Arenosols (from L. *arena*, sand) are sandy soils with slight to moderate profile development. These soils are widely distributed and form one of the more extensive major soil groups in the world. FAO (1991) estimates Arenosols to cover about 900 million ha (Table C9), or 7% of the land surfaces; if shifting sand and active dunes are included, the coverage is about 10%. Sandy coastal plains and coastal dune areas are, of course, of smaller extent but ecologically very important. Although Arenosols occur predominantly in arid and semiarid regions, they are typical azonal soils that occur in the widest possible range of climates from very arid to very humid and from hot to cold. Arenosols occur predominantly on eolian sands, either dunes (Figure C46) or flats, but have also formed on marine, littoral, and lacustrine sands of beach ridges, lagoons, deltas, lakes, etc. Other names for Arenosols include Psamments (Soil Survey Staff, 1975, 1992), sols mineraux bruts (France), siliceous, earthy and calcareous sands, and various Podzolic soils (Australia), red and yellow sands (Brazil), and raw sands (Britain and Germany), among others. Arenosols thus have linkages with most other major soil groups. Only a few groups, such as Vertisols, have no linkages. The limits are determined by either textural requirements or the occurrence of certain diagnostic horizons within specified depths. Of most importance in their development are factors that limit soil horizon development in wetlands, alluvial lands, sand lands (Figure C47), rocky areas, and various unconsolidated materials. The spatial distribution of Arenosols indicates that many factors are involved, which operate in various combinations to limit profile development: (1) dry but hot to warm to cold climates and microclimates that parse the amount and duration of water movement in the soils (Arctic, subArctic, Antarctic, and temperate and intertropical desert zones provide these conditions), (2) mass wasting and solifluction remove surficial material faster than

Figure C46 Primary coastal dune on the Atlantic coast of southern Eleuthera Island, Bahamas. These Holocene carbonate dune sands are stabilized by vegetation and anchored to a rocky headland (photo center). Beachrock outcropping on the beachface helps to protect the dune foot from erosion.

most pedogenic horizons can form, (3) cumulization adds new material to the surface of the soil faster than new material can be assimilated into a pedogenic horizon, (4) immobilization of the soil plasma in inert materials, in carbonate-rich flocculated materials, and in some highly siliceous sediments to inhibit profile differentiation by illuviation, (5) exceptional resistance to weathering (pedologic inertia) of some initial materials, (6) infertility and toxicity of some initial materials to plant growth that inhibits biogenetic differentiation (e.g., on serpentine barrens), (7) saturation with water or even submergence for long periods, (8) short exposure of initial material to active factors of soil formation (e.g., marine flats newly exposed by uplift), and (9) a recent drastic change in the biotic factor that initiates formation of a new pedogenic regfime in an old one, which in turn serves as initial material (Buol *et al*., 1980).

Regosols

Regosols (from Gr. *rhegos*, blanket) are well-drained, medium-textured, deep mineral soils that are derived from unconsolidated materials and which have been traditionally separated from shallow soils (Lithosols, Leptosols, etc.) and from those of sandy or coarser texture (e.g., Arenosols). A Regosol does not have assemblages of diagnostic horizons, properties, or materials that are definitive for any other group of soils. Most properties of Regosols are associated with the materials themselves and not with genetically developed soil features. Conceptually, Regosols are the initial state for pedogenesis representing recently deposited or recently exposed, earthy materials on a groundsurface; these weakly developed soils contain poorly defined horizons. Some soil materials, which represent a late stage of weathering with few distinguishing characteristics, are recognized as Regosols. For example, thin ferralitic materials that cannot go into Cambisols and may be classified with Regosols (Spaargaren, 1994). Although there are examples of initial stages of soil development in all landscapes throughout the world, the areal extent of Regosols is often limited and these soils are often inclusions in other soil units. Although of generally limited extent on a global scale (Table C9), Regosols can be important soils in specialized environments (e.g., tundra), such as Arctic plains in northern Canada where Cryic Regosols account for about 23.5% of Canada's land area (Clayton *et al*., 1977), extending from Labrador and Baffin Island on the east to the Mackenzie Delta in the west. Nearly 3,000 km^2 of Cumulic Regosols (Dystric Fluvisols in *Soil Taxonomy*) occur in tidal marshes adjacent to the Bay of Fundy in the Maritime Provinces as well as on coastal floodplains adjacent to the Yukon and Mackenzie deltaic river systems. In the terrain, Regosols are mostly associated with degrading or eroding areas, while other soils occur on aggrading, depositional, or stable areas. As time passes and soil formation proceeds, Regosols may develop into many other soils depending on the most important soil forming factor(s). Sand dunes on the central Delmarva Peninsula of Maryland and Delaware, for example, contain weathering zones that are represented by Regosols (Entisols in *Soil Taxonomy*) with profiles that are only a meter or two in thickness (Denny and Owens, 1979). Basal horizons in the dunes constitute an ancient weathering profile, truncated at the top and overlain by a younger deposit of sand. These so-called two-cycle dunes thus contain an older basal dune that is Wisconsinan in age and the early episode of weathering may have been early Holocene, a comparatively warm Hypsithermal interval. The surface sand may be no more than a few hundred years old, the result of

Figure C47 Exposure of fine-grained calcareous dune sands on the landward side of dunes shown in Figure C. The imprint of pedogenesis is minimal and basically associated with accumulation of organic matter on the dune surface. Translocation of organic compounds down into the profile is limited to the upper half-meter or so.

deforestation and cultivation in colonial times (Denny and Owens, 1979). The Sharon Coastal Plain in Israel is predominantly comprised by sand dune fields and eolianite ridges. Cliffs along this plain contain three major sand accumulation periods between 65 and 50 ka, from 7 to 5 ka, and from 5 to 0.2 ka (Frechen *et al*., 2002), that in turn seem to correlate with periods of sapropel formation in the Mediterranean Sea and so with periods of strongly increased African monsoon activity. The uppermost eolianite (calcareous sandstone) seems to correlate with a sapropel formed at about 7.8 ± 4.0 ka BP. Major phases of soil formation occurred between 35 and 25 ka resulting in a Rhodoxeralf soil (Grumusolic Dark Brown soil) and between 15 and 12 ka forming a Rhodoxeralf (hamra) soil. Frechen *et al*., (2002) identify at least seven weak pedogenic phases resulting in weakly developed horizons of Regosol-type soils that are intercalated in the eolianite sequences. The oldest eolianite layer contains kurkur (caliche) and seems to be about 55 ka BP in age.

Coastal plain soils

As a general rule, soils of younger landscapes are less differentiated (i.e., they contain simple sequences of horizonation and plasmic soil materials are unorganized) than those of older surfaces where weathering profiles tend to contain highly organized soil materials with complex horizonation (e.g., Butler, 1959; Huggett, 1975; Buol *et al*., 1980; Gerrard, 1981; Ollier and Paine, 1996). Because considerable time is needed to form differentiated soils where soil horizons and materials are highly organized, it is possible to sequentially arrange soils in chronological order with soils developed in young deposits placed before those formed later. Soils arranged in this way represent a sequence of development, referred to as a *chronosequence* (Jenny, 1941). If prior conditions of weathering continue, the young soils in time develop characteristics seen in the oldest (Gerrard, 1981; Ward and McArthur, 1983). This is a simplistic interpretation of uniform and uninterrupted development, but other more complicated (interrupted) sequences are possible, such as apparent trends due to secular changes in climate, drainage, or biota. Investigation of elemental mass balance trends, based on element translocation patterns in response to climate forcing, show promise for estimating the weathering flux under drier or wetter mean annual precipitation regimes (e.g., Stiles *et al*., 2003). Optical dating of young coastal dunes (e.g., Ballarini *et al*., 2003) provides a tool for reconstructing coastal evolution on a timescale of decades to a few hundred years. Quartz optically stimulated luminescence (OSL) dating is based on the fact that OSL dates of less than 10 years are very well-zeroed prior to deposition and burial, as demonstrated by Ballarini *et al*., (2003) for an accretionary coastal segment near Texel, The Netherlands. Other luminescence sediment dating methods, more amenable to timescales of a very few thousand years, have found application in the study of the activation and stabilization of coastal dunes on a North Carolina barrier island (Berger *et al*., 2003). Here, the quartz SAR (single-aliquot regenerative-dose method) is preferred for photonic dating in this region because of the relative abundance of quartz. These kinds of dating methods provide tight controls for estimates of pedogenic phases and the estimation of time intervals required to produce specific horizonation sequences in coastal dunes.

Radiocarbon dating is limited by the availability of datable materials and the technique can be applied only to younger soils ($<$50,000 yr BP) that range from latest Pleistocene to Holocene in age (e.g., Vogel, 1980; Bowman, 1990). The prospect of dating and correlating coastal and bottom deposits as well as terrestrial–marine weathering sequences, as seen in coastal soils, is best achieved along the littoral where sedimentation and subsequent soil development are closely associated with changes in sea level (e.g., Karpytchev, 1993). Lake-level histories as well can sometimes be gleaned from radiocarbon dates for coastal dune fields, as demonstrated by Arbogast and Loope (1999) for Holocene coastal dunes on the shores of Lake Michigan. When marine deposits are correlated with terrestrial weathering sequences by stratigraphic linkage at the coast, pedogenesis can be related to sea-level change and erosion–deposition cycles (Kukla, 1977). If dates related to sea-level changes can be assigned to coastal landforms, then the chronology can be extended inland by using local markers (Ward and McArthur, 1983). At the coast, abundant shells can supplement wood and peat as a basis for radiocarbon dating (Mook and van de Plassche, 1986).

If there is uncrystallized coral present, then dates back to 200,000 years can be obtained from uranium decay methods, and on volcanic shores potassium/argon dating provides useful information. For coasts where these methods are not applicable, the principal means of dating refers to the correlation of stranded shorelines. If the former shores in one locality cannot be dated directly, it is sometimes possible to relate them to the shores in other localities where dates exist, assuming that changes in sea level are instantaneous and global (ward and McArthur, 1983).

Because the earth's crust is in dynamic equilibrium with the asthenosphere and tectonic adjustments are always taking place, no coastal landmass can be regarded as completely stable, no matter how free it is from seismic activity or neotectonism. Few coasts are so mobile, however, that they contain no part of the eustatic record. Landforms in the coastal zone are complex and not all are only the product of terrestrial processes or marine action.

The apparent simplicity of most coastal plains is suggested by their lack of relief, which disguises these plains from their true nature as terminal geomorphic surfaces of complex transgressive–regressive depositional units laid down during glacioeustatic fluctuations. Bounded at the surface by terrestrial and marine erosional, transportational, and depositional landforms, the stratigraphic units (including paleosols) are limited below by unconformities of terrestrial and marine origin. Sedimentary facies between these surfaces reflect coastal plain (alluvial, palustrine, and eolian), estuarine, and marine open-shelf environments (e.g., Curray, 1978; Davis, 1978). Their evaluation requires a complete stratigraphic examination, as offered by Haq (1995) in summaries of the principles and concepts of sequence stratigraphy (the study of rock relationships within a chronostratigraphic framework wherein the succession of rocks is cyclic and is composed of genetically related stratal units viz. sequences and systems tracts).

Ideally, two main sedimentary sequences occur within a transgressive–regressive unit (e.g., Blum *et al*., 2001). The terrestrial sequence, which develops as sea level regresses seaward through lowering, results from extension of alluvial erosion and sedimentation, and of soil formation, into the coastal zone. The marine sequence forms during subsequent landward transgressions or rise of sea level when marsh, estuarine, beach, dune, and deltaic sediments are introduced. The relative thickness, significance, and spatial extent of these sequences depend on the dynamics of coastal processes and on sediment volumes brought to the shore by rivers. When major rivers deposit large volumes of alluvium at the shore, the marine contribution to the sedimentary pile is limited. Coastal landforms thus result predominantly from alluvial distribution.

Coastal strand plains with no alluvial contribution, such as those forming in the Holocene landscape of Gippsland, Victoria, in Australia (Ward, 1977), lie at the other extreme of the scale. Relative placement of terrestrial and marine sediments here is determined by gradients at the coast, and by the history of eustatic fluctuations relative to the land. If, for example, sea level rises above a previous high stand, the earlier deposits will be truncated, buried, or partially submerged. Conversely, a eustatic fall will leave the earlier deposits stranded as a terrace.

Almost all the soils on the Swan Coastal Plain, southwestern Australia, are formed by material deposited by rivers (fluvial, alluvial soils) and wind (eolian soils). The Yilgarn Block (part of the West Australian craton), east of the Darling Scarp bordering the Swan Coastal Plain, was epeirogenically uplifted as part of cymatogenic movement and warping about 40–50 million years ago. This tectonic uplift increased the differential between base level and the plateau surface causing erosion of the craton by rivers and streams. Detritus from deep chemical weathering (e.g., laterite profiles) or saprolite was either deposited onto the Swan Coastal Plain or carried to the sea (Fairbridge and Finkl, 1980). The eroded material formed new parent materials for soil development on the Plain.

Broadly there are thus two major groups of soils on the Swan Coastal Plain. The first is a series of dune systems near the coast formed as a result of deposits from the sea, and including material originally derived from erosion of the Yilgarn block mixed with marine sediments. Once formed, the dunes can be eroded by strong winds. The sand is mostly eroded from the dunes nearest the coast, and is redeposited on the dunes further inland. The second major soil types are a series of soils formed by deposits directly eroded from the Yilgarn block and which comprise soils on an alluvial (Pinjarra) plain, occurring between the dunes and the scarp. There is a third, very narrow strip of soil, called the Ridge Hill Shelf, next to the scarp, formed from material eroded from the scarp.

Although different conditions prevail in different locations, some general principles emerge from regional comparisons. It is impossible to review the development of all coasts, but some cases illustrate the salient principles that are involved.

Soils of coastal dune systems

Several distinct features characterize coastal sand dune systems (e.g., Cooper, 1966; Nordstrom *et al.*, 1990). The dunes themselves often show a regular succession from the more active and unstable foredunes at the back of the beach to older, more stable vegetated dunes inland (cf. Figures C46 and C47). The other major element is the system of slacks or swales (low-lying, narrow coastal wetlands) that occur between the main dune or beach-ridge trends (cf. Figure C42). Dune slacks are low-lying areas within dune systems that are seasonally flooded and where nutrient levels are low. They occur primarily on the larger dune systems in the United Kingdom, for example, especially in the west and north where the wetter climate favors their development when compared with the generally warmer and/or drier dune systems of continental Europe. The range of plant communities found in slacks is considerable and depends on the structure of the dune system, the successional stage of the dune slack, the chemical composition of the dune sand, and the prevailing climatic conditions. When a coastal dune forms, dune sand accumulates seaward if there is an abundant sediment supply or the dune grows to its maximum height and then moves landwards (Gerrard, 1981). If the dunes are carbonaceous, leaching progresses with increasing age and when coupled with an increase in organic matter, there is a transition in soil reaction from alkaline to acid conditions. The rate of leaching is initially rapid but declines as the amount of carbonate, rather than the amount of rainfall, becomes a limiting factor. The rate of leaching in the early stages also depends on the nature of the shell fragments and matrix grain size, being slower if the fragments are large. The process is temporarily halted if material is added to the dune system by wind action because leached and organic-rich layers are buried.

Differences in soil moisture between the younger and older dunes, and between dunes and swales direct soil formation in regard to oxidation of organic matter (Gerrard, 1981). Young swales are initiated with a considerable advantage because nutrients and other minerals accumulate in the wetlands, a situation that is ultimately reflected in the soil profiles and pH values. The rate of increase of organic content depends on the initial lime content of the dunes. On lime-deficient dunes, early colonization by vegetation takes place with a concomitant increase in the rate of litter accumulation. As more acid conditions prevail, litter breakdown is inhibited and organic matter build up is promoted.

Swan Coastal Plain, southwestern Australia

The tectonically stable limestone coastline of southwestern Australia is well suited to preservation signals of former sea levels. The eustatic record is limited by the time frame when lithified dunes formed in middle to late Pleistocene times. Fairbridge (1961) interpreted the field evidence in calcarenite sequences and Paleosols as fluctuation of sea-level against the backdrop of a stable landmass, incorporating the curve in a proposed global standard. The sequence of former sea level stands was based on wave cut benches, submerged and stranded beach cobble deposits, karst, and marine bands associated with the Pleistocene limestone.

The Swan Coastal Plain in southwestern Western Australia presents a complex chronosequence of mid-Pleistocene to Holocene dune soils, the oldest interior sets (Bassendean dunes of siliceous sands with Podzol morphology) merging with a series of laterite-covered spurs of the Ridge Hill Shelf that form the foothills of the Darling Scarp (McArthur and Bettenay, 1979). The Bassendean Dune System is the oldest of the dune systems of marine origin and today consists of a series of low hills varying from 20 m to almost flat, which rise to 110 m above sea level. They were formed as a belt of coastal dunes and associated shoreline deposits that accumulated mostly during a period of high sea level, about 115,000 years ago during the Riss–Würm interglacial period (McArthur and Bettenay, 1979). Secondary or epidiagenetic calcrete commonly occurs in an interdunal area (between the Spearwood and Quindalup dunes), which is marine or estuarine in origin, as a cap on top of fossiliferous limestone that in turn is covered by a shallow sandy soil. The Swan Coastal Plain contains alluvium and dune sands (McArthur and Bettenay, 1960). The fluviatile deposits, displayed as coalesced alluvial fans, are of different ages and limited to the west by sequences of coastal dunes. The oldest Bassendean dune sequence is siliceous and Podzols have developed on them. The next Spearwood sequence has a core of eolianite beneath the weakly podzolized siliceous sand (Figure C48). The Quindalup dunes are calcareous and sequentially the youngest. Properties of the dune soils change in an orderly fashion with age. Assuming that the oldest was originally calcareous, there is progressive loss of carbonate, a lowering of the pH, and formation of Podzols. Between the two younger dune sequences is a zone that is marine in origin.

In the southern extension of the Swan Coastal Plain, the Quindalup dune systems extends along the coast and are backed by soils of the Stirling Swale, a marsh environment, and soils developed on older dunes farther inland (McArthur and Bettenay, 1956). Alluvial and swamp soils occur still inland on the coastal plain. This sequence of dune systems, often calcareous near the coast and siliceous on the landward side of the coastal plain, separated by intervening swales is typical of many coastal plains around the world. Alluvial soils truncate these sequences as rives make their way to the coast and swamps often prevail in older degraded dune systems.

Gippsland Area, Victoria, Australia

The coastal zone south of the Dividing Range in Victoria is separated from the sea by a narrow sand barrier (Ward, 1977). Generally characterized as extensive lowland with broad, low-lying sand plains and swamps around lagoons, 14 marine terraces elsewhere rise in shallow steps to the 130 m contour. Dune sands form low ridges on the marine terraces and alluvial terraces beside the main rivers terminate at former shorelines defined by stranded marine terraces, except for the youngest one that passes beneath present sea level. Three groups of soils are defined whether the parent sediment is eolian sand, alluvium, or stranded marine terraces. The soils on the eolian sands show progressive development of Spodosol characteristics when viewed in order of age. In the other groups, the most striking feature is the progressive development with increasing age of a contrast in texture between solum and subsoil. Changes in clay mineral suites and chemical composition accompany these changes in morphology.

Figure C48 Exposure of the Spearwood Dune System on the Swan Coastal Plain, southwestern Western Australia, near Perth. This dune system was formed during the Würm I interstadial about 80,000 years ago. The surface soils are leached and the carbonate has been precipitated below to form layers and columns of hard, compact limestone deposited from solution by percolating waters. Infilled solution pipes are clearly evident in these calcareous dunes that show multiple phases of solution and precipitation, erosion and deposition, and soil formation. Many solution pipes contain a thin rind of travertine in addition to being infilled with Terra Rosa type soil materials.

Southeast South Australia, Australia

The most widespread soils of the Kingston—Mt. Gambier region in southeast South Australia are derived mainly from calcareous beach sands (Podzols and Terra Rossa profiles) or from estuarine and lacustrine deposits (Groundwater Rendzina and Solodized Solonetz profiles) (Blackburn *et al*., 1965). The calcareous beach sands occur in about 30 stranded Quaternary beach ridges that comprise a soil chronosequence with the oldest soils occurring more than 80 km inland from the present coast. Variation in morphological properties of the main kinds of soils shows gradual transition in age sequence that is represented by depth of red soil, thickness of kunkar, and occurrence of ferruginous concretions (iron-rich pisolites). The time span for soil formation for some of the older soils appears to be on the order of several hundred thousand years (Blackburn *et al*., 1965). Most of the ridges are consolidated, immobile structures on which soil profiles show little evidence of truncation. In some places there is evidence of truncation in the form of secondary siliceous sand dunes and exposed kunkar. Most of the older landsurfaces are represented by non-truncated soil profiles of sand Podzolics.

Soils of Polar Coastal Plains

Cold soils occupy roughly one-third of the world's land area (Rieger, 1983). Maritime and continental climatic types are recognized, but each has varying degrees of expression. In maritime types, precipitation is high and uniformly distributed throughout the year, and temperature differences between winter and summer are minimal. Many sediments and soils in Polar regions have a complex history, particularly as they relate to cyclic deposits, glacial activity, wind action, solifluction, as well as cryogenic processes (Tedrow, 1977; Allard, 2001). The coastal plain on the northern tip of Alaska is flat and the drainage pattern is poorly integrated. Barrow is a low-relief emergent region where lakes, marshes, or former lake basins occupy 50–75% of the region. The remainder of the coastal plain consists of initial surface residuals, areas that do not show evidence of thaw-lake activity. Black (1964) reports that the complexity of the surficial materials near Barrow makes it difficult to subdivide the geologic deposits. Beaches, bars, distributary deposits, and deltaic deposits are interspersed with shallow-water marine sediments and lagoonal, lacustrine, and fluvial deposits. The extremely low ground and air temperatures subdue chemical and biological activity that inhibits pedogenesis. Studying weathering in northeastern Greenland, Washburn (1969, 1973) defines the major weathering processes in terms of oxidation, formation of desert varnish, case hardening, rillenstein formation, carbonate coating, salt wedging, granular disintegration, differential weathering, exfoliation, cavernous weathering, frost cracking, and frost wedging. More recently, Rieger (1983) pointed out the morphological impacts of freeze-thaw cycles, hydrostatic mounding and fissuring, and cryoturbation (viz. turbation accompanied by ice-wedge formation), on soil formation in cold regions. Study of cryoturbated Paleosols associated with past ice-wedge activity on late-Holocene sandy fluvial terraces in northern Québec (e.g., Allard, 2001), for example, corresponds with paleoclimatic information obtained from existing Arctic-wide and regional proxy records. The Little Ice Age stands out as a period of intense ice-wedge activity, followed by a warm thawing-out interval during the first half of the 20th century. From AD 1946 to 1991, climatic cooling reactivated ice-wedge formation (Allard, 2001). In some situations, especially in the main coastal tundra zone, some of the physical and chemical weathering processes are inseparable from incipient soil-forming processes (Tedrow, 1977). Due to the adverse and specialized conditions in these cold lands, researchers recommend different kinds of soil classification systems, which are reviewed in Tedrow (1977). Modern soil classification systems tend to incorporate soil on cold coastal plains as part of more comprehensive approaches, rather than have separate systems for specialized soil environments. In the Canadian system (Clayton *et al*., 1977), for example, those cold region coastal soils that show weak profile development fall into the Podzolic

(Humo-Ferric Podzol) great group. Mostly Spodic Cryopsamments (in *Soil Taxonomy*) and the Brunisolic order (Cambisols in FAO/UNESCO; Inceptisols, excluding Aquepts in *Soil Taxonomy*) provide for the more normal soils. The Regosolic order (equates to the concept of Entisol, excluding Aquents, in *Soil Taxonomy*) provides for various soils with little or no profile development. Gleysolic orders (Aquepts, Aquents, and some Fluvaquents in *Soil Taxonomy*) include the gamut of poorly drained mineral soils with an organic layer up to 30 cm thick. Within the Canadian system, *cry* is attached to the names of 10 subgroups. The names Cryic Regosol and Cryic Gleysol indicate similarity to Regosol and Gleysol but also to those soils that are underlain by permafrost within a depth of 100 cm from the surface. The major genetic soils (excluding Ranker) of the tundra zone can be arranged in caternary form as described by Tedrow (1977) viz. Arctic Brown, Upland Tundra, Meadow Tundra, and Bog soil. The Arctic Brown represents zonal soils whereas the Tundra soil is indicative of hydromorphic conditions. Organic soils occur in low-lying, poorly drained coastal areas referred to as bogs, swamps, marshes, or muskegs. Since many coastal landscapes have been free of glacial ice within the Holocene (past 10,000 years) there are many depressions in the landscape, water-impoundment areas, and flat plains with sluggish surface drainage. Recently deglaciated landscapes tend to exhibit poorly developed surface drainage patterns that result in water-saturated environments and the formation of Bog soils. Russian investigators commonly refer to the presence of organic deposits in sectors that have "sculpture-accumulative" relief (Tedrow, 1977). Where coastlines are elevated, the organic deposits are usually intermixed with windblown sand. South of Barrow in the Meade River basin, surficial deposits have a sandy character with numerous blowouts, sand dunes, and vegetative mats that are buried by blowing sand. The coastal plain west of the Colville Delta contains geologic materials that incorporate a marine facies with dunes and loess. Because floodplains and sandbars are exposed to the wind action in summer, soils in the vicinity of coastal rivers and deltas contain admixtures of windblown sediments. The sand and silt is blown inland by onshore winds and deposited along the banks. Soil properties are characteristic for a xeric, willow-vegetated dune system along the river but where the dunes merge with tundra inland, the terrain is poorly drained and wetland soils develop.

Interesting organic-rich soils of cold regions are the ornithogenic soils of coastal continental Antarctica (Casey Station, Wilkes Land) where penguin guano plays an important role in nutrient cycles in the ecosystem (Beyer *et al*., 1997). During the breeding season, seabirds bring huge amounts of organic matter from the sea to the land and this organic matter has accumulated to considerable thickness and consists of a friable layer of droppings, feathers, shells, bones, and dead penguins (Ugolini, 1972; Tedrow, 1977). On Signy Island (maritime Antarctica), 5% of the total snow-free surface is made up of ornithogenic soils from penguin guano. The chemical properties of the ornithogenic soils changes rapidly after the abandonment of the rookeries by the penguins, mainly because of CO_2^- evolution and N and P release in the sea (Tatur, 1989). Other processes include the formation of oxalic acids in the first few centimeters and simultaneous concentration of recalcitrant soil compounds such as chitin, urates, and phosphate minerals. Leaching of iron and organic P fractions and the accumulation into the subsoil in maritime Antarctica produces a spodic Bh dark brownish (5 YR 3/1.5) horizon under a pale gray (10 YR 5/2) AE horizon, which are typical of Podzols in temperate regions (Beyer *et al*., 1997).

Coastal barriers and soils as transitional biophysical systems

Barrier systems are widespread throughout coastal areas (Jelgersma *et al*., 1970; Leatherman, 1979) and form the parent materials of soils. The barrier usually forms offshore, and a lagoon or backbarrier flat develops between the main barrier and the mainland; barrier–lagoon systems usually show transgressive, stationary, and regressive facies assemblages as seen along the coast of China (Li and Wang, 1991) and elsewhere. Distinctive soil suites similar in age develop on the barrier and the backbarrier flats (Daniels and Hammer, 1992). Some barriers form on the mainland, so only the soils seaward and those in the geomorphically equivalent estuaries or lagoons are the same age as the barrier. Goodwin (1987) describing coastal soil–landform relationships, reports that on the Coastal Plain of the Carolinas in the United States, soils on the landward Talbot Plain are older than the soils on the seaward Arapahoe Ridge or the Pamlico Plain. The Arapahoe Ridge and its association with the Talbot Plain is an example of why stratigraphic relations must be proven because the form alone often leads to incorrect conclusions.

Barrier systems may be wide, such as those in South Carolina, or very narrow as the Arapahoe Ridge in North Carolina (Goodwin, 1987) or the Atlantic Coastal Ridge in southeastern Florida (Finkl, 1994). These systems may be very smooth, broad flats with little local relief, or irregular as in prograding beach ridge systems (e.g., Tanner, 1995; Rink and Forrest, 2003). Most barrier systems are a series of barrier and backbarrier flats where the seaward soils tend to develop on sandy parent materials.

Soils formed in the barrier sediments typically are 80–95% sand, with fine and medium sands dominating (Markewich *et al*., 1986). Spodic or humate horizons are common in the sandy barriers; in the Netherlands, peat and gytia interfinger with older dune systems and on top of the Older Dunes there is a strongly developed Podzolic soil (Jelgersma *et al*., 1970). The Younger Dunes began to form in the 12th century and are weakly podzolized. The spodic horizons may be very few centimeters thick beneath dryer sites, or 6 or 7 m thick beneath broad flats with deep-water movement. Most soils on the Arapahoe Ridge have spodic horizons, as do soils on the beach ridge complex. The soils on the beach ridge are complex sands. The A1 and spodic horizons on the ridge are often discontinuous and thin. The soils in the swales have thick organic-rich A horizons and distinct spodic horizons. Soils and vegetation change abruptly in response to differing hydrological gradients across the ridge and swale sequence.

Soils on the backbarrier flats can have a wide range of textures. Many backbarrier systems are extensive, have a nearly level surface, and have finer textures than the adjacent barrier.

Coastal Paleosols

Paleosols are soils that formed on landscapes of the past (Yaalon, 1971). They are identified on the basis of soil-forming processes, which produce the soil profile morphology, that no longer operate due to changes in climate (Figure C49), local environmental conditions, or because of burial by younger (terrestrial or marine) sediments (cf. Figure C49), lava, or inundation (drowning) by the sea. Ruhe (1965) recognized three main types of Paleosols: buried, exhumed, and relict. *Buried Paleosols* form at the landsurface but are subsequently covered by sediment or other materials, a process that separates and removes the soil from the contemporary soil-forming zone (Figure C50). The depth of burial or integrity of the covering layer (e.g., lava) must suspend the soil-forming processes and yet be rapid-enough to prevent development of a Cumulic soil profile. Common examples occur in coastal dune fields, on overwashed barrier flats or spits, or on chenier plains where the rate of episodic shifting sands is slow-enough for soil formation to proceed and the new material to be incorporated into the soil profile. Epidiagenesis is common and resulting changes in original soil properties and horizons (formed prior to burial) must be considered in interpretation of Paleosol composition. *Exhumed Paleosols* occur at the land surface when a buried Paleosol is uncovered by erosion of the blanketing material. These soils may be out-of-phase with existing environmental conditions, as they occur at the time of reexposure. Exhumed Paleosols are commonly found in calcarenite sequences or active (including periodiclly reactivated) dune environments. *Relict Paleosols* formed on preexisting landscapes but were never buried all the while environmental conditions changed to a different regime, leaving behind weathering products that characterized prior landscape conditions. Common examples occur in a variety of landscapes, but those associated with ancient tropical and subtropical land surfaces are exemplars viz. Seaquisols, Ferralsols, Alisols, Acrisols, Luvisols, and Lixisols.

A common example of buried coastal Paleosols occurs in horizontally bedded sequences, as in tropical southern Florida where there are five distinct marine units punctuated by episodes of subaerial weathering (Enos and Perkins, 1977). Exposure to the atmosphere and chemical weathering of the exposed rock by dissolution resulted in the formation of discontinuous bands of dense caliche-type crusts (pedogenic calcrete as also reported in the Bahamas by Brown, 1986), Paleosols, freshwater limestone, and laminated crusts (Enos and Perkins, 1977; Beach, 1982). Identification of subaerial exposure surfaces is an accepted means of identifying boundaries (unconformities) between different stratigraphic sub-divisions of the Quaternary units. Interestingly, some of these weathering surfaces are radioactive and referred to as Secondary Depositional Crusts (SDC) (Krupa, 1999). These SDCs are typically associated with increased natural gamma radiation immediately below subaerial exposure surfaces. These SDCs seem to be related to the paleo groundwater interface (Krupa, 1999; Harvey *et al*., 2002), which was formed by residual downward percolation of rainfall through the vadose zone. The SDCs exhibit elemental abundances (e.g., Ca, Mg, Al, Sr, Fe, U, Th, and K) above the natural background level for the area.

Figure C49 Weakly developed phases of pedogenesis in the disturbed upper part of a glacial till associated with the Ronkonkoma Moraine on Long Island, New York, USA. Two phases of soil formation (layers A and B), separated by intervening unweathered reworked sediments, occur near the upper part of the moraine, which advanced about 21,000 years ago as part of the latest Wisconsin glaciation cycle. Soil layer (A) is a buried soil or paleosol. Soil layer (B) is a contemporary surface soil. This most recent phase of soil formation is represented by an organic-rich accumulation at the surface and melanization of underlying materials. The translocation of organic compounds and oxidation of iron imparts a darker color to the subsoil. View is from Long Island Sound toward an erosional exposure that provides morainic sediments and weathered materials to the littoral system.

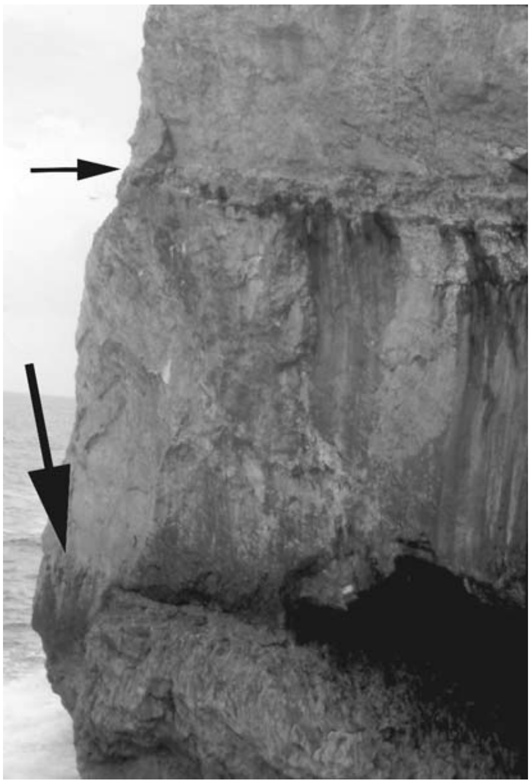

Figure C50 Paleosol bands (arrows) within a calcarenite sequence on the Atlantic coast of northern Eleuthera Island, Bahamas. These weak phases of soil formation took place during stable phases with the Wisconsin glacial cycle. Reactivation of dune formation imitated additional cycles of deposition followed by stabilization and soil formation. The dark color of the soil bands is due to oxidative weathering of iron-rich minerals that accumulated in the profile by eolian accession. Note that the seaward portion of the dunes and intercalated soils have been eroded, leaving soil layers and dune stratification projecting outward to where the dunes once stood.

The Bermuda record is a complex mosaic of carbonate eolianites, shoreline–marine limestones, calcarenite *protosols* ("accretionary Paleosols"), and Terra Rossa Paleosols (Vacher and Hearty, 1989; Herwitz *et al.*, 1996). Sayles (1931) was among the first to recognize that alternation of marine limestones, eolianites, and Paleosols in local sections provides a record of Pleistocene sea-level fluctuations. Bretz (1960), drawing diverse observations into a comprehensive history, established the correlation that eolian and marine limestones were deposited during Pleistocene interglacials when the shallow platform (-20 m) surrounding Bermuda was submerged and that Terra Rossa Paleosols formed during glacial-age platform emergences. Solutional depressions often formed in the eolianites subsequent to dune stabilization and weathering to produce solution holes or pipes. These depressions were sometimes infilled with fine-grained sediment (Fe-rich dust) that weathered to red soils or Terra Rossa (Herwitz and Muhs, 1995) (cf. Figure C48). The recurrent stratigraphic pattern, as reported by Vacher and Hearty (1989), features an erosional coastline marine deposit overlain by a regressive eolianite. Where the interglacial complex is entirely exposed above present sea level, high-stand erosional coastline deposits can be traced downdip into laterally extensive beach deposits of a depositional coastline. The beach deposits thus grade upward and laterally into eolianite, which in turn extends landward over the marine deposit and oversteps the erosional coastline deposits.

Bahamian paleosols, by way of another example of buried and exhumed Paleosols (Figures C51 and C52), are predominantly calcium carbonate and contain minor amounts of mineral-insoluble residue (quartz, plagioclase, and clay minerals) (Boardman *et al.*, 1995). There are at least four megascopically distinct Paleosols: laminated crusts, homogeneous crusts, breccia/conglomerate, and homogeneous matrix. All four types of Bahamian Paleosols and all mineralogic varieties of paleosols are found on stratigraphically equivalent rock units (Boardman *et al.*, 1995). The number and character of Paleosol-bound parasequences on New Providence Island (Nassau), Bahamas, suggest that at least five interglacial cycles are distinguishable. Whole-rock amino acid racemization (AAR) ratios confirm the stratigraphic sequence and indicate that isotope Stages 1 through 11 are likely included among eight depositional packages (Hearty and Kindler, 1997). The Bahamian stratigraphic and pedogenic sequences, not unlike other calcarenite environments elsewhere, are complicated by the intricate stacking of similar materials in complex geomorphological settings that respond to fluctuating climates and sea levels (e.g., Carew and Mylroie, 1994). Similar late Pleistocene– Holocene coastal dune sequences and buried soils are described for the southeast Queensland coast by Ward and Grimes (1987), who suggest that Holocene sea level soon after 3,900 radio-carbon years BP was lower than present.

Figure C51 Buried paleosol in the supratidal zone on the northeastern Atlantic coast of Eleuthera Island, Bahamas. This buried Paleosol is now partially exposed along the landward margin of an abrasion platform, indicating active erosion of dune cover sands.

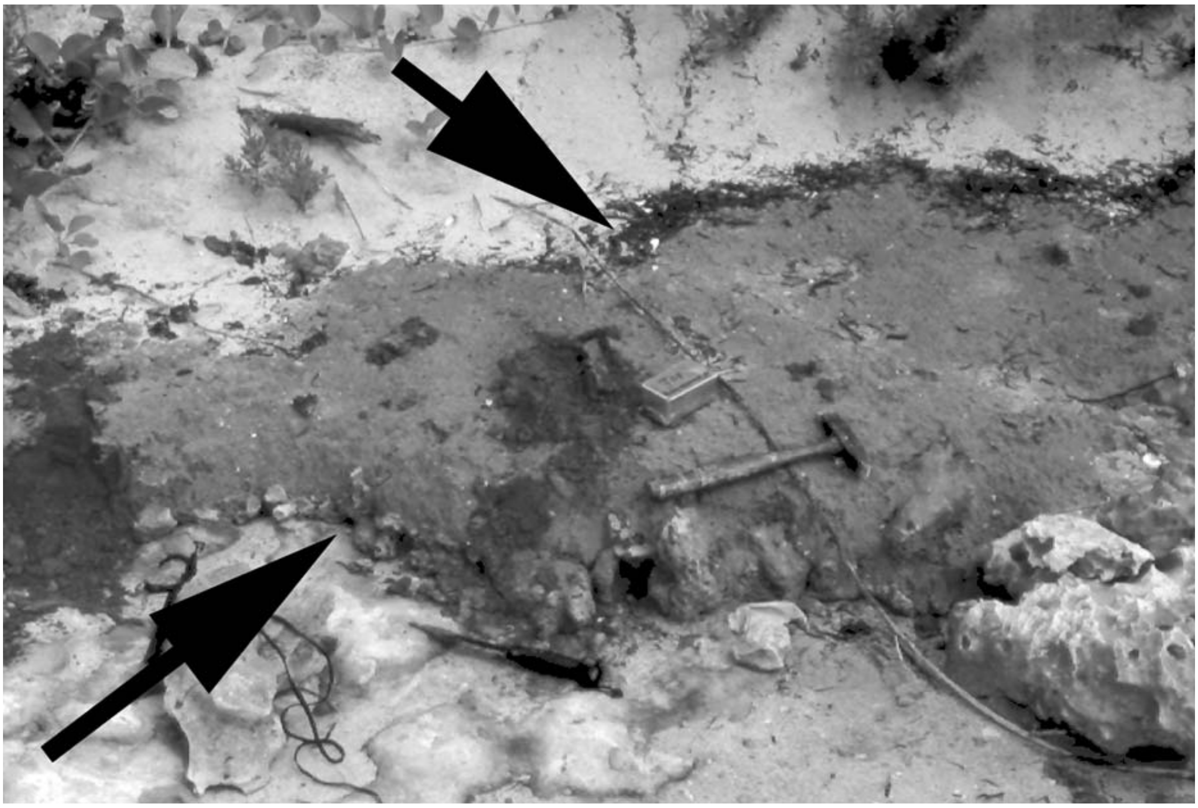

Figure C52 Close-up shot giving details of the buried soil layer seen in panoramic view in Figure C51. The abrupt stratigraphic boundaries above and below the soil layers (arrows mark boundaries) and contrasting nature of all three materials verifies the independence of the soil layer, now partially truncated leaving just the stump of a former profile. The hammer and Kubiena box (for collection of undisturbed, oriented samples) are for scale.

In addition to calcareous precipitates, other kinds of indurated materials related to ferruginous crusts and intensely weatherized materials are also common on coastal plains. Delaney (1966), for example, describes interesting mixed and contra-genetic sequences of caliche and laterite (Fe-duricrust) on the Rio Grande do Sul of southeast Brazil and northern Uruguay. Here, Quaternary units consist of a perched blanket of sand (the Itapoã Formation), arkosic sands and gravels (Graxaim Formation), the Serra de Tapes Laterite (a soil- stratigraphic unit), and a marine quartzose sand (Chuí Formation). The relict Serra de Tapes Laterite is not forming today and must have formed during a climate with high temperature and moderately high precipitation, conditions that do not exist on the coastal plain today. Pleistocene caliche was formed in a climate almost opposite to that of the Serra de Tapes Laterite.

Similar kinds of relationships are found in cold regions where ice-permafrost sequences on the Siberian coastal plain, with large polygonal ice wedges, represent excellent archives for paleoenvironmental reconstruction. Such deposits contain numerous well-preserved records (ground ice, Paleosols, peat beds, fossils), which permit characterization of environmental conditions during a clearly defined period of the past 60 ka (Schirrmeister *et al.*, 2002). Lake plains along the eastern shore of Lake Michigan provide analogous setups where buried soils occur in dune fields with cyclical development after relatively long (>100 year) periods of low sediment supply (Loope and Arbogast, 2002). Because soil formation takes place during stable landscape conditions, the presence of buried soils facilitated construction of a general hypothesis for late Holocene interaction of foredune and perched dune models on this lake plain, as it relates to multicentury lake-level fluctuations. It seems, on the basis of this study of 32 dune fields and included Paleosols, that the modern landscape originated after the postglacial peak in lake level (i.e., after the Nipissing transgression, about 5,500–5,000 cal year BP) (Loope and Arbogast, 2002).

The aforementioned descriptions feature Quaternary soils in contemporary coastal landscapes, but there are numerous other Paleosolic developments along ancient shores where old weathering sequences persist in the form of deep weathering profiles of the lateritic or bauxitic type in senile landscapes. Salients among these examples are found in the formation of lateritic bauxites in Cretaceous and Tertiary coastal plains. Bauxites commonly form elongate belts hundreds of kilometers long, parallel to lower Tertiary shorelines in India and South America (Valeton, 1983). Typical sediment associations are found in India, Africa, South and North America, that are characterized by: (1) red beds rich in detrital and dissolved material of reworked laterites, (2) lacustrine sediments and hypersaline precipitates, (3) lignites intercalated with marine clays, layers of siderite, pyrite, maracasite, and jarosite, and (4) marine chemical sediments rich in oolitic iron ores or glauconite. The geographic relationship between *in situ* lateritic bauxites and the shoreline at the time of bauxite formation are interesting, if not some what controversial. Occurrences of bauxites residing parallel to ancient coastlines is documented for the karst bauxites of the Mediterranean (Southern France, Greece, Yugoslavia). Most of these types of lateritic bauxites, which are soft at the time of formation, belong to the Aquox subgroup of the group of Oxisols in *Soil Taxonomy*. The Fe-rich parts eventually form hard ferricretes whereas the Al-rich parts form hard alucretes (Goudie, 1973).

Alternating sequences of landscape stability and instability, as related to phases of soil formation in shield areas, are comprehended in the *cratonic regime* (Fairbridge and Finkl, 1980). This model recognizes a thalassocratic–biostatic condition (a long-term stable phase) during which prolonged deep chemical weathering takes place. In contrast, the epeirocratic–rhexistatic condition is a shorter-term unstable phase when there is general ecological stress and erosion of weathering profiles. The dual-phased, long-term–short-term regime was developed from experience on the West Australian craton (Yilgarn Block) but is applicable to other cratonic margins around the world. The significance to coastal soils relates to occurrences of laterites, bauxites, and associated materials along contemporary coastlines and ancient shores. Phases of soil formation are related to landscape stability and high sea levels; erosional phases where there is stripping of weathered materials from the land surface is associated with low sea levels. This sequence of events along cratonic margins produces a wide range of distinctly contrasting coastal Paleosols that include and which are derived from residual weathering that juxtaposes Quaternary coastal plain soils with relict Tertiary and older weathering profiles.

Epeirocratic–rhexistatic phases on the Yilgarn Block (West Australian craton) have, for example, resulted in the stripping of regolith materials form the craton surface to produce a series of etchplains that represent degrees of soil removal (Finkl and Churchward, 1973; Finkl, 1979). The least amount of stripping is associated with incipient etchplains, which occur on the seaward-most margins of the craton, along the north–south trending Indian Ocean coastal boundary and along the east–west trending Southern Ocean coastal fringe. Buried etchplains occur on the southern margin of the craton where deep chemical weathering profiles are intersected by present sea level and overrun by coastal dune systems.

Conclusion

Coastal soils are, in a certain sense, almost enigmatic because most soils occurring in coastal zones have complex histories and are related to environmental conditions that no longer predominate. This fact is perhaps not surprising because coasts themselves are extremely complex, resulting from combinations of land movements and fluctuations of sea level. Some coasts thus have histories of ingression where relative sea-level rise drowns preexisting landscapes (Kelletat, 1995). The accompanying soils become drowned or are buried by younger coastal sediments and new phases of soil formation. In other cases, the seabed becomes emergent by sea-level fall or neotectonic uplift providing new parent materials for soil formation. In other situations, the land–sea boundary remains more or less stable long enough for soils to develop in coastal deposits such as mangrove muds. Whatever the mechanisms involved, there exists a diverse range of soils in coastal zones. Some are clearly "coastal" in the sense that they are closely related to present shoreline materials and conditions; they are therefore younger Holocene in age. Other soils occurring in coastal zones are not strictly "coastal" because they can form independently of maritime conditions. The complex array of coastal zone soils is not easily comprehended without careful study and some background in pedological concepts, principles, practices, and field experience. Complex terminologies of different soil classification systems also tend to confound all but the most intent coastal researchers who make the effort to ferret out the details. Coastal soils are an interesting topic that offers scope for studying coastal change or evolution as recorded in the pedological record.

It is seen that coastal zones contain the youngest soils on earth as well as some of the oldest. Newly exposed seafloor muds form parent materials for acid sulfate soils and Solonchaks, recently stabilized coastal dunes host youngest Holocene Regosols whereas some older dunes feature strongly differentiated Pleistocene Podzols. Holocene Gleysols and Histosols form in juxtaposed swales and slacks where drainage is poor. Planosols and Solonetz occur on marine terraces and deltaic regions along with Histosols, whereas Cryosols and Leptosols characterize cold region coastal lowlands. Developed on older coastal plains in the low to middle humid latitudes there is a range of pedogenic formation that includes Podzols, Planosols, Aliosls, Luvisols, and Arenosols and Calcisols in drier realms. Deltaic plains often feature Fluvisols, Planosols, Solonetz, and Histosols. Ancient surfaces truncated by coastal erosion, especially in intertropical regions, show Sesquisols, Ferralsols, Alisols, Acrisols, and Lixisols. Last but not least there are Anthrosols that characterize pedogenic regimes in coastal areas where there has been a long record of human habitation and cultivation of field crops. This description of coastal soils may seem like a long digression, but it is actually a light vignette because the situation is far more complex than what has been alluded to here.

This overview nevertheless provides a fair indication of the range and complexity of pedogenesis in coastal zones as well as indicating the close interrelationships between coastal processes, landforms, vegetation, hydrology, maritime climates, sediments, and the imprint of biochemical weathering on coastal landscapes and seascapes. More importantly, however, is the fact that coastal soils provide much biophysical information that is useful in attempts to unravel some of the major events in coastal evolution, especially phases of soil formation that correspond to sea-level stillstands and landscape stability.

COASTAL SUBSIDENCE

Introduction and terminology

Coastal subsidence, which can be described as the downward displacement of the land relative to sea level, often occurs in deltaic regions associated with riverine and estuarine sedimentation. These regions are commonly sites of thick deposits of Tertiary, Pleistocene, and Holocene sediments, exceeding 12,000 m in the Mississippi River delta, for example (Penland *et al*., 1988). Coastal subsidence in these depositional zones are a function of five processes, each described in detail below: (1) downwarping, (2) tectonic activity, (3) consolidation of Tertiary, Pleistocene, and Holocene deposits, (4) shallow subsidence, and (5) underground water and gas extraction (Figure C53). When only natural processes are considered, 1 + 2 + 3 define deep subsidence. Shallow and deep subsidence combined equal total subsidence (Cahoon *et al*., 1995).

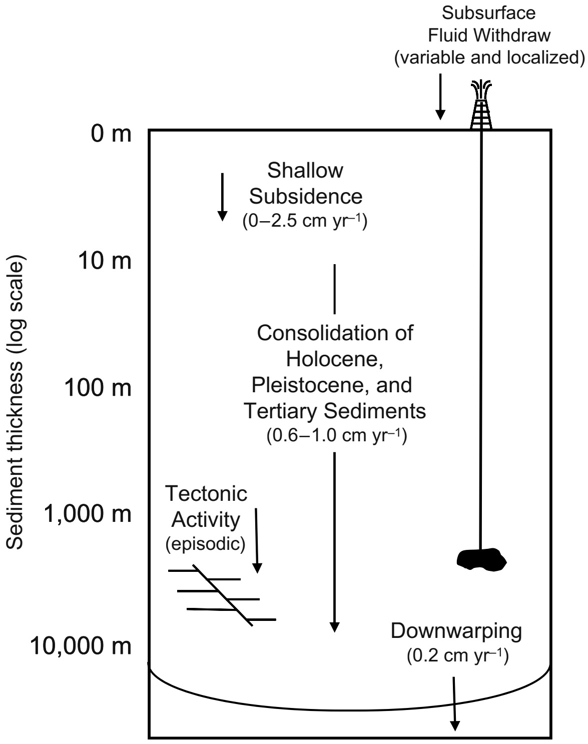

Figure C53 Processes contributing to total subsidence in coastal regions. Comments and numbers in parentheses indicate the relative magnitude of each process in the Mississippi River delta, a region where coastal subsidence has been intensely studied (modified and redrawn from Penland *et al.*, 1988).

Eustatic sea-level rise (the global sea-level rise due to changes in the volumes of glaciers and ice caps, and due to density-temperature relationships) can also be viewed as a “relative” land sinking or subsidence process. On a global scale, eustatic sea levels have risen approximately 125 m since the last glacial maximum 18,000 yr BP. Current rates of eustatic sea-level rise are estimated at 0.15 cm yr^{-1} (Church *et al*., 2001). The term “relative sea-level rise” is used to describe deep subsidence plus eustatic sea-level rise because it is often difficult to differentiate deep subsidence rates from eustatic sea-level rise along the world’s coasts.

Downwarping

The weight of thick sediment sequences deposited during the Quaternary by major rivers that have discharged considerable sediment load, such as the Amazon, Yangtze, Mississippi, Yellow, and the Ganges/Brahmaputra has caused downwarping of the underlying crust (Figure C54) (Coleman, 1982; Chen *et al*., 2000). For example, in the Mississippi River delta, the combined weight of Cenozoic deposits accumulating in the geosyncline off the river mouth has resulted in the slow downwarping the Mesozoic basement. However, this process, estimated to be occurring at an average rate of 0.2 cm yr^{-1}, accounts for only a small fraction of total subsidence in the region (Penland *et al*., 1988).

Tectonic activity

The tectonic-fault framework that exists in coastal regions can sometimes control the geomorphic configuration of the coast-delta extension (Coleman, 1982; Chen and Stanley, 1995) and the intensity of the fault motion plays an important role in influencing the overall subsidence rate (Stanley, 1988; Chen and Stanley, 1995). On a large-scale, fault tilting can trigger the diversion of large rivers from one region of a coast to

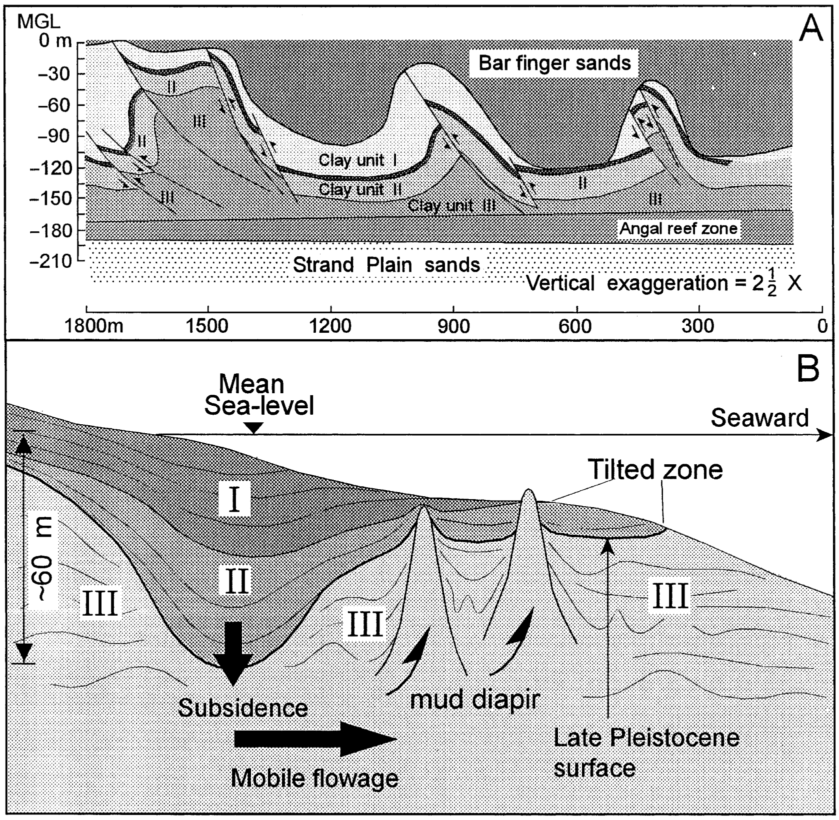

Figure C54 Diagram showing the gravitation subsidence both in the Mississippi and Yangtze estuarine depocenters. (A) The Mississippi model indicating the more seaward displacement than the downward, resulting in tremendous reverse mud slump in front of the river mouth region (modified after Coleman; 1982), and (B) The Yangtze model indicating downward and seaward sediment displacement.

another. Consequently, the estuarine depocenter marked by the thickest sediment sequences, and the most active subsidence, switches laterally. The subsidence triggered by tectonism is a long-term and episodic, geologic processes that is difficult to distinguish from the subsidence caused by the long-term compaction of Cenozoic sediments. A regional estimate of tectonic subsidence along the coast can be made by evaluating subsurface data including petrologic, litho- and chronostratigraphic descriptions from a series of boreholes through sedimentary sections.

Consolidation of Tertiary, Pleistocene, and Holocene deposits

The consolidation of Tertiary and Pleistocene marine and riverine deposits can be a significant component of total subsidence. However, it is the consolidation of Recent sediments that is considered the primary cause of background subsidence in coastal regions. Large amounts of riverine sediments deposited over the past 15,000 years have accumulated along coastal depocenters resulting in high rates of subsidence, regionally. This consolidation, or compaction, is caused by the dewatering of sediments (primary consolidation), the rearrangement of sediment structure (secondary consolidation), and the decomposition of organic matter. In some parts of the Mississippi River delta, subsidence rates due to consolidation exceeds 0.6 cm yr^{-} (Penland *et al.*, 1988).

Shallow subsidence

The compaction in the upper 5–10 m of the sediment contributes a shallow component that is often overlooked when calculating total subsidence in coastal regions (Cahoon *et al.*, 1995). Shallow subsidence is the result of primary consolidation and the decomposition of organic matter. It is an especially important process in coastal systems under stress (from flooding or salt, for example) where below ground plant structures, such as roots and rhizomes, die and decompose, leading to rapid subsurface collapse. In the Mississippi River delta, for example, high rates of relative sea-level rise in the coastal marshes have lead to increasingly long periods of flooding, plant mortality, and rates of shallow subsidence that exceed 2.5 cm yr^{-1}.

Underground water and gas extraction

In some coastal regions, large amounts of fresh groundwater have been extracted along the coast for industrial, agricultural, and domestic use. Rates of subsidence due to this process can be alarmingly high, although the effects are usually localized. For example, subsidence rates within the Po delta of Italy and the Yangtze delta of China have, in the some past years, exceeded 30 cm yr^{-1}, due largely to groundwater withdrawal (Cencini, 1998; Chen, 1998). The reinjection of salt water into the substrata, to replace extracted fluids, has been successfully used to slow down or even halt, but not reverse, extraction-induced subsidence. Hydrocarbon extraction along the coast has the same potential for causing land subsidence, but has been less studied.

Methods of measurement

Estimates of deep subsidence are usually based on long-term records from tide gauges that are mounted on stable piers, bridges, and pilings that extend through the shallow subsidence zone (and thus do not include shallow subsidence). A tidal gauge record spanning at least 18.6 years is required to factor out variations due to the moon's nodal cycle. Typically, mean annual or monthly water levels are regressed against time to yield a rate of relative sea-level rise (Emery and Aubrey, 1991). To estimate the deep subsidence component of relative sea-level rise, the eustatic component (currently 0.15 cm yr^{-1}) is then subtracted. Eustatic sea-level rise is derived from the analysis of tide gauge data from coasts worldwide that are assumed to be geologically stable (Penland *et al.*, 1988).

In addition, a radiocarbon-dated stratigraphy can help to calculate the net subsidence rate along the coast (Stanely, 1988). Stratigraphic analysis of sediment borings can serve to define the subsurface configuration of Recent deposits. Isopachous maps of the Holocene sediment sections can also reveal thickened sediment sequences along the coast. Moreover, high- resolution seismic profiles can provide evidence of Recent subsidence. Deformed late Quaternary strata, mud slumps, diapirs, tilted bedding, and gas-deformed structures in Holocene sequence imply remobilization of underconsolidated sediment within and adjacent to the estuarine depocenter (Chen *et al.*, 2000). Deformation types and their specific position relative to the depocenter record the displacement of sediments as a result of compaction due to sediment overburden.

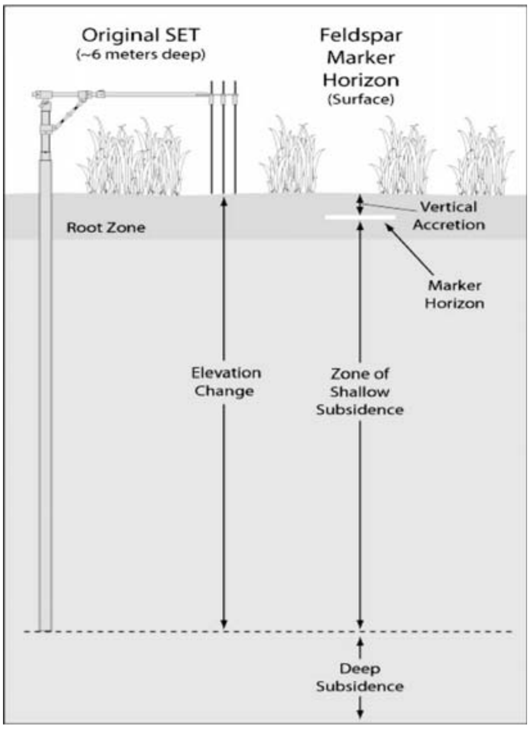

Figure C55 A surface elevation table (SET), shown in use with a feldspar marker horizon, used to estimate rates of shallow subsidence in coastal systems (Figure courtesy of Jim Lynch, and Don Cahoon, United States Geological Survey).

The tidal gauge technique for estimating subsidence (described above), and most estimates of subsidence reported in the literature, measure only deep subsidence, even though rates of shallow subsidence can greatly exceed the rates of either of these processes in some marshes (Cahoon *et al*., 1995). A recently developed field technique that uses a sediment marker horizon (such as feldspar clay) in conjunction with a surface elevation table (Figure C55), an instrument that measures changes in elevation relative to a shallow subsurface datum, has made it possible to measure shallow subsidence (Cahoon *et al*., 1995).

Subsidence and its implications

In stable or prograding coastal systems, relative sea-level rise is usually balanced by the accretion of fluvial or reworked marine sediments. However, extensive hydrologic alterations such as dams and levees have sharply reduced the amounts of fluvial sediments transported to coastal regions. As a result, saltwater intrusion, flooding, and coastal erosion has become much more prevalent in the past 100 years. In the Mississippi River delta plain, for example, land loss rates exceed 65 km^2 yr^{-1}, due largely to a subsidence/accretion imbalance. To add to this problem, the eustatic sea-level rise component of relative sea-level rise is expected to accelerate over the next 100 years due to global warming (Church *et al*., 2001). Therefore, accurate measurements of coastal subsidence are vital for planning coastal protection in densely populated and low-lying region vulnerable to marine inundation.

COASTAL TEMPERATURE TRENDS

Coastal temperature trends—temperature change per unit time—are an indicator of global climate change. Few long-term records of water temperatures are extant, but from many tide gauge sites of the US Coast and Geodetic Survey (USC&GS—now incorporated into the NOAA National Ocean Service), there are hand-written observations covering much of the 20th century. Herein a comparison is made between trends calculated from USC&GS water temperatures at selected tide gauge sites and air temperature trends from the Historical Climatology Network (HCN) of the United States.

Prior to development of acoustic tide gauges and digital data-logging and transmission, trained Tidal Observers would visit USC&GS primary tide gauge sites, typically on a daily basis. Their duties included comparisons between the marigram and the tide staff, measuring sea surface water temperature and density, and routine maintenance. The sea surface temperature (SST) values were recorded on standard forms and mean monthly and annual values were calculated by hand. These data forms were then archived, and largely ignored. Only 20 or so USC&GS tide gauge station temperature records of significant multi-decadal length have been recovered, and are analyzed in detail by Maul *et al*. (2001).

Tidal Observers determined SST by lowering a bucket from the pier or other structure supporting the tide gauge, retrieving a sample of water, and measuring the temperature with a standard mercury-in-glass thermometer. Seawater density was measured with a hydrometer (USC&GS, 1929). In typical Coast and Geodetic Survey tradition, all instruments were numbered and routinely calibrated, with emphasis on data quality dating back to 1807 when President Thomas Jefferson founded the agency.

The HCN was established in 1984 to provide a dataset suitable for detecting and monitoring secular changes of regional rather than local climate. There are over 1,200 stations in the HCN, with observations dating to the early 19th century, including air temperature, humidity, barometric pressure, and winds. The NOAA National Weather Service trains weather observers of the HCN—many of whom are volunteers. HCN air temperatures (AirTs) are mostly free from urbanization effects (the warming due to changing the environment from rural to urban). As

* °C per century.

Figure C56 Map of the contimerous United States showing the location of the 13 SST and AirT sites summarized in Table C10. Only sites with at least 35 years of data have been selected for analysis.

with the USC&GS tide gauge SSTs, HCN data are well regarded as the benchmark for high-quality observations in the United States.

In Table C10, trends in SST and AirT are summarized. Stations were chosen to reflect long-term SST trends at coastal locations somewhat evenly distributed around the United States (Figure C56), but the HCN and SST sites are not exactly coincident geographically. The HCN dataset is generally more complete than the SST dataset, and the controlling dates were driven by the availability of tide gauge temperature observations (N is the number of annual mean water temperature values available to be used in each trend calculation; due to missing data, N is not equal to starting year minus ending year). In all cases, the same years are used for the SST/HCN comparison, with the early 1990s limiting the SST data due to the change from human Tidal Observers to digital stand-alone instrumentation.

Trends in annual mean SST and AirT are calculated by standard linear least-squares methods where an equation of the form $T = a{\cdot}t + b$ (where T is temperature, a is temperature trend ($\partial T/\partial t$) in °C per century, t is time, and b is the linear intercept) is fitted to the data. The standard error in the trend a is typically ±0.03–±0.05°C/century. As can be seen in the summary row at the bottom of Table C10, both SST and AirT seem to be increasing in general, 0.8 ± 1.0 and 0.7 ± 1.2°C/century, respectively, where ±1.0 and ±1.2 is the standard deviation of the average of the corresponding trends.

There is a significant degree of variation from locale to locale. The largest SST trend is at Boston, MA. This unusually large trend, a = 3.6°C/century, may be caused by the geography of Boston Harbor, by a general warming of the Gulf of Maine, and/or by urbanization of the marine environment. Nearby tide gauge sites at New York, NY, Atlantic City, NJ, and Baltimore, MD have trends that are half or less that of Boston. For the northeast as a general value, the trend at the open coastal site of Atlantic City, a = 0.9°C/century, appears to be most representative of the region.

The southeastern United States, including the Gulf of Mexico, on the other hand, shows no statistically significant warming or cooling. SST trends at Charleston, SC are slightly negative, but nearby Mayport, FL are slightly positive. At Key West, FL, the southeastern region's most oceanic site, a = −0.0°C/century, a slight cooling trend.

Along the US west coast, the SST trends amongst the California sites are most similar, averaging about +0.7°C/century. There is an important difference between Seattle, WA and Neah Bay, WA. Seattle is well within Puget Sound with no large rivers to flush the estuary, and Neah Bay is at the western entrance to the Strait of Juan de Fuca near Cape Flattery—an oceanic environment. The zero SST trend at Seattle is unusual among the west coast stations, but serves to illustrate the variability in seawater temperature trends from place to place.

The HCN air temperature trends in Table C10 show a similar range of values compared to the SSTs. In general, the northeastern United States has warming air, the southeastern United States has cooling, and

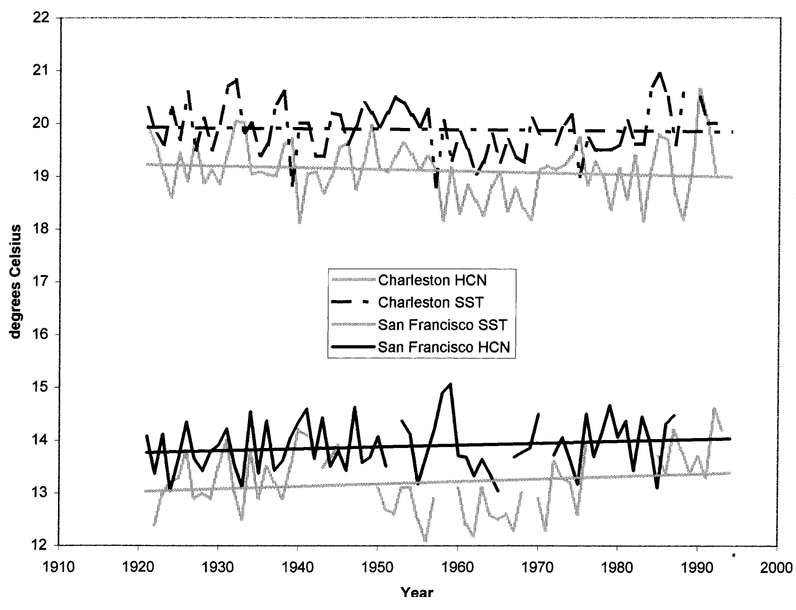

Figure C57 Time series plots of SST and AirT from Charleston, SC and San Francisco, CA. Note the missing data, which is typical of many such geophysical records, and the interannual variability.

the west coast again has warming. Many differences (SST minus AirT—column 6 in Table C10) exist between the tide gauge SST trends and the HCN air temperature trends from juxtaposed sites, the average difference being 0.1 ± 1.4°C/century. The very large difference at La Jolla, CA, for instance, may be more of a reflection that the SSTs are from an open ocean site (the Scripps Pier) and the HCN from an inland site a few kilometers away. A similar explanation is possible for Mayport, FL, but such differences illustrate the vagaries of climate monitoring.

Perhaps the most telling statistic is the value of the coefficient of determination (r^2) between the air and water trends, shown in the summary row in Table C10. A value $r^2 = 0.06$ is a statement that only 6% of the SST trends are explained by the AirT trends, and *vice versa*. The statistical relationship between these two important climate indicators suggests the relationship is nearly random.

To illustrate two of the datasets used to construct Table C10, the mean annual SST and AirT from Charleston, SC and from San Francisco, CA are plotted in Figure C57. Charleston is an example of cooling temperatures and San Francisco shows warming temperatures. It can be seen that temperatures have substantial variability about trend lines—a statement of inter-annual variability caused by climate cycles such as the El Niño–Southern Oscillation or the North Atlantic Oscillation. Figure C57 also shows that there typically are differences in the mean temperatures; in Charleston the mean SST is higher than the AirT, and in San Francisco the mean AirT is higher than the SST (San Francisco's famous fogs are in part caused by the air being cooled by the water).

This entry demonstrates the complex nature of climate change in the coastal United States using a homogenous dataset. As with sea-level change and other indicators of global change, SST and AirT are seen to be site-specific, and that it is poor scientific practice to extrapolate to other regions of Earth. It also shows the challenge and value of data archeology. Many climatic records are not yet digitized and many are deteriorating or are already lost. While these data do not improve clarity in the climate change debate, they offer an important opportunity to learn more about the evolving nature of our planet's geophysical history.

COASTAL UPWELLING AND DOWNWELLING

Definition

An interruption causes a horizontal motion of water to turn into a vertical flux to satisfy the mass balance. This vertical flux of water at the coast is known as coastal upwelling or downwelling, depending on upward or downward movement, respectively. Among others, wind-generated water surface current and its interruption by the coast is a major cause of coastal upwelling and downwelling. Therefore, most of these phenomena have seasonal timescales, while others are event-dependent. Coastal upwelling is more noticeable because it brings cooler subsurface water upward to the surface in the case of a thermally stratified water column, and is accompanied by primary productivity and abundance of fish resources. The phenomenon has considerable economic significance because it affects fisheries, weather, and oceanic currents in many parts of the world. This has prompted much interest in research on upwelling systems around the world. Some executed in the 1970s, including those under the umbrella of Coastal Upwelling Ecosystems Analysis (CUEA), were compiled through an International Symposium on Coastal Upwelling (Richards, 1981). The upwelled water often forms a plume with fronts that can be identified by remote sensing technologies. Upwelling and downwelling scales vary from localized episodes to large ocean areas. Upwelling speeds are very low and vary from 1 to 10 m/day, but upwelling regions may cover thousands of square kilometers.

The following sections describe the physics and types of coastal upwelling and downwelling systems, major places of their occurrence, environmental consequences, mathematical models of upwelling motion resulting from longshore windstress, and measurements.

Physics and types

The upwelling and downwelling processes can be discussed under four fundamentally different initiation mechanisms.

Longshore win

The most important episodes of coastal upwelling and downwelling, in terms of size, duration, and economic importance, occur due to longshore wind. When wind blows parallel to a long coastline for a considerable period of time (for a steady state to develop), a dynamic balance is established between the wind stress on the water surface and other hydrodynamic terms in the equation of motion. Figure C58 illustrates schematically the mechanism of coastal upwelling development due to longshore wind. Two simplifications of the hydrodynamic equation can best explain the cross-shore motion and the resultant episodes of upwelling or downwelling. The first is popularly known as Ekman transport that results from considering a dynamic balance between the

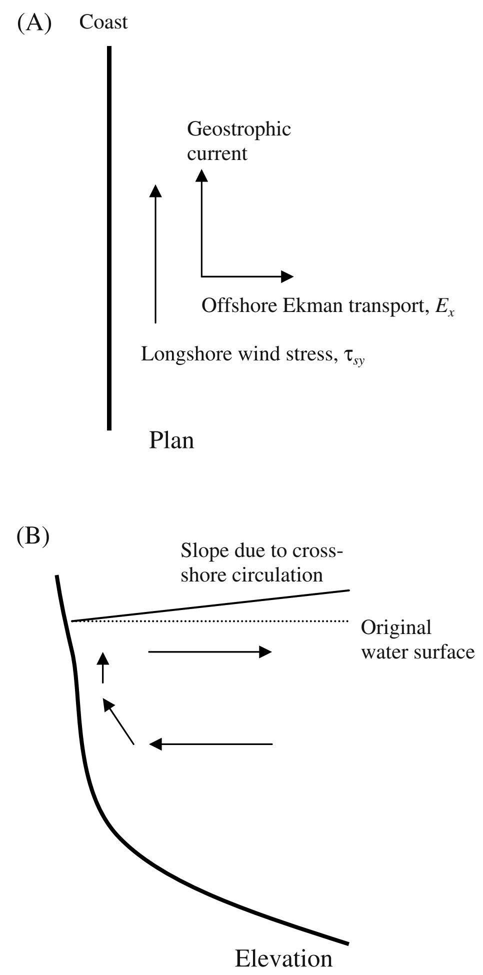

Figure C58 Coastal upwelling mechanism due to longshore wind.

wind-induced frictional force at the water surface and the Coriolis force. Swedish oceanographer Ekman (1905) first introduced this concept to explain quantitatively the ice-drift observations of Nansen in 1893. Due to a balance between these forces, a mass transport of water takes place in the surface layer, which is directed to the right of the blowing wind in the Northern Hemisphere (to the left of the blowing wind in the Southern Hemisphere). Depending on the wind direction relative to the coastline, water level is lowered or elevated along the shoreline, and mass conservation requirement causes vertical motions of upwelling or downwelling, respectively. For the northwesterlies along California and Oregon coast, this creates an offshore transport of water mass, and underwater upwells to the surface (McEwen, 1912). The second simplified explanation of the same motion is based on a geostrophic balance between the pressure gradient force induced by cross-shore Ekman transport and the Coriolis force. The pressure gradient force arises due to the development of a slope in the water surface (Figure C58). Further discussion of this mechanism is given in the section on mathematical models of coastal upwelling and downwelling.

Offshore and onshore wind

On a more localized scale, upwelling and downwelling also occur due to offshore and onshore winds. Onshore winds pileup water along the coast and downwelling occurs to satisfy the mass conservation requirement. The opposite happens, when an offshore wind lowers the water surface at the coast, and the underwater upwells to the surface. Thomson (1981) and Henry and Murty (1972) reported occurrence of upwelling due to an offshore wind in the Departure Bay of the Strait of Georgia. They found that due to upwelling, surface water temperature dropped by 4°C within less than 24 h of offshore wind blowing. Field *et al*. (1981) measured upwelling and downwelling episodes in response to offshore and onshore windstorms, respectively, in a kelp bed in southern Benguela off Cape Peninsula in South Africa.

Underwater ridges, shoals, and large-scale bedforms

When interrupted by underwater ridges, shoals, and large-scale bedforms, the horizontal flow upwells to the surface in the form of a surface boil. Such local upwelling, especially when associated with large horizontal current, may occur in many places in response to a large discontinuity of the seabed. Thomson (1981) reported several upwelling episodes in many passes of the Juan de Fuca Strait and Strait of Georgia along the British Columbia coast.

Open ocean divergence and convergence

From June to October, southeast trade winds cause upwelling in the equatorial Pacific (Thomson, 1981). The Coriolis force deflects the trade-wind generated South Equatorial Current to northward in the north of the equator and to southward in the south of the equator. A belt of divergence, known as *Equatorial Divergence* is thus created that prompts upwelling of cold underwater to the surface. A similar divergence is caused at about 10°N latitude in response to northeast trade winds. Divergence also occurs due to a moving pressure field associated with cyclones. A cyclonic low-pressure system causes surface-water divergence and upwelling occurs around the eye of the cyclone.

Geography

The following areas are some of the notable large-scale upwelling regions in the world (Bowden, 1983; Smith, 1983).

1. In the North Pacific, between 25°N and 45°N, along the California and Oregon coast in response to the equatorward California Current during summer northwesterlies.
2. In the South Pacific, between 5°S and 30°S, along the Peruvian coast in response to the equatorward Peru Current.
3. In the North Atlantic, between 10°N and 40°N, along the northwest coast of Africa in response to the equatorward Canary Current.
4. In the South Atlantic between 5°S and 30°S, along the southwest coast of Africa in response to the equatorward Benguela Current.
5. Along the east coast of Africa and south coast of the Arabian Peninsula in response to the poleward Somali Current during the southwest monsoon.

Consequences

Coastal upwelling is a very well-known phenomenon because of its practical interest. The important consequences of upwelling are abundance of fish resources in the upwelling region, influence on coastal climate, development of sea fogs, and intensification of existing coastal currents.

Very often, the upwelled water brings upward with it a higher concentration of nutrient than that at the resident surface water. The reason for a lower concentration in resident surface water is that overtime the available nutrients are used up by the growth of phytoplankton. The nutrients are usually nitrate, phosphate, and silicate salts. The enhanced nutrient content of surface water helps in the growth of phytoplankton that supports a greater zooplankton concentration. This primary productivity maintains a high fish population and the whole interdependence of lives in the region is known as an upwelling ecosystem. Most of the important marine fisheries of the world are found in regions of upwelling. Although coastal upwelling areas comprise only 1% of the total area of the ocean, they are estimated to produce more than 50% of the total marine fish harvest.

In an upwelling region, the cold upwelled water causes a drop in air temperature of the region, and sea fog develops locally in the presence of moist air. Thomson (1981) mentioned such effects along the west coast of Oregon and the British Columbia coast. Investigations off Oregon and Washington coast showed that the broad and slow southward flowing California Current is intensified into a narrow jet of stream with speeds exceeding 100 cm/s in the upwelling region.

Mathematical models

In this section, some mathematical models are described that deal with large-scale coastal upwelling due to longshore wind. In most models of large vertical motions in the ocean, the Coriolis force is balanced against different forces such as pressure gradient force, friction force, etc. In the simplest form of this model, known as the Ekman–Sverdrup model of upwelling, the Coriolis force is balanced against the steady wind forcing in homogeneous water. Together with continuity equation, the solution of the system of equations (taking x-axis across and y-axis longshore) gives the Ekman transport (Pond and Pickard, 1978; Bowden, 1983; Smith, 1983),

$$E_x = \rho_w wL = \rho_w uD = \frac{\tau_{sy}}{f}, \tag{Eq. 1}$$

where E_x is offshore Ekman mass transport, ρ_w is density of water, w is vertical velocity of upwelling, L is length across the shore of upwelling influence, u is cross-shore horizontal velocity, D is Ekman layer depth, τ_{sy} is wind stress on the water surface in the longshore direction, f is Coriolis parameter, and is given by $2\Omega \sin \phi$, where Ω is angular speed of the earth (7.29×10^{-5} rad/s) and ϕ is latitude. The wind stress can be estimated using quadratic friction law as,

$$\tau_{sy} = \alpha \rho_a U_{10y}^2 \tag{Eq. 2}$$

where α is air friction coefficient (~ 0.0015), ρ_a is air density (= 1.25 kg/m^3), and U_{10y} is the wind velocity at 10 m above mean sea level in the longshore direction.

The offshore Ekman transport is expressed in terms of Upwelling Index (UI) (Bakun, 1973),

$$\mathrm{UI} = \frac{E_x}{\rho_w}. \tag{Eq. 3}$$

The UI is also referred to as Bakun Index. The National Marine Fisheries Service of NOAA publishes monthly summaries of Upwelling Indices for major upwelling regions along the US coast.

Hidaka (1954) obtained an analytical solution to the system of hydrodynamic equations that considered a balance between the Coriolis forces and the diffusive transports in the vertical and horizontal directions. From his findings, some scales of upwelling motion could be estimated,

$$S_v = \sqrt{\frac{N_v}{f}}, \tag{Eq. 4}$$

$$S_h = \sqrt{\frac{N_h}{f}}, \tag{Eq. 5}$$

and

$$\frac{w}{u} = \frac{S_v}{S_h} = \sqrt{\frac{N_v}{N_h}}. \quad \text{(Eq. 6)}$$

In these relations, S_v is vertical length scale, S_h is horizontal length scale analogous to mixing length, N_v is vertical eddy viscosity coefficient, and N_h is horizontal eddy viscosity coefficient. Garvine (1971) made an analysis by including the longshore water slope and showed that beyond the narrow coastal boundary layer frictional effects could be neglected.

In reality, ocean water is stratified, and a complete solution can only be obtained by taking into account all the forces. Some early contributions in this direction were given by Yoshida (1967), Allen (1973), and Hamilton and Rattray (1978). Their solutions are dependent on defining some characteristic baroclinic terms:

$$E_v = \frac{N_v}{fh^2}, \quad \text{(Eq. 7)}$$

and

$$R_b = \frac{Nh}{f}. \quad \text{(Eq. 8)}$$

where N is Brunt-Väisälä or buoyancy frequency and is given by

$$N = \sqrt{-\frac{g}{p_w}\frac{\partial \rho_w}{\partial z}} \quad \text{(Eq. 9)}$$

In these relations, E_v is Ekman number in the vertical direction, R_b is baroclinic Rossby radius of deformation, z is vertical coordinate and is positive upward, h is water depth, and g is acceleration due to gravity. Note that Ekman number is a ratio between the friction force and the Coriolis force, and R_b defines a horizontal offshore scale in which upwelling occurs.

Measurements

Field measurements of surface temperature and conductivity in horizontal and vertical directions, and anomalies of these parameters from the expected variation provide a quantitative indication of upwelling and downwelling. Some examples of the stable expected variation in the vertical direction (measured positive upward) are: (1) a positive temperature gradient, (2) a negative salinity gradient, and (3) a negative density gradient. Visible and infrared satellite remote sensing of color and temperature are also used to identify and show the dynamics of upwelled water (Chase, 1981; Petrie *et al.*, 1987).

The best reference texts for coastal upwelling are *Introductory Dynamic Oceanography* by Pond and Pickard (1978), *Coastal Upwelling* by Richards (1981), *Physical Oceanography of Coastal Waters* by Bowden (1983), and a technical report *Physical Features of Coastal Upwelling Systems* by Smith (1983).

COASTAL WARFARE

Most people today live near the coast, and that concentration has prevailed far back into prehistory. As a result, military history includes many chapters on coastal warfare. Invading armies attack from the sea, and defenders build fortifications to attempt to keep them back. This recorded history starts with Homer's story of the Trojan War, and most recently includes the British recapture of the Falkland Islands and the US Marines night landing in Somalia under the glare of television cameras.

Coastal warfare involves all the elements of warfare: knowledge and use of the environment (terrain, weather, and tides), fortifications and obstacles, deception and surprise, concentration of force at the decisive point, mobility, logistics, leadership, and technology. Coastal operations include naval battles, land battles in coastal plains, and sieges of coastal fortresses. Table C11 list some important coastal battles.

Many naval battles have been fought in coastal waters, both because of strategic considerations and the need to support operations on land. Two classical battles exemplify this category of operation. In 480 BC the Greek fleet defeated the Persians at Salamis. The Greeks used constricted coastal waters to negate the size advantage of the Persian and Phoenician ships, and the naval victory ended the Persian invasion of Greece. In 31 BC, Octavius blockaded Marc Anthony's fleet at Actium on the western coast of Greece. Anthony's fleet finally sortied, with his 220 heavy ships fighting 260 lighter ships. A day of bloody but indecisive fighting ended when Cleopatra fled with 60 ships. When Anthony followed, his remaining ships despaired and Octavius won the battle that propelled him to sole leadership of Rome.

Coastal plains often provide key avenues of approach. In 490 BC, the Spartans and their allies defended the pass at Thermopylae to stop the Persian advance along the coast. Betrayed when the Persians learned of a path around their positions, the Spartans conducted a heroic and doomed fight to buy more time for the Greek forces. As at Marathon earlier that year, topography along the coast dictated the location of the battle.

Coastal fortresses control land and sea avenues of approach, increasing their importance for both attacker and defender. King Edward I of England created a series of "Edwardian" castles in Wales. Of these six castles, perhaps the finest examples of medieval castle design, five had coastal locations. Resupply and reinforcement by sea provided an important

Table C11 Selected coastal battles

490 BC	Marathon	Athens defeated landed Persian force on constricted coastal plain
490 BC	Thermopylae	Persians annihilate Spartans defending a choke point along the coastal plain
480 BC	Salamis	Greek naval forces defeat Persians in coastal water where the Persians cannot take advantage of larger ships
31 BC	Actium	March Anthony's naval force defeated while trying to break out of blockade by forces of Octavius
1274, 1281	Mongol invasions of Japan	Two invasions of Japan defeated by typhoons
1453	Fall of Constantinople	Ottoman siege of Byzantine coastal capital, cutoff both by land and sea
1759	Quebec	British assault force landed at night, scaled the Abraham Heights, and captured the city
1915	Gallipoli	British land at multiple locations along the Gallipoli peninsula but cannot advance inland and eventually withdraw
1943	Tarawa	US forces capture a small and heavily defended Pacific atoll
1944	D-Day invasion of Normandy	Allied forces unleash the largest amphibious assault ever on German defenders
1950	Inchon	UN forces broke out of the Pusan perimeter with an amphibious landing far behind enemy line
1982	Falkland Islands	British recaptured the islands using naval and amphibious forces without a land base anywhere near the islands

aspect of their military importance. Perhaps the greatest siege in history ended the millennium-long rule of the Byzantine empire, when the Ottoman Turks cutoff Constantinople by land and sea. Until the very end, the defenders hoped for relief from the sea. Improvements in technology have decreased the value of fortresses, and such sieges have become much less frequent. Stalingrad was not a coastal city, but the fighting there in World War II shows that the potential still exists for urban siege warfare in a coastal setting.

Amphibious assaults

The amphibious assault in the face of a defended beach marks the culmination of coastal warfare. It requires cooperation among army, navy, and air force units, and reached its highest development during World War II. Previous conflicts had moved armies by sea and landed them to begin combat operations, including invasions of Britain by Julius Caesar and William the Conqueror, but as late as World War I landings at Gallipoli used standard ships and small boats to land troops. In the early 1930s, the Japanese developed landing craft with a bow ramp. Copied by the allies, World War II saw the development and fielding of specialized landing craft and amphibious vehicles specifically for amphibious assaults. (Table C12). Four different theaters saw amphibious landings: leapfrogging along New Guinea to the Philippines (Figure C59) in the Southwest Pacific under General Douglas MacArthur, island hopping in the Central Pacific under Admiral Chester Nimitz, the Mediterranean theater movements from North African to Sicily and finally Italy, and the largest single amphibious operation with the landing in Normandy under General Dwight Eisenhower.

In 1950, UN forces in Korea under General MacArthur staged a repeat of the World War II Pacific landings, with old landing ship tanks (LST) and many Marine veterans recalled to active duty. This landing exemplifies many characteristics of an amphibious assault. On environmental grounds Inchon presented an unlikely site. A narrow river channel and wide mudflats restricted ship operations. A 10 m tidal range, and the necessity for two high tides during daylight, restricted the landing to a few days each month. Surprise and impeccable execution overcame the environmental drawbacks to make the Inchon landings a turning point in the Korean War.

