An aliquot of these cells was removed and dispensed into the various culture vessels on day 0. All vessels were sampled and the titers assayed throughout the culture period. The data shown compare the titers of product produced by cells in the different vessels on day 5 of culture. 1K, 1,000-L fermenter; SP, 1-L spinner; RB, roller bottle; PL, 60-mm tissue culture plate in CO_2 incubator; SF-S, static shake flask in incubator; SF-M, shake flask mixed using a stir bar in incubator.

Although attached cell culture systems can be scaled up via roller bottle microcarrier culture, hollow fiber systems, and so forth, these devices have generally been used for medium-scale rather than very-large-scale production. Each introduces a different set of variables that should be understood to design a small-scale equivalent system for optimizing medium, as described later. Again, any improvements should be compared directly to the standard conditions before adoption.

Some parameters change, of necessity, when going from static cultures to fermenters. The method of pH control differs because base and acid addition are used to regulate pH in fermenters in addition to the bicarbonate buffer. This results in a more stable pH over the course of a run in fermenters, compared to plates, but at the cost of a greater increase in osmolarity in the fermenters because of the added salts. Shear and foaming are also factors in fermenters, but not plates. Components of the medium that are added to fermenters to prevent shear and foaming should also be added to plate experiments when optimizing medium to allow for better concurrence between large- and small-scale results. Finally, the control of P_{O_2} is quite different in plates (diffusion) and fermenters (air or oxygen sparging). Adjusting the total surface area to volume in plates and spinners can have a significant effect on protein production and cell number and help in creating closer agreement between small- and large-scale data.

Some parameters such as pH, temperature, and P_{O_2} can be adjusted or controlled more easily in a fermenter. These parameters are best optimized directly in experiments performed in fermenters after the nutrient and growth supplements have been optimized at small scale and tested at large scale. It is important to optimize these parameters both for improved cell growth and, on occasion, to improve product quality. With a few experiments to directly compare small- and large-scale culture, and an understanding of the principle underlying differences in plate and fermenter cultures, the former can be an invaluable tool in the process of obtaining optimized media for large-scale industrial processes.

Nutrient Component of the Medium

For convenience, the culture medium can be divided into two components: the nutrient portion and the added growth factors and growth-promoting substances. The nutrient components are generally part of the commercially available powdered nutrient mixtures, such as MEM (minimal essential medium), DMEM (Dulbecco's Modified Eagle's Medium), Ham's F12 nutrient mixture, RPMI 1640, or F12/DME. These media were all empirically derived for very specific cell types and growth conditions (12), none of which are very similar to a suspension culture of genetically modified cells in a fermenter. However, they still make a good starting point for optimizing the culture medium for the specific production line of choice. An initial screen should compare several commercially available or proprietary media to determine which is optimal for the

production line. If the medium is being optimized before the cells are transfected, cell number can be used as the end point. If the line is already producing the protein of interest, protein titers should be measured. If the conditions for obtaining maximal titers and maximal VCD are the same, this is a good starting point for optimizing the nutrient portion of the medium. If different media give optimal VCD and titer, then more studies should be undertaken to understand the biology behind this phenomenon. This will prove useful in designing the optimal production system.

Once a medium is found that works well, there is a temptation to move on the assumption that this adequate. However, large-scale commercial culture is one situation in which it is almost always worth the time and effort required to obtain a truly optimal medium. Optimizing the nutrient portion of the medium is important not only for the increased yields it will afford directly but because optimizing nutrients will lead to a decreased requirement for parts of the growth supplements such as serum or growth factors (13). Additionally, optimizing VCD will lead to the ability to prolong culture time while minimizing damage to the product caused by enzymes released from dying cells. Even a 10% increase in VCD can be significant, and improvements of 2-fold to 10-fold in titer are frequently seen with optimized media. Because it is very difficult to change a process after clinical trials have begun, these early improvements will result in accrued benefits extending over many years that are often worth millions of dollars during the life of a production process.

The available nutrient mixtures generally contain amino acids, a carbohydrate source (usually glucose), inorganic salts, vitamins, some type of buffering system (usually CO_2, bicarbonate, and phosphate), fatty acids or more complex lipids, and other components that may vary from medium to medium (e.g., nucleosides, nucleotides, coenzymes, detergents). These components interact with each other so that the optimal concentration will depend to some extent on concentrations of other components in the mixture. Many producers of cell culture media and components have developed their own proprietary cell culture media for specific cell types used in production of recombinant products (e.g., CHO-S-SFM, #12050 or Hybridoma-SFM, #12045 Gibco/BRL, and products from other companies such as JRH, Hana Biologics, and Sigma). These media may offer a shortcut when proteins must be produced in short order; however, incomplete disclosure of the medium components can be a cause for concern, and costs are frequently higher than those of media formulated in-house.

Optimization of the medium starts with choosing the best existing commercial or proprietary nutrient mixture. Then, media components are made up individually and in groups (12,13), and individual media are prepared missing only one component. That component is then titrated using the desired end point of viable cell number or product titer, if a good high throughput assay is available. Figure 3 shows the response of CHO cells to three media components: inositol, KCl, and isoleucine. It is obvious that the omission of KCl or isoleucine results in cell death over the production period and consequently very low protein yields. However, the omission of inositol had, if anything, a positive effect. Conversely, increasing the inositol concentration 20-fold had little detrimental effect, whereas increasing isoleucine was beneficial and high levels of KCl were toxic. Using these data, one might then adjust the inositol concentration downward by 10-fold, the KCl downward by 2-fold, and the isoleucine upward. By using the data from all the titrations, one can then determine the optimal concentrations for each component and make up the best medium. This titration can then be performed again, using the best medium as a starting point. Each successive round of optimization would be expected to yield less benefit as the optimum is approached. A comparison of titers from a production cell line in the starting (control) and round-one optimized medium is shown in Figure 4. This one round of optimization more than doubled the titers during the 8-day production period. This benefit was achieved in large part by increasing the VCD in the culture. Note that significant changes in the culture process, such as changing cell lines, changing inoculum density, changing the supplements, or going from attached to suspension culture, might well require reoptimization of the medium. With experience, it is possible to identify a few medium components that are most important and check only these after the initial optimization. Conversely, once an optimal medium is designed for a given cell line (e.g., CHO), the cells can be grown in that medium during transfection and amplification in order to select for cells that grow optimally in the medium designed.

Growth Factor Additions

The nutrient mixtures discussed in the previous section are generally supplemented with either undefined mixtures, such as serum, that promote the growth of cells or defined mixtures of growth factors, transport proteins, and hormones. The choice of whether one will attempt to reduce or eliminate serum and which supplements to use is based on the characteristics of the product and the cell line as well as cost and safety considerations. Most established cell lines have been carried in serum for years and are therefore well adapted to growth in serum. It may be difficult to achieve equivalent growth rates or titers in a serum-free medium. Table 3 illustrates the effect of medium supplementation on tissue plasminogen activator (tPA) production by Bowes melanoma cells. Even though higher specific productivities can be reached in defined medium, when compared to serum-containing medium, the total yield is lower because of the much-reduced cell growth. Note also that some of the additions primarily affect cell number, whereas others (e.g., nerve growth factor) increase specific productivity with little effect on cell yield. The cells in Table 3 are not recombinant; however, similar effects can be seen using recombinant proteins and 293, CHO, or other host cell lines. In this case, a subset of factors will increase cell number (via decreased cell death or increased cell division), and another set of factors might increase titer via increases in specific productivity of the cells or increase protein stability. The former factors might be useful for all CHO-derived production lines, whereas the latter may be product specific.

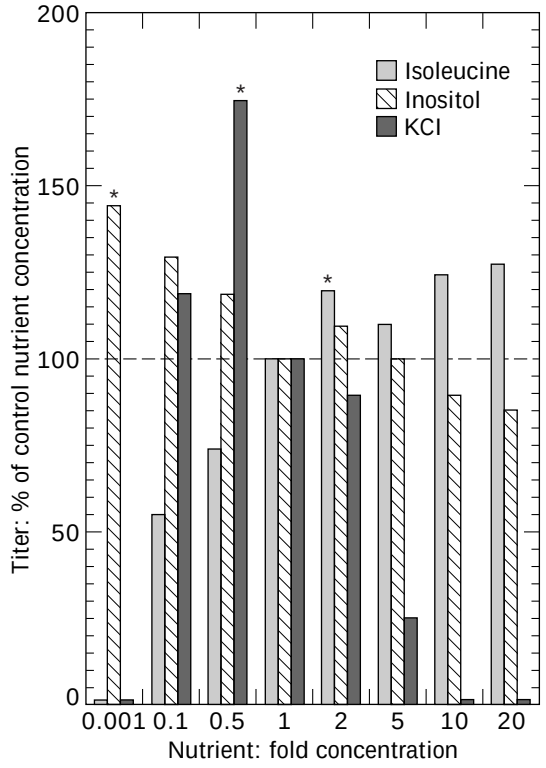

Figure 3. Titration of individual medium nutrients. CHO cells transfected to produce a recombinant protein were grown in production medium from which each of the indicated components had been omitted. These components were then titrated at the indicated concentrations. Cells were plated at standard inoculum and media collected to assay for product on day 6. All cultures were in 60-mm plates at 37 °C in triplicate. Values are expressed as percent of control where the control is the normal concentration (1×, *dotted line*) of each component in the medium. The ordinate values are the fold increase or decrease of the single component compared to control. The asterisks indicate the optimal concentration for each component that will then be chosen for use in the next round of medium optimization.

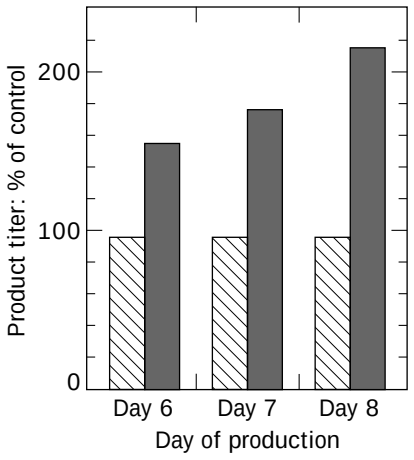

Figure 4. Comparison of titers obtained using the same cells before (control, *hatched bars*) and after (*filled bars*) optimization of the nutrient portion of the medium. These differences result entirely from changes in concentrations of the nutrients. Results are expressed as percentage of control where the control is the starting F12/DME medium.

Table 3. Cell Number, Titer, and Specific Productivity of Cells Producing tPA

		Plasminogen activator	
Supplement	Cell no. × 10^5	ng/10^5	ng/mL
Serum free	0.69	<30	Lts
+I	0.86	<30	Lts
+I+TF	1.08	<30	Lts
+I+TF+NGF	1.06	54	57
+I+TF+NGF+P	1.09	55	59
7.5% FBS	6.00	30	178

Note: Bowes melanoma cells were grown in F12/DME supplemented as indicated. Medium was collected after 5 days in culture. Lts, less than standard; I, insulin; TF, transferrin; NGF, nerve growth factor; P, progesterone; FBS, fetal bovine serum.

However, there are several reasons to eliminate serum, where possible, even if this results in a decrease in titer. Serum is expensive, contains high levels of many unknown proteins (about 40 mg/mL) that must then be purified away from the recombinant product, and contains enzymes and binding proteins that may affect product quality. For example, the production of tPA in the presence of serum will yield predominantly two-chain cleaved tPA rather than single-chain material. This is because the recombinant plasminogen activator produces plasmin from the plasminogen in the serum, which in turn cleaves the tPA. Thus, the tPA produced from the cells in Table 3 in the serum and serum-free conditions would have different characteristics. If single-chain material is desired, it is best to try and improve the cell yield by adding other supplements or adjusting the nutrient mixture.

One straightforward method for reducing contaminating proteins from serum is to simply reduce the serum concentration. This makes the medium less expensive in many cases, simplifies purification by eliminating serum proteins, and often improves product quality or cell growth. The general practice is to wean the cells by reducing the serum concentration over several passages (e.g., from 10% to 5%, 2%, 1%, 0.5%, 0.1%, etc.) allowing two or more passages at each concentration if a reduction in growth rate is observed. This method often works, but it is exceptionally time consuming. Eliminating serum altogether over one to two passages is often a reasonable solution for cells that do not have very fastidious growth requirements, although the resultant titers might not be optimal. A better solution is to derive a set of supplements that substitute for serum without any adaptation being required. In our experience, one can usually obtain titers in serum-free medium similar to, or even better than, those obtained in serum, although some thought must be taken as to the parental cell lines used for expression (see "The Cell Line").

With the advent of bovine spongiform encephalitis (BSE), it is likely that more processes will be driven to

become serum free for safety considerations. Because testing for BSE on each lot of serum is time consuming and expensive, elimination of serum from the process is an easy way to avoid this problem. However, the entire process must be carried out serum free if one is to avoid the chance of infection. This is a more stringent growth condition than growing cells for only one passage serum free and requires more complete supplementation.

The question of which supplements to add is again one that can only be answered in the context of the desired end point. It should be emphasized in this context that optimizing the nutrient portion of the medium can reduce growth factor (and serum [13]) requirements. Optimizing the nutrient portion of the medium is generally less expensive than adding supplements such as serum or growth factors. For production, minimizing expense and optimizing product quality may be more important than maximizing titer. It is the final yield of purified product as a function of fermentation plus purification cost that is the determining factor in deciding what the best medium will be. In an optimized serum-free culture process, the recombinant product may comprise 10 to 80% of the total protein in the harvest medium. This makes purification easier and less costly. In contrast, if one is growing up cells for the seed train, minimizing the doubling time to have cells ready for inoculation may be of more importance than the cost of the medium because cells are grown in smaller volumes. The quality of the protein produced is also not an issue in the early passages after thaw. However, it is generally best to not make too many major changes in media while bringing cells from the thawed vial to the production tank in order to avoid lag time as the cells adjust to new conditions.

Much has been written concerning optimizing the supplements for serum-free media. Our preference is to use small-scale culture experiments to obtain defined supplements that will provide cell numbers and product titers equivalent to or higher than those obtained in serum-supplemented medium. The elimination of serum necessitates the addition of hormones, growth factors, trace elements, and lipids (12,14–16). Because of the low concentrations of these components, the absence of binding and carrier proteins provided by serum, and the instability of the components in culture medium, these must be added to the media after filtration and just before use. The most commonly required additives are insulin (1 to 10 μg/mL), transferrin (1 to 100 μg/mL), and selenium (10 to 30 nM); however, some cell lines have an added requirement for lipids. One can then determine, based on experimental data, whether the increased product yield obtained by adding the most expensive components of the medium (for example, an epidermal growth factor requirement) are worth the expense. Using such data, one can then determine a minimum required medium that contains the most cost-effective supplements. A more complete description of deriving the appropriate hormone supplement in order to eliminate serum is given by Barnes and Sato (15) and Hewlett (17). For cell lines that are particularly fragile, Pluronic F-68 (18) or Pluronic F-127 can be added to the medium to prevent shear-associated cell lysis. Finally, if the product is sensitive to proteolysis, one might wish to add protease inhibitors, as discussed more fully later.