Following the success at Inchon, technology improvements have greatly increased the ability of large navies to successfully land forces on a hostile beach. Helicopters, and specially configured aircraft carriers to support them, allow airlifting of troops ashore and bypassing of coastal defenses. Parachute and glider units filled this role in World War II landings like Normandy, but the helicopters can return to the ship and bring in additional troops and supplies or move troops ashore as needed. The squared-off bow ramps have been replaced with extendable ramps that allow a hydrodynamic bow and greatly increase the cruising speed of the amphibious ships while still allowing roll-off of the assault vehicles. Large landing ship docks (LSDs, over 3 times the size of the 18 built during World War II) feature a large docking pool that can be flooded, allowing the smaller amphibious vessels to rapidly float away to begin the assault. LCACs—landing craft air cushioned—use jet engines to float on a air cushion of air, riding rapidly over the waves and obstacles up to 1.2 m high, and up onto the beach. Only one conflict has tested the new technology, the British recapture of the Falkland Islands in 1982. Due to time constraints when the Argentines attacked without warning, and because budgetary cuts meant the British did not have a full complement of new amphibious equipment, the British success relied as much on rapidly requestioned and modified commercial vessels as on the specialized naval vessels. In the First Persian Gulf War, the American amphibious forces had a diversionary role without actually performing a landing, and the new equipment and doctrine did not receive a battle test.

Military principles of amphibious assault mirror those of any offensive action. The attacker must mass forces at the critical location, and then rapidly exploit the advantage. In many cases this proves relatively easy to achieve, because the defender must spread his forces over a large area and many beaches. Until the defender knows where the main attack will take place—and the danger of mistaking a diversionary landing for the main attack always dulls the reaction time of defenders—the attacker can exploit numerical superiority on the landing beaches. Surprise and deception keep the defender guessing about the location of the assault, and keep forces spread over a large area. Throughout history, many defenders have decided that beaches cannot be defended, and have kept most of their forces in reserve prepared to fight a mobile defense once the situation becomes clear. German and Japanese attempts to fortify the beaches and stop the attacker at the water's edge never succeeded in World War II.

The key to the offense becomes rapid exploitation of the initial numerical advantage—failure here doomed the landings at Gallipoli in World War I, and led to the stalemate after the Anzio landings during World War II. In contrast, the 1759 British capture of Quebec resulted from a nighttime landing, and an immediate scaling of the cliffs the French had considered impassible. Rapid exploitation requires good planning, forceful leadership on the beach, and the ability to rapidly reinforce the beach. In almost all opposed landings, the units in the first wave become militarily ineffective. Despite planning and rehearsals, boats land units at the wrong place and split up unit integrity, and casualties due to enemy action and the surf decimate units. Junior leaders and individual initiative can carry the assault well inland and secure the beachhead, but the strategic goals of the invasion require that additional units be rapidly landed with unit integrity and supporting armor, artillery, and air defense support. These units in the follow-on waves must seize the initiative and expand the beachhead before the defenders can respond and mass their units. Then the initial assault units can regroup for later action.

Concurrently with the follow-on combat units, the attacker must land supplies to keep the units on the beach moving inland. At Gallipoli, the British had trouble keeping units supplied with water which had to come in over the beach, and despite multiple successful landings at different locations and times they never exploited the initial success to expand the beachheads. At Inchon, the large tidal range required that LSTs be beached overnight, because they had to come in at high tide to get over the impassible mudflats, and it was impossible to unload them before the tide began to ebb. Beached LSTs provide a tempting target, a necessary risk because the assault troops needed heavy vehicles and the supplies they carried. Logistics remain important until ports can be captured. Allied efforts to create artificial harbors in Normandy failed when a major storm damaged the structures, which meant supplies had to come over the beach for much longer than the logisticians wanted.

Environmental considerations

The requirements for logistical support and combat reinforcement often dictate the time of a landing. A significant tidal range usually restricts landings to a few days each month, because planners want two tides during daylight hours. The first tide near sunrise brings in the assault waves, and the second tide twelve and a half hours later brings supplies and a second wave. Depending on conditions, planners may prefer to assault with a low or high tide. At Normandy for D-Day, the assault came at low tide. This exposed the largest number of obstacles in the surf zone, but did not make the job of combat engineers easy as they tried to neutralize obstacles—the tide rose faster than they could deal with the obstacles. At Inchon, planners chose the high spring tide so the assault vehicles could get to the seawall without getting mired in the mudflats. Neap tides might be selected to avoid the extremes in tidal range, and insure there is enough water to get over obstacles even at low water. Poor knowledge of the tides at Tarawa led to problems because the reef grounded many of the assault vessels, and there were not enough amphibious tractors which could drive over the reef and up out of the water, but a strategic need for speed led planners to accept risks as militarily necessary. At Tarawa, the actual tide encountered did not correspond to either the predictions or later hindcasts, demonstrating the large effects that meteorological conditions can have when the normal tidal range is only about 1.2–1.9 m. Depending on the tides involved, favorable windows can be either two weeks (Normandy) or four weeks apart (Inchon). Tidal currents can also influence the assault timetable, since at Inchon the maximum current speed equaled the speed of many of the amphibious assault vessels.

Geologic conditions for an assault beach generally require two factors: low slope and firm sediment. On a reflective–dissipative continuum, this generally places assault beaches somewhere in the middle of the spectrum. Assaults cannot target beaches backed by cliffs because there these lack easy egress, although the landings at Quebec in 1759 and the American Rangers scaling the cliffs at Normandy to capture key coast artillery positions show that even this rule can be violated to achieve complete surprise or to provide supporting assaults to the main attack. Moderate slopes offshore allow amphibious vehicles easy egress from the water, and moderate slopes ashore allow rapid expansion of the beachhead. The landing beaches at Gallipoli were all chosen because they were small sandy pocket beaches along a coast that generally provided steep terrain right up to the water. Extreme low slopes generally must be avoided, because they come with small sediment sizes that will not allow heavy military vehicles to operate and rapidly exit the beach. The landing at Inchon needed to come at high tide to avoid the extensive mudflats; the selected "beaches" allowed the landing craft to get to the base of a seawall and minimized the problems that would have been encountered on mudflats. Favorable geologic conditions accompany favorable wave conditions, as low slopes correlate with smaller wave heights. Following the experience at Tarawa, assaults also generally try to avoid offshore reefs. At Tarawa, the landing craft approached from inside the lagoon, but grounded on the reef and dropped Marines into the water where many drowned in the deeper water between the reef and the shore. Other dropped gear to get ashore, and then had no weapons or supplies.

Weather always affects amphibious operations. Two Mongol attempts to invade Japan in 1274 and 1281 ended in defeat in large part due to intense cyclones that destroyed much of the invasion fleet. The Japanese called these Kami-kaze, or "divine winds," and used the term during World War II for suicide attacks, many at ships massed to support Allied amphibious landings. The D-Day landings had to wait one day, and nearly had to wait two weeks for the next favorable tide conditions because of a severe storm over the Atlantic. The Inchon fleet suffered minor damage from one typhoon while preparing for the landing in Japan, and put to sea a day early to avoid a second typhoon. The next favorable date for the Inchon landings was a month away, the Pusan perimeter required relief immediately, and the North Koreans were likely to begin mining the channel into Pusan if given more time. For both D-Day and Inchon landings, correct favorable weather predictions by the staff meteorologist allowed the invasions to proceed without having to wait weeks for the next available date with favorable tides.

While defenders have put obstacles in the water and along the beach to slow or stop the defenders, and dug and reinforced positions for their weapons and themselves, these obstacles and fortifications defeated no major landings in World War II. Conversely, despite massive naval and air bombardments preceding most of the landings in World War II, the attackers never dislodged and rarely seriously disrupted the defenders until the assault boats hit the beaches. This paradox has led many military thinkers to assert that a mobile defense back from the beaches will work better than attempting to build the Maginot line at the shore, while for the attackers, a relatively short bombardment maintains surprise while achieving almost the same effect as a much longer bombardment.

Supporting landing operations can be among the costliest naval actions. During the campaign for the Gilbert Islands, the Marines lost 1,115 dead and missing on Tarawa. The sinking of the escort carrier *Liscome Bay*, supporting the army landing on Makin Island, led to the loss of 644 men. The largest naval battle ever fought, the battle of Leyte Gulf, occurred when the Japanese attempted to destroy the forces landing in the Phillipines and the ships supporting them. US losses included two escort carriers, including one lost to kamikaze. During the invasion of Okinawa in April 1945, kamikaze attacks sank 36 ships and landing craft. In the Falklands campaign, the British saw 9 of their 23 frigates and destroyers either sunk or seriously damaged.

The SEAL (Sea, Air, and Land) Teams date only to 1970, but have become respected both in the military and Hollywood. Their primary missions involve military special operations along coastlines.

Coastal warfare promises to remain a major focus of the world's militaries well into the 21st century. Further reading on this subject may be found in the following bibliographic listing.

Historical background

Water in arid and semiarid land is one of, if not the most important and vital factor, for the existence of people, livestock, and farming all along the history of mankind. Therefore, in many regions where freshwater was not available, occupation was very difficult and much sporadic if at all. In general, people were dependent on permanent water sources such as springs or rivers that supplied water all year round, and temporary sources such as seasonal rivers, natural water cisterns, etc. Later, when agricultural and farming irrigation systems were developed, an immense need for larger water quantities existed. Throughout history, when there has been a necessity and demand for expansion of settlements, either as a result of political pressure or due to the growth in population, people moved (to their sorrow), from the prolific and rich water regions into much poorer areas.

Coastal areas in general, and more specifically the near-littoral zone, reached an ever-growing importance when the sea became another nutrient source to the communities of the gatherers and hunters. As a result, they looked for new water resources, preferably natural, and if these did not exist, they searched and created artificial sources.

In arid and semiarid regions where natural water sources are very scarce, settling was totally dependent on their talent to either transport water to these regions, or locate and discover other sources, mostly underground. The existence of ground-water at a relatively shallow depth below the surface in the nearshore region permitted water exploitation through well digging at least as early as the Pre-Pottery Neolithic Period (ca. 7,900 years BP; Galili and Nir, 1993). This period parallels the beginning of the development of canal irrigation systems in China and Anatolia (Hübener, 1999).

There is no doubt that during the early periods of humanity, people experienced seasonal living along the coast (Oren, 1992), in regions where mountains reach the coastal zone, in most cases where there had been no water problem. Springs or river water easily covered the daily needs of people and their livestock. While in shallow relief or hilly coastal plains, in those semiarid lands where no springs or rivers exist, the water problem was very crucial to their survival.

Coastal water wells

At a certain stage of development, people discovered the fact that fresh or semi-fresh water may be reached very easily by digging shallow holes on a sandy beach quite close to the coastline (perhaps in imitation of animal behavior). It is assumed, although there is very little chance of finding any evidence at all, that this method was practiced for a very long period at much earlier stages before digging of water wells commenced.

The oldest known well in Israel is found at 10–12m. water depth in an Atlit Pre-Ceramic Neolithic village, located offshore, opposite the southern flank of Mount Carmel (Galili *et al.*, 1988; Galili and Nir, 1993; Nir, 1997). This well is about 5 m deep, mostly built of stones. It was found in a relatively large prehistoric site with many dwellings and other village installations. The well, dug in a clayey soil reached, at its lower part, a permeable carbonate cemented quartz–sandstone layer, the Pleistocene "kurkar" rock, which is known to contain a very prolific high-quality aquifer.

The majority of the historical wells are dug as a vertical pit, having a cylindrical shape, with inner diameters varying from 80 to 200 cm (Forbes, 1955; Nir and Eldar-Nir, 1987, 1988). Wells of this type are technically constructed from top to bottom, layer after layer, strengthening its

Figure C60 A typical Antillian coastal well at Tell Ashqelon, located on the southern coast of Israel (photo: Y. Nir).

walls with local stones, undressed in the old wells, but nicely dressed and fit with the well's round shape in the more "modern" wells from the Hellenistic and Roman periods and on to the present.

The water sources of the coastal wells depend on the ground water table, water flowing from inland higher topography to the drainage basin—the sea. This water table fluctuates with changes in sea level that fully controls its level.

In the coastal plain of Israel, and no doubt in similar geologic terrain elsewhere around the Mediterranean and other coastal regions, groundwater has an average slope of about 1/1000, and its surface is almost linear (Kafri and Arad, 1978). Many sub-recent wells were dug along the coastal plain of Israel, most of which are in the nearshore strip. One of the most famous sites, where a high concentration of wells is found, is at Tell Ashqelon, located on the southern coast (Nir, 1997). More than 50 water wells of ages from Roman to the 20th century were mapped there (Figure C60).

Water wells of the dug-pit method have been in operation up to the present time, mainly in underdeveloped regions. Wells of different shapes, construction materials, depth, etc., exist along most of the world coasts, located in all regions where the ground water table is close to the surface. Their importance in the developed countries, has dropped, while in the developing countries where there are no other natural sources they are still of high importance to the coastal population.

COASTAL WIND EFFECTS

Wind can have several effects on the processes influencing coastal geomorphology. These include wind stress on the water surface in major storms, such as hurricanes or typhoons, inducing short-term above normal sea elevations or storm surge, short "choppy" waves in estuaries and fetch-limited harbors, downwelling and upwelling processes in the coastal oceans, and sea breeze effects.

Storm surge is caused by the frictional wind stress on the water surface inducing a current in the surface water. Empirically, the resulting current in the top few centimeters of the sea surface will be about 2% of the wind velocity (Komar, 1976). For Class 5 storm (hurricane) winds, a considerable mass transport is advected along the sea surface waters in the wind direction, so that onshore storm winds force the seawater up against the land. Of course this occurs concomitantly with large, wind-forced, storm waves. The total wind effect is therefore a combination of both the direct wind stress effect and the indirect wave run-up effect. Storm wind stress effects are maximized over broad shallow continental shelves and semi-enclosed seas, such as the Gulf of Mexico, the North Sea, and the Baltic Sea, where extreme surge effects can raise the still water level by ~5 m and flood over the low-lying barriers, estuarine wetlands, and coastal land. The storm surge effect enhances the beach erosion process along open sandy duned coastlines by raising the water table in the beach and lowering intergranular friction between the sand grains, so that the pore water pressure from the raised water table induces the sand from the lower beach face to flow out into the surf zone. But wind-generated surge also piles up tidal waters inside estuaries, tidal inlets, and river mouths, often leading to saline flooding of adjacent low-lying coastal land. As a result of the onshore winds and storm surge, the tidal cycles within the estuaries are altered to a much higher than normal tides and reduced low tide.

Short steep, "choppy" waves are generated by fetch-limited winds inside estuaries and semi-enclosed seas. These "choppy" waves have a number of effects including stirring of the bottom muddy sediments in the shallow nearshore creating the characteristic high muddy suspended load "turbid fringe" observed around shallow estuaries on windy days. These waves may even generate "fluid" mud in muddy estuarine environments from the constant bottom agitation of the loosely cohesive bottom mud sediments. Wind-forced choppy waves in enclosed bays, on top of a storm surge, result in erosion cutback of low terraces and marshland above the normal high tide levels, and the lagoonal shore of barrier islands and spits—this is the prime mechanism for shore erosion within sheltered harbors and estuarine lagoons.

Downwelling and upwelling in the coastal zone are largely wind-generated processes (Figure C61). These processes have marked, but often overlooked, influence on the diabathic (cross-shore) sediment transport. For the case of significant onshore winds blowing for some hours, surface waters are forced up against the beach and dunes, raising the still water level at the beach. As a requirement of continuity, the onshore surface current in turn generates a bottom return current (downwelling). Thus sandy sediment grains initially eroded off the beach in a storm, when uplifted by the bottom orbital motion of the waves, are acted upon by the downwelling current as they fall back to the seafloor, and thus become transported offshore, typically to "closure depth." Conversely, with consistent significant offshore winds, wind stress on the sea surface forces the surface water out to sea, and lowers the still water level. This generates an onshore-directed bottom return current (upwelling), and as the longer period (non-storm) swell waves uplift the bottom sediment, it is transported onshore to the beach, facilitating beach face accretion, and rapid rebuilding of the beach berm. Of the two processes, the latter likely transports bottom sandy sediment at a greater rate because the longer period waves have greater bottom orbital

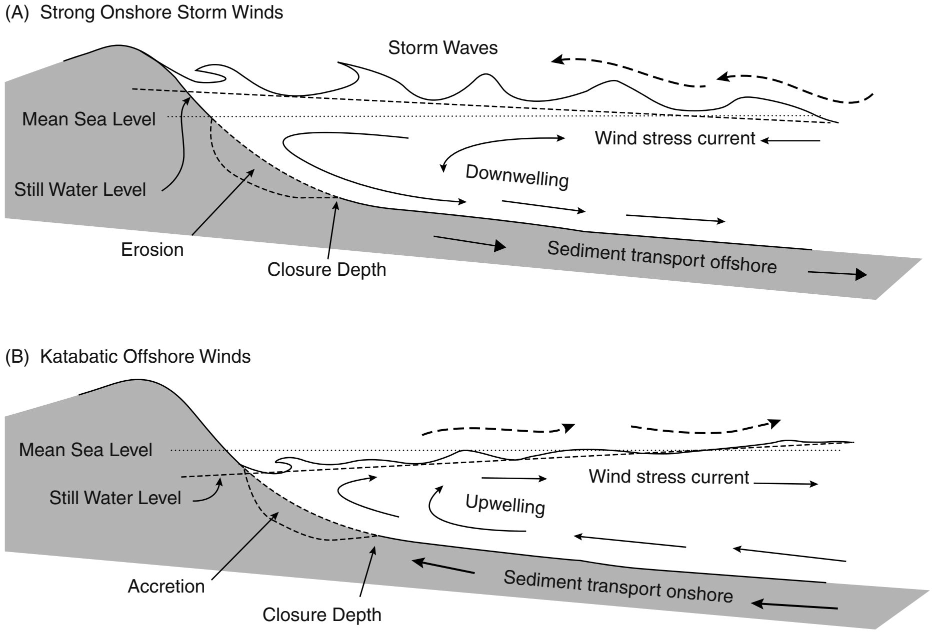

Figure C61 Effect of wind generation inducing coastal upwelling and downwelling and associated diabathic sediment transport.

velocities which uplift more sediment. It is often observed that beach recovery at the end of a storm (when winds reduce in strength and change to an offshore direction) is more rapid than the loss of sand from the beach during the erosion phase.

Sea breeze effects arise from the thermal heating of the land generating a steady onshore wind. The effect of sea breeze on beach morphodynamics has been studied on the Western Australian coast, where sea breezes are some of the strongest in the world. Here the sea breeze cycle is an important influence on beach processes, with onshore winds reaching magnitudes >8 m/s. Masselink and Pattiaratchi (1998) researched the effects of the sea breeze on the nearshore processes, demonstrating how with the onset of a strong onshore sea breeze of 10 m/s, the root mean square (rms) wave height increased from 0.3 to 0.5 m, the wave period decreased from 8 to 4 s, and mean cross-shore flows reached velocities of 0.2 m/s directed offshore. The short period sea breeze-generated waves became superimposed on the background swell. During the sea breeze event, nearshore sediment resuspension became almost continuous, and cross-shore transport was directed offshore. But in addition, the sea breeze affected the beach longshore transport rates when it approached the coast obliquely, and the longshore-suspended sediment transport rate increased by a factor of 100. These sea breeze-induced hydrodynamic changes were associated with erosion of the beach face, and deposition in the surf zone, with a consequent flattening of the profile. The effect was similar to a storm of medium intensity.

COASTAL ZONE MANAGEMENT

Coastlines around the world vary greatly in morphology, natural processes, and human usage. From those which experience intensive tourism, to those which are overdeveloped and polluted, or those where property and important natural habitats are threatened by erosion, all need some degree of management intervention to prevent further deterioration. It is for these reasons that the technique of *Coastal Zone Management* (normally abbreviated to *CZM*, and also sometimes referred to as *Integrated Coastal Zone Management—ICZM*) has increased in popularity as a method with which nations can protect and manage their coastal resource. By definition, CZM can be said to be:

> An integrated process which manages all areas of coastal activity which occur along a stretch of coastline, in an holistic manner, so that minimal impacts occur which may be detrimental to the coast itself.

It is a potentially powerful tool, by which the multivariate uses of coasts, such as leisure, residential, industrial, conservation, protection, etc., can be integrated into a management scheme so as not to conflict. The outcome of CZM should be a management plan which identifies coastal problems and outlines solutions which should be appropriate to both the resource value and the natural process "value" for each coastal issue (see Arthurton, 1995).

The historical development of CZM

Ever since humans started to build structures along the coast or to utilize coastal resources, they have been interfering with natural coastal processes. A seawall may protect a coastal development, but it will also stop an important supply of sediment to the coastal sediment budget and may cause wave-induced scour that removes beach sediment. Similarly, a harbor jetty or yacht marina will prevent the longshore drift of sediment, thus starving beaches further along the coast. Both of these examples, will lead to the initiation of new erosion problems on adjacent sections of the coastlines. In a similar manner, a factory or harbor development may lead to increased coastal pollution, and a leisure development to increased public pressure on natural habitats, such as sand dunes. From these types of problem, management issues arise. Historically, such problems have been made worse by the attitudes of society that pervaded at the time. During the 19th century in particular, the tendency to view all natural systems as: (1) "resources" to be exploited for the benefit of humans; and (2) something over which humans should have total control; laid the foundations for many of our contemporary coastal management problems. Planners and local people just did not consider the coastline as something that could possibly be changed because of their impacts on ecology or natural processes.

While in the current climate of increased knowledge and environmental awareness, it is easy to criticize such attitudes, it must be remembered that many of these historic actions were carried out in good faith, but without the relevant knowledge needed to understand their full implications. We now understand that the coastline is not a feature that is fixed in time, but is something which is transitory and liable to considerable temporal and spatial variation in response to natural processes, often with short notice. Similarly, we also know that many coastal habitats are very vulnerable to change, and have experienced great changes due to human interference. As a result, many contemporary coastlines exist with human-induced habitat degradation and/or large areas of inappropriate development, which are now producing serious management issues which need to be addressed. For example, work by Boorman (1976) found that only 40 passes a month across a sand dune (i.e., only 20 people walking to the beach and back) were sufficient to reduce vegetation height by 75%, while 150 passes (75 return journeys) could lead to 50% bare ground. Frequently, these same areas also contain leisure development and infrastructure.

During the 1970s, there was a general worldwide increase in environmental awareness, both in official sectors, such as government and planning, but also within the general public. This was very much a transitory phase for coastal management because while people became more concerned for environmental welfare and protection, civil engineering still pervaded as the generally accepted solution to coastal problems and the general worldwide increase in disposable wealth in the developed nations increased the demand for, and subsequent development of, coastal tourism. The result of this was the continued development of the world's coastlines, which thus allowed the continuation of many of the impacts associated with erosion, sediment starvation, and user conflict. By the 1990s, the development of environmental awareness and understanding had progressed sufficiently to produce a switch to greater emphasis on the preservation of natural processes and restoration of habitats. The result of this has been the increased acceptance of soft defense techniques, such as beach feeding and managed realignment or even abandonment of defenses, over the construction of solid structures (see also *Shore Protection Structures*). The one main driving force to come out of the 1990s was the Earth Summit in Rio de Janeiro, Brazil in 1992 (Quarry, 1992). This led to the production of Agenda 21 as a blueprint for environmental action. Within this document, chapter 17 deals exclusively with oceans and coastlines, and probably represents the strongest international commitment to CZM that currently exists. Agenda 21 commits coastal nations to the implementation of integrated coastal zone management initiatives, and to the sustainable development of coastal and marine areas under their jurisdiction. Within this, a number of objectives commit signatory nations to more specific aspects of coastal management.

1. To provide for an integrated coastal policy and decision-making process so as to promote compatibility and balance of coastal uses. This also stipulates the inclusion and cooperation of government departments, ministries, and agencies which have control over specific aspects of the coast (i.e., to prevent conflicting usage and non-sustainable visitor pressure).
2. To apply preventive and precautionary approaches in respect to coastal development, including prior assessment and systematic observation of the impacts of major projects (i.e., limiting coastal development in unsuitable areas).
3. To promote the development and application of techniques (such as Cost Benefit Analysis and Environmental Impact Assessment) which reflect changes in value resulting from uses in coastal areas. Such changes include pollution; loss of property and land value due to erosion; loss of natural resources and habitat destruction; and, conversely, the increase in hinterland value due to development (i.e., costing benefits and impacts both financially and environmentally).
4. When managing a coastline, to liase with all interested groups, to provide access to relevant information, and to provide opportunities for consultation and participation in planning and decision-making processes associated with the development of management plans (i.e., consider all views, including those of local residents).

These policies have also been supported from other sources, such as the Intergovernmental Panel on Climate Change (IPCC, 1990) which has recognized the need for contemporary management, but also management which allows for the continued protection of the coast in the light of sea-level rise (see also *Changing Sea Levels* and *Sea-Level Rise, Effect*).

Some common coastal resource conflicts—key issues for CZM

The coastal zone is a finite "resource" in that it can only support a certain amount of activity, before its limitations are realized. This process is often termed the "carrying capacity" of the coast, but can mean many different things to different people. For example, an ecologist might argue that the carrying capacity is an ecological term, referring to the degree of human impact an environment (such as a sand dune community) can take before its ecological structure is impaired. Similarly, a tourist might argue that the carrying capacity of a beach refers to the number of people who can use it before personal enjoyment suffers. All such definitions of carrying capacity, regardless of how scientifically valid they may be, are important in CZM because they all reflect impacts on the coastal zone in different ways. It is important that CZM identifies these varying carrying constraints and provides a strategy to prevent them from being reached and exceeded. If this were to occur, then the outcome would be competition and environmental degradation. The key issues that need to be addressed are:

1. Coasts are used for recreation by many different user groups for many different things, producing conflicts of interest and locally intense usage.
2. Coasts are used by developers for many forms of structure, from urban to industrial. This may attract more people to the area (increased visitor pressure), or put people off coming (declining tourism); may cause pollution; or may interfere with natural processes.
3. Coasts experience a series of natural processes which can be modified by, or impinge on, human activity. This relationship of people to process is, therefore, critical because it will govern how the coastal environment undergoes change. This change can be unpredictable in both its rates and style.
4. Activities inland (catchments) and out to sea can also affect the coast. For example, dam building may stop sediment reaching the coast, or oil spillages may cause coastal pollution. Completion of the Aswan Dam, for example, reduced sediment supply to the Nile Delta from 124 to just 50 tonnes a year, leading to extensive erosion (Stanley and Warne, 1993), while the Akosombo Dam reduced sediment supply to the Volta Delta by 99.5% (Ly, 1980). Also, oil spillages can cause slicks that wash up on the coast, with impacts on coastal fauna and flora. See Figure C62 for an overall summary.

CZM needs to reduce impacts to a level that does not induce any further environmental modifications. However, doing this also represents one of the more subjective issues of CZM, in that assessing each form of use or conflict includes some subjective assessment which needs to be balanced against other views when composing the plan. For example, does land claim mean increased farmland/cheap land for development, or does it mean the loss of intertidal habitat, coastal squeeze, and the increased need for coastal defenses in the future?

In carrying out CZM it will be necessary to side with one particular viewpoint, with full justification in the final report for the reasoning for choice selection. Such a decision may well depend on the nature of the coastline and the precise circumstances in question. Using the above example, land claim may be considered beneficial for increased farmland in a country where fertile land is scarce, with management having a role in protecting this resource, but may be considered as detrimental along a coastline with high conservation potential in a country with surplus agricultural production.

While accepting that there will always be some areas of ambiguity involved in making management decisions, there will also be certain factors which are always going to feature highly in any CZM scheme.

Protecting the coast from storms

Many coastal areas are in danger of damage from natural processes. This danger can take many forms, ranging from the rare event, such as earthquakes and tsunami generation; to those which occur more frequently, such as storms, hurricanes, and storm surges; and to those that occur over the long-term, like sea-level rise. The impacts of earthquakes are difficult to provide adequate protection for, with management largely restricted to emergency relief planning. However, CZM can make recommendations which could be important for damage limitation, such as proper coastal zoning where development is not permitted

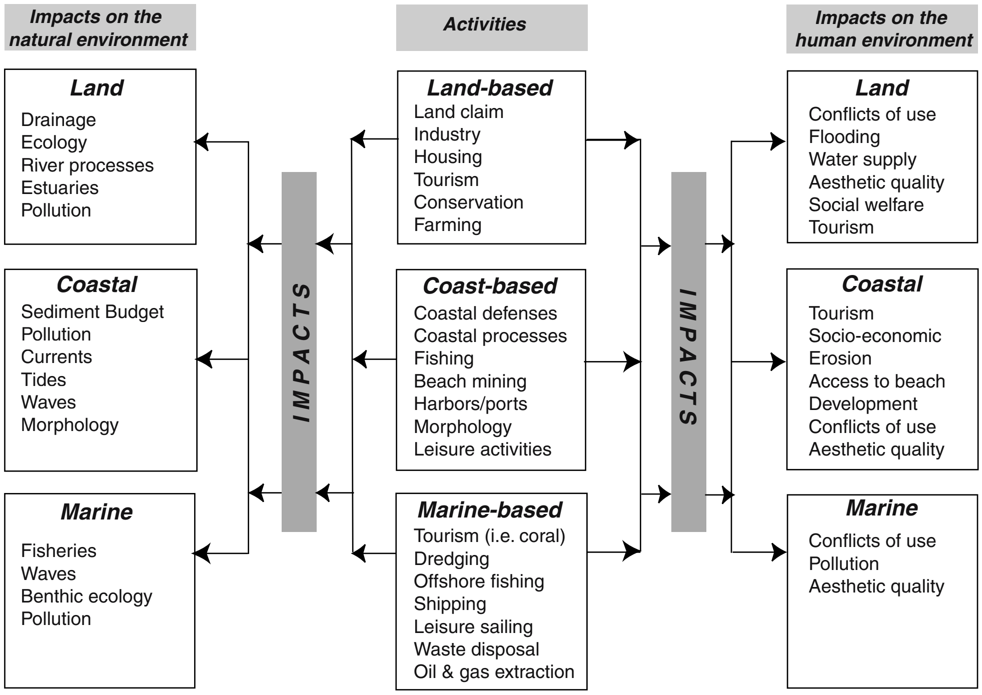

Figure C62 The link between the diverse range of coastal activities and their impacts on both the human and natural environment.

on reclaimed sediments which may undergo liquefaction during earth movements. Storms and hurricanes occur more frequently and can cause sudden and dramatic effects on the coastline, potentially involving the loss of life and property, and also with the potential of altering the coastal morphology by large-scale erosion and the breaching of sea defenses. CZM may decide to develop increased defense provision to cope with these eventualities or, alternatively, to opt for an early warning system which will ensure public safety through evacuation procedures, but not protect property.

In order to protect coasts from storms and hurricanes, there are a series of measures that could be implemented by CZM:

1. In some storm-vulnerable areas, the protection of property by increased defense provision may not be financially viable. In this situation, the protection of human life is of prime concern and so it may be sufficient to arrange evacuation procedures in response to early warning systems.
2. In situations where protection is feasible, CZM may adopt a policy of reinforcing or increasing the height of seawalls.
3. One main concern of storms is the possibility of a storm surge (meteorological tide). Estuaries which are prone to such features, or which contain significant areas of high-value hinterland, need to be protected by tide surge barriers.
4. If hinterland values are low, sufficient protection to property could be provided through the provision of flood lands to take excess water.
5. One of the main causes of problems during storms is the increase in the size of waves. By adopting a policy of artificially building up beaches by beach feeding, sufficient wave attenuation can reduce the impacts of storms at the coast, and thus remove the need for increased hard defenses. Such solutions may be preferable in tourist areas where aesthetics and access considerations are important (see also *Beach Nourishment*).
6. The best form of protection is prevention. Hence, one of the prime management recommendations of CZM should be to avoid building in high-risk areas. Such planning controls can remove the necessity for any of the other methods mentioned here.
7. On coasts where people want to live but which are subject to severe storms, CZM can recommend planning regulations to ensure the construction of "storm-proof" buildings which can withstand the impacts of storm activity. However, it should perhaps be considered that if, after information is made available, people still insist on developing unsuitable areas, then they alone are responsible for the outcome, and should expect no protection to be forthcoming.
8. The impact of storms is also likely to become greater as a result of sea-level rise (see also *Sea-Level Change, Sea-Level Rise, Effect, Waves*). As sea level rises, wave base could deepen, thus increasing the force of a coastal storm. This makes coastal planning even more important, and indicates the need to identify areas susceptible to storm surge inundation.

Managing coastline erosion

One of the main dilemmas facing CZM is whether or not to defend an eroding coast. All such decisions should be taken on the basis of a detailed cost benefit analysis (CBA) and environmental impact assessment (EIA). On this basis, an area that is undeveloped is likely to be left to erode in order to maintain sediment supply to the intertidal zone. When there are homes, places of employment and infrastructure at risk, the decision becomes more complicated as it depends on the value put on the land as to whether it is defended or not. This is determined by a simple CBA, where the value of the land (in terms of property value and income from any resource based upon it) is determined over a fixed time period (normally the life-expectancy of a preferred coastal defense scheme), and compared to the cost of constructing the preferred defense.

An additional consideration in this CBA is the sediment budget (see also *Sediment Budget*). As the successful functioning of the coast as a natural system, and hence its management, is largely based on the movement of sediment from its point of input to its site of deposition, any structure which interferes with this balance will cause a knock-on effect for other parts of the coast, and the setting up of a whole new set of management problems. CZM has to reflect this dynamism, while protecting important areas. In order to assess the importance of sediment input, therefore, it is also common to undertake an EIA to investigate the impacts which any preferred defense method may have on the local environment.

In general terms, in order to maintain a balance between sediment supply (erosion) and deposition (accretion), CZM should opt for defense where necessary, but allow other areas to erode to maintain sediment inputs, even if this means the loss of isolated houses, small villages, or farmland. Only by making such sacrifices can greater protection and stability be given to other, more highly valued coastal areas.

Protection from polluting activities

Many coastlines are subject to a variety of pollutants from industrial, urban, or agricultural sources which can produce physical, chemical, or aesthetic impacts on the coastal environment. Ultimately, all aquatic life forms and much water-based leisure activity depends on water quality for survival and success. However, pressure on the water resource has traditionally been great, with the historical tendency being to treat the seas as a large waste-disposal unit. In addition, pollution is also multi-sourced, and includes industrial pollutants, storm drains, and domestic drainage. In addition to land-based sources, many industries actively dump at sea, both legally and illegally, along the principal of out of sight, out of mind. Often this dumped material is highly toxic or hazardous (see also *Marine Debris*).

CZM should recommend strategies for dealing with such issues. This should cover both routine discharges as well as the risk of accident caused by marine accident. Increased adoption of the "precautionary approach" which arose out of the 1972 Stockholm conference on the Human Environment has allowed easier management of this problem. Subsequently, this has been further supported in legislation by the 1972 London Dumping Convention, 1974 Paris Convention, the 1974 Helsinki Convention, and the 1980 Athens Protocol (Barston, 1994). Many countries deal with these issues directly by instigating methods of emission reduction. In the United States, for example, the use of Best Management Practices (BMPs) are common as a means of input reduction. For example, BMPs for agriculture include contour ploughing, crop rotation, filter strips, and animal waste control as methods to reduce the impacts of agricultural wastes on river and coastal areas. BMPs for urban areas include storm water collection and treatment, and the use of porous surfaces to reduce runoff and even out the storm hydrograph.

Other issues relate to the direct discharge of waste into the marine environment through pipelines. Modern pipelines discharge well beyond the low-water mark, and so the material readily becomes dispersed by marine currents and does not recontaminate the beach. They do, however, have the potential to affect marine organisms and fish stocks. Many countries, however, have old sewage systems and storm water discharge outlets. Typically, these tend to discharge into the intertidal zone, with the result that tidal currents can bring material back inshore. Solid material is often easily detected and CZM plans should have strategy recommendations in place to deal with any situations as they arrive. More seriously, problems occur with water-soluble pollutants which are not as readily detected and can go un-noticed until major environmental problems result. As part of standard CZM recommendations, new waste discharge pipes have to be built to beyond mean low water of the lowest tides.

In estuaries, where dredging may be common as a means of maintaining access for shipping, the problems of disposal of dredged spoil may be particularly acute. One main problem is that these sediments can be highly contaminated due to industrial activity. One possibility is to identify licensed offshore dump sites where dredged material can be placed. However, this material also represents a loss of sediment to the sediment budget and so could lead to issues of sediment starvation elsewhere along the coast. By adopting a wider perspective, CZM can recommend other uses for suitably unpolluted dredgings, such as beach feeding (see also *Beach Nourishment*).

Maintaining biodiversity and protecting habitats

The prime use of many coastal areas is for recreation and tourism. This can lead to some of the greatest conflicts which CZM has to deal with because of the diverse range of uses which a tourist coast has to support. Habitat fragility can be highlighted by problems such as trampling at sensitive sites, such as dune and coral reef areas; while beach resorts may experience widespread conflicts of usage, such as those caused by incompatible activities, such as bird watching and wildfowling, or jet-skiing and swimming. To minimize such conflicts, CZM needs to study which activities occur along the coast under study, to identify which can coexist harmoniously, and methods by which to accommodate others, such as by zoning usage. While conflict and zoning issues can be overcome with good management practice, the protection of habitat may be more difficult. In 1979, the Council of Europe instigated the Convention on the Conservation of European Wildlife and Natural Habitats (more commonly known as the Bern Convention). This has been frequently utilized in European CZM as a means of protecting coastal habitats at risk from development or over-usage. Similarly, in other parts of the world, fragile reef areas have received protection under different legislation, such as by designation as marine conservation areas or marine parks (see also *Marine Parks*).

Threats to biodiversity from tourism, however, is not just a question of people being by the coast. Tourist activities demand support services, infrastructure, accommodation, and land-based entertainment. All such development threatens the habitats already present on the hinterland. Many coastal areas support a wide biodiversity that can be severely reduced by tourism-induced habitat loss. While the Bern convention is applied in Europe, in the United States, Habitat Conservation Plans (HCPs) can be used to balance development and conservation interests. Within these plans, states actively seek land areas to purchase for conservation and habitat creation in order to balance areas of land lost due to development. While this may appear ideal, it does not solve the problem of replacing like with like. In this respect, it is important to consider that in many cases, created habitats do not function or behave in the same way as natural ones.

Access to the coastline

As well as protecting the natural environment, CZM also needs to consider that people need to be considered as part of the management plan. Any development of habitat protection measures, or physical coastal defense structures must protect visitor access to the shore. The coast is an immense recreational resource, earning huge amounts of tourist dollars. As development increases, however, it is possible for the levels of access to parts of the coastline to be reduced. To protect such interests, planning needs to consider the length of coastline and to allow access steps or ramps accordingly. Eroding coasts may, for example, experience loss of steps as cliffs erode, effectively isolating beaches from public access. While this could be seen as a management tool in itself (i.e., make access difficult as a means of protecting vulnerable areas), it will concentrate people into others, thus increasing visitor pressure proportionately.

The protection of coastal development

CZM has to consider the role of hinterland development in two ways. First, and perhaps most obvious, is the protection of infrastructure from erosion and flooding. In this respect, CZM needs to focus primarily on the methods available for coastal defense, and to recommend an holistic defense strategy for use along the coastline in question. When deciding on which defense policy to recommend, a series of points need to be considered:

1. What is the existing situation with respect to defense provision? The coastline can be mapped, marking seawalls, groins, breakwaters, undefended, etc.
2. What state of repair are these structures in? If they are in a poor state of repair, and likely to fail within the lifetime of the CZM plan, further points need to be raised, such as:
   - Is the current defense type still the best form of defense? If yes—plan reconstruction.
   - Is another type of defense better (see *Shore Protection Structures*)? If so what type? Typically, CZM plans should always consider the possibility of replacing hard defenses with soft, or removing defenses altogether.
   - The CZM recommendations need to fit with the holistic strategy for the whole coastline?
   - What will be the emergency response should any existing defenses fail? (rebuild, strengthen or change?)
3. If defenses are still sound, do they fit in to the longer-term defense strategy for the coastline?
4. For un-defended parts of the coastline, is this situation still tenable, or is development likely to become threatened within the lifetime of the plan?

Protecting the "identity" of coastal communities

A second aspect of tourist coast development concerns the social cost of tourism. When coasts experience rapid expansion, such as happened around the coast of the Mediterranean during the 1970s and 1980s and more recently in the Caribbean, it can often lead to small towns and villages losing their identity when they are swallowed up in development. This can, therefore, destroy the social structure of the local inhabitants. Many tourist areas are guilty of this form of identity loss, with coastal villages expanding so that they merge with neighboring villages undergoing similar development. As well as losing all identity and uniqueness, the result is a continuous development along much of a popular tourist coast which also removes any possibility for natural habitat management. CZM needs to recommend strict guidelines in such areas, so as to preserve uniqueness. For example, Canon Beach, in Oregon, has a ban on large fast-food outlets to protect it from mass tourism and day-trippers. Other methods include tight building regulations with regards to style of building and the materials used, limits on how many floors a development can have, and tight rules concerning the provision of open spaces.

Defining limits

From what has already been said, it can be seen that CZM needs to encompass a range of coastal uses, some of which will be marine-based, and some land-based. Clearly, such a distribution of use is going to vary from coast to coast and so the coverage and content of CZM will also need to vary accordingly. Hence, in developing a CZM plan, it is necessary to determine what the main activities are, what part of the coastline they impact, and thus to define the area of land and sea which CZM needs to cover. On coasts where the land-based activity is important, such as tourist-dominated coasts, there is a need to focus CZM more on the land. Conversely, on coasts where marine activities are important, such as for fisheries, there will need to greater CZM emphasis on the sea.

Defining the landward boundary

One of the key problems in deciding how far inland the landward limit of a CZM plan should be is whether to select one based purely on environmental grounds (perhaps the best considering the environmental rationale to the whole process), or one which coincides with an existing administrative boundary (convenient when it comes to actually running the process). In reality, it is very rare that the two should coincide. Possibilities include:

1. The landward limit of maritime climate influence, such as the limit of salt spray, or onshore sediment transport. This limit would allow CZM to protect sensitive supratidal habitats, such as cliff-top grassland communities and sand dunes.
2. Mean high-water mark may be a preferred choice where the main CZM concern is with intertidal habitats. Such a limit would, however, omit any land-based habitats or development or landward vegetation transitional communities.
3. Selecting the boundary of watersheds would include the whole of a river catchment and would encompass any activity which could impact on the coast. For example, the construction of a dam could impact dramatically on sediment loads being brought down river, and thus affect the sediment budget (see also *Dams, Effect on Coasts*). Similarly, land management practices, such as deforestation, could mobilize large volumes of sediment which could swamp sensitive coastal habitats, such as some coral communities, such as occurred in Kanehoe Bay, Hamaii (Jokiel *et al*., 1993).
4. An arbitrary limit determined with respect to local conditions, such as topography, land-use, or habitats.
5. Limit of coastal development, to allow the protection of tourist interests.
6. The administrative boundary of the maritime authority in question.

Clearly, each possibility has relevance for particular coastal scenarios. Possibility (1) would be relevant on dune coasts, while (2) would be of importance in salt marsh or mangrove situations. However, in reality, the landward limit selected may well be a compromise between several of the above possibilities. Possibility (3), for example, involves huge areas of land and may, in many situations, be unmanageable. In many cases, the distance adopted by CZM tends to be arbitrary, in that a typical distance of ca. 2 km inland from the mean high-water mark of ordinary spring tides (MHWOST) is used, modified according to the geography and issues relevant to a particular coastline.

Defining the seaward boundary

Designating the seaward extent of CZM is often more difficult than landward, because there are no clearly identifiable morphological limits. In reality, therefore, the limit of a country's national jurisdiction may be an obvious choice but could also be problematical where processes which influence the coast, such as shipping, fishing, or oil/gas extraction, occur seaward of this limit. In other circumstances, where no significant marine-based activity occurs, this limit may be too large, and so an alternative may be needed. Such possibilities include:

1. Using the mean low-water mark will include the intertidal zone but ignore all areas seaward of this. Clearly, such a distinction will be only useful where the marine-based activities are of only minor importance.
2. Using the edge of the continental shelf will include more of the sea area, and so cover some fisheries and sediment stores. This latter point may be important where sediment is frequently dredged for coastal sediment recharge or where dredged sediment is disposed of. Clearly, this is a geological limit which will vary between nations. Furthermore, some nations, such as Germany, Holland, and Denmark, do not have a clearly defined shelf of their own.
3. Using a seaward limit determined by some predetermined water depth is useful for the protection of marine flora or fauna, but can lead to a mobile limit in areas of high sediment mobility, or lead to several where water depth becomes deeper and then shallow again.
4. Using one of the existing internationally recognized administrative boundaries makes a useful administrative boundary. In the United Kingdom, for example, there are three such boundaries:
   (a) 3 nautical miles—limit of controlled waters.
   (b) 6 nautical miles—limit of exclusive fishing rights.
   (c) 12 nautical miles—limit of territorial waters.

The CZM process

Many nations now realize, and may have also experienced, many of the impacts associated with the diverse range of activities and interests that occur around their coastlines (see Figure C62). As a result of this and Agenda 21, many have put in place a range of management initiatives to correct and manage them. This growing realization of the problem of both user conflict and historic lack of environmental awareness on our coastlines has brought CZM from an environmental "movement" into the international arena. The advantage of doing this is the development of improved information systems and international standards, yet its drawback is that increasingly, the process has been taken away from coastal managers and put into the hands of politicians.

With the key background issues and coastal problems identified, we are now in a position to look at developing a CZM plan to combat them. First, in order to successfully carry out CZM, it is essential to get away from the traditional piecemeal approaches to management which tend to be sectorially orientated and fragmented, and instead, go for the holistic management based on the coastal cell. In this way, the problems that need managing are dealt with in the context of the coastal process "unit" and thus, the two are carried out relative to each other. However, while the rationale for developing a CZM scheme may be clearly laid out it does raise some important questions. Most important in this are questions such as who does what? Who formulates the plans? Who enforces them? Who pays? This brings us onto the next important consideration, actually turning the concept into a workable framework and plan. This represents perhaps the prime area in which the above ideology has faltered in many cases.

The construction of a management plan

It is important to remember that CZM aims to protect a stretch of coast or an estuary by allowing multi-usage by industry, members of the pubic, and developers, in such a way that impacts on the natural functioning of the coastline is minimized. There is, therefore, a great risk of conflict between these groups if the whole thing is not done well. As the ultimate purpose is to allow the citizen to enjoy the coast in a sustainable way, whether for recreation, work, or as a place to live, it becomes vital that such people have a say in the eventual management plan. The wrong approach (often used) is where a panel of experts, including ecologists, sociologists, engineers, coastal scientists, has developed CZM, with no local consultation. These plans tend to act as a decree, issuing rules and regulations, and dictating to user groups what they can and cannot do. The net outcome of many of these plans is that they meet great opposition by people who resent being told what they can and cannot do in their own neighborhood, with the result that they can sometimes be completely disregarded and so fail to work. A second important consideration is that nothing in the plan is irreversible. The CZM document is advisory and subject to frequent updating and modification to reflect changes in usage patterns, the relative impact of these uses, and the changing natural environment.

Procedure for CZM

There are a series of steps necessary for successful plan implementation:

1. Necessary preliminary decisions and investigations.
   - The coverage of the plan (defining the coastal zone: how much land, how much sea).
   - The main coastal issues for area to be studied (users, conflicts).
   - The main user groups and stakeholders.

- The main environmental processes, erosion/accretion trends, sediment budget, etc.
- Any existing plans and whether or not they are working (development plans, defense strategies, local area plans, etc.). If they are, then they can form the basis of the relevant sections of the CZM plan.
- Amount of monitoring data for the coastline that is already available. Material should aim to cover all areas of concern, such as coastal defense, fisheries, heritage and landscape, industry, transport and development, land management, pollution, recreation and tourism, and wildlife. Data for each of these areas should come from as many sources as possible, including the environment itself, historical records, scientific literature, unpublished records, and members of the public/user groups/societies, etc.

2. Issues during CZM plan constructing and implementation.
   - Investigation of coastal usage and the nature/severity of conflicts (these can be between different user groups, or between activities and natural processes).
   - Incorporation of all user groups and the public in discussions.
   - Classification of the coastline on the basis of any issues of concern and their severity (developed/undeveloped; defended/undefended, etc.). Within each of the issues categories used, it is necessary to make management decisions covering both the current issues, and the future, that is, how will future infrastructure development be managed? How will recreation be controlled? What areas will be defended?
   - On the basis of the above, recommendations should be made relating to planning guidance, use zonation, conservation designation, etc.
   - The design and construction of any structure which CZM has recommended.
   - The design and implementation of regulatory measures (set-back lines, development zones, etc.).
   - The education and persuasion of local people to adopt and apply the plan.
   - Identification of funding sources.
   - Setting up and instigation of a detailed monitoring program.
   - Identification of future coastal defense strategies and the definition of any replacement strategies.
   - Formulation of hazard warning plans (if necessary for threats of flooding, tsunami, hurricanes, etc.).
   - Notification of a date for CZM plan revision (i.e., after 5 years) when all objectives and recommendations are reviewed, any new information assessed, and the report updated and reissued as a second version.
3. Post implementation.
   - Monitor successfulness of recommendations.
   - Obtain data on natural coastal functioning.
   - Make remedial changes if plan is failing in some areas.
   - Prepare for revision and update after designated period.

If all of these are satisfactorily completed, then the final plan will be a document which will:

(a) integrate user-group needs and actions harmoniously between groups;
(b) improve the understanding of how the coast is "working;"
(c) predict how the coast is likely to react to a range of likely environmental scenarios;
(d) provide various emergency response plans to protect local interests;
(e) provide coastal defense and identify future holistic strategies for this;
(f) identify sites, and plan for future development;
(g) identify ecologically vulnerable sites for special designation and protection.

Because CZM is responding to a series of issues which have arisen due to conflicts and problems from existing activity, potential problems arise in dealing with the range of interest groups involved. Few countries operate CZM which has any back-up in law. Most plans are advisory and need the good will of the people who use the coast if they are to succeed. It is for this reason that it is critical to incorporate these people in all stages of the planning and implementation of CZM. In support of plans, however, governments tend to make it a strong recommendation (and possibly a condition of funding) that any coastal development is made with reference to any CZM document.

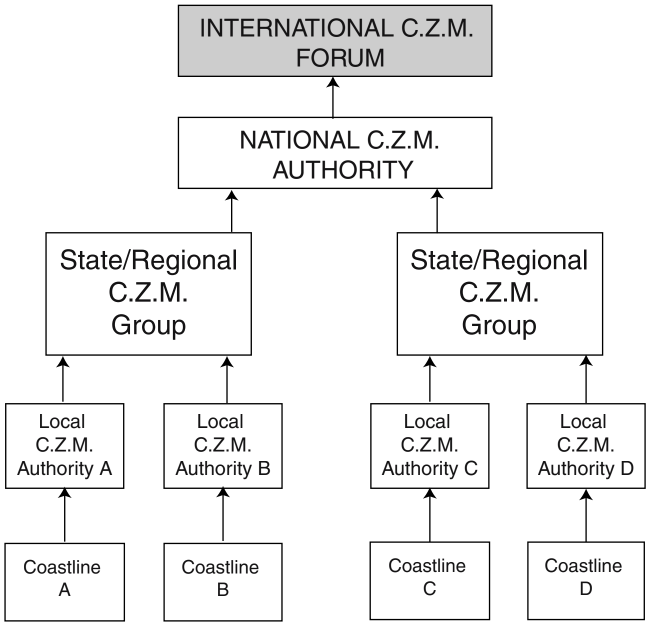

Figure C63 Groups responsible for the production and management of CZM plans.

Running the CZM process

As can be seen from the discussion above there are, potentially, a whole series of groups who have a vested interest in the coastal zone and could, therefore, claim responsibility for running CZM. At a local level, one group needs to oversee the formulation of a plan for a particular stretch of coastline from a neutral standpoint. In the United States, for example, the passing of the CZM Act in 1972, allowed state authorities to develop CZM at the local level. This process involves the appointment of local groups to develop CZM for parts of the coastline, with the relevant state acting as lead authority for all schemes under its jurisdiction (see Figure C63). In other countries, the nature of the lead group may be different but the same principals apply. Typical lead authorities and areas include regional government administrative authority boundaries, or the regional boundaries of an environmental protection agency.

In a similar manner, at a national level a single group needs to oversee the operation of state or regional groups (see Figure C63). Again this is partly to maintain both consistency between local groups and the integrity of the process; but also to liase with similar national bodies in adjacent countries (after all, a coastal cell boundary may not occur conveniently at a country's borders). A further key factor here is that many countries have complicated ownership rights in the coastal zone. In the United Kingdom, for example, the Crown owns the intertidal zone, meaning that it is common for government to get involved at this level.

By using CZM ideology, a successful coastal management authority should ...

1. ... Provide advice and elements of good practice in CZM matters.
2. ... Facilitate contact and discussion between different CZM holders.
3. ... Provide a national framework for CZM planning.
4. ... Ensure comprehensive and standardized coverage of all relevant issues.
5. ... Co-ordinate internationally with other similar national bodies.
6. ... Allocate and seek funding.
7. ... Implement CZM recommendations by making sure that they are known about and followed.

Regions for CZM

One of the main recommendations for CZM is that it should be an holistic study of a piece of coastline. This suggests that it is also necessary to link natural processes with human activities, and so the geographical area over which CZM plans are constructed needs to be based on the behavior of coastal processes. We know that sediment movements around the coast occur in set patterns, with erosion from one area leading to deposition in another and that such processes create a balance within clearly defined areas of the coast, known as coastal cells (see also *Beach Processes* and *Longshore Sediment Transport*). It is important, therefore, that CZM plans take account of these cells, as any management schemes will have to take note of sediment movement, sources, and stores so as to avoid complications with the sediment budget. For example, if one CZM plan recommended the protection of a cliff from erosion, and this supplied sediment to a beach in another CZM authority, this will cut off a major source of sediment supply. If the whole process was covered by one plan, such situations would not arise.

CZM in the longer-term

CZM represents a framework which can be used as a basis for all management plans. By using effective CZM plans, it is possible to effectively manage a coast with sensible development, reduce user conflicts, and to determine the most suitable defense types. Furthermore, the coast can be maintained in a natural form, permitting unimpeded movement of sediment and promoting wildlife habitats. This is fine for the management of human influence. Natural processes, in contrast, are harder to manage because they are less predictable and cannot read CZM plans! Regardless, however, CZM still needs to incorporate natural processes because they will, undoubtedly, impinge upon human activities and so cause conflicts to occur. Typical natural variation in coastal behavior that needs to be considered includes those associated with global warming, such as sea-level rise, increased storminess, increased frequency of extreme events, and hydrological and ecological changes in catchments.

It has been argued by some authorities that this is a rather idealist approach to CZM and could never be achieved. Certainly no one would ever suggest that all the world's coasts have to be naturalized, but it is clear that many parts can. What is perhaps the most frustrating factor in all of this is that huge amounts of money are being spent on outdated forms of defense, when less money could be spent using newer ideas and methods to protect the coast more naturally, more effectively, and for longer, before new investment is needed. The underlying problem lies in lack of education. Governments and national CZM bodies need to inform and convince their populations that to give land back to the sea is not such a bad thing, and in many cases, can be a most efficient use of tax-payers' money.

Further reading sources

As well as cross-referencing to other sections in this book, other key texts may also be of use to the reader as a way of expanding on the information given here. The book by Kay and Alder (1999) covers the process of CZM in some detail and takes the reader through the process, using examples. Similarly, the United Nations Environment Program produced a set of guidelines for integrated management of coastal zones in 1995. A summary of the CZM process is given by French (1997) while details on the types of coastal defense structures, including arguments for and against their usage, is given in French (2001).

COASTLINE CHANGES

Coastline changes (here defined as changes on the high-tide shoreline) can be mapped and measured on various coastal sectors over time scales ranging from a few hours or days (related to tidal cycles, weather events, earthquakes or tsunamis) to long-term trends over decades or centuries. Evidence of changes can be obtained from comparisons of dated historical maps, charts, air photographs, and satellite imagery with the present coastal configuration. Such evidence is available on many coasts over the past century, but in some countries, such as Britain and Denmark, maps and charts surveyed around the beginning of the 19th century permit the determination of changes over longer periods. In the Mediterranean region, and locally elsewhere, there is sporadic evidence of coastline changes over periods of at least 2,000 years, using historical descriptions and dated archaeological sites. On some coasts there is geological evidence of changes over the past 6,000 years, since the Late Quaternary marine transgression brought the world's oceans to approximately their present levels: cliffed coasts have receded and depositional coasts have advanced, and some coasts show evidence of alternations of advance and retreat during this period.

Advance or retreat of a coastline may result from combinations of erosion and deposition, emergence and submergence (Figure C64). Coastline changes are usually expressed in linear terms, as the extent of advance or retreat measured at right angles to the land margin, but they can also be considered in areal terms, as the extent of land gained or lost on a coastal sector, or volumetric terms, as the quantity of material added to, or lost from, the coast. Measurements made over varying periods are commonly averaged as gains or losses per year, but coastline changes may be sudden or intermittent rather than steady and gradual. Attempts have been made to document the advance or recession of coastlines in several countries: the Royal Commission on Coast Erosion in Britain (1907–11), the National "Shoreline" Study in the United States (US Army Corps of Engineers, 1971), and the survey of the Netherlands coastline by Edelman (1977); and in 1984 the International Geographical Union's Commission

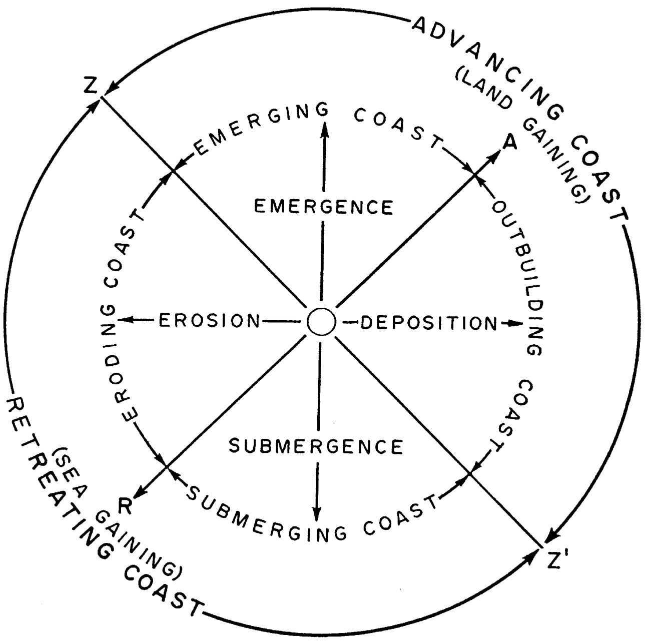

Figure C64 Analysis of coastline changes, based on Valentin (1952), ZZ′ indicates a stable coastline where erosion has been offset by emergence or deposition by submergence, or where no changes have taken place (O).

on the Coastal Environment completed a global review of coastline changes over the preceding century (Bird, 1985). More recently there has been monitoring of changes on particular coastlines using remote sensing and photogrammetry, but this has not yet been pursued systematically around the world's coastline.

Some coastlines have changed very rapidly (advance or retreat >100 m/year), but changes of more than 10 m/year are unusual, and few have changed by more than +/−1 m/year. If, as is predicted, a worldwide sea-level rise develops and accelerates as a consequence of global climatic warming resulting from the enhanced greenhouse effect, submergence and erosion will become widespread, and coastline changes are likely to intensify (Bird, 1993). Coastline changes can be considered in the following categories.

Cliffed coastlines

Cliffs in hard, massive rocks have changed little over the past century, even where they are exposed to stormy seas, but cliffs in soft materials can be cut back very rapidly. Sample rates of cliff retreat were tabulated by Sunamura (1992: Appendix 2). Recession of up to a meter a day has been measured on cliffs cut in unconsolidated volcanic ash, as on the Isla San Benedicto, off the Pacific coast of Mexico, and cliffs cut in alluvium and peat weakened by seasonal freeze–thaw oscillations have retreated up to 100 m in a few summer months before a winter cover of snow and ice briefly stabilized them. On parts of the Polish coast, cliffs cut in glacial drift deposits have shown an average recession of a meter a year, but have lost up to 5 m in a single storm, and similar rates have been documented on the east coast of England, notably on the Holderness cliffs. Recession of cliffs cut in soft formations is often accelerated by slumping and erosion by runoff after heavy rain or from melting snow.

Glaciated coastlines

Where glaciers and ice sheets reach the sea, as in Icy Bay, Alaska, southernmost Chile, and sectors around the Antarctic continent, the coastline may advance with forward movement of the ice, or retreat as the result of melting. Ice cliffs have receded at rates of up to a kilometer per year in Antarctica as the result of melting and calving induced by recent climatic warming. In the Gulf of Alaska, however, rivers augmented by glacifluvial outwash from melting ice have advanced parts of the coastline by more than a kilometer in recent decades by building deltas and prograding beach ridge plains. Rapid progradation occurred on the southeast coast of Iceland when melting of ice, hastened by volcanic eruptions, generated torrential outwash, delivering large quantities of sand and gravel to prograde beaches and build barriers and spits.

Emerging and submerging coastlines

Where land uplift has occurred the coastline has advanced. Isostatic uplift of formerly glaciated areas in Scandinavia and northern Canada has led to the emergence of former nearshore sea floors, as in the Gulf of Bothnia, where the coastlines of Sweden and Finland have advanced more than 100 m over the past century. On some sectors progradation has been augmented by shoreward drifting of sea floor sediment, notably sand from submerged eskers, to build up beaches. Sudden emergence during earthquakes has advanced coastlines on Montague Island, Alaska (1964), Talcahuano in Chile (observed by Charles Darwin during the voyage of the *Beagle* in 1835), the Orontes delta in Turkey (1958), the Makran coast in Pakistan (1945), Cheduba Island in Burma (1762), Tokyo Bay in Japan (1923), and Wellington (1855) and Napier (1931) in New Zealand. Emergence occurred during the phase of sea-level lowering between 1929 and 1977 on the coasts of the Caspian Sea, when islands expanded and became attached to the mainland, while shoals emerged as islands.

Submergence results in coastline recession, except on vertical cliffs or where it is compensated by coastal deposition. Land subsidence in the vicinity of the Mississippi has led to the submergence and erosion of former subdelta coastlines, and land subsidence in the Netherlands, augmenting the effects of a rising sea level, would have submerged a large part of the country had the coastline not been maintained by seawalls and reclamation works. Subsidence in the Venice region, due partly to subsurface compaction and the extraction of groundwater, has accelerated beach retreat on the Lidi barriers and diminished the extent of salt marshes in the Venice Lagoon. Increasing depth and frequency of storm surge flooding here indicates that submergence is partly due to a rising sea level in the Adriatic. Since 1977 the Caspian Sea has been rising and the coastline receding, much of the coastal land that emerged previously having been inundated. Sandy barriers have formed and are migrating landward (Ignatov *et al.*, 1993).

Sudden submergence during earthquakes led to coastline recession at Anchorage in Alaska (1964), in southern Colombia (1979), at Concepcion in Chile (1960), and on the Indus delta (1819, 1845). Tsunamis following sea floor mass movements have caused sudden recession of the Valdez delta in Alaska and along the beach-fringed Ivory Coast.

A correlation has been noted between alternations of water level in the Great Lakes and the advance or retreat of bordering coastlines. During phases of falling lake level the coastline advances as the result of emergence and shoreward drifting of sand to accreting beaches, while during phases of rising lake level the coastline retreats as the result of submergence, beach erosion, and increased cliff recession.

Volcanic coastlines

Volcanic eruptions prograde the coastlines where lava and ash are deposited, as on the southeast coast of Hawaii. They also augment river sediment loads, leading to the advance of deltaic coasts, as on the Rio Samala in Guatemala, and the progradation of beaches, as in the Bay of Plenty, New Zealand after the Tarawere eruption in 1886 and the south coast of Java after recurrent eruptions of the Merapi volcano.

Some oceanic islands are entirely of volcanic origin. Surtsey, off the south coast of Iceland, was built by volcanic eruptions in 1966–67, and has since been reshaped by the rapid recession of cliffs cut in lava and ash on the more exposed southern coastline, generating sand and gravel that have drifted round to accumulate on a triangular northern foreland. The explosive eruption of Krakatau Island, Indonesia, in 1883 left caldera-side cliffs and a surrounding mantle of ash which initially advanced the coastline, but has since been cut back as cliffs receding at up to 6.6 m/year.

Mass movements

Coastal landslides and rock falls temporarily prograde the coastline, forming lobes and fans that are subsequently cliffed and cut back by marine erosion. This sequence has been documented at Tillamook Head in Oregon, Pacific Palisades, California, Black Ven and Fairy Dell in Lyme Bay, Dorset, Rosnaes, and Helgenaes in Denmark, and on the Bulgarian and Crimean coasts of the Black Sea. On the Dorset coast erosion pin measurements have shown intermittent mudslide movements totaling 8 cm in 30 h, graded movements of about 3.5 m in 17 h and surge movements of up to 3 m in 20 min (Allison and Brunsden, 1990). Some landslide lobes have persisted long-enough to act as natural breakwaters, intercepting drifting beach sediment and causing local progradation, as at Golden Cap in Dorset.

Deltaic coastlines

The arrival of large quantities of fluvial sediment at the mouth of a river has led to rapid accretion of sectors of deltaic shoreline, with rates of up to 80 m/year at the south-west Pass of the Mississippi delta and up to 70 m/year on the Irrawaddy delta. On the north coast of Java deltas fed by sediment-laden floodwaters have prograded by up to 180 m/year. Progradation results from deposition of fluvial sediment on river banks to form natural levees, prolonged seaward as sedimentary jetties, and the delivery of sand and gravel to prograde bordering beaches. In addition, there is often a seaward advance of bordering salt marshes, as on the Fraser delta in Canada, or mangrove swamps, as on most tropical deltas, and sedimentation within these eventually builds up new land at high tide level.

Even where deltas have not formed, sediment supplied by rivers can prograde adjacent coastlines. Sand from the Columbia River on the Pacific coast of the United States was distributed northward and southward to prograde Long Beach and the Clatsop Plains. Fluvially nourished beach progradation has also occurred on the west coast of South Island, New Zealand and in north-east Queensland.

Where the mouth of a river is diverted during a major flood, the coastline that had formerly prograded begins to recede, while new progradation develops at the diverted outlet. This has happened on the Huanghe in China (1852), the Rio Sinu in Colombia (1942), the Ceyhan in Turkey (1935), the Medjerda in Tunisia (1973), and the Cimanuk in Java (1947). Artificial diversion of a river mouth by canal cutting has had similar effects on the Brazos delta in Texas (1938), the Rioni in the eastern Black Sea (1939), the Shinano in Japan (1922), and the Cidurian in Java (1927).

Progradation of deltas and coastal plains has accelerated where river sediment yields have increased as the result of soil erosion in their catchments, due to deforestation, overgrazing, or cultivation of steep hinterlands. In Java this has led to rapid progradation of deltas in Jakarta Bay and the Segara Anakan on the south coast is shrinking rapidly as the result of increased sediment input from the Citanduy river. On some coasts, progradation has followed an increase in fluvial sediment yield due to hinterland mining. Hydraulic sluicing in the Sierra Nevada a century ago led to the growth of the Sacramento delta into San Francisco Bay, and open-cast mining has resulted in beach progradation at Par and Pentewan in Cornwall, Chanaral in Chile, Jaba on Bougainville, and around New Caledonia, especially on the Thio and Népoui deltas.

Reduction in fluvial sediment yield to the coast following the building of dams on rivers has led to the onset or acceleration of erosion on many deltas. The best-known example is the Nile delta coastline, which

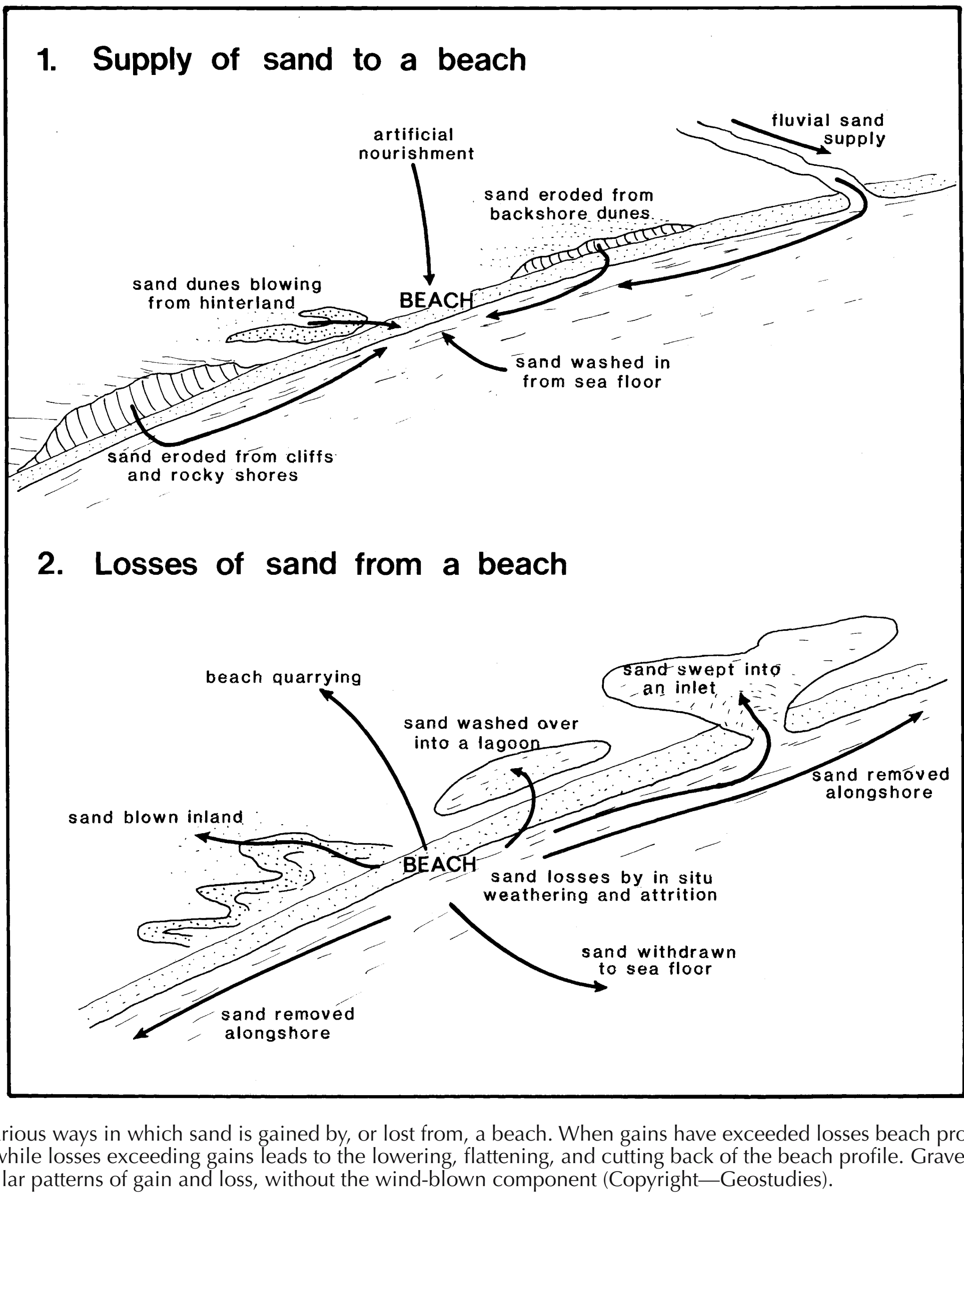

Figure C65 The various ways in which sand is gained by, or lost from, a beach. When gains have exceeded losses beach progradation is likely to occur, while losses exceeding gains leads to the lowering, flattening, and cutting back of the beach profile. Gravel (shingle) beaches show similar patterns of gain and loss, without the wind-blown component (Copyright—Geostudies).

Table C13 The causes of beach erosion

1. Submergence and increased wave attack as the result of a rise in sea level or coastal or nearshore land subsidence: the "Bruun Rule."
2. Diminution of fluvial sand and shingle supply to the coast as a result of reduced runoff or sediment yield from a river catchment (e.g., because of a lower rainfall, or dam construction leading to sand entrapment in reservoirs, or successful revegetation and soil conservation works), or the natural or artificial diversion of a river outlet, or because of the removal of much or all of the weathered mantle from slopes in the river catchments, exposing bare rock that yields little or no sediment to runoff.
3. Reduction in sand and shingle supply eroded from cliffs or shore outcrops (e.g., because of diminished runoff, stabilization of landslides, a decline in the strength and frequency of wave attack, or the building of seawalls to halt cliff recession), or the exposure by cliff recession of formations (such as massive resistant rock, or soft silts and clays) that do not yield beach-forming sediment.
4. Reduction of sand supply to the shore where dunes that had been moving from inland are stabilized, either by natural vegetation colonization or by conservation works, or where the sand supply from this source has run out.
5. Diminution of sand and shingle supply washed in by waves and currents from the adjacent seafloor, either because the supply has declined (e.g., where ecological changes have reduced the production of shelly or other biogenic material), because the transverse profile has attained a concave or steeply declining form which no longer permits shoreward drifting, or because such drifting has been impeded by increased growth of seagrasses or other marine vegetation.
6. Removal of sand and shingle from the beach by quarrying or the extraction of mineral deposits, or losses from intensively used recreational beaches, for example, as the result of beach cleaning operations.
7. Increased wave energy reaching the shore because of deepening of nearshore water (e.g., where a bar or shoal has drifted away, where seagrass vegetation has disappeared, where dredging has taken place, or where the seafloor has subsided).
8. Reduction in sand and shingle supply from alongshore sources as the result of interception (e.g., by a constructed breakwater or groins) or interruption by the growth of a fringing coral reef or some other depositional feature.
9. Increased losses of sand and shingle alongshore as a result of a change in the angle of incidence of waves (e.g., as the result of the growth or removal of a shoal, reef, island, or foreland, or because of breakwater construction or a change in wind regime).
10. Intensification of obliquely incident wave attack as the result of the lowering of the beach face on an adjacent sector (e.g., as the result of dredging, or scour due to wave reflection induced by seawall or boulder rampart construction or beach mining).
11. Increased losses of sand from the beach to the backshore and hinterland areas by onshore wind action, notably where backshore dunes have lost their retaining vegetation cover and drifted inland, lowering the terrain immediately behind the beach and thus reducing the volume of sand to be removed to achieve coastline recession.
12. Increased wave attack due to a climatic change that has produced a higher frequency, duration, or severity of storms in coastal waters.
13. Diminution in the caliber of beach and nearshore material as the result of attrition by wave agitation, leading to winnowing and losses of increasingly fine sediment from the beach, either landward into backshore dunes or seaward to bars and bottom deposits.
14. Diminution of beach volume by weathering, solution, attrition, or impaction (e.g., by heavy vehicle traffic), resulting in lowering of the beach face and coastline recession.
15. Increased scour by waves reflected from backshore structures, such as seawalls or boulder ramparts, leading to reduction of the beach that fronted them.
16. Migration of beach lobes or forelands as the result of longshore drifting—there is progradation as these features arrive at a point on the beach, followed by erosion as they move away downdrift.
17. A rise in the water table within the beach, due to increased rainfall or local drainage modification, rendering the beach sand wetter and thus more readily eroded.
18. Increased losses of beach material due to outwashing by streams or from drains carrying an augmented discharge of water, either because of increased rainfall or from melting snow or ice, or because of natural or artificial modifications (such as urbanization) in the catchments that have increased runoff through beaches.
19. Intensification of wave action where tide range has diminished, as on the shores of a bay or lagoon that has been partly enclosed by natural or artificial structures, impeding tidal ventilation.
20. Erosion where driftwood deposited on the beach is jostled by wave action, leading to erosion of sand and gravel from the beach face.
21. On Arctic coast beaches the removal of a protective sea ice fringe by melting, so that waves reach the beach (e.g., for a longer summer period).

has shown recession of up to 40 m/year since the completion of the Aswan High Dam upstream in 1964. Similar erosion has been documented on the Rhône delta in France. Deltaic coastline erosion has also followed extraction of sand and gravel from river channels or the reduction of runoff by irrigation schemes, soil conservation works, and afforestation in catchments, notably in Italy, Greece, and Turkey.

Beach-fringed coastlines

Changes on beach-fringed coastlines result from variations in the rate of supply of sediment from various sources or in losses from the beach system, as shown in Figure C65. Progradation of beaches and growth of spits supplied with sand and gravel from the erosion of nearby cliffs is well illustrated on coasts dominated by glacial drift deposits, as on Puget Sound on the west coast of North America, New England and the Canadian Maritime Provinces on the east coast of North America, and the coasts of the North Sea and the southern Baltic. Beach erosion can occur when the sediment supply from eroding cliffs diminishes as the result of seawall construction or stabilization, or a reduction in incident wave energy, as at Bournemouth and Brighton in southern England, the Melbourne Bayside coast on Port Phillip Bay and Byobugaura in Japan.

The spilling of waste from coastal quarries has prograded beaches, as at Hoed in Denmark, Porthoustock in Cornwall, and Rapid Bay in South Australia. At Workington in Cumbria, the dumping of waste from coal mines and steel works has locally augmented beaches. On the other hand, quarrying of sand, gravel, or shelly material from beaches has not only depleted them, but has led to accelerated erosion on nearby cliffs, as at West Bay and Seatown in Dorset, Gunwalloe in Cornwall, Hallsands in Devon, and St. Ouen's Bay in Jersey.

Information supplied to the International Geographical Union's Commission on the Coastal Environment in 1972–84 indicated that about 20% of the world's coastline consists of sandy beaches backed by beach ridges, dunes, or other low-lying sandy terrain. Of this, more than 70% had shown net erosion over the preceding few decades and less than 10% sustained pro- gradation, the remaining 20–30% having been stable, or shown no measurable change. The initiation or acceleration of beach erosion was attributed to several factors, listed in Table C13. The relative importance of these factors differs from one coastal sector to another, but analysis of particular eroding beaches have shown that usually more than one has contributed. A detailed discussion is provided in Bird (1996).

Swampy coasts

The seaward margins of salt marshes and mangrove swamps (generally close to the mid-tide shoreline) have advanced seaward where the sediment supply has been abundant, particularly on coasts sheltered from strong wave action and on the shores of prograding deltas. Sedimentation within the widening salt marshes and swamps eventually builds them up to high-tide level, so that the coastline advances. Extensive salt marsh progradation has occurred around Chesapeake Bay during the past 350 years, and has been attributed to increased sediment yields from inflowing rivers as the result of soil erosion in their catchments. Mangrove swamps have prograded on some tropical coasts, particularly near growing deltas, as on the shores of southern and eastern Kalimantan in Indonesia. On the west coast of Peninsular Malaysia, mangroves spread seaward by up to 54 m/year between 1914 and 1929 when sediment yields from agriculture and mining were high, but after dams were built on rivers and tin mining activity reduced erosion became prevalent (Kamaludin, 1993).

On many coasts the seaward margins of salt marshes and mangrove swamps have retreated in recent decades, so that they terminate in small cliffs, fronted by tidal mudflats or sandflats. In southern England and north-western France, and in New England, seaward cliffing is very extensive, and similar features are seen on mangrove swamps on the west coast of Peninsular Malaysia, in Thailand, and the Philippines, possibly in response to a relative sea-level rise in recent decades.

Artificial coastlines

Many coastlines have become artificial, especially during the past century, as the result of the construction of seawalls, boulder ramparts, and other structures intended to halt erosion on cliffs, beaches, and deltas. Spits such as Ediz Hook in Washington and Sandy Hook in New Jersey, previously variable in configuration, have been armoured with seawalls or boulder ramparts. Breakwaters built to shelter harbors or form marinas are now widespread on the coasts of North America, Europe, and the Mediterranean, and some coastal areas have been embanked and reclaimed for ports, industry, and urban development, notably in the Netherlands, China, Singapore, and Tokyo Bay. Reclaimed areas are typically bordered seaward by earth banks or concrete walls, which have become extensive on the coasts of Britain, Europe, and Southeast Asia, particularly Japan, where about a quarter of the coastline is armoured with seawalls and tetrapods (Walker and Mossa, 1986).

The building of artificial structures is still a widely preferred response to erosion and submergence of coastlines, but increasing use is being made of beach nourishment as a means of defending coastlines against erosion which also provides a recreational resource of scenic value.

COASTS, COASTLINES, SHORES, AND SHORELINES

Origins of terms

The word shore comes from the middle English word *Schöre* that came from the middle low German word Schöre. Shore is also an archaic past tense and past participle of shear. In the German language, the verb shear is scheren (Betteridge, 1965). Schere (or shear) means shearing, cutting, or a point of division. Thus, the middle English and low German schöre translates as the sheared line (or shoreline) between the ocean and the land. In the German language, schöre is a line and not a region. However, the English usage of shore (from schöre) became a description of the *area* adjacent to a body of water. Webster's unabridged dictionary defines shore as "land at or near the edge of a body of water" (McKechnie, 1979). The term shoreline is used to describe the *line* marking the edge of a body of water.

The German language actually uses a different word to describe the strip of land adjacent to a body of water. The German word *ufer* is used for bank, shore, beach, or edge. Thus, ufer is more akin to the English shore, and schöre is more akin to the English shoreline.

The word coast comes from the middle English and old French word *coste* meaning rib, hill, or shore. In Webster's unabridged dictionary, coast, is the edge or margin of land next to the sea. The close similarities between the words shore, shoreline, coast, and coastline have lead to many ambiguous and inaccurate usage that are unacceptable for scientific dialogue. Scientific usage of these terms are very specific and require explanations related to their description and use.

Geometric attributes

Coasts, coastlines, shores, and shorelines have geometric characteristics that have precise denotations in scientific nomenclature. Casual usage of the words line, surface, and prism is not appropriate because they are too imprecise or ambiguous. Below are formal definitions of these terms as they should be used in scientific dialogue.

Shorelines and coastlines are lines designating the boundaries between fluid and solid media. A *line* is a one-dimensional construct used to signify the sheared edge between two different materials. A line has length but not breadth. The term coastline and shoreline are both boundary lines between water and land. The term coastline is generally used to describe the approximate boundaries at relatively large spatial scales. Shoreline is used to describe the precise location of the boundary between land and water.

Strips of land adjacent to shorelines and coastlines are called shores and coasts, respectively. Shores and coasts are bounded on one side by a body of water and on the other by a change in terrain to an upland landscape. The *surfaces* of these land strips are two-dimensional features having length and breadth but no thickness. While shore surfaces may have relief, the relief does not give the surface a thickness that implies a volume. The relief only describes elevation changes on a two-dimensional surface. The main difference between a shore and a coast is one of scale. Shores are relatively narrow strips of land adjacent to water bodies, whereas, coasts generally depict relatively broad bands of land adjacent to water bodies.

In a geologic context, processes of erosion, transportation, and deposition sculpt the relief on land surfaces. These processes involve the removal, transport, or deposition of a volume or mass of material, and imply a three-dimensional quality of the shore. The shore must be considered a three-dimensional prism when considering the processes that build or destroy it.

Shore surfaces are two-dimensional areas capping the three-dimensional shore prism. Shorelines are one-dimensional boundaries at the edge of the shore. Generally, the terms shore and coast are used to describe the prism of material below the elongate land surfaces at the edge of a body of water.

Coasts and coastlines

The terms *coast* and *coastline* are used for describing the boundary between the land and the water at broad regional scales. The coast is a strip of land of variable width that extends from a body of water inland to a regional break in terrain features. The coastline is the line that forms the boundary between the coast and a major body of water.

At regional to global scales, the term coastline (rather than shoreline) is used to differentiate the boundaries between the land and the sea. At these scales, changes in margin shapes and boundary orientations are used to describe continents, oceans, and marginal seas. Even at smaller regional scales, coastlines are used to describe the marginal shapes and boundary orientations of estuaries, bays, deltas, barrier islands, and spits. Coastlines may be accurately portrayed on maps having global or regional scales, but the widths of lines constructed at these scales are too large to locate the precise physical position of the sheared boundary between land and water. For example, a volcanic island on a very broad-scale map may look elliptical in shape, but upon closer inspection the border between the land and the sea may illustrate a serrated boundary created by headlands and pocket bays (Figure C66). The same effect would occur at regions of long straight coasts where the precise water boundaries of small estuaries and bays are scarcely discernible at large scales. The broad-scale maps "smooth-out" small coastal irregularities. Thus, the coastline is generally not as precise as the associated shoreline that traces the land–sea boundary at much finer detail. The coastline is a line connecting the most seaward promontories into the sea. Consequently, a length of shoreline is generally much longer than the associated length of coastline (Figure C66).

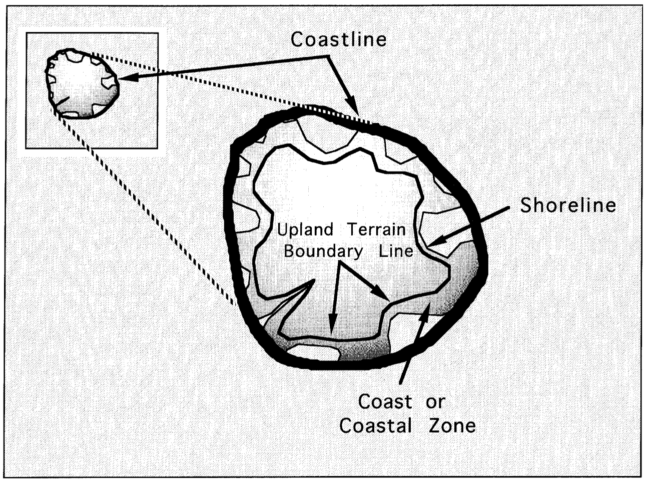

Figure C66 Hypothetical planview of a volcanic island showing the apparent shapes of the island from a broad-scale view and a close-scale view. The coastline is oval-shaped, whereas the shoreline illustrates all of the shore irregularities.

Since the coast is a strip of land adjacent to the coastline its precise boundaries are indefinite and general. The coast is the strip of land between the coastline and a change in terrain to upland landscapes. The coast includes specific coastal environments or landscapes that are distinct from the upland (e.g., bays, estuaries, coastal dunes, maritime forests, maritime climates, tidal waters, etc.).

At early periods in the Earth's history, there were no images or surveyed maps to precisely locate land–water boundaries. Boundaries could only be deducted from other indirect sources of data. Coastlines from these data sources have imprecise locations with respect to their spatial and temporal setting. For example, at periods of 10^4–10^5 years, water volumes in the ocean fluctuate in response to the expansion or contraction of continental glaciers. Glacial waning increases the volume of the sea causing water to transgress over the land surface, while glacial expansion causes water to regress off the land surface. The vertical shift in water level produces horizontal shifts in the position of the boundary between the two media. A paleogeographic depiction of the coastline during these periods may be reconstructed using terrain slope and sea-level projections. These are generalized locations of the boundaries, rather than precise paleo-shoreline locations. A time series of coastline positions on a map may be used to illustrate the regression of water off a land surface, or the transgression of water over a land surface. Thus, temporal scaling also influences our interpretation of coasts and other large-scale areas. Since short-term events generally produce small changes to coastal landscapes, the record of these events cannot be observed at large coastal scales. At broad spatial scales, only large changes produced over long temporal intervals can be observed.

As the sea transgresses over, or regresses off a land surface, the process necessitates a lateral shift in the position of the coastline. At large spatial and temporal scales, the antecedent topography might be considered a passive surface being inundated by rising water. The process is "morphostatic," meaning that the coastline shift is driven by flooding of a surface rather than erosional sculpting of the surface.