The empirical derivation of medium formulations optimizing both the nutrient portion of the medium and the supplements is time and labor consuming. It is seldom undertaken in a thorough fashion. One often-expressed wish is the desire to be able to predict what the optimal medium will be for a given cell line. Unfortunately, at this time, it is not possible to do this with any degree of assurance. We can make good guesses, largely based on experience gained by performing previous experiments on similar cells, but this will probably result in a good enough, not an optimal, medium. The only cases in which a full optimization of the medium is undoubtedly justified are (*1*) those research laboratories interested in understanding the nutritional and hormonal requirements of cells in vitro and (*2*) in the development of a commercial process where small gains in titer, viability, and stability would, over many years of production, be expected to repay the initial effort expended in the optimization. Most large-scale culture processes fall into this category.

OPTIMIZING SPECIFIC PRODUCTIVITY

Specific productivity is the amount of recombinant protein produced per cell per specified time period. Given that the cells are growing in an optimal medium, this will be a function of the expression system (promoter, enhancer, etc.) chosen and how well that particular system works in the host cell chosen, the integration site and orientation of the recombinant plasmid, the copy number of the gene to be expressed, and any specific or nonspecific inducers used. A discussion of the many expression systems available (19) is beyond the scope of this article. However, the method used to select and clone transfected cells and amplify gene copy number frequently impacts the performance of the cells in the production culture medium and will be discussed briefly.

The process of obtaining a stable cell line expressing a foreign protein involves a method of permeabilizing the cells to allow the plasmid containing the foreign DNA to enter the cell, a method of selecting for the minority of cells that have integrated the DNA into the nucleus, cloning to select a clonal cell line producing high levels of protein, and frequently several rounds of amplification of the DNA, each followed by cloning. This process allows ample opportunity for both genetic changes in the host line and the selection of a subpopulation from the initial population. Usually, the primary, if not the sole, concern is to maintain the gene containing the recombinant protein in the cells. However, the phenotype of a good production cell line also includes the ability to grow rapidly and to high saturation density while maintaining a high viability. If one has made the effort to optimize the medium for the growth of the parental cell line, it is desirable to maintain the ability to grow well in this medium, including serum-free and suspension growth. To maintain the desired phenotype, selective pressure should be maintained for these growth characteristics during the process of transfection, amplification, and cloning. If the cells are grown in the process medium whenever possible, they will be much easier to handle when they reach the production setting. To the ex-

tent that this is not possible, the production cell line selected might benefit from a period of adaptation to the process medium and growth conditions before being banked.

OPTIMIZING PRODUCT STABILITY

The production medium is designed to provide the maximum number of cells secreting protein over the maximum amount of time. The longer the productive run time, the longer the product can accumulate in the medium and the higher the resultant titer. However, this medium, along with the metabolites and proteins being secreted into it by the cells, is also the storage medium for the proteins being produced and secreted. An environment that is 37 °C, neutral pH, fully oxygenated and stirred and where proteases and other enzymes are separated from the proteins by, at best, a layer or two of cell membrane would hardly be considered optimal for protein storage by any biochemist. This is, however, what recombinant proteins produced in the first days of the production run have to withstand for the duration of the run. Therefore, some thought should be given to protein stability in the production medium. This will be in large part dictated by the characteristics of the protein being produced. Figure 5 illustrates the accumulation of titer during a production run with two different proteins. One is stable and accumulates linearly during the run; the other is easily proteolyzed and begins to degrade faster than it is produced when the cells in the culture begin to die. Continuation of the culture at this point leads to loss of product. The most important change in this process would be to optimize the medium components to prolong cell viability. One might then adjust the inoculum density so that the number of viable cell days is optimized. Too high an initial inoculum can result in early cell lysis and degraded product, whereas too low an inoculum results in too long a production period to reach the desired titer, resulting in overly long product residence time in the medium. One might also adjust the temperature to minimize cell death (11), shorten the run (including using processes that shorten the product residence time, such as perfusion), or add protease inhibitors to the medium. Protease inhibitors can be nonspecific (e.g., serum albumin) or specific (e.g., aproteinin or small molecular weight inhibitors). The small molecular weight inhibitors are frequently toxic to cells in culture, whereas inhibitors such as aproteinin are well tolerated but very expensive for production use.

THE MARRIAGE OF THE MEDIUM AND THE PROCESS

As discussed in the introduction, medium formulation and optimization should not proceed in a vacuum but should be an integral part of the overall process design. From the initial choice of cell line through to the final purification, there should be consideration of the entire final process that will result.

The Cell Line

The production cell line should be chosen not only for its protein secretion rate measured under laboratory conditions but also for its ability to perform well in the special conditions that occur in large-scale culture (Table 2). The cells may be adapted to these conditions after transfection, as discussed earlier, or the parental cell line may be engineered to optimize its performance as a production cell line before transfection. Cells can thus be adapted to grow in suspension or serum-free medium and then be banked for use as parental cell lines. If they are maintained in these conditions during transfection and selection, then the recombinant protein producing the cell lines will have these important characteristics. Even if they cannot be handled in suspension or serum-free conditions at every step of the

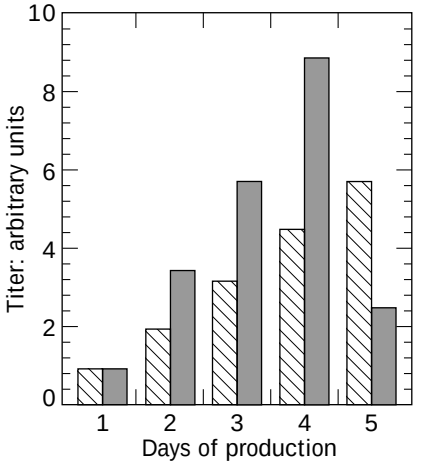

Figure 5. Titer as a function of run length. The figure shows the cumulative titers during two runs of recombinant cells, each expressing a different protein (*open bars* and *hatched bars*). The assays used only measure intact protein. Data are expressed as fold increase over control, where the control is the titer on day 1 of the culture.

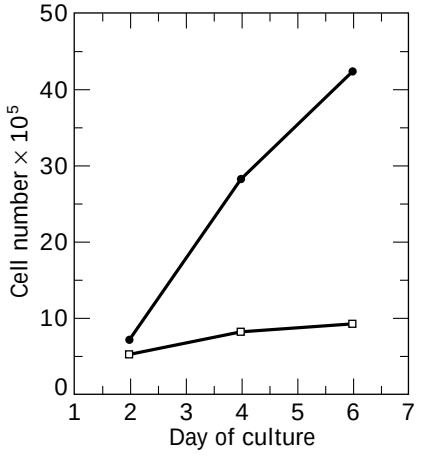

Figure 6. Insulin-independent growth of CHO cells transfected with the proinsulin gene. These cells can grow as well in the absence of insulin as their parent line can grow in medium supplemented with 10 μg/mL insulin. CHO-parent line (*squares*) and dp12-proinsulin transfected clone (*circles*) were grown in the absence of insulin.

transfection process, they will be more likely to retain the desired characteristics.

Additionally, one can genetically engineer the parental cell line to have traits that are optimal for a production cell line. One example of this is to transfect the production cell line with a required growth factor, allowing autocrine growth at large scale without exogenous addition of the factor. Figure 6 demonstrates that CHO cells that have been transfected with the proinsulin gene have become insulin independent for growth. This will, of course, alter the composition of the medium used to grow these cells.

Equipment

It is obvious that the optimal medium for a process will depend, in part, on the equipment used and the configuration of the process. Clearly, suspension cultures and attached cells might require different media. The optimal nutrient mixtures for batch cultures and for perfusion cultures would be quite different. The inoculum density and amount of growth that will be required of the cells at each stage of the scale-up process will depend on the tank sizes used to inoculate each stage. The equipment to be used for the final process should be considered from the first stages of medium optimization so that one is sure that the medium designed does, in fact, support the cell growth and viability required in the process.

Downstream Purification

Because the final goal of the process is to obtain a highly purified active protein, the downstream purification methods to be used should be considered from the beginning. Some protein characterization should be performed throughout the medium development process, in addition to a simple measurement of titer. Medium changes can alter protein characteristics as well as titers. It is therefore important to make certain that the desired product characteristics are maintained when medium changes are made to improve titer.

Finally, everything that is put into the medium by the formulation or by the cells in the culture must be removed from the final protein product. Wherever possible, it is always best to use supplements that will not raise safety considerations. Additionally, it does not make sense to add supplements to increase titer if the resulting product will be lost because of the extra purification steps that must be added. There is not as much room to alter pH, salt concentration, and so forth in a cell culture medium as there is in protein purification processes, but some understanding of the constraints and problems of both ends of the process will help make for a smooth transition and a reproducible process.

In summary, the time and effort required to optimize all components of the production medium will pay off many times over in a mammalian cell culture process. Optimal medium not only optimizes protein titers but can lead to improvements in protein quality and stability, more stable cell lines, more reproducibility from run to run, and improved use of facilities. To obtain maximal benefit from medium design it must be done in concert with the transfection and selection of the production cell line, the configuration of the manufacturing plant, and the design of the downstream purification process. All these factors working together have made large-scale mammalian cell culture an economically important part of the modern biotech industry.

ACKNOWLEDGMENTS

We would like to acknowledge the invaluable interactions with other members of Genentech's process sciences division, especially the cell culture R&D department, the cell genetics department, and assay services group. All these people contributed to the experiments and experiences described in this article.

OUTLINE

INTRODUCTION

The ubiquitous presence of microorganisms, as well as their metabolic diversity, has made them important factors in industrial applications and product development. Bacteria, fungi, and yeasts have been used for the production of food, medicinals, solvents, enzymes, and numerous other products. They have also been used as standards for bioassay and bioremediation applications. In addition, advances in bioengineering have enabled the incorporation of genes into microorganisms for the production of mammalian proteins and peptides.

During the past 20 years, cell line technology grew dramatically to enable the isolation and maintenance of a wide variety of tissue lines from any species of interest. The initial use of cell lines for vaccine production was expanded by developments in cell hybridization, transduction and transfection, and genetic manipulation to include the production of monoclonal antibodies, cytokines, and other pharmaceutical products. Lines that have been genetically engineered have been successfully expanded and grown in fermenters for large-scale production.

The development of microbial and cell cultures represents an enormous investment in time and money and is an important asset to industry. These cultures must be protected from accidental loss by means of standardized preservation techniques. The primary aim of culture preservation is to maintain the culture such that it is as close as possible to the original strain or line exhibiting the desired phenotypic or genetic traits. Often, industrial cultures are not analogous to taxonomic strains in that they have been modified to have special properties, either rapid growth, more active metabolic rates, or other features.

Many methods have been used to preserve bacteria and fungi, but not all species respond in a similar way to a given method. Unfortunately there is no universal method that can be applied to all microorganisms. It should be emphasized, however, that the success or failure of any preservation technique also depends on the use of the proper growth medium and cultivation procedures and on the age of the culture at the time of preservation. This is particularly true when working with microorganisms that contain plasmids or recombinant DNA, or that exhibit growth phases such as morphogenesis or spore formation.

The following provides practical information for the maintenance and preservation of bacteria, fungi, yeast, and cell lines. It should be noted, however, that not all microorganisms will be preserved by these methods, and some experimentation with cryoprotective agents and other factors may be necessary for success. Additional information on bacterial, fungal, and cell-line preservation may be found elsewhere (1–3).

CULTURE AND PRESERVATION OF BACTERIA

Short-Term Preservation

Subculture. Most bacteria can be preserved by periodic serial transfer to fresh medium. The period between transfers varies with the organism, medium employed, and the external conditions. In general, minimal media are preferred for subculturing because they lower the metabolic rate of the organism and thus prolong the interval between transfers. In rich media, growth is often much faster, with the accumulation of metabolic products. These compounds may alter environmental conditions such as pH and gas phase and shorten the interval between transfers. Some bacteria such as pathogens need complex media (4) for growth, or their retention of specific physiological properties require the addition of complex compounds to the medium. The subculturing interval for these organisms must be determined by experience.

When preserving bacteria by serial transfer, it is important to use containers that can be securely sealed. Glass test tubes or 6-mL bottles with rubber-lined screw caps are widely used. The bacteria can be grown with slightly loose caps until adequate growth is obtained and then tighten to prevent dehydration. Solid media are preferred to broth because contaminants can be readily seen. Duplicate tubes should be maintained as a precaution against loss, at least until the subculturing interval is determined. The cultures should be examined for purity after each transfer, and abbreviated characterization tests must be run periodically

to ensure retention of desired traits. Storage in a refrigerator is the preferred method for subcultures. Many bacteria can be kept for 3 to 5 months between transfers if proper precautions are taken to avoid dehydration of the medium.

It should be noted, however, that the maintenance of cultures by serial transfer is precarious, time-consuming, and expensive. The frequent transfer of cultures can result in contamination, mislabeling, and the selection of strain variants.

Other methods involve storing cultures at refrigeration temperatures, drying in sterile soil, glass beads, filter paper, and other substrates. Detailed descriptions of these methods can be found in Refs. 5–7.

Short-term maintenance and preservation procedures are not recommended for industrial strains because a number of problems can occur using these methods. The main hazards are contamination, population changes through selection resulting in the loss of key genetic and physiological properties, and the expense of maintaining cultures under these conditions.

Ordinary Freezing. The use of the freezer compartment of a refrigerator or an ordinary freezer with a temperature range of 0 to −20 °C to preserve bacteria is not recommended because the freezing process (see "Long-Term Methods", Deep Freeze) damages the cells. In addition, most refrigerators that have a freezer compartment in the range of 0 to −20 °C are frost free. The frost-free state is achieved by an alternating warming and cooling cycle, which can result in further damage to the cells and a loss of viability.

Long-Term Methods

Freeze-Drying, or Lyophilization. Freeze-drying, or lyophilization, is one of the most economical and widely used methods for long-term preservation of bacterial cultures and other microorganisms. Many metabolically diverse bacterial species have been successfully preserved by this technique and have remained viable and unaltered for more than 60 years.

Freeze-drying is a complex process that involves the removal of water and other solvents from a frozen product by sublimation (8,9). Sublimation occurs when a frozen liquid goes directly to a gaseous phase without passing through the liquid phase. There are three stages in the freeze-drying process: *(1)* prefreezing of the suspension to ensure a solid frozen starting material, *(2)* primary drying during which most of the water is removed through sublimation, and *(3)* secondary drying to remove the bound water.