Shore and shorelines

The terms *shore* and *shoreline* are used for describing the boundary between the land and the water at very fine local scales. The shore is a strip of land of indefinite width that extends inland from a body of water. The terrain of the shore is primarily composed of forms generated by active or recent marine and marine-related processes. The landscape of the shore generally has a unique plant community draped over the terrain. The landward limit of the shore is located at a boundary separating these terrains and plant communities from upland landscapes. The shore is a dynamic area that has many ephemeral forms sculptured by a variety of marine processes. The landward part of the shore that is primarily molded by aeolian processes is called the

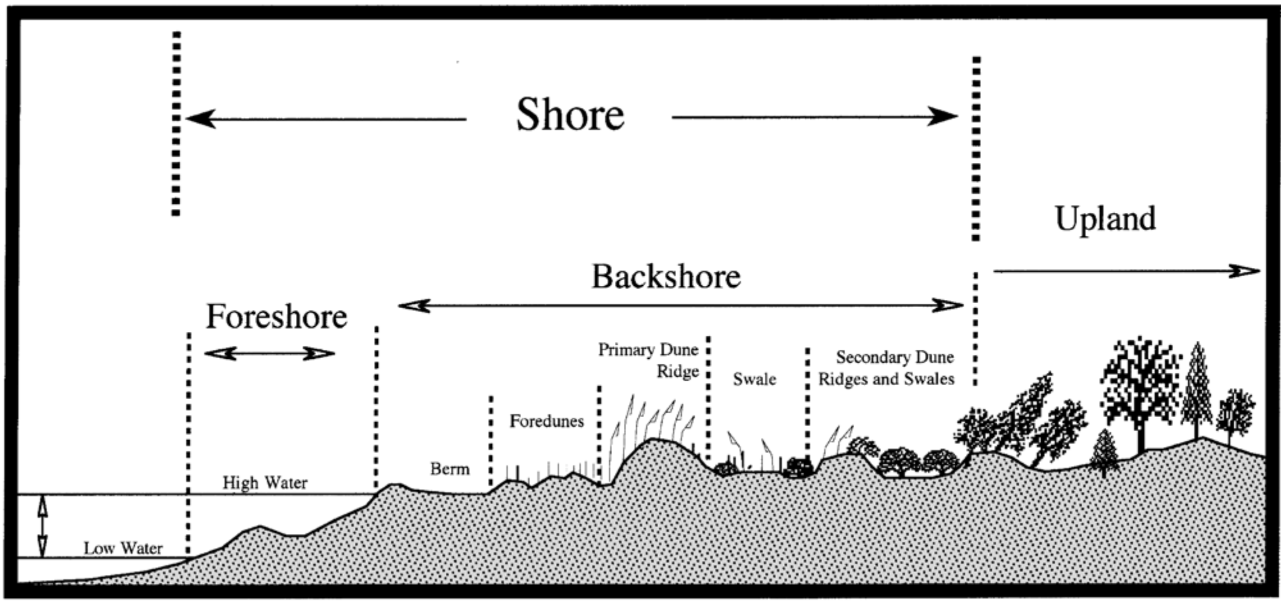

Figure C67 Hypothetical cross section of a shore showing the classification into backshore and foreshore based on topographic features and water levels.

backshore (Figure C67). The surface of the backshore often has a succession of plants draped over a chronosequence of dune ridges between the water's edge and the upland areas. The berm and foredune areas of the backshore are located on shifting sandy surfaces that are sparsely vegetated with specialized herbaceous plants and grasses that tolerate intense light, heat, drought, burial, and salt spray. Dune ridges and swales are located on relatively stable surfaces that have dense concentrations of stress-tolerant grasses and shrubs.

Common grasses that colonize dune surfaces in warm temperate zones include sea oats (*Uniola paniculata*), American beach grass (*Ammophilia breviligulata*), and running beach grass (*Panicum amarum*). Common shrubs in the swales between dune ridges include wax myrtle (*Myrica cerifera*), bayberry (*Myrica pensylvanica*), and silverling (*Baccharis haliminfolia*).

The seaward part of the shore is called the foreshore, which is defined by tidal range (Figure C67). The high-water elevation defines the upper limits of the foreshore, and the low-water elevation defines the lower limit of the foreshore (a more comprehensive description of foreshore zones is described below). The foreshore is the portion of the shore where wave-energy is dissipated on the land. The foreshore is sculptured by the dispersion and shifting of granular particles by the energy of waves and littoral currents. The resultant patterns of erosion and accretion make the foreshore one of the most dynamic areas of the shore.

Shorelines

The shoreline is a line that demarks the precise boundary between the shore and the water. Since the position of the water shifts with the elevation of the tide, then the position of the line at high tide is different from its position at low tide. On Figure C67 it is apparent that there is a high-water shoreline at high tide and a low-water shoreline at low tide. Sea level is generally defined as the elevation halfway between the high- and low-water elevations, and the generic "shoreline" is meant to describe the line associated with sea level, rather with high or low tide. However, during the rise and fall of the tide, there are an infinite number of shorelines between high tide and low tide.

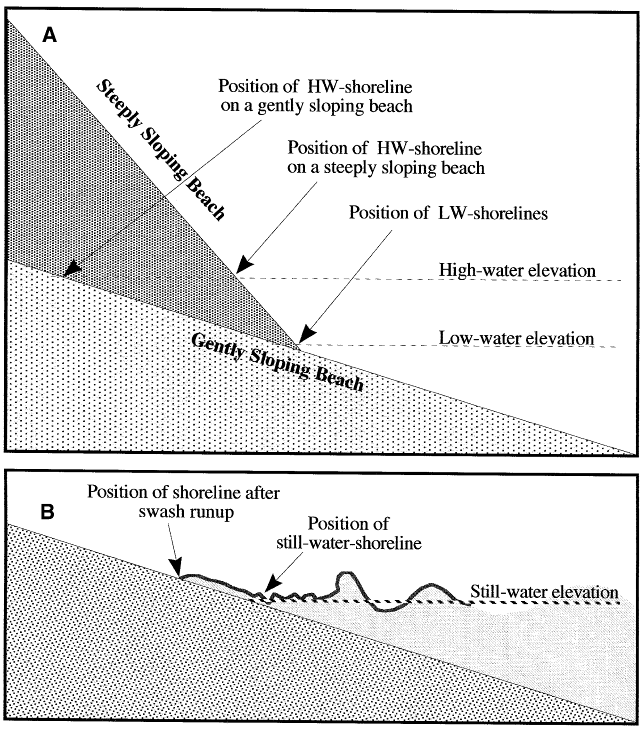

Figure C68 (A) Cross-sectional sketch of a steeply and gently sloping shore. Given a constant vertical tidal range, the horizontal spreads of water across a gently sloping surface is considerably greater than across a steeply sloping surface. (B) After a wave breaks, the rush of water up the beachface (swash) shifts the location of an observed shoreline landward of the projected still-water-shoreline.

The elevations of high tide and low tide are not constant. They are dependent on changes in the magnitudes of gravitational and centrifugal forces pulling on the water surface. Changes in the gravitational forces result from the motion and changes in the relative alignments of the Sun, the moon, and the Earth. When the positions of the Earth, moon, and Sun have additive gravitational effects, then the greatest tidal bulges occur (spring tides). A favorable alignment for gravitational addition occurs twice a month producing spring tides. However, the gravitational forces offset each other twice a month producing, small tidal ranges (neap tides). The elevations of each progressive high and low tide are different with the incremental changes in the resultant gravitational forces of the three celestial bodies. In fact, there are over 140 factors involved in the generation and alteration of the tides. The gravitational force of the moon plays a major role in tidal variations. However, the moons orbit around the Earth is slightly irregular and it takes about 9.3 years for the plane of the moon's orbit to shift above and then below the plane of the solar ecliptic. The cycle is completed in about 18.6 years. These factors can be used to mathematically predict the tidal ranges. An average of all of the high tides and low tides over 18.6 years provides the mean-high and mean-low tide elevations for those predictions. The relationships also can be used to predict the elevations of water level at any position in the 18.6-year cycle, but it assumes no elevation changes are caused by atmospheric conditions. The 18.6-year mean of all high-tide elevations is called mean high water (MHW), the 18.6-year mean of all low-tide elevations is called mean low water (MLW), and the 18.6-year mean of all sea-level elevations is called mean sea level (MSL). There are also means for spring high (MHWS) and spring low tides (MLWS), as well as neap high (MHWN) and neap low tides (MLWN). These temporally averaged elevations can also be affixed to associated sheared lines (shorelines) between the ocean and the land. To standardize the use of the term shoreline, it is appropriate to affix it to a specific water level, such as mean high-water shoreline (MHW-shoreline), mean sea-level shoreline (MSL-shoreline), mean low-water shoreline (MLW-shoreline).

Atmospheric conditions also have influences above and beyond the gravitational effects described above. Low-pressure systems can elevate water surfaces, winds can pile water on the shore, and waves may runup on a shore above the still-water elevation of the sea. Daily effects of these atmospheric events on water level result in "actual" water levels that are generally different from predicted values.

The slope of the shore profile also has a very important influence on the how far water levels may shift up the shore surface (Figure C68). Typically, beaches have slopes between 1 and 3°. At gentle slopes, a 1 m rise in water level related to atmospheric conditions may cause the position of a shoreline to shift landward 188 m. This type of shift can be accomplished without any addition or removal of sediment from the shore ("morphostatics").

Breaking waves are other processes that influence the position of the wet and dry boundary at a shore (Figure C68(B)). As waves break at the toe of the shore, the wave-bores surge forward and strike the beachface. The momentum of the water continues forward and the water (called swash) rushes up the beach profile. Swash often rises 1.5 times the wave height above the still water level (SWL). Since wave climate is spatially and temporally variable, then the average elevation of the swash limit is seasonally different, and different along dissimilar areas of the coast. If an average wave height can be estimated for a region's wave climate, then a mean swash elevation (MSE) can be estimated for any reach of shore. Similarly, a standardized mean swash shoreline would represent the wet/dry boundary of a shore influenced by its associated wave climate. Thus, on any given day the predicted water levels from gravitational tides are rarely accurate because of the variability in atmospheric phenomena. Field and remote observations of shoreline locations are temporally very specific, and the sheared line between the water and the land is generally not related to a specific standardized elevation.

Geologists and oceanographers do not agree on the placement of shorelines on maps and charts. Since geologists are primarily interested in depicting land surfaces, the high-water shoreline is generally used as the datum for these maps. Topographic quadrangles published by the US Geological Survey (USGS) place the shoreline at mean high water or at the North American Geodetic Datum (NAVD 29) which is generally very close to mean high water. On the other hand, the National Oceanographic and Atmospheric Administration (NOAA) publishes charts that are primarily for navigational purposes. Oceanographic cartographers consider any surface that is subaerially exposed as land whether it is always exposed or only exposed periodically by tidal inundation. The datum (and shoreline) for NOAA charts is positioned at MLW or mean lowest low water. It is for this reason that the intertidal zones on maps and charts are often not surveyed, and are simply described as flats and marsh without elevation data.

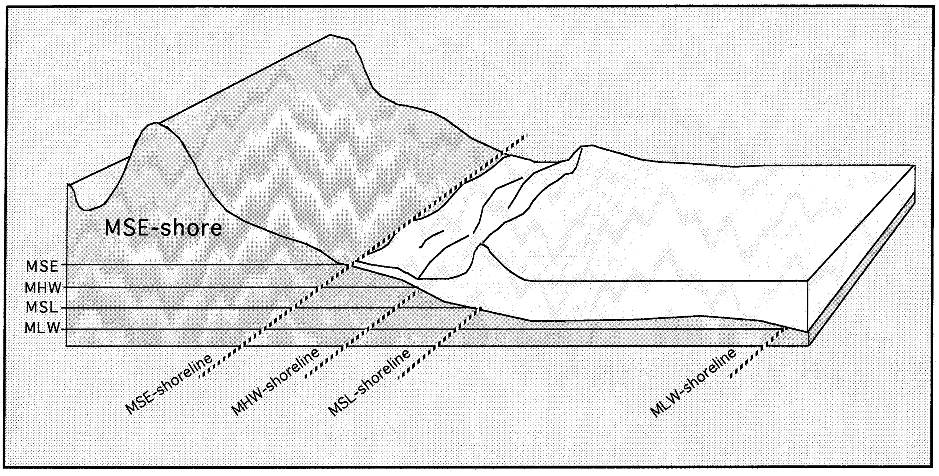

Figure C69 A block-diagram sketch illustrating the relationships among four "mean" water levels, four mean shorelines, and four shore prisms located above each horizon.

Shoreline dynamics

Short- and long-term processes govern the positions of shorelines. A change in shore form created by shifting volumes of sediment is called morphodynamics. The processes of sediment erosion, transportation, and deposition along the shore often result in shifts in shoreline positions. Magnitudes of shoreline shift are expressed as linear units (e.g., meters or feet) where negative values often indicate landward retreat and positive values indicate seaward shifts. During short-term events, shorelines at different elevations on the beachface respond differently. During storms, material is often eroded from the upper part of the shore and deposited at the toe of the shore. As a result, the MHW-shoreline may shift landward, while MLW-shoreline shifts seaward. In this case, the directions of shift for the MHW and MLW-shoreline are opposite, while the MSL-shoreline may have remained stationary. Thus, the use of only one shoreline is insufficient to study the short-term morphodynamic events. However, over long periods, the shift direction of the upper, middle, and lower shorelines tend to be the same, and a specific shoreline might be reliable for studying long-term changes.

Rates of shoreline shift may be used to describe how fast a shoreline is shifting. The rates of shoreline shift are expressed in linear units per time (meter/year or feet/year). During short-term events, consistency in the use of a specific shoreline is important since the upper and lower parts of the beachface respond differently to storms. During long-term intervals (annual to decadal), the gross shift rate and the net shift rates may be significantly different since the directions of long-term shift are bipolar. For example, if a shoreline retreated landward 5 m in 5 years and then advanced 5 m seaward for the next 5 years, the gross shift rate would be 1.0 m/yr, while the net shift rate would be 0.0 m/yr. At very long-term rates (centuries to millennium), shoreline shift rates are impacted by the chronic Holocene rate of sea-level rise.

Shores and shore prisms

Since a shore is a strip of land associated with a shoreline, a standardized subdivision of a shore is logically defined by the series of mean shoreline described above. The mean shorelines are associated with specific elevations on the shore surface. These elevations are associated with a horizontal planar surface that extends under the land surface (Figure C69). The material above each planar surface represents the sand prism of a specific portion of the shore. For example, the mean low-water shore (MLW-shore) is the prism of sand located above the mean low water elevation (and between the MLW-shoreline and the landward limit of the backshore). Each of the standardized shorelines has an associated standardized shore. The mean sea level shore (MSL-shore) is the prism of sediment located above the elevation of mean sea level. The mean high-water shore (MHW-shore) is the prism of sediment located above the elevation of mean high water. The mean swash elevation shore (MSE-shore) is the prism of dry sand located above the mean limit of swash runup on the shore (Figure C68B). These shore prisms are valuable units for describing specific changes to the shore. Since each prism is composed of a specific volume of material, then removal of a portion of that volume is by "geological" definition called erosion. The addition of a volume of material by definition is called accretion. Note that erosion and accretion requires the addition or removal of a mass or volume of material.

Shore accounting

Beach profiles are often made perpendicular to the shoreline to study beach processes. The area between the profile and MLW elevation represents a two-dimensional section of the shore. When combined with a one-dimensional length of shoreline, the resultant prism is a three-dimensional section of shore. Thus, pairs of profiles can be used to estimate the volume of sand stored in reaches of shore. Standardized elevations can also be used to determine the volume of material stored in each of the standardized sections of a shore prism. Thus, an accounting of material can be made for each shore zone that provides information on the erosional and accretional characteristics of the shore. Using the technique of profile comparisons along a stretch of shoreline, rate scales can be devised to normalize the change rate per unit length of shoreline and/or period of time (Oertel *et al.*, 1989).

During storms, material is often eroded from the upper portions of the shore and deposited on the low portions of the shore. The process may result in no net gain to the total shore volume although there was a shift in the location of a large amount of material. An accounting of material in the total MLW-shore might illustrate a stable volume suggesting a passive condition. An accounting of material in the MSE-shore would illustrate erosion, while the accounting of material in toe of the shore between MLW and MSL would show accretion. The dynamic nature of the shore can only be realized by an accounting of material in vertically stratified zones. The shore zones (related to mean water levels) provide a valuable framework for relating patterns of shore-volume change and shoreline shift.

Common misusage

The most common misuse of shoreline is the expression "shoreline erosion" and "shoreline erosion rate." A shoreline is a one-dimensional construct on a planar surface. It has length but no width or depth. In this case, it is a line that denotes the boundary between a solid (land) and a fluid (water). By definition erosion is the removal of a mass or volume of material. Since, the line is one-dimensional, it has no volume or mass. Eroding the line would be equivalent to erasing the boundary between land and water. In strict scientific terminology the expressions "shoreline erosion" or "shoreline erosion rate" are nonsensical. Shorelines shift landward or seaward across a surface, but do not erode. The landward shift of a shoreline should be described as shoreline retreat, while the seaward shift of a shoreline is called shoreline advance. A rise or fall in water level (that does not require the processes of erosion or accretion) may induce shoreline shifts, or it may be a response to erosion or accretion of material from parts of the shore. The advance or retreat of a shoreline is expressed in linear units (meters or feet). The terms erosion and erosion rates must apply to the change in the size of a volume or mass of material.

Since erosion is the removal of a mass or volume of material, shore erosion is used to describe the removal of material from all or part of a section of shore. It is a three-dimensional process requiring a reduction in the size of the shore sediment prism. An increase in the size of a shore sediment prism is described as shore accretion. A decrease in the size of a shore sediment prism is described as shore erosion. Erosion and accretion are expressed in units of volume (generally cubic meters or cubic feet). Erosion and accretion rates are as expressed in volume units per time (e.g., cubic meters/year of cubic feet/year).

The gross amount of material transported in the littoral system is often used as a surrogate for shore erosion. This is another incorrect use of terminology. Material transported in the littoral zone is described as littoral drift. The rate of littoral drift is generally expressed in units of volumetric units per time (e.g., cubic meters of sand per year). This is a transport rate, and is not a substitute for an erosion rate. The rate is a gross amount of material being transported in the littoral zone. Since, erosion is a measure of the removal of material (not transport) the two may not be equivalent. For example, the gross amount of sediment entrained in a littoral current (in a section of shore) may be constant at about 15,000 m^3 in a month. During the transport of this material, the littoral current can remove and add material to the shore. If the amount removed is equal to the amount added then there is no change to the shore sediment prism. However, if the rate of littoral drift is not constant along adjacent sections of shore, then erosion or accretion may result. Gradients in the rates of littoral drift along a section of shoreline may be used to imply erosion or accretion rates. That is, if more material is being transported into a section of shore than is being transported out of a section of shore, then the rate of accretion will be the net difference between the input and output rates.

The use of remotely sensed data is a popular tool for studying rates of shoreline shift. By comparing shoreline locations at two different times, the amount of shift can be estimated over a specific duration. The resultant rates are often used to predict rates of change. Typically, the shoreline is defined by the wet/dry boundary found on an image. Since, each image represents a "snap shot" in time and not one of the standardized elevations (described above), then it is difficult to discern whether any shift was caused by changes in the volume of sediment at the shore (morphodynamics), or changes in water level (morphostatics). Changes in water levels could be a response to different combinations of tidal stage, barometric pressure changes, waves runup, and wind stresses. On a flat beach, these forces could combine to produce several meters of water-level rise resulting in over 200 m of shoreline shift (without a change to the position of a MSL-shoreline or any change in the size of the shore sand prism). This is the +/− error that should be attached to shoreline shift measurements at low-profile beaches. Therefore, it is very difficult to use remotely sensed data to analyze rate of shoreline change without vertical control.

COHESIVE SEDIMENT TRANSPORT

Introduction

Sediments are a major component of the suspended load and sediment bed in coastal water bodies (estuaries, lagoons, river mouths, tidal flats, etc.). These sediments can be classified as cohesive and noncohesive. Cohesive sediments are comprised primarily of clay-sized (<2 μm) and silt-sized (<75 μm) particles, mixed with organic matter, and, sometimes, quantities of very fine sand. Noncohesive sediments are primarily sand and gravel-sized material (>75 μm). The underlying property that distinguishes cohesive sediments from noncohesive sediments is that they are cohesive in nature. Cohesion is the predominance of attractive forces over repulsive forces, such that particles in close proximity can bind together to form flocs (aggregates). This can be attributed to the presence of clay and colloidal particles with surface physico-chemical forces that are significant. A clay fraction greater than about 10% is generally sufficient for the sediment to exhibit cohesive properties (van Rijn, 1993).

Cohesive sediments are transported to coastal waters from alluvial and marine sources. Alluvial sediments are derived from various terrestial processes and human activities and are comprised of both cohesive and noncohesive material. The fine sediment load is often termed as wash load in river mechanics. The coarser sediments are deposited in the upper reaches of the river/estuary while the fine sediment fractions are carried further downstream into the estuarine/coastal waters where salinity enhances aggregation, forming flocs that possess higher settling velocities. These aggregates then deposit in areas where velocities are sufficiently small. Marine sediments originate from the nearshore bottom. They are first suspended into the water column by the action of waves and currents and are subsequently transported upstream by the net upstream near-bed flow to zones of low velocities where they eventually deposit. Understanding cohesive sediment transport thus requires knowledge of both sediment behavior and water movement.

Because of the affinity of pollutants to cohesive sediments as a result of adsorption, cohesive sediment transport plays an important role in characterizing the transport and fate of pollutants (e.g., heavy metals, radionuclides, pesticides, and nutrients) input to coastal waters. These pollutants originate from various land-use and marine activities (e.g., urbanization, deforestation, industrialization, mining, agricultural practices, hydrosystem construction works, and dredging/disposal activities) posing a potential threat to receiving waters. Ways to mitigate critical water quality problems are receiving the concentrated attention of environmental engineers, biologists, and ecologists. As a precursor to assessing the impact of pollutants input to a water body, a precise understanding of cohesive sediment dynamics is first necessary.

Dynamics

Cohesive sediments in coastal waters come under the influence of various complex processes. In addition to the transport processes of advection and dispersion in the water column, the principal processes influencing cohesive sediment dynamics are aggregation, settling, deposition, consolidation, and resuspension. These mechanisms are not only dependent on the inherent physico-chemical characteristics of the sediment but also on their interaction with the flow field. It is this interdependence that makes the problem of cohesive sediment transport so complex.

Aggregation

Aggregation refers to the formation of flocs comprised of primary sediment particles. The process of aggregation results from destabilization and collision. When the double layer around each sediment particle is compressed by divalent ions, the particles are destabilized and van der Waals attractive forces predominate, creating a condition conducive to aggregation. Collision occurs as a result of three primary mechanisms: Brownian motion, internal shear, and differential settling. Brownian motion occurs when the sediment particles are bombarded by fluid particles moving in random motion resulting from thermal gradients. Internal shear is due to the presence of velocity gradients in the suspending medium. Differential settling is caused by larger aggregates colliding with smaller aggregates. Brownian motion is responsible for aggregation in stationary or quasi-stationary waters forming aggregates that are weakly bonded. Internal shear predominates in dynamic aquatic systems and the aggregates produced are more dense and durable. Differential settling is important during near-slack periods where concentrations are high. The resulting aggregates are weak and have low density. Aggregation transfers mass through the particle size spectrum toward large-sized aggregates that can be characterized by their higher porosity, increases irregularity and fragility, and higher settling rate (Krone, 1963). Aggregation is influenced by sodium adsorption ratio, pH, salinity, sediment size, shaper, gradation, density, turbulence, temperature, and the efficiency of collision between particles.

Settling and deposition

The settling velocity of cohesive sediments is dependent upon the aggregation process, the suspended sediment concentration, and the ionic concentration of the suspending medium. For low concentrations of sediments in the water column (0.1–0.3 kg m^{-3}), the settling velocity is independent of the concentration. With increasing concentration (1–10 kg m^{-3}), the settling velocity increases due to the formation of stronger, denser, and larger flocs. At high concentrations (>10 kg m^{-3}), a sharp lutocline is formed and the underlying sediment forms a nearly continuous matrix. Interstitial water cannot escape upwards as easily so hindered settling occurs. A high-density suspension characterized by hindered settling is referred to as fluid mud. Reported values of settling velocity in estuarine and coastal waters range from 10^{-7} to 10^{-3} m s^{-1} (Mehta *et al.*, 1989).

As the aggregates settle toward the bed, the near-bed turbulence controls whether the particles bond with particles on the bed or are broken up and reentrained into the water column. The stochastic nature of the near-bed turbulence is characterized by a "probability of deposition," which is defined as the probability that particles reaching the bed actually stick to the bed. This is conveniently expressed as a function of the bed shear stress and a critical shear stress for deposition. The critical shear stress is a function of the type of sediment in suspension and is generally determined from laboratory flume studies. If the critical shear stress for deposition is equal to or less than the bed shear stress, then deposition will cease provided the sediment has uniform properties (Mehta *et al.*, 1989). The deposition rate is thus a function of the aggregate settling velocity, near-bed concentration, and the probability of deposition.

Consolidation

Once the sediment aggregates reach the bed, the flocculated structure breaks down and the aggregates will move close together. The sediments then consolidate under their own weight when particle-to-particle contact is made. The effective stress (i.e., the difference between the total hydrostatic pressure and the pore water pressure) of the soil increases with the release of pore-water pressure. The void ratio of the bed decreases with depth of sediment (i.e., the density and shear strength both increase with depth). Consideration of the consolidation of cohesive sediment beds is crucial for determining whether the bed is susceptible to erosion and how much material can be eroded. The shear strength of consolidated sediments has been estimated from empirical relationships between shear strength and dry density. Experimental results indicate that the shear strength increases with an increase in the clay content, organic matter, salinity, sodium adsorption ratio, and cation exchange capacity. The shear strength decreases with an increase in temperature, pH-value, and the sand concentration in the sediment bed.

Resuspension

Sediment resuspension depends upon the bed shear stress induced by the flow and the resistance of the bed to erosion. In coastal waters, bed shear stresses are computed for the combined effect of waves and currents. These shear stresses can be quite large compared to shear stresses due to currents alone. The resistance to erosion depends upon the sediment type and mineralogy, pore and eroding fluid concentrations, the time history of deposition (i.e., whether the sediments are recently deposited, partially consolidated, or part of a more dense bed), and chemical and biological processes. To account for the multiple-dependence between the above factors and their spatial variability, investigators have relied on laboratory and field experiments to assimilate and analyze sediment cores from various locations. The results of these studies have indicated the need to obtain system-specific data if accurate predictions of erosion are to be realized. The nature of the deposit (i.e., the bed properties) is generally characterized by a critical shear stress for erosion. Investigations on sediment erosion have indicated that when the bed shear stress at the sediment water interface is greater than the critical shear stress of the surface in contact, then the material will erode. The amount of material that can erode is described as a function of the stress in excess of the critical shear stress.

There are two primary modes of erosion, namely mass erosion and surface erosion. Mass erosion refers to the resuspension *en masse* of sediments when the bed shear stress exceeds the critical shear strength of the bed at some depth below the sediment–water interface. Clumps of sediment are eroded. This erosion mechanism occurs when the flow is rapidly accelerating as in zones of strong tidal currents and under storm conditions. Surface erosion, on the other hand, occurs at low to moderate values of the excess shear stress where currents are low to moderate (Mehta *et al.*, 1989). Surface bed sediments are eroded particle by particle until the bed shear stress is less than the critical shear stress for resuspension. The amount of material that can erode from the bed is limited to a finite amount. Laboratory experiments (Parchure and Mehta, 1985; Tsai and Lick, 1987) and field studies (Amos *et al.*, 1992) have revealed that only a finite amount of sediment can be resuspended from a cohesive sediment bed exposed to a constant shear stress as a result of the increase in shear strength with depth of sediment.

Mathematical modeling

To effectively assess the impact of sediment input to coastal waters, it is necessary to predict their spatial and temporal distributions in the water column and in the sediment substrate. In order to do this, it is imperative to consider the interaction between sediment transport processes and the flow field. The advent of sophisticated mathematical models coupled with inexpensive computing power has spearheaded major advances in developing simulation models. These models now strive to incorporate more complex sediment processes into tractable computational techniques. Since the accuracy of cohesive sediment transport predictions is contingent upon the accuracy of the flow field, an understanding of the hydrodynamic circulation processes is essential. In lieu of this, models for hydrodynamics and waves are generally coupled to a sediment transport model so that the various models operate within the same computational framework, in conjunction with one another, with output from one serving as input to another.

The simplest model for cohesive sediment transport is based on zero-dimensional modeling (e.g., Krone, 1985). These models are based on the sediment conservation equation, which represents the mass balance between sediment inflows, outflows, and storage (i.e., sediment deposition). The spatial variability of the sediment properties is ignored. Other models of cohe-sive sediment transport range from simple one-dimensional to sophisticated three-dimensional models. Some of the available models are described in Martin and McCutcheon (1998). The governing equation is based on the mass conservation principle in one-, two-, or three-dimensions, with boundary conditions of no-sediment flux at the free surface, and net erosional or depositional flux at the sediment–water interface. Odd and Owen (1972) used a two-layered one-dimensional model to simulate cohesive sediment transport in the Thames Estuary. Other one-dimensional models (e.g., Lin *et al.*, 1983) do not describe the near-bed concentrations which are required for determination of deposition rates. Two-dimensional models may be depth-averaged or laterally averaged. The assumption is that concentrations are well-mixed over the depth or in the lateral direction. Depth-averaged models (Ariathurai and Krone, 1976; Onishi, 1981; Cole and Miles, 1983; Lick *et al.*, 1994; Shrestha, 1996; Shrestha and Orlob, 1996) compute the sediment deposition rates from mean sediment concentrations averaged over the vertical. Laterally averaged models (Ariathurai *et al.*, 1977; Onishi and Wise, 1982) describe the distribution of sediment concentrations in the longitudinal and vertical directions. Quasi-three-dimensional models account for the vertical distribution of sediments using approximations (e.g., calculates the vertical concentration profile based on the vertical velocity distribution) (Lou *et al.*, 2000). The current state of the art is to utilize three-dimensional finite difference or finite element models for sediment transport (Hayter and Pakala, 1989; Sheng, 1991; Onishi *et al.*, 1993; Shrestha *et al.*, 2000). These models are suitable for applications to systems where the three-dimensionality of the flow, the salinity and temperature structure, and the associated suspended sediment distribution are important.

Sediment processes embedded in the model generally include aggregation, deposition, consolidation, and resuspension of sediments. In addition to the flow field, model inputs include bed properties (i.e., bed type, grain-size distribution, dry density, and sediment resuspension characteristics), fixed and/or time-varying sediment loading from various sources, and sediment settling parameters. Sediment aggregation is generally embedded in the settling velocity formulation and is described as a function of the sediment concentration. In most models, sediment consolidation is accounted for by discretizing the bed into arbitrary layers. Each layer is assigned a certain thickness, density, and a critical shear stress for erosion based on laboratory or field estimates of consolidation. In other models, consolidation is simulated by using a vertically segmented bed model (Shrestha *et al.*, 2000), where the sediment layers depend upon the time after deposition. The assumption is that a recently deposited bed is more susceptible to erosion than an aged bed. The resuspension from the bed is then based not only on the excess shear stress but also on the age of layer. Output from the sediment transport model includes the spatial and temporal distribution of suspended sediment concentrations, the mass of sediment eroded or deposited, and subsequent change in bed elevations.

Model performance is generally assessed through model-data comparison of suspended sediment concentrations and sedimentation rates. Sensitivity of the model input parameters are also assessed. Experience has shown that sediment-loading rates need to be estimated correctly if realistic predictions are to be realized.

The hydrodynamic model is essentially the driver for the sediment transport model. It provides the necessary transport information. Martin and McCutcheon (1998) review a variety of hydrodynamic models ranging from one-dimensional to three-dimensional. The dimensionality of the model is selected based on the intended use of the model. The governing equations include the continuity, momentum, and constituent (i.e., temperature and salinity) transport equations, with an equation of state relating density to temperature and salinity. Inputs to the hydrodynamic model include hydrographical (steady-state and/or time-varying flow rates from rivers and non-point land-based runoffs), astronomical (tides), meteorological (winds and heat fluxes), and internal density gradients (temperature and salinity distributions). Hydrodynamic models should possess the capability to predict different time scale events, ranging from semidiurnal tide scale, diurnal scale, meteorological scale (few days), spring and neap tidal scale (15 days), in addition to monthly and seasonal time scales. Model output includes water surface elevations, currents, horizontal and vertical diffusivities, and distributions of temperature and salinity. The predictive capabilities of the model are assessed via extensive comparisons with data and a confidence is established that the model realistically reproduces the predominant flow dynamics. As an example of a particular three-dimensional model application and its comparison with field data, the reader is referred to Blumberg *et al.* (1999).

Bed shear stresses due to currents and waves are crucial for calculating sediment resuspension and deposition fluxes. Wind waves are high frequency short waves of periods 3–20 s. These waves not only increase mass and momentum fluxes, but also increase bed shear stresses by inducing large velocities near the bottom of the water column. The development of wind waves in coastal waters is based on a balance between wind energy input, wave energy, and wave energy dissipation. The wave climate is predicted from a wave model such as SWAN (Holthuijsen *et al.*, 1993), HISWA (Booij and Holthuijsen, 1995), the Great Lakes Environmental Research Laboratory (GLERL) wave model (Schwab *et al.*, 1984), SMB (USACE, 1984), WAVD (Resio and Perrie, 1989), or ACES (Leenknecht *et al.*, 1992). Inputs to the wave model are bathymetric depths and a two-dimensional, time-dependent surface wind field. Linear wave theory is used to translate the wave height and period into a near-bed peak orbital velocity and peak orbital amplitude. A wave–current model can be used to calculate the bed shear velocity. The bed shear stress is then calculated as the product of the fluid density and the square of the shear velocity.

One of the critical features in the application of the above models is the type and quality of data available for creating model inputs and for calibration and validation of the model. In this regard, data assimilation and analyses represents a core component of any modeling effort. Because of the widespread use of such modeling tools, sediment transport studies are often supplemented by field sampling and monitoring programs. For many studies involving the fate and transport of sediment-associated pollutants, hydrodynamic, wave and sediment transport computations are linked to one or more water quality models.

Summary

This entry emphasizes the key mechanisms influencing cohesive sediment transport in coastal waters. These processes are complex because of the interaction between the physico-chemical properties of the sediment and flow parameters. Mathematical modeling provides a tool to assess the impact of the predominant processes on the transport and fate of sediments discharged to coastal water bodies.

CONSERVATION OF COASTAL SITES

Conservation of coastal resources has been practiced throughout human history as communities have endeavored to manage the food, water, and other resources of the coast in ways which ensure that each season or year will bring at least comparable bounty from the sea and the land. Protection of coastal sites in the historic past usually meant protection of areas to be used for elite recreation or as locations where coastal resources were to be conserved. Only in recent centuries, however, have communities begun to take specific action to conserve coastal sites for their natural flora and fauna. This has meant that some areas of coastal land and water have been designated as more important for conservation than others. This may have led to distortions in the behavior of coastal ecosystems which are just as important as the distortions which conservation is intended to prevent.

What does "conservation" mean? Usually, it means management in ways which protect the inherent natural and human features and processes of an area. Conservation is often confused with "preservation," but natural features change. Change is normal, but it is usually a means by which sites retain their resilience.

There are many different types of coastal sites which are conserved, including archaeological, biological, cultural, geological, geomorphological, and zoological sites. There is also a wide variety of approaches to their identification, designation, and protection (Table C14).

Conservation for biological reasons

Ehrenfeld (1976) argued that protection of ecosystems was usually justified by two purposes: scientific and human. Typically, these include research and education, the need to protect genetic information, and as parts of the worldwide and interconnected pattern of ecosystems. Often, however, they have been protected because of the perceived importance of particular species. Usually, these are rare and, commonly, higher plants and animals. Conservation was often a response to particular lobby or pressure groups, sometimes even individuals, whose concern about losses of species and habitats led them to establish groups to provide protection to pressure governments into protecting vulnerable species. This was particularly the approach in 19th century North America and Europe. Today, the responsibility lies more with government bodies or conservation nongovernmental organizations (NGOs).

Conservation for geological or geomorphological reasons

Geological and geomorphological sites are usually protected so that stratotypes, fossil assemblages, or structures can be observed and studied or so that specific important features are preserved and protected. The coast is a particularly good location for the observation and investigation of geological features because erosion constantly exposes new strata and because large sections can be observed without excavation. In many countries, the coast provides an accessible location for earth sciences research and education. Sites may also be important because they demonstrate the processes which mold the landscape both now and in the past. Geological sites commonly fall into two groups: "process" sites

Table C14 Typology of coastal conservation sites

Level of designation	Features of importance for designation	Examplar categories	Examplar sites
Global	Having features of ecological, biological, geological, cultural, archaeological significance at international level	World Heritage Site Biosphere Reserve Ramsar Site	Great Barrier Reef (Australia) Danube Delta (Rumania) Karavasta Lagoon (Albania)
Regional	Habitats of regional significance Sites of importance for migrating birds	European SACs European SPAs	Chesil and the Fleet (UK) Wadden See (NL, D, and DK)
National	Key habitats or species	NNRs Biological Reserve National Wildlife Refuge	Studland (UK) Isla del Caño (Costa Rica) Kodiak (USA)
	Protection of fauna and flora with extensive recreational activities	National Parks	Fuji-Hakone-Izu (Japan)
	Protection of fauna and flora with limited recreational activities	National Monument Marine Parks	Fort Jefferson (USA) Oshimoto (Japan)
	Protection of marine areas	Marine Sanctuary MPA Marine Life Conservation District	Farallon Islands (USA) Milieuzone Noordzee (NL) Waikiki (USA)
	Protection of sensitive estuarine areas	National Estuarine Research Reserve	South Slough (Oregon, USA)
	Protection of site of scientific importance (geological or biological)	SSSI Site	Dungeness (UK) Anse du Gris-Nez (France)
	Recreational site with ecological significance	National Recreation Area	Oregon Dunes (USA)
	Protection of archaeological, anthropological, or historic site	Area of Archaeological Importance (AAI) Anthropological Reserve National Historic Site	Hengistbury Head (UK) Cota Brus (Costa Rica) San Juan Island (USA)
Local	Protection of locally important habitats or species	Local Nature Reserve (LNR) Ecological Reserve	Lundy Island (UK) Tomales Bay (USA)
	Protection of fauna and flora and provision for recreational activities	State Park	Humboldt Lagoons (USA)
	Local protection of marine habitats with extensive recreational activities	Municipal Marine Park State Seashore	Balicasag Island (Philippines) Del Norte (USA)

Table C15 Selected geomorphological coastal conservation sites

	Dungeness	Chesil beach and the fleet	Seven Sisters and Beachy Head	North Norfolk coast
Feature	Cuspate shingle foreland	Shingle tombolo and lagoon	Chalk cliffs	Barrier beaches and spits
Key geomorphological importance	Shingle ridges in sequence from c 5,500 years BP	Large coastal fringing tombolo Sediment grading	Rapidly retreating chalk cliffs Intertidal platforms	Barrier islands Complex spits and recurves
Archaeological importance	Reclamation from Roman period to present		Cliff-top Iron Age settlements	Reclamation from mediaeval times
Biological importance	Holly (*Ilex aquifolium*) wood Invertebrates	Little Terns (*Sterna albifrons*) Intertidal and subtidal organisms	Rock-boring organisms Intertidal flora and fauna	Salt marshes
Conservation status	SSSI Geological Conservation Review Site (GCR) SPA	SSSI GCR SAC SPA	SSSI GCR SAC	SSSI GCR SAC SPA

and sites which display features of geological significance. The British Geological Conservation Review which describes all designated geological and geo- morphological sites of national and international importance in Great Britain refers to “process” and “integrity” sites (Table C15). Most fossil locations or stratotypes are integrity sites. At Dungeness, for example, the ridge sequence provides a time sequence which is an integral part of recent coastline history. If it disappears that part of the history goes with it, hence it is an “integrity” site. In contrast, chalk cliffs of the Seven Sisters exemplify well the processes which occur at the coast and so this is predominantly a “process” site.

Archaeological and historical sites

Archaeological and historical sites include major buildings and structures located at the coast as well as sites where artifacts have been identified and excavated. Some sites are now well removed from their original coastal location by the effects of emergence, whereas others have been submerged. In shallow coastal waters, there are often very important submarine archaeological sites associated with wrecks, especially in the more active sea lanes. Some archaeological sites are at risk of disappearance as erosion cuts into them. Unless the site has considerable architectural or historical importance, erosional sites are usually not protected.

Conservation legislation

Although the purpose of conservation laws is usually the same, that is, the protection of features or processes of high scientific or cultural value, the detailed legislation depends upon the legal framework of each nation or state. France, the United States, the United Kingdom, and Japan each have well-developed systems of conservation legislation which lay down specific procedures for the identification, designation, and management responsibility for scientifically important sites. These include coastal sites. The way in which management takes place also depends upon local tradition and legislation. Thus in Britain, coastal conservation is carried out both by statutory bodies such as English Nature (a government body) and by NGOs such as the National Trust and the Royal Society for the Protection of Birds (RSPB). In addition, smaller local bodies such as Wildlife Trusts also own or lease land so that they can conserve and manage areas in which rare or endangered habitats or species occur. However, the statutory bodies often are advisory organizations rather than owners of the sites. Site management depends upon the landowner or occupier of the site. This means that there may be many different organizations involved on conservation of coastal sites within short distances of each other. Their conservation policies and practices may conflict.

In many countries, there is little or no tradition of nongovernmental conservation bodies practicing coastal conservation and so responsibilities lie with government. Thus in France, the government sponsored body, the Conservatoire de l’Espace Littoral et des Rivages Lacustres (CELRL) was established to make coastal lands more accessible at the same time as protecting landscapes and properties of national importance. Modeled in part on the UK’s National Trust, it is a governmental body rather than a nongovernmental membership body such as the National Trust. In some locations, First Peoples have traditionally regarded coastal lands as sacrosanct, but have no tradition of legislation to protect these lands. As a result, there are conflicts in conservation practice between traditional views of the value of coastal sites and their legal protection. Examples include the conflicts between European-based legislation and traditional approaches of the Maori in New Zealand. Legislation derived from British law conflicts with traditional law.

There may also be differences between local, national, or international legislation. Thus in the United States, both federal and state legislatures can define sites of coastal conservation and in Europe, the system of Directives which are mandatory on all member states may supplement or even override national conservation practices. The European Union’s Birds (European Commission, 1979) and Habitats (European Commission, 1997) Directives have established Europe-wide networks of sites including many at the coast. These are known as Special Protection Areas (SPAs) and Special Areas of Conservation (SACs). In Britain, the seaward boundary of coastal sites such as National Nature Reserves (NNRs) and Sites of Special Scientific Interest (SSSIs) established under the national legislation lies at Low Water Mark, but the boundaries of SACs and SPAs can extend to the territorial limit. There is a very wide range of types and levels of conservation designations worldwide which includes World Heritage Sites, Biosphere Reserves, and Ramsar Sites designated at international level, National Parks, and Marine Sanctuaries at national level and local nature reserves (Table C14).

Conservation measures in different countries

In Europe, there are considerable differences in the history of coastal conservation, usually as a result of the relative importance of government and nongovernmental involvement and action at the coast. Furthermore, there has been considerable conservation action in the past decade as a result of initiatives by the European Community.

France has the longest established nature conservation legislation in Europe. Protection of sites is the responsibility of the Ministère des Affaires Culturelles, with advice provided by the Commission Supérieure des Sites, Perspectives et Paysages and the Commissions Départmentales des Monuments Naturels et des Sites. Decisions at local level must be approved by the national Commission Supérieure. The designation of sites followed the Laws of May 2, 1930 and July 10, 1976, which identified the following criteria for classification of sites as nature reserves:

(1) the preservation of animal and plant species and habitats which are either in danger of extinction in all or part of the national territory or have outstanding characteristics;
(2) the restoration of animal or plant populations or habitats;
(3) the conservation of botanical gardens and arboreta forming reserves for plant species which are rare, unusual, or nearing extinction;
(4) preservation of biotopes and outstanding geological, geomorphological, or speleological features;
(5) preservation or establishment of staging points on the great migration routes;
(6) scientific and technical studies necessary for the development of human knowledge;

(7) preservation of sites of particular interest for studies of the evolution of life and the activities of mankind.

This approach is reflected within the European Union Directives on Birds and Habitats both of which include important coastal areas.

The largest of the French coastal nature reserves is the Camargue (13,171 ha) on the Rhone delta. In contrast, when it was designated as a Site in 1930, Port Cros, a small island off the coast of Provence, had an area of only 140 ha. The initial designation was based on landscape protection, as more was known about the newly protected site, especially its flora and fauna, the significance of the surrounding seas was acknowledged. The site was extended in 1963 to include the surrounding sea, and became the first Marine Protected Area in the Mediterranean. The inclusion of the surrounding sea recognized the importance of such species as Neptune Grass (*Posidonia oceanica*) and Grouper (*Epinephelus marginatus*). This example typifies the development of coastal conservation as sites are first identified to protect a particular species or habitat and then expanded to account for improved understanding of the site and its surroundings. However, conservation can be very slow in practice. For example, at Port Cros the conservation objectives have been restricted by the impact of over half a million visitors annually and local resistance to conservation measures, such as a ban on angling from the shore which restricts traditional coastline activities.

The 62 coastal Départements may designate for protection the habitats of protected species that are threatened and acquire land financed through the Taxe Départementale des Espaces Naturels Sensibles (TDENS: Departmental Tax for Sensitive Natural Areas), often in association with the CELRL (Meur-Férec, 1997). The Law of May 2, 1930 allows for designation of either Site Classé (classified site) or Site Inscrit (listed site) for sites of special natural and built importance and has been used extensively in the protection of coastal sites (Meur-Férec, 1997). The 1986 Loi Littoral (Coastal Law) provided a statutory framework which recognized the economic, social, and heritage importance of the coast and the unique nature of the coastal zone (Cicin-Sain and Knecht, 1998). This provided a context for individual sites, including, for example, a setback zone of 100 m wide for the whole coast, in which development is prohibited. Marine areas can be declared protected under the 1968 Law of Maritime Hunting, essentially to protect wildfowl! In many countries with long-established traditions of hunting, conservation of these species has often meant controlled management of habitats. Although there are some strongly held objections to game conservation, it is important to emphasize that without these conservation measures many sites which are valued today for their biodiversity would not exist. The 1960 Loi Relative à la Création de Parcs Nationaux (Law for the Creation of National Parks) includes Marine Protected Areas (MPAs) by allowing the terrestrial parks to extend into the maritime region (IUCN, 1994). European Union (EU) regulations and directives further supplement the national policies. Under the Birds (1979) and Habitats (1992) Directives, 133 sites have been proposed for inclusion within the European Community-wide Natura 2000 network of sites.

Two government bodies also have a role in French coastal conservation. The most important is the CELRL established in 1975. It is a public body charged with acquiring coastal and lakeside land, maintaining its ecological character and allowing public access to its sites (Cicin-Sain and Knecht, 1998; European Union for Coastal Conservation, 1995). Once purchased, the land is managed by the CELRL on behalf of the state in perpetuity. However, any acquisition has to take account of the area development plans and prior consultation with the Départements and Communes. This is because the day-to-day management and costs of an acquired site are handed back to the commune(s) or relevant landowner after purchase (EUCC, 1995). It currently owns over 49,000 ha along 650 km of coastline (Meur-Férec, 1997), including the D-Day beaches in Normandy and the Domaine de Certes at Arcachon. The Office National des Forêts (ONF, the National Forestry Office) manages 100,000 ha along 500 km of coastline, mainly forested dunes, such as the Landes. It works with the CELRL and other related administrative bodies to produce management plans for the forests. In the coastal region, ONF's work is more social and ecological than its predominantly economic role on the inland forests (Favennec, 2000). In particular, it is responsible for dune stabilization work, where it often has to balance the needs of conservation with tourism and public access. Thus at Pointe d'Arçay it has implemented a management plan devised with public participation and at Cap-Ferrat has successfully reintroduced marram grass (*Ammophila arenaria*) to the dunes.

Coastal conservation in Britain started, as so often there, with voluntary bodies such as the National Trust and the Royal Society for the Protection of Birds. Previously, conservation measures were largely in the hands of individual land-owners or the Crown and were mainly concerned with management of game or food resources. In 1949, the National Parks and Access to the Countryside Act established the Nature Conservancy as well as the national parks. The Nature Conservancy and its successors (three country agencies: English Nature, the Countryside Council for Wales (CCW), and Scottish Natural Heritage) were concerned with the geological and biological importance of sites for research and education. National Nature Reserves were established together with areas designated as SSSIs. The Royal Commission on Historical Monuments describes and studies sites of historical and archaeological importance, including many coastal sites. The Ancient Monuments and Archaeological Areas Act 1979 provides for the protection of archaeological sites and monuments and does appear to extend into territorial waters, although there is no record of designations at sea. These Acts and bodies are generally empowered only to deal with sites above Low Water Mark. However, the European Directive on Habitats specifies Marine SACs and so specific attention now has to be given to subtidal and submarine sites around the UK coastline. The Directive has force for the coastal waters of all European member states, although the detailed legislation is made at national level.

Submarine and marine sites are dealt with under different legislation. The Merchant Shipping Act 1995 deals with wrecks and salvage, requiring reporting of finds and the Protection of Wrecks Act 1973 provides some protection for important or dangerous wrecks or their sites. War graves may be designated under the Protection of Military Remains Act 1986: diving on and interference with a designated war grave is an offence. International agreement to protect graves in civilian shipwrecks in international waters was given effect in the Merchant Shipping and Maritime Security Act 1997.

The biological sites were reviewed in detail by Ratcliffe (1977) and coastal geomorphological and geological sites have been the subject of a major national review (the Geological Conservation Review (GCR) which has identified almost 100 coastal geomorphological sites (May and Hansom, 2003), plus a number of coastal landslide sites and several hundred geological sites. The Nature Conservation Review (Ratcliffe, 1977) described three stages in site classification:

(1) recording the features of each site to describe the range of ecosystem variation in terms of environmental and biological characteristics;
(2) comparing the quality of these sites; and
(3) choosing a series of nationally important sites.

The criteria used in both assessment and selection of key sites were

(1) size of the site;
(2) diversity;
(3) rarity of the species;
(4) naturalness, that is, areas which have been modified least by humans in so far as they are identifiable;
(5) fragility: habitats which are highly fragmented, rapidly decreasing in number and/or area, difficult to recreate or threatened with extinction;
(6) typicalness;
(7) the recorded history of the site;
(8) the position within an ecological or geographical unit;
(9) the potential natural value of a site;
(10) the intrinsic appeal of a site.

The Nature Conservation Review identified 140 coastal SSSIs with a mean area of 1,957 ha; 8 sites exceeded 10,000 ha in area. At the same time, France had 131 sites of average size 456 ha. 78% French sites were less than 100 ha in area, whereas 42% British sites exceeded 1,000 ha. For coastal geomorphological sites, criteria have included not only the specific importance of the site, but also the processes affecting particular rock-types or structures. As a result, sites with comparable geological conditions have been selected with micro- and meso-tidal ranges and different wave climates. There are 100 geomorphological sites which include large shingle structures such as Dungeness, major landslides such as the west Dorset coast, major dunes such as Morrich More on the east coast of Scotland, and world-renowned features such as Lulworth Cove and the stack of the Old Man of Hoy.

Although their coastal conservation is based upon different traditions both in coastal use and in their laws, France and Great Britain show very well how complex the legislation and administration of coastal conservation has become. Countries with shorter experience have been able to adopt different, and sometimes more efficient, approaches. Furthermore, the European Community has adopted its own framework for conservation in order to establish a community-wide network of related sites.

Funding of coastal conservation is similarly complex and depends upon receiving levels of funding which allow management to be carried out. The British model relies heavily upon voluntary support, membership, industrial support, bequests, and fundraising (Figure C70).

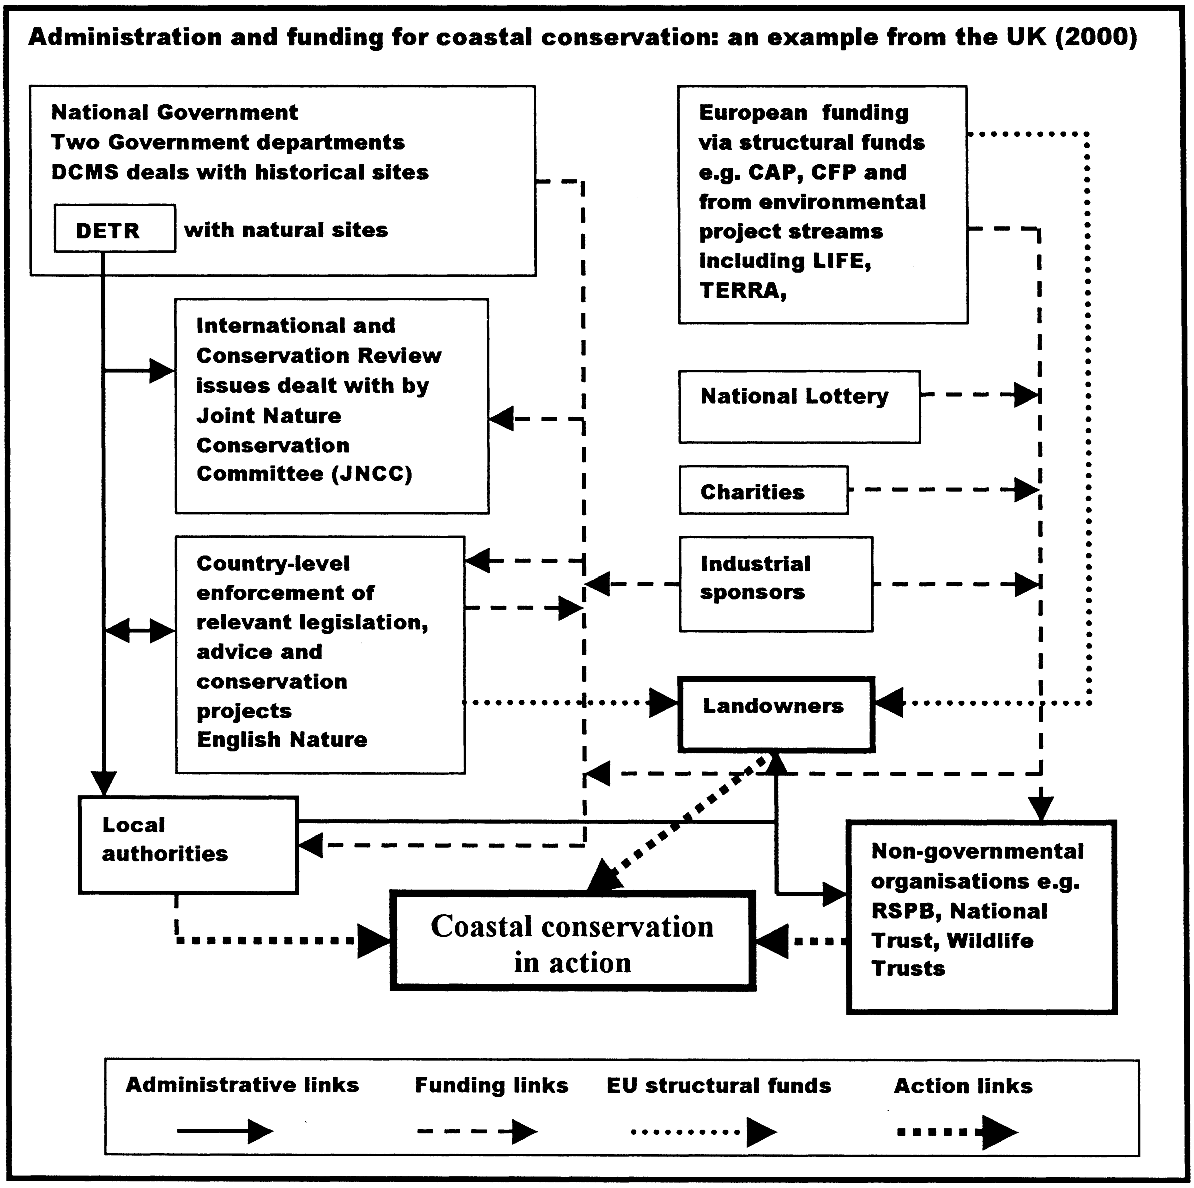

Figure C70 An example of funding for conservation of coastal sites. Key: DCMS = Department of Culture, Media and Sport; DETR = Department of the Environment, Transport and the Regions; CAP = Common Agricultural Policy; CFP = Common Fisheries Policy; RSPB = Royal Society for the Protection of Birds.

Typically, the largest voluntary bodies have strong marketing and sales departments. Funding from national and local government is limited in amount and has to be competed for. Such funding is often restricted in time. In contrast, in France or the United States, for example, conservation is predominantly funded by official sources, with the national and local governments largely responsible for both funding and operation of the conservation sites. The manner and volume of funding may change with a change of government. Thus, although the arrangements shown in Figure C70 for government funding applied in 2000, a reorganization of government departments following a General Election in June 2001 altered some of the responsibilities. In Britain, local authorities have only limited inputs into conservation funding, whereas the French Départements have considerable fiscal and legal tools at their disposal. They may, for example, acquire land financed through the TDENS (Departmental Tax on Sensitive Sites). Often these acquisitions are made in conjunction with the CELRL, and all the 62 coastal Départements have used these powers to purchase land (Meur-Férec, 1997). The day-to-day management and costs of an acquired site are handed back to the commune(s) or relevant landowner after purchase (EUCC, 1995). The majority of funding comes from the state but legacies and public/corporate donations also help with the acquisition and management of sites. Apart from the State, the CELRL is France's second largest landowner but interestingly, its budget is one-fifth of the National Trust's, a British NGO that operates a similar protection by acquisition policy (Meur-Férec, 1997).

At the time of the French Law of 1976, many European countries had hardly established relevant legislation. Greece, for example, had very good legislation concerning its archaeological sites, but was only just beginning to identify natural sites (May and Schwartz, 1981). Similarly, Norway's Nature Conservation Act of 1970 initiated action to preserve and protect plants, animals, and birds and areas of importance to nature conservation which, within a decade, established a network of 13 national parks, almost 200 nature reserves and over 200 locations which were of natural scientific importance. Many are at the coast. In contrast, Poland created its first National Park inland at Bialowieza in 1932 and there are now eight protected coastal areas including two National Parks, the Slowinski (founded 1967: present area 18,619 ha) to the west of Gdansk and the Wolinski Park near the German border (founded 1960: present area 10,937 ha). The Polish Environmental Protection Bill 1992 provides for three "levels" of designation: Strict (usually no admission to the public: 22% of sites), Partial (where management controls are flexible: 59%), and Landscape

Protection (where so-called "soft laws" apply: 19%). This recognizes that although some areas must have strict controls over access in order to protect sensitive areas and species other areas are more resilient and more appropriate for human activities such as recreation. National ecological policy requires that 30% of Polish territory (including coastline) should eventually be designated as "protected," 22% of the area had been designated by 1997. Coastal conservation in Poland is thus a national responsibility rather than a regional or local one. This is a typical pattern of many countries which have relatively recently begun to conserve coastal sites. The strength of national legislation often, but not always, ensures that designation and appropriate funding occur.

Spain combines national and local approaches to conservation. It has a long history of environmental legislation but the first specific conservation (in its modern sense) legislation was the 1975 Law on Espacios Naturales Protegidos (ENPs: Protected Natural Areas). This proposed four categories of protected area: national park, natural park, natural area of national importance or interest, and reserve of scientific interest. Other later laws have established over 25 different categories (WCMC, 1992). The national body responsible for administration of protected areas is the Instituto Nacional para la Conservación de la Naturaleza (ICONA: National Institute for the Conservation of Nature). Set up in 1971, its functions include the encouragement of renewable resource use and maintenance of ecological balance; the creation and administration of national parks and sites of national interest; and the development and exploitation of inland fishing and hunting assets. With decentralization of the government in 1978, responsibility for many conservation issues passed to Spain's 17 autonomous communities (Comunidades Autonomas) which are responsible inside territorial waters for the protection of marine and coastal areas from human activities. The 1989 Law on the Conservation of Natural Areas, Flora, and Wildlife strengthened this responsibility further. The protection of coastal areas is covered by the Ley de Costas (the Shore Act: July 28, 1988) based on the French model (Barragan, 1997). The Shore Act requires protection of the sea up to 100 m offshore and restricts the number of road and pedestrian routes to the coast. It also defines a zone extending 500 m inland which affects land and urban planning as well as prohibiting the disposal of waste in this area (WCMC, 1992). As in France, this provides a national framework within which conservation of coastal sites may take place. Laws concerning sustainable use and conservation of living marine resources have been adapted from the Directives of the European Community since these require member states to bring them into force.

The Waddensee—an example of international cooperation in coastal conservation

International cooperation is sometimes essential if the integrity of coastal ecosystems is to be protected, one of the best examples being the Waddensee in the southern North Sea. The Wadden Sea is the largest unbroken stretch of intertidal mudflats in the world and is extremely productive. With a biomass considered equivalent to rainforests, it is recognized as one of the most important wetland areas in the world. Up to 30 km wide, the Waddensee extends from the northeast Netherlands through Germany to the southwest coast of Denmark and includes low barrier islands, tidal flats, salt marshes, sand dunes, woodland and grassland, and low barrier. It is a very important breeding and overwintering area for a high proportion of the coastal birds of the North Sea. It is also, however, an area of reclamation, oil and gas extraction, commercial fisheries, and resort development. The three countries have cooperated in its conservation since 1978 using a joint memorandum which provides the basis for planning, conservation, and management of the area. In 1997, they adopted the Waddensee Plan, which was developed by involving all stakeholders and has as its focus the conservation, restoration, and development of all the region's ecological features. The interests of the local population, traditional uses of the area, and habitat conservation must be balanced with the other needs of sustainable management and preservation. Seven principles have been used to bring about regulation of activities that threaten its environment and to provide for active intervention as necessary, namely (de Jong *et al.*, 1999):

- Careful decision making—based on using the best available information
- Avoidance—avoiding potentially damaging activities
- Precautionary principle—avoiding damaging activities, even if there is insufficient scientific evidence to link them to specific impacts
- Translocation—moving damaging activities to areas where they will cause a reduced impact
- Compensation—using compensatory measures to offset unavoidably damaging activities
- Restoration—restoring areas which have been damaged
- Best available techniques and best environmental practice should be adopted.

The most important lessons are that international cooperation is essential for the conservation of some vital sites, that there must be agreed targets and procedures, and that local people must be involved especially when their traditional activities form part of the ecosystem as a whole.

In contrast, although some of the less-developed countries of eastern Europe have taken few steps to conserve coastal sites, the role of international conventions such as the Ramsar Convention on Wetlands of International Importance, 1971 and international cooperation in species protection, especially for marine turtles, have had an impact. In some respects, the significance of tourism as an economic driver for conservation has been overlooked although tourism provides a very strong incentive for conservation and sustainable activities. In Albania, for example, the isolation and centralization of the economy and society over the last 50 years affected community behavior as local communities were excluded from the planning process and decision making about natural resources upon which they depended. Not surprisingly, they consider that conservation and habitat protection have ignored their needs and imposed restrictions without providing benefits.

Albania designated its first Ramsar site in 1994 (RAMSAR, 1996, 2001), comprising the Karavasta Lagoon and adjacent Divjaka National Park. In the 1960s, much of the wetland was drained for agriculture, affecting the biodiversity of the lagoon, as well as the surrounding catchment, the Divjaka forest and hills, and its human communities. The total area of the site is 20,000 ha, made up of native forest of *Pinus pinea*, a species unique to the Albanian coast, and the lagoon itself (5,800 ha) which is a brackish water system connected to the sea by artificially maintained channels. The freshwater input to the lagoon comes from runoff from the surrounding agricultural land and Divjaka hills. Karavasta Lagoon has the only coastal breeding population of the Dalmatian pelican (*Pelecanus crispus*) along the Adriatic and Ionian coasts, supporting up to 5% (700–1,000 individuals) of the total world population. A significant proportion of the European breeding populations of Little Tern (*Sterna albifrons*) and Collared Pratincole (*Glareola pratincola)* use the Karavasta wetlands during migration, as well as large numbers of waterfowl, gulls, and terns, including the globally threatened pygmy cormorant, and white-headed duck.

Despite its designation as a Ramsar site, the lagoon has been seriously threatened by inappropriate tourism development which has often damaged fragile coastal habitats upon which its wildlife depend. Pollution and overfishing have added to the stresses on the lagoonal ecosystem. Some of the reclaimed wetlands are affected by high levels of salinity and so are of limited agricultural value. The area is state-owned and managed jointly by the General Directorates of Forestry and Fisheries (both part of the Ministry of Food and Agriculture). In practice, management depends upon a small number of rangers with limited experience of specialized wetland management, training, or equipment. Future strategies include improved planning and management of the lagoon to both protect the ecosystem and its biodiversity (including the pelicans) and derive economic benefits for local communities. A management plan for the site was prepared with international, technical, and financial cooperation through the European Union's PHARE program (PHARE, 1996). The Karavasta Lagoon is an example of where there is a need to involve local communities in biodiversity conservation activities and demonstrate their benefits. Karavasta exemplifies the problem that conservation of coastal sites depends upon management of the human systems which decide how the area will be sustained.

The United States of America

A very wide range of different designations are used in the United States, many within the framework of the National Parks legislation. They range from areas such as National Parks where they exist for both preservation of natural and cultural features and for recreation to specialized research areas, such as the National Estuarine Research Areas that are devoted to research (Table C14). There is a wide network of sites at state and federal level, but the initial establishment of important sites depended upon very strong individual lobbying of the federal government and the role of individuals such as John Muir in getting presidential support. Coastal sites were generally established later than inland sites.

Table C16 Coastal conservation in the United States—California examples

Site	Designation	Responsible authority	Key features	Area (ha)
Southeast Farallon Island	Bird Reservation (1909)	Presidential order following pressure initiated by Director of California Academy of Sciences	Major seabird nesting site Protection to prevent large-scale damage to birdlife by commercial egg companies	26
Southeast Farallon Island	Farallon Reserve (1911)	Re-designation. First statutory protection	Public concern over wildlife Endemic Farallon weed Major seabird nesting site	26
Farallon Islands	National Wildlife Refuge (1972)	US Fish and Wildlife Service and Point Reyes Bird Observatory	300,000 birds in 12 species nest annually. Over 350 species of birds migrate via the islands World's largest nesting populations of Ashy storm petrels, Brandt's cormorants and Western gulls Northernmost breeding site for Northern elephant seals	40
Farallon Islands and surrounding waters up to 6 nautical miles offshore between Bodega Head and Rocky Point and waters within 12 nm of the islands)	Gulf of the Farallones National Marine Sanctuary (1982)	Gulf of the Farallones National Marine Sanctuary (Federal Agency)	Diverse productive marine ecosystem based on upwelling	
Point Reyes National Seashore	National Seashore	National Parks Service	San Andreas Fault Very diverse ecosystems >360 bird species recorded	Almost 29,000
Limantour Estero	Reserve (within National Seashore)	National Parks Service	Estuarine habitats: removal of all life forms prohibited without permit	202
Bodega Dunes	Sonoma Statem Beach	State Department of Parks and Recreation	Dunes up to 50 m high	364
Bodega	Marine Reserve Marine Life Refuge	University of California statewide Natural Reserve System State Department of Fish and Game	Undisturbed habitat for research Marine area up to 330 m offshore	132
Duxbury Reef	Marine Reserve	State Department of Fish and Game	Largest exposed shale reef in state Endemic acorn worm and one of only two sites for burrowing anenome (*Halcampa crypta*)	ca. 16
Tomales Bay	Ecological Reserve	State Wildlife Conservation Board	Wetlands and salt marsh	>200
Tomales Bay	State Park	State Department of Parks and Recreation	Sand beaches	
Bolinas Lagoon Olema Marsh	Nature preserve Not designated	Marin County Audubon Canyon Ranch	Marsh habitats and species Privately owned research and wetland restoration project Freshwater marsh	485 16

The origins and variety of the coastal sites is well illustrated by the coastline north of San Francisco (Table C16). From very humble beginnings, some sites such as the Farallones Islands have grown to major national coastal and marine sites. Designations overlap so that within the Point Reyes National Seashore, for example, there are not only marine and terrestrial reserves, but also historic ranches within the Philip Burton Wilderness Area (California Coastal Commission, 1987). State, county, and private parks and reserves also occur. However, there are few sites owned or managed by private organizations. Estuaries, such as San Francisco Bay, have been extensively reclaimed with the accompanying loss of wetland habitat. This is a worldwide feature of coasts and serious concerns about the loss of biodiversity and productivity have been expressed within the United States for many decades. Since 1850, reclamation has cut off over half of the bay's tidal marshes and open water from tidal action and 95% of the original wetland habitat has been lost (California Coastal Commission, 1987). Nevertheless, San Francisco Bay contains 90% of the coastal wetlands of California and remains a major part of the Pacific coast bird migration route. Responsibility for the wetlands is divided between the Bay Conservation and Development Commission (tidal wetlands) and the US Corps of Engineers (nontidal wetlands), a division which does not recognize the natural hydrological links between them.

In many less-developed countries, funding for conservation is largely provided through tourism receipts, or by international aid programs and funding from international bodies such as the World Wide Fund (WWF) for Nature. Pressure for conservation action and designation typically comes from pressure groups. The implications of conservation action and site or species protection are not always well considered. For example, a ban on turtle fishing along the Pacific coast of Mexico had immediate impacts upon the local economy and knock-on effects to other parts of the coastal ecosystem. The contrast between the approach in many less-developed, but biologically rich, regions is well demonstrated by two examples, Costa Rica and the Mexican state of Oaxaca.

Table C17 Examples of the variety of coastal conservation sites in Costa Rica

Location	Cabo Blanco	Isla del Caño	Manuel Antonio	Ostional
Status	Strict Nature Reserve	Biological Reserve	National Park	National Wildlife Refuge
Area	1,172 ha	300 ha land 5,800 ha marine	682 ha	162 ha land 587 ha marine
Key faunal features	Largest Brown Booby (*Sula leucogaster*) colony in Costa Rica	Coral reefs	Major nesting site for Brown Booby 109 species of mammal, 184 bird species, 10 species of sponge, 19 coral, 24 crustacean, 17 algae, 78 fish	One of the world's most important nesting sites for Olive Ridley Turtle (*Lepidochelys olivacaea*) on beach only 900 m in length Also important for Pacific Green (*Chelonia mydas*) and Leatherback turtles (*Dermochelys coricea*) 102 bird species
Key plant features	Mainly evergreen forest with especially spiny cedar (*Bombacopsis quinatum*), chicle tree (*Manilkara chicle*), and Espave (*Anacardium excelsum*)	Tall evergreen forest dominated by Cow Tree (*Brosimum utile*) Coral reefs	Range of habitats: primary and secondary forest, mangrove swamp, marsh and littoral woodland and lagoons Major nesting site for Brown Booby	Forest includes deciduous trees (especially Frangipani: *Plumeria rubra*), mangrove, cacti and succulents. *Acanthocerus pentagonus* cactus grows on beaches and provides shelter for ctenosaurs (*Ctenosaura similes*)
Archaeological importance		Pre-Columbian cemetery	Pre-Columbian turtle trap	
Geological and geomorphological importance		Plate tectonics: subduction of Cocos Plate beneath Caribbean Plate along Middle American Trench	Sand tombolo	

Costa Rica

The Central American country of Costa Rica has a well-established system of designation and protection of its ecosystems and biodiversity, including coastal sites. As the examples in Table C17 show, these sites include very large areas of land and sea which protect different habitats and some small sites which are most important for particular species. These sites are all nationally designated and form part of a network of sites designed to represent and preserve Costa Rica's wide biodiversity.

Mazunte—an example of conservation in action

Mazunte on the Oaxacan coast of Mexico is, unlike the Waddensee, in one of the poorest areas of the world. It shows how changes in conservation policy can be accompanied by local community involvement in coastal conservation especially when this is focused upon sustainable development. However, it also demonstrates the tenuous nature of much coastal conservation in less-developed areas.

For more than 30 years, Mazunte (the name comes from a Nahuatl word meaning "please lay eggs") was dependent upon turtle catching and canning. Most people in the village were either fishermen or worked in the cannery. A Presidential decree in 1990 banned all turtle fishing following significant lobbying by WWF. The immediate effect was to remove the community's main source of income, as the local community express it, throwing "our people into misery!" Protection of one species (turtles) was enacted at the cost of another. Some local people abandoned the area and moved inland to occupy land within the coastal dry forest, the associated clearance having potentially damaging effects on coastal lagoons as sedimentation increased. The turtle populations were recognized as being under stress from poaching, predators, and disease. The Mexican Center for Marine Turtle Research (CMT) was established in late 1991, using the buildings of the former Society of Industrial Fisheries of Oaxaca, and now has a unique role as the only center which studies seven out of the eight species of marine turtle. In addition, a community-based project known as Ecosolar and a Reserva Ecologica Campesina were established. Within Mazunte itself, a small ecotourism project was based upon sustainable principles and designed to provide accommodation for mainly foreign visitors to the area. Further to the south, the large-scale resort development of Huatulco had a major impact on the unusual dry coastal forest and the coastal beaches and lagoons.

The attempts to conserve not only the turtles and their nesting beaches but also to build a sustainable community have not proved easy, for both human and natural intervention have conspired to threaten the coastal ecosystem. In the aftermath of an uprising in 1994 in Chiapas, there was considerable local unrest which affected Huatulco in August 1996. This had a serious impact on the turtle ecology because, when police were sent to the resort, up to 200 poachers went to local beaches where Olive Ridley turtles were arriving to lay eggs. It is estimated that up to 1 million eggs were lost and large numbers of turtles killed. In October 1997, the area was struck by Hurricane Pauline which caused serious damage to both the CMT and other buildings but also devastated the nesting beaches. 806,000 nests were affected, with half all the nests on Escobilla beach, 4 million eggs and up to 10 million hatchlings lost. Nevertheless, the turtles continue to nest on these beaches. The CMT carries out detailed studies of turtle behavior and ecology both in the Center and on the beaches and the growth of the resort of Huatulco has brought increasing numbers of visitors to Mazunte. The concept of the Reserva Ecologica Campesina is unusual in that it links deliberately the human community with the coastal ecosystem. Knowledge which once served the commercial interest of turtle canning has been harnessed to develop an approach to sustainable development which has shown itself to be very resilient to significant human and natural disruption. The financial support for the CMT is very small, less than US$70,000 annually, and receipts from the ecotourism project are also small. Conservation here is not about conservation of a site, so much as conservation of a whole ecosystem (including its human occupants). For many communities, this will be the future for coastal conservation for it is firmly based in local knowledge, the needs of the local community, and their own initiatives.

Conclusion

The conservation of coastal sites takes many different approaches, often with detailed legal and administrative frameworks for designation and protection, but also in relatively informal ways with the involvement of NGOs and private ownership. In some countries, it has only been through the effective active involvement of individuals and NGOs that conservation has been put into practice. The example of Mazunte is a modern, but more community-based, expression of people's wish to protect and conserve features of their environment which they value which was expressed in different words and actions by the founders of the National Trust or John Muir and the Sierra Club. Once established, such initial routes to coastal conservation need the support of the national and international communities to make sure that they are truly sustainable and not threatened by external political, economic, and social pressures. Although coastal conservation is well established in practice, there are nevertheless enormous threats to many sites from urbanization, resource extraction, tourism, pollution, large-scale coastal projects such as barrages, and reclamation and neglect. Sea-level change and climate change also threaten many sites, although their history shows that most sites are resilient to change provided that human activities allow natural resilience.

Note

The International Union for the Conservation of Nature (IUCN) World Conservation Monitoring Centre (WCMC) in Cambridge, England, is the most important source of information regarding protected sites.

CONTINENTAL SHELVES

Introduction

Continental shelves are the submarine platforms that surround continents. They are found in the open ocean and in many of the coastal seas. Similar features surround subcontinents, such as Greenland, and many oceanic islands. These features exhibit a wide variety of physical dimensions and characteristic relief. Most commonly, they are relatively flat with slopes varying between $1 : 10^2$ and $1 : 10^4$. Depths at the seaward edges of continental shelves are generally on the order of 80–100 m, although there are places where depths are less than 50 m or greater than 200 m. Beyond the shelf edge is the continental slope, which is typically inclined on the order of $1 : 10^2$ to $1 : 10^3$ and frequently has much more local relief than the continental shelf.

General morphology

In most places the continental shelf has distinct subzones. Although the nomenclature is not standardized, it is customary to divide the zone between the surf zone and the shelf edge into four major reaches. These are: (1) the *shoreface*, (2) the *inner shelf*, (3) *the mid-shelf*, and (4) the *outer shelf*. On most open-ocean shelves the shoreface, with a slope on the order of $1 : 10^2$, occurs between depths of 5–25 m. It has a convex upward slope which is steeper at its top. This zone is also occasionally called the shorerise and is considered by some to be part of the inner continental shelf. The inner continental shelf is usually taken to extend seaward to the point that the costline no longer sig-nificantly influences wind-driven circulation. This distance is strongly affected by the strength and duration of the wind at any given time. It is usually on the order of 5–15 km wide.

The outer-shelf and mid-shelf environments are also defined by their dynamic processes. The outer shelf is where there is significant interaction between deep ocean and shelf circulation patterns. On the mid-shelf, circulation responds to the restricted depths but is not dominated by interaction with ocean currents or near-shore circulation. Because continental shelves have widths in the range of 10^0–10^2 km, the characteristics of these subzones are quite variable.

Large-scale characteristics

Continental shelves can also be divided according to their modes of origin, dominant processes, and geographic locations. In most places around the world where the coastline has been tectonically stable the shelves are broad and of low relief. Often these are simply submerged continuations of adjacent coastal plains, which themselves are extensive. Conversely, where continental margins are overriding adjacent seafloor as a result of continental drift, the shelves tend to be narrow and steep. These are often adjacent to coastal mountain ranges. The inner part of continental shelves at low latitudes is a common site for coral reefs and other forms of carbonate platforms. Shelves around the Antarctic continent, the Arctic Ocean, and certain other high-latitude places are strongly influenced by processes related to sea ice. On some high-latitude shelves, permafrost can be found a few tens of meters below the sea bottom. This attests to the combined effects of severe cold and the relatively recent rise of sea level.

The sedimentary environments and deposits on continental shelves are quite varied. In some places rock platforms extend beneath the shelves and sediments are distributed as thin sheets or in patches. These conditions are encountered where the underlying rock is relatively young (such as in volcanic areas), where the supplying of sediments is limited (e.g., west Florida Shelf), or where recently drowned shelves had been scoured by glaciers. Deposits greater than 10^3 m occur where prolific sources of sediments exist (Mississippi Delta foreshore). In some places, the predictable patterns of sandy nearshore sediments grading to silt and mud near the shelf edge are found. However, there are few general rules. In some locations muddy sediments occur all the way from the shore to the shelf edge. Elsewhere, the entire shelf is covered with sandy sediments, possibly with local patches of silt and mud.

Many broad continental shelves, especially those in stable tectonic areas, are sediment-starved today. In these areas the coastline is characterized by broad estuaries. Sediments, transported in river bedload accumulate at the estuary head. The sandy adjacent continental shelves are the result of reworking of previous deposits. In many cases, the previous deposits represent ancient shore processes from times of lower sea level. At the opposite extreme, there are cases where river deltas extend across the modern shelves so that the seaward face blends into the continental slope. The delta of the Mississippi River is an especially good example.

Shelf features

Although continental shelves tend to have broad areas of low relief, there are many morphological features that characterize this environment. These can be conveniently divided between erosional features, depositional features, and modified relic features. The most common erosive features originated during periods of low sea level when rivers extended entirely across to the shelf edge. Because there were several major sea-level excursions during the Pleistocene, there have been several extended periods where river and river canyon development have been promoted. In some cases, there are no remnants of these ancient river courses evident in the bathymetric shape of the bottom. However, subbottom profiles show channels now filled with sand. In other cases, quite obvious river valleys extend across the continental shelves to submarine canyons that extend down the continental slope. In some places drowned river terraces and bluffs can be found.

Depositional features dynamically coupled to present sedimentary processes and features representing the reworking of previous deposits are both found. The dynamic sedimentary features include sand ridges, sand waves, and a host of lesser bedforms. *Sand ridges* are long features with characteristic heights of 1–10 m, spacings (i.e., wavelengths) of 10^3 m and lengths up to several kilometers. These may be either shoreface-connected or freestanding sets on the lower shoreface and mid-shelf regions. The *shoreface-connected sand ridges* tend to be oriented obliquely to the shore with the acute angle pointing in the direction of dominant longshore sediment transport (Duane *et al*., 1972; Swift and Field, 1981; Caballeria *et al*., 2001; Calvete *et al*., 2001). These features are generally thought to migrate slowly down the coast. The freestanding sand ridges occur in sets in a wide range of shelf environments (Nemeth *et al*., 2001). They may occur on the tops of shallow sand banks close to the shore. They are also common features in mid-shelf environments. These too are prone to slow migration, although shelf sand ridges in some locations occupy remarkably stable locations.

Sand waves are geometrically similar features that are smaller than sand ridges. They have heights on the order of a few meters, are spaced at distances (i.e., wavelengths) on the order of 10^2 m, and extend 10^2–10^3 m in length (Nemeth *et al*., 2001). These may appear in extensive fields over broad sandy areas or as secondary features on the crests of sand waves and sand banks. Recent research has shown that sand waves are dynamically stable bottom forms that are brought about by shelf currents through a complex feedback mechanism that includes systematic changes in the structure of turbulence. These large bed forms are stable as either fixed or migrating features.

Shoreface-connected and open-shelf sand ridges as well as sand waves tend to occur in parallel sets with quasi-regular spacing. Many other forms of bottom relief are less regular in shape and spacing. These include sand ribbons and irregular bars. The reasons for these features are generally poorly understood, although many represent the results of reworking of sand deposited during an epoch of lower sea level.

In order to explain many of the morphological features that have been developed on continental shelves through the reworking of previous features, it is necessary to briefly consider sea-level history. Many of the shelf features developed as a result of the migration of the shore across the shelf since the last glacial maximum approximately 18,000 years ago. Worldwide sea level rose approximately 110 m, but the rate was not uniform over this period. The rate of sea-level rise was greatest between 12,000 and 7,000 yr BP. However, throughout the entire recent period the rate of rise has varied within shorter intervals (1,500–4,000 yr). More details are provided in Donoghue *et al*. (2003). Variations in the rate of sea-level rise have caused the shore migration rate to change considerably. At times of slow rise, or rise-reversal, the shore position remains nearly constant. Shore features become well-established and considerable deposits of sand develop. Subsequent episodes of rapid sea-level rise can cause overstepping of these features. They are reworked, but not entirely obliterated. As the availability of dense bathymetric data sets has increased it has become easier to detect and explain these features.

The concept that barrier islands retreat landward in the face of rising sea level is well established. This is brought about by processes that carry sand over and behind the islands while the seaward face erodes. Features formed off the seaward side of these islands can be preserved if their initial volumes are large. In several locations along the northern Gulf of Mexico coast, the huge volumes of sand in ebb tide delta are too great to be disbursed as they are drowned by the ongoing rise of sea level. This results in leaving elongated sand bodies stretching many kilometers onto the shelf. In most cases these features correlate with a position of present estuaries, although they may not be aligned with present tidal inlets.

Because the rate of sea-level rise since the last glacial maximum has been unsteady, with millennia-scale fluctuations, the migration of shore features has also been episodic. In areas where there are plentiful supplies of sand, barrier island complexes extending from the shoreface, across the island, and including the washover deposits in the lagoon, have tended to form during periods when the rate of sea-level change is low. Again, these huge sand deposits resist obliteration when they are drowned during episodes of rapidly rising sea level. Much of the upper portion of these *shore-complexes* is reworked and lost. However, the general morphology can be distinguished where there are sufficiently detailed bathymetric data. In these places subbottom profiles reveal dipping beds representing lower shoreface and back bay deposits (Donoghue *et al*., 2003).

Many ancient coastal river deltas have also been large enough to avoid being obliterated during periods of rapid sea-level rise. These are now located on the continental shelf. The shelf edge is where many of these are found because the last sea low-stand was below this elevation. Additionally, some major sand shoals on the continental shelf originated as deltas during the transgressive phase of the past sea-level cycle.

Subaqueous deltas are also found on continental shelves. These are sediment clinoforms with nearly flat tops and seaward-dipping foreset beds. However, unlike coastline deltas, these features formed with their tops on the order of 10 m below sea level. Examples of these can be found off the mouth of the Amazon River (Nittrouer and DeMaster, 1996), and in the Italian Adriatic (Trincardi *et al*., 1996). Unlike the drowned deltas described above, these subaqueous deltas are actively forming at the present time.

There are many extensive morphological features, consisting largely of sand, which occur as isolated *banks* or *shoal complexes*. Although many of these have complex histories and origins, there are others that are members of feature classes with common explanations. Swift (1973) has introduced the term *massif* in conjunction with these features. Generally, a massif is a very large volume of sand that has originated near the coastline and has subsequently been drowned and reworked due to sea-level rise. *Shoal retreat massifs* originated from the complex of sand shoals that form across the mouth of many broad estuaries. The ancestral location of these estuaries may be far out on the present shelf. As sea level rose, both the estuary mouth and the related shoals migrated landward leaving huge volumes of sand behind. Although these are now being reworked by the action of waves and currents, the very size of these deposits protect them against obliteration. However, there must be many cases where smaller features have not been so persistent.

Cape shoal retreat massifs have also been described (swift *et al*., 1972, 1973). These are thought to originate at the apex of coastline capes in barrier island systems that existed far out on the shelf. The system was subsequently drowned by sea-level rise and traces of the barrier islands obliterated. However, the large collection of sand at the point where the littoral transport systems converged produced a linear shoal mass that extends far onto the present shelf. These are often still connected to capes in barrier island systems.

Shoal retreat and cape retreat massifs, along with many other sand banks that originated from the reworking of previous massive sand deposits, often provided the sites for extensive sand ridge and sand wave fields. This is an excellent example of how a portion of many shelf features represents the result of ongoing processes while other aspects of the same features represent more ancient causes.

The work that resulted in this entry has been assisted by ongoing research in the ONR EuroStrataform Project (Contract Number N00014-03-C-0134).

CONVERSION TABLES—See APPENDIX 1

CORAL REEF COASTS

Coral reef coasts occur almost entirely between the Tropics of Cancer and Capricorn, though functional exceptions involving fossil reefs may extend beyond these limits. The reef component of a coral reef coast is constrained by the physiological requirements of the corals themselves, which include clear, warm water, neither too fresh from river outflows (>30 ppt) nor too saline from high evaporation (<40 ppt), with a temperature range of between about 15–30°C, and not heavily sedimented. Exposure levels are rarely limiting; corals thrive from very sheltered to extremely exposed conditions.

Because reefs grow vertically to the low tide level, they provide very effective shelter to the coast, which in turn greatly affects the habitats which lie in their lee. The more closely a reef is located to the coastline, the greater the shelter will be. Extremely sheltered coasts lie behind fringing reefs with broad reef flat components, over which water always remains <1–2 m deep. Reef development may take place some distance offshore, in which case greater fetch and depth between reef and shore leads to higher energies impinging on the coast. In numerous cases, the series of coastline reefs may lie far offshore (east Africa, Great Barrier Reef), possibly even on a line along the edge of the continental shelf, so that coastlines are little protected, added to which the presence of the reef itself may funnel longshore water movement which may add to net coastline erosion and dynamics. In numerous locations, fringing reefs and more distant barriers of reefs, or series of patch reefs, combine to provide complex patterns.

Reefs are biogenic limestone structures, sometimes called bioherms. Thus, over time, reef development shapes the coastline itself, and the shape and morphology of the system decreasingly depends on, or even reflects, the inherited landscape form. While it is usually the case that the limestone-depositing organisms usually can only settle on preexisting

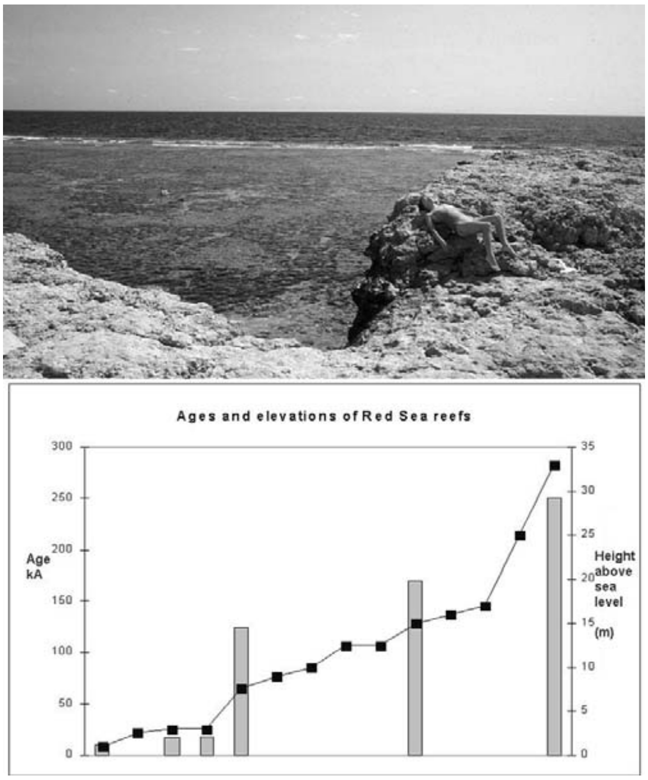

Figure C71 (Top) A central Red Sea fringing reef, whose reef flat is at low tide level. The edge of the reef flat is seen <100 m to seaward, following which the slope dips steeply to hundreds of meters. The person is lying on a tectonically raised fossil reef whose elevation is about 4 m. (Below) Plots of ages of reefs and their heights above sea level. [Data taken from review material in Sheppard *et al*. (1992), table 1.1.]

Figure C72 Fringing reef backed by "hard substrate" mangroves and, on the shallow reef flat, dark patches denote areas of rich seagrasses. The three habitats of reef, mangrove, and seagrasses are closely linked. (Location is in the Sinai peninsula and these mangroves are amongst the most northerly in the world.)

Figure C73 The spur and groove structure along the seaward edge of an oceanic atoll. Formed from growth of calcareous algae (*Porolithon* spp.) it is the primary defence against erosion for the reef and the shore behind (Chagos atolls, Indian Ocean).

hard substrates, they also may develop on unconsolidated substrate where the latter exists in sufficiently sheltered conditions. Good examples of this are found in the Red Sea, a region famous for both its general aridity and excellent fringing reefs lying close to and contiguous with the coast. Here, cores have shown layers of solid reef alternating with layers of unconsolidated sand and rubble of mainly terrestrial origin. The formation of these series comes from alternating phases of reef growth, followed by reef obliteration when heavy rains and sediment deposits carried by flash floods deposit terrestrial materials in thick blankets over the reefs. Alluvial fans develop, prograding to seaward, which then support vast areas of productive shallow water between their leading edge and the shore. Sheltered conditions then allow a new cycle of reef growth to develop on the fans. Depending on current patterns (and repeat episodes of heavy rain) these fans may then infill, extending the land to seaward until greater depth and steep slopes at the seaward edge precludes further progradation.

Uplift of reefs also affects coastline morphology. Clear examples again occur in the Red Sea (Figure C71) where series of tectonically uplifted reefs extend inland on the coastal plain. The Red Sea is an example of a spreading plate with current seismic uplift but, equally, substantial examples of uplifted old coral reef coastlines occur on most continents, notably east Africa and Australia.

Biological systems

Biological systems supported along reef shores are usually rich and diverse. Apart from the productivity and biodiversity of the reefs themselves, any areas of hard substrate between the reef and shore are likely to be colonized extensively by corals. Sand accumulates along these shores from wave pumping over the reefs—mostly the sand being limestone, derived from eroding reef material, and fragments of coral and coralline algae. Soft substrates commonly dominate the shoreward coastal marine environment. If stable enough, seagrasses may thrive, themselves being a rich habitat supporting high productivity and a considerably greater biodiversity than adjacent, uncolonized sand. Once these angiosperms take root, they stabilize the habitat further.

Along the coastline itself in such areas, mangroves may dominate the intertidal habitat, particularly if estuarine or at least slightly lowered salinity conditions prevail. These forests may be extensive and grade inland into true terrestrial forests, or may be very shallow-rooted in very limited sediment (Figure C72) and are known as "hard substrate mangroves." Most mangrove trees have roots and shoots which trap and stabilize sediments. This can also lead to progradation of the coastline to seaward as well as laterally alongshore. The existence of the mangroves, as with seagrasses, commonly is the direct result of the shelter provided by the reef lying to seaward. Conversely, the existence of the large, shore-colonizing stands of rooted plants, traps and consolidates substantial amounts of sediments that otherwise would reach and adversely affect the reefs, which are extremely intolerant of sedimentation. Thus, complex feedback processes determine both the physical and biological nature of the coral reef coastlines, as well as their physical extent. Seaward progradation may attain a balance, depending on the extent of shallow substrate

Figure C74 The capital city and island of Malé, Republic of Maldives; a coral reef island city. The reef flat is almost entirely infilled. A breakwater (on left) was built by Japanese aid following devastating surges and loss of land. Water abstraction has left the water table damaged, now with saline and sulfurous water.

on which the reef exists and over which it may extend, but rates of progradation are fairly slow; considerably slower than may be the case, for example, where mangroves extend the land seaward near heavily sedimented estuaries in the absence of reefs.

Coral island shores

These are a special case in which reefs themselves are the only component of the coastline. The modern component may be only a veneer on pre-Holocene reefs, or may themselves develop into thick deposits. Their shallow existence traps sediments, then limited vegetation, birds and further vegetation, in well-documented patterns of biological succession. Known as cays, keys, or islets of atolls, globally their total coastline is considerable, especially in deep oceanic regions distant from continental coasts. In these, all hard substrate is limestone, and all soft substrate is derived limestone sand. Most of the latter will undoubtedly be modern, though where hard substrate exists, outcrops of pre-Holocene material may be expected.

Typically, these coastlines have classical profiles of a low island, followed by a reef flat at low tide level, and a reef slope which dips to seaward, smoothly or in cascades. These reef slopes may be very narrow, less than 20 m wide, this distance in extreme cases being all that separates an island shore from water which rapidly attains depths of several hundred meters. More commonly, reef flats extend for upwards of 100 m, and may be dry or become extremely shallow for up to about a quarter

Figure C75 Beach rock formation. Where freshwater seeps into the intertidal, microbial growth leads to solidification of the fine sands. These appear to be extremely important in the creation of dipped limestone slabs in some areas (Chagos atolls, Indian Ocean).

of the tidal cycle. In exposed areas these may be bordered by an algal ridge; a construction of calcareous red algae which faces the oncoming waves (Figure C73). Usually algal spurs extend more or less regularly to seaward from the ridges for a further 100 m, dipping to 5–10 m depth. These structures have a tremendous wave-baffling role, in that their length and spacing appears to be "tuned" in such a way that incoming waves meet the outgoing swash from the preceding wave, their energies partly cancelling each other out. It appears that the very existence of many coral reef shores depends to some degree on this algal, biogenic coastline structure.

Human habitation on coral reef coastlines

Coral reef coastlines have always been populated, and because reefs and the other rich habitats along these sheltered shores are rich in food sources, notably fish protein, limitations on human numbers have commonly been due more to the availability of freshwater rather than to the supply of food (Sheppard, 2000). In rainy tropical areas, human populations have been considerable for long periods of time, while in arid locations, such as the Middle East, there usually have been far fewer—and more nomadic—people despite the richness of marine foods.

As well as the limiting effects of little or highly seasonal rainfall, the permeable nature of these fossil coral and modern coral island coastlines have long affected the amount of water which may be stored and extracted, and this also has greatly affected the ability of people to live on them. Freshwater lenses on modern coral islands are small and clearly change rapidly in size; they track the quantity of rainfall and they are clearly tidally linked, rising and falling diurnally, often with phase lags of only a very few minutes. They are thus very sensitive to over-abstraction. The available freshwater is also sensitive to increased runoff to sea which takes place following development of human habitation; here significant proportions of the land become covered with built-up areas which are impermeable, causing water to runoff rather than enter the water table. Both the latter and over-abstraction readily cause a collapse of the water table—one marked example is seen in the current sulfurous and saline nature of the water table on Malé, the very built-up and now artificially shaped capital town (and island) of the Republic of the Maldives (Figure C74). Interestingly, it has also been suggested that where the water table seeps laterally to sea in the region of the intertidal zone in carbonate shores, chemical changes, coupled with microbiological growth, causes solidification of "beachrock" a durable form of limestone which also contributes to coast line stability (Figure C75).

Where freshwater and biological systems are not overstretched, human populations may continue to live. The productivity of all three major habitats (reefs, seagrasses, and mangroves) are amongst the most productive in the world (Sheppard, 1995) and, in addition, offshore production in these areas may also yield substantial additional fish such as tuna.

However, numerous factors currently combine to create unsustainable conditions which have led to numerous system collapses and abandonment of coastal villages throughout tropical Asia, Africa, and Central and South America. Pollution from sewage and industries, unsustainable methods of fishing (e.g., dynamite and DDT "bombs"), unsustainable amounts of previously sustainable types of fishing, extraction of coral reef material for building, and infilling of the shallows between reefs and shore to create more land, have all caused ecosystem collapses in coral reef coastlines and have spelled disaster for the local inhabitants. Currently, nearly two-thirds of reefs have been damaged (Bryant *et al.*, 1998) though this figure is nearer 80% in areas such as Southeast Asia. Similarly, removal of the mangroves for timber or to clear space for unsustainable shrimp farming, and whose existence protected the seaward reefs by trapping terrestrial sediments, permits previously stabilized sediments to blanket and kill the reefs leading, eventually, to coastline erosion. Even poor agricultural practices far inland have resulted in massive movement of topsoil into these coasts via river flow, again causing mass mortality of habitats and starvation of people (Sheppard, 2000). Compounding the damage is the fact that such reef-sheltered coastlines tend to be dis- proportionately rich in their provision of breeding, spawning, and nursery areas for marine species.

Effects of climate change and sea-level rise

Although reefs grow vertically to the low tide level, and did so during the rapid and substantial Holocene transgression (the sea-level rise of about 150 m in about 8,000 yr), their ability to continue to do so under present conditions of rising sea level and temperature is not at all certain. First, sea surface temperature increases and El Niño events in recent decades have caused mass bleaching and mortality of corals. In 1998 in the Indian Ocean, for example, coral mortality in shallow reef areas exceeded 80% in many and probably most atolls, and in many patch reefs and fringing coral reefs in the Arabian Gulf, southern Red Sea and many continental shores. As of mid-2000, recovery appears poor. It is known that coral erosion continues, and since growth and erosion in a healthy reef are closely balanced (in favor of growth) net erosion may now be predicted with concomitant reduction of breakwater effect. The importance of the breakwater effect on reefs is marked, and can be seen when reefs have been removed previously by other reasons: for example, by coral "mining" on reefs around islands which have lowered the surface of the reef by 0.5 m, or from mortality of corals through disease which resulted in similar loss; in such cases the loss of the reef has led to severe erosion of the coastline, sometimes exceeding 1 m per year until a new stable point is reached. Given the attractiveness of development on "reef front" locations, infrastructure damage has often been substantial. Both of these forms of reef loss are likely to mimic the loss following recent episodes of temperature-induced mortality.

It is likewise known that coral growth and reef growth become "decoupled" as environmental conditions become increasingly severe (Sheppard *et al.*, 1992), and that even continued coral growth does not necessarily result in continued growth of the essential hard, durable reef. Further, while it is generally understood that reef growth results in deposition of vast quantities of carbonate, a point important in the consideration of possible carbon sinks to combat rising global CO_2 levels, in fact a rising atmospheric CO_2 level also alters water chemistry dynamics in the direction of *reducing* deposition of carbonate; estimates of a 21% reduction of carbonate deposition by 2065 have been postulated given Intergovernmental Panel on Climate Change estimates of CO_2 rise (Leclercq *et al.*, 2000). While the latter work has primarily been directed at the question of the global carbon sink, clearly reduced carbonate deposition on reefs which protect coastlines will become increasingly important too, as the fine balance between reef accretion and erosion becomes disturbed in favor of erosion.

Thus, while healthy reefs may continue to keep pace with a rise in sea level, as has been the case before, the increasingly stressed and damaged reefs appear to be decreasingly capable of fixing CO_2, have a decreasing ability to maintain rich coral- and reef-forming (limestone-depositing) communities, and possibly even a decreased ability to maintain food production for human populations. Evidence is accumulating to show that pressures on reefs, including over-fishing, lead to changes to their ecological stable states which cause them to be dominated by different species groups, even if or when the pressure initially causing the change is removed. The replacement biotic groups may be dominated by non-calcareous species, and the trend appears to be one-way, like a ratchet rather than a wheel. If confirmed further, substantial changes to coastlines currently protected by reefs are likely to occur, the direction of the changes being characterized by increased erosion, reduced productivity, and reduced ability of these coasts to support the human populations currently living there and dependent upon them.

CORAL REEF ISLANDS

A coral reef island is composed of rocks from coral skeletons, that is, biologically formed calcium carbonate materials derived from the adjacent coral reef and raised above sea level. Coral reef island sizes range from a few square meters to many square kilometers, and they come in all shapes and proportions. Their soils consist of coral fragments, calcareous algae and other limestone detritus, varied amounts of humus, guano from sea birds, volcanic ash, and drifted pumice (Fosberg, 1976).

Coral reef islands can develop only where suitable conditions sustain coral growth over time. These conditions include favorable physical factors (high temperature, high salinity, good light penetration, and low nutrients) and biological factors (especially a supply of coral larvae) in tropical regions that provide a firm substrate in the shallow photic zone (Birkeland, 1997). Coral islands are created in three ways, which are not mutually exclusive: (1) accumulation of dead coral reef rubble and sediments on top of a reef flat through wave and storm action, resulting in a low island (several meters in height) that may be ephemeral or stable; (2) emergence of a coral reef due to a drop in relative sea level; and (3) uplift of the ocean floor beneath the reef. Coral reef islands resulting from tectonic uplift of coral substrate may range from several to hundreds of meters in height.

The life span of coral reef islands is determined by the balance of erosional and depositional processes, and by sea-level rise. Coral islands drown when their corals are submerged below a critical depth for coral growth (Grigg and Epp, 1989). During their existence, these nonvolcanic islands may become vegetated and support a terrestrial fauna and flora. Coral reef islands are fundamentally different from so-called "coral islands" that consist of fringing coral reefs growing on a foundation provided by an island of volcanic or continental origin. Coral reef islands may be associated with volcanic or continental land masses if they form as the result of depositional processes arising from fringing or barrier reefs. These islands may lie on barrier reefs separated by a lagoon of varying widths from high land, and their proximity to this land may result in some terrigenous sediment input to coral reef islands.

Darwin's theory of reef formation asserts that the three main reef classes, fringing, barrier, and atoll, are each different stages of development of a coral reef (Darwin, 1842). Darwin did not define a coral reef island, simply referring to the islands on atolls as islets of various sizes and shapes. Dana (1872) defined "coral islands" as reefs that stand isolated in the ocean (= atolls), away from the shores of high islands and continents which harbor "coral reefs." His definition is clearly too restrictive, although he clarified it by stating that a coral island has a lagoon in the middle instead of a mountainous island and consists of a very low ratio of habitable land to area. Other terms associated with coral islands also have different local meanings. Extremely small coral islands on atolls are called islets or cays, while others refer to small coastal islands as cays ("keys" in Florida), some of which are not derived from coral reefs. "Coral cay" defines a small low coral reef island. "High" and "low" islands are terms often applied to coral reef islands. High islands are generally not coral reef islands since most consist of volcanic or continental materials with surrounding fringing or barrier reefs. However, uplifted coral reefs may attain a height similar to some high islands. Low islands are true coral reef islands if their sedimentary origin is coral reef material.

Classification of coral reef islands

Stoddart and Steers (1977) placed coral islands into seven different classes based on morphology and sediment characteristics, with vegetation used as a secondary diagnostic. Vegetation patterns depend on elevation, surface features, area, distance from sea, soil development, and human activities (Fosberg, 1976). Stoddart and Steers (1977) stress that these islands do not necessarily evolve from one class to another; any change results from external influences, primarily storms. The first class includes unvegetated and vegetated sand cays, which are low-lying accumulations of coral rubble and sand deposited by wave refraction on the reef. Sand cays are generally associated with barrier reefs and patch reefs in protected areas of reefs, for example, in lagoons behind barrier reefs. They occur on reef patches in shallow, wide lagoons and assume a variety of shapes depending on sea level, wave energy, and tidal ranges (Hopley, 1982). The windward margins of the cays tend to be composed of loose coarse rubble and the leeward sides accumulate sandy sediments. These terrestrial piles of coral material may eventually develop vegetation, mostly of plants from seeds deposited by birds or by ocean currents. A lagoon may form in between, with mangroves helping to stabilize the sediments (Guilcher, 1988). These islands range in maximum dimension from several meters to greater than 1,000 m, with a height of several meters. Unvegetated islands are lower in height and ephemeral in nature. The second class of coral island is the *motu*, which is the most common island in the Indo-Pacific. Motus have a seaward (windward) shingle ridge 3–5 m high and a leeward sandy shore and are generally vegetated. These islands occur most frequently on the exposed windward sides of atolls on the inner reef flat on Pacific atolls where sediments and rubble are deposited by strong unidirectional waves. Motus vary in number, size, and shape on a given reef or atoll. Islands in the Tuamotu atolls range from 250 to 300 per atoll, covering 30–35% of the atoll rim. Most atolls in the Marshalls, Gilberts, and Ellice groups contain more than 20 islands, while the Carolines support fewer than 10 islands per atoll (Stoddart and Steers, 1977). The number of islands on an atoll depends on the number of erosional channels ("*hoa*") cut through formerly continuous atoll rims. The vegetation on motus is strongly influenced by elevation above sea level and island size. A freshwater lens can develop on larger islands which will support a more diverse flora and fauna. The third and fourth classes of coral islands are the shingle cay and mangrove cay. The shingle cay is a storm-related event not common on coral reefs, while mangrove cays are formed by colonization of shoal areas by mangroves. Mangrove cays with a windward sand ridge form the fifth class, and low-wooded islands are the sixth class. The seventh class consists of emerged coral reefs (limestone islands). Examples of emerged coral islands include the northern Florida Keys, the Bahamas, and Bermuda in the Atlantic ocean and Aldabra atoll in the Pacific ocean. These are often dissected into karst topography with steep and strongly undercut shores, sharp peaks, and sinkholes.

Distribution of coral reef islands

Most coral reef islands occur in the Indo-Pacific region. There are over 300 atolls and extensive barrier reefs in the Pacific ocean and only 10 atolls and 2 barrier reefs in the Caribbean region (Milliman, 1973). The total number of coral reef islands is unknown, and varies according to change in sea level and storm activity.

Summary

Coral reef islands occur throughout the world at tropical latitudes. They are best viewed as products of the reef and as an extension of the reef ecosystem (Heatwole, 1976). Ecological studies are needed to determine the physical and biological linkages between the coral reef and its islands. Although most coral islands occur in isolated areas, human influences on the vegetation and fauna are highly evident and easily quantified. These land forms are excellent geological and ecological systems for studying interactions between marine and terrestrial ecosystems.

CORAL REEFS

Coral reefs are the largest structures built solely by plants and animals and many are clearly visible from space. Gross distribution is limited by a requirement for warm water with an average winter maximum temperature of 18°C generally regarded as providing the poleward margin for coral reefs which are thus found only in a few areas outside the tropics. High temperatures above 30°C may also be lethal to corals. Other requirements include good water circulation and a generally low nutrient status for ambient waters. In the open ocean where nutrient availability is very low, coral reefs exhibit a very efficient nutrient recycling, the marine equivalent of tropical rainforests. Inshore reefs can tolerate higher nutrient levels and may even respond with more rapid growth rates, though this may be countered by the skeleton laid down being more fragile. Turbid waters have a detrimental effect, limiting the penetration of light in the water column and compressing the vertical zonation of the coral reef. In clear open waters corals may grow to depths exceeding 110 m. In turbid water this may be limited to 10 m or less.

The importance of plants on the reef

Many of the restrictions on coral growth are imposed not by the corals themselves but by plants. Within the endodermal tissue of the coral polyps are unicellular algae, zooxanthellae, which have a close symbiotic relationship with the coral host. The zooxanthellae not only provide some of the nutrition for the coral but also aid as important primary producers of oxygen and carbon during daylight hours through the process of photosynthesis. They are also nutrient conservators, satisfying their own requirements from the host metabolic waste which they thus assist in removing. Most importantly, they are direct promoters of inorganic growth of coral skeletons. In daylight, the algae produce more oxygen than can be used by polyp respiration and some of the carbon dioxide produced by the respiratory process is refixed by the algae into new organic matter. As photosynthesis takes up C-12 slightly faster than C-13 the organic matter synthesized by the zooxanthellae has a relative preponderance of C-12 and a pool of carbon compounds enriched in C-13 is left behind. It is from these that the calcium carbonate skeleton is built, aided by pH variations associated with the diurnal photosynthetic process. Corals grow 2–14 times more rapidly in light as opposed to darkness and twice as fast on a sunny day as opposed to a cloudy day.

Other algae also participate in the growth and maintenance of the coral reef. Crustose coralline algae infill and cement the coral structure especially on the high energy margins of the reef where they build distinctive pavements and ridges. *Halimeda* producing delicate plates of calcium carbonate can be extremely prolific in producing sediment and, given appropriate nutrient pulsing, can build bioherms as significant as the coral reefs (as for example in the northern Great Barrier Reef, and the Makasser Straits of Indonesia). At their poleward limits competition from macro algae which can overshade the corals, is a factor in coral reef distribution.

Coral reef diversity and ecology

Coral reefs are amongst the most complex and diverse ecosystems on earth (Dubinsky, 1990). A variety of marine invertebrates and plants contribute to the accumulation of the limestone which are the most massive bioconstructional features in the geological record. Symbiosis with zooxanthellae occurs not only in the corals but in other major calcifying organisms including giant clams and foraminifera which are a major producer of reef sediment. Other important calcifers include bryozoans, sclerosponges, echinoderms, and a wide variety of molluscs. They contribute to both the reef framework and the infilling sediments.

At the scale of the total reef ecosystem gross primary organic production is very high but conversely, because of the amount of recycling which occurs, net productivity may be close to zero. In contrast, calcification is the most active of any ecosystem on earth. With an estimated total area of 617,000 km^2 the estimated total annual production is estimated at 929 million tonnes $CaCO_3$.

The stony scleractinian corals are the most important of the reef biota and their diversity typifies that of many other reef-dwelling species including coral reef fish. It is currently estimated that there are about 220 coral genera and at least 1,300 species, though many are rare and/or azooxanthellate. However, there are two distinct centers of diversity. The most diverse is the Indo-Pacific centered on the south-east Asian archipelago, most significantly the Molucca and Banda Seas of eastern Indonesia. Here there are about 450 species belonging to 80 genera. Individual sites may have as many as 140 species. The other center is in the western Atlantic and is much less rich with only 20 genera and 50 species.

The reasons for this lie in the evolutionary history of the scleractinia which evolved from the earlier rugose corals of the Paleozoic (Veron, 1995). The first scleractinians appeared in the middle Triassic about 250 million yr ago in the western Tethys Sea approximating to southern Europe and the Mediterranean. Corals occupied a circumglobal seaway which included the Tethys Sea and the gap between the two American continents. During the Mesozoic and Tertiary, as the African, Indian, and Eurasian plates collided the Tethys Sea was closed from the west, its diverse coral fauna pushed eastwards into what is now the final relict consisting of the islands and peninsulas of south-east Asia. The Atlantic fauna was isolated first from the east, then in the Pliocene from the west as the Isthmus of Panama isolated the Atlantic from the Pacific.

The gross pattern of diversity is thus a result of geological history. However, local diversity is also dependent on the range of ecological niches available (particularly wide-ranging in south-east Asia) and the frequency of disturbances such as hurricanes, earthquakes, volcanic eruptions, or crown of thorns starfish outbreaks (Connell, 1997). As coral reproduce mainly through a single annual spawning event, a medium frequency of disturbance can allow planula larval recruitment from a wide range of ecological niches because of the longevity of the larval phase which can be several weeks, allowing dispersal over hundreds of kilometers.

Rates of growth and accretion and the importance of bioerosion

The majority of corals are colonial organisms and annual extension rates for single colonies may be more than 10 cm/yr for branching species and 1 cm/yr for massive corals. Each year's increment consists of a wider high-and narrower low-density band which can be clearly identified by x-radiography. The high-density band is normally laid down during a period of stress imposed by either ambient environmental conditions or reproduction.

However, as the corals and other organisms are laying down calcium carbonate, many others are bioeroding the reef substrate. Some of the sediment produced may help to infill the reef framework but much is lost from the immediate vicinity of the reef. Bioeroding organisms include rock grazers in search of epilithic and endolithic blue-green algae on the reef surface, rock browsers which consume reef fabric and sediments such as parrot fish and holothurians, and a wide range of burrowers and borers. Rate of breakdown can match or exceed the rate of calcium carbonate production. For example, individual chitons can consume up to 13 cm^3/yr, grazing fish in Barbados reefs produce 1–2 tonnes/ha/yr of sediment, clionid boring sponges 5–10 tonnes/ha/yr, and grazing echinoids up to 97 tonnes ha/yr, 65% of which is lost from the reef. Boring worms such as Sipunculids and Polychaetes produce up to 20% of the porosity in the reef framework. On Rongelap atoll in the Pacific it is estimated that up to 100,000 tonnes of lagoonal sediment passes through the acid gut of grazing holothurians each year.

Coral reefs which are under stress may have bioerosion rates which exceed the current rate of limestone deposition. However, most healthy reefs are actively accreting. Rates of reef growth are commonly calculated in two different but complementary ways. Biogeochemical measurements of changes to water chemistry over a coral reef can give instantaneous calcification rates related to total reef metabolism (Kinsey, 1985). Such measurements have been made worldwide and when converted to annual rates give remarkably uniform results for the different reef environments. All reefs accrete through the mix of three absolute modes of calcification:

100%	coral cover	10 kg $CaCO_3$ m^2/yr
100%	algal pavement	4 kg $CaCO_3$ m^2/yr
100%	sand and rubble	1 kg $CaCO_3$ m^2/yr

Different zones of the reef are thus accreting at different rates. Sediment is produced from the highly active zones such as the reef front, to the less-active parts of the reef such as lagoons. Taking into consideration the density of the calcium carbonate produced (2.9 for aragonite) and the porosity of coral and reef frameworks (about 50%) these results give an upper limit of about 7–9 mm/yr for reef accretion.

Using the geological record through drilling and radiocarbon dating of reef cores provides an alternative long-term method for calculating coral reef accretion rates, which are nonetheless very compatible with those from reef metabolism. The synthesized results from the Great Barrier Reef (Davies and Hopley, 1983) have been reproduced from many other reef-drilling projects. Framework accretion rates ranged from 1 to 16 mm/yr according to the density of the fabric (lowest for algal pavement, highest for open branching coral frameworks) though the modal rate of 7–8 mm/yr is identical to that from water chemistry. Drilling has also produced rates for detrital sedimentation. In lagoons and sand aprons it is 1–4 mm/yr for sand flats, 7–9 mm/yr for steady trade wind accumulation and 13–18 mm/yr for high-energy low-frequency events.

Coral reefs and sea-level change

Coral reef growth is highly constrained by sea level. Uppermost growth may exceed the mean low water mark in moated pools in reef flats and will die off with any fall in relative sea level. Single tectonic events causing uplift of the land can cause mortality across an entire reef flat and in areas of constant uplift in the tropics, such as at tectonic plate margins, suites of raised reef terraces may occur to several hundreds of meters of elevation. Radiometric dating of such terraces in locations such as the Huon Peninsula in Papua New Guinea and Barbados has determined not only the rates of uplift locally but also global eustatic sea-level records.

As coral reefs have existed for such a long period, global changes in sea level have had a major impact. Global cooling during the late Tertiary and Quaternary, resulting in waxing and waning of ice sheets at the poles and in the northern hemisphere have resulted in falls in sea level of up to 150 m, exposing all extant coral reefs and removing active growth to deeper banks and slopes perhaps severely restricting the area of coral growth at the low sea level times. Fringing reefs were exposed as limestone terraces, shelf barrier reefs as chains of limestone hills, and atolls and other oceanic reefs as limestone islands. The records of sea-level change suggests that over the last million years coral reefs have been exposed for far greater a period than they have been inundated. Reef accretion has been limited to the relatively short high sea-level phases of interglacials.

During periods of exposure, which may have been as much as 100,000 yr at a time, the reefs were subjected to karstic erosion processes. Indeed a series of models for the development of coral reef morphology at both the gross and detailed scale, have been hypothesized based on the karst land forms which were etched at low sea-level phases (Purdy, 1974; Hopley, 1982). This antecedent karst hypothesis has been used to explain the annular shape of atolls and the rim structures of barrier reefs as well as the labrynthine morphology of many reef surfaces (Figure C76) which have been likened to the complex ridges and enclosed depressions of tropical karst regions. Some features such as caves with speleothems, "blue holes" up to 500 m wide and 100 m deep are clearly derived from preexisting karst land forms. Blue holes on the Great Barrier Reef for example (Figure C77) are almost certainly collapse dolines over which a veneer of 10–20 m of Holocene reef growth has occurred (Hopley, 1982).

A problem with the antecedent karst hypothesis is the time available during low stands of sea level for major karst landforms to develop (see Hopley, 1982, chapter 7 for discussion). Recent studies have shown that some morphology previously attributed to karst interaction has in fact been derived from reef growth in the Holocene. However, it is also possible that the growth which occurs during an interglacial high sea level may enhance that produced by erosion in the previous period of exposure.

Figure C76 Complex lagoonal relief in the large reefs of the Pompey Complex, Great Barrier Reef Australia.

Figure C77 A blue hole approximately 300 m wide and 33 m deep in Molar Reef, Great Barrier Reef, thought to have originated from a collapsed doline.

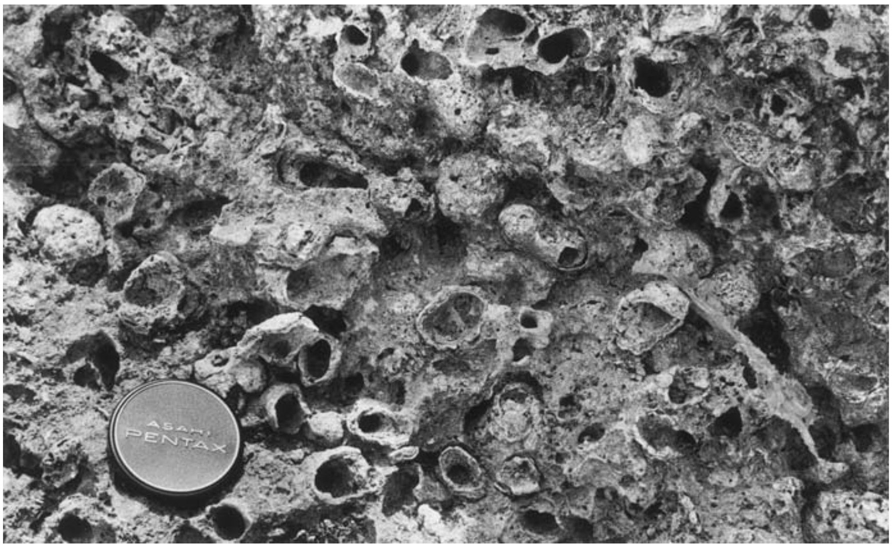

Figure C78 Diagenetically altered *Acropora cervicornis* in the Pleistocene reef tract, Barbados. The aragonite of the original corals has largely disappeared or altered into calcite. Low Mg-calcite molds result from the more rapid replacement of encrusting coralline algae.

Figure C79 A brecciated caliche profile with numerous brown micritic stringers developed on Pleistocene reef limestones ca. 84,000 yr BP on Barbados.

This is then further enhanced by the patterns of erosion during the next low sea-level stand. In all probability both growth and erosion produce the complex relief of coral reef systems.

In addition to the formation of karst landforms during low sea-level exposure, coral reefs also experience diagenetic changes. The original skeletal limestone is largely aragonite (corals, molluscs, *Halimeda*, sclerosponges) or high Mg-calcite (crustose coralline algae) which in subaerial and vadose environments is unstable and may be replaced by a coarser crystalline low Mg-calcite (Figure C78). Caliche crusts (Figure C79) may form on the surface and soils can be retained over parts of the surface even after reinundation. During the subsequent high sea-level phase the older reef is recolonized and new framework deposited over the older surface. However, it remains as a clearly identifiable discontinuity termed a “solution unconformity.” Beneath the Holocene reef framework the solution unconformity formed during the last glaciation is typically 10–20 m beneath the surface. Where coral reefs have been drilled to greater depth 10 or more solution unconformities have been identified especially in atolls and shelf edge barrier reefs which suggests continuous subsidence at these sites during the period of reef accretion.

Reef growth in the holocene

Modern coral reefs have developed entirely during the Holocene period, the majority forming a relatively thin veneer over older Pleistocene foundations which are no more than 10–20 m below modern sea level (Figure C80). Very few radiocarbon ages greater than 9,000 yr have been obtained for this Holocene veneer. Only where reefs were in deep water, such as open ocean atolls, were corals able to merely migrate to the flanks of the reef during the last glacial and thus recolonization was simple and immediate. This is also the situation for some of the mid-oceanic volcanic islands, which explains why the deepest and longest postglacial record comes from Tahiti. Here the postglacial reef is more than 90 m thick and basal dates older than 13,500 yr have been obtained. Australia’s Great Barrier Reef in contrast rises from a relatively shallow continental shelf generally less than 50 m deep. Even the lowest parts of the older Pleistocene reefs were inundated less than 11,000 yr ago (Hopley, 1995). Delays in re-colonization occurred due to the need for larval recruitment from more distant sources (probably Coral Sea Plateau reefs), and as the result of initially poor water quality as regolith was removed from the Pleistocene foundations and as a

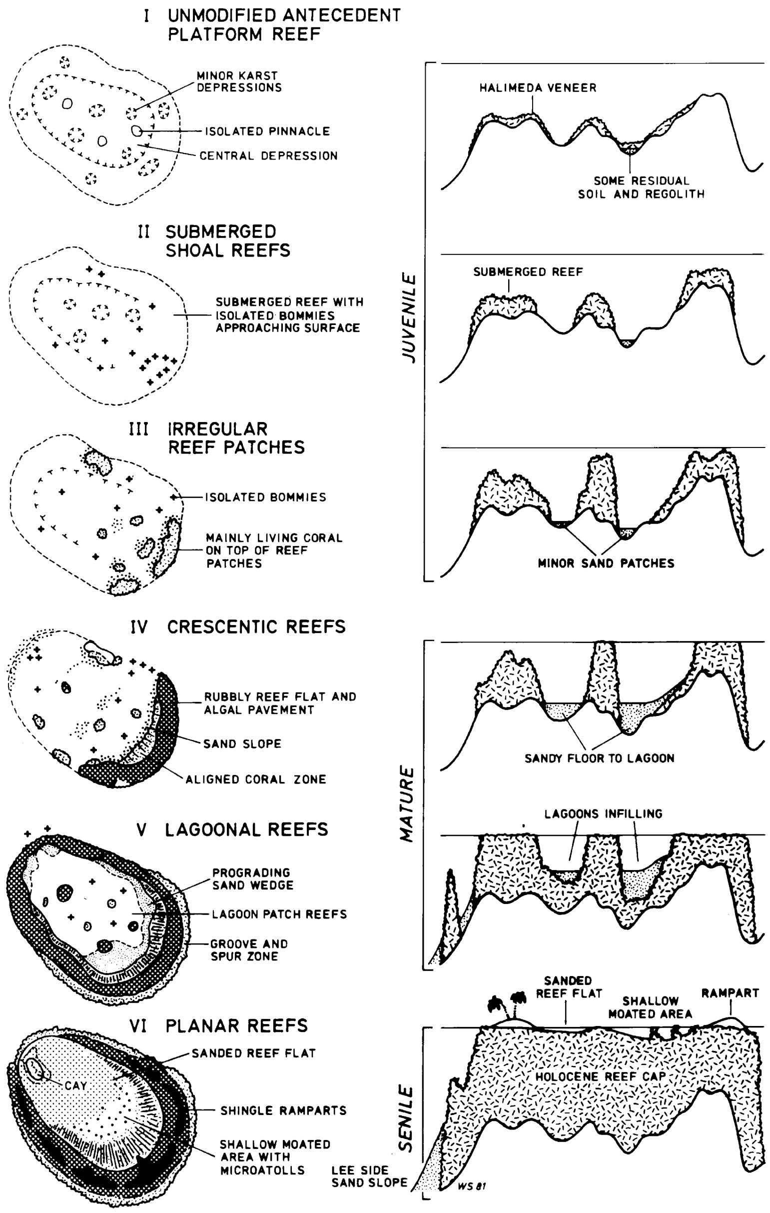

Figure C80 An evolutionary classification of Holocene coral reefs.

result of very close proximity of the mainland of the time to the main reef tract. The major part of the Holocene growth took place only after 8,500 yr BP by which time the mainland coastline was close to its present position and well removed from the outer reef.

On the Great Barrier Reef, and generally many other coral reefs, the major period of Holocene accretion took place between about 8,500 and 6,000 yr ago, when average vertical accretion rates of ca. 5 m per thousand years were achieved. Largely for hydroisostatic reasons (see Hopley, 1982, chapter 13 for discussion) the pattern of Holocene sea-level rise over this period varied in different parts of the world. Over much of the Indo-West Pacific modern sea-level had been achieved by as early as 6,500 yr BP while in the Atlantic relative sea level may have continued to rise right up to the present time, though at a considerably slower rate after 6,000 yr BP. Reefs have responded in different ways with three models recognized (Neumann and MacIntyre, 1985; Guilcher, 1988):

- Keep-up, in which the reef was able to accrete vertically at about the same rate as the rise in sea level and was never more than a few meters below sea level.
- Catch-up, in which the reef lagged behind the sea-level rise due to delays in recolonization and/or slow growth. At times these reefs may have been more than 10 m below sea level.
- Give-up, reefs which after becoming established in the early Holocene died off and remain only as drowned carbonate banks. Various reasons have been put forward. That they became too deep because of the rapid rise in sea level is unlikely in the majority of examples as most would have remained within the photic zone of active reef growth, unless there were also an increase in turbidity (which would have limited the depth of reef growth). Many "give-up" reefs are on shelf edges and sediment shed from upslope reefs may have been one cause of their demise. In the Caribbean, in particular, it has been hypothesized that as sea level first flushed the shelf, a new wave of sedimentation and eutrophication was the cause of shelf edge reef decline (MacIntyre, 1988). In addition, at high latitudes shallow shelf waters may also have killed off reef growth at the shelf edge.

Once coral reefs caught up with sea level then their upward growth phase was terminated and carbonate productivity has been directed into lateral rather than vertical growth.

An evolutionary classification of Holocene reefs

It is possible to examine the growth of modern reefs by way of an evolutionary classification (Hopley, 1982), based on the presumption that the majority of reefs are located over pre-Holocene reefal foundations at no great depth and with an irregular morphology resulting from both the original growth form of the last period of reef growth and the erosion which has taken place during subsequent exposure. This presumes transgression by the sea over the foundations and a sea-level rise which most reefs or most parts of reefs cannot match by upward growth (Figure C80).

Three phases of Holocene reef development are recognized in the classification. In the juvenile phases, initial colonization takes place on the antecedent foundation and upward growth of the reef lags behind sea level rise, enhancing the original relief of the foundation. In the mature phases, reefs reach modern sea level and develop reef flats over the highs in the antecedent surface and especially around the windward reef margins where reef growth appears to be most rapid. One or more lagoons typify this phase but in the later stages of maturity, lateral transport of sediment from the productive margins leads to initial infilling of lagoons, masking of the inherited relief forms, and widening of reef flats. The senile phase is reached when lagoons are infilled completely, and lateral movement of sediment from the windward margins leads to progradation to leeward.

The basic classification is applicable to medium-size reefs growing from antecedent platforms with single depressions. Smaller reefs, where antecedent surfaces may lack a proto-lagoonal relief may develop along similar lines but because the reef flat initially developed around the reefal margins may occupy such a high proportion of the total reef area, any lagoon which forms will be shallow and quickly filled and the mature phases will be either bypassed or be present for only a very short period. In contrast, the largest reefs will be at the mature stages for the longest period because of the low ratio of productive margin to lagoon area. These reefs may also differ from the basic classification during the mature phase by having more than one lagoon.

A major subgroup of reefs are ribbon reefs which form distinctive barriers. They grow from linear foundations which are either discrete antecedent platforms or higher rims on much larger and usually deeper platforms. The basic feature is depth of water behind the narrow reef flat which develops from the foundations. Although sediment moves to leeward, accretion is very slow and widening of the reef flat is retarded. However, the stages in the development of a ribbon reef can be equated with those in the basic classification.

Figure C81 The windward margin of a mid-shelf reef, Great Barrier Reef showing outer living coral zone with buttresses, algal pavement with isolated reef blocks, aligned and nonaligned coral zones.

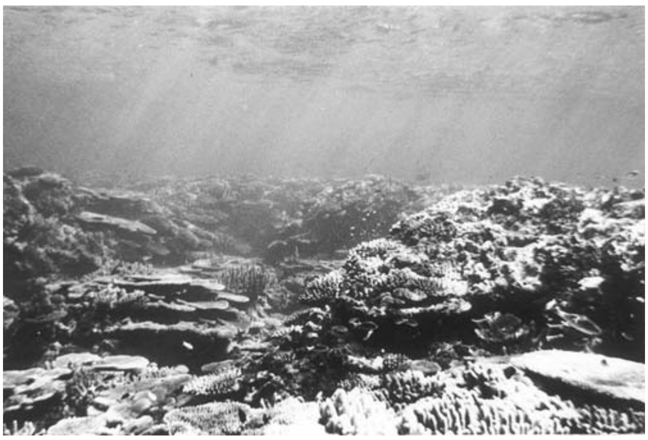

Figure C82 Reef front dominated by *Acropora* sp. close to wave base. Mainly corymbose are found on the higher crests of the spurs with arborescent and plate-like forms within the deeper channel.

Development of coral reef zonation

Distinctive morphological and ecological zonation of coral reefs is a characteristic which develops only after the reef has reached sea level and commenced horizontal growth of a reef flat (Hopley, 1982, chapter 10). During "catch-up" or even "keep-up" phases, the reef may be too far beneath effective wave base to allow the significant energy gradient from windward to leeward to exist. The reef may be a more homogenous environment of continuous coral cover with the only variable being the attenuation of light on the flanks and the development of more foliacious light capturing colonial forms. As the reef reaches sea level, however, the contrast between windward and leeward sides is enhanced by sediment movement, accumulation of detrital features, and the colonization of the various ecological niches by distinctive life forms. Zones develop parallel to the reef front, their width and distinctiveness determined by the length of time the reef has been at sea level and the strength of the energy gradient (Figure C81).

While the species which inhabit the various zones may differ geographically, the morphology of coral reef zones is similar worldwide and typically may consist of:

Fore-reef slope: Increasing light and wave energy are the controlling parameters on the deeper fore reef. At greater depth are flat, platey, and encrusting light capturing corals. Higher up the slope where light is not limiting branching forms may dominate. Moving into the higher energy wave zone at about 10 or 15 m, more compact or corymbose forms become dominant and coral cover is dense (Figure C82).

Reef crest: Particularly on high-energy reefs the crest develops massive spur and groove morphology. Originally thought to be inherited from karst rillen type features developed at low sea levels, most drilling investigations have indicated a growth origin for spur and grooves. They have developed as a baffle against the wave energy and are self perpetuating as the grooves act as surge channels along which sediment is swept.

Outer reef flat: The coral covered tops of the spurs are continued onto the outermost reef flat as a living coral zone of encrusting and resistant growth forms up to about mean low water mark.

Algal crest: Particularly on very high energy mid-oceanic atoll reefs a rim built by crustose coralline algae may rise to almost mean sea level. On lower energy reefs the feature may be far less prominent consisting of a rubble pavement cemented by the coralline algae. Under even lower energy conditions turf-like algae may dominate in this zone.

Detrital zone: Beyond the algal pavement, and often deposited over it may be a morphologically diverse zone characterized by deposition of coarse material derived from the reef front. This zone can consist of imbricated clasts of branching corals forming low irregular banks parallel to the reef front. Where tropical storms are relatively frequent a more prominent ridge or rampart may develop and, if stable for sufficient time, its lower sections will become cemented. Also in this zone, and on the reef flat to seawards may be much larger boulders and reef blocks the largest of which may be more than 10 m in diameter. These are sections of the reef front broken off in major storms or by tsunami waves.

The inner reef flat: Behind the energy-absorbing outer zones, the inner reef flat may be another zone of dense coral growth. Where wave set up provides a steady flow of water over the reef crest this zone may display an alignment of corals normal to the reef front. Elsewhere, at low tide pools may be moated by the rubble ridges or the algal crest and massive corals will be in the form of micro atolls.

Lagoons and back reef zones: In the deeper water of lagoons or back-reef, finer sand size sediment, which is swept across the reef flat, forms prograding sand sheets which may slowly bury lagoonal or leeward side patch reefs. This sand sheet may be up to 500 m wide and 10 m in thickness and is where much of the carbonate productivity of the outer reef

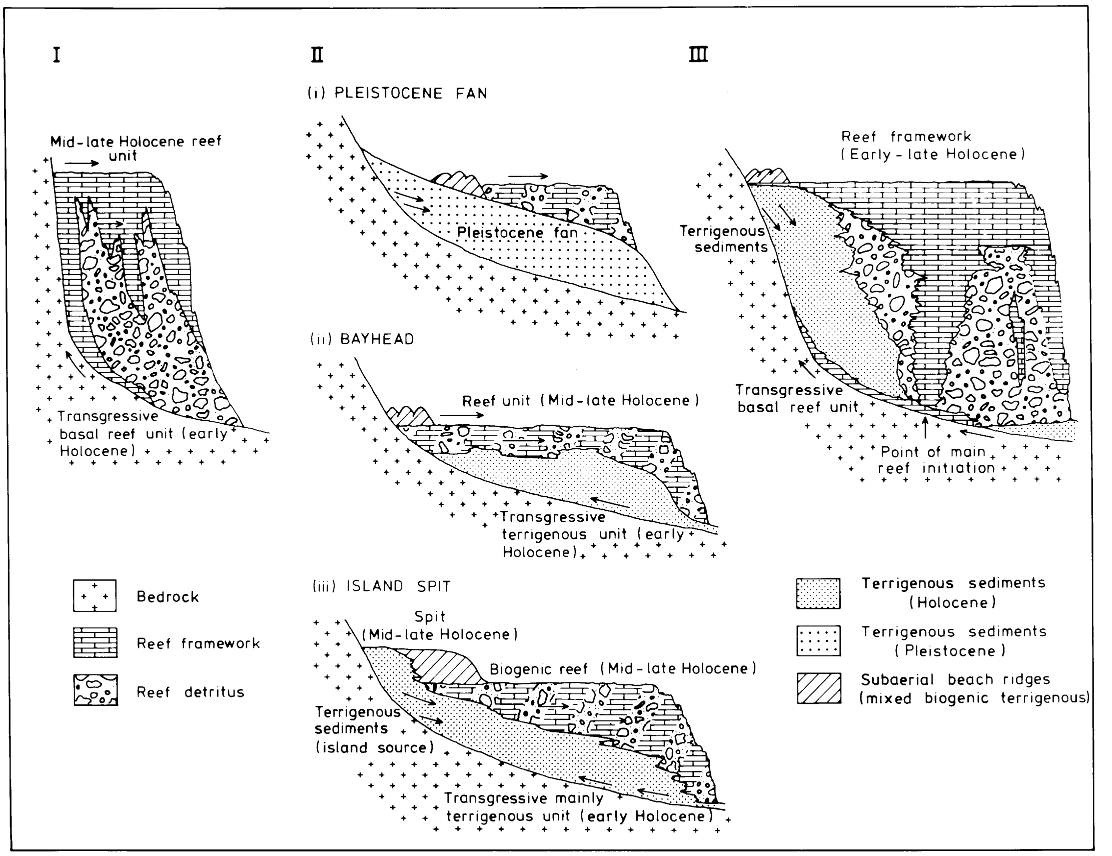

Figure C83 A structural classification of fringing reefs.

is finally deposited. Beyond this patch reefs of various forms may rise from the sandy lagoonal or back reef floor. Each patch reef may have its own "reef flat" surrounded by an algal rim. In shallower lagoons reticulate reefs forming a network of anastomosing ridges may form an intricate pattern of reef growth.

Leeward reef slope: The high energy wave zone is lacking from the leeward side of the reef and coral growth even near the surface may be in the form of branching thickets. If the leeward slope descends into deep enough water, at greater depth more light seeking platey forms may again dominate.

Fringing reefs

Fringing reefs, attached to the mainland or to a high island, may have the weakest zonational development, especially where sheltered by offshore reefs or other islands. They are the commonest reef type with an area exceeding 320,000 km^2 or more than 50% of total reef area. Many grow in turbid waters but can still flourish as long as sediment does not settle and smother the corals. However, because of the greater attenuation of light the vertical zonation of the reef front may be compressed into less than 10 m water depth.

Fringing reefs were formerly considered to be the simplest of reef forms, growing outwards from the mainland or island shoreline as originally advocated by Charles Darwin over 150 yr ago. However, over the last 20 yr a considerable amount of drilling and dating of fringing reefs has been undertaken and they have been shown to have a complexity which matches that of other reef types.

Because they have a foundation on which to grow immediately sea level stabilizes (the island or mainland shore) many fringing reefs have reef flats older than those of nearby offshore reefs. On the Great Barrier Reef micro atolls older than 6,000 yr BP are found on many fringing reef flats. However, reef establishment, growth and internal structure can show considerable variation. The structural classification (Figure C83) is based on the results from Australian fringing reefs, but records from fringing reefs elsewhere in the world suggests that it has a wider application. Three basic types are recognized:

1. Simple reefs formed from the foundation on the lowest portion of the rocky foreshore during the transgression. These reefs were developed while the sea level was still rising. Most of their development has gone into upward growth over the rocky slopes of the island, following the transgression. After the still-stand period and when the reef had reached sea level a small amount of outward growth may have been possible over the reef's own fore-reef talus slope. On the whole, such reefs are growing from relatively deep clear water and reef flat development is therefore limited due to the great vertical extent of these reefs. The structure is thus one of a basal framework unit immediately over rock and then a small biogenic detrital frontal unit with thin reef flat veneer.
2. Reefs developed over preexisting positive sedimentary structures. Reefs have long been regarded as requiring hard substrate for initiation. However, there is increasing evidence that the presence of even a muddy sedimentary structure with positive relief may greatly enhance or speed-up reef flat development. Such sedimentary structures may be in the form of terrigenous mud–sand banks or barriers, lee side sand spits attached to islands, boulder beaches, deltaic bar gravels, and low angle Pleistocene alluvial fans. During the transgressive phase, even though a bank may have existed previously, no reef development is possible because of the inhospitable nature of the substrate. However, once the rocky shores of the adjacent island or mainland are inundated reef colonization takes place rapidly on these shores at shallow depth. Progradation of the reef is then rapid over the preexisting structure with hard substrate now being provided over the sedimentary base by the fore-reef talus from the prograding reef front. The structure of such reefs is thus one of a basal terrigenous sedimentary unit, an inner framework with a prograding carbonate detrital unit extending over the terrigenous base, and an upper, thin, generally less than 4 m, reef flat framework veneer.
3. Reefs developed over more gently sloping substrate, particularly where older foundations of Pleistocene reefs may be present. In these instances, the reef foundation is initiated offshore from the present coastline, although would probably have started as a fringing reef as sea level would have been lower at this time. The rising sea level however, isolated this initial reef which continued to grow upwards during the transgressive phase as an offshore barrier. Possibly, because of poor

circulation and terrigenous input, growth behind this barrier was very slow. After the still-stand and after the reef reached sea level, the outer reef became attached to the island by lagoonal infilling, this infill coming from both the land as a terrigenous unit and from the outer reef as a biogenic carbonate unit. Following the still-stand, some small outward growth may also have taken place. The structure is therefore one of a framework unit offshore from the present shore and an interdigitated terrigenous and biogenic detrital fill behind the framework. A thin, reef flat framework veneer may be present over the entire reef and a small reef front biogenic talus may also be present.

Davies and Hopley (1983) indicated that fringing reefs grew at rates comparable to middle and outer shelf reefs, though usually at the lower end of the growth scale, that is, for framework construction in the range of 1–4 mm/yr. This may be in part a reflection of the greater proportion of massive as opposed to branching framework. As with outer reefs, the fringing reefs showed a bimodal detrital accretion rate, a lower range of 1–5 mm/yr representing accumulation under normal weather conditions, but with higher rates up to 15 mm/yr indicative of infrequent high energy cyclonic events. Fringing reefs generally show very low growth rates in shallow water, particularly when compared to the mid-shelf reefs which have both a protected situation and clear water. The lower rate for fringing reefs is probably a reflection of the turbid water conditions and periodic decline in salinities. However, at depths between 4 and 7 m, fringing reef growth seems to be at least equal to the rate of growth of both mid- and outer-shelf reefs. Below this depth there appears to be a rapid decline in accretion rate. This is interpreted as the result of the high turbidity of inshore waters and rapid decline in light levels at these depths. Equivalent decline in growth rates for outer reefs takes place below approximately 15 m.

The future of the world's coral reefs

While the store of knowledge about the functioning and evolution of coral reefs has expanded dramatically in the last 50 yr, great concerns are currently being expressed about the health and status of the worlds reefs. It is estimated that 10% of coral reefs of the world have already been degraded beyond recognition; 30% are in a critical state such that they will be lost in the next 10–20 yr; a further 30% are so threatened that they may disappear as living ecosystems in 20–40 yr; and only 30% are healthy and stable (Wilkinson, 1993).

The major reasons for this decline are from the anthropogenic stresses of organic and inorganic pollution, sedimentation, and overexploitation all of which are increasing with the exponential growth of human populations. Unfortunately, the majority of the most rapidly growing populations are in the tropics adjacent to coral reefs with subsistence economies at least partly dependent upon the reefs. However, superimposed upon these direct human pressures are the effects of global climate change with coral reefs being regarded as one of the most sensitive ecosystems to the predicted changes (Buddemeier, 1993).

Many believe that coral reefs are already showing detrimental effects of climate change with a significant increase in coral bleaching as a response to unusually high temperatures detected globally over the last 25 yr (Brown, 1997; Hoegh-Guldberg, 1999). Bleaching involves the expulsion of the symbiotic zooxanthellae (which gives the coral its color) from the coral tissue. Bleaching may be temporary and may be an adaptation mechanism that allows more resistant strains of zooxanthellae to recolonize affected hosts. However, as the zooxanthellae are so important to the metabolic functioning of the coral, severe bleaching leads to mortality of whole colonies. Bleaching events appear to coincide with El Niño episodes with significant occurrences in 1979–80, 1982–3, 1987–8, 1991–5, and 1998. As El Niño events are predicted to become more regular and severe in a "Greenhouse" world, the associated short-term higher temperatures will be superimposed on a more general global warming, leading to increased stresses for coral reefs.

There are other harmful effects, including increased sedimentation from more runoff as tropical areas receive more rainfall, possible greater damage from increasing frequency and severity of tropical storms, and inhibition of calcification with CO_2 enrichment of ocean water. Planktonic and larval stages of many reef organisms, including corals, may be particularly susceptible to increasing ultra violet B (UVB) and shorter ultra violet A (UVA) radiation associated with decreasing levels of ozone in the upper atmosphere.

Rising sea levels can produce some beneficial effects. Inundation of reef flats which have been at sea level for 5,000 yr or more may regenerate coral growth with reef flats contributing more significantly to carbonate production. Wave efficiency across reef flats may increase and sediments stored there may add to reef island construction. Some reef islands, contrary to popular opinion, can actually grow rather than erode as the result of rising sea level, but with reorientation of many islands also probable, the amount of inhabitable area with older cultivatable soils may decrease. Coral reef islands may not disappear, but their attractiveness for human habitation may decrease. Similarly, the structures which are coral reefs will not disappear as the result of anthropogenic stresses, but their dominance by animals (corals) may be overtaken by algae and other plants for which the Greenhouse scenario is more beneficial.

CORAL REEFS, EMERGED

Corals and other reef-building organisms such as algae live within the photic zone, rarely deeper than 100 m and are limited upwards by intertidal exposure. However, well-preserved reefs emerged up to hundreds of meters above modern sea level are found in many parts of the world. All types of reefs are found emerged although the most common are fringing reefs occurring as terraces built over volcanic or other non-carbonate foundations (Figure C84). Emerged barrier reefs appear to be rare, even in Indonesia which has both extensive, modern barrier reefs and numerous emerged fringing reefs (Tomascik *et al*., 1997). However, a section of the very long (2,000 km) Papua New Guinea barrier reef is emerged in Sabari Island (Figure C85) to the north of the Louisiade Islands, and in the Trobriand and Lusancay Islands to the north. Many emerged atolls occur in the Pacific (e.g., Henderson, Makatea, Mataiva, Nauru, Walpole) and in Indonesia (Maratua, Kakaban). Detailed descriptions of the geology and hydrogeology of many emerged reef examples can be found in Vacher and Quinn (1997).

Causes of emergence

It is generally accepted that world sea levels were last ubiquitously above present during the last interglacial about 125,000 years ago and reefs of this age up to 10 m above present sea level have been reported from many quasi stable areas of the tropical world (e.g., Western Australia, parts of Tonga, Aldabra, Curacao). However, most of the world's reefs were exposed during the periods of glacially lowered sea levels (up to 150 m below present). Landforms produced during exposure have been a major influence on modern reefs (see *Coral Reefs* entry). Emergence during the Holocene is more limited and for isostatic reasons is largely restricted to the Southern Hemisphere (Hopley, 1982, 1987). For example, in the Great Barrier Reef region of north-east Australia emerged reefs of about 1 m and with an age of about 5,000 years are found only on the inner shelf islands and mainland and consist of coalescing micro atolls rather than fully developed fringing reefs as the period at the high level was short and followed a rapid post-glacial rise (Chappell *et al*., 1983).

Figure C84 Tectonically uplifted emerged reef terraces rising to 270 m on Misima Island, Louisiade Archipelago, Papua New Guinea.

Figure C85 Notch and visor cut into the emerged barrier reef of Sabari Island, Louisiade Archipelago, Papua New Guinea. The reef is probably last interglacial in age.

Figure C86 The back of the 83,000-year reef terrace with sea stack displaying fossil notch and visor cut into older Pleistocene reef limestone, north-east coast of Barbados.

The most spectacular suites of emerged reefs occur in areas of strong uplift at the margins of the world's tectonic plates (e.g., Ryukyu Islands, Barbados (Figure C86), Papua New Guinea (Figure C84), Indonesia). In mid-ocean areas uplift may also occur around hot spot swells or over asthenospheric bumps and is especially responsible for emerged atolls such as Ocean, Nauru, and Marcus Islands (Scott and Rotondo, 1983). Long-term average rates of uplift may be as high as 5 m/ka with the highest reefs being of Tertiary age. For example, on Gunung Dirun Timur, Indonesia, terraces at 1,293 m are of Pliocene age (Tomascik *et al*., 1997). The majority of the best preserved reefs, however, are Pleistocene and because of the rate of uplift represent not only interglacial high stands but also reef-building periods at stable sea levels which were well below present. Emergence in these unstable areas continues with individual earthquakes having the potential to uplift living reef flats >2 m above sea level (e.g., Cortes, 1993).

Modifications after emergence

After emergence, coral reefs undergo changes to both the geochemistry of the reef fabric and to the morphology of the surface features. The original limestone deposited beneath the sea by coral and other plants and animals is largely aragonite or high magnesium calcite. Once uplifted, however, the limestone is unstable in the freshwater vadose and phreatic environments and diagenesis through solution and reprecipitation as stable phase low magnesium calcite takes place (Matthews, 1974). The open framework of the original reef becomes denser, infilled, and with greater cementation (Figure C78, *Coral Reefs* entry). A coarse calcite crystalline structure is produced and in the uppermost layers a caliche horizon may be formed consisting of a distinctive brown crust with numerous micritic stringers (e.g., Hopley, 1982), (Figure C79, *Coral Reefs* entry). These processes also operated on reefs exposed during major sea level falls of the Pleistocene. Subsequent recolonization during post-glacial transgressions results in distinctive unconformities (see entry *Coral Reefs*), several of which may be found beneath modern reefs.

Erosion of emerged reefs may be relatively slow as the permeable limestone does not support surface drainage. Karst processes dominate but whether or not they have been rapid enough to produce large-scale relief features during the limited exposure of reefs emerged only by sea level fall as suggested by Purdy (1974) is debatable (Hopley, 1982, chapter 7). Bloom (1974) has suggested a facies control over rates of solution which would emphasize the constructional relief differences between reef rim and lagoon floor. Even in ancient reefs, structure may remain evident through facies guidance of solution. For example, the Devonian reefs of Western Australia were buried beneath Permian sandstones then truncated by a Mesozoic–Tertiary planation surface, yet uplift and rejuvenation has resulted in emerged reefs (the Limestone Ranges of the Canning Basin) which faithfully mimic the original morphology. Reefs which are permanently emerged by tectonic uplift do have sufficient time to produce a range of karst landforms including cave systems, solution holes, and gorges. Their surfaces are an intricate network of holes and pinnacles either completely exposed or buried under soil and in some instances, commercially valuable phosphate deposits. Numerous local terms have been applied to this rocky relief (*makatea, feo, ironshore, champignon, platin, pavé*).

Emerged reef erosion may also take place horizontally with processes of bioerosion aided by some solution and physical abrasion creating an intertidal notch with overhanging visor (Figure C85) at rates of up to 7 m/ka (Hopley, 1982). Undercuts of several meters may occur and remain etched into the sides of emerged reefs as they are uplifted, providing erosional evidence of former relative sea levels, in addition to the reefs themselves (Figure C86).

The value of emerged reefs for scientific research

The accessibility of an ecological community and landform which is normally underwater, the relatively tight constraint in the relationship of a raised reef surface to a former sea level, and the accuracy of radiometric dating of constituent corals make emerged reefs highly valuable to several branches of scientific research. For example, they have been used in the development, calibration, and refining of dating techniques (e.g., Grün *et al*., 1992) but they have made particularly prominent contributions to the understanding of past eustatic sea levels, including those of the last glacial period. In some areas, at least, average uplift rates have remained constant over the latter part of the Pleistocene and are calculated from the present level of reefs for which the original eustatic level is well constrained (e.g., the mid-Holocene or the last interglacial). The uplift rate is then applied to other terrace levels which are dated by radiocarbon or uranium series methods to obtain a past sea level. These techniques were developed originally in Barbados (Broeker *et al*., 1968; Mesollela *et al*., 1969) and the Huon Peninsula in Papua New Guinea (Bloom *et al*., 1974; Chappell, 1974). Results are continually being refined (e.g., Ota *et al*., 1993) and the degree of agreement between results from different areas justifies the basic assumptions.

Evidence from emerged reefs has also been used in geophysical modeling to develop theories of seafloor spreading, and processes associated with hot spots or melting anomalies, including lithosphere loading, cooling subsidence, and asthenospheric bumps (McNutt and Menard, 1978; Scott and Rotondo, 1983). They have also aided in the understanding of upper earth rheology, flexure of the ocean lithosphere, and global isostatic responses.

Accessibility allows complete species inventories to be made and corals in particular may remain well preserved in even the oldest elevated reefs. From the data collected, the evolution of genera and species can be followed (Veron, 1995) or the changes in ecological communities deduced from timescales ranging through millions of years to the Holocene (Veron and Kelley, 1988; Budd, 2000).

CROSS-SHORE SEDIMENT TRANSPORT

Cross-shore transport

Cross-shore transport refers to the cumulative movement of beach and nearshore sand perpendicular to the shore by the combined action of tides, wind and waves, and the shore-perpendicular currents produced by them. These forces usually result in an almost continuous movement of sand either in suspension in the water column or in flows at the surface of the seafloor. This occurs in a complex, three-dimensional pattern, varying rapidly with time. At any moment, some sand in the area of interest will have an onshore component while other sand is moving generally offshore. The separation of the total transport into components parallel and perpendicular to the shore is artificial and is done as a convenience leading to a simpler understanding of a very complex environment (see entry on *Longshore Sediment Transport* for shore-parallel transport).

Cross-shore transport has been well studied because of its importance to beach erosion. Unlike longshore transport, which is difficult to observe, cross-shore transport can result in large and highly visible changes in the beach configuration over intervals as short as one day. Because of the complexities associated with cross-shore transport, its magnitude and direction is usually inferred from changes in the elevation of the beach and the adjacent ocean bottom. Elevation profiles across the beach and through the surf zone are obtained with conventional surveying techniques, augmented as necessary with water depth measurements from a boat or other floating platform. A reduction in the amount of sand above mean sea level and a corresponding increase in the volume below this reference, for example, would be interpreted as offshore transport. If the beach volume increases at the expense of submerged sand levels, this implies shoreward transport. If the measurements were error-free and the transport was entirely in the cross-shore mode, the amount of sand in the system should remain constant. Gradients in longshore transport, however, can result in local accumulations or losses that make the precise assessment of cross-shore transport difficult.

Small cross-shore adjustments occur during each tide cycle along coasts with significant tide ranges. Much larger cross-shore transport events are associated with major storms, which may last for several days. These changes can be expressed in substantial beach or dune erosion or in rapid formation or migration of bars or other submerged formations. Intervals of smaller waves, and particularly swell of low steepness, can reverse the effects of storms and repair eroded beaches or move bars shoreward. These reversals have much longer timescales, perhaps as long as weeks or months. The accumulated effects of many storms during winter months and long intervals of low waves in summer, for example, can produce seasonal effects through cross-shore transport, as illustrated in Figure C87. Winter beaches may be characteristically lower and narrower with pronounced bars near the location of the largest breakers, while summer beaches are wider and with smaller, less-distinct bars closer to shore. Local wave climates, tide ranges, and sediment size influence these seasonal types, but the changes are a direct result of cross-shore transport.

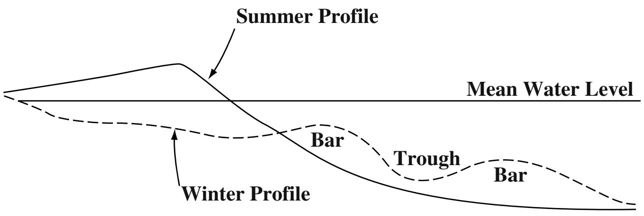

Figure C87 Cross-shore transport. The figure shows schematically how seasonal changes in wave climate affect beach profiles. During winter storms, the dry beach is eroded and seaward cross-shore sediment transport results in the formation of one or more offshore bars. Typically, the envelope within which the shoreline ranges retreats seaward in winter and shoreward under the milder wave climates of summer.

A number of investigations have been made in an attempt to predict what wave conditions would result in a shift between offshore and onshore transport. Much of the early work was done in laboratory wave tanks, using simple waves (Johnson, 1949). Johnson associated the shift between the formation of summer and winter waves with a critical incident wave steepness in deep water. Other investigators found that the absolute size of the wave changed the critical steepness ratio. A second dimensionless parameter, the ratio of the wave height to the mean sediment diameter, was added by Iwagaki and Noda (1963) to account for scale. Seymour and Castel (1989) review the performance of six simple predictors for the direction of cross-shore transport, which involve some nondimensional combination from among wave height and period, sediment size and fall speed, and beach slope. The best of these was successful only about two-thirds of the time. Bailard and Inman (1981) introduced physics into the study of cross-shore transport with a predictive model that was based upon energetics, the balance between gravitation tending to move sediment downslope and the upslope stress produced by wave asymmetry. More recently, numerical models have been developed to predict storm wave erosion (Larson and Kraus, 1990).

One of the earliest concepts about cross-shore transport concerned the tendency for waves to selectively move coarser sediment sizes shoreward (Cornish, 1898). This results from the asymmetry of waves in shallow water (see entry on *Waves*). As waves approach the beach, the crests become steeper and the troughs longer. The shoreward flows under the crests are higher and for shorter duration than the offshore-directed flows under the troughs. Because larger sediment sizes require higher flow speeds to initiate movement, they tend to be preferentially moved by the shoreward flows. This was later refined to the null point hypothesis in which there is a stable offshore distance for a given sediment size, with a continuous gradation from coarse on the beach to fine in deep water (Ippen and Eagleson, 1955). A number of field investigations have shown that sediment sizes are sorted in the cross-shore direction in nature, although bars and other features tend to produce locally mixed sizes as exceptions to regular gradation.

The study of cross-shore transport has resulted in the concept of an equilibrium underwater profile (Dean, 1991). The shape of the offshore profile is approximated by

$$h(y) = Ay^{0.67},$$

where $h(y)$ is the depth at distance (y) and A is a scale factor related to the grain size distribution of the sand forming the beach. This is an engineering simplification that assumes, under the constant application of a given incident wave, a particular beach will evolve toward a certain profile shape. The incident wave can be further generalized to include all of the seasonal variation, resulting in a single equilibrium profile configuration for that beach. The actual profile may never achieve this contour because the incident waves are constantly changing. However, it is useful to coastal engineers and scientists concerned with understanding the natural variability of beaches. The simple exponential model for the equilibrium beach does not include any provision for bars or other contour complexities such as rock outcroppings.

CROSS-SHORE VARIATION OF GRAIN SIZE ON BEACHES

The distinctive sorting and cross-shore distribution of clastic beach particles is often evident even to the casual observer. The position at which a sediment particle comes to rest on a beach profile and the net patterns of particle size variation resulting from sediment transport processes have long been of interest to scientists and engineers attempting to understand the fundamental relationships governing process and form on beaches.

Beach particle equilibrium and the null-point hypothesis

The null-point concept was introduced to express stability of a beach profile and the associated distribution of sediment on the profile as a reflection of the equilibrium between asymmetric fluid forces (including wave asymmetry, steady currents, and the effects of percolation), bottom slope (gravity force), and the size and weight of sediment (Cornaglia, 1889). Details of the original hypothesis as expressed by Cornaglia did not predict particle and beach morphological behavior as observed, however. Bowen (1980) and Bailard (1981) improved the null-point hypothesis by applying Bagnold's (1966) sediment transport model. According to Bowen, sediment coarser than the equilibrium grain size on the local slope has a smaller value of β/W_s (ratio of local slope and particle settling speed, descriptive of suspended load) and $\beta/\tan\phi$ (ratio of local bottom slope and grain friction angle, descriptive of bedload). Therefore, assuming a shoreward asymmetry in the velocity field, the term involving gravity is reduced, and coarser particles move shoreward to a position having the limiting slope. Similarly, finer particles should move offshore, as observed (e.g., Zenkovitch, 1946).

Sediment transport and profile formation are more complex than are described by the theoretical models of Bowen, Bailard, and others. The concept of a sediment grain being in equilibrium with forcing requires the choice of appropriate temporal and spatial scales for analysis. Time scales as short as a single or even half wave cycle may be involved in the sorting and concentration of mineral grains according to size and density within beach laminae in the swash zone (Clifton, 1969). At somewhat longer timescales, antecedent conditions, such as recent storms or periods of swell, spring/neap variations in tide level, water table variations, or a locally significant change in sediment supply or exposure can alter the shape and location of beach profile features and influence the distribution of sediments comprising the beach. At still longer timescales the relative sea level, sediment sources, prevailing climatology, and offshore bottom slope comprise the framework on which beaches and their particle size distributions develop.

Processes of selective sediment transport

The equilibrium profile depends on the sorting (standard deviation) and shape of the sediment as well as its size. Poor sorting results in less percolation and flatter profiles compared with well-sorted sediments of the same size (Krumbein and Graybill, 1965; McLean and Kirk, 1969). The sorting processes themselves are dependent on the particle properties as well as the hydrodynamics. Sand-sized particles are sorted according to differences in densities, sizes, and shapes of the sediment particles. Four basic processes of dynamic equivalence or selective sorting act on beach sediments (Komar, 1989; Hughes *et al*., 2000). Settling equivalence, hydraulic equivalence (Rubey, 1933), or suspension sorting is the principle that permits a larger grain of lower density to be deposited simultaneously with smaller grains of higher density. Entrainment equivalence or selective entrainment (Komar and Wang, 1984) refers to the difficulty of entraining smaller and heavier particles within a matrix of comparatively larger and lighter particles. Smaller particle size can be a direct factor in reducing particle mobility in terms of both relative exposure to flow and larger size of pivoting angle. Selective transport refers to the differential rate at which particles are carried by a flowing fluid by virtue of their position in the flow. Dispersive pressure equivalence or shear sorting refers to the process in which coarser grains tend to migrate upward to zones of lower shear while finer and denser grains move downwards to the zone of maximum shear (Bagnold, 1954). The operation of such selective processes in the swash zone may lead to heavy mineral enrichment particularly in erosional episodes.

Part of the cross-shore selective sorting of sediment can be attributed to the patterns of orbital motions under waves as they shoal. Orbital motions under a Stokes-type wave, for example, consist of a forward orbital motion of short duration but high velocity under the crest while the return flow under the trough is slower but of longer duration. Cornish (1898) hypothesized that Stokes asymmetry might explain the shoreward movement of coarse particles and the seaward movement of fine particles. The idea has been verified in experiments (Bagnold, 1940) and modeled with some success (Horn, 1992). A grain may move incrementally shoreward by falling back to the bed before a wave near-bottom orbital trajectory has completed its half-cycle. A grain that is thrown into suspension and falls to the bed in a longer time than one-half the wave period may be deposited seaward of its initial location (Dean, 1973; Nielsen, 1983). Ahrens and Hands (2000) compared sediment stability values with the maximum near-bottom velocity under the breaking wave trough, U_t, calculated with Stream Function Wave Theory to reliably discriminate onshore and offshore sediment transport. Large absolute values of U_t are associated with high suspended load and bedload transport offshore by undertow, and small absolute values of U_t with net onshore bedload transport. Although most of the attention has been focused on the dominant incident waves that arrive at the outer edge of the surf zone, the relative roles of waves of different lengths or frequencies in the selective sorting process in the nearshore zone has not been investigated in detail.

Recent field and laboratory experiments have begun to examine the vertical and temporal coupling between the sediment in transport and the near bed fluid motion to gain further insights regarding the fractionation process (see review by Greenwood and Xu, 2001). Osborne and Vincent (1996) demonstrate the importance of the phase coupling between the unsteady flow at different elevations and the vertically varying instantaneous suspended sediment concentrations in determining the direction and magnitude of sediment transport in combined waves and currents over rippled beds. Prototype scale wave flume measurements document distinct horizontal fractionation of sediment by size (Greenwood and Xu, 2001). Sediment became progressively coarser onshore and progressively finer offshore in the wave flume from the same homogeneous source suggesting that the sorting is explained by suspension transport alone and is controlled by: (1) an increase in the proportion of fines and a decrease in mean size with increasing elevation above the bed; and (2) vertically stratified sediment transport with net onshore transport near the bed and net offshore transport at higher elevations. Direct field measurements are needed from a range of nearshore environments and wave height and period combinations to confirm the relative importance of the mechanisms involved.

Cross-shore variation in grain size and sorting

Mean grain size may decrease both shoreward and seaward from the plunge point at the base of the swash zone at sandy shores. A secondary coarsening of sediments has been observed on the offshore bar, where wave breaking is initiated (e.g., Fox *et al*., 1966; Greenwood and Davidson-Arnott, 1972). Gravel and coarse sand lags as well as heavy mineral placers can also develop in the troughs or embayments between nearshore bars due to the interaction of waves with strong longshore currents and rips (Komar, 1989). Mean grain size decreases up the foreshore, as a reflection of the diminishing swash intensity. Sediment sorting is poorest (standard deviation of sizes is largest) where energy dissipation is greatest. Skewness is most positive (or least negative) also at the plunge point, indicating a mixing of an over-abundance of fines with coarser sediments, relative to a lognormal distribution of sizes. Bascom (1951) observed a similar pattern, with the additional finding of the second coarsest beach material on the summer berm, and hypothesized that deposition occurred by wave uprush that had overtopped the berm crest and subsequent winnowing of finer fractions by wind.

Beach sand sampled at transects across the active profile at Terschelling (North Sea barrier island of The Netherlands) showed consistent cross-shore pattern of grain size distribution over a period of 19 months (Guillén and Hoekstra, 1996). The proportion of sample in each grain size fraction (50 micron increments) showed a distinctive cross-shore pattern, unique for each size fraction and termed the equilibrium distribution curve. The distribution of the fraction across the profile, relative to the total presence of the fraction, expresses the probability concept in cross-shore sorting.

Application

Engineers and planners need to reliably project structural and beach fill performance, in terms of offshore and longshore losses of beach material, or the change in beach profile or character of the beach face, after the material is sorted by natural processes acting over a period from years to decades. Studies of grain sorting also have relevance to understanding the formation of placers, which may have economic or intrinsic value. Understanding the processes that cause size variation of sediments across a beach profile, and the impact of the material composition on shore morphology is key to wise management of coastal resources.

CUSPATE FORELANDS

Cuspate Forelands are accretionary features, which occur on many coastlines of the world; Cape Kennedy (Cape Canaveral) on the east coast of the United States and Dungeness on the south coast of Britain being but two of the more well-known examples (King, 1972). While they vary considerably in shape and size they are generally triangular in outline with the base attached to the coastline and the apex facing the open sea or ocean. Although similar in overall shape, cuspate forelands must not be confused with cuspate spits; the former are cuspate forms which have grown by progradation, usually with nested shore-parallel beach ridges. Cuspate forelands are related to beaches, tombolos, spits, and barriers but whereas the related accretionary features tend to smooth out the coastal outline cuspate forelands accentuate coastal irregularities.

Formation

A number of theories have been forwarded to account for their origin. They may develop in the lee of an offshore island that shelters a segment of the coast in the shadow of the predominant oncoming wave front (Bird, 1984). Waves are refracted to either side of the offshore island and concentrated wave energy affects the mainland shore to either side. Immediately behind the protective island diminished wave energy allows longshore moving sediment to accumulate. If the offshore island is sufficiently near the mainland the cuspate foreland may extend to the island itself in which case a tombolo develops. This has been observed in South Australia at Gabo Island. Here a cuspate foreland developed, it then joined the offshore island to form a tombolo and subsequent storm breaching made it a cuspate foreland once more. Formation in the lee of a protective offshore island however is only one way in which they can form.

More difficult to explain are cuspate forelands which develop on an open coastline with no protective offshore islands (Steers, 1964). The east coast of England affords many examples of this type. Lowestoft Ness (the most easterly point of the British mainland) is one such feature. Whereas the cuspate forelands formed in the lee of protective islands remain relatively stationary, forelands with no such protection can, and very often do, migrate along the coast (Russell, 1958). Surveys in the British Isles have tracked such features migrate along a coastline many kilometers. Banacre Ness in Suffolk has moved northwards by some 2 km over the last 100 years in spite of the dominant longshore drift being to the south (Robinson, 1965). In some cases, the longshore migration has oscillated with periods where a foreland has migrated in one direction followed by periods where reverse migrations have occurred (Hardy, 1966). Occasionally two adjacent cuspate forelands on an open stretch of coast have migrated in opposite directions. Such variations and contrary movement defy simplistic explanations relating foreland development merely to longshore drift.

While beach drifting and dominant waves are important, offshore current residuals and changing seafloor topography are significant contributory factors. Offshore from the British east coast examples can be found of bank and channel complexes developed by the ebb and flood of the tide. Ebb- and flood-dominated channels tend to be separated by sand banks and adjacent to the apex of each foreland can be found an offshore sandbank trending toward the coast (Robinson, 1964). Over time any change in the position of the offshore bank has resulted in a change in the position of the foreland, albeit after a short time lag. The supply of sediment arriving on the beach from the offshore bank is greater than the removal of the sediment along the beach and hence the local build-up of sediment at the landward termination of the adjacent sand bank. The movement of sand onshore from the adjacent sandbank together with wave refraction caused by the offshore sand bank itself accounts for the creation of the foreland and can account for its movement along the coast, which may be in a contrary direction to the main longshore drift.

Surface gravel, which is often present on the British cuspate forelands, is usually found in ridges—it is the tracing of these shingle ridges, which gives a clue to both their formation and migration, (Lewis and Balchin, 1940). The shingle moves along the surface of the beach and accumulates in the area of lower wave energy. While the offshore sandbanks offer less protection than adjacent offshore islands the lesser influence on wave refraction is made up for by their contribution of sediment to the adjacent coastline.

DALMATIAN COASTS

A Dalmatian coast is a prototype of a primary coast by ingression of the rising postglacial sea into a relief of coast-parallel anticlines and synclines from a young orogenesis (Holmes, 1965; Kelletat, 1995; Jackson, 1997), and is named after the landscape of Dalmatia (Croatia, former Yugoslavia, Adriatic Sea, Mediterranean). This type of coastline is very rare, a major example may be the Island of Sumatra with the Mentawai Islands strongly parallel in the Indian Ocean. More resistant elongated cuestas may build the island chains instead of anticlines. The narrow channels between these long islands are called "vallone" or "canale" (from the Italian word for channel or valley), and the Dalmatian coast therefore is named a canale- or vallone-coast, as well (Figure D1). The coastlines of the central part of Croatia, built up mostly by Mesozoic limestones, show only very little forming by true littoral processes. Beaches are missing as well as extended cliffs. The first is because of the small discharge or limited discharge area in a limestone environment with strong karstification, the second because of a very weak surf energy along the Adriatic Sea or inside of the canale and vallone with small fetch. Therefore, the coastlines nearly exactly follow a contour along an older relief, formed during longer periods of terrestrial

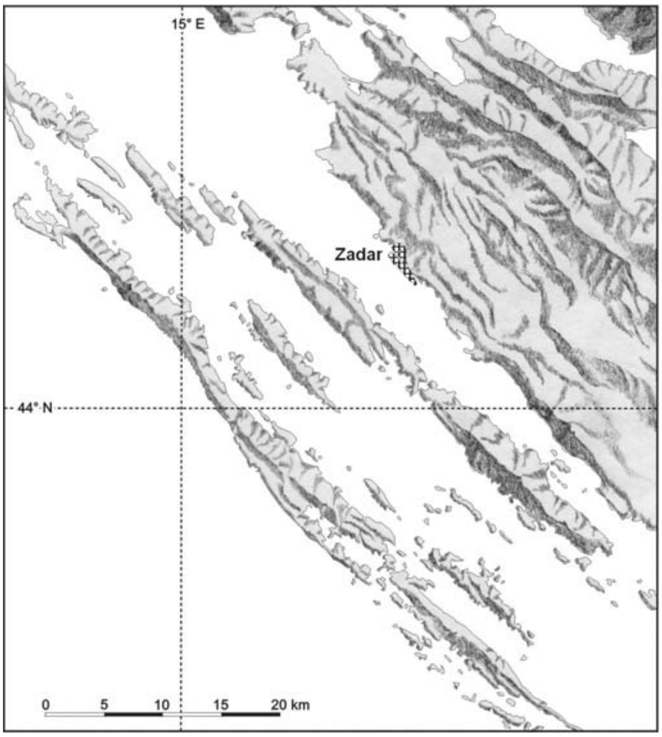

Figure D1 The central part of the Dalmatian coast with many parallel vallone or canale as waterways, and anticlines or cuestas as island chains (from Kelletat, 1995; with permission of the *Journal of Coastal Research*).

denudation. Partly drowned karst features (dolines, uvala, poljes) decorate some of the coastlines, in particular along the mainland coast, where freshwater karst springs occurring at the coast or even under the sea are numerous. The overall picture of the Dalmatian coast gives the impression of submergence and down warping. Indeed higher coastal terraces or deposits from earlier interglacial sea-level highstands are missing. This picture will change very little during a further sea-level rise or sea-level fall, because in the first case the ingression will drown the next depression, while the outermost islands will disappear under a rising sea level, and in the second case new island chains will emerge, while canale or vallone will be transformed into inland depressions.

DAMS, EFFECT ON COASTS

People have constructed dams, weirs, or barriers on rivers to utilize and manage water resources for thousands of years. The utilization of water energy also has a long history, such as waterwheels and watermills, etc. The initial dams were used to control water resources and to supply water for irrigation and domestic purposes. Later, the energy of rivers was harnessed behind dams to power primary industries directly, and more recently still, hydroelectricity has been generated using water held in reservoirs, allowing the impoundment and regulation of river flow. The modern era of major dams dates from the 1930s and began in the United States with the construction of the 221 m-high Hoover Dam on the Colorado River. But in the last 50 years there has been a marked escalation in the rate and scale of construction of large dams all over the world, made possible by advances in science and technology. Some major rivers in the world have been intensively manipulated in this way.

Today, approximately one-third of the countries of the world rely on hydropower for more than half of their electricity supply. The hydropower provides 20% of all electricity globally. If this electricity were produced by the combustion of fossil fuel, carbon dioxide emissions would increase by 2 billions tons a year. The construction of dams on rivers, as an infrastructure of national economy, plays an important role in controlling flood, hydroelectricity generation, irrigation, navigation, water supply of industry and agriculture, etc. There is no doubt that the construction of large dams has been successful in achieving their socioeconomic benefits. However, dams alter river hydrological regimes, accordingly induce structure and function changes of ecosystems, and inevitably have marked effects on nature and ecological environment of river drainage basins. An estuary is the only pathway of materials from the drainage basin into the sea. The coastal area far away from dams is the sink of riverine freshwater, sediments, and nutrients. Dams on rivers alter their downstream material discharge into the sea, accordingly induce impacts on estuaries and the coastal zone, such as estuarine channel evolution, the actions between runoff and tide, coastline changes, saltwater intrusion in estuarine and land salinization in delta areas, and ecosystem variations in estuaries and seas. Thereby, damming has positive and negative socioeconomic effects, but in the coastal area it has more negative effects.

Status of dam construction

The International Commission on Large Dams (ICOLD) defines *large dams* as usually >15 m from foundation to crest. Dams of 10–15 m can also be defined as large dams if they meet the following criteria: crest length of 500 m or more; reservoir capacity of at least 1 million m^3; maximum flood discharge of at least 2,000 m^3/s; "specially difficult" foundation problems, or "unusual design." *Major dams* meet one or more of the following criteria: at least 150 m-high; having a volume of at least 15 million m^3; reservoir capacity of at least 25 km^3; or generation capacity of at least one gigawatt.