The rate of cooling during the prefreezing step and the final temperature of the frozen material can affect the freeze-drying process. The removal of water during the primary drying stage requires an environment that allows the water molecules to migrate from the frozen material. This is achieved by using a vacuum pump. A large-capacity pump must be used to prevent the water vapor load from compromising the efficiency of the system. The procedure also requires a moisture trap or condenser to collect and remove the water molecules before they enter the vacuum system. The condenser temperature must be lower than the frozen material for sublimation to occur. The sublimation rate is dependent on the differential vapor pressure between the frozen material and the condenser. Because the vapor pressure varies with the temperature, heat can be carefully applied to the frozen cell suspension to increase the vapor pressure and promote a faster primary drying rate. Precautions must be taken during the application of heat to prevent the frozen cell suspension from thawing. Most commercial instruments have sophisticated controllers that allow the input of heat to the frozen material to achieve maximum drying rates without damaging the product.

When the primary drying is complete, some bound water remains. This water cannot be eliminated by sublimation and requires the application of external heat to the material under low pressure and low condenser temperature. The moisture remaining in freezed-dried cells is termed residual moisture. A residual moisture content of 1–3% seems to be required for the long-term shelf life of bacteria. For an in-depth review of the complex freeze-drying process, the reader is referred to several excellent reviews (10–12).

Centrifugal freeze-drying and prefreezing are two of the most commonly used methods of lyophilization of bacteria. In centrifugal freeze-drying, the suspensions are initially frozen by evaporative freezing under a vacuum while centrifuging to prevent frothing due to removal of dissolved gases. After primary freeze-drying, the vials are constricted using a narrow flame and then placed on a manifold for secondary freeze-drying. A detailed discussion of centrifugal freeze-drying can be found in articles by Rudge (13) and Lapage (14). The prefreezing method employs a controlled rate of cooling to freeze the cell suspension and then a primary drying phase, as discussed earlier.

The simplest system consists of a vacuum pump capable of an ultimate pressure of less than 10 μmHg (a pump rated at 35–50 L/min is usually adequate), a small stainless steel condenser for cooling with dry ice, a thermocouple vacuum gauge to monitor the vacuum system, and heavy-walled vacuum/pressure tubing to connect the components. The connection of these modules into a single system is often termed a component freeze-dryer. The main components are the vacuum pump, thermocouple vacuum gauge, and a condenser that can be attached to several manifolds, to which glass vials can be attached by means of vacuum-tubing nipples, or the manifolds can be connected to a stainless steel pan containing the vials. The manifold system is relatively simple, and it has been used successfully by many laboratories to preserve cultures. A small amount of cell suspension (0.2 mL) containing a cryoprotectant is dispensed into sterile ampules, which are plugged with sterile cotton. A 1-inch piece of nonpowdered amber latex IV tubing is attached to the rim of each ampule (by using a tube stretcher) and then to the manifold. The ampules are then immersed in an ethylene glycol (50%) dry-ice bath at −40 °C to freeze the cell suspension. The freeze-drying cycle is initiated by starting the vacuum pump and allowing the temperature of the bath to rise of its own accord to ambient temperature. In general, runs

can be started early in the afternoon and allowed to proceed overnight. At the end of the drying cycle, the ampules are sealed using a double-flame air/gas torch and stored at 2–8 °C. For specific details on the equipment and methods see articles by Gherna (15) and Simione and Brown (16). Details of other procedures and equipment are given by Haynes et al. (17).

The American Type Culture Collection (ATCC) has successfully lyophilized many of the bacteria described in the literature. It currently uses three methods:

1. *Component freeze-dryer*. Samples are freeze-dried in cotton-plugged inner vials, which are then sealed in outer vials under vacuum.
2. *Commercial freeze-dryer*. Cultures are freezed-dried in the double-vial system in a commercial freeze-dryer.
3. *Preceptrol cultures*. Cultures are lyophilized in a commercial freeze-dryer using glass serum vials that are sealed with a rubber stopper and metal cap.

It should be noted that after the drying cycle is complete in the commercial freeze-dryer and Preceptrol methods, the vacuum in the drying chamber is replaced with cooled nitrogen gas (2–8 °C) that has been passed through a 0.2-μm Pall filter. The condenser temperature must not be allowed to rise above −50 °C. The nitrogen gas may have to be passed through a copper coil immersed in liquid nitrogen.

Culture Preparation. Successful freeze-drying depends on using healthy cells grown under optimum conditions on the medium of choice for each strain, which ensures the retention of the desired features of the bacterium. Bacteria can be grown on agar or in shaken or static broth cultures. The cells are harvested at maximum stability and viability, in the late logarithmic or early stationary phase, and suspended in a medium. The cell suspension should contain at least 10^7–10^{10} cells/mL in order to achieve optimal results. Anaerobic cultures must be grown, harvested, and dispensed under anaerobic conditions (18).

The viability of freeze-dried cultures is greatly influenced by the suspending medium. The choice of suspending medium for freeze-drying depends on the type of bacteria and on the method used.

The ATCC uses two suspending media for the commercial freeze-drying method:

1. Reagent 18
   0.75 g trypticase soy broth
   10.0 g sucrose
   5.0 g bovine serum albumin fraction V
   100.0 mL distilled water
   Filter sterilized through a 0.2-μm filter
2. Reagent 20
   10.0 g bovine serum albumin fraction V
   20.0 g sucrose
   100 mL distilled water
   Filter sterilized through a 0.20-μm filter

Reagent 18 is more commonly used for freeze-drying bacteria and fungi. Reagent 20 is employed for bacteria that are adversely affected by trypticase soy broth and is added to an equal volume of cell suspension in the broth.

In the component freeze-drying method (double-vial), the additive is a 20% (wt/vol) sterile solution of skim milk, prepared by autoclaving a 20% skim milk solution at 116 °C for 20 min in 10-mL tubes. For cultures grown on agar surfaces, the cells are washed off with the 20% skim milk solution. Broth cultures are centrifuged, and the cell pellet is resuspended with the sterile skim milk to give a suspension of 10^8 cells/mL. Skim milk should not be used for bacteria that are inhibited by milk, instead use a 24% (wt/vol) sterile sucrose solution diluted equally with growth medium to yield a 12% (wt/vol) sucrose solution (final concentration) for the single-vial manifold or commercial freeze-dryer method. As soon as the cell suspension is prepared, it should be dispensed into the ampules. The interval between dispensing and freeze-drying should be kept to a minimum to avoid possible alteration of the culture. Other investigators have used 10% (wt/vol) dextran, horse serum, inositol, raffinose, trehalose, and other cryoprotective chemicals in the suspending medium (19–21).

Most bacteria can be lyophilized using these methods; for those cultures that require special conditions, the reader is referred to Ref. 16. The same methods have been employed successfully to freeze-dry most bacteriophages; exceptions are stored in liquid nitrogen. In general, bacteriophages can be grown in a soft agar layer or in broth. The phages are harvested by scraping off the soft agar with a sterile glass rod or rubber policeman, macerating and dispensing into a sterile centrifuge tube, and centrifuging at low speed to sediment the agar and most of the unlysed bacteria. Broth-gown cultures are centrifuged at low speed to remove the unlysed bacteria. The supernatant is then filtered through a 0.45-μm and then through a 0.2-μm Millipore filter. The filtrate should be titrated to determine the concentration of phages; a titer of 10^8 pfu/mL is desirable. The phage can be freeze-dried using 20% skim milk and the component freeze-dryer method.