Table D1 Watersheds with more than five major dams

Watershed	Number of dams
Paranà (South America)	14
Columbia (North America)	13
Colorado (USA)	12
Mississippi (USA)	9
Volga (Russian)	9
Tigris and Euphrates (Mid-East)	7
Nelson (Canada)	7
Danube (Mid-Europe)	7
Yenisey (Russian)	6
Yangtze (China)	6

Based on the definition above, there are some 45,000 large dams, most of which were built in the past 50 years, that now obstruct the world's rivers. There are 306 major dams in the world today and 57 are planned in the near future (Revenga *et al*., 1998). The most active phase of large dam construction was in the period between 1950 and the mid-1980s, when 885 dams were completed on average each year. At the end of 1960, there were 7,408 such dams registered. By 1986, the total had reached 36,562. Of those constructed, 64% were in Asia, with no less than half of the world total in China. Excluding China, most of the new structures have been built in the temperate zone, but tropical and subtropical countries such as Brazil, Mexico, India, Thailand, Indonesia, Zimbabwe, Nigeria, Cote d'Ivoire, and Venezuela have also become prominent in dam construction. Of these dams 79% are less than 30 m in height, and only 4% exceed 60 m. In total, the world's major reservoirs were estimated to control about 10% of the total runoff from the land in the 1970s. That figure had risen to 13.5% by the early 1990s (Postel *et al*., 1996) and must be nearing 15% today. The world's largest impoundment, the 8,500 km^2 Volta Reservoir behind Ghana's Akasombo Dam, flooded 4% of that nation's land area. There are 10 watersheds with more than 5 major dams (Table D1).

To date, China has built almost half (22,000–24,000) of the world's estimated 45,000 large dams, and remains one of the most active dam-building countries today. Over 22,000 of the estimated 85,000 significant reservoirs and dams in China are considered as large dams, though there are perhaps a few million small-scale and localized water diversions, check dams and weirs built by local collectives or individual farmers that are unrecorded. China has thus built more than three times the number of large dams in the United States and over five times the number in India. Virtually, all these dams were built since the founding of the People's Republic of China in 1949, as only 22 large dams existed before that time. The water resources controlled about 100 billion m^3, risen to 565 billion m^3 today. At least 90 dams over 60 m are under construction, including the Three Gorges dam on the Yangtze (175 m) and Xiaolangdi on the Yellow River. The utilization rate of river water resources increased to 19.9% in 1997, while the Yellow, Huaihe, and Haihe River are all over 50%, and the Haihe River is nearing 90%. In the United States, 5,500 large dams make it the second most dammed country in the world.

Effects of dams on coast

Alternation of material discharge into the sea

Dam construction on a river changes the flow regime of almost the entire river, both changing its seasonal variations and/or reducing its overall volume, and further change and/or reduce sediment and nutrient outflow. Consequently, almost all parts of the estuarine and coastal environment can be impacted by changes to flow, sediment, and nutrients.

First, damming and reservoir construction change water discharge into the sea. The nature of the impacts depends on the design, purpose, and operation of the dam, among other things. For instance, following construction of the Aswan High Dam on the Nile River, Egypt and Lake Powell River dam on the Colorado River, USA not only altered the seasonal variations of natural flow but also reduced its overall water volume into the sea. One well-documented example of additional stresses created by dams pushing an ecosystem toward collapse has been documented in San Francisco Bay. Prior to 1850, approximately 34 km^3 was discharged on average into San Francisco Bay from the San Joaquin and Sacramento River systems. Today, there exists more than 20 km^3 of water storage capacity in the Central Valley. Approximately 40% of the flow in the these Central Valley rivers are removed for local consumption and 24% is pumped from the San Francisco Bay Delta and exported to Southern California and the Central Valley. Less than 40% of the river flows are now discharged to the Bay (Nichols *et al.*, 1986). In the extreme drought of 1977, releases dropped to 100 m^3/s, from the customary dry season discharges of 400 m^3/s.

Second, because of damming, sediments are intercepted in reservoirs behind dams and reduce sediment discharge into the sea. Before the Aswan High Dam, the Nile River carried about 124 million tons of sediment to the sea each year, depositing nearly 10 million tons on the floodplain and delta. Today, 98% of that sediment remains behind the dam. The construction of the Three Gorges Dam on the Yangtze River, China, will not change total water discharge into the sea, just change seasonal distribution of runoff, but will reduce sediment outflow by approximately 20%. Otherwise, besides reducing sediment discharge, dams may also change the grain size of sediments, large amounts of wash load are intercepted in reservoirs, reducing the supply of fine-grained sediments to estuaries.

Dams not only alter the pattern of downstream flow and sediment (i.e., intensity, timing, and frequency) they also change nutrient regimes. Nutrients carried by runoff and sediments discharge changes with water and sediment outflows. The Colorado, Nile rivers have weak nutrient levels, probably because of high abstraction rates from large reservoirs, leaving little discharge into the sea.

Dams alter the conditions of water, sediment, and nutrient discharges into sea, leading to huge impacts on the environment and ecosystems in estuaries and on coasts (Figure D2), such as coastal erosion, saltwater intrusion, and position changes of mouth bars in estuaries, nursery ground for many valuable fishes. Dam construction on an upstream river, although it does not alter overall volume of outflow, changes its seasonal variations and reduces sediment discharge, which all have profound effects on a river mouth and its adjacent coast.

Coastal erosion

A coastline is dynamic and constantly changing due to coastal erosion and accretion, and its change rate is determined by natural processes, such as rough seas, sea-level rise, high tides, nearshore currents, runoff, as well as human developments that can restrict or accelerate the volume of sediment available for shores. A constant supply of sediment is necessary for depositional coasts to form and be maintained along this coastline. Many human activities reduce the supply of sediment that reaches the sea and, in turn, deprive coasts of replenishment. These activities include dam construction and other developments. Lack of sediment replenishment creates greater vulnerability for coastlines that have always been subject to varying levels of erosion. A principal coastal concern today and in the foreseeable future is coastal erosion. It is estimated that 70% of the world's sandy shoreline are eroding (Bird, 1985). In the United States, the percentage may approach 90% (Leatherman, 1988). This worldwide extent of erosion suggests, that eustatic sea-level rise is an important underlying factor, while many other processes, especially reduced sediment discharge into the sea, are important causes. Dam construction on rivers which intercepts sediments in reservoirs is one of the causes for reduced sediment discharge into sea. Because of dams, the sediment supply to an estuary and its adjacent coast is reduced, thus accelerating coastal erosion. Even in a coastal delta of rich sediment supply, such as the Yangtze Delta, dams on the river may slow its accretional rate and gradually transfer to erosion.

Reduced sediment discharge directly affects coastal delta progradation, leading to loss of beach. For example, the slow accretion of the Nile delta was reversed with the construction of the delta barrage in 1868. Today, other dams on the Nile, including the Aswan High Dam, have further reduced the amount of sediment reaching the delta. As a result, much of the delta coastline is eroding by up to 125–175 m/yr. Deltas below impoundments tend to shrink, reducing habitats, because of the capture of sediments by impoundments. The Nile Delta, Egypt, has shrunk at a rate of 125–175 m/yr (Rozengurt and Haydock, 1993). The consequence of reduced sediments also extends to long stretches of coastline where the erosive effect of waves is no longer sustained by sediment inputs from rivers. Another example of this problem is along the mouth of the Volta River in Ghana. Akosombo Dam has cut off the supply of sediment to the Volta Estuary, affecting also neighboring Togo and Benin, whose coasts are now being eaten away at a rate of 10–15 m/yr. The break-off water discharge in the lower Yellow River, China results in a sharp decrease of sediment discharge into the sea and its delta erosion. The major causes are damming and water transfer. The delta erosion of the Yellow River is an issue that needs to be urgently solved due to water and soil preservation and construction of Xiaolangdi Reservoir.

Accelerated coastal erosion has been detected as a result of regulated flows and dams reducing sediment discharge to the littoral cells. For example, local coastal regions along the Egyptian Mediterranean coast have experienced erosion rates that were three times greater than in the period prior to the Aswan High Dam (Smith and Abdel-Kader, 1988). The construction of the Yangtze Three Gorges Dam will reduce sediment discharge and increase sediment transport capacity of flow in its estuary. Although it is of benefit to the sedimentation of navigation channel, it increases the action of bed sediments and leads to channel instability. Furthermore, it will increase coastline erosion and slow tidal flat accretion seaward (Chen and Xu, 1995).

Saltwater intrusion

Estuarine salinity varies with runoff, wind wave, and tidal current, and has complex spatial and temporal changes. Generally, estuarine salinity is higher during a dry season and is lower during flood season. There is a negative correlation with water discharge. Therefore, the water discharge is an important cause of saltwater intrusion. The change of water discharge leads to the alternation of the saltwater intrusion pattern: distance and intensity. Decreased discharge rates can result in saltwater intrusion along estuaries, and pollute estuarine water and groundwater. It will affect the development of freshwater resources, especially domestic and agricultural water. In the delta area, because of impounding upstream, the aquifers underground becomes saline, and leads to a shortage of fresh groundwater. Besides, the alternation of seasonal distribution of runoff also affects seasonal saltwater intrusion, thus altering the position of estuarine balance zone.

Reduced water discharge due to dams undoubtedly intensifies saltwater intrusion in estuaries. However, seasonal regulation of dams may mitigate saltwater intrusion due to increased water outflow during the dry season. For instance, salinity intrusion is a problem in the Yangtze Estuary because of the vast area using water from the Yangtze. The water stored by Three Gorges at the end of the flood season will be released to increase the dry season flow and may help to alleviate the salinity problem in the estuary.

The intrusion of seawater into delta areas when river flows have declined due to reservoir impoundment is another common downstream effect. Construction of the Farakka Barrage on the River Ganges in India in 1975 has significantly increased the amount of cropland plagued by salinity problems in Bangladesh, as dry-season discharge has declined. Nationally, nearly 350,000 ha of land in Bangladesh was affected by

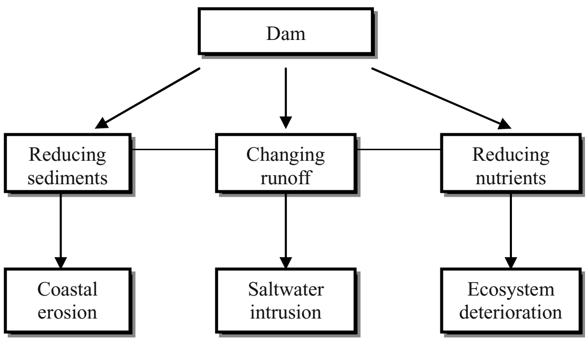

Figure D2 Effects of dam construction of rivers on coast.

salinity problems before the barrage was built, but by the mid-1990s this total had more than doubled to 890,000 ha. Downstream changes in salinity due to construction of the Cahora Bassa Dam in Mozambique are also threatening mangrove forests at the mouth of the Zambezi. Besides, reduced sediment discharge due to dams not only affects delta erosion but also intensifies land salinization.

Effects of ecosystem and biodiversity

A river's estuary, where freshwater meets the sea, is a particularly rich ecosystem. Some 80% of the world's fish catch comes from these habitats, which depend on the volume and timing of nutrients and freshwater. The riverine nutrients exist in water flow and sediments, carried and transported by flow and sediments, increase the nutrient level in estuaries and the adjacent sea. The decrease and alteration of the flows and nutrients reaching estuaries have marked effects on coastal and marine ecosystem and biodiversity, such as the nursery ground of fishes in estuaries and marine fish catch. The alteration of the flows reaching estuaries because of dams is a major cause of the precipitous decline of sea fisheries in many estuaries of the world.

The influence of diminished freshwater outflow to bays, estuaries, and coastal wetlands has become generally accepted during the past decade. One well-documented example of additional stresses created by dams pushing an ecosystem toward collapse has been documented in San Francisco Bay. This reduction in freshwater inflow contributed to a drop in phytoplankton biomass to less than 20% of normal, and zooplankton was also significantly reduced. These conditions resulted in striped bass, one of the key indicator species of the health of the ecosystem, being reduced to the lowest recorded levels (Nichols *et al.*, 1986). Water withdrawal on the North Caspian had the following effects (Rozengurt and Hedgpeth, 1989): (1) the mean salinity increased from 8 to 11 ppt; (2) the estuarine mixing zone was compressed and moved up to the delta; (3) the nutrient yield, especially phosphorus, and sediment load were reduced by as much as 2.5 and 3 times, respectively; (4) biomass of phytoplankton, zooplankton, and benthic organisms were decreased by as much as 2.5 times; and (5) a substantial part of the Volga flood plain that served as a nursery ground for many valuable fishes was transformed into drying swamps or deserts. The regulation of the Volta River in Ghana by the Akasombo and Kpong dams has led to the disappearance of the once-thriving clam industry at the river's estuary, as well as the serious decline of barracuda and other sport fish. The effects of increased salinity on fishes of the Nile Delta have been documented that out of 47 commercial fish species in the Nile prior to the construction of the Aswan High Dam, only 17 were still harvested a decade after its completion. The annual sardine harvest in the eastern Mediterranean has dropped by 83%, probably the effect of a reduction in nutrient-rich silt entering that part of the sea. The effect of lowered nutrient input is generally the greatest in the first year of life of the fishes.

Decreased discharge rates can result in an increase in salinity in estuaries and change the composition of species in this zone. The Danube Delta, central Europe, coastline is receding at a rate of up to 17 m/yr, threatening benefits from tourism down to bird life. The delta supports large populations of bird species that are generally widespread over Europe; some 170 species of birds breed in the delta, including pelicans, herons, ibises, and terns. Impoundments upstream, including seven major dams, on the 2,860-km-long river, channelization and the loss of the nutrient absorption capacity of upstream floodlands has meant that nutrients and other pollutants are affecting delta water quality. Bird populations are at a fraction of their historical numbers. So, although reservoirs may provide new habitat upstream their impacts on birds may be negative in the long-term.

The effect of dams on the ocean might be expected to be significant. The Three Gorges Dam on the Yangtze River in China is expected to reduce the productivity of the East China Sea, one of the largest fishing grounds in the world. It has been estimated that if the Yangtze River outflow is cut back by 10%, the cross-shelf water exchange will be reduced by 9% with a similar reduction in the onshore nutrient supply. Primary production and fish catch in the East China Sea is expected to diminish by a similar proportion (Chen, 2000).

Conclusion

Dam construction on rivers is a great act that human conquers nature and modifies nature. It has twofold effects: positive and negative. The positive roles are irrigation, power, flood control, and water supply, etc. In the meantime, it also leads to negative effects on environment, involving entire river basin, estuary, coast, and sea. The effects of dams on coast include coastal erosion, saltwater intrusion, ecosystem, and biodiversity, etc., and these effects are profound and mostly negative.

DELTAIC ECOLOGY

A system overview

Deltas are depositional areas where rivers meet the sea, often forming extensive, coastal, alluvial fans. Although there is much variability, deltas tend to develop where high-energy rivers deposit their sediment loads into shallow, low-energy marine systems or, more generally, where river energies exceed marine energies. For example, the Mississippi River discharges an average of 6.2×10^{11} kg of sediments per year into the shallow, low-energy waters of the Gulf of Mexico, allowing for the development of an extensive delta complex spanning 30,000 km^2. Although deltas can dominate the coastal landscape, they are by no means static; characteristically undergoing a cycle of growth, channel

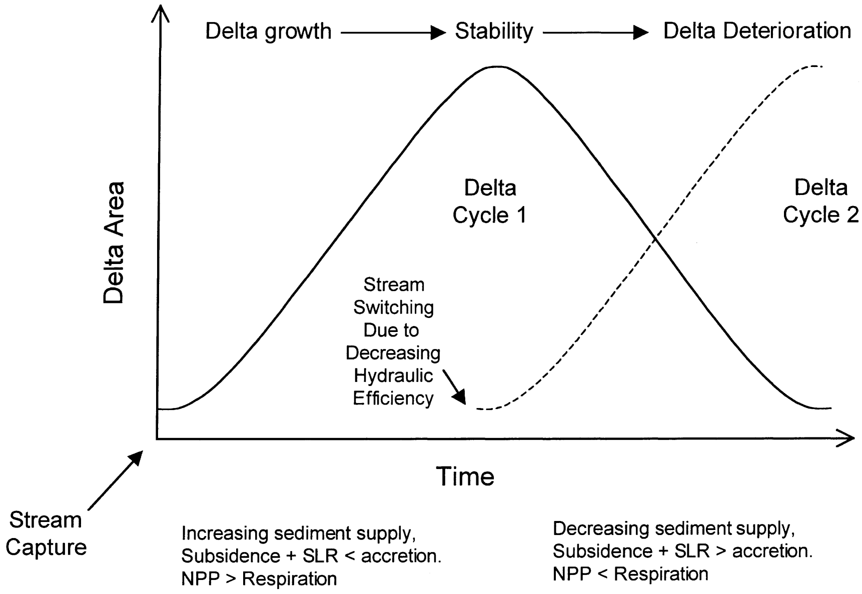

Figure D3 The delta cycle (modified from Roberts, 1997).

abandonment, and deterioration (Figure D3). Thus, the ecological populations and communities associated with deltas are unique in that they are subject to powerful allogenic riverine and marine forces, and to the overarching pattern of the deltaic cycle itself. For this reason, an introductory discussion of deltaic ecology is best approached at an ecosystem level, which considers the interactions between the biota and the abiotic forces that simultaneously drive, stress, and subsidize them.

Ecosystem types

Since an entire deltaic complex can span hundreds of kilo-meters, a wide variety of ecosystem types can be associated with them. Although natural upland habitats can be found along the landward edge of the delta and on the levees that form alongside stream channels, the systems that characterize and dominate deltas are wetlands. Wetlands are distinguished by; (1) the presence of water, either above the surface, or in the rooting zone, (2) hydric soils that develop under anaerobic conditions, and (3) vegetation that is adapted to wet conditions. Since deltas are ecotones where rivers meet the sea, concentrations of salts in the waters associated with these wetlands can range from hypersaline (>35 ppt salt) to fresh (0 ppt salt). In general, the hydroperiod (the pattern of water levels and flooding in a wetland) and the salinity control the types of wetland communities that can be found within a given delta.

In temperate zones, salt and brackish water marshes (marshes are wetlands dominated by herbaceous vegetation) characterize the saline habitats. Freshwater tidal marshes and swamps (swamps are wetlands dominated by trees) characterize either the inland regions of the delta or those areas dominated by freshwater inputs from the active delta lobe. Between latitudes 25°N and 25°S, forests called mangrove swamps characterize the saline habitats. The term "mangrove" is not a taxonomic term, but rather describes a group of 12 genera of woody halophytes adapted to growing in intertidal regions of the tropics. Mangroves show remarkable adaptations to salt and flooding stress, but not to freezing temperatures, therefore they are replaced by salt marshes in the colder temperate zones.

Primary producers and net primary productivity

For several reasons, wetlands associated with deltaic systems are among the most productive in the world. First, several types of primary producers (organisms that assimilate the energy from light to synthesize organic compounds) can be found within one wetland including; photosynthetic bacteria, algae (e.g., phytoplankton, periphyton, and macro algae), bryophytes, and vascular macrophytes ranging from sea grasses to trees. Second, delta systems receive multiple subsidies such as riverine inputs that supply nutrients, sediments, and freshwater, and tides that flush plant toxins from the sediments and maintain moderately aerobic conditions. Finally, although the vascular plants that dominate most wetlands are subject to the stress of periodic flooding and salt, they are still capable of relatively high rates of production because they have evolved numerous strategies that allow them to adapt to, or avoid entirely, anaerobic stress and high concentrations of salt. These strategies include the development of specialized tissue (aerenchyma) that transport oxygen down to the roots, and root-level micro-filters that prevent salt from entering a plant.

Ecologists typically quantify the productivity of a system by measuring its net primary productivity (NPP). NPP is defined as the rate at which biomass is accumulated by photosynthesizers, after accounting for losses due to respiration. NPP is most often expressed in units of carbon, or dry weight, per some unit of time. For example, primary producers in deltaic systems can have rates of NPP exceeding 2.5 $kg\,m^{-2}yr^{-1}$ (above ground dry weight). This is equivalent to rates of NPP measured in tropical rain forests (Whittaker and Likens, 1973). Ecologically, the concept of NPP is relevant because it represents the total amount of energy available to heterotrophs, or secondary producers, in the system, assuming no other inputs from outside the system. In deltaic wetlands, rates of NPP are controlled by (among other things), solar radiation, temperature, nutrients, salinity, and the availability of oxygen.

Secondary production

The biomass accumulated by primary producers in a wetland can be consumed directly by either herbivores, organisms that feed on dissolved organic matter, or detritus feeders (detritivores), and indirectly by carnivores. Secondary production is the rate at which biomass is produced by these consumers of primary production. Due to the inefficiencies of energy transfer, secondary production within a marsh system is much less than primary production, unless there are significant sources of organic matter coming into the wetland from outside the system. This can be the case in some riparian wetlands, for example.

It is estimated that almost 75% of primary production in marsh ecosystems is broken down by bacteria and fungi. Early studies suggested that secondary production in saltmarsh wetland systems was driven, in large part, by these detritivores feeding upon the vascular plants growing within a marsh (Odum, 1980). However, more recent research suggests that a large fraction of secondary production in salt marshes may be directly linked to fauna that consume phytoplankton and benthic algae (Kreeger and Newell, 2000).

Ecological forcing functions

Definition

Forcing functions are the exogenous variables that drive an ecosystem. For example, the sun is the ultimate forcing function that drives primary production, but of course, it is not unique to deltaic ecosystems. As

Table D2 Hierarchy of pulsing events in deltaic systems (modified from Day *et al.*, 1995)

Pulsing event	Time scale	Impacts
Avulsion	1000+ years	New delta lobe formation
Major river floods	50–100 years	Major sediment deposition Enhanced productivity
Hurricanes/ tropical storms	5–20 years	Major sediment deposition
Seasonal river floods	Annual	Sediment deposition Nutrient inputs Decrease salinity Enhance production Organism transport
Spring tides	Bimonthly	Organism transport
Storm events (frontal passages)	Weekly	Sediment deposition Organism transport
Daily tides	1–2 cycles per day	Drainage Enhanced marsh production Flushes accumulating salt and sulfides Organism transport

mentioned earlier, deltaic ecosystems are unique because they are driven by powerful forcing functions that can either subsidize or stress them. For example, river flooding contributes to anoxic conditions in a wetland (a stress), but also brings nutrients to the system (a subsidy). The following section outlines several types of forcing functions that characterize and define deltaic ecosystems.

Pulsed forcing functions

Perhaps more than most systems, deltas ecosystems are subject to pulses of energy, ranging from daily tides to once-a-century category 5 hurricanes, that subsidize the ecosystem. These energetic events, which occur at varying timescales (Table D2) affect primary productivity, material fluxes, and the evolution of the delta itself (Day *et al.*, 2000). Daily tides flush accumulated salts and sulfides that inhibit plant growth, thus enhancing primary productivity. Higher tides, which occur during full and new moons, allow fish to utilize interior marshes for feeding. The sustained winds associated with cold fronts can profoundly affect the hydrodynamics and associated sediment resuspension and deposition in deltaic regions. Annual river floods distribute sediments, nutrients, and freshwater to deltaic systems and have been shown to be positively correlated with primary and secondary productivity. On a longer term, major storms such as hurricanes can deposit several centimeters of sediment onto deltaic marshes and can be a critical process for maintaining a balance between rates of sea-level rise and rates of marsh accretion. Major river floods, which occur only once or twice a century are also associated with substantial sediment deposition and even the channel switching that starts a new delta cycle.

River switching, the ultimate pulsing event

The initial growth of a deltaic lobe starts as river sediments fill in areas along the coast and marine shelf. Eventually, as the delta extends seaward, the existing river becomes longer, the channel slope to the sea decreases and becomes hydraulically inefficient, and the entire river switches to a new channel. This switching event (an avulsion) often occurs abruptly, during a major flood, for example, when an upstream levee is breached and the river captures a new, shorter, and steeper course to the sea. In the final phase of the delta cycle, water and associated sediments are directed to the new channel, and the old deltaic lobe deteriorates as rates of subsidence become greater than the rate that sediments accumulate (Figure D3). Of course while the old delta is deteriorating, a new delta, associated with the new river channel, is forming. The rate of channel switching is governed by the characteristics of the river and the receiving basin. For the Mississippi River delta, perhaps the most studied in the world, the river changes course approximately every 1,000 years. Although pulsing events like the ones described above control ecosystem dynamics on the short term, it is the ecosystem's temporal position within the delta cycle that ultimately controls it.

Subsidence and sea-level rise

Natural rates of subsidence in many deltaic systems can be quite high due to the compaction, consolidation, and downwarping associated with the rapid deposition of alluvial sediments. This subsidence, plus the global eustatic sea-level rise (currently 0.15 cm yr^{-1}), defines the rate of relative sea-level rise (RSLR). Some of the highest rates of RSLR (1.1–1.3 cm yr^{-1}) have been recorded in the Mississippi River delta of the United States. In wetlands, high rates of RSLR can lead to increasingly long periods of inundation that are associated with decreased primary productivity and plant mortality. Therefore, RSLR can be thought of as a forcing function that stresses, rather than subsidizes a wetland ecosystem.

Deltaic wetlands can persist in the face of RSLR when vertical accretion equals or exceeds the rate of subsidence. The rate at which a wetland accretes depends upon sediment and nutrient supply, tidal range, vegetation, and climate. Current models suggest that coastal wetlands can remain stable against a RSLR rate as high as 1.2 cm yr^{-1} (Morris *et al.*, 2002). Since this rate is equal to or higher than the current rate of RSLR in many deltaic systems, this would suggest that these systems are sustainable. However, best estimates suggests that, due to the impacts of global warming, the eustatic sea levels could rise 48 cm by the year 2100 (Church *et al.*, 2001). Recent studies have suggested that few deltaic wetlands would be able to keep pace with this predicted increase in sea-level rise (Day *et al.*, 1999). Exacerbating this problem, reductions in sediment deli-very have led to rapid wetland loss in many deltaic regions worldwide. This is discussed further in the next section.

Anthropogenic disturbances

Although it is technically correct to position humans within an ecosystem, it is not out of order to consider some anthropogenic actions as allogenic forcing functions. For example, as previously discussed, seasonal river flooding deposits sediments onto wetlands that contribute directly to elevation gain, and counterbalance the effects of RSLR.

However, many of the world's major rivers that are responsible for the creation of deltas in the first place have now been dammed. This has not only trapped large amounts of sediments in the reservoirs behind the dams, but has also prevented the seasonal flooding that once distributed sediments onto the delta. For example, due to upstream dams, the sediment load has been reduced by 95% in Nile, Indus, and Ebro rivers, by 75% in the Po and Mississippi rivers, and by over 50% in the Rhone river (Day *et al.*, 2000). Additionally, because of the creation of extensive levee systems along these rivers, the remaining sediment that does reach the coast often discharges directly into deeper waters of the receiving basin, rather than accreting on the deltaic plain. Finally, many wetlands in deltaic regions have become hydrologically isolated by dense networks of canals and spoil banks constructed during the past several centuries. Spoil banks impede drainage and often physically impound wetlands, thus preventing the overland flow of any remaining sediments into coastal wetlands. As an example, because of the combined effect of high rates of RSLR and decreased sediment delivery, wetlands in the Mississippi River delta complex are currently being lost at a rate of 100 km^2 yr^{-1}.

While the hydrologic alternations that reduce pulses are perhaps the greatest anthropogenic forcing function threat to deltaic ecosystems, they are by no means the only ones. Other anthropogenic disturbances include eutrophication, organic enrichment, thermal pollution, toxic inputs, over harvest, and exotic species introduction. Also, because of their position in the landscape, deltas are, and always have been, desirable places to live, farm, and conduct commerce, and humans continue to encroach on these systems.

Toward the conservation and restoration of deltaic ecosystems

Deltaic wetlands provide numerous valuable services such as fisheries production, disturbance regulation, and water quality improvement to a global population that is increasingly concentrated near the coast and dependent upon its resources (Nuttle *et al.*, 1997). Scientists and resources managers have become aware that, to prevent the further loss of these systems, landscape scale solutions directed toward the restoration of sediment supplies are required. Some of the more successful projects have included: (1) creating gaps in the artificial levees that line most distributory streams, (2) removing sea-side dikes to restore tidal flushing, and (3) creating large-scale diversions of river water to re-introduce nutrients, freshwater, and sediments to wetlands that have been hydrologically isolated.

The Caernarvon Freshwater River Diversion project in coastal Louisiana, USA, which has been operating since 1991, is one of the best examples of this third type of restoration. The project consists of a structure containing 5 m^2-gated culverts that divert water from the

Mississippi River into a part of the delta that was losing approximately 400 ha yr^{-1} due to high rates of RSLR. Construction was completed in February 1991 at a cost of US $26.1 million, and the estimated net benefit for fish, wildlife, and recreation is over US $9 million per year. In a 1998 project summary, the Army Corps of Engineers reported a net increase in marshland of 165 ha within a monitored area that originally contained 930 ha of marsh. Oyster and fish productivity, and waterfowl usage has increased dramatically as well.

DELTAS

Deltas are coastal landforms comprised of subaerial and subaqueous packages of fluvial-transported sediments that have formed an alluvial landscape by deposition at the mouth of a river. Deltas form at the coastal interface where riverine sediment supplied to the coastline is not removed by tides or waves. The term delta derives from Herodotus who, in the 5th century BC, noted a geometric similarity between the tract of land at the mouth of the Nile River and the Greek letter "Δ" with its apex directed landward (Moore and Asquith, 1971). Although this distinctive morphology is absent in many river-mouth landscapes, the term has nonetheless been accepted to describe the geographical region near a river mouth and the sedimentary package that develops at a fluvial entrance into a depositional receiving basin.

Globally, deltas can be found on all continents and in all climates (Figure D4). In a general sense, the locations of deltas are similar; at the terminus of a catchment basin that provides sediment load into an ocean, gulf, lagoon, estuary, or lake. Although a delta may form regardless of the size of the fluvial system or receiving basin, some tectonic settings are more conducive than others to the development of major deltaic landscapes. Using the Inman and Nordstrom (1971) tectonic classification of coasts, trailing-edge coasts typically have the largest drainage basins followed successively by marginal-seacoasts and leading-edge coasts. Of the 58 major river systems in the world with drainage areas greater than 10^5 km^2, 56.9% are on trailing edge coasts, 34.5% along marginal-seacoasts, and 8.6% on leading-edge coasts.

Trailing-edge coasts provide a geologic setting favorable to delta development because of their tectonic stability and geologically old, low-relict terrains with extensive river systems that provide an abundant supply of sediment. Moreover, trailing-edge coasts often border broad continental shelves, which provide ideal shallow-water platforms for the formation of deltas. Marginal-seacoasts typically provide a low-energy setting with many trailing coast characteristics that are conducive to delta development. However, the mountainous and immature drainage systems of tectonically unstable, leading-edge coasts with small catchment basins and low sediment supply generally limit the likelihood of extensive deltaic deposition. Table D3 lists the sizes and locations of the some of the world's major deltaic systems.

Delta types and formation

Previous summaries of the world's deltas have primarily focused on the major large deltas (e.g., Coleman and Wright, 1975). A review of the recent literature on late Quaternary deltaic systems reveals that deltas can be classified into four basic types depending on sea-level stage (highstand or lowstand) and/or sediment supply (high or low) (Kindinger, 1988; Boyd *et al*., 1989; Nichol *et al*., 1996). The four basic types of deltas are lacustrine, bayhead (or lagoonal), continental shelf, and continental margin. In an evolutionary sense, these four types of deltas can represent a developmental continuum. Thus, during a sufficiently long sea-level stillstand a fluvial system with adequate sediment supply could result in a lacustrine deltaic system that evolves into a continental-shelf margin deltaic system through progradational outbuilding.

Lacustrine deltas

A lacustrine delta consists of deposits located landward of the coast or paralic zone within an inland lake or sea. The environmental setting in such cases is typically a shallow-water basin with a low-energy regime. Along the Gulf of Mexico, the best example of a lacustrine delta is the Grand Lake delta within the Atchafalaya drainage basin of south-central Louisiana. At the start of the 19th century Grand Lake within the Atchafalaya Basin was a shallow, low-energy lake (Tye and Coleman, 1989). However, by the 1950s a large lacustrine delta had filled this lake and started bypassing into the Atchafalaya Bay as a result of the progressively increasing Mississippi River flow into the Atchafalaya basin (van Heerden and Roberts, 1988). Historically, if left uncontrolled, the Mississippi River would have avulsed from its modern course into the Gulf of Mexico past New Orleans to the Atchafalaya course located farther west. Other lacustrine delta examples are present within Lake Geneva and Lake Constance (Switzerland) (Müller, 1966; Reineck and Singh, 1973).

Bayhead/lagoonal deltas

Bayhead/lagoonal deltas are located in the upper reaches of the coastal zone. In many cases they represent an evolutionary step from a lacustrine delta during a sea-level stillstand or withdrawal, which allows the delta to build into the coastal or paralic zone. Bayhead-delta settings are typically protected by barrier-island systems or remnants of preexisting antecedent topography, resulting in a low-energy environment. Examples of bayhead deltas are found within the northern part of Mobile Bay Alabama (Kindinger *et al*., 1994), Trinity Bay, and San

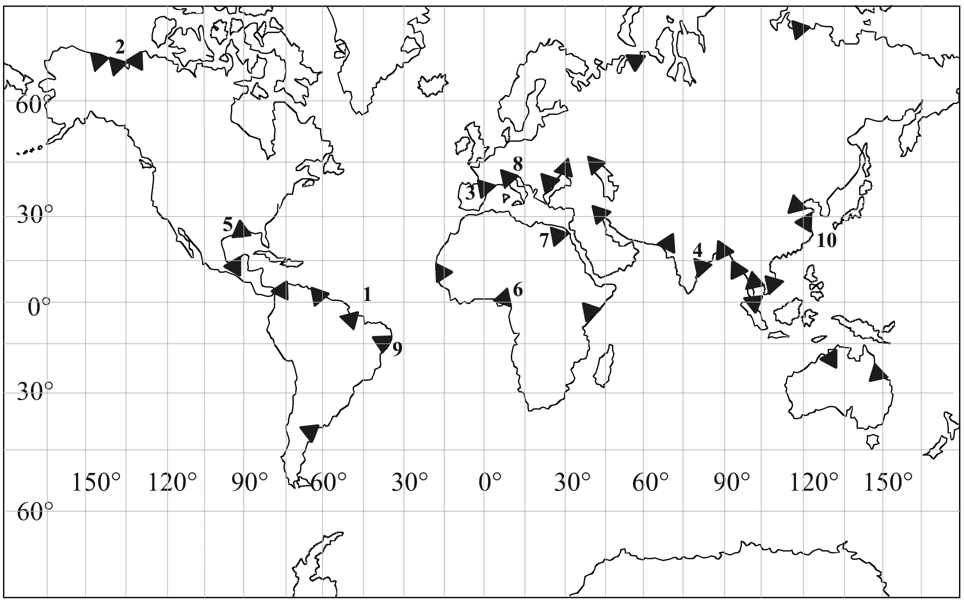

Figure D4 Map showing the global distribution of major deltas. Note that most of the major deltaic systems are located along trailing-edge coastlines close to the equator (modified from Coleman and Prior, 1980). Numbered locations refer to deltas listed in Table D3.

Table D3 Names, locations, and sizes of major deltas (from Wright, 1974, data compiled from Colemon & Wright, 1975).

River	Location	Receiving body of water	Deltaic area (km^2 × 10^3)
Amazon (1)	South America	Atlantic Ocean	467.1

Antonio Bay Texas; (McEwen, 1969; Donaldson *et al.*, 1970; van Heerden and Roberts, 1988).

Continental-shelf deltas

Continental-shelf deltas develop during prolonged sea-level still-stands and/or a sea-level fall. These deltas build out onto the continental shelf. Trailing edge or marginal sea continental-shelf deltas typically are characterized by an abundant sediment supply and their geomorphology reflects the wave, riverine, and tidal conditions in which they develop. Examples of continental-shelf deltas include the Mississippi (US, Louisiana), the Ebro (Spain), and the Colville (US, Alaska) (Frazier, 1967; Maldonado, 1975; Naidu and Mowatt, 1975; Alonso *et al.*, 1990).

Continental-shelf margin deltas

Continental-shelf margin deltas are typically most well-developed during sea-level lowstands or formed by rivers with very large sediment loads during prolonged sea-level stillstands. The majority of shelf-margin deltas in the recent geologic record have developed during falling sea-level or sea-level lowstand conditions as river valleys lengthen, incise across subaerially exposed continental-shelf sediments, and discharge their sedimentary load at the shelf margin (Suter, 1994). With sufficient sediment load and/or during lowstand conditions these deltas continue to build seaward, creating an apron of deltaic sediments along the shelf edge that extends the preexisting continental margin into deeper basinal waters. Numerous lowstand shelf-margin deltas, formed during the late Wisconsin sea-level fall and lowstand that culminated at approximately 18,000 yr BP, are found seaward of the Rio Grand and the Mississippi River deltas (Morton and Price, 1987; Suter *et al.*, 1987; Suter, 1994). Sufficiently large rivers carrying substantial sediment loads may however, construct shelf-margin delta deposits during sea-level highstand conditions. An example of a shelf-margin highstand delta is the depocenter of the main stem of the modern Mississippi River delta, the representative "Bird Foot" delta (Boyd *et al.*, 1989).

Delta processes

Deltas result when sediment-laden fluvial water decelerates upon entering a receiving basin and sediment transport competence of the river is lost. Consequently, fluvial characteristics and river-mouth processes constitute an important controlling factor in the nature of deltaic deposition (Bates, 1953). A consideration of fluvial processes is particularly important in deltaic environments where receiving basin processes such as wave and tide regimes are minimal. In such environments the primary fluvial factors, influencing the nature of deltaic deposition, include the volume of riverine discharge and transported sediment, as well as the textural character of the sediment load. Generally, the forces associated with these factors that dictate the character of fluvial-margin deposition are: (1) the riverine effluent inertia and diffusion, (2) friction between the sediment load and the floor of the receiving basin, and (3) density contrasts between the effluent and the receiving basin waters (Bates, 1953; Wright, 1977; Orton and Reading, 1993).

Homopycnal conditions

Homopycnal flow describes river discharges where the density contrast between riverine and basinal waters is small. Discharge patterns are most heavily influenced by inertia of the riverine water, which allows the effluent to radially spread into the receiving basin. As a result of deltaic progradation, fine-grained bottomset sediments are overlain by relatively coarser grained topset beds and river mouth-bar deposits, creating the classic coarsening upward depositional units common to deltaic systems. Gilbert (1884) first described this type of deltaic system in lakes of the western United States; hence, they are termed Gilbert-type deltas.

Hyperpycnal conditions

Hyperpycnal discharge conditions occur when the riverine inflow is denser than the waters of the receiving basin. Consequently, the sediment-laden effluent moves along the receiving basin bottom as a density current. This type of discharge process is rare and typically restricted to deltaic systems rich in silt and coarse-grained sediments such as in the Bella Coola fjord delta of British Columbia (Kostaschuk, 1985).

Hypopycnal conditions

Hypopycnal discharge conditions occur when the riverine inflow is less dense than the waters of the receiving basin, a condition commonly present in lakes and inland seas. Most of the world's deltas form under hypopycnal conditions. In hypopycnal settings, as the riverine inflow enters the receiving basin it undergoes turbulent mixing resulting in the deposition of the sediment load. Finer-grained sediments are transported well into the receiving basin as the freshwater sediment plume disperses above relatively more dense basinal waters, whereas the relatively coarser grained sediments are deposited in close proximity to the river mouth. In shallow-water hypopycnal discharge conditions, friction between the receiving basin bottom and the riverine leads to multiple bifurcations of the distributary system. Conversely, in deep water during hypopycnal discharge conditions, buoyancy dominates during the dispersal of the effluent, producing elongated distributaries such as present at the modern Mississippi River depocenter (Suter, 1994).

Delta components

The delta plain is the subaerial and subaqeous zone where sediments are discharged from the alluvial valley and accumulate in the receiving basin. Typically, a delta plain is subdivided into an upper delta plain and a lower delta plain, each of which are characterized by different vegetation, morphology, and depositional processes (Figure D5) (Reineck and Singh, 1973; Coleman, 1981; Elliot, 1986). Many of the features of the upper delta plain are inherited from its alluvial valley. In the upper delta plain deposition is primarily fluvial and as the main stem of the river leaves the alluvial valley it discharges onto the upper delta plain and undergoes channel bifurcation. The vegetative landscape of the upper delta plain is a freshwater environment, generally beyond the influence of marine incursions created by the tidal regime of the receiving basin. The major landform includes distributary channels with their subaerial natural levees, point bars, and crevasse splays, as well as interdistributary environments characterized by low-lying swampy areas.

Seaward of the upper delta plain is the relatively lower relief of the lower delta plain that is within the realm of tidal incursion. The lower delta plain is the site of more active deposition through overbank flooding processes. Because the elevations of the natural levees are lower, channel crevassing and distributary shifting is a common and very dynamic process characterizing the lower delta plain. These processes disperse sediment from areas within the upper delta plain into brackish to saline environments of the lower delta plain. Distributary shifting common in the lower delta plain results in a complex distribution of multiaged distributary channels in all stages of evolution (Figure D5). The lower delta plain contains active and abandoned distributary channels in all stages of regressive and transgressive evolution (Penland and Suter, 1989). Because the lower delta plain is a transitional environment influenced by fresh-water fluvial and saline marine waters the vegetative landscape generally contains species tolerant of both brackish and saline water.

Deltaic sediments

In general, deltaic sedimentary packages contain a coarsening upward vertical stratigraphy that reflects seaward progradation of the delta into its receiving basin. At any given time there is typically a well-developed gradient of grain sizes extending seaward from the subaerial to subaqueous portions of a delta. The relatively coarsest grained material is deposited proximal to the river mouth where transport competence is highest, whereas the finest-grained material is carried farther seaward and deposited in more distal locations. Thus, as sediments are delivered to the receiving basin from the river mouth they accumulate in a subaqeous, fine-grained depositional zone referred to as the *prodelta*. The prodelta forms the platform across which deltas prograde and subsequently aggrade. The prodelta sedimentary package is a widespread laterally continuous interval primarily composed of the finest sediment fraction transported by the fluvial system. Thus, the overall finest sediment is found at the base of the prodelta sequence and the whole sequence coarsens upwards. Moreover, the initial prodelta deposits are the thinnest at the base and the beds thicken upward as a result of deltaic progradation. Bioturbation of prodelta sediments is limited by the rate of deposition.

The delta front is located between the zone of fine-grained prodelta deposition and the more landward located, coarser-grained distributary mouth deposits of a progradational deltaic system. The relatively coarser-grained sediments of the delta front generally consist of interbedded clays, silts, and sands. This zone is dominated by the interaction of fluvial and marine processes, resulting in sand-rich accumulations landward of the advancing prodelta. The delta front also represents a zone of transition between deposits representative of progradation and aggradation.

In a progradational deltaic sequence, distributary channel deposits overlie the relatively finer grained delta front and prodelta deposits. The framework of distributary channels consists of distributary mouth bars overlain by natural levee deposits. Distributary mouth bar deposits are primarily subaqueous deposits that grade laterally into relatively finer grained deposits; locally, mouth-bar deposits may contain fine-grained beds within the generally sandy matrix of the mouth bar. The presence of fine-grained deposits primarily represents deposition during low-flow conditions. During flood conditions, natural levee ridges can be over-topped and breached creating crevasse splays. These splays within the distributary network provide conduits for sediment dispersal into interdistributary bays and the origin of crevasse-splay deposits.

Interdistributary bay and marsh sediments are generally as volumetrically significant as prodelta sediments. The interdistributary area is a low-energy depositional environment and less dynamic than areas of the delta plain characterized by multiple channels, channel bifurcations, and channel avulsions. Interdistributary deposits characteristically consist of fining upward deposits consisting of clay-rich bay sediments overlain by organic-rich marsh deposits. This fine-grained depositional environment is punctuated by sandy depositional events associated with overbank flooding and crevasse splay events.

Delta morphology

Although sediment delivery to a delta is by a fluvial system, it is ultimately the dynamic interaction of riverine and basinal processes that control the morphologic, stratigraphic, and sedimentologic variability of a deltaic accumulation. Water depth and basinal configuration, tidal range, wave climate, and coastal currents are the primary basinal processes that control delta morphology. The dynamics of these processes and complex interaction between them leads to a highly variable array of deltaic configurations (Coleman and Wright, 1975).

One of the first and simplest attempts to describe deltaic variability as a function of processes involved depicts the morphology of river deltas as a function of sediment influx and marine processes such as waves and longshore currents (Figure D6). The tidal regime of the receiving basin was not considered in formulation of this model. Fundamentally, this model describes the processes leading to deltaic

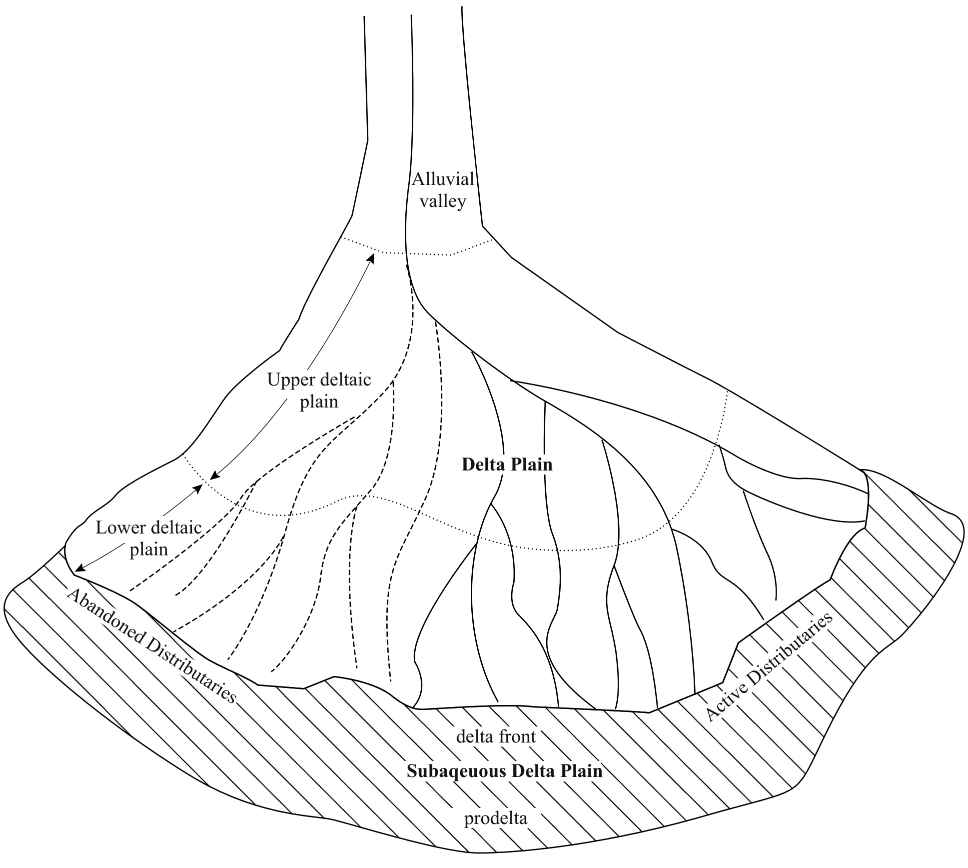

Figure D5 Schematic diagram showing the primary physiographic components and depositional environment of a delta (modified from Coleman and Prior, 1980).

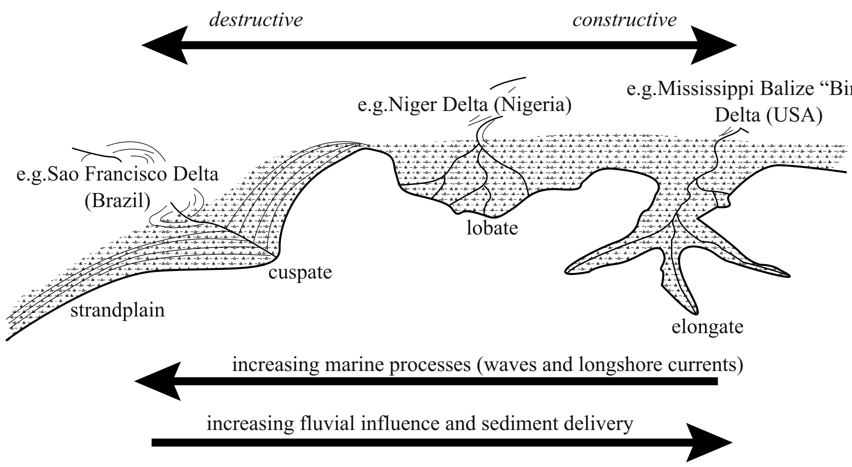

Figure D6 Schematic diagram showing the variation in deltaic geomorphology as a function of the relative influences of fluvial and marine processes (Fisher *et al.*, 1969, with permission of University of Texas, Bureau of Economic Geology).

deposition as either constructive or destructive (Davis, 1983). Deltas dominantly influenced by the nearshore wave climate are termed destructional, characteristically cuspate shaped with poorly developed distributaries and well-developed strand plains such as in the Sao Francisco delta of Brazil. Intermediate between destructional and constructional forms, is the lobate-shaped delta, typified by the Niger delta of Africa. Lobate deltas possess well-developed distributary networks and a smooth coastal outline. Deltas that are strongly influenced by sediment influx are essentially constructional and are characterized by distinctive elongate distributaries. An example of this type of delta is the modern "Birdfoot" depocenter of the Mississippi River.

In the 1970s, new process-response approaches to understanding morphologic variability of deltas incorporated features of the constructional/destructional approach but also considered the effects of the receiving basin tidal regime. In the Galloway (1975) scheme a variety of previously documented delta morphologies (e.g., Fisher *et al.*, 1969; Wright and Coleman, 1973) were classified within the framework of a ternary diagram that effectively differentiated delta morphology as a function of sediment input, wave-energy flux, and tidal energy flux (Figure D7).

Deltas dominated by sediment input are supplied by a large well-developed drainage system, capable of transporting large volumes of sediment to the deltaic coastline. Distributary switching is an important process, resulting in a highly constructive elongate to lobate deltas with straight to sinuous active and abandoned channels. The bulk composition of the sediment supply is muddy to mixed and the framework facies include distributary mouth bar, channel-fill sands, and delta-margin sheet sands (Table D4).

Deltas shaped primarily by waves are usually characterized by a small catchment basin with little sediment influx. The high-energy wave environment leads to winnowing of fine-grained sediments and leaves behind a relatively coarser-grained sediment fraction. Consequently, the bulk composition of wave-dominated deltas is typically sandy. The primary distributary channels are meandering and the framework facies are coastal barrier and beach-ridge sands (Table D4).

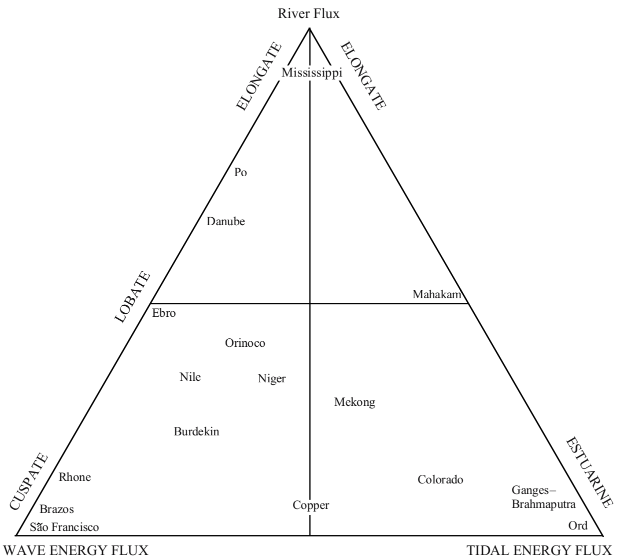

Figure D7 Ternary classification of deltas on the basis of dominate processes and the resulting morphology (after Galloway, 1975).

Deltas shaped primarily by tides are similar to wave-dominated deltas in that tidal currents winnow away much of the fine-grained sediments delivered to the coast. However, a fundamental difference is that tidally formed sand bodies are oriented shore normal. The distributary channels flare seaward and in some cases are straight and oriented parallel with the tides. The bulk composition of tide-dominated deltas is highly variable. The primary framework facies include fine-grained estuarine fill and coarse-grained sand ridges (Table D4).

Modern deltas

Globally, modern deltaic systems are geologically young features that have formed since the initiation of late Wisconsin deglaciation at approximately 18,000 yr BP. Although the development, existence, and evolution of deltas along modern coastlines is contingent upon sea-level change, sediment delivery, and marine processes, the timing of formation for modern deltas suggests that sea level has been a primary factor controlling delta development and stability (Stanley and Warne, 1994).

At the height of the late Wisconsin glacial period approximately 18,000 yr BP, sea level was approximately 120 m lower than present sea level (Fairbanks, 1989). During this interval of lower sea level rivers crossed subaerially exposed continental shelves within incised channel systems. Large volumes of sediment were debouched along bordering continental margins and locally, thick and extensive shelf-margin deltas developed (Morton and Price, 1987; Suter *et al.*, 1987). Subsequently, as the late Wisconsin glaciers melted and sea level rose, exposed shelves were flooded and transgressed with marine waters. Initially, sea level rose so rapidly that the global paralic zone was forced tens of kilometers landward. Marine processes at the leading edge of the transgressing marine waters reworked the formerly exposed continental shelf leaving a marine truncation surface and transgressive coastal-zone deposits in the form of ravinement surfaces and transgressive coastal marine deposits, inner shelf shoals, sand sheets, and shoreface ridges.

Following the initially high eustatic rise rates associated with deglaciation the rate of sea-level rise dropped below a critical threshold rise rate allowing global landward migration of the paralic zone. Beginning approximately 7,000 yr BP, the rate of sea-level rise appears to have slowed enough to allow for deltaic progradation and a relatively synchronous development of the world's deltas (Figure D8). The temporal uniformity in delta development suggests a decline in the rate of sea-level rise, following the melting of late Wisconsin ice sheets, strongly influenced Holocene deltaic formation (Stanley and Warne, 1997).

Deltas and society

Deltaic environments have played an important role in our global society. Deltaic environments served as the culture hearth for early civilizations throughout the world because of their tremendous variety of food resources such as fish and wildlife. Moreover, the rich alluvial soils of deltaic landscapes allowed for the establishment of bountiful crops vital to the establishment and expansion of early cultures (Stanley and Warne, 1997). Today, deltaic wetlands that were more recently viewed as uninhabitable wasteland are once again considered to be of utmost ecological value. Additionally, ancient deltaic deposits are actively explored as they often contain a wealth of fossil fuels such as hydrocarbons and coal, resources that helped spur the industrial revolution and continue to be critically important to our modern technologically driven society.

Table D4 Morphologic, stratigraphic, and sedimentologic characteristics of delta depositional systems that result in fluvial, wave, and tide-dominated systems (modified from Galloway, 1975).

Characteristics	Fluvial-dominated	Wave-dominated	Tide-dominated
Geomorphology	Elongate to lobate	Arcuate	Estuarine to irregular
Channels	Straight to sinuous distributaries	Meandering distributaries	Flaring straight to sinuous distributaries
Sediments	Muddy to mixed	Sandy	Variable
Framework facies	Distributary mouth bar and channel fill sands, delta margin sand sheet	Coastal barrier and beach-ridge sands	Estuary fill and tidal sand ridges
Framework geometry	Parallels depositional slope	Parallels depositional strike	Parallels depositional slope

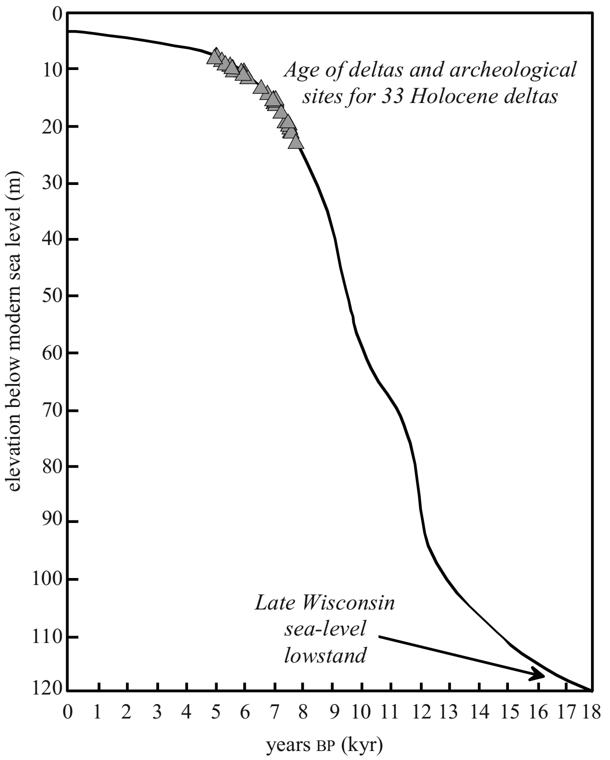

Figure D8 Graph showing the time of formation for latest Quaternary deltaic systems and ages of deltaic archeological sites in relation to deceleration in the rate of sea-level rise following the late Wisconsin sea-level lowstand (ages from Stanley and Warne, 1997; sea-level curve from Fairbanks, 1989).

However, as humans have populated the world's deltas, harnessed the rivers that built them by flood-control structures, and altered natural deltaic coastlines the delicate balance of these dynamic systems has been compromised. Deprived of water and sediment, most of the world's deltas are undergoing dramatic coastal land loss and habitat change as a result of anthropogenic induced as well as naturally occurring subsidence and rising sea level along coastal zones. As a result, a new multidisciplinary field of coastal restoration science is emerging as humans embark to rescue and effectively manage deltaic landscapes. The future of modern deltas will be dependent on our ability to balance environmental protection and economic development, while developing new restoration technologies for their maintenance and restoration.

DEMOGRAPHY OF COASTAL POPULATIONS

Introduction

To most observers who live along a coast it seems clear that the resident population is growing rapidly. But how fast is population growing? Will future growth be concentrated in the coastal zone? Do such demographics portend well for sustainable development?

To answer these questions we have combined the recent work of Burke *et al*. (2001), who reported the fraction of a country's population living within 100 km of the coast, with United Nations (1996) population figures to calculate the 2000 and 2025 coastal populations for 122 countries. Burke *et al*. relied on the work of the Center for International Earth Science Information Network (CIESIN, see reference in Burke *et al*.) at Columbia University, to obtain the coastal population fraction. In our work, we made no attempt to reanalyze the work of CIESIN. Rather, for country-by-country, we multiplied the fractional coastal population reported in Burke *et al*. by United Nations 2000 and 2025 population values (United Nations, 1996).

The United Nations based its calculated demographic projections for each country on birth, death, fertility rates, and age structure of the population. We assumed that the 2025 coastal population fractions would remain unchanged from the 2000 values reported by Burke *et al*. (2001). It is likely, however, that for some countries, such as the United States, coastal populations will grow faster than non-coastal areas (Culliton *et al*., 1990), as aging populations will live longer and will seek to live near marine environments. Thus, the 2025 populations reported herein should be considered minimum values.

Coastal properties and demographics by country and region

Table D5 lists the results for the 123 countries (column 1) *in thousands of people*. The countries are grouped within eight geographic regions (Burke *et al*., 2001), with each country listed beneath the region. Coastal lengths and claimed Exclusive Economic Zone are from Burke *et al*. (2001), and the total population values (column 4) are from United Nations (1996). Each country's demographics are broken down into the 2000 and 2025 total populations, the 2000 and 2025 coastal populations (persons living within 100 km of the coast), the difference between 2000 and 2025 coastal populations (column 9), and the relative increase or decrease over the 2000 population (%). The footnotes at the base of Table D5 specify the calculations.

Not surprisingly, China has the largest coastal population, 306 and 355 million people for 2000 and 2025, respectively, or 16% growth in 25 years. Belgium and Denmark will experience 1%, or less, growth in their coastal population from 2000 through 2025. Fifteen other countries in Europe, plus Japan, will experience decreasing coastal populations in 2025. All in all, only 16 countries are projected to have declining coastal populations in the next quarter century or so.

Figures D9–D12 show the overall 2000 and 2025 demographics trends for the eight geographic regions. Figure D9 shows the total *coastal population* estimated for the year 2000, and that projected for 2025 in millions of people. Figures D10 and D11 compare overall total population, by region, with the corresponding total *coastal population*, for 2000 and 2025, respectively. In Figure D12 we present the *population increase per kilometer of coastline* for the eight regions summarized in Table D5.

Middle East and North Africa and sub-Saharan Africa coastal populations will grow by 52% and 81%, respectively, from 2000 to 2025 (Figure D9). Combined, these changes represent an addition of approximately 209 million people living in the coastal area by 2025 over the 2000 coastal population of approximately 330 million people.

The Asian region (which excludes the Middle East), which includes heavily populated China, India, and Indonesia, will experience relatively smaller percentage growth: 25%, by 2025. However, in absolute terms Asian coastal region will be home to 1.6 billion people in 2025, an increase of 325 million over 2000.

North America, Central America and the Caribbean Islands, South America, and Oceania will experience increased growth by 20, 39, 32, and 32%, respectively, or an increase of 121 million people by 2025; the calculated total coastal population in 2025 for these four regions is 528 billion (Table D5).

Europe is the only region were coastal populations may decrease rather than increase. In 2000, the European coastal population is estimated at 287 million people (Table D5); by 2025 we calculate that the coastal population to be 280 million, a drop of 7 million people. The reason for the decrease in coastal population is due to population stability (zero growth rate) or in some cases negative population growth rates.

Figure D12 shows the 2000 and 2025 coastal populations normalized to coastal length, a factor that can indicate "environmental stress" (Culliton *et al*., 1990). By 2025, the regions of Asia, Middle East/North Africa, and sub-Saharan Africa will contain more than 4,000 persons per kilometer of coastal length. The impacts of such a high density of people along a coast will include marine pollution, over-fishing, and loss of natural habitat.

Consequence of increasing coastal populations

Much of humanity lives in the coastal zone, and probably has done so for millennia. That a 32% increase in coastal population, compared with a 30% increase overall by 2025, should be no surprise, given the uncertainty of such calculations. We estimate then that globally, the coastal populations will grow slightly faster than the overall population, but that the difference is not statistically significant. Clearly, however, sub-Saharan Africa coastal populations will grow much more rapidly than the global average (~81%), while Europe (−2 or −3%) will be much less.

In terms of gross numbers however, it is Asia, with a projected 25% increase translating to 325 million more persons living in the coastal zone by 2025 that is of greatest potential environmental impact. Sub-Saharan Africa's 81% increase equates to 115 million more people in their coastal zones. These two regions, totaling 450 million more coastal dwellers by 2025, account for 69%—more than two-thirds—of all population growth. Socioeconomically, it might well be argued that these two regions also represent the lowest *per capita* income of all Earth's people.

Rapid coastal population growth coupled with limited financial and natural resources is a well-documented recipe arguing against sustainable development (see Maul—*Small Islands*—this volume). The weathered mantra "Give a man a fish—feed him for a day; teach a man to fish—feed him forever" will not withstand the scrutiny of the population statistics in Table D5. Humankind requires resources to survive, infrastructure to provide protection from natural hazards, and a society to provide essentials of public health and governance. Coastal resources are finite, as is Earth's ability to provide in extra-coastal regions. Overfishing is perhaps only the first sign that coastal-dwelling humankind is growing beyond sustainable limits.

While feeding burgeoning populations is an essential enterprise, "sustainable development" must also include some other aspects of quality of life. In many tropical regions, the great storms variously called hurricanes, typhoons, or cyclones, have been the cause of more loss of life

than any other natural hazard. In the 20th century, an estimated 1,000,000 souls have been lost to this one hazard. With a 69% increase in coastal populations in Asia and Sub-Saharan Africa by 2025, the risk is substantially increased. In extratropical environments, these storms are still extremely destructive, not to mention the intense winter storms of upper mid-latitude flailing against coastal populations. Modern weather forecasting with satellite and radar observations in developed countries clearly is mitigating the risk to coastal communities of such storms.

Another coastal natural hazard, tsunami waves, knows no latitudinal boundaries, as do tropical storms. Although often thought of as a natural hazard of the Pacific Basin, tsunamis are in fact a source of great risk to coastal dwellers in all oceans, especially the Mediterranean and the Caribbean seas. The great Lisbon earthquake and tsunami of 1755 would cause orders-of-magnitude more loss of life and socioeconomic disruption today if repeated in the North Atlantic Ocean.

Beyond the natural hazards, those of geophysical origin, are the biogeographical hazards of intense coastal population growth and development. Humankind produces domestic and industrial wastes. These wastes can be hazardous to others of our species—producing numerous and well-known toxicities or communicable diseases. Given that the greatest growth of our species is in two coastal regions—Asia and Africa—it is reasonable to project increased reports of waterborne public heath outbreaks. Implantation of acceptable waste management practices, for example, alone, is potentially of a magnitude to overcome all financial resources of intergovernmental banking agencies in the next quarter-century.

Finally, we briefly compare future coastal population with future tourist population. According to Goldberg (1994) world tourism in 1970 grew from 160 million to 341 million people in 1985, or an annual growth rate of 5%. If one projects this growth rate exponentially from 1985 through 2025, total world tourism will grow to 2.5 billion, or

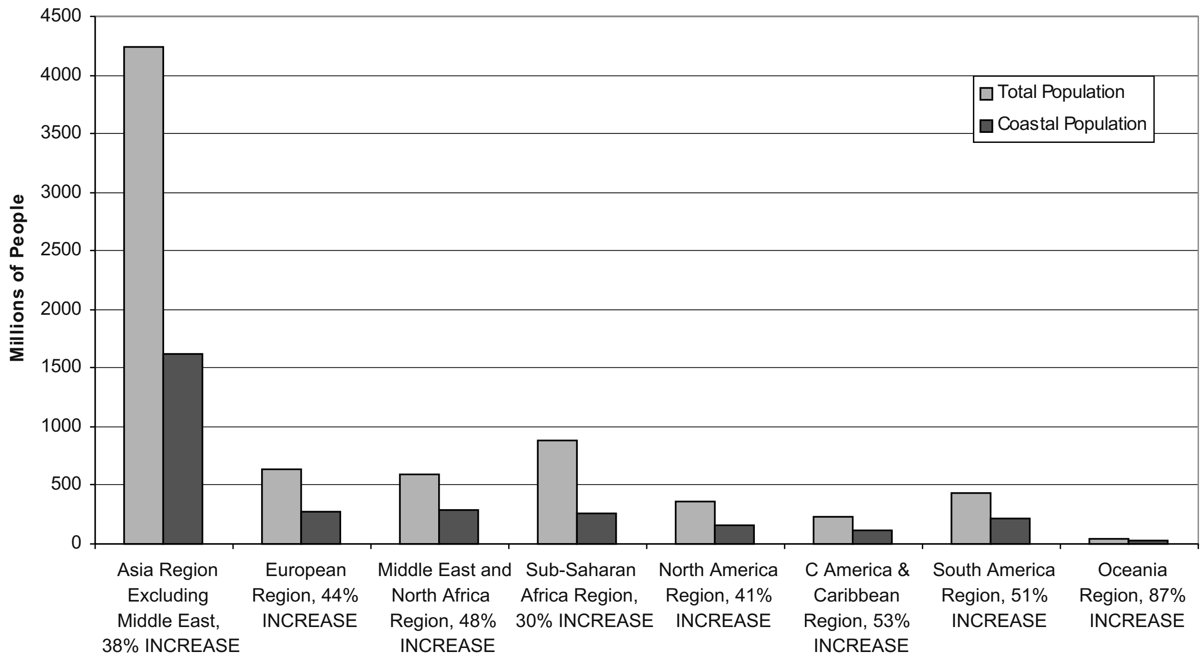

Figure D11 Total population, 2025 (countries with a coastal zone) and coastal population living within 100 km of the coast, by region, 2025.

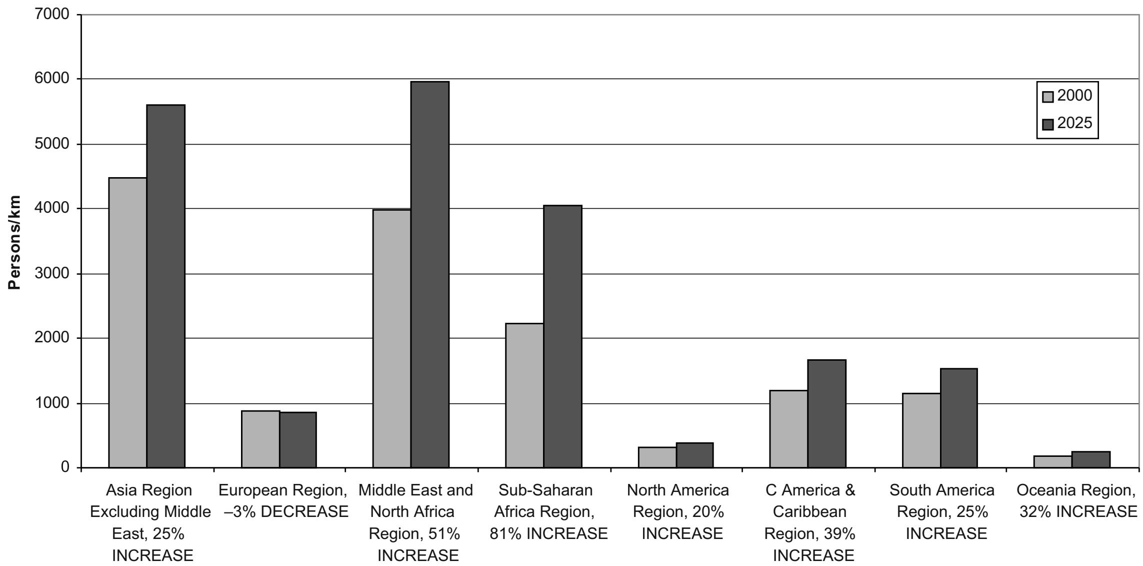

Figure D12 Population per 1 km of coastline, 2000 and 2025, living within 100 km of the coast, by region, relative (%) increase or decrease.

approximately four times the increase in the world resident coastal population calculated (Table D5). While it is problematic whether world tourism can sustain such a large growth, and surely not all tourists seek only the coastal zone, the calculation does demonstrate that some coastal countries may need to either limit tourism or develop new or more efficient infrastructure to accommodate the growing numbers of people living and/or recreating on beaches or in water. For example, the economies for many of the countries in Central America, Caribbean Region, and Oceania are driven by tourism. Thus, such countries will need to carefully consider their options in the areas of waste disposal, habitat, and pollution in order to optimize conditions leading to clean and natural environments to sustain both the local and national economy.

Conclusions

It is not our intention to paint a bleak picture of our coastal future—but of a realistic scenario of population growth and environmental and socioeconomic consequences. Earth is remarkably resilient to humankind's activities. Our planet's ability to dilute pollution is not infinite, and our coastal impacts will exacerbate the global problem. Surprisingly, the global population growth is not significantly different from what is reasonable to expect in the coastal zone—that is within 100 km of the shore. The environmental and socioeconomic impact, however, may be more. The essence of this increased potential impact is simply gravity.

The rivers and streams that bring mid-continent discharges to the coastal waters are essentially pressure gradient forces forced by gravity. Communities that discharge their wastes into coastal waters, whether by gravity or pumping, inject their wastes into littoral ecosystems. The 651,691,000 (±) more of us living within 100 km of the coast by 2025 will impact the very small fraction of Earth's surface area we consider home to 40% of humankind. Surviving that percentage growth is a taxing but not insurmountable challenge.

No other challenge will tax the intellect of humankind more than population growth. It is comforting perhaps that the challenge in the coastal zone is not more daunting than in other regions. However, oceanographers have long known that coastal ecosystems are particularly at risk from human activity. These fragile natural communities are increasingly seen as endangered, not only because of those living within 100 km of the coast, but also because of all others whose effluent reaches the coast.

Iver W. Duedall and George A. Maul

DEPTH OF CLOSURE ON SANDY COASTS

Kraus *et al*. (1999, p. 272) proposed the following definition of the *depth of closure* (DoC):

> The depth of closure for a given or characteristic time interval is the most landward depth seaward of which there is no significant change in bottom elevation and no significant net sediment exchange between the nearshore and the offshore.

Figure D13 illustrates the concept by showing the change in the nearshore profile resulting from a single storm. In this case, the DoC is 6.45 m as there is little change in the bottom deeper than this. Thus, the DoC separates the active nearshore from a less-active offshore and therefore is an important parameter in many coastal engineering projects. For example, in order to build out the entire beach profile, nourishment quantities are often computed by multiplying the desired added beach width by the DoC. In another application, numerical models of beach change use the DoC as an offshore limit to their computations. Because of its importance, the DoC is a topic of considerable research on how to predict and measure it, and on what it represents with respect to sediment transport.

Analytical prediction

Hallermeier (1977, 1978, 1981a, b, c) developed the first predictive formula for the DoC. Using laboratory tests and limited field data, he hypothesized two limit depths, d_l and d_i (Figure D14). He defined the inshore limit depth, d_l, as the seaward limit of the *littoral zone*, where "intense bed activity (is) caused by extreme near-breaking waves and breaker-related currents" (Hallermeier, 1981c, p. 258). Seaward of d_i, the deeper limit, only insignificant onshore–offshore transport by waves occurs. Between these two limits, is the shoal zone, a buffer region zone where expected waves have neither a strong nor a negligible effect on the sandy bed during a typical annual cycle of wave action.

Hallermeier (1978) suggested an analytical approximation, using linear wave theory for shoaling waves, to predict an *annual* value of d_l:

$$d_l = 2.28H_e - 68.5\left(\frac{H_e^2}{gT_e^2}\right) \qquad \text{(Eq. 1)}$$

where d_l is the annual DoC below mean low water (MLW), H_e is the nonbreaking significant wave height that is exceeded 12 h per year (0.137% of the time), T_e is the associated wave period, and g the acceleration due to gravity.

According to equation 1, d_l is primarily dependent on wave height with an adjustment for wave steepness. Hallermeier (1978, p. 1501) proposed using the 12 h exceeded wave height because it allowed sufficient duration for "moderate adjustment towards profile equilibrium." Equation 1 is based on quartz sand in salt water with a submerged density of $\gamma' = 1.6$ and a median diameter between 0.16 and 0.42 mm, which typifies conditions in the nearshore for many beaches. Because d_l was derived from linear wave theory for shoaling waves, d_l must be seaward of the influence of intense wave-induced nearshore circulation. However, because of various factors, Hallermeier (1978, p. 1502) "proposed that the calculated d_l be used as a minimum estimate of profile close-out depth with respect to low(er) tide level." Because tidal or wind-induced currents may increase wave-induced near-bed flow velocities, Hallermeier suggested using MLW as a reference level to

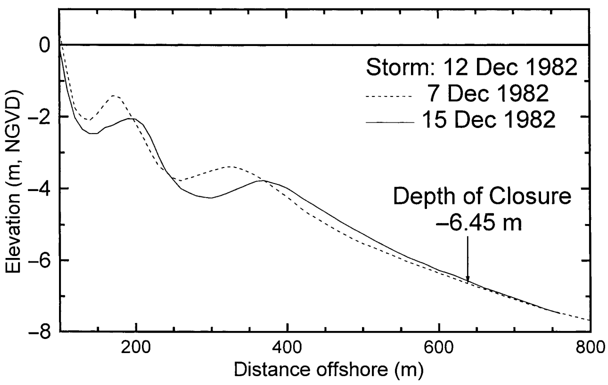

Figure D13 Example nearshore profile change caused by a single storm event with the DoC located at the deepest point of significant bottom change (in this case, <6 cm). Data from the Corps of Engineers' Field Research Facility at Duck, NC, USA.

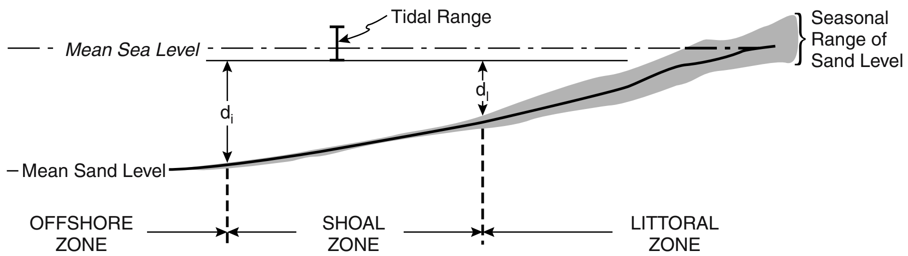

Figure D14 Definition sketch showing limits d_i and d_l, where d_l is the maximum water depth for nearshore erosion by extreme (12 h per year) wave condition (from Hallermeier, 1981c).

obtain a conservative DoC. Although Hallermeier considered only an annual period, Stive *et al.* (1992) extended equation 1 to other time periods by defining H_e as the 12-h exceeded wave height over any time period.

Birkemeier (1985) used two years of profile data from Duck, North Carolina, to examine equation 1. He reasoned that since any storm could be the annual event, an event-dependent d_l could be computed for each storm. Taking this approach, he showed that the functional relationship proposed by Hallermeier appeared reasonable, but equation 1 overpredicted the observed DoC by about 25%. Nicholls *et al.* (1998) expanded on this analysis using 12 years of profile data to examine the parameters in equation 1. Using a depth change criteria of <6 cm between surveys as an indicator of the DoC, they confirmed that using the 12-h exceeded wave height and a datum of MLW provided a conservative estimate of the observed DoC (Figure D15). They also examined the variation of the DoC with time and found that equation 1 became less capable at prediction as the time interval was increased beyond 4 years. They hypothesized that this indicates that, as the time interval increases, the DoC will be governed by other processes beside the highest wave height.

On eastern Lake Michigan, Hands (1983), using 9 years of profile surveys, determined that the closure depth was equal to twice the height of the 5-year return period wave height (H_5):

$$Z \simeq 2H_5 \qquad \text{(Eq. 2)}$$

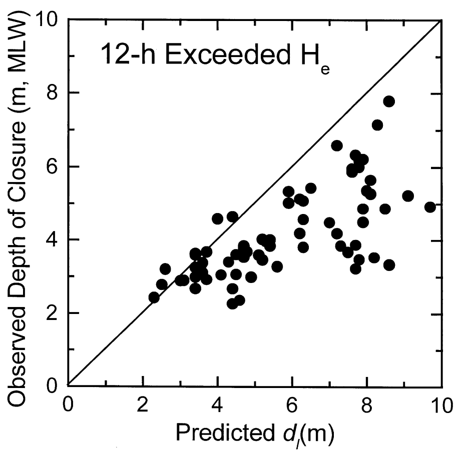

Figure D15 Observed versus predicted DoC using equation 1 for erosional events measured in Duck, NC, USA (modified from Nichols *et al.*, 1998). Except for a few cases of $d_l < 4$ m, equation 1 overpredicts, providing a conservative estimate of the actual observations.

This relationship is similar to equation 1, being based on wave height. One requirement of both equations is that they assume sand-rich profiles and require knowledge of the near-breaking wave climate.

Empirical prediction

The DoC can also be determined empirically by examining seafloor elevation changes measured by repetitive beach and nearshore surveys and identifying the depth at which changes become insignificant (see also Stauble *et al.*, 1993; Grosskopf and Kraus, 1994; Nicholls *et al.*, 1998; Kraus *et al.*, 1999). Since surveys integrate the impact of all processes acting on the profile, they inherently include the influence of storm and calm conditions along with important parameters not included in equation 1 such as grain size, sediment transport, and underlying geology.

In order to identify at what depth changes become insignificant, Kraus and Harikai (1983) examined the standard deviation in depth change computed from a series of surveys, and defined closure as the depth where the standard deviation decreased markedly to a near-constant value. They interpreted the landward region of this depth to be the active profile, where the seafloor was influenced by gravity waves and storm-driven water level changes. The offshore region, of smaller and nearly constant standard deviation, was primarily influenced by lower frequency sediment-transporting processes such as shelf and oceanic currents (Stauble *et al.*, 1993).

An example of how closure was determined empirically at Ocean City, MD, is shown in Figure D16. A clear reduction in the standard deviation occurs at a depth of about 5.5–6 m below the National Geodetic Vertical Datum (NGVD) for the 13 surveys conducted over a period of 5 years. For the 5.6 km of shoreline surveyed at Ocean City, the DoC ranged between 5.5 and 7.6 m. This longshore variation may reflect complex nearshore bathymetry resulting from shore-attached linear shoals. A similar longshore variation in the DoC is shown in Figure D17 for 110 south shore Long Island profile lines. Generally, the depth increases toward the east, with Rockaway Beach averaging 5 m below NGVD and the Montauk zone averaging 7.6 m. These values were based on four high-quality surveys collected between 1995 and 1996 (Morang *et al.*, 1999). The depth increase toward the east corresponds to an eastward increase in wave energy and further reflects the wave height dependency of equation 1. These data also demonstrate that there can be considerable variation in DoC along an 80 km, relatively straight stretch of shore.

While survey data can be used to determine the DoC, surveys have several limitations that require careful consideration. Most importantly, a repetitive survey program should cover at least the time interval of interest with enough frequency to resolve the natural variation which occurs. In general, the longer the program, the more different conditions will be monitored and the more robust the closure depth determination will be. To resolve small changes in depth and in standard deviation, highly accurate surveys (± 2–3 cm) are required and profiles must extend offshore far enough to include the entire active shoreface. In the United States east coast, surveys to 10 m water depth are normally sufficient.

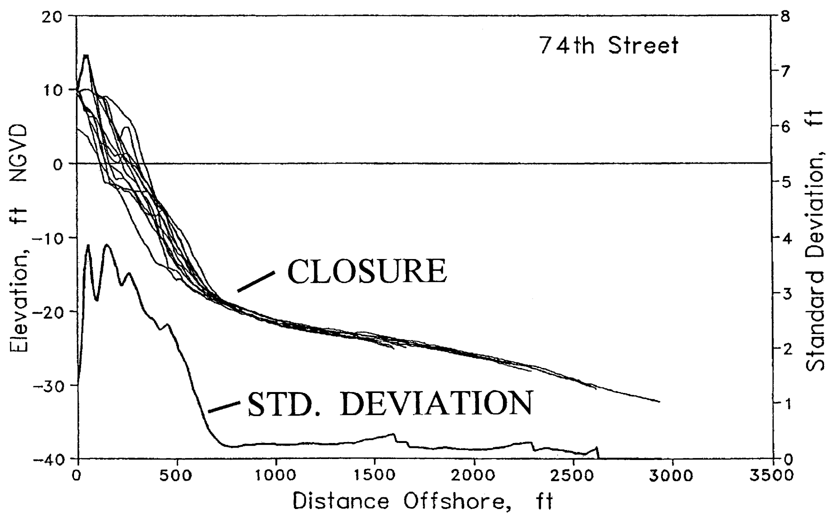

Figure D16 Profile surveys and standard deviation of seafloor elevation at 74th Street, Ocean City, MD (adapted from Stauble *et al.*, 1993). Surveys conducted from 1988 to 1992. Large changes above the datum were caused by beach fill placement and storm erosion.

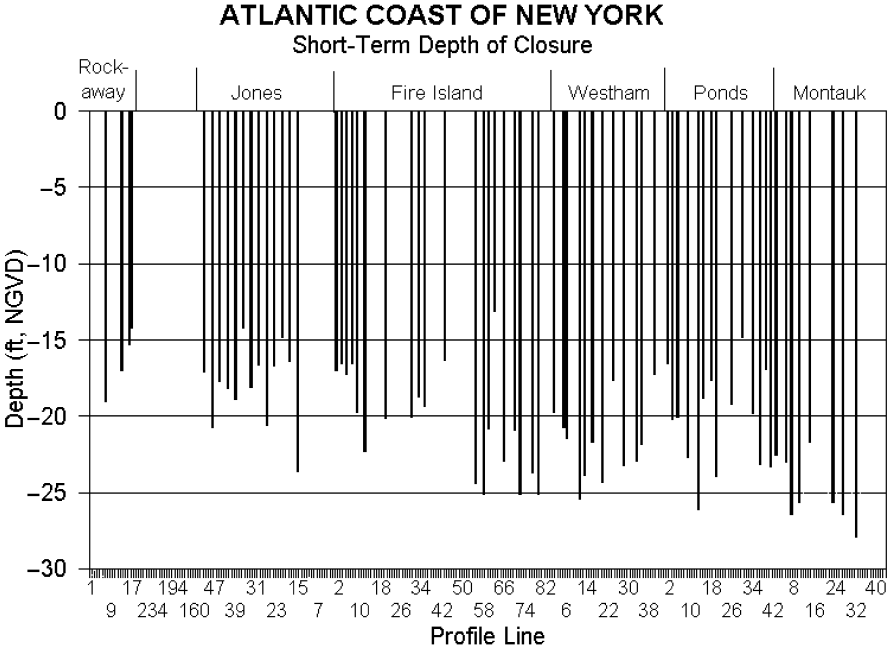

Figure D17 Variation in short-term closure depth along the south shore of Long Island, NY, computed for four survey dates in 1995 and 1996 (adapted from Morang *et al.*, 1999). Zones indicate south shore barriers or regions.

Application

Closure depth is used in a number of coastal engineering applications such as the placement of mounds of dredged material, beach fill, placement of ocean outfalls, and the calculation of sediment budgets. The time dependent nature of the active portion of the shoreface requires a coastal engineer to consider return period. The closure depth that accommodates the 100-year storm will be deeper than one for a 10-year storm. Therefore, a closure depth must be chosen in light of a project's engineering requirements and design life. For example, if a berm is to be built in deep water, where it will be immune from wave resuspension, what is the minimum depth at which it should be placed? This is an important question because of the high costs of transporting and disposing material at sea. It would be tempting to use a safe criterion such as the 100- or 500-year storm, but excessive costs may force the project engineer to consider a shallower site that may be stable only for shorter return period events. The prediction techniques described above allow for both the determination of a closure depth and for the consequences of picking a shallower or deeper depth to be quantified.

Most research into the closure depth have been carried out on sandy beaches with a thick sand layer in wave-dominated environments. Therefore, assumptions behind the concept hold best on open coasts far from structures and inlets and may be less valid for beaches where the morphology is largely controlled by underlying geology, for example, where the active sand is only a veneer above rock or clay. Also, little is known about the DoC for coasts where most sediment is moved by unidirectional currents, such as rivers and tidal channels or where there is long-term net loss of sediment.

DEPTH OF DISTURBANCE

Definition

Depth of disturbance, is the depth to which wave action can be expected to disturb the underlying bottom sediment. Sources of disturbance other than wind waves are not discussed. The sediment is considered to be unconsolidated particles in the sand size range.