Freeze-dried bacteria and bacteriophages can be stored at 2–8 °C. A longer shelf life has been obtained when cultures are stored at −30 or −70 °C in a mechanical freezer. Freezed-dried cultures should not be stored in a freezer compartment of a frost-free refrigerator because of the alternate heating and freezing cycles, nor should they be stored at room temperature.

Although lyophilization has facilitated the long-term preservation of bacteria, viability checks must be done before and after lyophilization to determine the effectiveness of the process. Quality control procedures must be in place to check for purity, retention of essential characteristics and periodic viability to determine the shelf life of the culture.

Deep Freeze. The long-term preservation of bacterial species not amenable to freeze-drying has been achieved through storage in the frozen state at a temperature of −70 °C or, more advisable, at the temperature of liquid nitrogen (−196 °C) or liquid vapor phase (−150 °C).

The freezing process results in several events that can be destructive to the cells. As the bacterial suspension begins to cool, the liquid water turns to ice at 0 °C (the exact temperature depending on the nature of the bacterial suspension). Ice formation occurs first in the external aqueous environment, resulting in an increased concentration of solutes outside the cells. The differential osmotic pressure causes water to migrate from the cells. The rate and extent of the water loss are dependent on the rate of cooling and the permeability of the cells. Removal of too much water leads to a concentration of solutes within the cells that may be harmful. If too much water is left in the cells, internal ice crystals may form, which would result in intracellular damage. It is important to maintain the critical balance between the two events by controlling the rate of cooling while freezing the cells, and warming as rapidly as possible when the cells are thawed. Chemical compounds such as glycerol and dimethyl sulfoxide (DMSO) can be added to the cells to minimize the damage caused by freezing. These compounds, labeled cryoprotective agents (see "Cryoprotectants"), exhibit certain properties that are essential for good cryoprotection (22,23). They must be nontoxic to the cells, show good permeability, and bind either the electrolytes that accumulate or the water molecule to delay freezing.

The physiological condition of the cells plays an important role in survival of freezing. In general, actively growing cultures harvested at the mid to late logarithmic phase of growth will survive the freezing process better than those harvested at an earlier or later phase. The bacteria should be grown under optimum conditions in the appropriate medium that best retains the prominent characteristics of the strain. Bacteria can be grown on broth that is static or shaken, or on agar. Shaken cultures generally reach optimal cell density faster than agar-grown cultures. Some strict anaerobes require prereduced media and anaerobic procedures for harvesting and dispensing.

Cells grown in broth cultures are harvested by aseptic centrifugation, and the resultant pellet is resuspended in sterile broth containing 30–50 % (vol/vol) sterile glycerol. Bacteria grown on agar are harvested by aseptically washing the growth with sterile broth containing the cryoprotectant. Dispense 0.4 ml of the cell suspension, containing at least 10^8 cell/mL into each sterile, prelabeled vial. Plastic presterilized screw-capped vials (such as Nunc) are recommended for bacteria. Place the filled vials into a mechanical freezer set at −70 °C. The cells are recovered by rapidly thawing the frozen cell suspensions in a 37 °C water bath.

A wide variety of bacterial have been successfully preserved at −70 °C using glass beads and 15 % glycerol as the cryoprotectant (24). The glass beads are prepared as described in Ref. 15, and 30 beads are placed in 2-mL glass screw-cap vials and sterilized for 15 min at 121 °C. The vials must be prelabeled with ink that will not come off at ultralow temperatures. Cell suspensions are prepared containing approximately 10^8 organisms/mL in sterile 15% glycerol, and 0.5 mL is dispensed into each vial. The vials are shaken gently to ensure that all the beads are wetted with the bacterial suspension, and then the excess liquid is aseptically removed with a sterile pasteur pipette. The vials are placed into a mechanical freezer at −70 °C. The cells are recovered by aseptically removing a bead from the vial with a sterile spatula or forceps and placing the bead in sterile broth. It should be noted, however, that the contents of the vial should not be allowed to thaw; this can be prevented by placing the vial in crushed dry ice and removing the bead after ensuring the beads will remain frozen. This technique has been used to preserve bacteria obtained from extreme environments such as hypersaline pools.

Precautions must be taken against electrical shutdowns and compressor malfunctions. Adequate back-up systems (such as alarms, back-up freezers, or an electrical generator) will help to prevent the loss of a valuable collection. However, additional alarm systems are recommended, such as the sound/off power-temperature monitor (Arthur H. Thomas Co.), which has a temperature range of −75 to + 200 °C. The unit is battery powered and can be mounted on a wall.

Ultrafreezing, or Cryopreservation. Although the long-term maintenance of bacteria in liquid nitrogen has been considered expensive, the successful preservation of physiologically diverse bacteria by this method, along with minimal handling and lower labor cost, makes this method feasible to use. The ATCC has successfully preserved many bacteria and bacteriophages, including fastidious ones, in liquid nitrogen for over 36 years without the loss of phenotypic properties.

A large variety of liquid-nitrogen refrigerators are now commercially available, with a wide assortment of features and storage capacities. The sizes range from 10 to 1,000 L, allowing storage of 300–40,000 ampules.

The physiological condition of the cultures plays an important role in the survival of bacteria under liquid-nitrogen freezing. Bacteria are grown in the appropriate medium and harvested at mid-late logarithmic phase of growth (25). Cultures grown in broth are harvested by aseptic centrifugation, and the resultant pellet is resuspended with sterile fresh medium containing either glycerol or DMSO. For agar-grown cells, the growth is washed off from the agar surface with sterile broth containing the appropriate cryoprotectant. Cryoprotective agents must be added to the suspending medium to protect cells from freeze damage. Cryoprotectants fall into two main classes: compounds such as glycerol and DMSO, which are permeable and appear to provide both intracellular and extracellular protection against freezing; and agents such as dextran, glucose, lactose, mannitol, polyglycol, polyvinylpyrrolidone, and sucrose, which seem to exert their protective effect external to the cell membrane. The first class of cryoprotectants has proven to be the most effective, and in general, glycerol and DMSO seem to be equally effective in protecting a wide range of bacteria. It is advisable to conduct a tolerance test on new species to ascertain whether the cryoprotectant is toxic or beneficial.

DMSO and glycerol are routinely used at concentrations of 5 % (vol/vol) and 10% (vol/vol), respectively, in the proper suspending medium. Glycerol is normally prepared as a double-strength (20 %, vol/vol) solution and then mixed with an equal amount of the cell suspension. Glycerol is

sterilized by autoclaving at 121 °C for 15 min and stored in 6-mL volumes at 2–8 °C. DMSO is filter sterilized with a 0.22-μm-pore-size Teflon (polytetrafluoroethylene) membrane (Gelman or Millipore) that has been prewashed with methanol and DMSO, collected in 10 to 15-mL quantities in sterile test tubes, and stored in the frozen state at 5 °C (DMSO freezes at 18 °C) and protected from light. An opened bottle of DMSO should not be used for more than 1 month because of the accumulation of oxidative breakdown products.

Cell suspensions containing at least 10^8 cells/mL are dispensed into prelabeled sterile vials. There are a variety of vials available commercially, ranging from prescored glass to sterile plastic. With glass vials, care must be taken when sealing and storing because improperly sealed glass vials can explode when retrieved from the liquid nitrogen as a result of the rapid expansion of the liquid nitrogen that enters the vials through microscopic holes. Plastic screw-cap vials that are not properly sealed can fill with liquid nitrogen if stored in liquid phase; retrieval of the vials to a warmer temperature can result in liquid nitrogen expansion, causing the contents of the plastic vials to spray into the laboratory environment. Plastic screw-cap vials should always be stored in the vapor phase. Protective gloves and face shields should be worn when handling frozen liquid-nitrogen vials.

The rate of cooling is important in liquid-nitrogen storage. In general, the best results for preservation of bacteria have been achieved with slow cooling. This step can be controlled using programmable controllers such as the Linde BF 3-2 (Union Carbide Corp.), which has an adjustable cooling rate. The cells are frozen at a controlled rate of 1–3 °C/min to −40 °C and then at a more rapid rate of 10 °C/min to −90 °C. After this temperature is reached, the vials are transferred to a liquid-nitrogen tank and stored in the liquid phase at −196 °C or above in the vapor phase at −150 °C.

If a programmable freezer is not available, slow cooling can be obtained by placing the filled glass or plastic vials in a stainless steel pan at the bottom of a mechanical freezer at −60 °C for 1 h and then plunging the vials into a liquid-nitrogen bath for 5 min. The rate of cooling to −60 °C is approximately 1.5 °C/min. The frozen vials can then be stored in the liquid-nitrogen tank in the liquid or vapor phase.

It has been reported that the best recovery of cultures from liquid-nitrogen storage is obtained by rapid thawing (26,27). This has also been the experience with cultures frozen at the ATCC. The events during thawing are complex, and slow warming rates can lead to ice crystal formation; a rapid warming rate of approximately 100 °C/min will minimize the damage due to ice formation. A rapid rate of warming can be achieved by quickly immersing the frozen vials in a 37 °C water bath with moderate agitation until all the ice melts. This usually takes about 50 s for glass vials and 90 s for polypropylene ones.

Cryopreservation of strict anaerobic bacteria must be performed under anaerobic conditions. Technical details of the procedures involved have been described by Hill et al. (28). The reader should consult various sections of *Bergey's Manual of Systematic Bacteriology*, volumes 1 through 4 (29–32), for information on the maintenance and preservation of representative bacterial genera.

The successful cryopreservation of plasmid-containing bacteria depends on the stability of their plasmids (33). These organisms are less genetically stable and more likely to lose their foreign genetic material (34). In general, bacteria containing unstable plasmids should be grown on antibiotic-containing liquid medium at 30 °C, frozen with 10 % (vol/vol) glycerol, and stored in the vapor over liquid nitrogen.

CULTURE AND PRESERVATION OF FUNGI AND YEAST

Short-Term Preservation

Subculture. Many filamentous fungi can be successfully maintained by serial transfer on suitable media. It is important, however, to use optimal media and growth conditions to ensure healthy cells that retain their morphological and physiological characteristics. A list of suitable media and incubation temperatures for a variety of fungi is provided by Onions and Pitt (35). In general, a medium that promotes good sporulation is considered to be the most desirable. When possible, it is best to cultivate the fungi on agar slants in test tubes or culture bottles. Transfers should be made only from the growing edges of the culture, taking precautions to ensure that contamination is prevented. Some fungi degenerate when maintained on the same medium for extended periods, thus media should be alternated from time to time. A minimal medium such as potato/carrot agar can often be used to induce sporulation in a culture that has deteriorated (36). Also, the continual transfer of spores from some aging fungal cultures such as *Mucorales* can result in a deterioration of the culture; the transfer of mycelium and spores seems to minimize this problem.

The interval between transfers varies from fungus to fungus; some require transfer every 2–4 weeks, the majority every 2–4 months, while others may survive for 12 months without transfer. Cultures grown on agar slants can be stored at room temperature. Storage in the refrigerator or cold room at 5–8 °C can extend the transfer period to 4–6 months. However, there are some fungi, such as the thermophiles, that are sensitive to storage at these temperatures.

The maintenance of fungi by serial transfer has many disadvantages. The most notable are contamination, selection of variants, mislabeling of cultures, infestation with mites, and labor intensity.

Yeasts have been successfully maintained by serial transfer on either solid or liquid media. In general, many yeasts will survive for longer periods when grown on solid media rather than in broth, especially nonfermentative yeast. Fresh medium is inoculated with actively growing cells and incubated at the appropriate temperature. After sufficient growth occurs, the cells are stored at refrigerated temperature (+4 °C). The majority of yeast species will remain viable for a least 6 months. The interval between transfers must be determined by experimentation. Serial transfer is not recommended for extended maintenance because genetic drift has been observed. In addition, asco-

sporogenous strains may sporulate on agar slant media stored for prolonged periods, resulting in strain variability.

Many fungi and yeast can be preserved for years by drying on a suitable menstruum such as soil, silica gel, and filter paper (37), and drying under vacuum from the liquid state (L-drying) (38).

Silica Gel. Sterile anhydrous silica gel (6–22 mesh, nonindicator) is prepared by dispensing the gel into growth bottles so that they are one-quarter filled, and sterilizing in an oven at 180 °C for 2–3 h. The bottles containing the sterile gel are cooled by placing in a pan containing ethylene gycol and dry ice to the depth of the gel layer or by placing the bottles in water in a mechanical freezer at a temperature of −17 to −24 °C. Fungal spores are suspended in a sterile 5% skim milk solution that has been cooled to 4 °C. The spore suspension is added to the cooled silica gel until three-quarters of the gel has been moistened. It is important to avoid saturating the gel. The growth bottles are left in the ice bath for approximately 20–30 min and then agitated to ensure thorough dispersion of the suspension. The bottles are held at 25 °C for approximately 1–2 weeks until the crystals easily separate when shaken. Inoculated bottles are sealed with screw caps and stored over indicator silica gel in an airtight container at 4 °C. To recover the fungal spores, a few crystals are sprinkled on an appropriate medium and incubated. This method has been used successfully for a variety of fungi (39). This method has produced variable results with yeast; some are not viable after 3 months of storage, whereas other survive after 2–5 years (40).

Soil. A variety of fungi have been maintained in soil (41). The method involves the inoculation of approximately 1 mL of a spore suspension into soil that has been sterilized by autoclaving twice, 24 h apart, at 121 °C for 15 min. The soil is incubated at room temperature for 5–10 days and then stored in a refrigerator at 4–8 °C. Cultures are recovered by inoculating a suitable medium with a few grains of soil.

Paper. Yeasts have been preserved by drying on paper discs or squares and storage over the desicant silica gel (42). Whatman No. 4 filter paper is cut into small squares or discs about 10 mm across and placed on a small aluminum foil, which is folded into a packet and autoclaved at 121 °C for 15 minutes. The sterile discs or squares are inoculated by immersing into drops of a heavy yeast suspension prepared in 5% skim milk. The packets are dried in a desiccator for 2–3 weeks at 4 °C and then placed in an airtight container and stored at 4 °C. Cultures are recovered by aseptically removing a piece of filter paper and inoculating the appropriate solid or liquid medium. Yeast maintained in this manner have been viable after 2–3 years.

L-Drying. L-drying refers to liquid-state drying in such a way as to prevent freezing. Drying occurs under vacuum at temperatures generally no colder than 5–10 °C. The method has been improved and simplified by Malik (43) for the preservation of sensitive microorganisms that are damaged by freezing or freeze-drying. The technique has been used to successfully preserve some yeasts and filamentous fungal spores.