Background

The approach adopted is to develop analytic expressions to estimate the depth of disturbance through the use of the velocity ratio,

$$U = u_{-h\,\max}/u_{\mathrm{crit}}, \qquad \text{(Eq. 1)}$$

where $u_{-h\,\max}$ is the maximum near-bottom orbital velocity of the wave and u_{crit} is the critical velocity required to initiate sediment movement under the wave. If U is greater than 1.0, then movement of the sediment would be expected; if U is less than 1.0, sediment movement would not be expected. Ahrens and Hands (1998) found the parameter U very effective for distinguishing between beach erosion/accretion events. For shallow water conditions, $u_{-h\,\max}$ will be estimated using Stream Function Wave Theory (SFWT), Dean (1974). For deep water, $u_{-h\max}$ will be estimated using linear wave theory. The critical velocity will be estimated using the relation,

$$u_{\mathrm{crit}} = \sqrt{(8\Delta g d)}, \quad \text{for } 0.0625 \le d \le 2.0 \text{ mm}, \qquad \text{(Eq. 2)}$$

where g is the acceleration of gravity, d is the sediment grain diameter, and $\Delta = (\rho_s - \rho)/\rho$, where ρ_s is the density of the sediment and ρ is the density of water; equation 2 is based on research by Hallermeier (1980).

Concepts and development

It is convenient to approximate the dimensionless near-bottom velocity as a function of relative depth, that is, $u_{-h\,\max}T/H \approx f(h/L_0)$, where H is the wave height, h is the water depth, and L_0 is the deep water wave length given by $L_0 = gT^2/2\pi$, where T is the wave period. The general functional form used is:

$$f_i(h/L_0) = \exp[C_0 + C_1(h/L_0)](h/L_0)^{C_2}, \qquad \text{(Eq. 3)}$$

where C_0, C_1, and C_2 are dimensionless coefficients developed from regression analysis. Table D6 gives the values of the coefficients for the two wave theories and ranges of relative depth.

The breaker height, H_b, consistent with SFWT, can be estimated quite accurately as a function of relative depth using the relation,

$$H_b = 0.171 L_0 \tan h\,[0.73(2\pi h/L_0)], \qquad \text{(Eq. 4)}$$

Ahrens and Hands (1998). In general, the wave height can scaled as a fraction of H_b, that is, $H = H_b/a$, where $a = 1.0$ or 4.0 in this article. When the above relations are brought together, the following equation is obtained,

$$U = 0.171 \tan h[0.73(2\pi h/L_0)] f_i(h/L_0)/a\,[16\pi\Delta(d/L_0)]^{1/2}, \qquad \text{(Eq. 5)}$$

where $f_i(h/L_0)$ can be any of the three functions indicated by Equation 3 and Table D6. Equation 5 shows that U is a function of three variables,

Table D6 Coefficients used to estimate dimensionless bottom velocities

Function	Wave theory	Wave height	Relative depth range	Coefficients		
				C_0	C_1	C_2
f_1	SFWT	H_b	$0.002 \le h/L_0 \le 0.2$	−0.227	−2.078	−0.600
f_2	SFWT	$H_b/4$	$0.002 \le h/L_0 \le 0.2$	0.0835	−2.819	−0.601
f_3	Linear	All	$0.2 \le h/L_0 \le 2.0$	1.930	−6.368	0.103

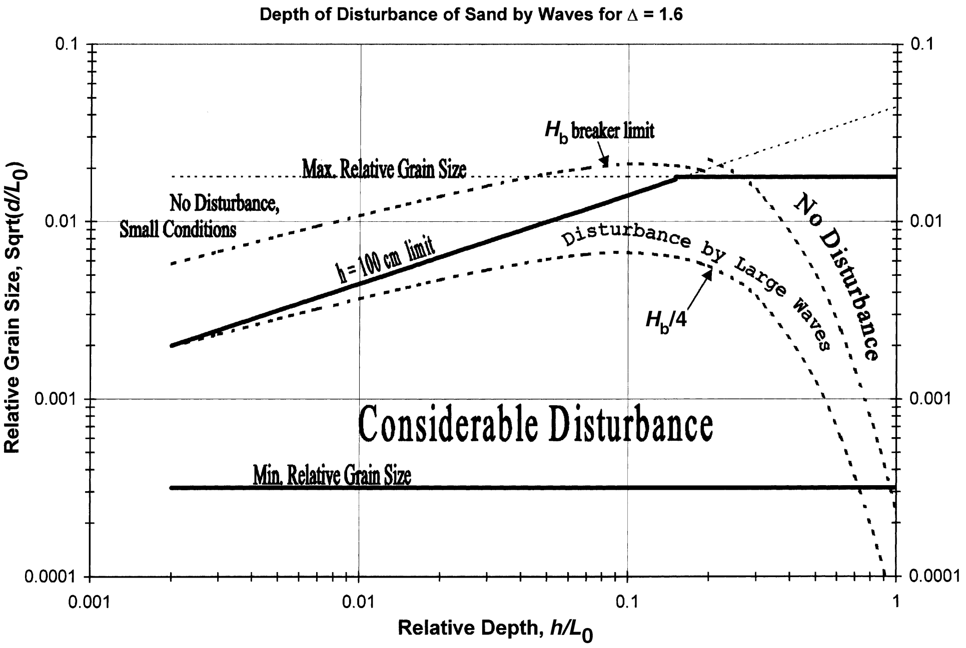

Figure D18 Depth of disturbance plane, relative grain size, $\sqrt{(d/L_0)}$, versus relative depth, h/L_0.

h/L_0, d/L_0, and Δ, however, typically Δ only varies over a small range. To obtain a visual impression of the influence h/L_0, d/L_0, on the depth of disturbance, U is set equal to 1.0 and $\Delta = 1.6$ to produce Figure D18.

Two roughly parallel curves arch across Figure D18 the upper curve is associated with H_b and the lower curve with $H_b/4$. There is a slight discontinuity in the H_b curve because linear wave theory and SFWT are not quite consistent at the transition depth, $h/L_0 = 0.2$. In Figure D18 the area of primary interest is outlined by three heavy, straight lines. The maximum and minimum relative grain sizes are based on the grain size range of $0.0625 \leq d \leq 2.0$ mm and the range of wave periods considered, $2.0 \leq T \leq 20.0$ s. The "h = 100 cm limit" line indicates where the upper limit is 100 cm deep; above this line depths are less than 100 cm and the scale of the wave action is small.

Summary

Figure D18 is a map of the depth of disturbance plane for two wave heights; one equal to the breaker limit, H_b, and the other one quarter the breaker limit. On the right side of the figure, in deep water, is a region of no disturbance. Next to the no disturbance region is a region which is disturbed by large waves, that is, $H_b/4 \leq H \leq H_b$. Beneath this region is a region considerably disturbed by large waves. Above the h = 100 cm limit is a region disturbed by relatively large waves and surprisingly a region of no disturbance. However, above the h = 100 cm limit wave conditions are small since the water depth is less than 100 cm.

DESALINATION

Water is a valuable natural resource, necessary for domestic, industrial, and agricultural activities. Because of the worldwide population growth, economic development, and erroneous management choices, humanity is nowadays facing an increasing scarcity of satisfactory quality water. This threat is stronger in the arid and semiarid areas (Kulga and Adanali, 1990) but could extend to other regions in the context of a global climatic change which could modify the precipitation patterns at a worldwide scale (Pearce, 1996). The possibility of utilizing saline underground and seawaters, by removing soluble salts from water by desalination technology, is therefore considered today with an increasing attention.

Major processes of desalination

Important research programs had been put in place by the 1980s. Taking into account industrial requirements, three major processes have emerged. Distillation is the older method. Saline water is evaporated partially, leaving the salts behind. The desalinated vapor is then condensed in a separate container. Electrodialyse is based on the mobility of ions in an electrolyte submitted to an electric field. Membranes are placed between a pair of electrodes. Negative ions (anions) migrate toward the anode and positive ions (cations) toward the cathode, creating concentrated and diluted solutions between the alternating membranes. Reverse osmosis is the more recent, and today the most common, technology. The natural osmotic flow is reversed by applying pressure that forces the salt water through a membrane, permeable only for pure water.

A number of other methods may prove valuable under special circumstances or with further development. Freezing is based on the principle that water excludes ions when it crystallizes to ice. In the ion-exchange process, water passes through a bed of specially treated synthetic resin which extracts ions from the solution and replaces them with ions that form water.

Costs of desalination

Total costs of desalination include initial technological investment and energy costs. The minimum energy requirement represents the energy necessary for obtaining freshwater from saline water in the case of an ideal reversible thermodynamic transformation (Nebbia, 1968). In practice, the existing desalination methods consume an amount of energy which is at least 70 times greater than this theoretical minimum (Pearce, 1996). This energy consumption is one of the causes for the high costs of desalination. The selection of an appropriate method depends thus on these economical considerations. Distillation is the more expensive process because of the great quantities of fuel required to vaporize salt water. Electrodialysis and reverse osmosis, which can desalt water much more economically, have therefore replaced distillation for the desalination of brackish water. Because of the high cost of membrane replacement however, these two processes are less suitable for desalinating seawater. Technological advancement has also allowed some reduction in the total desalination cost, by improving energy efficiency (multiflash distillation or hybrid systems), by facilitating transfer processes, by energy recycling (process of cogeneration) or by using solar energy.

Ecological impacts of desalination

Wastewater effluents may have potentially adverse effects on the environment. They present excessive salt concentrations, increased temperatures, and increased turbidity levels and can be charged with chemicals, organics, and metals. In addition, distillation entails an oxygen depletion. These problems can be avoided by treating the effluents before releasing them in the environment but this constraint again increases the cost of desalination.

Conclusion

Desalination offers a nearly unlimited potential of freshwater, particularly in coastal areas. However, this technology is still not extensively developed, because the cost of freshwater production remains a problem. Some countries, which have opted for large-scale desalination, are now searching for more economical solutions (Nativ, 1988). Desalination is essentially utilized to solve survival problems and development of arid and semiarid areas. The use of desalinated water in agriculture is by far less important, particularly because irrigation does not need high water quality (Rhoades *et al.*, 1992). The limits of salinity are generally two to five times those tolerated for industrial and domestic water (Nebbia, 1965). In the case of salinity sensitive crops such as citrus, however, partial desalination by mixing a part of desalinated water to saline underground water, is an interesting solution (Matz, 1965). Because of industrial research and because of the rise in cost for conventionally treated water, desalination turns out to be more and more feasible, economic, and reliable and its importance is expected to increase in the future years. However, even if the problem of freshwater rarefaction can be, in the more or less long-term, technologically solved, we must wonder if an increasing demand for freshwater is compatible with the current will of preserving ecosystems and biodiversity. Excessive water utilization has serious consequences on the function of precarious ecosystems like wetlands (Pearce, 1996). Better management options, centered on conservation and economy of resources constitutes a cheaper, more durable, and more ecological solution in face of water scarcity.

Water Quality

DESERT COASTS

Very great environmental differences exist among the coastal deserts of the world. On an overall worldwide basis climate is the best criteria for subdivions. Climatically, the coastal deserts fall into four principal types which can be called hot, warm, cool, and cold (Figures D19 and D20).

Hot desert coasts

The hot coastal deserts cover the largest areas (Figure D21). Their approximate length is 10,000 miles (16,000 km). This truely tropical hot climate exists only along the southern half of the Red Sea and adjacent coasts of Arabia and the Somaliland horn of Africa (Figures D22–D25). The equatorward sections are warm even in winter with winter temperatures getting above 80°F (25°C) in the heat of the day and only dropping to 70°F (21°C) in the coolest part of the night. The poleward or subtropical type prevails along the Persian Gulf and the Indian Ocean margins of northwestern India, Pakistan, and Iran the northern Red Sea; the Gulf of California, and northwestern Australia.

Most of the hot coastal deserts have relatively little cloud or fog but very high solar radiation. Owing to shallow sill restrictions at the mouths of the Red Sea and the Persian Gulf the water does not mix freely with the colder water of the open ocean, and as a result the water temperature is higher by several degrees. In summer the surface temperature in the southern part of the Red Sea is above 86°F (30°C) and in winter over 77°F (25°C). The Persian Gulf is hotter than the Red Sea in summer, but much cooler than the Red Sea in winter.

Warm desert coasts

The second type of coastal desert can be called warm rather than hot because summers are less hot, with mean temperatures, even in the warmest month being less than 86°F (30°C).The longest single stretch of this climate, about 1,600 miles (2,600 km), is along the Mediterranean Sea, where the Sahara Desert reaches the coast (Figures D26 and D27). Though occasional short rainstorms occur during the winter season, most of the days are bright, mild, and sunny. It might be noted that the climate plus the nearness to densely populated Europe, makes this one of the important winter seaside resort areas of all coastal deserts.

Warm coastal desert climates along exist along the west and south end of Baja California, Mexico (Figure D30), with winter rainfall in the north, summer showers in the south, and non-seasonal very slight rainfall in the center. All the other west-coast deserts of the world also have warm climates in their equatorward positions, such as Angola, Maruritania, Peru, and Australia (Figures D28, D29, D31, and D34). Like the southern end of Baja California (Figure D30), these coastal areas all have their rainy season, such as that occurring, in summer, which is in harmony with their marginal tropical locations. A small but distinct area of this type of warm desert occurs at the southwestern coast of Madagascar (Figure D29). Tourism is developing in some of these areas, especially the southern end of California where visitors from the

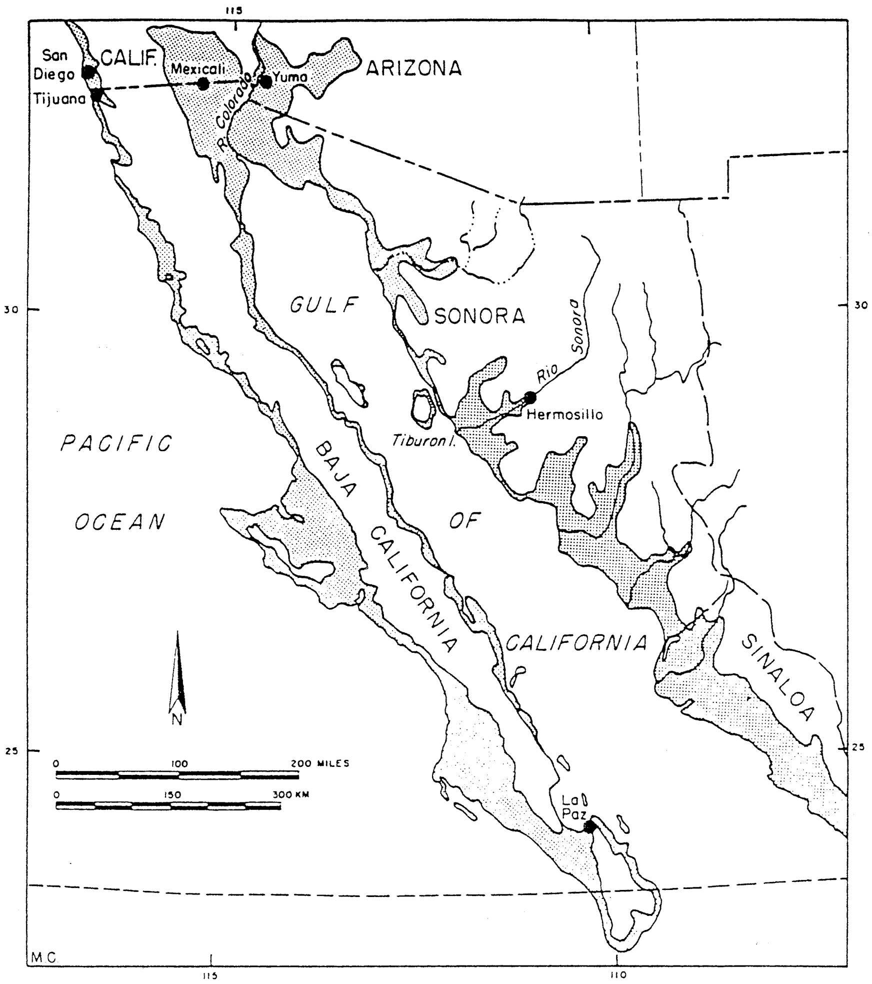

Figure D30 Coastal deserts of western Mexico and Baja California (adapted from Meigs, 1966).

United States and mainland Mexico come by air, sea, or some by road. Near their equatorial ends, these west-coast warm deserts are relatively free from cloud or fog. Toward their polar ends, especially in Peru, southwestern Africa, and Baja California (Figure D29–D31), there is frequent low cloud or fog is summer, as the warm deserts merge into the cool deserts.

A particular tourist and biological resource of this part of Baja California is the gray whale, which travels thousands of miles, from the North Pacific to breed in Scammon's Lagoon, at 27°45′N latitude.

Cool desert coasts

Type 3, the cool desert coasts from the poleward portion of all five west-desert coasts. They occur nowhere else if the shores of the Great Bight of Australia (Figure D35) is considered an extension of the west-coast desert. The longest stretches of this cool desert coast are along the Peru-Chile coast, 2,100 miles (3,400 km) (Figure D32).

Nowhere else on earth is there a coastal desert of such intense aridity which spans so many degrees of latitude as the Chilean-Peruvian desert. The extreme dryness is all the more interesting when one considers that no part of this desert is far from a tropical ocean, for at a maximum it is never more than a few score miles (kilometers) in width, and the fact that the atmospheric humidity is high is attested to by the presence of a great deal of low stratus cloud, fog, drizzle, and heavy dew. Still it seldom rains. Obviously, the dynamic controls making for drought are amazingly well-developed.

Among the climatic anomalies of the Chilean-Peruvian desert two are particularly notable, (1) the unusual intensity of the dryness in conjunction with its latitudal extensiveness and the abruptness with which it ends on both the north and south, so that a transitional steppe climate is only meagerly developed, and (2) the brief periods of heavy rainfall and high temperatures which vary occasionally affect mainly the northern parts of this desert area, this temporarily revolutionizing its weather and changing it to wet tropical conditions. In addition, the Peruvian-Chilean desert has uncommonly well developed those special features of climate which are peculiar to dry western littorals bordered by cool currents. Such as relatively low annual temperatures, small annual and daily ranges of temperature, and the existance of much low stratus fog, cloud, and even drizzle.

Other locations where Type 3, the cool desert coasts, occur are the west coast of Namibia and South Africa, 1,200 miles in length. (2,000 km) (Figure D29), while smaller sections include northern western Sahara and southern Morocco (Figure D28). Baja California has a short segment just south of the California border (Figure D30). These are foggy deserts with fog forming over the cool waters offshore and moving onto the adjacent land either as "high fog or low cloud," or at times directly along the ground. To the cooling effect of the cold water onshore can be added the reduction of solar radiation by the fog blanket. It can also be added that there are regional differences in the season of maximum fog. Along the Chile-Peru coast the season of great fog is in winter; while along the Baja California and northwest Africa coasts there is a summer maximim of the fog. Solar radiations is also affected by high clouds associated with the seasonal rainfall regimes of the neighboring human-occupied areas: winter in most of the cool desert climates, while summer occurs in the main part of the Peruvian coast. However, it can be said, the deserts of the coast provide attractive relief for people from the hot interior valleys or deserts. It might be added

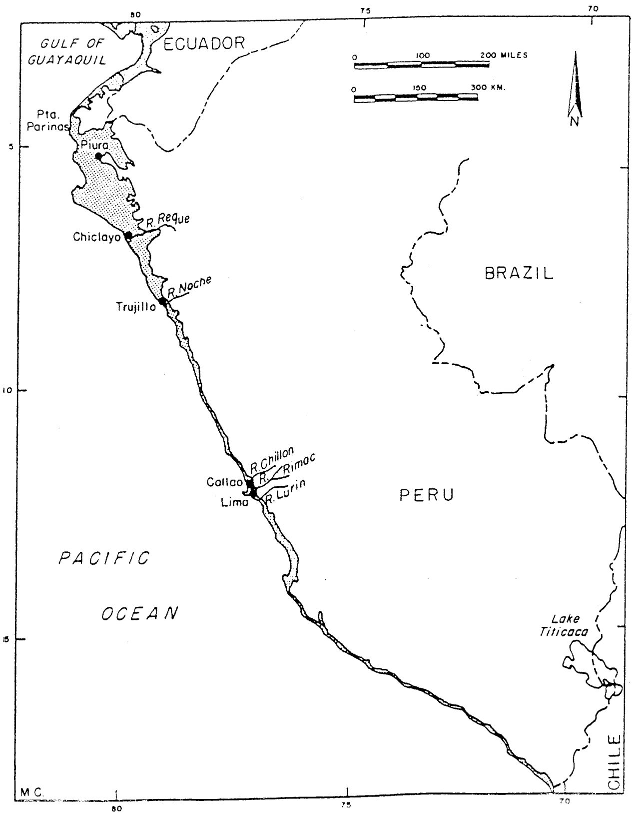

Figure D31 Peruvian coastal deserts (adapted from Meigs, 1966).

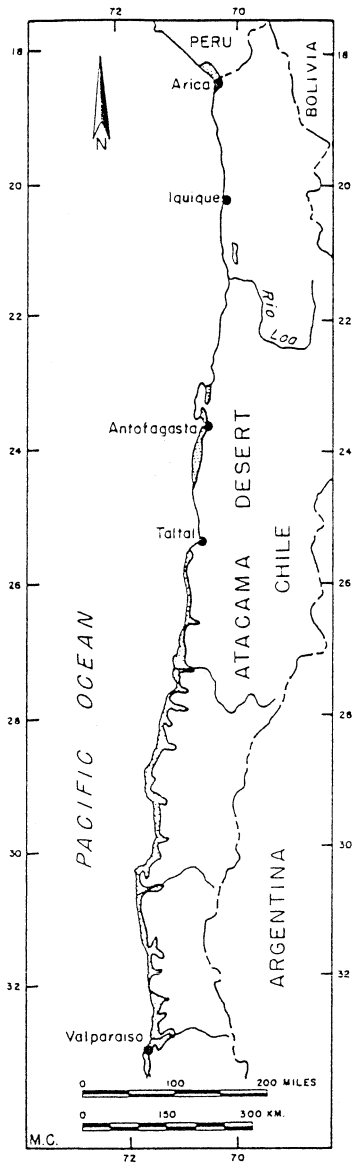

Figure D32 The Atacama desert (adapted from Meigs, 1966).

that the special circumstances of cool to cold ocean waters offshore has resulted in great fishing grounds.

Cold desert coasts

The coldest coastal desert of all, Type 4 of the classification, occurs along the southeast coast of Patagonian Argentina (Figure D33). Here a cool to cold ocean current reinforces the dry rain-shadow effect of the Andes on the westerly storms that normally prevail in these latitudes. This desert extends to more than 50°S latitude, which is farther poleward than any other coastal desert in the world. The mean temperature of the coldest month is below 50°F (10°C), and the temperature of the warmest month is between 50° and 72°F (10° and 22°C). With such limited heat only the hardiest vegetation and crops grow in this region. Other resources must provide the principle economic basis for settlement.

This account considers only the connecting, not even the oceans. The inland lakes and seas are not considered, not even the large Caspian Sea. This sea has a climate quite different from those of other coastal deserts. Most of its climate (except along the southwest borders) is continental: colder in winter than the coldest of the coastal deserts (Type 4), with averages below freezing; and ranging with the warmest deserts (Type 2) (Figures D34 and D35) in summer. The sea affects the temperature of the land immediately adjacent to it, as occurs with other coastal deserts.

Coastal desert environments

A great variety of landscapes and landforms occur along desert coasts, in fact nearly every type of landform. Desert and semidesert coastal lands make up about 20–25% of all such world regions. Coastal dunes and desert plains predominate but long stretches have steep escarpments or plateaus which rise directly from the sea. In places such as the Makran coast of Pakistan, quite recent uplifted terraces predominate.

The source of sand for desert coasts comes mainly from the sand left on beaches which is moved inland by changing tides and waves plus coastal winds. Another major way for sand to reach desert coasts is by intermittent rivers and streams which carry the sand in short flash floods. The sand is either carried into the sea and then moved by waves and currents along the beaches or picked up by winds in river beds and moved to coastal dunes. There is a changing balance between wind transport of sand and by running water in river bads.

Most aeolian bodies occur in basins in the desert. The Pleistocene probably saw periods of more intense fluvial erosion than the present. Many coastal ergs are fashioned out of deposits of Pleistocene or late Tertiary alluvium.

Clay dunes are perhaps surprisingly better authenticated than silt dunes and are more obviously dune like. They have been reported from the Gulf of Texas, northern Algeria, Australia, and the Senegal Delta.

Although it is not difficult to recognize a desert, opinions vary as to the physical features of the environment that should be used as criteria for defining a desert climate. Rainfall must obviously be taken into account, and desert conditions usually prevail in tropical regions when the average rainfall is under 5 in. (127 mm), with semidesert conditions occurring when the average rainfall is over 5 in. (127 mm) but under 15 in. (381 mm). But such figures can be only approximate, because what matters is not only the amount but the effectiveness of rain; and the effectiveness of rain depends on its seasonal occurrence, its rate of evaporation, and the nature of the soil (Cloudsley-Thompson, 1975, p. 8).

The aridity of coastal deserts that results mainly from a lack of rain is often due to the way in which the atmosphere circulates, particularly

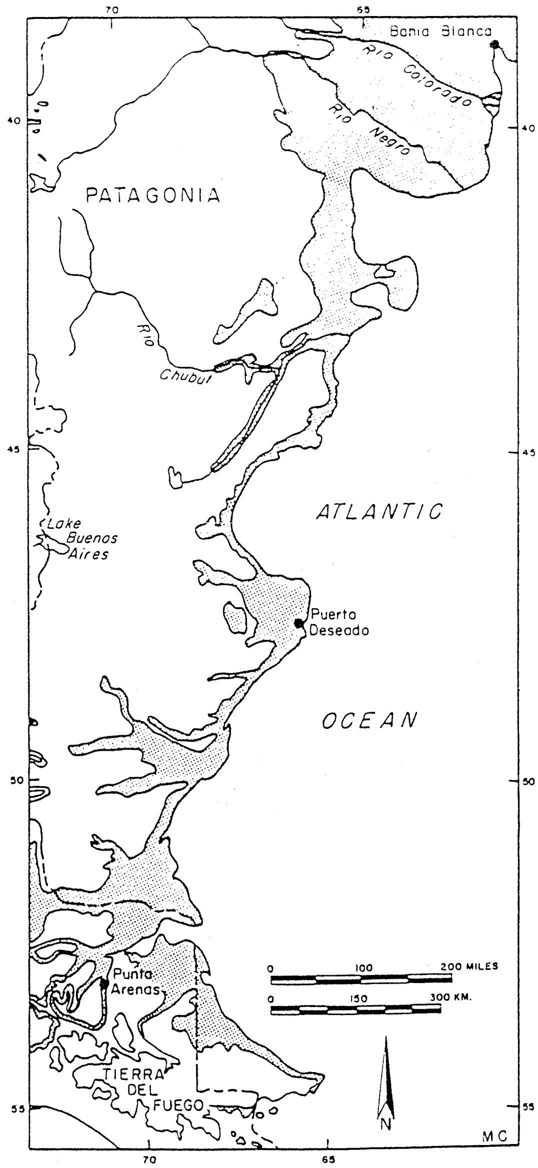

Figure D33 Coastal deserts of Patagonia (adapted from Meigs, 1966).

in its lower layers, and this partly explains the geographical distribution of the world's coastal deserts: near latitudes 30°N and S, the direction of the winds tend to vary, and the air sinks. When this happens, it is warmed by the hot ground, and clouds are dispersed. At the same time, high-pressure belts that separate the polar westerly winds and the tropical easterlies occur near these latitudes. Consequently, the disturbances associated with low pressure, which usually cause rain, are rare. Then, too, there are some local factors that quite often result in low rainfall. These include the rain-shadow effects of mountain ranges, which cause the air to drop all its moisture as it crosses them. For example, the Patagonian desert including the Argentina coast, is the result of both the rain-shadow effect of the Andes Mountains, which block the path of the westerlies, and the cool Faulklands current alongshore.

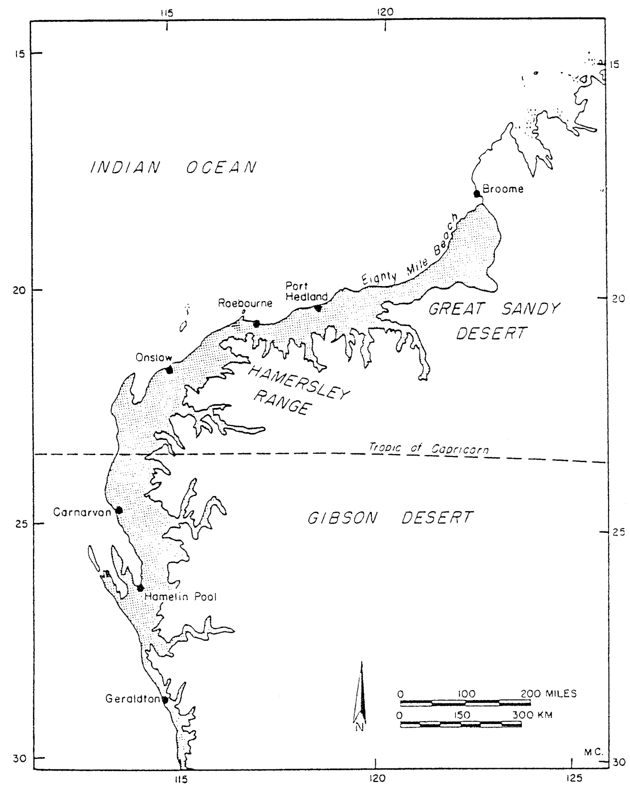

Figure D34 Coastal deserts of western Australia (adapted from Meigs, 1966).

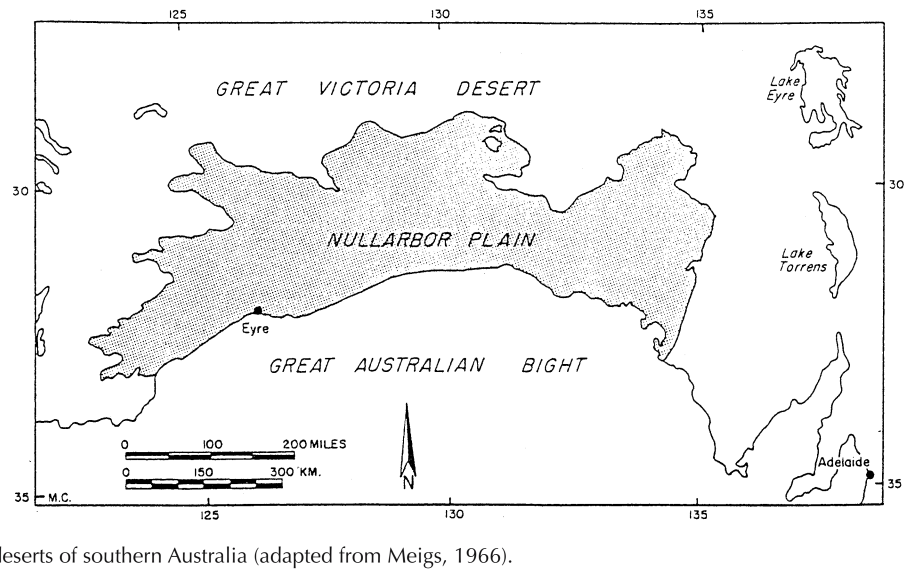

Figure D35 Coastal deserts of southern Australia (adapted from Meigs, 1966).

Desert coastal vegetation

Most desert coasts support a *xerophytic* type of scrub vegetation which grows sparsely in most areas. A few scattered trees, mostly the acacia type in tropical coastal deserts, can be found. In years with more than 8 in. (200 mm) of rainfall, a thick layer of grasses, herbs, and shrubs covers the ground. Climate is the major determinant of vegetation types, and rainfall is much more significant than temperature, however the amount of salt comes into play. In general, it can be said that along most desert coasts many of the shrubs are woody and stunted being about 12 in. (300 mm) high with round cushion-like out-lines. With bleached stems and few leaves many look like skeletons of plants. A few annuals begin sprouting when warmer days occur. Although the number of families is large in most cases the number of species is small.

Again, speaking generally, the first dunes behind the back-shore differ in vegetation from the inland dunes. The difference is due mainly to high salinity and a high water table which often is only 0.5–4.0 ft (0.15–1.2 m) below the surface.

Natural and human factors disturb desert coastal vegetation and lead to temporary changes in plant cover. Disturbed areas result from such natural causes as varying moisture, wind and soil conditions, and destruction by sudden floods. Human activities along the coast which disturb plant successions include the clearing or destruction of the original vegetation for purposes of cultivation, fuel, fodder, and building material. Animal grazing is the most destructive factor.

Several desert coasts have unusual vegetation types. For example, the Namib coast has vegetation that lives off of fog; both the Baja desert coast and the Galapagos Islands have unusual vegetation probably because, for a long period of time, they were so isolated, new species of plants developed.

Animals and plants

It is not easy for plants and animals to survive in desert coastal regions where extremes of drought and flood, of erratic rainfall, or no rainfall at all, only fog and dew, can occur. Therefore, it is not surprising that animals and plants have adaptations that are correspondingly extreme. Desert animals usually run faster than their relatives in temperate regions. Venomous forms are more poisonous than their allies beyond the desert's fringe. Spiny plants are more prickly, and distasteful ones more unpleasant, than anywhere else.

Most desert and semidesert costal regions support some degree of vegetation. The smallest amount of plant life exists in areas of rocky *hammada* and cracking clay; but plants can grow even in such soil whenever it is traversed by wadis. And sandy desert usually supports a flora of some kind, except on the dunes, which tend to stay quite bare. Many plants, such as annual grasses and other small herbs, evade the more extreme desert conditions by completing their life cycle during the short rainy season and passing the remainder of the year lying dormant as fruits or seeds in the soil. Dry seeds can often survive high temperatures without losing their ability to germinate later under more favorable conditions (Cloudsley-Thompson, 1975, p. 26).

Most plants of arid regions have evolved mechanisms not so much of drought tolerance as of resistance to drought. They fight the battle against water loss in a number of ways, often combining different protective devices within a single plant. One means of retaining moisture is to have leaf surfaces coated with fatty substances and resins; these making it harder for water vapor to escape. Other structural adaptations to drought include the presence of dense, hairy coverings (which again keep moisture from escaping) or of pores sunk deep into the leaf tissue so that the dry wind cannot blow directly into them. Smaller and fewer leaves also help resistance to water loss. And— perhaps most important of all devices—a number of desert plants have developed internal tissues for storing water over long periods of time and for giving increased mechanical support to the bloated, water-filled organism after a heavy rainfall. Such plants (among them the cacti) are known as *succulents* (Cloudsley-Thompson, 1975, p. 29).

Some plants can survive on moisture from the air; and at night, with the drop in temperature, dew condenses on their leaves and stems and runs down into the soil around the roots. The welwitschia of the Namib Desert in southwestern Africa is such a plant. It bears two curling leaves, split longitudinally into strips, on which dew condenses, providing water for the shallow roots. The ability of vegetation such as the welwitschia to absorb moisture from the night air, even when dew does not form, can make vitally needed water available for snails, insects, and other small animals of the desert.

Desert vegetation is not entirely ephemeral. There are many plants that habitually grow where evaporation stress is high and water supply low, and that do not need to evade extreme coastal desert conditions. Such plants, all of which show characteristic adaptations to their environment are termed *xerophytes* (from the Greek words meaning “dry” and “plant”). Among them are trees, perennial grasses, and species that develop bulbs, corms, or tubers. Some xerophytes are characterized by the ability to survive long periods of drought and dehydration of the tissues without suffering injury. They are extremely resistant to wilting, and a few species can lose up to 25% of their water content before they begin to wilt.

Another characteristic feature of most desert coastal plants is that they posses painfully sharp thorns and spikes. The probable function of these is to afford protection against browsing and grazing animals. Many contain poisonous or irritant latex. Other secrete resins or tannins in the bark or levels; the pods of some contain strong purgatives. All such devices tend to make the desert plants unpalatable to animals (Cloudsley-Thompson, 1975, pp. 27–30).

Case study of the Pakistan–Iran climate regime

The Pakistan part of this desert coastal type is interesting because it is an area of transition between the Indian summer monsoon system to the east, and the winter cyclonic system of southwest Asia to the west. As a transition area, it receives scanty, unreliable rainfall, averaging less than 10 in. (250 mm) per year from several storm types. Six main weather patterns cross the region, the large subtropical anticyclonic high-pressure cell which predominates most of the year; western depressions originating over the Mediterranean Sea; a modified monsoon pattern; eastern depressions originating over the Bay of Bengal and central India and local thunderstorms and dust storms.

The seasonal division of rainfall for southern Pakistan is shown in Figure D21. Nearly all of Sind and the eastern part of Baluchistan, particularly the Las Bela area, have a pronounced summer monsoon maximum coming in June, July, and August. This line conforms to the eastern slopes of the Kirthar and Sulaiman mountain ranges which act as a barrier to storms from the east. Iran and the western part of Baluchistan have a winter maximum coming from November to March with very little summer precipitation. Central Baluchistan is a region having both winter and summer rainfall with a slight winter maximum, while a thin band in eastern Baluchistan is an area having both winter and summer rainfall, but with a slight summer maximum.

DEWATERING—See BEACH DRAIN

DEVELOPED COASTS

The term "developed coast" often implies a natural system altered by human action. The type, frequency, and magnitude of alterations are influenced by the social and economic value humans place on the resource. Today, developed coasts are modified and physically maintained by humans to enhance navigation, recreation, and protection of settlements. Human modification of the coast has resulted in changes to the dimensions and locations of coastal landforms and the spatial and temporal scales of cycles of erosion and accretion. Globally, human presence on the coast dates back to tens or even hundreds of thousands of years, with some of the earliest documentation on the Mediterranean coast (Nordstrom, 2000). Deforestation and overgrazing were perhaps the earliest human actions that significantly altered the coast by increasing the quantity of sediment delivered (Walker, 1985). Grazing initiated dune migration when practiced directly on the coast. Channelization, diversion, and impoundment of water resources had the opposite effect on the coastal sediment budget; levees and dams decreased sediment delivery from river sources, with the most conspicuous effects occurring in the 20th century.

Direct human alterations to the coast increased in scale with increased occupancy and technological advances associated with the availability of steam power (Marsh, 1885) that enabled the creation and removal of landforms and redistribution of sediment. Pronounced changes to the landscape occurred about the mid-19th century. Harbors were constructed and inlets were regulated through sediment dredging and jetty construction.

Coastal tourism and resort development, beginning in earnest during the second-half of the 19th century, resulted in further alteration of the coast. Seasonal house construction and infrastructure development (transport, utilities, marinas) along the coast resulted in elimination of dunes and elimination of marsh by filling to increase upland width or by dredging to construct marinas. Development occurred near the coastline, increasing vulnerability to wave attack and flooding during storms and requiring shore protection. Large-scale shore protection efforts, primarily groins and seawalls, were initiated in the late 18th century in Europe and in the mid-19th century in the United States (Nordstrom, 2000). Use of these structures, referred to as hard stabilization, increased with increased construction of buildings and support infrastructure. There is considerable debate on the use of these structures in long-term coastline management (Kraus and Pilkey, 1988). Beach nourishment (placement of sediment on the beach and nearshore profile from another source) was first used in the early 20th century and became popular in the second-half of the 20th century. Identified as soft stabilization, nourishment is now the preferred alternative to protect development from storm erosion and flooding (National Research Council, 1995). Introduction of large volumes of sediment to developed shorelines that previously had a sediment deficit has created opportunities for the restoration of many geomorphic features lost to human development.

Characteristic landforms

Many of the characteristic landforms found on developed coasts differ from their natural counterparts in size, location, and spatial and temporal scales of change but are identified using similar terminology. The attributes of landforms found on developed coasts can be the intended or unintended outcome of their modification for human use. Over time, assemblages of human-altered landforms may be accepted as natural and require further human modification to maintain their resource value (van der Meulen *et al*., 1989).

Beaches on developed coasts are generally narrow, due to the reduction of sediment supply, but nourishment can displace the high-tide shoreline seaward and create a beach that is initially wider than a natural beach. Nourished beaches, when designed for shore protection, are often higher in elevation than their natural counterparts, but beaches downdrift of shore protection structures such as groins will be lower in elevation. Most direct human modifications to beaches are intended to reduce high-tide shoreline mobility over the long-term, although mobility may be higher than expected immediately after the modification such as inlet creation, closure and stabilization, or beach nourishment. The characteristics of sediment found on nourished beaches is dependent on the source, which may be derived from offshore, including inlets.

The location and size of dunes are controlled by direct human actions, such as bulldozing and placement of sand fences, and indirect actions through the passive influence of shore protection structures that trap sediment transported by wind. Human modification by fencing, vegetation planting, or mechanical grading creates forms designed to optimize human values such as shore protection, views of the sea, or ecological enhancement. Small incipient dunes are often lacking because beach litter is eliminated by beach cleaning operations. Secondary dunes are often lacking because that zone is occupied by human structures. Sedimentary characteristics and internal structure of dunes that form around human structures by aeolian processes are similar to natural dunes. Dunes created by bulldozing have poorly defined internal structure and contain sediments that may be too coarse or too fine to be transported by local winds. Dunes created by humans are often less mobile than those created by aeolian processes alone because fencing or buildings constructed close to the shore restrict migration.

Assessing change

Landforms on developed coasts respond to energy inputs according to the same laws as natural landforms, but the spatial and temporal scale of change can differ because of human action (Nordstrom, 2000). Assessment of post-storm recovery of landforms in developed and undeveloped coastal areas reveal that recovery of the backbeach and dunes by natural processes is impeded by the presence of houses in developed areas (Morton *et al*., 1994), but recovery by human modifications can occur at a far more rapid rate. Closure of inlets created during storms, bulldozing of sediments onto the backbeach from overwash deposits on streets, and reconstruction of dunes using sand fences or earth-moving equipment rapidly restore the coast to the pre-storm landscape to achieve social and economic resource values. Human alterations to the coast may be more dramatic in the future in response to sea-level rise (Titus, 1990).

Assessing landform change on developed coasts requires identification of both human and physical processes that govern change as well as the interactions between them. Human action can be considered either external to or a part of the natural system (Phillips, 1991). As an external influence, human action can be considered an overlay to a natural coastal system. As a part of the natural system, human action must be considered an integral process to assessing change, enabling a better understanding of the functioning of the developed coast, and ways to manage it to achieve both natural and human resource values (Nicholls and Branson, 1998).

DIKES

Introduction

Dikes, especially sea dikes, are coastal constructions build to avoid flooding. The risk of flooding is detrimental to the safety of people and economic, cultural, and ecological values. This aspect has been of great importance since people first thought about defending their dwellings against flood hazards. In the distant past, dwelling mounts were built to protect families or small communities from the sea. They are known from several low-lying coastal areas in the world, for example, from the North coast of Germany and the adjacent Dutch coast, where they have been occupied ever since 2500 BP, as well as from the chenier coast of Suriname, where they date back to 1800 BP.

Population increase urged to a more active method of flood prevention. The people started to construct dikes to keep the water out of whole regions, thus protecting lives and properties against the sea. In the Netherlands, dikes have been built as a community activity from about AD 1100. Ever since, coastal defense has become more and more an engineering activity. Presently, the design criteria for sea dike construction are determined by three important groups of aspects: hydraulic, subsurface, and construction. The first two groups mainly determine the required height and strength of the dike. The last group of aspects is particularly important for the dike's duration of life. Details about the various aspects are given by U.S. Army Corps of Engineers (1984).

Hydraulic aspects

Hydraulic factors influencing the marine water level at small temporal scales are the tidal range, wave height, wave run-up, and the setup of the water level due to wind conditions. Because dikes have to be calculated for extreme water levels, especially a coincidence of extreme conditions of these factors are at stake, for example, high-water spring tide and wave characteristics and setup of the water level during storms. For the establishment of extreme water levels, high-water exceedence frequency curves are used. This method is based on the finding of a systematic relation between the height of a flood-tide level and the number of times this specific level occurs in a century. Extrapolation of the high-water exceedence frequency line enables a probability calculation for the chance that an extreme high-water level, not observed before, may occur. Moreover, the effects of long-term changes in sea level and storm frequency must be taken into consideration.

The final height of a sea dike is determined by the degree of risk of flooding, within the applied economic constraints, the community is willing to accept. In the Netherlands, for instance, the sea defense system is at "Delta height." However, for the distinguished coastal sections of the Dutch coast this "Delta height" has different values. For the uninterrupted West-coast, which protects the most densely populated and economic heart of the country, the minimum height of the dunes and dikes is determined by a water level exceedence chance of 1 in 10,000 years. For most of the barrier islands in the north of the country the "Delta height" corresponds with a high-water exeedence chance of 1 in 2,000 years.

Subsurface aspects

Subsurface aspects like subsidence and tectonic movements codetermine the behavior of the sea level. The Netherlands, for instance, are suffering from a relative rise in sea level, which is the combination of the eustatic sea-level rise and the subsidence of the land (Jelgersma, 1961). Subsidence in this case is mainly due to the isostatic rebound after the last glaciation and the dewatering of the peaty subsoil in the coastal area for agricultural reasons, resulting in compaction. Especially in the past, this drainage has contributed to the general subsidence. At the same time, the central part of the Dutch coast is influenced by a graben system.

In the decision-making of the final height of a sea dike, the compaction of the subsoil due to the weight of the overlying dike body has also to be considered, as well as some compaction in the dike body itself.

The composition of the subsoil is relevant with regard to groundwater flow. A dike is meant to be impermeable for water. However, groundwater can be pressed to flow through the subsoil underneath a dike, due to a difference in hydrostatic pressure on both sides of the dike. The flow velocity depends on the volume of the overhead and on the permeability of the subsoil. This seepage causes saltwater intrusion landward of the dike. In case the currents are sufficiently strong to erode the underlying sediment, this process affects the stability of the dike and ultimately may result in the collapse of the dike.

Construction aspects

The construction of a dike requires building material. In the past, the preferably clayey material was locally dug. Nowadays, however, dikes usually have a sand nucleus, covered by clay to make it impermeable. Suitable clay usually is scarce, whereas sand occurs in large quantities. The advantage of this method is that sand not necessarily needs to be transported on a truck, but can be supplied in suspension by pipeline.

Because of the difference in hydrographic pressure on both sides of a dike, a groundwater table is formed in the sandy dike body. Although the clay cover has to be impermeable for seawater, it must simultaneously be able to let an excess of water from inside the dike through.

Generally, dikes have a delta form. To reduce the effect of wave run-up, the slope of the seaward bank of a dike has to be small. On the contrary, the width of a dike increases in that case. A balance has to be found between cost and safety.

In the flood disaster in the Netherlands in 1953, the effect of overtopping water on the landward side of the dikes appeared to be the most important cause of dike failure. In order to reduce the effects of overtopping water, for example, the penetration of water into the center of the dike body, various degrees of unevenness can be applied.

To avoid erosion of the banks and undermining of the dike body revetments are applied. Usually these revetments are provided with a filter layer, to prevent erosion of the underlying material. Permeable as well as impermeable revetments are applied. It is necessary that the material used is flexible and tight to follow the compaction of the underlying sediment.

DISSIPATIVE BEACHES

Definition and classification

Dissipative beaches are systems where most wave energy is expended through the process of breaking. Guza (1974) was apparently the first to use the term dissipative beach. He indicated that the wave-energy status of a nearshore system could be determined using the surf-scaling parameter, ε:

$$\varepsilon = \frac{\alpha\omega^2}{g\tan^2\beta}$$

where α is the wave amplitude at breaking, ω is the wave radian frequency ($\omega = 2\pi/L$, where L is wave length), g is the gravity constant, and β is the beach slope in degrees. The proportion of incident wave energy that is dissipated by breaking increases as ε increases. When ε is less than about 2.5, most wave energy is reflected off the foreshore. For beaches where ε is larger than 20, most energy is dissipated by the turbulence associated with wave breaking. Guza (1974) designated these latter beaches as dissipative. Thus, the relative degree of dissipation or reflection of incident wave energy in a nearshore system may be used as a rationale for the classification of beaches. This is usually accomplished under the rubric of nearshore morphodynamics.

Morphodynamics

The concept of nearshore morphodynamics was developed to characterize systems where form and process are closely coupled through feedback mechanisms. On beaches, waves (*q.v.*) interact strongly with sediments and morphology, and the form of wave breaking is one manifestation of these interactions. For constant wave steepness, H/L (where H is wave height), the breaker type will change as the nearshore slope changes. On a very low gradient slope, spilling breakers would be expected. As the gradient increases, there should be a progression through plunging and collapsing breakers. Finally, on very steep beaches, surging breakers should occur (Galvin, 1968). For a constant nearshore slope, the same sequence of breaker types will occur as wave steepness decreases. Breaker type is closely associated with the expenditure of wave energy in the nearshore (e.g., dissipation or reflection) and the development of nearshore morphology. The morphology, in turn, controls breaker type. These relationships are the underlying bases for the concept of nearshore morphodynamics (see summary by Wright and Short, 1984). The recognition of characteristic sets of dynamic relationships provides the basis for using morphodynamic regimes (or states) as a means for classifying beach types. For example, spilling breakers tend to occur on dissipative beaches. This contrasts with reflective beaches (*q.v.*), where collapsing or surging breakers are common. Plunging waves tend to occur on the intermediate beach states of the morphodynamic model, where neither dissipation nor reflection dominate the response of nearshore morphology.

Characteristics of dissipative beaches

In cross section, morphodynamically dissipative beaches display the classic forms of "storm" or "winter" beach profiles (e.g., Sonu and Van Beek, 1971). According to Wright and Short (1984), other distinguishing characteristics include low gradient nearshore and beach slopes—about 0.01 and 0.03, respectively, and with relatively fine sediment sizes. Dissipative beaches tend to have a substantial sediment volume and at least one linear nearshore bar, although multiple bar–trough systems are common. In dissipative systems, the beach and nearshore zone will exhibit minimal alongshore variability—the system is approximately two-dimensional. Incident wave energy is maximum at the break point, and decreases shoreward. The classic dissipative system displays several coincident sets of spilling breakers (Figure D36), and there is minimal energy remaining at the landward extremity of uprush. Infragravity motion dominates the inner surf zone, and frequently causes linear scarping of the foreshore (e.g., Short and Hesp, 1982). On meso- and macrotidal beaches, the nearshore may be dissipative only at lower tidal stages and reflective at high tide (Short, 1991; Masselink and Hegge, 1995). Short and Hesp (1982) have also linked the dissipative beach state to the formation of large-scale transgressive dune sheets—at least in the Australian context. This linkage was a key development for the derivation of later models of beach–dune interaction (e.g., Sherman and Bauer, 1993).

Douglas J. Sherman

DREDGING OF COASTAL ENVIRONMENTS

Definition of dredging

Dredging is moving material submerged in water from one place to another in water or out of water with dredging equipment. Dredging is applied in projects of navigation, for maintenance of beaches, for reclamation, to secure construction materials, and for environmental dredging.

Dredging for navigation

From the very beginning of civilization, people, equipment, materials, and commodities have been transported by water. Ongoing technological developments and the need to improve cost-effectiveness have resulted in larger, more efficient ships. This, in turn, has resulted in the need to enlarge or deepen many of the rivers and canals, our "aquatic highways," in order to provide adequate access to ports and harbors. Nearly all the major ports in the world have at some time required new dredging works—known as capital dredging—to enlarge and deepen access channels, provide turning basins and achieve appropriate water depths along waterside facilities. Many of these channels have later required maintenance dredging, that is, the removal of sediments which have accumulated in the bottom of the dredged channel, to ensure that they continue to provide adequate dimensions for the large vessels engaged in domestic and international commerce.

Dredging for Construction, Reclamation, and Mining

Dredging is an important way of providing sands and gravels for construction and reclamation projects. In the last two decades, the demand, and the associated extraction rates, for such offshore aggregates have significantly increased. Dredged aggregates have a wide range of uses.

Dredging for the environment

Dredging can be undertaken to benefit the environment in several ways.

Dredged materials are frequently used to create or restore habitats. Recent decades have also seen the increasing use of dredged materials for beach replenishment.

Another environmental use of dredging has been in initiatives designed to remove contaminated sediments, thus improving water quality and restoring the health of aquatic ecosystems. This so-called "remediation" or "cleanup" dredging is used in waterways, lakes, ports, and harbors in highly industrialized or urbanized areas.

Types of dredgers

Dredgers come in two different classes: mechanical and hydraulic.

Mechanical types include the *clamshell* or *grapple dredges* (Figure D37). Larger dredges of that type are no longer favored. The endless *chain bucket* (bucket-ladder) dredge (Figure D38) was used widely earlier in Europe but not in the United States, although they were employed on a few projects like the Panama Canal. For environmental reasons they may still be placed back on the market.

The *mechanical dipper dredge* with its heavy bucket (Figure D39) moved by a very strong arm and boom is still used for dredging relatively loose (usually not solid) rock. The bucket may be provided with special cast iron teeth. Its volume may be several cubic meters.

The *hydraulic dredge* is the most important piece of dredging equipment. The *plain suction dredge* (Figure D40) has no cutter but sucks material off the bottom and discharges it through a stern connected pipe leading to a spoil disposal area.

The *cutterhead pipeline dredge* (Figure D41) has a rotating cutter on the end of the ladder and excavates the material from *in situ* condition and discharges it through the stern to pontoon and shore pipe. The dredge is controlled on stern-mounted spuds and is swung from one side of the channel to the other by means of a swing gear.

The *self-propelled hopper dredge* (Figure D42) has a large hopper in which the dredged material is loaded for later dumping through doors in the bottom. This type of dredge is normally employed where the water is too deep for a pipeline dredge or where spoil areas for such a dredge are not available within economic distances.

The hydraulic dredge has, without any doubt, become the most important piece of equipment in the entire harbor engineering field. Without

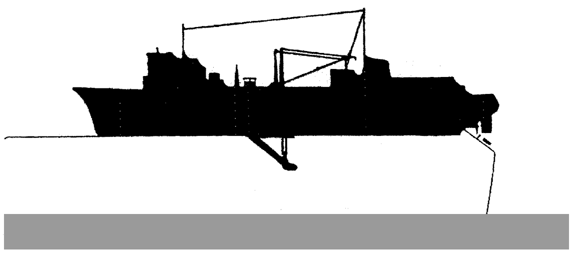

Figure D42 The self-propelled hopper dredge (adapted from Bruun, 1990b).

the dredge, commercial navigation of waterways and rivers would be ended. Waterborne industry would collapse. Ocean shipping as it is known would be nonexistent.

Hydraulic dredges dig canals, ports, and harbors, do maintenance dredging in rivers, canals, and waterways, and excavate for construction of piers, wharves, docks, dams, and underwater foundations. They provide spoil for the reclamation of swamps and marshes; they construct dikes and levees, and dredge sand, gravel, and shell, as well as coal, gold, diamonds, and many other minerals for commercial purposes. The dredge's scope of operation is broad. Most of them have cutterheads.

Small hydraulic dredges, 20–40 cm diameter pipe, operate in water only a few meters deep. Large dredges, 65–90 cm diameter pipe, require more draft but can dig to greater depths. With the aid of booster pumps the distances solids can be pumped are unlimited.

Although the dredge's output is understandably greater in soft materials than in hard, it can excavate almost anything. It digs mud, silt, loam, clay, sand, hardpan, gravel, coral, and even rock. Boulders weighing 500 kg and more have been excavated and transported by dredges.

The self-propelled hopper dredge moves freely without any kind of mooring system. It can operate by pumping holes in the bottom side by side through a usually circular intake which is the reinforced end of the suction pipe, or it can trail along with its trailing suction head attached to the end of the suction pipe "vacuum cleaning" the bottom. This method is more practical and effective than the plain pipe sucking procedure where deep holes may become sediment traps for material which otherwise may have been flushed away. Various organizations like the IADC (International Association of Dredging Companies), the CEDA (Central Dredging Association), the WEDA (Western Dredging Association), and the WODA (World Organization of Dredging Association) organize conferences and publish magazines. (See *Acronyms*).

Special dredgers

Wheel dredgers

The IHC's (The Netherlands) Scorpio Dredger has a dredging wheel that consists of bottomless buckets to which sticky soil does not adhere (Figure D43). They are arranged to form a tunnel from which dredged material cannot easily escape. This effectively prevents the ingress of debris. The result is higher solids concentration, no spillage or blockage, and reduced downtime. Several such dredgers are now in operation all over the world.

The Water Injection Dredger

The Water Injection Dredge (WID) was developed in Europe in the mid-1980s and has been used regularly there since 1987 and recently tested in the United States by the US Army Corps of Engineers (USACE). The principle of WID is to fluidize the shoaled material to a condition that a gravity-driven density current is formed, which transports the sediment down a slope into deeper water where it is no longer an obstruction to navigation, and natural sediment transport processes can take over. This density current remains close to the bottom, minimizing turbidity. Fluidization is accomplished by injecting water directly into the sediment voids under relatively low pressure, through a series of nozzles evenly spaced on a horizontal pipe. A pump mounted on the dredge, barge, or other vessel forces water into the horizontal pipe or head. The pipe pivots from the dredge, allowing the head to be lowered with the aid of a winch. During operation, the head with the injection nozzles is as close to the bottom as possible, while the dredge proceeds across the cut area (Bruun, 1990a, 1996).

Sidecasters

Sidecasters sidecast the dredged materials. They come in various sizes. Small sidecasters are excellent for emergency and shallow water operations, for example, in channels.

The McFarland (Figure D44) also has a hopper. It was put in commission in 1967 and assigned to maintenance of Gulf Coast inlets

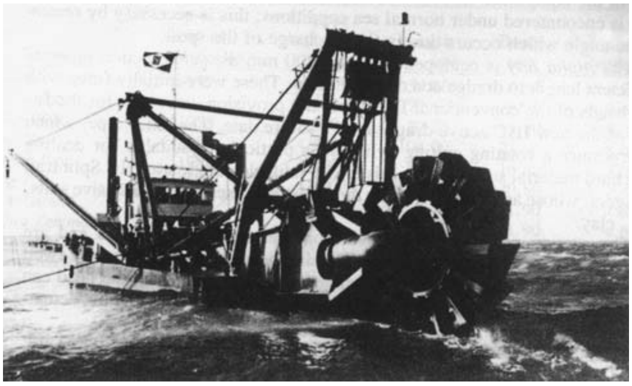

Figure D43 The Wheel dredger SCORPIO (adapted from Bruun, 1990b).

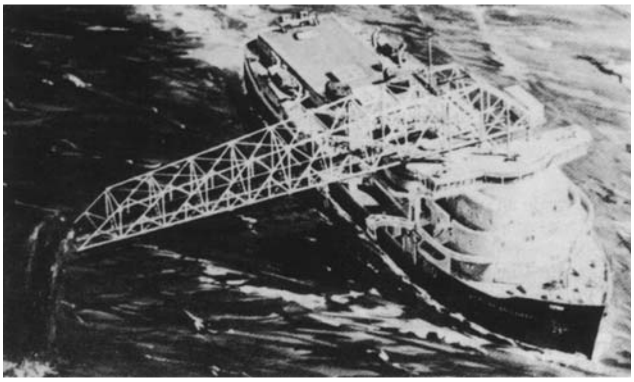

Figure D44 The sidecaster and hopper dredge McFarland (adapted from Bruun, 1990b).

(USACE). It is 91 m long, 22 m wide, with a loaded draft of about 7 m to permit efficient operation in relatively shallow water.

Other types of dredgers are mentioned in the following section on the latest development of dredging equipment.

The latest development in dredging equipment

The latest decades and years have produced dredging equipment on a scale never seen before including hopper dredgers of capacities up to 33,000 m^3, with suction pipes of 1.4 m diameter reaching down to 60 m depth, with deep dredging suction up to 131 m depth, and outputs exceeding to 10,000 m^3/hr. Large projects in the Far East (Hong Kong, Singapore, Thailand, China, Persian Gulf) and also in South America (Argentina, Uruguay) utilize these dredges. Large fills for industrial development including airports, deepening of navigation channels and basins all over the world are in progress or planned. This includes many projects in the United States (New York, Charleston, Savannah, Galveston, Los Angeles, Columbia River, etc.). Materials are used for fills or dumped offshore in designated areas.

The dredging companies involved are mainly Dutch or Belgian. They compete in producing the most effective equipment provided with the latest inventions in survey technique, controls, and maneuvering. They are applied in projects with quantities of tens of millions of cubic meters capital dredging. Smaller size equipment includes hopper dredgers of a few thousand cubic meters hopper capacities for relatively smaller projects, capital as well as maintenance.

Some larger cutterhead hydraulic pipeline dredgers are still being built, in particular for work on harder bottoms and in narrow or protected environments. Some of these are ocean-going with discharge pump capacities of many kilometers. An example is the Bos Kalis 89 cm "ORANJE."

Amphibious "crawl cats" and "crawl dogs" (Bruun, 1996) and underwater pumps like the PUNAISE (Visser and Bruun, 1997) have been built and tested in practice.

One of the most recent additions to the international fleet is the "LANGE WAPPER," a 13,700 m^3 capacity trailing suction hopper dredger which entered service in May 1999. The 20,000 dwt new vessel boasts the extremely shallow draft of 9 m fully laden, setting it in competition with vessels in the 8,000–10,000 m^3 range—yet with substantially higher production rates.

Built by IHC Holland, the Lange Wapper is 120 m long, with a beam of 26.8 m. The total installed power is 13,400k W and dredging depth is in the range 30–50 m. For a draught of 8 m, the vessel can carry a deadweight of 15,500 tonnes.

The Lange Wapper features state-of-the-art computer software to integrate all dredging, navigation, and surveying systems. It is thought to be the first software of its kind in the industry.

Specially designed by DEME, together with IHC Systems (the electronics subsidiary of the IHC group), the software provides a single program capable of handling all data relating to dredging, navigation, and surveying. Previously, software systems could only communicate with each other from standalone packages. Furthermore, up to 10 extra systems were required onboard and extra personnel needed to operate them. The software onboard the Lange Wapper will be available via a number of networked computer terminals and will also be able to access additional data by satellite.

Enhanced controls and accuracies are the main advantages of this new system. Tight dredging parameters will be possible, which will enhance performance in environmentally sensitive conditions and offshore trenching or pipe covering operations.

All dredging projects, however, depend upon hydrographic surveys. As ports and channel systems throughout the world continue to involve expansions and extensions, the need for effective survey programs becomes essential. Throughout the past year there have been some major developments within this sector of the port construction industry.

Dredging for nourishment of beaches

Artificial nourishment of beaches is the most practical and economical measure of coastal protection. Suitable material must be available. Figure D45 shows split-hull dumping of dredged material. Figure D46 is a trailing suction hopper dredge pumping material on the beach and in the nearshore bottom, or through a buoy connected to shore by a (submerged) pipeline. In the United States, nourishment is often done by a hydraulic pipeline dredge connected directly from the borrow area to the beach by (submerged) pipeline.

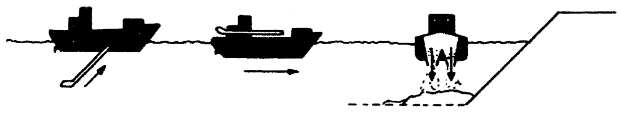

Figure D45 Direct dumping in the nearshore zone with hopper dredger (from Brunn, 1990b).

Figure D46 Trailing hopper dredger pumping through nozzle placed in bow of the vessel (from Brunn, 1990b).

Profile nourishment

The normal nourishment profile includes a wide horizontal berm with a front slope of about 1 in 10. Because beach nourishment is generally paid for by a public authority, public opinion is important in acquiring sufficient funds. Therefore, it is wise to design beach nourishment in such a way that the public sees that the beach is somewhat wider after the nourishment, but that there is no major adaption in the beach shape during the first storms in autumn. If the purpose of the nourishment is to make a wide recreational beach, this is very important. If the purpose is to prevent flooding, the best place is as high as possible on the beach. If the purpose is to combat chronic erosion, the best place is in the breaker zone.

Profile nourishment (Bruun, 1990a, b) attempts to follow the natural profile in the nearshore as much as this is practically possible. The advantage of profile nourishment is that it decreases the introductory losses of fill producing a more stable condition. OVER THE BOW PUMPING (Figure D46) is most suitable for such operations undertaken in countries like Holland, Denmark, Germany—and at its start in the United States. The Shallow Water Hopper dredgers, in short supply in the United States, are well suited for such operations. They may pump over the bow, if bottom is steep enough, or through a short pipeline (Bruun and Willekes, 1992).

Dredging and the environment

Introduction

The development of navigation requires still deeper and wider channels and basins, as well as fills for industrial harbor and other developments. This, in turn, carries with it the needs for major disposal areas for dredged materials.

Maintenance of depths requires removal of deposited materials which are sometimes—or often—polluted.

Beaches and shores are eroding and need protective nourishment by clean material which will then have to be relocated. Dredging may also be a useful tool for remedying past environmental interference. However, by its very nature, the act of dredging and relocating dredged material has an environmental impact. It is, therefore, of the utmost importance that we should be able to determine whether any planned dredging will have a positive or negative impact on our environment. Evaluation of environmental impact should examine both short- and long-term effects, as well as the sustainability of the altered environment.

While spoiling of material from dredging of tidal inlets on sandy shores has involved little difficulty because the material was clean and ample offshore dumping areas were available, dredging of harbors estuaries, bays, lagoons, and waterways without tidal flushing, has gradually caused many problems with respect to the location of spoil areas.

In either case, a severe disturbance of the area's biology has resulted. This has necessitated a great number of regulations on the extent of such operations.

When using dredging techniques, we must be aware of the environmental effects of the changes we are trying to achieve, as well as the effects of the dredging activity itself which may include: alterations to coastal or river morphology; addition or reduction of wildlife habitat; changes to water currents and wave climates, which might affect navigation, coastal defense, and other coastal matters; reduction or improvement of water quality, affecting benthic fauna, fish spawning, and the like; improvement of employment conditions owing to industrial development; and removal of polluted materials and their relocation to safe, contained areas.

The marine environment is a complex combination of natural features and phenomena, supporting a diverse but largely concealed population. Because of this complexity it is extremely difficult to predict the effects of human-induced changes and short-term operations.

Past environmental ignorance has resulted in many rivers, ports, and harbors in the industrialized nations containing soils that have been contaminated by undesirable levels of metals and chemical compounds. When dredging in these soils, contaminants may be released into the water column and thence into the food chain. Thus, the environmental effects of dredging and relocation of the dredged material may be more severe and will require more detailed analysis. In certain cases, it is the very existence of the polluted soils that has led to dredging: by removing the polluted soils and relocating them to a more secure situation, the environment is improved. Long-term improvement does, of course, depend ultimately on preventing pollution at its source. The treatment and storage of polluted soils is a highly complex subject and requires detailed study.

Many rules and regulations have been issued regarding the handling of polluted materials. International conventions, for example, the London 1972 meeting (Bruun, 1990), have resulted in published advices. The PIANC (Permanent International Association of Navigation Congresses) has issued a number of guidelines including:

- Report of the International Commission. Study of Environmental Effects of Dredging and Disposal of Dredged Materials. Supplement to Bulletin No. 27 (1977)
- Report of the International Commission. Classification of Soils and Rocks to be Dredged. Supplement to Bulletin No. 47 (1984)
- Report. Disposal of Dredged Material at Sea. Supplement to Bulletin No. 52 (1986)
- Beneficial Uses of Dredged Material (1992)
- Dredged Material Management Guide (1997)
- Handling and Treatment of Contaminated Dredged Material, Vol. 1 (1997) and Vol. 2 (1998)
- Management of the Aquatic Disposal of Dredged Material (1998)
- Confined Disposal Facilities for Contaminated Dredged Material

The ADC (Association of Dredging Companies) and the CEDA have printed several reports, here particularly noted and referred to is the 1999 report on "Environmental Aspects of Dredging." In the United States, the USACE, Coastal Engineering Research Center in Vicksburg, MS, through its Dredging Research Division has published a great number of reports as mentioned later.

Management

Management alternatives for dredged material can be grouped into the following four main categories (listed in order of significance): beneficial use, open-water disposal, confined disposal, and treatment.

Beneficial use

The definition of "beneficial use" according to the Dutch ADC and CEDA Guide #5, 1999, is "any use which does not regard the material as a waste."

Dredged material is increasingly regarded as a resource rather than as a waste. The London Convention's Dredged Material Assessment Framework (DMAF) recognizes this by requiring possible beneficial use of the material to be considered before a license for sea disposal may be granted.

Open-water disposal

Open-water disposal is the placement of dredged material at designated open-water sites in oceans, estuaries, rivers, and lakes such that the dredged material is not isolated from the adjacent waters during placement. Open-water disposal generally involves placement of clean or mildly contaminated material.

Open-water disposal of highly contaminated material can also be considered with appropriate control measures. This category includes unrestricted placement on flat or gently sloping waterbeds in the form of mounds or placement with lateral containment (e.g., depressions). For contaminated material, a cap of clean material can provide isolation from the benthic environment. If capping is applied over the mound formed by unrestricted placement, it is called level-bottom capping (LBC). If the capping is applied with lateral containment, it is called contained aquatic disposal (CAD).

Confined disposal

Confined disposal is the placement of dredged material in an engineered containment structure (e.g., dikes, natural, or constructed pits) enclosing the disposal area and isolating the dredged material from surrounding waters or soils during and after placement.

Treatment

Treatment is defined as a way of processing contaminated dredged material with the aim of reducing the amount of contaminated material or reducing the contamination to meet regulatory standards and guidelines. Each project may raise environmental concerns and not only when the material in question is contaminated. For instance, the "beneficial" use of clean, beach-compatible sand for beach nourishment may damage well-established sensitive marine habitats or species. Or the unrestricted open-water placement of clean material may have unacceptable direct physical impacts, such as smothering of bottom-dwelling organisms or local increases in suspended solids concentrations.

Assessments

The environmental assessment of management alternatives (with controls) should consider all potential impacts. Many countries require Environmental Impact Assessment (EIA) studies to be undertaken and the results must be documented in formal Environmental Impact Statements. (EIS.) Even if the law does not require such studies, it is advisable to include them in the project planning as EIS may prove to be very useful in the permitting procedure and in gaining public acceptance for projects.

For decision making, the following eight steps are identified in the Dutch Guide #5, by the IADC and WEDA (1999): establishing the need for dredging, characterization of dredged material, assessment of beneficial use options, preliminary screening of potential disposal alternatives, detailed assessment of disposal alternatives, selection for final design and implementation, permit application and processing, monitoring program design.

The World Bank (1990) distinguishes five main types of dredged sediments:

1. Material from maintenance dredging of ports, harbors, and navigation channels usually consist of fine-grained silt and clays and is often rich in organic matter and contains contaminants.
2. Material from maintenance dredging of sand bars at the entrances to harbors or channels usually consist of fine- to coarse-grained sand and is much less contaminated than (1).
3. Material from capital dredging within a port may vary considerably along the vertical profile. The upper layer is usually fine-grained, organic-rich, and contaminated, and the underlying layer is coarse-grained and uncontaminated. In some circumstances, even the deeper layers might contain elevated levels of contaminants from historical discharges.
4. Material from capital dredging of channels or outer harbor areas is likely to be coarse-grained and uncontaminated.
5. Material derived from remediation dredging is usually fine-grained, organic-rich and, by definition, highly contaminated. Its relocation requires special control measures.

Physical properties

The basic physical characteristics are form and composition, grain size, specific gravity, plasticity, water content, shear strength, water-retention characteristics, permeability, settling behavior, consolidation behavior, compaction, and organic content.

Chemical properties

They include pH-values, calcium carbonate equivalent, cation exchange capacity, salinity, redex potential (electrive activity), dissolved oxygen, biochemical oxygen, organic carbon, nutrients, carbon/nitrogen ratio, potassium, and contaminants of any kind.

Biological properties

Biological characterization of sediments may involve testing for the presence of microbial constituents and testing for toxicology.

Microbial constituents of concern include pathogens, viruses, yeasts, and parasites. Sediments should be tested for these constituents whenever dredging sites are close to sewage discharges and placement sites are close to sensitive areas such as drinking water intakes, recreation beaches, or shellfish beds.

Acute toxicity bioassays test the effects of short-term exposure. Toxicity is expressed as median lethal concentration (LC_{50}), that is, concentration which theoretically would kill 50% of the test organisms within a specified time span. The duration varies from hours to days.

Chronic toxicity bioassays assess sublethal effects which can result from prolonged exposure to relatively low concentrations. Such effects include physiological, pathological, immunological, terratological, mutagenic, or carcinogenic effects. Chronic toxicity bioassays may take several weeks. Toxicity bioassays may be used to evaluate: potential impacts of dissolved and/or suspended sediments on water-column organisms (elutriate bioassays); and potential impacts of deposited sediments on benthic organisms (benthic bioassays).

Metals

Metals may exist in the aquatic environment in four basic, but interactive forms. These dissolved forms are: free metal ions; complexed molecules; particulate forms absorbed to the surface of solid particles; and precipates (mostly sulfides).

In free mode (the most toxic), metals are transported with the water and easily taken up by organisms. The particulate associated forms are relatively inactive. In sediments under natural conditions (anoxic, reduced, near neutral pH) only a small fraction of heavy metals is dissolved; the major portion is bound by sulfides or by structurally complex, large organic compounds. Release of these may be induced by increased salinity, reduced pH, and increased redox potential.

Sediment properties versus dredging placement methods

In addition to the original properties at the dredging site, the behavior of sediments during and after placement will also largely depend on the specific characteristics of the dredging and placement techniques.

Dredging techniques may be subdivided into two categories: mechanical and hydraulic dredging.

Mechanical dredgers (e.g., bucket or clamshell) use mechanical force to dislodge, excavate, and lift the sediments. The material is generally placed and transported to the site of discharge by barges. Barges may have bottom doors or split-hulls and the material can be released within seconds as an instantaneous discharge. Cohesive sediment dredged and placed this way remains intact, close to the *in situ* density through the whole dredging and placement process.

Hydraulic dredgers remove and lift the sediments as a slurry (mixture of sediment solids and large amounts of dredging site water). The slurry is transported to the discharge site via pipeline or in hoppers and released with large amounts of entrained water. Hoppers may release the material through bottom doors or through pump-out operations. Hydraulic dredging and transport break down the original structure of sediments.

Beneficial use of dredged materials

The main application is for fills. Recent years have also introduced a number of practical structural usages.

Publications providing guidance on beneficial use include: Beneficial Uses of Dredged Material; Engineer Manual (USACE, 1986); Beneficial Uses of Dredged Material, A Practical Guide (PIANC, 1992); Handling and Treatment of Contaminated Dredged Material (PIANC, 1997); Guidelines for the Beneficial Use of Dredged Material (HR Wallingford, 1996).

Engineering usages

For practical use of dredged materials, one may distinguish between rock, gravel, sand, silt, mud, and clay, differing greatly in grain sizes and shape. Sand and silts may become "quick." Clay is cohesive.

Gravel and sand are dredged for construction purposes. Different kinds of heavy minerals are extracted from sands in sometimes major operations, including from the deep sea (Bruun, 1990).

Coastal protection

Dredged material is used for artificial nourishments of beaches which today is the most common coastal protection measure. The material dredged offshore or in entrances and navigation channels is pumped ashore if suitable for widening and raising the beach elevation.

Materials may also be used to produce protective offshore berms which may be designed as feeder berms, hard berms, and soft berms.

Feeder berms

Feeder berms produced by dumping of materials nearshore serve partly as source of materials for a possible transfer of materials to the beach.

Hard berms

The construction of hard berms involves the placement of suitable material, in depths up to 13 m, to create a permanent feature on the seabed approximately parallel to the shoreline with gentle side slopes that will intercept the troughs of incoming storm waves and decrease erosion of the shoreline. If the berm is made of sand, it will be modified in profile and some of the material will be lost, implying that some maintenance will be necessary. This technique may still be cheaper and more convenient (i.e., causing less disturbance to recreation) than direct beach nourishment.

Soft berms

Naturally occurring underwater mudbanks are known to absorb water wave energy and thereby attenuate waves that pass over them. Energy reductions of 30–90% are not uncommon even in the absence of wave breaking. Attempts have been made to replicate this action by creating underwater mud berms from dredged material.

Open-water disposal

Material dredged may be disposed of in deeper waters or in shallow designated waters. Bypassing at tidal entrances is a common usage. Offshore disposals may be capped to protect the material from being eroded away. Polluted materials may be placed inside dikes. Figure D47 shows the large "Slufter" used by EUROPORT for disposal of dredged materials which are polluted. Land disposals may also use dikes. An impermeable membrane is then placed to avoid penetration of pollutants to the surrounding areas. Material may also be placed in dredged pits in the bottom provided with a proper protective cover.

The dredging research program in the United States by the USACE

The USACE is involved in virtually every navigation dredging operation performed in the United States. The Corps' navigation mission entails maintenance and improvement of about 40,000 km of navigable channels serving about 400 ports, including 130 of the nations 150

Figure D47 The "Slufter" offshore diked disposal are used by EUROPORT (Rotterdam) for polluted materials (adapted from Brunn, 1990b).

largest cities. Dredging is a significant method for achieving the Corps' navigation mission. The Corps dredges an average annual 230 million m^3 of sedimentary material at an annual cost of about US $400 million. The Corps also supports the US Navy's dredging program in both maintenance and new work.

The Corps will continually be challenged in pursuing optimal means of performing its dredging activities. Implementation of an applied research and development (R&D) program to meet demands of changing conditions and generation of significant technology, adopted by all dredging interests, are means of reducing the cost of dredging the nation's waterways and harbors.

The Shallow Water Hopper dredger has always been on their agenda. There are a couple of additions to the fleet financed by private industry. They are of medium-size with about 5,000 m^3 hopper capacity.

Reports on the development of dredging and on the Environmental Effects of Dredging, Technical Notes, are published regularly, the latter category covering the subjects of Aquatic Disposal, Upland Disposal, Wetland Estuary Disposal, Regulatory Management, Beneficial Uses, Equipment, and Miscellaneous as described in numerous reports. Copies may be acquired from the USACE, Waterways Experiment Station, Vicksburg, MS.

The Long-Term Effects of Dredging Operations (LEDO) program by the Dredging Research Division of the USACE, Vicksburg, MS, "focus on cost-effective, environmentally responsible techniques for dredging and dredged material disposal in aquatic, wetland, and upland environments. Current research emphasizes risk-based procedures for effects assessment, exposure assessment, and risk characterization. The Program objective is to provide the latest proven technologies for identifying, quantifying, and managing contaminated sediments in support of cost-effective, environmentally responsible navigation."

"The primary benefit is a more timely complete, and cost-effective execution of the Corps' responsibilities under the Clean Water Act (CWA), Marine Protection, Research, and Sanctuaries Act (MPRSA), Resource Conservation and Recovery Act (RCRA), and Water Resources Development Act (WRDA). This R&D program provides dramatic cost avoidances annually for achieving restoration goals for contaminated dredged material disposal as mandated by law.

Recent major products include:

1. A chronic/sublethal and genotoxic assay that meets national regulatory requirements.
2. National guidance for confined disposal facility contaminant loss assessment procedures. The guidance document was established as Corps policy to meet regulatory mandates.
3. A new analytical screening method that measures bioavailable dioxin and similar compounds with a 90% reduction cost and time required by previous methods (co-sponsored with another research program).
4. The Environmental Residue Effects Database (ERED), the first WWW-accessible database of bioaccumulation effects to improve the accuracy and defensibility of environmental impact predictions while significantly reducing evaluation costs.

LEDO research benefits/value-added to district projects can be demonstrated on a recent example. Since the bioaccumulation interpretation database is Web-accessible, it is immediately and cost-effectively available to all district projects in need of contaminated material assessment."

Dredging and disposal problems in the New York and New Jersey Harbors are mentioned in reports by WEDA (Mohan *et al*., 1999; Wakeman, 1999). The World Bank, 1990, has also issued its guidelines.

Conclusion

1. A strong development of the Dredging Industry is taking place with still larger and more efficient equipment. This development is most predominant in the low countries in Europe which virtually have taken over the world market.
2. Major projects on improvements of navigation channels and harbors remain. Artificial nourishment of beaches is still increasing.
3. Disposal areas for dredged materials are often running short due to environmental concerns. Diked areas, onshore and offshore, are becoming practices.
4. Environmental dredging is an important factor which requires much attention, planning, and monitoring. Beneficial usages of dredged polluted materials are developing.

DRIFT AND SWASH ALIGNMENTS

Drift alignments are found on beach-fringed coasts where the dominant waves arrive obliquely to the shore and (with accompanying currents) maintain a beach parallel to the direction of the resulting longshore drift. They are typically found on straight or saliented coasts where the obliquely arriving waves move sediment alongshore. Swash alignments develop where beaches have been shaped by waves arriving parallel to the shore, usually in curved patterns resulting from wave refraction. They are typically found in embayments where longshore drifting is limited and beach outlines run parallel to the crests of incoming waves. Figure D48 shows how an incoming south-westerly swell has produced beaches with drift alignments in Western Port Bay, Australia, and beaches with swash alignments on adjacent Phillip Island. Drift and swash alignments can be developed experimentally on beaches in a wave tank (Davies, 1980, Figure 90): they are sometimes described as drift-dominated and swash-dominated beaches.

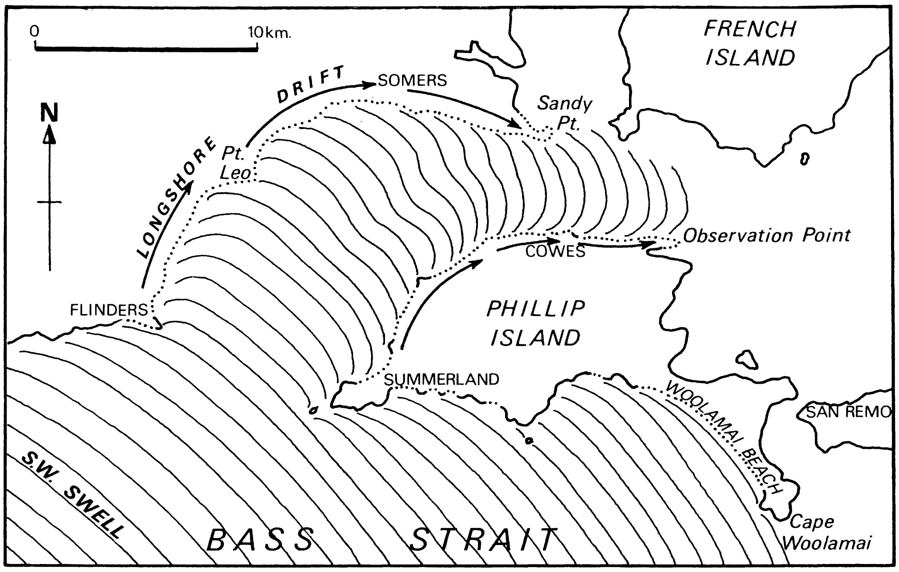

Figure D48 South-westerly swell entering Western Port Bay, Victoria, Australia, produces drift alignments on beaches to Sandy Point and along the north coast of Phillip Island, and swash alignments in bays on the south coast of Phillip Island, notably at Woolamai Beach (Copyright-Geostudies).

Drift alignments

Drift alignments are best developed where waves arrive at an angle of 40°–50° to the coastline. They are typically sinuous in detail, with intermittent lobes and cusps that migrate downdrift, and longshore spits and bars that diverge slightly alongshore. Variations in transverse profile occur as these features pass along the beach. A cyclic equilibrium may be attained where the beach alignment becomes adjusted in such a way that oblique waves impinging on the shore provide sufficient energy to transport the sediment arriving at one end of a drift-dominated beach through to the other, the configuration being maintained. Most beaches on drift alignments have an entirely updrift source of sediment (eroding cliffs or a fluvial input), but some incorporate sediment derived from eroding cliffs or river mouths along the shores, as on the north coast of Hawke Bay, New Zealand (Bird, 1996).

If the angle of wave incidence becomes greater or less than the optimum 40°–50° there is a slackening of longshore rifting and consequent deposition of sediment, but the drift alignment is soon restored when the oblique waves return to the optimum angle. A beach alignment can also be changed by variations in the rate of updrift sediment supply, and by erosion or accretion on updrift sectors of the coast.

Some drift-aligned beaches terminate in spits, such as the Langue de Barbarie on the Atlantic coast of Senegal in West Africa, which has grown southward in response to the dominant north-westerly swell and ends in recurves at the mouth of the Senegal River. Cuspate forelands and recurved (angled) spits may include both drift-aligned and swash-aligned beaches, and as sediment eroded from the drift-aligned shore is carried round the point to be deposited on the swash-aligned shore they migrate downdrift. Dungeness, on the south-east coast of England, is a major shingle foreland that has migrated in this way. Such structures were termed traveling forelands by Escoffier (1954).

Alternatively, beaches on drift alignments may end in sectors of accretion alongside headlands, river mouths, lagoon outlets, or protruding breakwaters.

Swash alignments

Beaches on swash alignments are smoother in outline than those on drift alignments, but are subject to alternations of profile erosion and losses of sediment offshore during storms and profile restoration by onshore sediment flow during calmer phases, a sequence known as "cut-and-fill."

Swash alignments are well developed on beaches in embayments where intervening headlands exclude waves from all but one direction. The curving beach behind Disaster Bay, in southern New South Wales, a narrow embayment between high parallel sandstone cliffs, has a swash alignment with an outline shaped by incoming refracted ocean swell, but too limited in length for oblique waves to generate much longshore drifting. Numerous parallel dune ridges indicate that progradation has maintained this curved plan.

Swash alignments are also well developed on beaches on open coasts where the incoming waves arrive consistently from one direction. In these situations, there is typically a simple relationship between beaches with curving swash alignments and the pattern of incoming refracted waves. In southern Australia, there are long, gently curving beaches which receive south-westerly ocean swell from the Southern Ocean, refracted by nearshore shallowing: Encounter Bay is a good example. South-easterly swell entering Jervis Bay on the east coast produces is refracted into wave patterns that fit the curving swash-dominated outlines of bordering bay eaches that face in various directions, and a similar pattern has been documented in Storm Bay, Tasmania (Davies, 1980). On the New South Wales coast a series of long asymmetrical beaches has developed on swash alignments, where incoming south-easterly waves are refracted round intervening headlands. Swash alignments occur on beaches on the Atlantic coasts of Europe, as on the coast of South Uist in the Hebrides, Rhossili Bay in Wales, and the Bay of Audierne in France.

Once established, gently curving beaches on swash alignments maintain their outlines through cycles of cut-and-fill when beach material is withdrawn seaward from them by storm waves, then swept back onshore in by a gentler swell. Any temporary divergence between incoming wave crests and the coastline initiates local longshore drifting which quickly restores the swash alignment.

Intermediate cases

Few beaches are entirely swash- or drift-dominated. Chesil Beach in Dorset is a shingle beach which has a swash alignment shaped largely by south-westerly swell and storm waves, but longshore drifting occurs on such beaches when westerly waves move sediment south-eastward and when south-easterly waves move it back westward. This alternation has led to lateral grading of this beach from granules at the western end to pebbles and cobbles toward the south-eastern end, near Portland Bill (Bird, 1996).

On the other hand, beaches on drift alignments such as Sandy Hook in New Jersey or the beaches north of the Columbia River in Washington State, are occasionally modified by waves coming in parallel to the shore, and sometimes show alternations of cut-and-fill with onshore–offshore (swash–backwash) sediment movement. The existence of parallel beach and dune ridges formed by progradation behind beaches that appear to be drift-dominated, as on the North Beach Peninsula in Washington and Orford Ness in East Anglia, indicates occasional significant swash domination.

Changes in beach alignments

A lateral transition from a drift alignment to a swash alignment occurs on drift-dominated beaches that curve into sectors of accretion alongside headlands or breakwaters.

Where a beach outline is more sharply curved than the approaching waves it is drift-dominated, with a convergence of longshore drifting of beach sediment toward the center of the bay, where the beach progrades until it fits the outline of the arriving swell and so becomes swash aligned. Convergent longshore drifting in Byobugaura Bay, near Tokyo, has prograded the central sector at Katakai in this way, with sediment derived from the erosion of the northern and southern parts, and a similar evolution from drift alignments to a swash alignment has taken place at Guilianova on the east coast of Italy.

Where the beach outline is less-sharply curved than the approaching waves, there is divergent longshore drifting from the center until the beach outline fits the wave pattern and assumes a swash alignment. This has occurred on the shores of the Andalusian Bight, in southern Spain, where erosion of the central sector has been balanced by progradation at Matalascanas to the south and Mazagon to the north.

The beach on the northern flank of Rheban Spit, in south-eastern Tasmania, was built and prograded on a drift alignment as long as it received a longshore sediment supply from the north, but when this diminished the coastline was reshaped by updrift erosion and downdrift accretion until it developed a swash alignment adjusted to waves approaching from the north-east.

On some coasts, paired or opposed spits bordering embayments have grown on drift alignments, as the southern entrance to Menai Strait and in Portmadoc Bay in North Wales. Convergent growth of such spits can lead to the development of a curving beach which becomes swash aligned. Beach ridge patterns on the Swina barrier in Poland indicate such an evolution on the coast of the Pomeranian Gulf.

A change from a swash alignment to a drift alignment may occur where incoming wave patterns are modified by an artificial structure such as a breakwater or by shoal deposition or the growth of a coral reef. At Kunduchi in Tanzania, the sandy coastline had prograded on a swash alignment under the dominance of easterly swell, but the growth of reefs and shoals reduced the effectiveness of these ocean waves, and allowed locally generated and previously subdominant south-easterly waves to supervene, resulting in erosion as the beach assumed a drift alignment.

DRIFTWOOD

One of the pleasures of beachcombing is viewing and collecting driftwood of innumerable shapes and sizes which have washed up on a beach. Driftwood is the collective term for all types of freely floating wood on a water body or lodged upon a beach. Driftwood can be found on most marine shores of the world, but is generally in highest concentrations along the shores of the middle and higher latitudes in the boreal forest and arctic regions of the world.

Trees along forested coastlines undermined by wave erosion are a source of driftwood and drift logs, but streams and rivers emptying into the sea are the primary contributors. Limbs, root masses, and whole trees are eroded from the stream banks, or are products of logging practices or log storage and rafting. Trees and logs enter river channels to be transported down river during high flows or are lost within estuaries during log storage and log rafting. The drifting wood can become temporarily lodged in estuaries or flushed directly into the sea. One estimate is that over 30 million board meters of logs enters the sea annually from coastal logging operations from Alaska to California (Sedell and Duval, 1985).

Driftwood movements

The fate of driftwood discharged into the sea is determined by coastal winds, waves, and currents. Some driftwood can transit entire oceans ultimately washing up on some foreign shore. The majority of the wood afloat is more likely to be carried by nearshore waves and currents. Along the Pacific Northwest of the United States, nearshore waves and currents seasonally reverse. In the winter, southwesterly winds drive waves and nearshore currrents to the north. Driftwood floating in these currents tend to end up on beaches far to the north from their river or estuary of origin. During the summer, northwesterly waves and currents carry driftwood southward along the Pacific coast. The volume of driftwood movement during the summer months is usually less as river flows are lower carrying fewer logs to the sea and waves are less energetic, dislodging less wood from beaches.

Large concentrations of driftwood are found along arctic beaches of Siberia, Canada, and Greenland. Rivers of northern Siberia and Canada's Mackenzie River carry driftwood into the Arctic Ocean during the summer. The wood is conveyed by the clockwise Pacific Gyral between the pole and Arctic Canada and the Transpolar Drift Stream from the New Siberian Islands toward the Svalbard and east coast of Greenland (Haggblom, 1982).

Driftwood on beaches

Driftwood and floating logs are driven ashore by waves and rising tides. Smaller pieces of wood can be thrown high on a beach by waves. Large logs, 20–30 m long and 1–2 m in diameter are shoved up the beach face by the repetitive thrusting of oncoming waves. Strong storm-driven waves cram logs and driftwood into dense piles high on the beach face and backshore. Driftwood deposits differ in quantity along any given stretch of shore from a few scattered logs and smaller pieces of wood to huge matted piles up to 3 m high and tens of meters wide. The largest concentrations of driftwood are trapped in coastal embayments such as river mouths and pocket beaches. But large deposits can also be found on the backshore and berms of wide sand beaches and steep rocky high-energy beaches. The wood is driven high up on the shore during storm conditions. There the wood may ultimately become buried by beach sediment. But for much of the wood, the beach is a brief stop off until it is again dislodged and refloated by the next series of storm-driven waves. The unrelenting pounding by waves and rolling in the surf chips away at the bark, branches, and root masses sculpting driftwood into smooth and artistic shapes.

Ecology of driftwood

Driftwood is capable of remaining afloat for long periods of time. Large and small pieces attract growths of epifauna and flora as well as selected insects. It is well-known that both commercial and recreational fish are attracted to floating wood at sea. Tunas and dolphin-fish are routinely found under or near masses of driftwood (Gooding and Magnuson, 1967). The reason is not clear, but it is thought that these fish are simply seeking shade or smaller fish attracted to the driftwood upon which they can prey (Maser *et al.*, 1988).

Once lodged on beaches, accumulations of driftwood tend to trap wind-blown beach sand and coarser swash carried sediments. They create an organic fabric that helps beaches grow or accrete. This is probably best seen near river mouths where river-borne sediments and wood accumulate along the seashore forming sand spits mantled with driftwood and logs. If there is a sufficient volume of sediment delivered to the shore, driftwood helps to capture wind-blown sediment. The wood not only traps sediment but provides decaying organic matter for pioneering plant and dune grass species to take root. The buried wood also creates an internal structural fabric within the building beach or sand spit. It is not uncommon to see large drift logs buried many years ago protruding from the face of an eroding beach scarp. Carbon-14 dating of uncovered driftwood is useful in determining the ages of beach deposits and other environmental conditions. Thus accumulations of driftwood along beaches are thought to help stabilize and contribute to beach accretion processes. Conversely, accumulations of driftwood at the base of beach cliffs can become powerful forces of erosion by battering and abrading cliffs especially when driven by storm waves.

Numerous species of birds are attracted to accumulations of driftwood on beaches and within estuaries. Bald eagles, herons, and pelicans use the logs as perches to rest upon and capture nearby aquatic animals in the surf or mudflats of estuaries.

Driftwood hazards

Driftwood clearly has some ecological benefits, but it also presents some liabilities especially for boaters and beachfront home owners. Floating driftwood, especially large logs, create a navigation hazard for ships and smaller pleasure boats. Driftwood is found in highest concentrations near the shore, in bays, and estuaries generally in same location as ships and boats. Ships' hulls are usually strong-enough to withstand the impact of a floating logs, but damage can occur to rudders and propellers. Smaller pleasure boats traveling at high rates of speed are especially vulnerable to impact damage. Large pieces of driftwood can crack and even pierce hulls as well as inflict serious damage to rudders and propellers. In some waterways around the United States, driftwood is "tagged" with small flags for better visibility by boaters or hauled out of the water.

Shorefront property owners who build their homes closer to the shore than is wise are not only exposing themselves to wave erosion and flooding, but to the intrusion of their homes by wave-driven logs. Such incidents are relatively infrequent, but there are documented cases of large drift logs thrown into the living rooms of shorefront homes in Washington State's Puget Sound.

Beachcombers are attracted to the aesthetic beauty of beaches laden with driftwood. Unfortunately, the wood that is so attractive can also be hazardous. It is not uncommon to learn of a beachcomber who has been killed or injured by a drifting log thrown into the unknowing beach stroller. The State of Washington has posted signs along the shore warning the public of large driftwood.

Driftwood management

Driftwood has long been harvested for firewood and even for minor building projects. For years the practice of harvesting driftwood from beaches has been accepted. However, some have questioned the advisability of continuing such practices, especially in light of the better understood ecological role driftwood plays in estuaries and on beaches. Recognizing the benefits of driftwood to natural ecological systems, the State of Oregon has adopted a policy prohibiting the removal of drift logs. This policy does not preclude the beachcomber from collecting pieces of driftwood, but it is intended to prohibit the large-scale removal of large logs for firewood or other uses. The State of Washington licenses individuals who wish to retrieve drift logs afloat or on beaches. Beyond licensing, Washington does not appear to have any driftwood removal policy applied to the general public.

DUNE RIDGES

Dune ridges are known variously as "beach ridges" (Goldsmith, 1985; Komar, 1976), "parallel dunes" (Bird, 1972) or "low foredunes" (Davies, 1977). They are a product of a prograding coast with plentiful sediment supply, low tidal range, shallow nearshore slopes, and relatively low-energy refracted swell wave conditions (Figure D49). Continuing progradation is associated with plentiful diabathic onshore sweep of beach sediment, alternating with episodes of cut and fill, leading to the formation of a series of beach ridges (Davies, 1957). Each ridge is thought to represent the previous location of a beach berm, upon which over time a low foredune develops from "aeolian capping" (Bird, 1972). The height and spacing of the dune ridges is also a function of the effectiveness of the dune colonizing vegetation in binding the sand.

Geomorphically dune ridges may be as low as 0.5 m in elevation above mean high water springs, but more typically 4–8 m high. In width they vary from 50 to 200 m, and individual crests may extend shore-parallel for many kilometers (Figure D49). The ridge alignment parallel to the shore (hence their name "parallel dunes") is suggestive of the swell wave environment breaker alignment. The ridges are normally composed of sand but may also contain gravel. The parallel dune fields are comprised typically of Holocene sands and may be some kilometers wide. For example, Komar (1998) shows an illustration of the dune ridge field at Nayarit, Mexico, which contain some 250 individual ridges which could have evolved in as short a time as 12–20 years, although Pethick (1984) suggests that time intervals between dune ridges more typically varies from 70 to 200 years.

Separating the dune ridges are low swales characterized by impeded drainage and sometimes containing swampy vegetation. The variation in drainage characteristics leads to a tendency for variation in soil development on the well-drained ridge where oxidizing conditions prevail compared with the impeded drainage swale where reducing conditions and the podsolization process lead to dune podsol soils.

Dune ridges are widely associated with Holocene sandy barrier systems. They occur particularly along the Atlantic and Gulf coasts, Mexico, and southeast Australia, and New Zealand. Stratigraphically the dune ridges consist of aeolian low-angle cross-bedding in fine sands overlying low-angle dipping laminae of the beach face and berm, which overly marine deposits of the shoreface. These dune ridge systems evidently formed relatively rapidly (within ~1,000–2,000 years) after the sea reached its approximate present level from the postglacial transgression, presumably as a result of an abundance of sand being swept up with the postglacial transgression.

DYNAMIC EQUILIBRIUM OF BEACHES

Dynamic equilibrium of beaches describes the tendency for beach geometry to fluctuate about an equilibrium which also changes with time, but much more slowly. Beaches, as discussed here, refers to the visible beach including the shore and its underwater extension to a depth that is nearly static over the long-term. Beaches respond on a wide range of spatial and temporal scales to natural and anthropogenic forcing. Natural agents include waves, tides, currents, winds, and other elements whereas anthropogenic agents include interruption of sediment supply and induced subsidence through withdrawal of ground fluids including water and hydrocarbons. Changes of beach position can occur with or without corresponding changes in the beach profile volume. Over a long time period, coastline position can be considered as the superposition of a long-term trend about which substantial fluctuations occur. Some of these fluctuations are quasi-periodic and others appear random. The paragraphs below discuss the coastline trends followed by the fluctuations.

Long-term changes

Worldwide, the most dominant cause of long-term coastline change is sea-level rise. The global rate of sea-level rise is approximately 12 cm/century, although there is concern that global climate warming may increase this rate substantially in the future through melting of ice and thermal expansion of oceanic waters. The concept of an equilibrium beach profile is useful in considering the effect of sea-level rise on coastline position (Dean, 1991). This has been formalized by Bruun (1962) as the so-called "Bruun Rule." A sea-level rise will cause the profile to be out of equilibrium since the depth at a distance from the coastline is now greater than before and equilibrium can only be restored through a decrease in depth which, in the absence of external sediment addition, must be provided by volume eroded by coastline retreat. The Bruun Rule is a simple equation which depends on a number of factors including wave climate, and sediment characteristics and is expressed as the coastline retreat being a multiple of the sea-level rise, with the multiple usually ranging from 50 to 100. Thus in one century, the expected average worldwide coastline retreat would range from 6 to 12 m; however, the coastline trend at a particular location can deviate from this value by orders of magnitudes ranging from coastline retreat to coastline advancement. In addition, the Bruun Rule can be applied to *relative* sea-level rise resulting from natural or anthropogenically induced subsidence. An example is near the Mississippi River outlet where the relative sea-level rise rate is on the order of 10 times the worldwide rate noted earlier. Entire islands vanish in periods of decades.

Short-term changes

The most rapid short-term changes in coastline position occur during severe storms when the beach may retreat on the order of 50 m in several hours. The primary elements are the elevated water levels (storm tides) and high waves which can cause significant modifications to the nearshore geometry including shore and dune retreat. As discussed for sea-level rise, the storm tide causes the profile to be in temporary disequilibrium and the waves provide the energy to accomplish the profile adjustment. Averaged over long sectors, the primary sediment transport during storms is seaward where a new deposit called an "offshore bar" may be formed or additional sand stored in an existing bar which may be displaced farther seaward during the storm. Elevated water levels and accompanying large wave heights can cause large coastline changes without corresponding changes in the sand volume in the profile. An example illustrating this is a wave tank in which the sand volume is constant; however, the sand can shift offshore resulting in coastline retreat. Coastline retreat associated with a storm and for which there is no volume change will generally be followed by coastline advancement and complete or near complete recovery of the pre-storm coastline position. The timescales of the recession and recovery (advancement) phases differ markedly with the recession occurring in hours to days and the recovery requiring months to years. The modes of profile recovery also differ. The profile changes during erosion as the sediment is transported seaward tend to occur with the profile "hinging" about a subaqueous point with the elevations decreasing landward of the hinge point and increasing seaward of the hinge point. The recovery phase is much more complex with the landward transport of sand occurring in individual sand "packets," each of which, upon reaching the shore, advances the coastline seaward. During long periods of milder wave conditions following a major storm, a number of recovery packets may occur in order to complete the recovery phase. The interest in anticipating and designing for storm-induced beach and dune erosion has led to the development of numerical models (Kriebel and Dean, 1985; Larson and Kraus, 1989). These models are much more effective in representing the erosional phase than the more complex recovery phase. Seasonal coastline changes, described as the average annual coastline fluctuations are poorly understood and vary substantially for various coastlines. The seasonal coastline change range in Florida is approximately 10 m whereas along the south shore of Long Island, NY, the range is about 30 m. The range in southern California is relatively large and is evident by the presence of sandy beaches during summer and rocky beaches left as a lag deposit in the winter when the sand removed has been stored in the offshore bar. Studies have documented that these seasonal coastline changes are related to the wave characteristics with the seaward transport associated with higher waves of shorter period which generally occur in the winter and the landward transport occurring during the milder summer conditions. Some beaches experience somewhat organized beach fluctuations which vary substantially along the shoreline. These appear as "sand waves" (Bruun, 1954; Bakker, 1968; Verhagen, 1989; Thevenot and Kraus, 1995) which propagate along the shore and may have amplitudes of tens of meters sometimes causing distress to property owners with homes located near the high-tide shoreline. The understanding of the causes and relative longevity of sand waves is poorly understood. Proximity to structures (natural or constructed) and/or inlets can increase the coastline fluctuations significantly relative to those along a long unobstructed coastline. The amplified fluctuations near structures is a result of changes in wave direction which causes accumulation of sand against and removal of sand from the beach adjacent to the structure. Similarly, high-tide shorelines in pocket beaches change their orientation in response to changes in wave direction causing large fluctuations near the ends of the beaches (Thompson, 1987). The changes near inlets appears to be primarily due to the influence of and the interaction with the deposit of sand, termed the "ebb tidal shoal." This feature can shelter the adjacent shores from waves causing accumulation, can shift in position thereby exposing the shore to increased wave energy and can release large amounts of sand to the shore in packets. Dredging of inlets can also cause large fluctuations (usually erosional) along the adjacent coastlines. Studies of the long-term coastline position data base in Florida has shown that the standard deviations around the coastline change trend line are approximately 10 m along long coastlines and are on the order of 50 m near natural inlets (Dean *et al*., 1998).

Summary

In summary, beaches are dynamic, generally exhibiting a trend of coastline change which can be either advancement or retreat, with fluctuations about this trend. Although the underlying processes governing beach change are well-understood qualitatively, our ability to predict quantitatively these changes is likely to remain poor for the coming decades.

ECONOMIC VALUE OF BEACHES

Beaches are economic as well as natural resources. As natural resources, they add beauty to the coast and provide habitats for many creatures including birds and sea turtles. As economic resources, they provide services to people and property that have an economic value. They also generate impacts on the economy and tax base.

Economic services provided by beaches

An important service provided by the beach at the coast is reduced storm damage to upland properties (US Army Corps of Engineers 1996, chapter 5). Beaches reduce storm damage by moving the water line further from upland property. During storm events, water travels less far inland as a result of the beach and so damage to upland property tends to be less. Of course, a beach does not eliminate storm damage to upland properties and in severe storms it may provide little or no protection. For example, the coastline impacted by the center of a hurricane may receive little protection from its beaches, but the upland properties impacted by the outskirts of the hurricane may receive very considerable storm damage reduction from their adjacent beaches. The second major service provided by a beach at the coastline consists of the opportunity for recreation provided to beach users. Although there is no direct fee charged in most places for recreational access to the beach, such recreational services have economic value just like playing a round of golf or a visit to the movies.

Beaches also generate impacts away from the coastline. Chief among these are the impacts on the local economy of the expenditures made by tourists attracted to the beach as a recreational resource (*tourism and coastal development, q.v.*) (Schofield, 1986, chapter 14). There will also be benefits at the regional (e.g., state or province) level to the extent that tourists are attracted from outside the region, and benefits at the national level from the spending by international visitors. The expenditures of beach tourists increase sales and production by impacted business resulting in increased business profits and increased earnings of employees. The well-known multiplier process, popularly called the "ripple effect," will cause these economic benefits to be passed in a chain from front line businesses to their suppliers, and from employees of those businesses to businesses which provide goods and services to those employees. Of course, such positive economic impacts vary depending on the size of the economy, which is impacted. In small economies, many of these impacts are lost to imports. There may also be disbenefits from beaches. For example, the tourists attracted to the beaches may contribute to traffic congestion. The congestion in turn increases travel time in the local area and the involuntary consumption of this time represents an economic loss to the travelers, which can be measured by their wage rates. Additionally, the congestion may increase the frequency of automobile accidents with associated property losses.

Government tax revenues will also be expanded as a result of beaches (Stronge, 1998). The particular impacts, of course, will depend on the particular tax and fee structure in operation in the beach area. In many local communities in the United States, local communities obtain revenues by taxing property values. Beachfront property values tend to be higher than property values away from the beach partly because land use tends to be more intensive at the beach. That is, there are more hotels and high-rise apartment buildings at the beach. But, even beachfront single-family homes tend to have high values relative to homes elsewhere in the community. Other things being equal, land values on the beachfront tend to be high relative to values elsewhere in the community because properties on the beach provide easier access to the recreational and amenity values of the beach. Structural values on properties tend to be positively correlated with land values, and so the high beachfront land values stimulate the construction of relatively expensive beachfront structures. It is not unusual to see small, inexpensive beachfront structures that are in good condition being demolished and replaced by larger, more expensive structures, because sharply increased demand for beachfront land has raised land values to levels where beachfront structures are out of equilibrium with underlying land values. The expenditures of tourists are usually subject to sales taxes, including accommodation taxes, general sales taxes, and taxes on gasoline. These revenue sources are favorably impacted by beach tourism. Finally, income taxes will tend to rise as a result of the increased earnings of workers in the tourist industry. Offsetting these positive impacts on governments may be the required increases in government expenditures resulting from beach tourism. Increased traffic congestion may result in increased expenditures for law enforcement personnel, for example. There will be increased expenditures to clean trash off the beaches and, perhaps, for lifeguards. The fiscal impact of a beach, therefore, is the net impact of the positive increases in government revenues less the required increases in the government expenditures.

Government policies on the beach

Governments regulate the activities of beachfront property owners because actions taken by one property owner may adversely affect nearby property owners or negatively impact the society at large (Fischer, 1990). Many beaches are subject to *beach erosion* (*q.v.*), steadily diminishing in size on an annual basis. Beaches are often dynamic systems losing sand during some seasons and gaining sand during others. Along an unbroken stretch of beach, with no headlands jutting into the sea, sand tends to travel along the coastline and it may travel in one direction during one season and reverse direction in another. The direction traveled tends to reflect the weather patterns and, in particular, the direction from which storms come. On an unbroken coastline with no headlands, storms move sand around on the beach but net losses may be low. In some cases, storms may push sand upland away from the beach and, in some cases, sand may be lost offshore. But in many cases, storms move sand away from the coastline and then natural processes of wave action will return most of the sand to its original position after the storm is over.

Inlets, including gaps between coastal islands and river mouths, represent holes in the coastline, which interrupt the flow of sand along the beach. When the tide is coming in sand is pushed into the inlet and when the tide is ebbing sand is deposited offshore. These movements often lead to an offset in the coastline as beaches on one side of the inlet lose more sand than beaches on the other. The asymmetric losses reflect the fact that storms from one direction may be stronger than storms from another. When new inlets are constructed, or old inlets are improved, the equilibrium relationship between adjacent beaches is disturbed and properties on one side of the inlet may be threatened by erosion. Such activities are usually undertaken to improve navigation, but they may also have desirable environmental consequences. In some cases, governments can remove the erosion threat to an adjacent beach by bypassing sand mechanically from one side of the inlet to the other or by dredging the inlet and depositing the sand on the eroding beach. Beachfront properties may also be threatened by erosion if they were originally constructed too close to the high water line. Such structures tend to be relatively old, dating from a time when beaches were regarded as static and, perhaps, when storm events had widened a beach beyond its long run equilibrium size. Older structures may also have been constructed at a time when regulatory authorities were unaware of the dynamic properties of the beach, or when enforcement of regulations was inadequate. In any case, many beaches have properties that are in danger of damage from erosion. Under these circumstances, property owners will often construct structures such as seawalls or revetments to protect their properties from storm damage. These structures may interrupt the flow of sand to adjacent properties or accentuate the force of the waves experienced by neighbors. As a result, such structures tend to stimulate the construction of similar structures along entire segments of the coastline. The actions of the first property owners have negatively impacted their neighbors, and because the structures protrude into the beach area the actions reduce the beach available to the public for recreational purposes and to birds and other creatures, which use the beach as a habitat. To avoid such negative externalities, governments regulate activities of beachfront property owners including, requiring building setbacks and requiring erosion control structures, to pass through a permitting process. In the United States, all three levels of government require permits for beachfront construction. This occurs because beach systems cross local government boundaries and, in some cases, state boundaries, and because there is a national interest in protecting wildlife and other environmental resources.

Beach nourishment

In some cases, erosion control may be accomplished by placing sand on the beach to widen it, often called *beach nourishment* (*q.v.*) (National Research Council, 1995). The conditions that would make beach nourishment successful will depend on the strength of the forces causing erosion. Additionally, it must be possible to obtain a source of sand that is cheap enough to make the project economically feasible. In other cases, it may be appropriate to relocate properties further away from the high water line. This solution is most appropriate where there is available land to accommodate the relocated structure, and where the structure is relatively small and easy to move. Such a structure might be a one or two story second home on a relatively large lot, for example.

When beach nourishment is an appropriate remedy for erosion (i.e., it would be successful), and when it is economically feasible, it has the added advantages of retaining the recreational and environmental values of the "natural" beach. Structural remedies, on the other hand, often reduce the available recreational beach and the available habitats for birds, turtles, and other creatures that use the beach. Additionally, off-beach benefits such as economic and fiscal impacts are also retained by beach nourishment as opposed to structural solutions. It is rarely economically feasible for one property owner, or even a small group of property owners, to undertake a beach nourishment project unless they own a relatively long stretch of coastline. This is because beach nourishment projects have large fixed costs largely unrelated to the volume of sand being placed on the beach. These include costs of sand searches, permitting costs, and mobilization and demobilization of equipment charges. For example, sand searches are expensive because not only must sand be found, but it must be compatible with the sand already on the beach. An archaeological survey may be required to ensure that there are no archaeological artifacts (ship wrecks) in the sand source. Various environmental studies may also be required as part of the permitting process. Additionally, equipment including a dredge may have to be brought from hundreds of miles away. Once at the site, there are setup charges and charges for dismantling the setup at the end of the project. On rare occasions, it may be possible to "piggyback" a small project on a large project that is occurring nearby, thereby greatly reducing the fixed costs incurred by the small project. But beach nourishment projects are highly complex and it is difficult to group projects together because all projects may not be ready for construction at about the same time. Even when a relatively large group of property owners is interested in undertaking a beach nourishment project, they may not be able to agree on a formula for cost sharing. Beach nourishment is a public good in the sense that it is usually not possible to prevent consumers of the services provided by the beach from benefiting from the project unless they have paid for them. This is because beach dynamics will redistribute new sand along the entire section of the beach, and property owners in the middle of the project will gain sand even if they have not paid. This is the well-known "free rider" problem associated with public goods. As a result, beach nourishment, when feasible, may not be selected by owners of properties threatened by erosion even when appropriate and, in principle, economically feasible. But because sand placement retains the recreational and environmental values of the beach, as well as the positive economic and fiscal impacts, society as a whole may wish to encourage beach nourishment when it is an appropriate remedy. Under such circumstances, governments may wish to encourage beach nourishment as a tool for erosion control (Stronge, 1995). At a minimum, government may take a leadership role, financing initial studies and educating property owners about beach nourishment. In many cases, however, governments also subsidize construction and maintenance costs. Such subsidies, of course, will be part of a regulatory regime designed to discourage the use of structures to the extent legally possible.

Measurement issues

Most US beach nourishment projects receive some federal subsidies through the Army Corps of Engineers budget. In order to qualify for such subsidies, beach projects must be economically justified, that is, they must yield benefits in excess of their costs. This requires an economic study to be undertaken in advance of project construction. The economic study projects the benefits and costs of the proposed project. A methodology has been developed over many years for projecting benefits.

A benefit projection methodology is, in effect, a model of how the project's benefits are generated. Like all models, a beach projection methodology involves a simplification of reality. In particular, the model identifies a limited number of key benefits and does not attempt to include all the benefits of the project. Additionally, there are key parameters imposed exogenously on the model, such as the length of the planning horizon and the discount rate used to convert future dollars to present worth or value. Given the potential for inaccuracy introduced by the modeling process, it is surprising that few follow-up studies have been undertaken that would evaluate the accuracy of the model in projecting benefits.

Because benefit projections are based on a model there are a variety of issues that have generated some debate. First, most beach projects are justified on the basis of a very limited number of benefits, namely, property protection and recreational values. At the federal level, off-site benefits such as economic and fiscal impacts are not included, although these benefits may be of the most importance at the local level. The value of environmental benefits is not usually measured, although projects can be prohibited or forced into redesign if they have significant negative environmental impacts. Finally, there may be externalities from beach projects. A beach is a highly visible piece of infrastructure and failure to maintain it may be used by potential migrants to a local community as an indication that the quality of invisible infrastructure (e.g., water, sewer) is poor. Restoration of the beach may lead to a general rise in property values over and beyond what would be predicted by projecting direct benefits.

Storm protection benefits are measured as the discounted value of expected dollar losses assuming the project is constructed, less the discounted expected dollar losses if the project is not constructed. The losses from storms are applied to structure values based on rules of thumb, such as assuming the proportionate dollar loss is twice the proportion of the structure that is damaged by a storm. Thus, for example, when 50% of a building is lost, all of its structure value is lost. Expected losses are calculated as the sum of the probabilities of storm events times the dollar losses resulting from those events. Storm protection benefits are discounted using an exogenously given real interest rate. The basis for the original interest rate is obscure, although it is adjusted regularly using a nominal interest rate on government securities. A lower interest rate makes it easier to justify projects and a higher interest rate makes it more difficult. Opponents of Corps of Engineers projects favor a high interest rate, while supporters of such project favor a low rate. Some people favor basing the interest rate on the government bond yield, but others argue that this will favor public over private projects since government borrowing costs are lower than private borrowing costs. An alternative interest rate could be based on the home equity loan market, under the assumption that taxpayers had to borrow in order to pay their taxes. Beach benefits are discounted over a 50-year period, assuming that the project is maintained on a projected schedule. The 50-year planning horizon is somewhat arbitrary, although if the discount rate is high future benefits and costs will be reduced to zero when discount factors are applied to values generated far into the future. Follow-up studies of the accuracy of projected maintenance intervals are needed.

Recreational benefits are measured based on willingness to pay by beach users. Two approaches have been taken. One is based on travel costs borne by the beach user, that is, out of pocket expenses and time expended by the beach user in traveling to the beach. This approach requires a variety of assumptions to be made about travelers. An alternative approach is to use surveys of beach users to collect information on willingness to pay. It is more common to conduct surveys as personal interviews on the beach rather than by telephone or mail in order to reduce nonresponse bias. There is a large literature in economics relating to contingent valuation surveys, including recommendations for wording questions (Portney, 1994). One issue relates to whether the interviewee realizes that dollars expended on a beach visit are unavailable for alternative products. A second issue relates to allowing an interviewee to select from a list of willingness to pay values, as opposed to giving a yes or no to a single value. Interviewees may have a tendency to pick a middle value on a list. Collecting information by obtaining a response to a single value, the so-called referendum method, requires a larger sample size of interviewees. In the case of beach surveys, there are also unique problems. A certain number of people on the beach strongly oppose user charges for entry to the beach and report little or no willingness to pay values in an effort to discourage the imposition of such charges. There may also be a group who say that the value of the beach is infinite, since it is a beautiful natural resource. Finally, there are difficulties with estimating willingness to pay for beach improvements by interviewing users of the unimproved beach. The number of new users and the increase in average willingness to pay may have to be projected using very limited data.

Issues relating to funding beach improvements

Many beach projects take place on stretches of coastline where the upland properties are at least partly privately owned. Moreover, the average income level of beachfront property owners tends to be high since, as noted above, beachfront property values tend to be high. As a result, benefits from beach improvements may be skewed in the direction of relatively affluent beachfront property owners. In many cases, the public perception that benefits are skewed to beachfront property owners leads to the use of specialized funding sources as a means of financing government subsidies. Thus, for example, a special taxing district may be established to collect additional property taxes from beachfront property owners. In another case, a tax on accommodations may be used, particularly if such accommodations have large clienteles of beach users. In some cases, local funding is obtained by charging beachfront property owners for their storm protection benefits and by charging non-beachfront property owners for their recreation benefits.

In the United States, there are also issues about funding by level of government. Under current law, federally approved beach nourishments may receive subsidies in amounts up to 65% of the total cost for initial projects and up to 50% of the cost of maintenance projects. There are some peculiarities in the federal program for subsidizing beach nourishments. The federal government requires that projects seeking subsidies be economically justifiable based on storm protection benefits alone and this is most easily achieved by projects with highly intense upland land uses, such as high-rise apartment buildings and hotels. On the other hand, the size of the federal government subsidy depends on the extent of public access and parking to the improved beach, that is, the size of the recreational benefits resulting from the beach improvement.

There have been efforts by the executive branch of the federal government to reduce the size of federal subsidies for beach nourishment projects. Most of these efforts have failed to obtain support in Congress. The Clinton administration attempted to limit the number of beaches that could qualify for federal subsidies by distinguishing between beaches of national interest and beaches of state and local interest in much the same way as highways are divided between national roads, state roads, and local roads. The same administration became concerned about the large subsidies that would be required to maintain existing projects, in an era of large budget deficits, and successfully reduced maintenance subsidies from a maximum of 65% of costs to 50%. Both the Clinton and Bush administrations believe that most of the benefits from beach projects accrue at the local level and, therefore, they argue that most of the funding should be obtained from that level. They argue that, from a national viewpoint, economic and fiscal benefits represent a redistribution across regions rather a substantial increase in the national totals. Recreational benefits also represent a redistribution, since beach users may use other beaches or alternative recreational facilities if a beach is not improved. The Bush administration has proposed lowering the maximum federal share to 35%. On the other hand, the federal government maintains control of local beaches as habitats for wildlife and at least some erosion has been caused by navigation improvements to federally maintained inlets. The federal government is arbitrarily adjusting cost sharing proportions without undertaking any study of the national benefits of beaches. Until such a study is undertaken, it is unlikely that an appropriate federal cost share will be obtained.

EL NIÑO–SOUTHERN OSCILLATION (ENSO)*

Local fisheries (Enfield, 1988, 1999)

The term El Niño (or "the child") was originally used by Peruvian fishermen in the 19th century to refer to a Christmastime warming of coastal sea surface temperature (SST), often associated with an abrupt decrease in productivity of the local fisheries. The Southern Oscillation (SO) portion of El Niño–Southern Oscillation (ENSO) describes the global-scale surface pressure oscillation documented by workers around the turn of the century and first studied in detail by Sir Gilbert Walker (for historical reviews, see Rasmusson and Carpenter, 1982; various chapters in Glantz *et al*., 1991; Diaz and Markgraf, 1992, 2000; Diaz and Kiladis, 1995; Allan *et al*., 1996; Diaz *et al*., 2001). It was not until the 1960s that Jacob Bjerknes linked the two processes and began to describe the complex

* Updated from the Encyclopedia of Environmental Science (1999) by the author and printed with permission of Kluwer Academic Publishers.

interplay between the ocean and atmosphere, which comprises ENSO and can lead to dramatic perturbations of the global climate system. Here, we will be concerned with the implications of climatic change on ENSO, as well as considering the possible importance of ENSO itself for low-frequency climatic variability.

The root of what is now commonly referred to as ENSO lies in the tropical Pacific, although its influences eventually spread far beyond that ocean basin. To begin to understand the ENSO cycle and its role in climate variability, the mean oceanic and atmospheric conditions over the eastern Indian and Pacific sectors are first considered, at least in general terms. We then examine the principal climatic anomalies worldwide that result from the development of the tropical anomalies. For further reading, see Streten and Zillman (1984) and Kiladis and Diaz (1989).

Mean conditions

The South Pacific high-pressure system is the primary atmospheric circulation feature of the eastern South Pacific Ocean. This semipermanent surface high is associated with equatorward flow along the coast of South America, and strong southeasterly trade winds over the tropical eastern Pacific. These southeasterlies cross the equator and merge with the northeasterly trades of the north Pacific subtropical high at a latitude of about 80°N, giving rise to a zone of surface convergence and heavy rainfall known as the *inter-tropical convergence zone* (ITCZ). Further west, the southeasterly trades weaken and recurve into northeasterlies in the tropical southwest Pacific, merging with southeasterlies from surface high-pressure systems moving eastward from the region of Australia. This produces another northwest–southeast oriented rainfall maximum called the south Pacific convergence zone (SPCZ; Trenberth, 1976).

The distribution of rainfall in the tropical Pacific is closely related to the SST pattern, which in turn can be understood to be driven by the surface wind stress and associated ocean currents (see Pickard and Emery, 1982). One result of the Earth's rotation is to cause surface water to flow to the right of the wind in the Northern Hemisphere and to the left of the wind in the Southern Hemisphere. Thus, easterly trade winds along the equator result in a divergence of water away from the equator, which leads to the "upwelling" of relatively cooler water from depth to conserve mass. Similarly, equatorward wind stress along the western coast of South America leads to divergence of water away from the coast and strong upwelling along the steep subsurface continental margin. Regions of upwelling comprise productive fisheries areas, as the subsurface waters are often rich in nutrients. This effect, along with the northward transport of cold water in the Peru Current, gives rise to the rich fisheries and relatively cold SST for its latitude along the coast of Peru and the Galapagos Islands.

A direct result of the coastal and equatorial upwelling is to increase the stability of the atmospheric boundary layer by the cooling effect of the SST. This, along with the reduced evaporation over colder water, results in the strong suppression of rainfall in these regions. As a result, the coasts of southern Peru and northern Chile are the driest deserts on earth. Anomalously dry climates are also experienced along the so-called "equatorial dry zone" in the central and eastern Pacific as a result of the strong upwelling there. As one moves westward, equatorial SST increases gradually as the trades and upwelling weaken, eventually giving way to the "warm pool" west of the dateline. This region is the largest area of high SST in the world's oceans, averaging greater than 28°C. The warm pool extends west-ward from the western Pacific through the seas surrounding Indonesia and into the eastern Indian Ocean, and is associated with high precipitation over these regions.

The ENSO cycle

ENSO fluctuations are associated with marked deviations from the mean atmospheric and oceanic conditions described above. In the eastern Pacific Ocean, its most obvious manifestation is an increase in SST along the equator and coast of South America, with an associated increase in sea level and depth of the thermocline. This results from a decrease in upwelling due locally to a weakening of the South Pacific high and associated trade wind flow, as well as the eastward propagation of equatorially trapped large-scale waves in the ocean, which suppress the thermocline (Philander, 1990).

The weakening of the South Pacific high is the eastern component of Walker's Southern Oscillation and is associated with an increase in surface pressure over Australasia. Figure E1 illustrates how the surface pressure varies inversely between Tahiti (Papeete) and Darwin, Australia, on timescales of several months and greater. Various indices of the SO have been constructed utilizing normalized pressure anomalies between stations near the poles of the oscillation such as Darwin and Tahiti (see Trenberth, 1984). However, the association between the SO itself and the eastern Pacific SST is not a simple one (Deser and Wallace, 1987). The SO is most closely coupled to SST variability along the equator from about 160°W to the Galapagos, and only loosely related to SSTs near the dateline and in the traditional El Niño region of coastal Peru. Figure E2 gives the temporal evolution of normalized

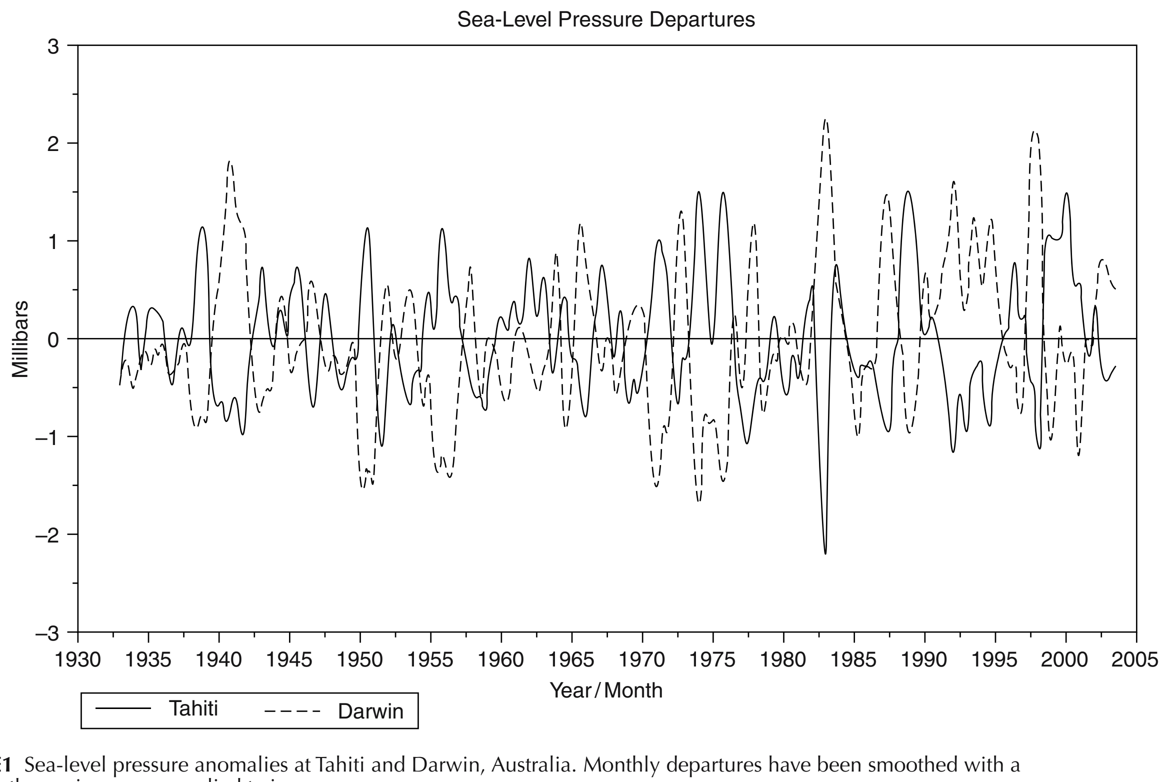

Figure E1 Sea-level pressure anomalies at Tahiti and Darwin, Australia. Monthly departures have been smoothed with a five-month running mean, applied twice.

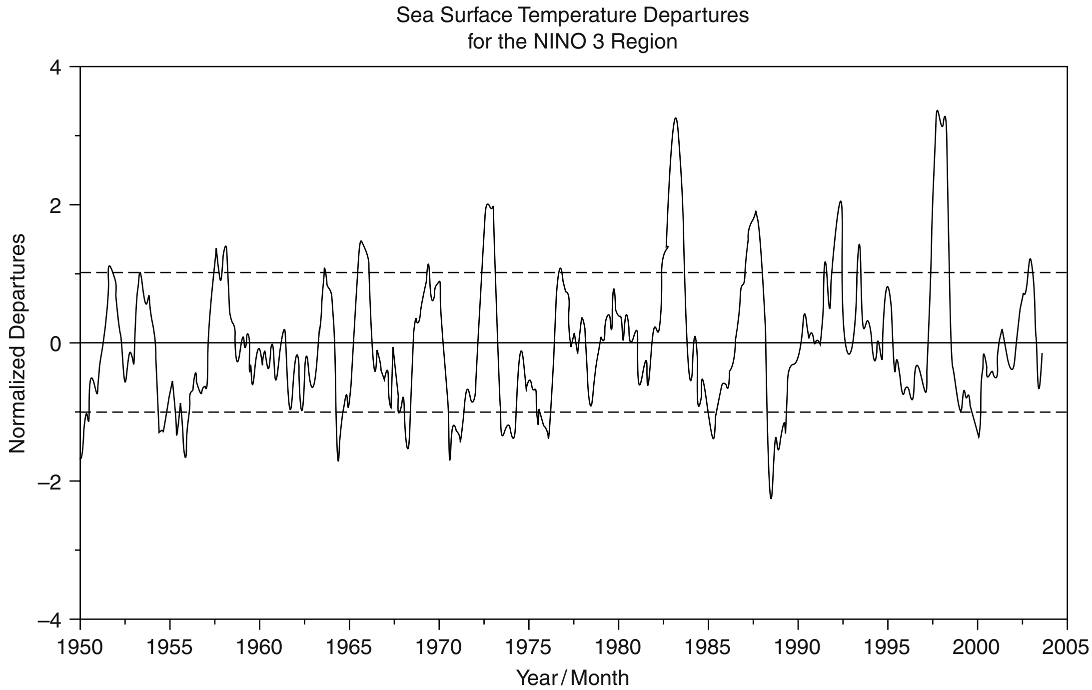

Figure E2 Standardized SST anomalies in the El Niño-3 region for the period 1951 through July 2003. Reference period is the full period of record; monthly data have been smoothed with a three-month running mean, applied twice.

SST variations in the equatorial belt from 6°N to 6°S, 150°W to 90°W, which is known as the Niño-3 region (Rasmusson and Carpenter, 1982). The correlation between the Tahiti minus Darwin sea-level pressure (SLP) difference and the Niño-3 SST is quite high (with about 64% of the variation in one series explained by variations in the other). The five most recent warm events can be seen on these plots, namely 1982–83, 1986–87, and 1991–92, 1997–98, a weak event in 2002–03, along with cold events in 1988–89 and 1998–2000.

Knowledge of the workings of the ENSO phenomenon can be obtained from an examination of its composite behavior (Rasmusson and Carpenter, 1982), along with study of individual cases, which deviate markedly from this mean view (Fu *et al.*, 1986). One interesting aspect of ENSO is the tendency for phase locking to the annual cycle. ENSO extremes often first develop during the northern spring, when the trade winds are weakest and SST is highest on average over the eastern equatorial Pacific. The fundamental instability involved concerns a relationship between SST anomalies and atmospheric convection. In the majority of events, a positive equatorial SST anomaly develops initially near the dateline. Since SST in this region is on average about 28°C, any positive anomaly in this region will create conditions conducive to anomalously active atmospheric convection Barnett *et al.*, 1991).

The development of ENSO events tends to peak during the late summer and early fall of the Northern Hemisphere. Notable exceptions occurred in the warm events of 1982, 1986, and 1991, which developed late in the calendar year and peaked during the northern winter and spring. The feedback leading to a reversal of ENSO conditions is often mediated by the seasonal development of the strong trade wind regime of northern fall, as well as the depletion of heat energy in the warm pool. Much of this energy is apparently transferred to the atmosphere through anomalously high rates of evaporation, and portions of it may also be transferred to higher latitudes by the oceanic meridional circulation. Once the heat content of the ocean is depleted, the stage is set for the transition to the opposite phase of ENSO, the so-called "La Niña" or cold event (e.g., van Loon and Shea, 1985; Philander, 1985, 1990). Cold events also involve an unstable interaction, as described above, for warm events, except that it occurs in reverse, as cold SST in the eastern Pacific help maintain a strong westward pressure gradient and trade winds, in turn favoring the continuance of the SST pattern itself.

ENSO teleconnections

Much of Gilbert Walker's early work was geared towards prediction of Indian rainfall, and the SO was of great interest, as it was known that the strength of the monsoon was inversely proportional to the surface pressure over southern Asia. In his investigations, Walker (1923) established that high pressure over the Australasian region was accompanied by drought over India and Australia and cool, wet winters over the southeastern United States. Surprisingly, little work on atmospheric teleconnections was undertaken until nearly a half a century later, when Bjerknes (1966) uncovered evidence that El Niño conditions were associated with a strengthening of the storm track over the North Pacific. Since then, a wealth of work has been done on the temperature and precipitation signals associated with ENSO. Much of the synopsis that follows has been taken from the work on large-scale ENSO signals of Rasmusson and Carpenter (1982), Ropelewski and Halpert (1986, 1987), Lau and Sheu (1988), Kiladis and van Loon (1988), Kiladis and Diaz (1989), Diaz and Kiladis (1995), and Diaz *et al*. (2001).

Although the term "El Niño" was first used to describe the annual warming of the waters along the Peruvian coast, in the 1960s it became synonymous with the concurrence of abnormally high SST and heavy rains in the usually hyperarid Peruvian coastal plains. Bjerknes (1969) noted that anomalously heavy rains during El Niño also occurred at Pacific island stations such as Canton and Christmas in the equatorial dry zone. As mentioned above, this signal is one manifestation of the equatorward shift of the convergence zones during equatorial warming of the SST associated with ENSO. As a result, the regions normally under the influence of these convergence zones, such as the Caroline and Marshall Islands, Fiji, and New Caledonia, experience drier than normal conditions.

The most pronounced signals occur during the year that an ENSO extreme first develops (here called "Year 0") into the following year (Year + 1), following the convention of Rasmusson and Carpenter (1982). ENSO appears closely tied to the Asian and Australian monsoon circulations, which are notably weaker during warm events (see Webster and Yang, 1992). While precipitation increases in the central and equatorial Pacific during warm events, it becomes markedly drier over regions bordering the western Pacific and eastern Indian Ocean, such as Indonesia and Australia (Allan, 1988; Nicholls, 1992), India (Rasmusson and Carpenter, 1983), and southeast Asia. Failure of monsoon rains during warm events can have catastrophic impacts (Kiladis and Sinha, 1991). Conversely, cold events are often associated with flooding events in India (Parthasarathy and Pant, 1985). The Australasian signal is more evident during the northern fall of year 0, and persists over the monsoon region of northern Australia into the December through February rainy season. However, during strong ENSO events, the entire continent of Australia can be affected by severe drought conditions (Nicholls, 1992). See also the reviews in the special issue of the *Journal of Geophysical Research* [Anderson *et al*. (eds.), 1998].

It should be emphasized that, while warm events can result in devastating precipitation deficits over monsoon regions, these areas generally still receive a large amount of precipitation in all but the most extreme cases. Over certain regions of the data-sparse Indian Ocean, there is some suggestion that warm events actually see above-normal precipitation in phase with that over the central Pacific. Sri Lanka, the Seychelles Islands, and coastal stations of equatorial Africa are certainly wetter than normal during their September–November rainy season (Kiladis and Diaz, 1989), and satellite data from three warm events (1982, 1986, and 1991) support the occurrence of enhanced rainfall over the southern Indian Ocean during the northern winter of those events. If so, this means that the main focus of precipitation over Australasia is actually not so much shifted eastward, but distributed more evenly across the equatorial Pacific and Indian Oceans.

As warm events evolve toward their "mature" phase during the northern winter season (DJF + 1), drier than normal conditions continue in the region of the western Pacific ITCZ from the Philippines eastward (Kiladis and Diaz, 1989), and east of Australia in the normal position of the SPCZ (Kiladis and van Loon, 1988). Similarly, a large region of southeastern Africa, including parts of Zimbabwe, Mozambique, and South Africa, has a marked tendency for drought during DJF + 1 of warm events. Precipitation in this region is highly seasonal, so this signal can have an especially large impact since it occurs during the normal southern summer rainy season (Nicholson and Entekhabi, 1986). Farther north in Africa, there are indications that warm events favor drought conditions from the Sahel eastward to the highlands of Ethiopia during the normal summer rainy season of JJA 0 (see Janowiak, 1988; Lamb and Peppler, 1991).

While coastal Ecuador and northern Peru often experience flooding during warm events, other regions of the Americas often also register large rainfall anomalies. A consistent dry signal is found from JJA 0 through DJF + 1 over northern South America (Rogers, 1988). Over northeast Brazil, the periodic occurrence of severe drought in the agriculturally rich Nordeste region in connection with El Niño events has resulted in severe economic hardship and occasional famines in this region (Hastenrath and Heller, 1977; Chu, 1991). Widespread and severe famine was reported during the great El Niño of 1877–78, while other severe El Niño episodes, including that of 1982–83, have led to great suffering. Although data are sparse, the northern Amazon basin also appears to be affected. In contrast, much of southern South America is wet during JJA 0, and this signal persists into SON 0 in Uruguay, and central Chile and Argentina (see Kiladis and Diaz, 1989; Diaz and Kiladis, 1995; and Diaz *et al*., 2001). A remnant of this signal is still present in DJF + 1, when the southeastern United States and northern Mexico also shows above normal precipitation. In the heavy rainfall areas of the upper Paraná and Paraguay River Basins, MAM + 1 precipitation tends to be above normal, and this contrasts with the relatively dry summer wet season over Central America.

Although the best correlations between ENSO and temperature are observed in the tropics and subtropics, the Americas can experience large mid latitude temperature anomalies during ENSO events. Strong and relatively mild westerly flow from the Pacific into the North America during warm events is responsible for a large region of positive temperature departures from southern California northward along the west coast to Alaska, then inland across western and central Canada. This signal over northwest North America is one of the most reliable in the extratropics from event to event (Kiladis and Diaz, 1989; Diaz and Kiladis, 1992). Cold events are equally reliable in being associated with anomalously cold winter seasons in this region. In those years, a tendency toward a weak jet stream over the central Pacific leads to atmospheric "blocking" patterns in the Gulf of Alaska, which in turn are associated with anomalous northerly flow over northwestern North America. The increased warm-event storminess over the southeast United States discussed above is also accompanied by cooler temperatures in that region. Similar enhanced zonal flow over sub-tropical South America leads to above-normal temperatures along the west coast; as in North America, this signal is most extensive during its winter.

ENSO and climate variations

It is important to recognize that the ENSO teleconnections represent statistical averages over the last half-century, and the strength of these waxes and wanes on decadal timescales for several reasons. For example, because tropical Pacific SSTs exert only a modest control on seasonal climate variations, random fluctuations of the teleconnections due to sampling alone can occur on multi-decadal timescales (Allan, 2000; Diaz *et al*., 2001).

It has been noted elsewhere that tropical Pacific SST variations were weak during 1920–40 compared with 1980–2000 (Trenberth and Shea, 1987; Allan *et al*., 1996; Allan, 2000). Given that the strength of teleconnections increases almost linearly with the amplitude of tropical Pacific SST anomalies (e.g., Kumar and Hoerling, 1998), a reasonable assumption is that stronger teleconnections will occur during decades when tropical Pacific SSTs exhibit larger interannual variance. An additional factor requires no change in ENSO temporal behavior *per se*, but involves slow, multi-decadal, changes in the climatological mean SSTs themselves. These can alter the atmospheric sensitivity to interannual variations in tropical Pacific SSTs because the teleconnections respond to the total, rather than to the anomalous, SSTs.

One plausible factor in this strengthening of ENSO teleconnections is a multi-decadal change in the life cycle of tropical Pacific SST anomalies during warm events (Trenberth, 1984; Mantua *et al*., 1997). The strength of teleconnection patterns emanating from changes in tropical convection associated with ENSO variability differed considerably before and after 1976 (Diaz *et al*., 2001). The origin for this change is not known, and may merely reflect the stochastic behavior of the equatorial coupled system itself. Nonetheless, the relevancy for the teleconnection process is large because the warm-event life cycle since 1976 has become closely phased with the climatological annual cycle, and in particular the prolonged anomalous warming in spring of year + 1 now coincides with the peak annual cycle SST warming.

In many areas where a significant ENSO modulation of precipitation is present, the strength of that teleconnection has varied over the past century. It is unclear to what degree the temporal variations of ENSO teleconnections in different regions are related. To the extent that there is a dynamical root to the changes observed in the past century, for example, due to changes in the ENSO SST forcing, then it is reasonable that changes in one region would be accompanied by changes in another.

Decadal scale patterns in tropical and north Pacific SSTs have been shown to correlate to decadal scale changes in the extra-tropical circulation, and associated temperature and precipitation patterns, particularly over North America. These changes have been statistically linked to different phases of a decadal-scale pattern of SST anomaly in the North Pacific known as the Pacific Decadal Oscillation (PDO) (Mantua *et al*., 1997); however, it is not clear what is cause and what is effect. One interpretation of recent modeling work on the connection between low-frequency changes in tropical SST, ENSO, and decadal scale changes in the general atmospheric circulation suggest a complex interplay between the canonical ENSO system, the slow changes in SST in the Indo-Pacific over the last century, and long-term changes in the atmospheric circulation itself.

ENDOGENIC AND EXOGENIC FACTORS

Endogenic (or endogenetic) factors are agents supplying energy for actions that are located within the earth. Endogenic factors have origins located well below the earth's surface. The term is applied, for example, to volcanic origins of landforms, but it is also applied to the original chemical precipitates. Exogenic (or exogenetic) factors are agents supplying energy for actions that are located at or near the earth's surface. Exogenic factors are usually driven by gravity or atmospheric forces. The term is commonly applied to various processes such as weathering, denudation, mass wasting, etc. In coastal science, these factors may be illustrated in two significant applications. One is the classification of coastlines and the other is the discussion of sea-level variations.

Factors in coastline classification

As early as 1885, Suess (as cited in Kennet, 1982) described the fundamental difference between the coastlines of the Atlantic and those of the Pacific Ocean. This distinction is now the basis for classifying the world's coasts into three categories based on the endogenic processes of plate tectonics (Inman and Nordstrom, 1971). Collision coasts are found at convergent plate boundaries such as along the west coasts of North and South America. They tend to be straight and mountainous with narrow continental shelves. Marginal sea coasts, the second category, are protected from the open ocean by island arcs. An example would be the coast of Korea. Trailing-edge coasts are found on the interior areas of tectonic plates. When newly created, like the coast of the Red Sea, trailing-edge coasts appear similar to collision coasts; they are steep, lined by sea cliffs, and have a normal shelf. With age, however, they tend to have broad coastal plains, wide shelves, and low relief like the east coast of the United States.

The evolution of trailing-edge coasts corresponds to early concepts in geomorphology on the aging, or maturing, of continental margins by exogenic forces (Dietz, 1952). Simply put, the continental crust is attacked by wave action and the continental margin shaped by the redistribution of marine sediment by coastal currents. Young, steep coasts are thereby replaced by the gently sloping surface of a thick wedge of coastal plain sediments. Turbidity currents and other elements of gravity-driven mass movements are then instrumental in the basic formation of the continental slope and rise. On a smaller scale, endogenic processes of faulting, volcanic, or other igneous structures provide other coastline types (Shepard, 1963). These are typically erosional, rocky coastlines in which the underlying geologic structure imposes the coastline pattern.

Coastal features formed by exogenic factors may be inherited or active. The surficial processes to which these coastal landforms owe their origin are no longer active. Coastlines formed by glacial action, such as fjords or drumlins, or drowned river valleys, are examples of inherited characteristics. Deltaic coasts, barrier islands, cuspate forelands, tombolos, etc. are all features shaped by exogenic factors since they owe their origin to the active redistribution of sediment by waves and currents. Collectively such features are characteristics of accretional coasts, notwithstanding the fact that such coasts may have serious erosion problems.

Factors in sea-level changes

Endogenic processes also control long-term eustatic sea-level changes. Deep-seated isostasy and the thermal structure of the oceanic lithosphere influence the relief of the ocean basin. Newly created seafloor stands in high relief being thermally expanded. With the passage of time, it cools, contracts, and subsides. As a result, changes in the rate of seafloor spreading and the total length of mid-ocean ridges changes the elevation of the oceanic platform, that is to say, the average depth of the ocean basin, and, consequently, the position of sea-level relative to the continents. A global drop in sea level of some 350 m at the end of the Cretaceous is attributed to the contraction of the mid-ocean ridge system, in part by the disappearance of spreading centers in the Pacific beneath North America.

Exogenic factors that control sea-level variations include seasonal cycles due to temperature variations, storm surges, or geostrophic adjustment of sea surface slopes by variations in the speed of coastal ocean currents. Anticipated sea-level changes, and other coastal impacts, due to global warming have exogenic origins. The current rate of eustatic sea-level rise is due predominantly to the combined effects of the liberation of water from the melting of glaciers and the thermal expansion of the surficial layer of the ocean.

Extraterrestrial factors

The term "exogenic" is also applied to agents having their origins outside the earth such as solar radiation, comets, or meteorites. A collection of features that owe their origin to the impact of meteorites, such as coastal deposits of a tsunami resulting from the Cretaceous impact event, could be ascribed to this class of exogenic factors.

ENERGY AND SEDIMENT BUDGETS OF THE GLOBAL COASTAL ZONE

The energy for the global coastal zone is primarily powered by solar irradiance and tides. The solar irradiance warms the earth's surface unevenly, driving wind and current systems that redistribute heat and generate storms with rainfall and snow that erode landmasses. The erosion products of sediment and dissolved solids are carried to the sea by rivers and glaciers. Winds, waves, tides, and currents transport and redistribute sediment and sculpt coastal landforms.

Solar irradiance provides an energy flux of about 1.8×10^{14} kilowatt (kW) to the earth. About 2.5×10^9 kW of mechanical energy in wind-generated waves is incident on the world's 440,000 km coastlines. Another 2.2×10^9 kW of tidal energy is expended in shallow seas. The total flux of mechanical energy of all kinds in shallow waters of the coastal zone is about 5.5×10^9 kW. Some of this energy is expended in coastal erosion and transport of the erosion products from the land, and the remainder drives frictional processes and is dissipated as heat. The erosion rate of land is about 6 cm/thousand years resulting in a flux to the sea of 5×10^9 ton/yr dissolved solids and 20×10^9 ton/yr particulate solids (1 ton = 1,000 kg).

Introduction

The oceans respond to many different kinds of steady and impulsive forces applied at their boundaries with the atmosphere and seafloor. Although most energy in the nearshore waters comes from wind-generated waves and tidal currents, energy from a number of other sources such as internal waves and ocean currents may also be important locally.

One approach to understanding the relative importance of nearshore processes is to compare the sea's potential to erode the land with the land's potential to supply terrestrial erosion products. Such a comparison ultimately resolves itself into the balance between the budget of power in waves and currents and the budget of sediments available for transport. Of course, this balance varies widely from place to place, and even in the best-studied areas is but poorly understood. However, order of magnitude estimates can be attempted on a worldwide basis, and their consideration here gives some overall perspective for the relative importance of the driving forces that are operative in nearshore waters.

In a practical sense, the waters of the coastal zone can be considered as including the shallow seas and the waters covering the continental shelves of the world, an area of 29×10^6 km^2, or about 5.5% of the surface area of the world and about 8% of the area of the world oceans (Table E1). The nearshore waters are bounded on the landward side by coastlines that total about 440,000 km in length, and to the seaward by the break in slope at the shelf edge (shelf break) marking the change from the relatively horizontal continental shelf to the steeper continental slope. The continental slopes are one of the striking geographic features of the earth and have a combined length of about 150,000 km.

Table E1 Dimensions of major topographic features

Feature	Area (10^6 km^2)	Length of coastline (10^3 km)
Continents	138.8	210
Large islands (larger than 2,500 km^2)	9.3	136
Small islands (25–2 500 km^2)	0.9	94
Total land	149.0[a]	440
		Length of shelf break (10^3 km)
Oceans (depths >200 m)	332.1	
Continental shelf (0–200 m)	29.0	149
Total marine water	361.1	
Total area earth	510.0	

[a] United Nations (UNEP, 1987) gives total land area of 145×10^6 km^2.
Source: Inman and Nordstrom (1971) for features with length scales greater than 10 km.

Conventionally, the depth of the shelf break is taken as 200 m or 100 fathom, although in some localities the depth may be as great as 400 m. On a worldwide basis, the average depth of the shelf break is about 130 m. The width of the shelf ranges from zero to over 1,300 km and averages about 74 km (Shepard, 1963). Although having little geomorphic basis, international law defines *territorial seas* as usually extending seaward 12 nautical miles (22.2 km) beyond the coastline and an *exclusive economic zone* as usually extending 200 nautical miles (371 km) seaward.

Budget of energy in shallow water

The current systems of the world's atmosphere and ocean are solar powered. The sun irradiates the earth with a total of about 1.8×10^{14} kW, or an intensity of 1.37 kW/m^2, the so-called solar constant. In terms of the rotating, spherical earth, this averages to about 342 W/m^2 of earth's surface. Of this amount about 30% is reflected and backscattered, 19% is absorbed by the atmosphere, and 51% is absorbed at the earth's surface (e.g., Gill, 1982). Solar energy heats the earth's surface unevenly and generates winds. The oceans are relatively opaque to solar irradiance, so that the effect on the oceans is to stratify and stabilize the surface water. As a consequence, the ocean responds much more to wind, even though the intensity of thermal energy from the sun greatly exceeds the mechanical energy from the wind at the water's surface. Averaged over the earth's surface, the intensity of thermal energy absorbed is about 175 W/m^2, while the sea surface stresses and pressures caused by a wind blowing 10 m/s expend about 1.3 W/m^2. In contrast, the mean heat flow to the earth's surface from the interior is approximately 0.1 W/m^2, and occurs mostly at the mid-ocean spreading centers (Pollack *et al.*, 1993). Thus, it is the solar powered atmosphere and ocean currents together that maintain the earth's heat budget by accounting for a poleward transport of energy at the rate of about 8×10^9 kW.

Studies of the energy budgets of the ocean and atmosphere (e.g., Webster, 1994) show that the total energy content of the oceans ($\sim 160 \times 10^{25}$ joule (J)) is 1,000 times larger than that of the atmosphere ($\sim 125 \times 10^{22}$ J). Because of greater mass and heat capacity, the oceans play a critical role in controlling and moderating weather and climate. However, in terms of the kinetic energy available for interacting with the oceans, the atmospheric kinetic energy ($\sim 6 \times 10^{20}$ J) is 200 times larger than that of the oceans.

The wind systems are the direct link between atmosphere and ocean and, through momentum exchange at the ocean's surface, expend kinetic energy at the rate of about 10^{11} kW (Malkus, 1962; Newell *et al.*, 1992). The prevailing wind systems cause all large bodies of water to have windward and leeward shores. The Pacific coasts of the Americas are in general windward coasts while the Atlantic seaboards are leeward coasts. The general wind flow is clockwise in the Northern Hemisphere around semipermanent, midlatitude areas of high pressure, for example, the north Pacific high and the Bermuda high in the Atlantic Ocean. Circulation patterns in the southern oceans are essentially counterclockwise flowing mirror images of those in the Northern Hemisphere (Figure E3).

Sea and swell

The most intense wave action in all oceans results from cyclogenesis over the poleward-flowing, western boundary currents. These warm water jets carry equatorial heat to higher latitudes and produce strong temperature gradients that spin-up intense storms (Figure E3). These boundary cyclonic events generate large, high-frequency *sea waves* along leeward shores and long waves that cross the ocean and appear as low-frequency *swell* on windward coasts. In the north Pacific, dry Siberian winds flowing over the warmer Kuroshio Current produce a series of cyclonic cold fronts that collectively have long fetches and generate the high waves for the Pacific coast of North America during the winter. These storms produce swell when they are distant and sea waves as their tracks near the coast.

Long, low-frequency swell is typically absent from leeward coasts. Rather they are subject to periodic, intense sea waves from the poleward and easterly traveling storm fronts. The tracks for tropical (summer/fall) storms for the middle Atlantic seaboard of the United States essentially

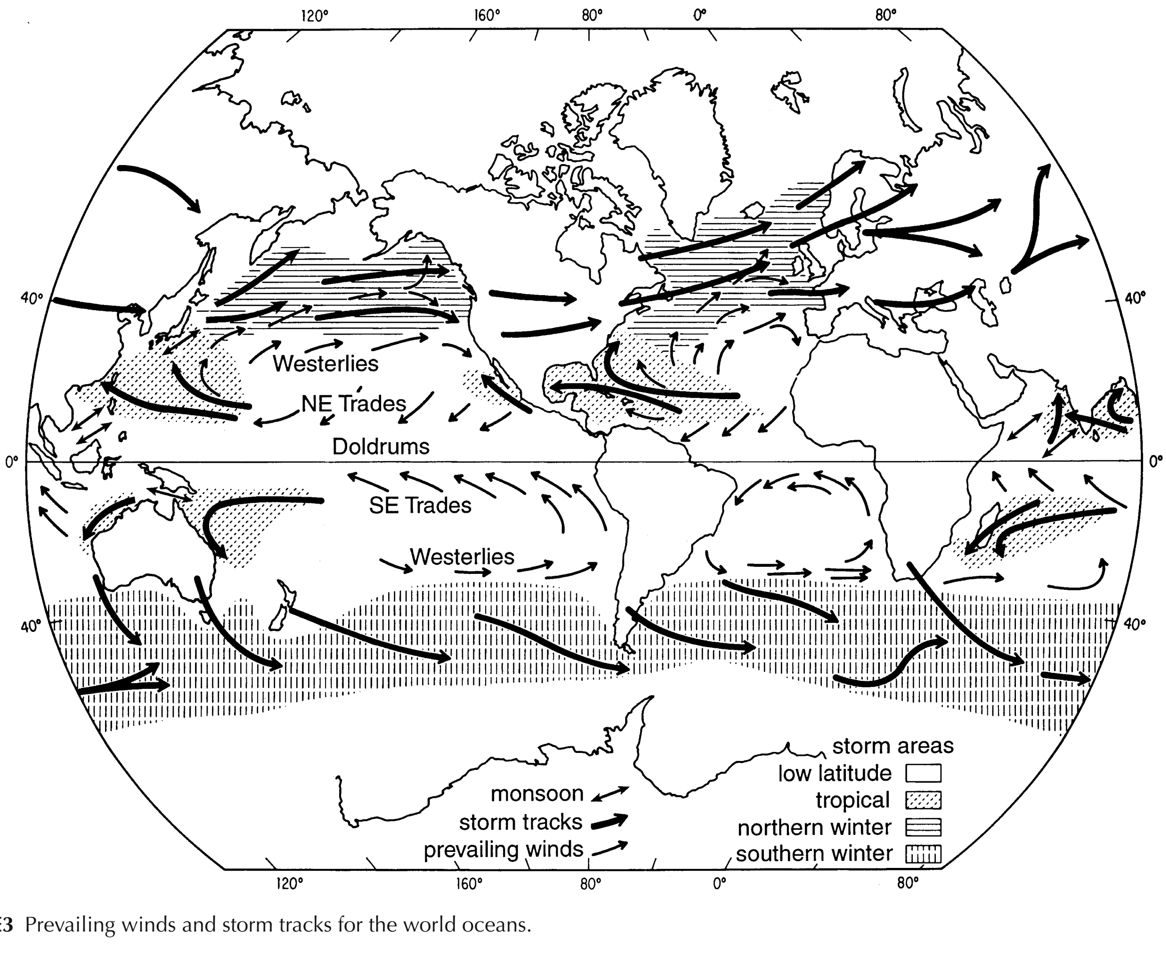

Figure E3 Prevailing winds and storm tracks for the world oceans.

follow the Gulf Stream, while the extratropical (winter/spring) tracks take a more easterly course. In midlatitudes the tracks are channeled between the coast and the perimeter of the Bermuda high. This channel is sometimes known as the Atlantic seaboard cyclone track (e.g., Klein and Winston, 1958). In the vicinity of Cape Hatteras, the highest waves from both extra- and tropical storms are from the northeast. The storm tracks are offshore and generally parallel the coast, so that the counter-clockwise flowing winds in the northwest quadrant of the cyclone (winds blowing from the northeast) are the strongest and have the longest fetch (e.g., Dolan *et al*., 1990). Thus, prevailing waves along the windward coasts and the strongest cyclonic sea waves along the leeward coasts both have net components toward the equator. As a consequence, there is a worldwide tendency in midlatitudes (20°–45°) for the net wave-induced littoral transport of sand to be toward the equator.

A three meter-high surface wave at sea transmits 100 kW for every meter of wave crest, or 100 MW/km. Since wave energy increases as the square of wave height, most coastal energy is from high waves during storms, particularly storms of long duration. For example, the northeast storm of March 1989 along the Outer Banks of North Carolina had average deepwater wave heights of 3 m (Dolan *et al.*, 1990). These were not unusually high waves, but they persisted for 115 h and had a power expenditure of 11,500 kilowatt hours per meter (kWh/m) of coastline. The average energy flux of waves on the Outer Banks is about 2 kW/m, which sums to a yearly total of 17,500 kWh/m (Inman and Dolan, 1989). Thus this one storm had a power expenditure (and sand transport potential) equivalent to 66% of that for the average year.

Data of instrumented buoys and light vessels in the North Atlantic and North Pacific all show that wave heights have increased significantly and continuously during the past 25 years (e.g., Graham and Diaz, 2001). The North Atlantic data show that the average annual (root-mean square) wave height has increased about 2% per year between 1962 and 1986. Over the 24-year period (1962–86) the range in average annual *significant wave* ($\sqrt{2}$ times root-mean square) height at Seven Stones Light Vessel off Lands End, southwest England, ranged from 2.2 to 2.9 m with an annual increase of 3 cm/yr. The "50-year return value" ranged from 12 to 18 m with an increase of 20 cm/yr (Carter and Draper, 1998). Data from six buoys between latitude 34° and 56° in the eastern North Pacific show similar increasing trends over the period 1975–99. The annual average significant wave height increased on average about 2 cm/yr, ranging for the six buoys from 0.4 to 4.2 cm/yr (Allen and Komar, 2000).

A preliminary estimate of global wave energy can be attempted from the data obtained from instrumented buoys and weather stations in the North Pacific and North Atlantic. The measurements for the eastern North Pacific cover the 25-year time interval from 1975 to 1999 (Allen and Komar, 2000). Over this period, the average annual (root-mean square) wave height increased progressively from about 1.6 to 1.9 m, generating a landward wave energy flux that ranged for these average waves from about 93×10^6 to 131×10^6 kW over the same period. Thus, the wave height increased about 20% while the corresponding energy flux increased about 40%. Similar wave conditions and wave height increases over about the same period were observed for the eastern North Atlantic Ocean (Carter and Draper, 1998). If it is assumed that the energy partitioning between periods of calm and storm results in an energy flux twice that estimated from the average annual wave height (i.e., the significant wave assumption), then the total annual energy flux over the 25-year period in the North Pacific becomes about 190 and 260×10^6 kW with an average for the period of about 230×10^6 kW for this 30°–60° latitude portion of the windward coast of North America.

When the energy flux of 260×10^6 kW for the North Pacific Ocean is extrapolated to the world oceans, the total wave energy flux to the global coastline becomes 2.5×10^9 kW (Table E2, footnote a). This is in agreement with earlier estimates (e.g., Inman, 1973) and gives an average energy flux of 5.7 kW/m to the 440,000 km of world coastline.

What is known about wave climate intensity suggests that windward coasts of oceans in the Northern Hemisphere are in phase with each other during El Niño and La Niña events and out of phase with lee coasts. In terms of decadal climate patterns, which are alternately El Niño or La Niña dominated, the prevailing wind stress and swell directions in the Northern and Southern Hemisphere appear to be out of phase (Trenberth and Hurrell, 1994; Chao *et al*., 2000). For example, during the La Niña dominated climate of the third-quarter of the 20th century, waves from the southern ocean appeared as "southern swell" along the California coast. Southern swell was absent from the California coast during the previous quarter of the century and again disappeared during the last quarter century (Inman and Jenkins, 1997). This is because of a global realignment in predominant storm tracks with changes in the phase of Pacific Decadal Oscillation (PDO), where El Niño storm tracks tend to be more zonal than those of La Niña storms. Consequently, the long waves of El Niño storms do not generally propagate out of the hemisphere in which they were generated. Conversely, the frontal circulation of La Niña storms is more meridional, generating waves that traverse latitude. Therefore, the Northern Hemisphere beaches are usually affected by Southern Hemisphere swells only when the Southern Hemisphere is in a La Niña dominated climate pattern.

Table E2 Estimates of the flux of mechanical energy in the shallow waters of the world in units of 10^9 kW

Wind-generated waves breaking against the coastline[a]	2.5
Tidal currents due to surface tides on shelves and in shallow seas[b]	2.2
Currents due to internal waves and tides over shelves[c]	0.5
Large-scale ocean currents in shallow seas[b]	0.2
All other sources	0.1
Total	5.5

[a] Assuming the average energy flux for the six instrumented NOAA buoys in the eastern North Pacific (Allen and Komar, 2000), proportioned over 30°–60° north latitude, is 230×10^6 kW (see text) and that for the 0°–30° portion of the eastern North Pacific is one-half, and that for the leeward ocean coasts is one third that of the windward coasts, giving a total for the coasts bordering the North Pacific Ocean of 460×10^6 kW. The global flux is assumed to be equivalent to that from five and one-half oceans like the North Pacific Ocean (i.e., North and South Pacific Oceans, North and South Atlantic Oceans, Indian Ocean, and one-half "ocean" equivalence for all marginal seas).
[b] Inman and Brush (1973).
[c] Conservative estimate from Wunsch and Hendry (1972).

Studies of windfields and pressure gradients indicate that the increase in wave heights in the eastern North Atlantic during the last quarter of the 20th century resulted from intensification of the pressure gradients between the Iceland low and the Azores high which could be related to climate change associated with the North Atlantic Oscillation (NAO) (Kushnir *et al.*, 1997). It is likely that some of the increase in wave intensity in the eastern North Pacific Ocean was associated with the PDO and increased sea surface temperatures during the last quarter of the century. However, it is unclear what portion of these increased wave heights in the North Atlantic and North Pacific oceans are also associated with global warming (Graham and Diaz, 2001). If the increases are mainly due to decadal oscillations, they suggest that decadal climate lead to ±30% changes in wave climate (see entry on *Climate Patterns in the Coastal Zone*).

Tsunamis

The most impressive waves in the sea are those generated by submarine earthquakes, landslides, and volcanic explosions (e.g., Van Dorn, 1987). These waves, called *tsunamis*, are well known because of the loss of life and great damage to coastal structures associated with their passage. Of the many types of surface waves, tsunamis contain the highest instantaneous power surges. They are reported to have caused runup to heights as great as 50 m above sea level in modern times and to greater heights in ancient times. The explosion and collapse of the volcanic island of Thera (Santorini) about 1400 BC is thought to have caused a tsunami, about 11 m high at Crete (Yokoyama, 1978), that may have ended Minoan maritime supremacy. The largest, well-documented tsunami was associated with the explosion and collapse of Krakatoa volcano in Sunda Strait between the Indonesian Islands of Java and Sumatra in August, 1883. The energy of the explosion is estimated to have been 2×10^{18} J (500 megatons of TNT) and it ejected 18 km^3 of material into the atmosphere (e.g., Simkin and Fiske, 1983). The resulting tsunami was estimated to be nearly 40 m in height; it drowned 36,000 people and destroyed 5,000 ships. One ship, the *Berouw* was carried 2 km inland on Sumatra where it remains today. The tsunami was observed on tide gauges throughout the world, and dust from the explosion covered the entire world causing brilliant sunsets for many years.

Detectable tsunamis have occurred about once a year. However, truly large tsunamis with energy content as high as 5×10^{15} J occur only about five times per century. Averaged over long periods, tsunamis would generate an energy flux of about 1×10^5 kW. Thus, because of their relative infrequency, these catastrophic waves contribute little to the worldwide budget of power.

Tides

The gravitational forces of moon and sun provide the driving forces for the ocean tides, with the moon's tide generating force being about twice that of the sun. The main lunar (semidiurnal, M_2) tide with a period of 12.42 h is the principal world tide; however, the interaction between lunar and solar forces provides a variety of tide-generating constituents. Locally, tidal amplitudes are determined in part by the interactions of the propagating oceanic tidal bulge with the shape of the ocean basin, favoring oscillations that are harmonics of the tidal forcing and the basin dimensions. The dominant tidal oscillations are usually referred to as *semidiurnal* (twice daily), *diurnal* (once daily), and *mixed* tides that are combinations of the two, such as those along the Pacific coast of the Americas.

The ocean surface tides, having wavelengths that are very long compared with the depth of the ocean, produce some motion even in the deepest water. However, this motion is usually only a few centimeters per second so that the energy dissipation by tides against the deep-sea bottom is slight. The principal tidal dissipation results from the flow of strong tidal currents in shallow areas, such as the Bering Sea and the Argentine shelf. One of the more impressive tidal coastlines occurs in Argentina. The tidal wave travels eastward through Drake Passage and then northward where it shoals over the broad Argentine shelf, attaining spring ranges of nearly 15 m at Rio Gallegos. From the southeastern tip of Tierra del Fuego to Bahia Blanca, a distance of 2,800 km, the tidal range is mostly in excess of 6 m.

"Tides are unique among natural physical processes in that one can predict their motions well into the future with acceptable accuracy without learning anything about their physical mechanism" (Cartwright, 1977). Their prediction from tide gauge records has been possible since Darwin formulated the rules of harmonic tide prediction in 1883. But, prediction from harmonic constituents can be in error when changing wind fields and warm water associated with El Niño events raise and lower sea level by 30 cm and more.

The energy dissipated by various kinds of tidal currents against the shallow sea bottom is one of the major factors that causes the rotational deceleration of the earth. Much of our present knowledge of this dissipation results from investigations by geophysicists into the possible causes of the deceleration in the earth's rotation (Jeffreys, 1920, 1970; Munk and MacDonald, 1960). Tidal dissipation causes a lag in the tidal bulge of the Earth relative to the rotation of the earth–moon system. This bulge exerts a torque that results in a decrease in both the earth's rotation rate and in the lunar orbital velocity.

From telescopic observations of sun and moon over the previous two and one-half centuries, Spencer Jones (Munk and MacDonald, 1960) determined that the moon's deceleration was 22.4 arcsec/century^2. This deceleration would be associated with an energy dissipation in the atmosphere, oceans, and solid earth of about 2.7×10^9 kW. More recently, measurements of the change in the moon's semimajor axis using laser ranging techniques show that the frictional energy dissipation due to the M_2 tides is 3.1×10^9 kW, giving a dissipation rate due to the solar and lunar tides of about 4.0×10^9 kW (e.g., Dickey *et al.*, 1994). The allocation by process for these revised dissipations of tidal energy is not yet understood. The best estimates for the lunar tidal dissipation in shallow seas is that of Miller (1966). He used the method of energy flux into shallow seas, rather than the less accurate method of summing the energy loss due to frictional drag on unit area of the bottom. His value of 1.7×10^9 kW for lunar tidal energy dissipation, when corrected for the solar tidal flux, gives a total energy dissipation for shallow seas of 2.2×10^9 kW (Table E2).

Internal waves

Internal waves are water oscillations that occur within the various density layers beneath the ocean surface. It appears that far more energy is transformed into internal (baroclinic) waves than was previously thought. The vertically integrated energy over the deep sea is typically about 4×10^{-3} J/m^2 (e.g., Garrett and Munk, 1979). Mechanisms generating internal waves include direct coupling between ocean surface waves and the density layers beneath the surface, scattering due to seafloor roughness (Cox and Sandstrom, 1962), and generation by impingement of deep-sea tides on the slopes of the continental shelves and submarine canyons (Rattray *et al.*, 1969).

Cox and Sandstrom (1962) found that internal waves were coupled to surface waves and estimate that the rate of conversion of tidal energy into internal wave energy in the Atlantic Ocean is roughly between 6 and 69% of the power of the surface tide. From this, Munk and MacDonald (1960) estimate that the conversion of energy from surface to internal modes on a global scale may be about 1.5×10^9 kW. Most internal wave energy is contained in the areas of deep ocean, but some of the energy travels into shallow water and is dissipated against the sea bottom. Winant (1974) estimated that the dissipation due to runup of breaking internal waves and surges on the shelves of the world may range between 2×10^5 and 2×10^7 kW.

Wunsch and Hendry (1972) measured currents from an array placed on the continental slope off Long Island, New York, and concluded that the onshore energy flux of internal waves was 6 W/m. Assuming this to be a typical value, they estimated that the worldwide onshore flux of energy would be about 0.7×10^9 kW. A value of about 0.5×10^9 kW for the energy dissipation by internal waves over the world's shelves appears to be a reasonable estimate (Table E2).

Ocean currents, large and small

The kinetic energy associated with large-scale ocean currents is very large compared with the energy in surface waves and tidal currents. Stommel (1958) estimates that the average kinetic energy of currents in the North Atlantic Ocean is about 2×10^{17} J. Flows such as the equatorial and Antarctic Circumpolar currents transport water at rates of 50–200 Sv (Sverdrup = million cubic meter per second). Even the relatively small California current transports about 12 Sv, a discharge that is greater than that of all the rivers and streams in the world. In addition to the surface currents, the world ocean has a surprisingly large circulation of deep and bottom water estimated to be 50 Sv (e.g., Schmitz, 1995).

Intense western boundary currents, such as the Gulf Stream, develop instabilities with horizontal waves or meanders. These meanders form large loops that may close or pinch-off, forming circular eddies or rings. These *mesoscale eddies* are typically 100 km and more in diameter, and since they are in cycloidal balance, conservation of angular momentum causes them to persist for many months to a year or so, as they move thousands of kilometers away from the main current. Eddies that breakoff from the poleward side of the currents have warm-cores and cyclonic rotation, whereas those shed from the equatorial side have cold-cores and anticyclonic motion (e.g., Gill, 1982). The details of the global distribution of the energy in mesoscale eddies is not well known except for satellite observations of western boundary currents. The effects of mesoscale eddies on the continental shelves is poorly understood, although it is known that shelf eddies are associated with wind changes and with coastal promontories (e.g., Davis, 1985).

While the flow of major ocean currents is predominantly in deepwater, their boundaries overlap the continental shelves, and the currents dissipate some of their energy against the shallow sea bottoms. For example, the Guiana (North Brazil) Current, with a volume discharge of about 29 Sv, flows with velocities up to 1 m/s over the 0.5×10^6 km^2 of shelf off the coastlines of the Guianas and northern Brazil (e.g., Fratantoni *et al.*, 1995). The Falkland Current flows with velocities of 25–50 cm/s across the 1×10^6 km^2 of shallow shelf off Patagonia. If the Guiana Current averages 50 cm/s and the Falkland Current averages 25 cm/s, they would dissipate energy at the rate of 0.13×10^9 and 0.03×10^9 kW, respectively. Therefore, it seems likely that the worldwide dissipation of energy from the flow of ocean currents in shallow water may be about 0.2×10^9 kW (Table E2).

Other sources

In addition to generating the ocean's waves, atmospheric winds, and pressures have important local effects nearshore. Pressure fronts generate shelf seiche, and the combination of pressure and wind stress on the water's surface produces local anomalies in sea level that induce circulation of water over the shelf and in submarine canyons. Shelf seiche up to a meter in height or more are common along the Argentine coast (Inman *et al.*, 1962), while the sea level anomalies associated with storm surges may exceed 4 m for severe storms (Pugh, 1987). Also, winds blowing over the coastal zone dissipate energy on beach and sand dunes. On a worldwide basis, this dissipation may be about 1×10^7 kW, and because of the prevalence of sea breeze and other onshore winds, results in a net inland transport of beach sand.

From the foregoing discussion, it appears that the total flux of mechanical energy in the shallow waters of the world is about 5.5×10^9 kW (Table E2). Dissipation and work by one process or another occurs over the entire shelf. The wind-generated surface waves expend their energy primarily nearshore, especially in the breaker zone, while tidal and other ocean currents and internal waves dissipate energy mostly over the outer portions of the shelf. Internal waves, edge waves, shelf seiche, and local winds may produce water motion over the continental shelf and submarine canyons.

Budget of sediment

The coastline is the junction of the realms of terrestrial erosion and marine deposition. Thus, it is the unique singularity between air, land, and sea, and the coastline is the critical datum for dynamical geology.

In 1955, James Gilluly calculated that sediment is now being carried across this boundary at a rate great enough, in the absence of mountain building, to "erase all the topography above sea level in less than 10 million years . . . ," a very short time on the geological timescale. Thus, the supply of sediment associated with runoff from the continents is large, and it has increased during the past 10 million years due to climate variability, especially during the Pleistocene and more recently due to human intervention. The principal sources of beach and nearshore sediments are the rivers that bring large quantities of sand directly to the ocean, the sea cliffs of unconsolidated material that are eroded by waves, and material of biological origin such as shells, coral fragments, and skeletons of other small marine organisms (Figure E4). Also, waves may transport onshore relict sands that were deposited along the inner shelf during lower stands of the sea (e.g., Inman and Dolan, 1989).

Sediment yield increases with the relief of the drainage basin and with decrease in basin size, factors that enhance the sediment flux of small rivers along mountainous coasts (Inman and Jenkins, 1999). Climate, rainfall, and type of geologic formation are also well-known factors in determining sediment yield. Maximum yield occurs for basins in temperate climates that receive an annual rainfall of about 25–50 cm, and decreases for precipitation rates either above or below this maximum (Langbein and Schumm, 1958). In arid climates, the occasional flash floods transport large volumes of sand (Figure E5).

Man's intervention in natural processes is accelerating erosion rates, perhaps by a factor of about two on a global scale (Milliman and Syvitski, 1992; Vitousek *et al.*, 1997). Significant anthropogenic effects began as early as 9,000 years ago with deforestation and the spread of agriculture from the "Fertile Crescent" (e.g., Heun *et al.*, 1997). Man's intervention has accelerated in this century with increased deforestation, expansion of mechanized agriculture, proliferation of dams (Meade, 1996), and since World War II with extensive urbanization of coastal lands particularly in central and southern California. Urbaniza-tion decreases erosion locally, but accelerates streambed erosion in response to the greater frequency and magnitude of peak streamflow due to runoff from impervious urban surfaces (e.g., Trimble, 1997).