Long-Term Methods

Freeze-Drying, or Lyophilization. The equipment, cryoprotectants, and theoretical aspects of freeze-drying have already been discussed. Fungi are grown under optimum conditions using media that will produce maximum sporulation. Mature spores are harvested by flooding the agar cultures with approximately 2 ml of a 20% sterile skim milk solution. The skim milk must be cold when used, and thus it is stored at 2–8 °C until required. The spores are gently scraped from the surface of the culture to yield a suspension containing at least 10^6 spores/mL. The spore suspension is pipetted back into the tube containing the remaining milk and mixed thoroughly. If more than one tube is used, repeat the procedure and pool the suspension in one tube to yield a concentration of at least 10^6 spores/mL. The spores of cultures grown in broth medium are centrifuged and resuspended in sterile 20% skim solution. Approximately 0.2 mL of the spore suspension is dispensed into sterile vials for freeze-drying. The interval between harvesting the spores and dispensing must be minimized because many spores begin to germinate when suspended in liquid. Spores should not be in the skim milk for more than 2 h before being processed. Filled vials should be refrigerated while awaiting further processing.

The fungi are freeze-dried using one of the ATCC methods already described. Lyophilized spores can be stored at 2–8 °C. Extended shelf life can be achieved by storing the vials at −70 °C in a mechanical freezer.

Freeze-dried fungal cultures are rehydrated with 0.5–0.9 mL of sterile water, then transferred to tubes containing 6 mL sterile water and allowed to soak for 50–60 min before transferring to solid medium.

At the ATCC, yeasts are processed in the same manner as bacteria for the component freeze-drying method. Cultures are grown on the appropriate solid medium and suspended in sterile 20% skim milk or reagent 18 to a concentration of at least 10^6 cells/mL. The suspension is mixed thoroughly, and 0.2 mL is dispensed into each vial. The cultures are freezed-dried using the component freeze-drying method described earlier.

Ultrafreezing, or Cryopreservation. The preservation of fungi at ultralow temperatures of liquid nitrogen (−196 °C for liquid phase and −150 °C for vapor phase) is presently considered the best method of storage. The method can be applied to both sporulating and nonsporulating strains, as well as those fungi that have been genetically altered or harbor plasmids. The freezing rates and cryoprotective agents described for bacteria are also applicable to the freezing of fungi. Spores or mycelial fragments are harvested by flooding slants or plates with 10% glycerol or 5% DMSO and gently scraping the surface of the cultures. The fungal suspension is dispensed in 0.5-mL amounts into sterile plastic freezing vials and frozen at a controlled rate. Fungi that produce sticky mycelia or whose mycelia grow embedded in the agar can be prepared for freezing by cutting agar plugs containing new growth (hyphyl tips) with

a sterile cork borer (5 mm). Three or four plugs are place into each sterile plastic vial with 0.4 mL of 10% glycerol and frozen at a slow controlled rate.

Cultures grown in broth are fragmented in a sterile Waring blender in a biological hood and suspended in equal parts of 20% glycerol and growth medium or equal parts of 10% DMSO and growth medium to give a final concentration of 10% glycerol (vol/vol) or 5% (vol/vol) DMSO, respectively. Some strains must be concentrated by centrifugation in order to obtain sufficient material for freezing. Pathogens must not be macerated in a mechanical blender because of the hazard of aerosol dispersion.

Some cultures, such as *Agaricus* strains, can consist of seeds, grains, or pollen and be frozen without the presence of a cryoprotectant. Slime molds can be preserved by freeze-drying or freezing. Spores, microcysts, and spherules are preserved by a controlled freeze in 10% glycerol and stored in the liquid-nitrogen vapor phase. Thawing of the frozen culture should be done rapidly in a 37 °C water bath with moderate agitation. Once the ice melts, the culture can be transferred to a suitable medium.

Yeast cells have been successfully preserved by controlled freezing to liquid-nitrogen temperature (−196 °C liquid, −150 °C vapor phase). The yeast cultures are handled in the same manner as bacteria and grown as described in the freeze-drying section for yeast. Cell suspensions are prepared in 10% glycerol to a concentration of at least 10^6 cells/mL. The yeast are frozen under controlled conditions as described in the bacterial section.

Several reports have described the loss of plasmid expression or the induction of respiratory-deficient mutants in yeast as a result of freeze-drying or improper freezing (44). Nierman and Feldblyum (33) reported that when plasmid-containing *Saccharomyces cerevisiae* were preserved by freezing in liquid nitrogen, no loss of viability was observed, and the fraction of plasmid-containing cells was the same before and after freezing. The preservation of plasmid-containing yeast is superior in liquid nitrogen with a controlled freezing rate than by freeze-drying.

CULTURE AND PRESERVATION OF CELL CULTURES

Long-Term Preservation

Ultrafreezing, or Cryopreservation. Storage in liquid nitrogen is currently the best method of preserving cultured cells. Cryopreservation methods for a variety of cell lines are well developed and used extensively for culture storage. For a detailed description of standard cryopreservation protocols see reports by Freshney (45) and Hay (46).

The general events that occur during freezing and the effect of the cooling rate, cryoprotective agents, and a controlled rate of cooling have been discussed in the bacterial section.

Cell suspensions are prepared in the same manner used for routine subcultivation; trypsin is added if necessary to produce a uniform suspension. The cell suspension is centrifuged at approximately 100 *g* for 10 min, and the resultant pellet is resuspended in an appropriate amount of fresh medium containing a cryoprotectant. Normally, 5–10% DMSO or glycerol is employed. The freeze medium should be prepared just prior to use by mixing fresh growth medium and the cryoprotective agent and kept at room temperature. The remaining cryoprotectant is discarded because oxidative contaminants can accumulate. A cell suspension containing approximately 10^6–10^7 cells/mL is satisfactory. The cell suspension is dispensed in 1-mL amounts into each glass vial or plastic ampule and frozen at a controlled rate of 1 °C/min to about −50 °C. The vials are immediately transferred into liquid nitrogen for storage in the liquid or vapor phase. Rapid thawing is essential for recovery of frozen cells, thus the frozen vials are immersed directly into a 37 °C water bath and agitated until the suspension is completely thawed. The thawed cell suspension is transferred to 10 mL of sterile growth medium and centrifuged at 100 *g* for 10 min. The supernatant containing the cryoprotectant is discarded, and the cell pellet is resuspended in fresh medium and propagated using standard procedures.

Quality Control. It is important that all preservation methods include standard operating procedures for the determination of culture purity, viability, retention of morphological and physiological characteristics, production of desirable products, and other key attributes. Purity checks must be conducted before and after processing microorganisms for freeze-drying and microorganisms and cell lines for freezing. Generally, the cell suspension is diluted and inoculated into suitable medium and incubated at optimum temperature. After growth appears, the cultures are examined for purity. It is also important to conduct pre- and postpreservation viability checks for freeze-drying and freezing to determine the effectiveness of the process. In addition, periodic viability assays should be performed to ascertain the shelf life of the culture.

Cell lines should also be examined for *Mycoplasma* contamination, because it has been estimated that about 10% of cell lines are contaminated (47). It is also important to conduct tests to verify cell-line identity; several rapid techniques have been developed that use DNA probes to identify the cell lines (48).

Documentation. Documentation plays an important role in the maintenance and preservation of cultures. Important data include the identity of the culture, isolation source and methods, the individual who isolated it, geographical location, morphological and physiological characteristics, maintenance data, and other salient features. If the culture was obtained from another investigator, the documentation should include the name of the investigator, culture history if available, and date of acquisition. The greater the amount of data recorded and regularly updated, the greater the value of the culture.