The effects of changing climate and sea-level rise have been studied extensively on a glacial/interglacial timescale (e.g., Hay, 1994) and during the Holocene on a millennial scale (e.g., Bond *et al.*, 1997).The effect of decadal scale climate changes on the sediment flux of the 20 largest streams entering the Pacific Ocean along the central and southern California coast was studied by Inman and Jenkins (1999). The annual streamflow ranged from zero during dry years to a maximum of 1.1×10^9 m^3/yr for the Santa Clara River in 1969 with an associated suspended sediment flux of 46×10^6 ton. Trend analyses showed that El Niño/Southern Oscillation (ENSO) induced climate changes recur on a multidecadal timescale in general agreement with the Pacific/North American (PNA) climate pattern: a dry climate extending from 1944 to about 1968 and a wet climate extending from about 1969 to 1998. The dry period is characterized by consistently low annual river sediment flux. The wet period had a mean annual suspended sediment flux about five times greater, caused by strong El Niño events that produce floods with an average recurrence of about five years. The sediment flux of the rivers during the three major flood years averaged 27 times greater than the annual flux during the previous dry climate (see entry *Climate Patterns in the Coastal Zone*).

The effects of climate change are superimposed on erodibility associated with basin geology. The sediment yield of the faulted, overturned Cenozoic sediments of the transverse ranges of California is many times greater than that of the coast ranges and peninsular ranges. Thus the abrupt transition from dry to wet climate in 1969 brought a suspended sediment flux of 100 million tons to the ocean edge of the Santa Barbara Channel from the rivers of the Transverse Range, an amount greater than their total flux during the preceding 25-year dry period. These alternating dry to wet decadal scale changes in climate are natural cycles that have profound effects on fluvial morphology, engineering structures, and the supply of sediment.

Cliff erosion probably does not account for more than about 5% of the material on most beaches. Wave erosion of rocky coasts is usually slow, even where the rocks are relatively soft shales. On the other hand, erosion rates greater than 1 m/yr are not uncommon in unconsolidated sea cliffs and dunes as found on trailing-edge coasts such as the east coast of the United States.

Following initial deposition at the mouths of streams entering the ocean, much of the sand-size portion of terrestrial sediments is carried along the coast by waves and wave-induced longshore currents. The sand carried by these longshore currents may be intercepted by submarine

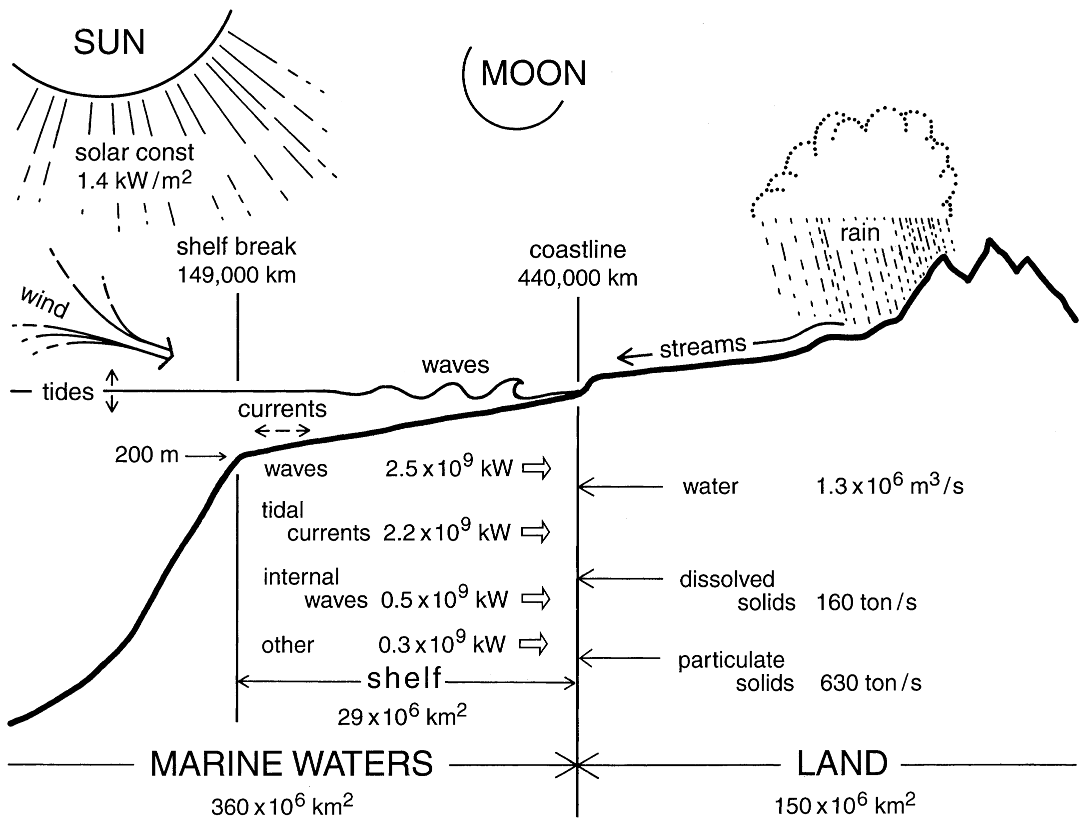

Figure E4 Schematic diagram of budget of energy dissipation in nearshore waters, and the runoff of water and sediment from the land (after Inman, 1973). Data from Tables E1–E3.

Figure E5 Streams carry erosion products from the land to the sea; El Moreno, Gulf of California, Mexico.

canyons that cut into the continental shelf and divert the sand into deeper water offshore. Since submarine canyons occur along most coasts, except those bordered by shallow seas, they probably account for most of the sediment lost into deepwater from the nearshore. Notable among the major sediment transporting submarine canyons of the world are Cap Breton Submarine Canyon on the Atlantic coast of France; Cayar and Trou Sans Fond, and Congo Canyons on the Atlantic coast of Africa; the Indus and the Ganges Submarine Canyons in the Indian Ocean; and the Monterey Submarine Canyon on the Pacific coast of North America. Observations by H.W. Menard (1960) suggest that most of the deep sediments on the abyssal plains along a 400 km section of the California coastline are derived from two submarine canyons: the Delgada Submarine Canyon in Northern California and Monterey Submarine Canyon in central California. These canyons cut the continental shelf almost to the shoreline, and consequently they trap and divert an estimated sediment volume of about 1×10^6 m^3/yr (see entry on *Littoral Cells*).

Traditionally, geologists have estimated long-term erosion and deposition rates from the amount of material deposited during geological time. Such estimates give erosion rates varying from about 1 to 4 cm per thousand years (cm/kyr) for drainage basins of moderate relief to as high as 21–100 cm/kyr for the Himalaya Mountains (e.g., Gilluly, 1955). Assessment of the volume of sedimentary material on the continental United States and in its adjacent seafloors indicates that the average erosion rate of the United States during the past 600 million years was 3–6 cm/kyr (Gilluly *et al*., 1970).

An increasing number of measurements of river discharge have provided an independent estimate of contemporary erosion rates of the land. The importance of large rivers in transporting the denudation products of the continents to the sea has been known since Lyell (1873) described the flux of sediment into the Bay of Bengal from the Ganges and Brahmaputra Rivers. Since then the contributions from large rivers have been updated and summarized in many studies (e.g., Garrels and Mackenzie, 1971; Inman and Brush, 1973; Meade, 1996) with estimates of the total flux of particulate solids to the ocean of about 16×10^9 ton/yr. The importance of small rivers to the global budget of sediment was first documented by Milliman and Syvitski (1992). They showed that small rivers (drainage basin $<$10,000 km^2) cover only 20% of the land area but their large number results in their collectively contributing much more sediment than previously estimated, increasing the total flux of particulate solids to about 20×10^9 ton/yr (630 ton/s) by streams and rivers (Table E3).

Table E3 Estimate of the natural runoff of fresh water and solids from the continents into the oceans and coastal waters of the world

Discharge of water into the oceans from all rivers[a]	1.3×10^6 m^3/s
Flux of dissolved solids[b]	160 ton/s
Flux of particulate solids[b]	630 ton/s
Flux of particulate solids from sea cliff erosion[c]	$>$2 ton/s
Flux of eolian particulate solids[d]	14 ton/s
Average erosion rate of land[b]	6 cm/kyr

[a] Average value (1.1×10^6 m^3/s) from Turekian (1971), Alekin and Brazhnikov (1961), and Holeman (1968) updated in proportion to increase in particulate solids from 530 to 630 ton/s.
[b] Assuming that continental rock of density 2.7 ton/m^3 erodes to form 20% dissolved load and 80% solid particulate load. Assuming flux of particulate solids is 630 ton/s (Milliman and Syvitski, 1992).
[c] Emery and Milliman, 1978.
[d] Windblown dust, volcanic and forest fire ash (Prospero and Carlson, 1981; Rea, 1994; Prospero *et al*., 2002).

Balance of the budgets of power and sediment

The global flux of erosion products from the land to the sea include 160 ton/s dissolved solids and 630 ton/s particulate solids (Table E3). The dissolved solids are incorporated into the 1.3×10^6 m^3/s flow of "fresh" water as added mass. Most of the particulate solids carried by streamflow are fine silt and clay size material that move as suspended load and washload. The remaining solids are sand and coarser material that move mostly as bed and suspended load. Once the stream discharges into the sea, there are significant differences in the transport paths of the suspended and bedload sediment. Most of the fine suspended sediment moves with the river water and flows out over the sea as a spreading turbid plume, and the sediment, which is subject to flocculation and ingestion by organisms, is eventually deposited in deeper water. The coarser bedload material remains near the river mouth as a submerged sand delta and is later transported along the shore by waves and currents to nourish the downcoast beaches. The few reliable measurements of bedload indicate that it is ca. ≤10% of the total load in large rivers but, in smaller, mountainous streams, may be considerably more (Richards, 1982; Inman and Jenkins, 1999).

It is of interest to compare the global fluxes of energy and sediments into the coastal waters of the world (Figure E4). Since energy provides the capacity for doing work, the flux of energy associated with waves and currents is a measure of their potential to transport sediment. About one-half (2.9×10^9 kW) of the total flux of mechanical energy is associated with currents of various types, internal waves, and turbulence, and this flux acts primarily upon the fine particulate solids that flow out over the ocean surface. The remaining energy (2.5×10^9 kW) is from ocean surface waves and works primarily on sand size solids that are deposited in shallow water. About 85% (535 ton/s) of the particulate solids are fine material, while about 15% (95 ton/s) are sand and coarser.

Waves move sand on, off, and along the shore. Once an equilibrium beach profile is established, the principal transport is along the coast. Theory and field measurements show that the littoral transport rate of sand along a beach is proportional to the energy flux of the incident waves, where the proportionality is a function of the direction of wave approach relative to the shoreline. If 10% of the world's estimated annual wave power at the coast (0.25×10^9 kW) is available for transporting sediment (i.e., the wave breaker angle is about 5°), the waves have the potential to transport the entire sand size load of solids in the world's streams (95 ton/s), a distance of 750 km along the coast each year. Thus, even under the inefficient coupling that exists in nature, it is apparent that the potential for sediment transport in nearshore waters is large.

ENGINEERING APPLICATIONS OF COASTAL GEOMORPHOLOGY

Coastal geomorphology

Literally, the title "geomorphology" comprises earth, shape and science with global aspects in that order. The study of earth science, from the strictly biblical concept of evolution to modern applied geomorphology, has been a long process in itself. In a generic term, geomorphology is indisputably a part of geology, but in institutional affiliation it has been a course in geography in almost all countries around the world. Coastal engineers have also contributed to its development in more recent time. Traditional geomorphology is concerned with the local landforms on the earth's surface and their processes over time. Coastal geomorphology, as a branch within the traditional geomorphology, is a relatively new discipline. It explores the relationship between coastal landforms and their processes affected by factors associated with climatology, oceanography, fluid mechanics, sedimentation, and geophysics.

Before the World War II, geomorphology—including coastal geomorphology—was largely Davisian, based on the concept of cyclic development and erosion, and of Johnsonian, in which the details in short-term coastal changes were ignored. Both approaches considered only the changes in vast stretches of time and space, and were once regarded as a "rather academic and, literally useless approach to coastal geomorphology" (e.g., Pethick, 1986, p. 235). Although these concepts had suffered a major change during the War, their influence can still be traced.

Beginning in the 1940s, detailed work and examples of applied coastal geomorphology have emerged. By the 1950s, the approach had become process-oriented. This advanced further, especially in the 1970s and 1980s. Since then, numerous reports have become available resulting from the work carried out by coastal engineers on various coastal problems around the world.

Between the 1950s and 1980s, another almost universal approach taken by coastal geomorphologists was to attempt a classification of coastal landforms—to recognize and describe coastal features. During this period, some major classifications on coasts were: (1) *submerged*, *emerged*, and *neutral* coasts due to past sea-level variations, (2) four regional types based on plate tectonic theory, (3) *primary* and *secondary* coasts based on the influence due to terrestrial agency or marine processes, (4) *high*, *moderate*, and *low-energy* beaches, (5) *east coast* and *west coast* environment depending on the relative location of the landmass, and (6) *storm* versus *swell* wave environments based on the level of wave energy inputs. However, applications of coastal geomorphology to stabilize eroding beaches were scarce.

Despite the diversity of these technical classifications, it is obvious that many physical features, in terms of the material and the types of physiographic units, can readily be identified along the ocean's edge. These include cliffs, rocky coasts, gravel beaches, sandy beaches, estuaries, deltas, lagoons, coral reefs, salt marshes, muddy fields, and mangrove swamps. For the sandy beaches, notable forms are beach cusps, salients and tombolos, spits, barrier islands, river mouth bars, straight beaches, and especially, curved or headland-bay beaches. These distinct landforms are produced by variable interactions due to the prevailing oceanographical and meteorological factors, as well as the geology of the physiographic units. Davies (1980) has demonstrated a global viewpoint between the orientation of a sandy beach and the direction of the persistent swell waves, resulting from the global wind system. Unfortunately, many basic textbooks in coastal geomorphology and engineering have continued to handle the beach processes at a local level without mentioning its global ramifications. Coastline curvature has been cited in some texts, but no further studies were made on its usage.

Geographers have been attracted by the similarity in the shapes and profiles of various landforms in order to find an appropriate mathematical expression to fit these shapes. This may be seen in the classical examples found in hill slopes, glacial valleys, and the longitudinal profiles of rivers. Researches on coastal landforms have produced a parabolic equation for equilibrium beach profiles (Dean, 1991) and a logarithmic spiral equation for the planform of headland-bay beaches (Yasso, 1965). The latter was widely accepted by geographers and engineers since its inception, until Hsu and his co-workers critically assessed it in the late 1980s. Summary of the development in bay beaches and its applications for shore protection can be found in Silvester and Hsu (1993, 1997).

Headland-bay beaches

The coastline along the boundary between the land and the sea may be either straight over a large length or curved in plan separated by headlands, natural or man-made. The curved beaches are aesthetically beautiful and much more stable, compared with their straight counterparts. They may be fully exposed to waves, partially sheltered or fully protected by natural headlands or engineering structures.

General characters of headland-bay beaches

Of the curved beaches, some may be curved gently, others more indented, or with secondary features along its length. This unique geomorphic feature is ubiquitous not only on oceanic margins, but also on coasts of enclosed seas, lakes, and river foreshores. The bay beaches formed between natural headlands on the coasts can be easily identified on nautical charts, maps, aerial photographs, remote-sensing images, and even in travel brochures. They also appear downcoast of groins, and as salient or tombolo in the lee of protruding headlands, detached (offshore) breakwaters, and breakwaters for harbors. These curved beaches are found in various shapes and sizes, in relation to the prevailing waves and natural outcrops or headlands. The curved planform is produced by the persistent swell waves diffracted from the tip of a headland, combined with wave refraction and a nearshore current circulation system in the lee of the headland.

The curved or embayed beaches have attracted numerous names (Silvester and Hsu, 1993), such as zeta curved bays, half-heart shaped bays, crenulate shaped beaches, logarithmic spiral beaches, curved or hooked beaches, headland-bay beaches, pocket beaches, and offset coasts. Despite their richness in existence and variety in names, stability of bay beaches was not fully tested by geographers and coastal engineers.

Since sandy beaches are constructed by persistent swell waves, their high-tide shoreline orientations are expected to align with the crest lines of these waves. Consequently, a series of asymmetrically curved bays can be found in many places. For example, they can be observed from Sydney to Fraser Island in eastern Australia, from Ilha de Santa Catarina to Rio de Janeiro in Brazil, and in other places. In these regions, the zeta shaped beaches have curved southern ends where they display a lower berm with finer sand particle and less steep beach faces than their straighter and more exposed northern ends. The consistency of coastline indentation and orientation can also be found in other continents around the world. It has taken some decades for this early recognition of bay shapes to become useful for stabilizing beaches in erosive conditions (Silvester, 1979).

Silvester (1960) has questioned whether a bay beach is a stable physiographic feature. He believed that the orientation of the bay beaches is nature's method of balancing wave energy and load of sediment transport. In this manner, beaches have been maintained in position for tens, or even hundreds of years. The orientation of these bays also serves as an excellent indicator of the direction of net sediment movement along the coast. This macroscopic view of the coast imposed by nature is an integrated part of the coastal geomorphology, in addition to the microscopic view of wave kinematics and sediment movements in the marine environment.

Before the stable bay shapes can be applied for useful purpose, its planform has to be quantified and its stability assessed. In geomorphic term, the stability of a bay beach (Figure E6) may be in *static equilibrium* or *dynamic equilibrium*, or even *unstable*. A bay beach is: (1) stable and in *static equilibrium*, if the littoral drift is negligible or supply from upcoast is nonexistent, or (2) stable but in *dynamic equilibrium*, when the littoral drift is still being supplied from upcoast and/or from sources within the bay, or (3) *unstable*, implying potential retreat due to imbalance of sediment input and output. While sand supplied to the system is balanced by that which can be removed by oblique waves, a bay beach can remain in place for decades in dynamic equilibrium. However, this is a rare case today. On the other hand, should supply decrease, due to various reasons to be discussed later in "Causes of man-made erosion," the high-tide shoreline will recede toward the static equilibrium shape, which is the final limit without the impediment of shoreline protection structures.

Three major mathematical expressions have been proposed to fit the planform of bay beaches since 1940s. They are: (1) the logarithmic spiral equation suggested by Krumbein (1944) and quantified by Yasso (1965), (2) the parabolic equation for bays in static equilibrium given by Hsu and Evans (1989) and later reassessed by Silvester and Hsu (1993), and (3) the hyperbolic-tangent equation suggested by Moreno and Kraus (1999). These empirically derived equations have different coordinates systems and origins, and controlling parameters related to bay orientations.

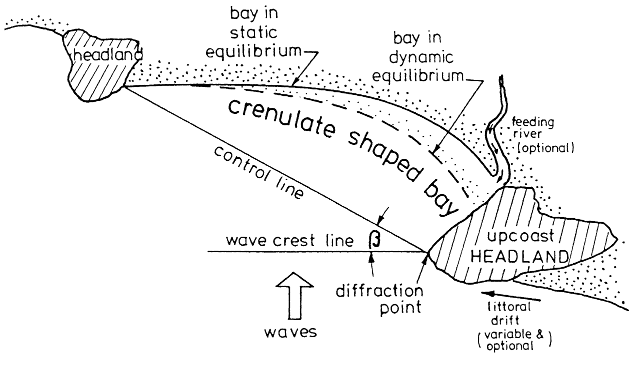

Figure E6 Headland bay beaches in dynamic and static equilibrium.

With a computer, all three methods can be applied to fit the planform of any bay beach (Moreno and Kraus, 1999). But there are some important differences, especially, in the recognition of the point of wave diffraction, the location of the coordinates origin, and beach stability requirement. The log-spiral and hyperbolic-tangent shapes have some drawbacks. First, their coordinate origins do not coincide with the tip of the headland (e.g., the point of wave diffraction). Second, these methods do not address the issue of beach stability or their equations were not produced from bays known in static equilibrium. Third, these two methods do not provide the resultant beach parameters, such as radii and angles, to ease potential applications. As such the log-spiral and hyperbolic-tangent forms cannot determine the effect of sheltering and future extension of any existing headland, or to predict the environmental effect of a new headland or structure on a bay beach.

Parabolic equation for bay beaches in static equilibrium

Hsu and Evans (1989) developed a parabolic equation to fit the peripheries of 27 cases of bay beaches believed to be in static equilibrium in prototype and model conditions. This equation is more preferred than the log-spiral and hyperbolic-tangent equations for the reasons mentioned above. The equation is reproduced here for further discussion:

$$R/R_0 = C_0 + C_1(\beta/\theta) + C_2(\beta/\theta)^2 \qquad \text{(Eq. 1)}$$

There are two independent parameters in equation 1. The first is the *reference wave obliquity angle* β, or the angle between the incident wave crest (assumed linear) and the *control line*, joining the upcoast diffraction point to the near straight downcoast beach. The second basic parameter is the *control line* of length R_0, which is also angled β to the tangent at this downcoast beach end. The radius R to any beach point around the bay periphery is angled at θ from the same wave crest line radiating out from the point of wave diffraction. The three C constants that vary with angle β were generated by regression analysis to fit the peripheries of the 27 data bays used. Examples of bay shape verification can be found in Hsu and Evans (1989) and Silvester and Hsu (1993, 1997). Flexibility in choosing the downcoast control point is a merit of this empirical approach.

Despite having variable dimensions and indentations between the tip of the headland and the downcoast sandy boundary, the stability of a bay beach can now be determined using this parabolic bay shape equation. Values of the non-dimensional ratios of R/R_0 versus increments of 1° or 2° of β from 20° to 80° can be tabulated. This facilitates potential applications to locate the pairs of (R, θ) manually without the need of a computer, once β and R_0 are determined from maps or aerial photographs. When points of (R, θ) are drawn on the plan of the existing beach, the nearness of the existing bay shape to that predicted for static equilibrium can be compared and the beach stability assessed. If the predicted curve, for a hypothetical static equilibrium, is landward of the existing beach, the bay beach is said to be in dynamic equilibrium, or it may become unstable, for diminishing sediment supply.

Beach erosion and conventional protection methods

Continuous conflict has taken place between humans and nature over the narrow belt directly landward of the coastline of the world, where human pressure has been extensive. Within the flat ribbons of sand, between the sea and the hinterland, there are numerous problems of coastal flooding and beach erosion.

Causes of human-induced erosion

The phenomenon of coastline changes are often complicated by oceanographic and meteorological effects on the inherent geological factors (form and material). With swell waves, nature helps move sediment landward to build up the berm and dune, while storm waves transport a large quantity of material to form a protective bar, causing beach disappearance. If waves approach a beach obliquely, a longshore current is induced, which promotes longshore sediment transport, or *littoral drift*. Compared with other landforms on the earth, which have evolved over a vast stretch of time and space, changes in high-tide shoreline positions and variations in beach profile may take place in a matter of hours. It is within this relatively rapid timescale in topographical change that has attracted the attention of many geographers and coastal engineers.

Coastline changes may be produced naturally or human-induced. Natural causes to beach erosion may include wave obliquity, storm attach, wind blown sand, existence of natural headlands, imbalance of sediment transport due to various topographical features, and sea-level rise. Although beach erosion has occurred naturally in many places, the problem is more serious due to the activities of people on the narrow coastal strips locally or elsewhere. Overall, the major causes of human-induced erosion may due to: (1) disturbance to continuity of littoral drift, (2) wave sheltering by coastal structures, (3) offshore movement of sediment, (4) reduction in sediment supply from upcoast, (5) dredging or extraction of sand and gravel for construction, and (6) land subsidence (Uda, 1997; Hsu *et al*., 2000). Among these, human intervention in and interception of sediment supply have been considered two of the most detrimental factors causing beach erosion in many countries around the world. However, some sources of erosion may be originated from a distant place away from the destination—the beach in erosion. For example, damming a river (for flood control, water supply, or power generation) reduces sediment supply to the beach. More recently, breakwater construction for fishing harbors and commercial ports have also caused beach erosion downcoast, with harbor planners and many consulting engineers responsible for the problems they have caused without considering the geomorphic effect on the beach.

Conventional coastline protection methods

The family of seawalls (including bulkheads, revetments, sea dikes, and normal seawalls) were the very first structures ever constructed on a coast for protection against beach erosion and coastal flooding. They are built parallel to the beach at variable locations in relation to the local beach and surf. Their faces fronting the wave action may be vertical or inclined, with or without armor protection. They may even incorporate wave dissipation blocks near and in front of their toes, to reduce wave energy that causes scouring to the bottom at the toe. Beach flanking immediately downcoast of a long seawall is also common, for which some protection is still required.

Later groins were used to intercept littoral drift at places where erosion had occurred. They usually run normal to the beach and may reach out to the limit of the surf zone. Their length and height vary depending on the purpose they meant to serve. This type of structure has been widely used in many countries. Modern groins may be slightly curved, inclined to the local shore, or even in L-, T-, and Y-shaped or fishtailed. A bay beach may form downcoast of a protruding groin or between two units, where the tip of the upcoast unit serves as the point of diffraction, or upcoast control point for the bay beach so formed.

After groins, construction of detached breakwaters has become popular worldwide. They are either single or mostly in groups, with sandy salient or tombolo formed in their lee. In Japan alone, there were 7,371 units of such structures around the country by 1996, totaling 837 km (MOC, 1997; Hsu *et al*., 2000). However, a new trend in Japan has been to replace them with submerged structures or artificial reefs, for aesthetic reasons.

More recently, beach nourishment has become the most "cost-effective" alternative for coastal protection and creating recreational beaches, especially in the United States (Bird, 1996). Often the beach fills were not protected by suitable structures, so replenishments were required at relatively frequent intervals. It has been envisaged that the cost of maintaining a wide beach would increase due to transporting the material from a distant source. In some cases, beach compartmentation was implemented.

Engineering applications of coastal geomorphology

A trend has recently emerged in applying the principle of coastal geomorphology, especially the concept of stable bay shape, for beach protection. Examples showing a range of other engineering applications can also be found in the literature (Silvester and Hsu, 1997).

Stability verification for existing bay beaches

With the parabolic bay shape equation (Hsu and Evans, 1989), it is now possible to verify the stability of an existing sandy bay beach. The general procedure is as follows (refer to equation 1, with Figures E6 and E7):

1. Draw a tangent from a point (referred to as the *downcoast control point*) on the straight downcoast section of a bay beach, and relocate this tangent to the point of wave diffraction (the *upcoast control point*), thus representing the *wave crest line* in the definition sketch (Figure E7),
2. Denote the *control line*, by joining the upcoast and downcoast control points, assign the distance between them as R_0; also measure the reference obliquity angle β,

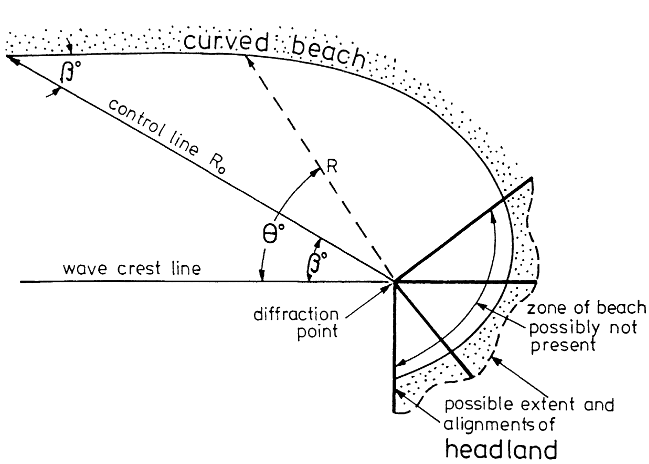

Figure E7 Definition sketch for a parabolic bay shape in static equilibrium.

3. Calculate the values of radii R for a range of corresponding angle θ (for $\theta > \beta$), using equation 1 or a prepared table of R/R_0, so to give sufficient pairs of (R, θ) on the beach,
4. Sketch the predicted bay shape in static equilibrium by joining the points (R, θ) drawn on the existing beach planform,
5. Determine the stability of the existing bay beach by its nearness to the curve given by the prediction.

Should the existing bay shape conform well to the predicted bay shape in static equilibrium, the beach is said to be in *static equilibrium* under the prevailing swell condition. On the other hand, if the existing shape is seaward of the predicted curve, the beach is in dynamic condition, implying either in *dynamic equilibrium*, when sediment balance is maintained, or *unstable*, should sediment supply decrease. However, it must be remembered that the stable high-tide shoreline being predicted applies to swell condition or calm weather. When storm waves arrive, the beach berm will be eroded and material transported offshore to form a submerged bar, which may take some days or longer to return. In the case of static equilibrium, the same high-tide shoreline may result later, but all infrastructures should be kept landward of the receded storm limit.

The stage of bay beach stability may be switched between static and dynamic equilibrium. It can be either from a dynamic to another dynamic condition, or from a dynamic to static, or from static to a dynamic condition, depending on the initial condition of the bay beaches and variability in sediment balance and construction or extension of breakwater (Hsu and Silvester, 1996). This concept of interchange ability for beach stability is extremely useful for practical applications. For example, it can be applied to: (1) the environmental impact study upon constructing or extending a jetty or breakwater within a bay beach in static equilibrium, and (2) the stabilization of a bay beach in eroding condition by locating the tip of a new headland to be installed at a proper location. In these situations, a stable bay beach in static equilibrium is created, thus minimizing the need for protective structures to be constructed downcoast later on.

Any new attempt to construct a jetty or breakwater for a marina or harbor at or within a bay beach already in static equilibrium will result in accretion in the lee at the expense of erosion downcoast, unless certain preventive measures are in place. This natural reshaping will take place within the entire embayment upon the construction of a new headland, despite some modest attempts with seawalls, groins, and detached breakwaters to prevent its fruition. On the other hand, should an engineering task be to construct a breakwater within a bay in dynamic equilibrium; the beach can conveniently be converted into static equilibrium by choosing a proper location for the tip of the new structure. This geomorphic approach of preventing beach erosion should benefit the community as a whole, in addition to the traditional engineering need for providing calm waves within a harbor.

Stabilizing eroding beaches

To combat widespread beach erosion, conventional methods have been used as mentioned in the previous section. Instead of constructing hard structures to defend the eroding beaches, it would be better to create a coastal environment in which the beach can protect itself by the formation of bays to meet the condition of diminishing littoral drift. This requires the reorientation of local high-tide shorelines to produce minimal or null littoral drift within the embayment. The concept is termed *headland control*, in which artificial headlands are used to help reorient the high-tide shoreline parallel to the crest lines of the prevailing swell waves. The concept can be applied to stabilize all shapes of eroding high-tide shorelines, be they straight, bayed, or convex in plan (Silvester and Hsu, 1993, 1997). The artificial headlands may be either one of the conventional protective structures of groins and detached breakwaters with large spacing, or in combination. This can also be used to help retain beach fill staying longer on a renourished beach.

On a straight coast, a system of groins and/or detached breakwaters at close intervals has been used in many countries around the world. The concept of headland control can be applied to modify the conventional protection scheme already in place by removing some units thus widening the distance between them, or to install new headlands if protection did not exist. However, the most important difference, in the headlands used in the conventional defense and the present *headland control*, is in the distance between two adjacent units and their relative orientation to the coast. For a stable beach to form in the vicinity of these artificial headlands the space between two units must be sufficiently large, often to several wave lengths, thus allowing a beach so formed to dissipate wave energy naturally under swell wave condition. The new beach should also have sufficient width and volume of material to satisfy the need of a design storm condition. Flexibility in varying the length, shape, distance offshore, and orientation of each unit would help optimize the performance of a stabilization scheme.

For a bay beach suffering erosion, due to reduction in supply upcoast and new breakwater construction for a harbor within an embayment, adding artificial headlands at appropriate locations can create several smaller bay beaches in static condition. The planform of these stable bays in static equilibrium can be sketched after simple calculations using equation 1, or aided by a prepared table of R/R_0.

On an eroding convex coast, such as a barrier beach or spit, its narrow section may be overwashed or breached by storm waves accompanied by storm surge. Most barrier beaches have retreated in the past decades due to the supply from upcoast being drastically reduced. Attention should be given to a geomorphic solution rather than by hard structure alone. A series of stable bay beaches is preferred to a system of groins. The headland control concept allows the units to be installed with variable length, inclination to the coast, distance offshore, and spacing between units. The distance offshore and space between units should be gradually reduced in a cascade manner, thus allowing the local coastal processes to approach natural conditions. The reference wave obliquity angle β used in equation 1 for the successive bays formed between headlands should vary, being greater at the farther downcoast, where closer spacing is also desirable.

Salient planform behind single detached breakwater

Waves diffract and refract in the lee of a detached breakwater and produce a nearshore current circulation system extending beyond the region of the shadow zone covered by wave diffraction. Consequently, sand accumulation in the form of salient or tombolo may occur behind the breakwater, depending mainly on the material available, the length of breakwater and its distance offshore from the original high-tide shoreline. Hsu and Silvester (1990) have demonstrated that the distance of the salient apex from the breakwater is preferred to that from the original high-tide shoreline, since the former relates more to the wave energy input and the effect of wave diffraction. Previous studies using the latter have resulted in unacceptable scatter when plotting the salient dimension versus the ratio of breakwater length and distance offshore.

They also illustrated that the curved beaches so formed can be related to the bay shape in static equilibrium, for which equation 1 can be applied. The analysis is limited to the case of normal wave incidence. The accretion assumes a parabolic form to a theoretical apex whose position can be determined using the dimensionless ratio of offshore distance to the length of the breakwater, for which a table has been available (Silvester and Hsu, 1997). This accretion is at the expense of the material beyond the extremities of the detached breakwater, and hence erosion at beaches downcoast. The final waterline at some distance either side of the breakwater will recede landward, implying beach erosion in this vicinity. However, to the knowledge of this author, this distance between the original high-tide shoreline and the receding one has not been fully quantified whether in laboratory experiments or in field conditions.

In the case of a salient formed in a multiple detached breakwater system, an accurate prediction method is not available. An attempt was made to analyze the planform using the same dimensionless ratios, as for single detached breakwater, and the gap width between units. However, the correlation based on the field data of the salients and tombolos collected in Japan did not yield reliable results for practical applications (Hsu and Silvester, 1989).

Stabilizing beaches downcoast of harbors

Many new harbors of variable capacities were constructed on coasts where no natural shelter is available, such as coastal indentation, offshore islands, headlands, capes, barrier spits, or reefs. This requires an initial breakwater to be built and possibly some extension over time as further commercial expansion demanding a large port, hence longer and larger structures. Even until recent time, harbor engineers and planners have considered that the construction of a harbor has priority over coastline evolution downcoast. They have often ignored the principle of geomorphology that would cause beach accretion in the lee of offshore breakwaters and erosion downcoast. Coastal scientists in Greece, Italy, Japan, and the United Sates have reported adverse effects on downcoast beaches (Silvester and Hsu, 1997).

Similar to the sand accumulation behind single detached breakwaters, salient forms in the lee of a harbor breakwater, inevitably cause beach erosion downcoast and a possible silting of the refuge basin at the entrance. Compared with the case of single detached breakwater, a harbor breakwater does not have a clear middle point along its longitudinal axis. With the need for a breakwater to be extended over time due to commercial demand for a larger port, it will produce a larger salient in the lee, and hence erosion further downcoast (Hsu *et al*., 1993).

Hsu and Silvester (1996, p. 3986) have examined the situation of stabilizing beaches downcoast of harbor extensions. They believe that

> In geomorphologic terms, the sandy shoreline of a bay downcoast of a harbor may be stable or in static equilibrium, or could be in dynamic condition, if sediment is still being supplied from upcoast or from downcoast to form a salient predicted by a static bay shape equation. Should commercial expansion demand a larger port, the general solution is to run a breakwater form the headland or existing structure. This has the potential to create a new static equilibrium beach, often with accretion in the lee at the expense of beach erosion downcoast. It is strongly recommended that geomorphic approach be incorporated to stabilize downcoast beaches early in the planning stage of a harbor, or as remedial measures. By creating bay beaches in static equilibrium, the potential beach erosion downcoast of a harbor will be kept to a minimum or may be prevented completely (Hsu and Silvester, 1996).

Thus, instead of employing the conventional coastal protection method, in which seawalls, groins, and detached breakwaters were used without much success after the erosion downcoast has become serious, bay beaches of variable sizes should be considered to stabilize the eroding beaches. The geomorphic approach, involving the construction of stable bay beaches aided with beach nourishment, can be regarded as a permanent solution for this occasion. With the macroscopic view of the whole coastline rather than looking at a limited section, a better picture of the erosive problem will become clear. As such, erosion can be predicted long before it is likely to take place, and hence means can be devised to prevent it. Case studies have been reported for harbors in Australia, Japan, Taiwan, and South Africa (Hsu and Silvester, 1996).

Designing recreational beaches

With the economic development around the world there is a community movement demanding a better coastal living environment and full utilization of the coastal zone. As a result, many artificial beaches have been constructed for recreation and tourism, as well as for the restoration of eroding beaches.

Silvester and Hsu (1997) have detailed the requirement for the creation of a stable bay shape for artificial and recreational beaches. One basic requirement is to construct suitable protective structures for preventing sediment loss from the artificial beaches and for providing a calm wave environment. Detached breakwaters with beach nourishment and/or groins have been used in all the cases so far reported in the literature.

Around the mid 1980s, two major Japanese ministries responsible for the preservation and protection of the coast against natural and man-made disasters launched two similar beach protection schemes incorporating hard structures and artificial beaches. These were the coastal community zone (CCZ) projects administered by the Ministry of Construction and the integrated shore protection system (ISPS) under the Ministry of Transport (Hsu *et al*., 2000).

Most of the beaches so designed are either partially or fully enclosed cells behind offshore breakwaters or between them, hence the term *pocket beaches*. Berenguer and Enriquez (1988, p. 1412) have observed that: "In the recent years, the increase of pocket beaches has been remarkable. In Mediterranean countries where tidal effects are insignificant, especially in Spain, Italy, France, and Israel, this system of beach regeneration has been widely used because of its rapid results and its economical nature. Japan also has a lot of experience in this kind of work. In Spain, there are over 40 beaches of this kind. They are usually situated on stretches of coastline where there is a lot of tourism and in which there is also a fairly rapid erosional process …"

Coastal management and planning

People have used public beaches for various purposes. But, many beaches around the world are still being subjected to erosion, due to improper coastal practices, human greediness and local political pressure for the convenient use on the narrow coastal strips. Coastal protection has also arisen from improper coastal zoning for residential and public development too close to the edge of the ocean, without knowing the stability of the beach involved. Many coastal communities have paid an expensive price through this experience of combating with the recurrent erosion problem. Another example is that landscape architects and consultants, who may not be familiar with the principle of coastal geomorphology, are engaged by an authority to beautify the coastal strips for tourism. Some of the additional facilities so created may fall prey to a storm, so the taxpayer's money is wasted.

It is essential in modern coastal management that beach managers in coastal communities be able to apply the principle of coastal geomorphology, and "to examine such questions as where the beach sediment came from, whether it is still coming, and whether the beach is stable, or shows long-term accretions or erosion, as distinct from short-term cut and fill or seasonal alternations." (Bird, 1996).

For any development proposal on a bay beach, the stability of the existing beach should be investigated, prior to giving permission for residential development or structures to be built close to the water. The concept of the stable bay shape of Hsu and Evans (1989) is readily applicable to such cases, without the need of engaging in an expensive and time-consuming exercise, such as physical modeling and computer simulations. If the bay beach is in a dynamic condition, residential development and infrastructures should not be allowed seaward of the predicted static bay limit, plus a little buffer for a storm. Even if the bay is already in static equilibrium, a buffer distance is also required for a storm to act in the future. This would save the need for costly protective measures to be built later. A full investigation may then be carried out only after the preliminary desktop study using the principle of coastal geomorphology, if an elaborate exercise is still warranted.

Geomorphic engineering: a future perspective

Coates (1980) has designated a specific term of *geomorphic engineering* to combine the fields of geology, engineering, and environmental science together, which used to work independently on coasts. It is also important that biological processes in coastal geomorphology be considered. The traditional single task of coastal protection should gradually be replaced by the preservation of the coastal environment, by creating stable and safe beaches to coexist with nature. It is in such a manner that a careful balance among the conflicting requirements of protection, development, and conservation can be met, with planning and management using coastal geomorphology fulfilling the central role.

ENVIRONMENTAL QUALITY

Introduction

Marine environmental quality has been defined by Harding (1992, p. 23) as "the condition of a particular marine environment (coastline, estuary, bay, harbor, nearshore and offshore waters, open ocean) measured in relation to each of its intended uses. It is usually assessed quantitatively and requires both indices of condition and change, and established guidelines and objectives set by environmental, health, and resource agencies." The assessment of coastal marine environmental quality typically considers the intrinsic value of the environment as well as whether the environment supports certain intended uses such as swimming, shellfish harvesting, or mariculture. As noted by Harding (1992), it is necessary to investigate ecosystem attributes (e.g., primary productivity, biomass production, nutrient cycling, species diversity, and disease incidence) to accurately measure ecosystem changes due to multiple stresses, particularly those associated with pollution and physical habitat disturbances, which can greatly impact environmental quality of coastal systems. It is important not only to determine that ecological change has occurred by evaluating structural characteristics but also to understand the processes forging change in the state of ecosystems (e.g., eutrophication).

The coastal zone is a transition area encompassing both terrestrial and marine components where the interaction between the land and sea is both intense and dynamic (Sorensen and McCreary, 1990). Investigations of environmental quality in this critically important zone, therefore, must consider estuarine and coastal marine waters together with neighboring watersheds, which, are closely coupled to them. Because more than half of the world's human population resides within ~60 km of the coast (Goldberg, 1994; Alongi, 1998), many valuable coastal habitats (e.g., wetlands, estuaries, beaches, and the nearshore ocean) are threatened by escalating land development, urbanization, industrial expansion, and maritime activities. More specifically, contaminant inputs from point and nonpoint pollution sources, as well as the physical alteration and destruction of habitat due to shipping, marine transportation, marine mining, energy production (oil and gas recovery, and electric power generation), fisheries exploitation, aquaculture, coastline development, and other types of human intervention, have degraded environmental quality of the coastal zone. Overuse or misuse of coastal resources, such as overfishing and excessive marine mining, can severely deplete resources beyond the limits of sustainability. Poorly conceived development control programs and inadequate resource management have contributed greatly to many of the acute and insidious environmental problems observed in this zone.

Deficient fisheries management provides an example. Strong evidence exists that the annual global fisheries catch of more than 80 million mt is approaching the maximum production obtainable; ~90% of this catch derives from coastal areas (Barcena, 1992). In addition, 35% of the 200 major fish stocks worldwide are currently classified as overfished. For US fish stocks where sufficient data have been compiled, more than 40% are overutilized (Sissenwine and Rosenberg, 1993). Overfishing reduces fisheries production as well as genetic diversity and ecological resilience (Costanza *et al*., 1998).

Many coastal habitats worldwide are in various degrees of degradation because of heavy human exploitation (Kennish, 1997; Alongi, 1998). Estuaries, beaches, and nearshore oceanic environments support multibillion dollar commercial and recreational activities. Shore tourism ranks among the most profitable industries in the United States. Estuarine and coastal marine fisheries contribute more than $20 billion annually to the US economy, and they supply employment for more than a million people (Pirie, 1996; Kennish, 2000). Most US commerce (98% by volume) is transported by water, with much of the goods passing through estuarine and marine waters (Kennish, 2000). Marine oil and gas production amounts to ~$16 billion annually (Pirie, 1996). The mining of sand, gravel, salt, phosphorite, and tin from beaches and nearshore marine substrates also supports multibillion dollar industries (Cronan, 2000; Pinet, 2000).

Stemming directly from human dependence on and usage of coastal resources and an often cavalier concern for conservation and long-term sustainability, shallow water estuarine and marine ecosystems—particularly in urbanized regions—are susceptible to multiple stressors (Yap, 1992; Kennish, 1997). While many adverse effects on these ecosystems are linked to development along the coast, activities in watersheds far removed from the coastal zone (e.g., dam construction, stream channelization, and careless land-use practices) can also be detrimental (McIntyre, 1992). Some local impacts may even originate from global sources, as in the case of certain widely distributed chemical contaminants (e.g., PCBs, lead, and radionuclides) delivered via atmospheric deposition. However, a global approach to maintaining marine environmental quality has not been effectively formulated. Currently, a patchwork of international and regional conventions, protocols, agreements, national laws, regulations, and guidelines exists to protect marine environments, although a comprehensive global marine environmental management framework is critically needed to preserve the integrity of marine systems (Côté, 1992). Hence, local and regional environmental management programs must be supplemented by an adequate global strategy to ensure long-term protection of the coastal zone (Nollkaemper, 1992). Aside from dealing with issues of science, this strategy must involve socio-economic policy, improved technologies, new educational initiatives, and international cooperation (Boehlens, 1992).

This contribution examines the environmental quality of coastal environments, assessing conditions in estuarine and nearshore marine waters and in the watersheds and airsheds that affect them. Environmental problems commonly encountered in the coastal zone are discussed along with the management programs instituted to remediate them. Furthermore, various measures of marine environmental quality are investigated to provide an analysis of coastal ecosystem health assessment.

Coastal environmental problems

There are multiple stressors in the coastal zone associated with anthropogenic activities that potentially influence environmental quality. These stressors can be divided into two major categories: (1) pollution, and (2) habitat and resource degradation. A vast array of industrial, municipal, and domestic pollutants enters coastal systems from land-based, atmospheric, and aquatic sources. The greatest concentrations of contaminants occur in urbanized and industrialized systems, notably those exhibiting "hot-spot" conditions (e.g., Boston Harbor, New York Bight Apex, Baltimore Harbor, and Puget Sound) (Kennish, 1992, 1997). Pollution is a serious concern because it degrades coastal water quality, causes both acute and insidious impacts on estuarine and marine organisms (e.g., behavioral, genetic, neurological, and reproductive abnormalities; debilitating diseases; and death), exposes humans to increased health risks, and results in diminished human use of coastal resources. Biotic communities inhabiting polluted environments often experience dramatic shifts in species composition, abundance, diversity, and dominance (Pearson and Rosenberg, 1978; Warwick *et al*., 1987; Simboura *et al*., 1995).

Many potentially damaging human activities extend beyond the introduction of pollutants to estuarine and coastal marine waters. Among the most significant are the physical degradation of habitats and overexploitation of living and nonliving resources. The draining of wetlands for land reclamation; siting of resorts, hotels, and marinas for purposes of tourism and recreation; and building of coastline industrial installations and harbors for marine transportation and commercial operations destroy many hectares of natural habitat each year. The loss and alteration of coastal habitats typically reduce vital spawning, nursery, or forage grounds for numerous organisms, and diminish the utility of these areas as sources of food and shelter (Yap, 1992; Kennish, 1997, 2000). When these impacts persist for a considerable period of time over extensive areas, significant changes in biotic communities usually arise, such as reduced species diversity and population abundance.

Overexploitation of living resources, where the rate of harvesting of a target species exceeds its reproductive capacity, has been responsible for the local collapse of fisheries in many regions of the world (Pinet, 2000). Overfishing is resistant to traditional resource management approaches, some of which are based on considerable uncertainty and may be ineffective or inappropriate (Costanza et al., 1998). In regard to nonliving resources, sand and gravel mining and other coastal mineral mining operations adversely affect benthic habitats and communities. In addition to disturbing the benthos, the mining of sand in nearshore areas can impact fisheries, deplete sand needed for beach replenishment, or exacerbate shore erosion.

Pollution

The Joint Group of Experts on the Scientific Aspects of Marine Pollution (GESAMP, 1982), an advisory body to the heads of eight organizations of the United Nations (i.e., UN, UNEP, UNESCO, FAO, IMO, IAEA, WHO, and WMO), has defined marine pollution as "the introduction by man, directly or indirectly, of substances or energy into the environment, resulting in such deleterious effects as harm to living resources, hazards to human health, hindrance to marine activities including fisheries, impairment of quality for use of seawater, and reduction of amenities." Many investigators do not consider this definition to be sufficiently comprehensive because it only addresses those anthropogenic activities that impact the marine environment as a consequence of the introduction of waste substances and energy (Bewers and Wells, 1992). Pollution differs from contamination which occurs "when a man-made input increases the concentration of a substance in seawater, sediments, or organisms above the natural background level for that area and for the organisms" (Clark, 1992). However, the concentration of this substance does not exceed the threshold beyond which measurable damaging effects are manifested.

There are five principal pathways by which contaminants enter estuarine and coastal marine environments: (1) nonpoint source runoff from land; (2) direct pipeline discharges; (3) riverine inflow; (4) atmospheric deposition; and (5) waste dumping (Capuzzo and Kester, 1987; Kennish, 1992, 1997, 2000; McIntyre, 1992). Prior to 1970, point sources of pollution, notably the direct dumping or pipeline discharge of waste materials, accounted for the largest fraction of pollutants in these environments. However, tighter legislative and regulatory controls commencing with passage of the Federal Water Pollution Control Act Amendments in 1972 and subsequent amendments in 1977 (Clean Water Act) and 1987 (Clean Water Act Amendments) greatly reduced point source pollutant inputs to estuarine and coastal marine waters. Most pollutants (>75%) now enter these systems via nonpoint source runoff from land (i.e., dispersed,

Table E4 Point and nonpoint sources of pollution in estuarine and coastal marine environments

Sources	Common pollutant categories
Point	
Municipal sewage treatment plants	BOD, bacteria, nutrients, ammonia, toxic chemicals
Industrial sewer overflows	Toxic chemicals, BOD
Combined sewer overflows	BOD, bacteria, nutrients, turbidity, total dissolved solids, ammonia, toxic chemicals
Nonpoint	
Agriculture runoff	Nutrients, turbidity, total dissolved solids, toxic chemicals
Urban runoff	Turbidity, bacteria, nutrients, total dissolved solids, toxic chemicals
Construction runoff	Turbidity, nutrients, toxic chemicals
Mining runoff	Turbidity, acids, toxic chemicals, total dissolved solids
Septic systems	Bacteria, nutrients
Landfills/spills	Toxic chemicals, miscellaneous substrates
Silvicultural runoff	Nutrients, turbidity, toxic chemicals

diffuse, and uncontrolled sources) and atmospheric deposition (GESAMP, 1990). Non-point source pollution is particularly problematic because it cannot be easily regulated or controlled by land-based technological measures. Moreover, biotic impacts of nonpoint source pollution are difficult to assess. Table E4 lists the types of point and nonpoint sources of pollution, which commonly affect estuarine and coastal marine environments.

Estuarine and marine organisms respond to pollutant inputs in several ways depending on the bioavailability of contaminants; their uptake, accumulation, and disposition in the body; and the interactive effects of multiple contaminants (McDowell, 1993). When exposed to elevated pollutant concentrations, some individuals exhibit acute physiological changes manifested by impaired growth, reproduction, and immunological function. Others display behavioral changes and greater susceptibility to disease. Chronic exposure to pollution stress usually results in marked changes in population structure, including reduced abundance and biomass, increased mortality, and altered age/size distribution. Recruitment of an affected population also may be significantly altered. At the community level, responses to insidious and cumulative pollution impacts frequently include: (1) decreased species diversity, (2) loss of rare or sensitive species, (3) opportunistic species dominance, and (4) shifts in the age structure of longer-lived species (Howells *et al.*, 1990). In addition, trophic interactions can be conspicuously modified.

Thousands of pollutants reach estuarine and coastal marine waters each year from land-based sources. Among the most serious pollutants in terms of potential impacts on environmental quality are halogenated hydrocarbon compounds, polycyclic aromatic hydrocarbon compounds, trace metals, and nutrient elements. The halogenated hydrocarbons (e.g., PCBs, DDTs, CCDs, and CDFs) consist of some of the most ubiquitous, persistent, and toxic substances found in coastal environments. They pose serious health risks to aquatic biota. Similarly, polycyclic aromatic hydrocarbons (e.g., anthracene, fluorene, naphthalene, and pyrene) are widely distributed organic pollutants that in sufficient concentrations threaten broad groups of organisms. A number of these compounds, particularly the high-molecular-weight varieties, are carcinogenic, mutagenic, and teratogenic to many estuarine and marine organisms. Trace metals (e.g., cadmium, copper, lead, mercury, and zinc), when present above a threshold availability, also are toxic to numerous biotic groups. Among the range of pathological, physiological, and behavioral responses observed in organisms exposed to toxic levels of metal contaminants are tissue inflammation and degeneration, neoplasm formation, and genetic derangement; feeding, digestive, and respiratory dysfunction; and aberrant physiological, reproductive, and developmental activity. Table E5 provides a list of many of these priority pollutants, which are now being monitored by the National Oceanic and Atmospheric Administration (NOAA) in US estuarine and coastal marine environments.

One of the most rapidly growing problems in estuaries and coastal embayments of the United States and abroad is eutrophication associated with nutrient loading (Livingston, 1996, 2000). Excessive nutrient inputs, notably nitrogen and phosphorus, can rapidly stimulate phytoplankton growth and lead to toxic or nuisance algal blooms that often degrade water quality by contributing to high oxygen demands in bottom waters and the buildup of toxins (e.g., sulfides). Aside from being linked to oxygen depletion events, algal bloom may directly impact benthic organisms by smothering them or creating deleterious shading conditions. The development of anoxia or hypoxia in shallow embayments ultimately culminates in large-scale mortality of benthic populations and fish and the reduction of useful habitat. In severe cases (i.e., hypereutrophication), imbalances in trophic systems may arise, manifested by acute changes in food web components and the elimination of valuable estuarine and coastal marine species.

Table E5 Chemical contaminants measured in the NOAA National Status and Trends Program

DDT and its metabolites
- 2,4′-DDD
- 4,4′-DDD
- 2,4′-DDE
- 4,4′-DDE
- 2,4′-DDT
- 4,4′-DDT

Chlorinated pesticides other than DDT
- Aldrin
- *Cis*-Chlordane
- *Trans*-Nonachlor
- Dieldrin
- Heptachlor
- Heptachlor epoxide
- Hexachlorobenzene
- Lindane (γ-HCH)
- Mirex

Polychlorinated biphenyls
- PCB congeners 8, 18, 28, 44, 56, 66, 101, 105, 118, 128, 138, 153, 179, 180, 187, 195, 206, 209

Polycyclic aromatic hydrocarbons
- 2-ring
  - Biphenyl
  - Naphthalene
  - 1-Methylnaphthalene
  - 2-Methylnaphthalene
  - 2,6-Dimethylnaphthalene
  - 1,6,7-Trimethylnaphthalene
- 3-ring
  - Fluorene
  - Phenanthrene
  - 1-Methylphenanthrene
  - Anthracene
  - Acenaphthene
  - Acenaphthylene
- 4-ring
  - Fluoranthene
  - Benz(*a*)anthracene
  - Chrysene
- 5-ring
  - Benzo(*a*)pyrene
  - Benzo(*e*)pyrene
  - Perylene
  - Dibenz(*a,h*)anthracene
  - Benzo(*b*)fluoranthene
  - Benzo(*k*)fluoranthene
- 6-ring
  - Benzo(*ghi*)perylene
  - Indeno(1,2,3-*cd*)pyrene

Major elements
- Al, Aluminum
- Fe, Iron
- Mn, Manganese

Trace elements
- As, Arsenic
- Cd, Cadmium
- Cr, Chromium
- Cu, Copper
- Pb, Lead
- Hg, Mercury
- Ni, Nickel
- Se, Selenium
- Ag, Silver
- Sn, Tin
- Zn, Zinc
- Tri-, di- and mono Butyltin

Habitat loss and alteration

Much deterioration of estuarine and nearshore oceanic environments is directly attributable to development along the immediate shore and in coastal watersheds. Here, physical destruction of habitat represents the most overt form of environmental degradation (Linden, 1990; Viles and Spencer, 1995; Alongi, 1998; Kennish, 2000). A multitude of human activities and structures modifies or destroys coastal habitats, chiefly:

- Domestic, agricultural, and industrial construction.
- Wetlands drainage, landfill, and reclamation.

- Grid ditching, dredging and filling, and dredge material disposal.
- Stream channelization (for flood control), canal excavation, and freshwater diversions.
- Mining, silviculture, and mariculture operations.
- Support infrastructure (roads and utilities).
- Dams, reservoirs, dikes, levees, and impoundments.
- Human-induced land subsidence (associated with water, oil, and gas withdrawal).
- Bank protection (bulkheads, revetments, and riprap).
- Shore protection structures (jetties, groins, seawalls, and breakwaters).
- Harbors, marinas, and shoreline installations.
- Moored structures (e.g., docks, piers, pilings).
- Shipping and marine transportation.

Physical habitat impacts are manifested most conspicuously by structural changes in watershed drainage patterns, coastal wetlands, beaches, coastline and bathymetric configurations, and other geomorphological features. These impacts can be exacerbated by nonstructural alterations, such as the introduction of aggressive, nonnative plant species or spills of chemical contaminants. Overall, habitat losses have been dramatic in the coastal zone during the past century. For example, more than 50% of the original tidal salt marsh habitat in the United States has been destroyed by anthropogenic activities (Watzin and Gosselink, 1992). In Long Island Sound, dredging and filling operations were largely responsible for the ~25–35% reduction in tidal wetlands area documented during the 20th century (Strieb *et al*., 1993). Nearly 25% of the original wetlands habitat of the Delaware estuary was eliminated by human activities over the 20-year period from 1954 to 1974 (Tiner, 1985, 1990). Development in the Barnegat Bay–Little Egg Harbor water-shed in New Jersey has resulted in the following habitat losses: (1) 13,731 ha or 20% of the upland forested area between 1972 and 1995; (2) 1,875 ha or 6% of the freshwater wet-lands area during the same period; and (3) 4,200 ha or 28% of the tidal salt marsh area during the past 100 years (Lathrop *et al*., 1999). Most of the tidal salt marsh losses occurred between 1940 and 1970. Since passage of the Coastal Wetlands Law of 1970, the loss of tidal salt marsh habitat in this watershed has decreased to <1.5%. Similarly, vegetated wetlands area in Galveston Bay, Texas, declined by 17–19% between the 1950s and 1989 mainly as a result of dredging and filling, drainage and conversion of land areas, subsidence coupled to groundwater withdrawal, and coast-line modifications (Pulich *et al*., 1991; Shipley and Kiesling, 1994). Direct human impacts accounted for at least 26% of the Louisiana wetland losses observed between 1955 and 1978 (Boesch *et al*., 1994). Of the original tidal marsh area in San Francisco Bay (i.e., ~2,200 km^2), only ~125 km^2 of undiked marsh remains (Conomos, 1979). Diking and filling of wetlands bordering the bay have had a devastating impact over the years. On the southeast coast of the United States, ~11% of the coastal marshes has been diked and flooded for insect control (i.e., mosquitoes and sandflies) and to attract wintering waterfowl (Alongi, 1998). Nearly 10,000 ha of coastal wetlands in the United States are lost each year primarily because of development impacts (Kennish, 2000).

The effects of physical habitat destruction are even greater in many other countries, particularly in developing nations. For instance, ~75% of the mangrove forests in Puerto Rico and more than 50% of the mangrove forests of Southeast Asia have been cleared. Other countries with significant mangrove habitat losses include India, Venezuela, and Ghana. The destruction of mangrove forests in these countries has been principally ascribed to reclamation, timbering, and mariculture (Hatcher *et al*., 1989; Ong, 1994; Eisma, 1998). Reclamation has been responsible for nearly the complete disappearance of natural salt marshes along the mainland coast of the Dutch Wadden Sea (Eisma, 1998).

Physical habitat destruction is perhaps most pronounced at ocean coastline resort areas. Here, heavy development and recreational pursuits significantly alter natural habitats. Developed coasts are replete with coastline high rises, condominiums, and lagoon housing. Global sea-level rise, compounded in some areas by local subsidence (e.g., northern Gulf of Mexico), poses a serious long-term threat to many shore communities. Relative sea-level rise increases the risk of damage from storm surges, hurricanes, and other natural events.

Of more imminent concern along many coasts is reduced sediment delivery as a consequence of increased dam construction and river diversions (Aubrey, 1993). Beach nourishment projects have been instituted nationwide to counter the effects of sand deficits and severe erosion problems. Many marine engineering structures have been erected off beaches to trap sediment moving alongshore (Nordstrom, 1994a,b). These shore-perpendicular features (i.e., groins and jetties), constructed of quarrystone, timber, or a combination of stone and timber, are designed to capture sediment entering from updrift areas. However, they frequently increase erosion downdrift, thereby creating beach problems for neighboring communities. In many regions, groin fields exist to reduce the rate of beach retreat and the seasonal fluctuations in beach profiles over extensive areas. They are blatant reminders of the mounting pressures of shore communities to stave off natural shore retreat.

Shore-parallel structures (e.g., seawalls) also provide an engineering strategy to control the forces of nature. These structures protect beachfront property as well as infrastructure from invasive damage of storm waves, flooding, erosion, and natural disasters (e.g., tsunamis). However, they often increase scour and erosion seaward, and commonly reduce beach width (Kennish, 2000).

Millions of dollars are spent annually in coastal states throughout the United States on beach revitalization programs and for the protection of beachfront structures. Much of this financial support is driven by the multibillion dollar tourism industry. However, future costs associated with beach restoration and shore-protection efforts are likely to escalate with eustatic sea-level rise, which is projected to increase by another 20–115 cm during the 21st century (Woodroffe, 1993).

Marine environmental quality

Pollution and habitat degradation potentially threaten the quality of coastal environments. Because of the dependence of human populations on coastal and marine resources, it is imperative for marine and coastal policy and management programs to formulate strategies that mitigate pollution and habitat loss. This will require a concerted effort on the part of government agencies (federal, state, and local), academic institutions, industries, stakeholders, and the general public to address the myriad of problems occurring in the coastal zone and the measures that must be implemented to restore, protect, and maintain the integrity and health of coastal environments.

Monitoring is vital to assessing marine environmental quality. Harding (1992) advocates a more integrated approach to environmental quality monitoring, incorporating attributes of marine ecosystems that, if impaired, may lead to significant changes in ecosystem structure, rather than focusing on effects at lower levels of biological organization. By monitoring processes (e.g., bioaccumulation, primary productivity, and eutrophication), assessment of the status and trends in eco-system health will lead to the development of more effective long-term environmental management strategies.

Marine environmental quality monitoring

Marine environmental quality monitoring programs should incorporate several components in assessing ecosystem health: (1) analysis of the main processes and structural characteristics of the ecosystem; (2) identification of the known or potential stressors; (3) development of hypotheses about how these stressors may affect the ecosystem; and (4) identification of measures of environmental quality and ecosystem health to test these hypotheses (Harding, 1992). Estuarine and marine monitoring efforts in the United States, Canada, and other developed nations are concentrating on the identification of the sources of stress (e.g., municipal and industrial discharges, ocean dumped materials, and oil spills), biotic exposure to contaminants (e.g., in the water column and bottom sediments), and pollution effects (i.e., on individuals, populations, communities, and ecosystems). Regular monitoring yields the data necessary for status and trends assessment (O'Connor, 1990, 1994; O'Connor *et al*., 1994; O'Connor and Beliaeff, 1995).

An integral component of coastal resource management entails the development of comprehensive environmental quality monitoring programs that supply sufficient data to define the extent and severity of pollution or other anthropogenic impacts and provide the information needed to devise effective measures to protect and rehabilitate the natural environment and its resources (National Research Council, 1990). Hameedi (1997) emphasized that there are two principal reasons for conducting environmental monitoring: (1) to define the status and trends in environmental quality nationwide or in a broad spatial context; and (2) to generate a database to address specific coastal research management needs in a regional or local context. As discussed by Hameedi (1997), the dual-purpose of environmental monitoring requires the implementation of a survey program with a tiered structure based on a sparsely distributed network of stations spread over a broad spatial extent, as well as designated regions embedded within this network of stations that are tailored to support specific coastal resource management needs. In addition, these environmental monitoring programs must include meaningful biological measures of contaminant exposure, contaminant-induced adverse biological effects, and susceptibility of biota to environmental degradation.

Because marine environmental quality monitoring programs are typically designed to describe the condition of the natural environment and the health of its resources, they generally focus on the following: (1) assessment of temporal trends in the levels of environmental degradation due to chemical contaminants and other anthropogenic sources; (2) determination of the magnitude and spatial extent of environmental degradation due to chemical contaminants and other anthropogenic sources; (3) incidence of pathological conditions, physiological dysfunction, and biological abnormalities in sentinel organisms resulting from environmental degradation; and (4) formulation of composite indices or sets of indicators that communicate information about the condition of the natural environment and are tractable toward public policy objectives (Hameedi, 1997). The trend in recent years has been to derive integrated measures of coastal ecosystem health by aggregating water quality and biological measurements in a quantifiable framework. The Index of Biotic Integrity, Ecosystem Distress Syndrome, Sediment Quality Triad, and Benthic Index provide examples (Fausch *et al*., 1984; Chapman *et al*., 1987; Weisberg *et al*., 1992; Hameedi, 1997).

Biological measures are now used more extensively by major marine environmental quality monitoring programs to assess coastal environmental conditions on local, regional, and national scales. Included here are national programs such as the Environmental Monitoring and Assessment Program (EMAP) administered by the US Environmental Protection Agency and the National Status and Trends (NS&T) Program administered by the NOAA (Paul *et al*., 1992; Wolfe *et al*., 1993; O'Connor, 1994). Both of these large-scale, long-term monitoring programs have generated comprehensive databases on temporal and spatial trends in environmental quality of US coastal waters.

National monitoring programs

The National Research Council (1990) stressed a decade ago that regional monitoring of coastal environmental quality is necessary because of the lack of sufficient data to properly assess environmental conditions of coastal habitats nationwide. Two main problems exist with this type of assessment: (1) difficulty in distinguishing natural from anthropogenic-induced changes in condition; and (2) inability to evaluate whether indicators of adverse change and the ecological consequences of such change are consistent over regional-sized areas (Hanson *et al*., 1993). Most of the more than $100 million spent on coastal environmental monitoring in the United States covers the cost of local (site-specific) compliance monitoring (e.g., wastewater discharges) (O'Connor, 1990). However, during the past decade, more effort has been expended on implementing regional and national coastal environmental quality monitoring programs, such as EMAP, the NS&T Program, and the National Estuary Program (NEP).

Environmental monitoring and assessment program

EMAP, initiated in 1990, was developed in response to the demand for information on the degree to which existing pollution control programs and policies protect the nation's ecological resources (Schimmel *et al*., 1994). The principal goal of the coastal and estuarine components of EMAP was to assess the condition of the nation's coastal ecological resources. More specific EMAP objectives were:

1. To estimate the current status, extent of changes, and long-term (decadal) trends in indicators of the condition of the nation's ecological resources on a regional basis with known confidence.
2. To monitor indicators of pollutant exposure and habitat condition and to seek associations between anthropogenic-induced stresses and ecological condition.
3. To provide periodic statistical summaries and interpretive reports on ecological status and trends to resource managers and the public (Paul *et al*., 1992).

The focus of EMAP-Estuaries, in turn, was to measure the status and change in selected indicators of ecological condition in estuaries and to provide a quantitative measure of the regional extent of estuarine environmental problems, most notably sediment contamination, habitat loss, eutrophication, and hypoxia (Kennish, 2000). The EMAP-Estuaries design consisted of seven well-defined regions or provinces in the continental United States (i.e., Acadian, Virginian, Carolinian, Louisianian, Californian, Columbian, and West Indian Provinces), four in Alaska (i.e., Alaskan, Aleutian, Arctic, and Bering), and one in the Great Lakes. Excluding the Great Lakes Province, estuaries in this regionalized scheme are defined by the landward boundary of the maximum inland extent of tide, and by the distal end of the continental shelf. Climatic zones and prevailing ocean currents represented the principal criteria used to establish the boundaries of the provinces (Terrell, 1979; Bailey, 1983; Holland, 1990; Paul *et al*., 1992).

The US Environmental Protection Agency established an integrated sampling strategy for near coastal ecosystems. It coordinated the near coastal component of EMAP, whenever possible, with the NEP and NOAA's NS&T Program. These programs, taken together, have provided for more effective and organized monitoring of environmental conditions that will facilitate delineation of the factors contributing most significantly to coastal environmental problems.

Although EMAP was coordinated with efforts of the NEP and NS&T Program, there are some fundamental differences. For example, sample site selection in EMAP was a vigorously random procedure, whereas the NS&T Program annually sampled at fixed locations. In addition, EMAP did not analyze chemical contaminant concentrations in biotic tissue (i.e., mussels or oysters), as in the case of the NS&T Program. However, both programs surveyed chemical contaminants in bottom sediments of estuaries. The goal of EMAP was to eventually sample and analyze sediments from about 800 sites nationwide, which represents approximately three times the total number of sites sampled by the NS&T Program (NOAA, 1991; Kennish, 1997).

In the case of the NEP, management conferences convened by the Administrator of the US Environmental Protection Agency examine environmental conditions and trends in nationally significant estuaries, identify the most significant problems in these systems, and develop action-oriented comprehensive conservation and management plans (CCMPs) to mitigate human impacts. The CCMPs have two primary goals:

1. To restore and maintain the chemical, physical, and biological integrity of nationally significant estuaries, including restoration and maintenance of water quality, a balanced indigenous population of shellfish, fish, and wildlife, and the recreational activities in these systems.
2. To assure that the designated uses of these estuaries are protected.

There are 28 estuaries which have been identified as NEP sites since 1987 (Table E6) (USEPA, 1994; Kennish, 2000).

Table E6 List of national estuary programs

Albemarle/Pamlico Sound, NC
Barnegat Bay, NJ
Buzzards Bay, MA
Casco Bay, ME
Charlotte Harbor, FL
Corpus Christi Bay, TX
Delaware Bay, DE/NJ/PA
Delaware Inland Bays, DE
Galveston Bay, TX
Indian River Lagoon, FL
Long Island Sound, CT/MA/NY/RI
Lower Columbia River, WA
Maryland Coastal Bays, MD
Massachusetts Bays, MA
Mobile Bay, AL
Morro Bay, CA
Narragansett Bay, RI/MA
New Hampshire Estuaries, NH
New York/New Jersey Harbor, NY/NJ
Peconic Estuary, NY
Puget Sound, WA
San Francisco Bay/Sacramento-San Joaquin Delta, CA
San Juan Bay, PR
Santa Monica Bay, CA
Sarasota Bay, FL
Tampa Bay, FL
Terrebonne-Barataria, LA
Tillamook Bay, OR

National status and trends program

NOAA created the NS&T Program in 1984 to monitor trends of chemical contamination and to assess the effects of human activities on coastal and estuarine systems nationwide. Sediment and biotic samples (bottom-feeding fish and shellfish) are collected from a network of sites located around the coastline of the United States and analyzed for a broad suite of trace metals and organic chemicals (Table E5) (O'Connor, 1992; O'Connor and Beliaeff, 1995). This program investigates the trends of chemical contamination in space and time and determines biological responses to that contamination. The immediate goal is a regional and national assessment of coastal environmental quality (O'Connor, 1990).

The NS&T Program consists of four main components: (1) National Benthic Surveillance Project; (2) Mussel Watch Project; (3) Biological Effects Surveys and Research; and (4) Historical Trends Assessment. NOAA initiated the National Benthic Surveillance Project in 1984 and the Biological Effects Surveys and Research, and the Mussel Watch Project in 1986 (Kennish, 1997). Several biological measures are used to assess the significance of chemical contamination in the coastal zone. NS&T surveys employ these measures (i.e., biological effects in sediments, bivalves, and fish) to ascertain the spatial patterns and extent of toxicity, the prevalence and severity of biological impacts, and the relationships between the measures of effects and the concentrations of chemicals in each survey area. The severity and magnitude of impacts among survey areas nationwide also can be compared using these data (Long, 1998).

Since 1986, the Mussel Watch Project has sampled seven bivalve species nationwide to assess the extent of chemical contamination in US coastal waters. Among these sentinel organisms are the blue mussel *Mytilus edulis* on the East Coast from Maine to (Cape May) New Jersey, the American oyster *Crassostrea virginica* on the East Coast from Delaware Bay southward and in the Gulf of Mexico, the mussel *Mytilus californianus* on the West Coast, the oyster *Ostrea sandivicensis* in Hawaii, the mangrove oyster *Crassostrea rhizophorae* in Puerto Rico, the smooth-edged jewel clam *Chama sinuos* at one site in the Florida Keys, and the zebra mussel *Dreissena polymorpha* in the Great Lakes (O'Connor, 1992; O'Connor and Beliaeff, 1995). Because of interspecies differences in contaminant bioaccumulation—even if the surrounding environments are identical—and the limited geographical distribution of the species, data comparisons among sites must be conducted with caution.

Results of NS&T monitoring surveys indicate that chemical contaminants are not uniformly distributed in US coastal and estuarine environments. The highest contaminant levels are recorded in sediments and biota of urbanized systems, such as those near the cities of Boston, Newark (NJ), San Diego, Los Angeles, and Seattle. Regionally, the highest contaminant levels are registered in the northeastern states, with elevated contaminant levels being relatively rare in the southeastern states and along the coastline of the Gulf of Mexico. Coastal and estuarine sediments of the northeast shelf large marine ecosystem region (i.e., Virginia to Maine) have a disproportionately large number of sampling sites displaying "high" concentrations of chemical contaminants. For example, more than two-thirds of all the sampling sites in the United States with "high" concentrations for most contaminants occur in this region, although less than one-third of all sampling sites nationwide are found here. The greater contaminant levels in sediments of the northeastern states are a function of the larger population numbers and associated development pressures observed in this region (O'Connor, 1996).

National estuary program

The NEP employs a holistic approach to manage estuarine environments and resources. This consists of a comprehensive evaluation of environmental conditions across a complex array of interconnected and interdependent systems from upland habitats of watersheds to the open waters of embayments. Subsequent to assessing these conditions, strategies are formulated and plans implemented to remediate pollution problems and other anthropogenic impacts, and to improve the long-term viability and ecological integrity of the estuary.

Some of the most serious problems encountered at NEP sites are those that may lead to ecosystem state changes. Examples are nonpoint source pollutant inputs, overenrichment of nutrients, introduction of pathogens and exotic species, and overexploitation of fisheries or other resources. They usually require a systematic, detailed, basinwide assessment. As a result, NEP investigations focus on comprehensive ecosystem health issues. Characterization reports prepared for NEP sites synthesize extensive databases, and they usually address the following points:

1. Status and trends of the water quality, natural resources, and uses of the estuary.
2. Linkages between pollutant loadings and changes in the water quality, natural resources, and uses of the estuary.
3. Description of human impacts on the water quality, natural resources, and uses of the estuary.
4. Identification of the priority problems in the estuary and the selection criteria used to determine them.
5. Hypotheses of cause–effect relationships for the priority problems and the research necessary to establish relationships.
6. Likely causes of the priority problems, examining data-bases on nutrients, chemical contaminants, and natural resources.
7. Final lists, historic descriptions, and background information on priority problems to be addressed in the CCMP.
8. Environmental quality goals and objectives established for the estuary, which form the basis for the monitoring program developed to evaluate the effectiveness of actions implemented under the CCMP.
9. Knowledge of uncertainties in the databases which can be used to direct further data gathering and research efforts and is important to the development of an effective sampling design in the post-CCMP monitoring program (USEPA, 1994).

Action plans in the CCMP specify the measures that must be taken to address priority problems in the watershed and estuary (USEPA, 1992). Arrays of possible management activities are considered, and those deemed to be most likely to result in positive change are implemented. Estuary restoration and maintenance at NEP sites depend most greatly on the implementation of carefully crafted action plans.

The strength of the NEP is that it forges partnerships between government agencies, business and industry, academic institutions, and the general public with a unified goal—to protect and restore the health of nationally significant estuaries and to enhance their living resources (USEPA, 1994). Critically important objectives of this program are to increase public awareness and understanding of pollution problems, as well as other anthropogenic impacts, and to ensure public participation in the decision-making process. A consensus-building process is necessary to establish effective pollution abatement and control programs, to revitalize damaged habitats, and to properly manage exploited resources.

Coastal zone management: conclusions

In recent years, it has become clear that the resolution of coastal environmental problems involves more than purely sectoral approaches to the management of land and marine habitats and resources. For example, atmospheric deposition alone delivers substantial amounts of contaminants to coastal systems often from sources at great distances. Hence, the governing council of the United Nations Environmental Programs (UNEP) favors a regional approach to marine pollution control. GESAMP, in turn, periodically publishes global reports on the state of the marine environment. The London Dumping Convention, in force since 1975, deals with regional or global pollution issues mainly through national legislation and regulations of countries contracting to the convention.

Future management programs must focus on more inte-grated and well-coordinated initiatives to counter the current narrow conservation and protection strategies, wasteful land-use practices, unsustainable coastal development, resource- use conflicts, and escalating habitat degradation in the coastal zone (Hildebrand and Norrena, 1992). Integrated Coastal Zone Management (ICZM) offers the framework for resolving many of the complex problems now facing coastal communities, such as resource conservation, environmental quality and amenities, and balanced human uses of aquatic systems (Hameedi, 1997). ICZM has been defined as a dynamic process in which a coordinated strategy is developed and implemented for the allocation of environmental, socioculture, and institutional resources to achieve the conservation and sustainable multiple use of the coastal zone (Coastal Area Management and Planning Network, 1989; Hildebrand and Norrena, 1992). It involves multi-sectoral, resource planning, and management approaches when dealing with human activities in coastal areas (Clark, 1996).

For ICZM to be effective, it is necessary not only to understand the ecological problems occurring in the coastal zone but also the economic, legal, and policy issues related to coastal resource use (Hameedi, 1997). Administrative demands of implementing ICZM require a high degree of coordination among various levels of government and between different governments. Hildebrand and Norrena (1992) advise that nations consider initiating ICZM programs on a regional basis, which will enable coastal planners and managers to concentrate on the most severe environmental problems. These investigators support the continued development of national and subnational coastal management strategies, in concert with appropriate applications in specific coastal regions.

An integrated management approach is the most viable strategy for improving environmental quality in coastal zones worldwide. An ICZM program has several advantages over traditional sectoral management schemes because it enables broad participation of parties for the resolution of conflicts between a variety of economic and development needs. It promotes sustainability of coastal resources and long-term protection of environmental health. A successful ICZM program, therefore, will effectively manage development as well as conserve natural resources in a complex dynamic environment (Bossi and Cintron, 1990; Hildebrand and Norrena, 1992; Clark, 1996).

EOLIANITE

Eolianite, also known as aeolianite, (a)eolian calcarenite, calcareous (a)eolianite, dune limestone, dune sandstone, kurkar (Middle East) or kunkar (India), is a generally consolidated coastal rock formation consisting of at least partially lithified wind-blown sand. Strictly eolianite could include any wind-blown sediment, such as silt (loess, brickearth), clay (parna), and volcanic ash, but conventionally it is restricted to dune sand, although finer sediment is sometimes present. Typically, the dune sand has been partially cemented by secondary internal precipitation of carbonates from percolating groundwater. There is often evidence of several stages of such cementation. The proportions of carbonate vary, but are typically at least 50% and often more than 90%, derived from shell debris, coralline material, bryozoans, and foraminifera, which lived on the seafloor. There are varying proportions of non-calcareous sediment, mainly quartz (quartzose sandstones with less than 50% carbonate are termed quartz-arenites).

Eolianite was originally described from Bermuda by Sayles (1931), although it had been noted by explorers on the Australian coast, where Vancouver in 1791 thought it coralline while Charles Darwin in 1844 reported that it consisted of wind-blown sand and associated limestone. It is usually of Pleistocene age, and may be overlain by unconsolidated Holocene dune topography. It often passes well below present sea level: for example, the eolianites of the Nepean Peninsula in Victoria, Australia, are Pleistocene dune formations, which extend more than 140 m below, and up to 60 m above, present sea level (Bird, 1993). It contains fossil shells, plant remains, and occasional evidence of land animals.

Eolianite dune formations have been emplaced on the coast during Quaternary oscillations of land and sea level. During falling and low sea-level phases, sand derived from calcareous seafloor organisms was winnowed and carried landward by onshore winds to be deposited as transgressive dunes in the vicinity of the present coast. Similar sand was also carried shoreward during marine transgressions to form beaches and backshore dunes, as well as multiple beach and dune ridges parallel to the coastline.

Many eolianite coasts have a series of partly overlapping transgressive dune formations, indicating alternations of surface stability, when a capping of soil and vegetation developed, and instability, when the next transgressive dune moved in (Figure E8). Each dune formation is capped by a soil horizon (paleosol) overlying a calcrete (limestone) layer formed by subsoil precipitation of carbonates. Contemporary vegetation produced calcareous fossil root structures (rhizoconcretions) in the subsoil. The interbedded soils are typically terra rossa, incorporating eolian silt and clay accessions to the dune surface. Occasionally, the footprints of animals or birds are found on outcrops of sandstone, which were temporary land surfaces, buried when dune accretion resumed. Locally, there are soil pipes, cylindrical hollows formed where root penetration was followed by the local subsidence of soil into depressions deepened by solution and encased by precipitated calcrete. Each phase of landscape stability came to an end with the arrival of the next transgressive dune formation, marked by dune sandstone, often with laminations indicating the intermittent advance of a dune front, and sometimes with calcareous fossil stem structures formed around buried vegetation. Subsequent erosion may expose root and stem concretions as "petrified forests," as at Cape Bridgewater, Australia. In places there are unconformities because the earlier dune landscape was eroded before the next dunes arrived.

Commonly eolianites are capped by Holocene dunes, but where these are absent (or have been removed by erosion) exposed calcrete layers can develop karst topography (limestone mounds or ridges, pedestals, clay-floored vases and ditches, solution hollows). Some dune sandstone formations remain relatively unconsolidated, and can be mobilized by wind action as active dunes if the overlying calcrete crust is removed.

Eolianite dune formations are generally sufficiently lithified to be cut back as cliffs up to 60 m high, the harder components (calcrete layers) dominating the profile while caves and coves are excavated in the less consolidated dune sandstones. These cliffs are fronted by subhorizontal low-tide shore platforms formed where shore rock outcrops are lowered by solution processes to a level that has become indurated by further carbonate precipitation (Hills, 1971) (Figure E8).

Eolianite dune topography is found on the southern and eastern coasts of the Mediterranean, in Morocco, on the Red Sea and southern Arabian coast, in western India, around the Caribbean (Kaye, 1959), on the Brazilian coast, in South Africa, on oceanic islands such as Mauritius and Hawaii, and extensively along the western and southern coasts of Australia (Fairbridge and Teichert 1953; Semeniuk and Johnson, 1985). On the eastern coast of Australia, beaches and dunes are quartzose, and eolianites have not formed: the dunes remain unconsolidated, either active and mobile or retained by a vegetation cover. On the eastern coast of the Mediterranean, there is a similar transition, the eolianite (kurkar) dune topography of the Israel coast passing southward into more irregular, mobile dunes on the coast of the Gaza Strip, where the sands have an increasing proportion of terrigenous (Nile-derived) quartzose sediment.

The submergence and dissection of eolianite dune topography formed during low sea-level phases is illustrated off the western and southern coasts of Australia. Some submerged eolianite ridges have been planed off by wave action on the sea floor, but there are also remnants of submerged eolianite dune topography. Similar submerged eolianite dune ridges occur off the Bahamas, northeast Brazil, and Sri Lanka, and some of these have become reefs with coral and algal crusts.

Eolian Processes

EOLIAN PROCESSES

Eolian processes are those processes relating to, or caused by the wind. The term eolian comes from the Greek *Aeolus*, the God of Wind. Eolian (aeolian—non-US equivalent) processes include the transportation and movement of sediments (particularly sand, clay, and silt), erosion of sediments, rocks and landforms, and the creation of dunes, sheets, and landforms. Eolian processes are most common on coasts and in arid environments, particularly hot and cold deserts.

Eolian sand transport is initiated when the wind velocity exceeds a critical threshold velocity. The threshold velocity required to initiate clay and silt transport is far greater than that of sand due to their platy nature and cohesive forces, but once motion is initiated, fine grained material (particularly silt) may stay in suspension for a considerable time period. Three main forms of grain transport take place, creep, saltation, and suspension. Creep refers to the movement of grains by rolling over the surface. Saltation (from the Latin *saltare*, to jump) is the bounding movement of grains in which grains rise almost vertically and then describe a long low trajectory downwind. Once saltation occurs, some energy is transferred to the surface by grain collisions and this aids creep and the ejection of further grains into the air stream. This process occurs at lower threshold velocities than that required for initiation of sediment transport and has been termed reptation by some authors (e.g., Lancaster, 1995). Suspension occurs where grains are lifted sufficiently to overcome gravity for some period of time. The initiation of eolian sediment transport and eolian processes are affected by surface conditions (e.g., moisture, cements, and bonding agents, vegetation) surface roughness and topography.

Eolian transport causes deflation, which may merely lead to the slight lowering of a surface (e.g., beach, dune or sand plain), but may also be the dominant process leading to the development of deflation hollows (and slacks), basins, and plains. In coastal and desert environments, deflation leads to the formation of blowouts, parabolic dunes, and wind-eroded plains. Here, deflation erodes the surface down to the seasonally lowest water table, a calcrete or indurated horizon, a palaeosol, or rock and boulder strewn surface. Eolian transport also causes abrasion of landforms. Wind transported sand grains abrade surfaces forming ventifacts (a polished, facetted and/or abraded stone or pebble), yardangs (sharp crested linear ridge of wind-eroded rock), and zeugen (desert rock pillars and yardangs, which are considerably undercut; Whittow, 1984).

In the coastal environment, eolian processes may lead to the development of various dune types. Where vegetation is important or present, coppice dunes, shadow dunes, foredunes, blowouts, and parabolic dunes may be formed. Where vegetation is less important and sediment supply is moderate to high, transgressive dunefields may occur and display a variety of dune types (e.g., sheets, barchans, transverse and oblique dunes, dome dunes, and star dunes) and associated landforms such as precipitation ridges and deflation plains and basins may be present (Hesp, 1999). Deserts may display a wide variety of eolian dune forms including dome dunes, barchans, transverse dunes, longitudinal and linear dunes, shadow dunes, sheets, and star dunes. Each tends to be related to sediment volume, wind directional variability, and average annual velocity (Cooke *et al.*, 1993). Vegetation processes are important in modifying eolian processes commonly leading to the complete colonization of once active dunefields in both coastal and desert environments.

EROSION: HISTORICAL ANALYSIS AND FORECASTING

Introduction

The ability to forecast future coastal positions has taken on increased importance as development along the world's coasts has risen dramatically over the past few decades. This is readily apparent, for example, in the United States where development has transformed many small beach villages into moderately to densely populated cities. Currently, about 350,000 structures are located within 500 feet of the US open-ocean and Great Lakes coasts (Heinz Center, 2000).

Rates of coastal erosion are calculated by monitoring the location of a representative geomorphic indicator, usually the high-water line (HWL; i.e., wet–dry boundary) or bluff line, over a specified time frame. Rates are obtained by measuring the location of two or more shorelines (hereinafter the term "shoreline" generally refers to the "high-water line," or "bluff line," unless noted otherwise, with no distinction made between cliff and bluff) from historical shoreline change maps. These maps are produced by digitizing shoreline change reference features from various sources, such as historical maps, aerial photographs, and Global Positioning System (GPS) surveys, followed by combining and overlaying the shorelines onto a common coordinate system. Historical shoreline change maps for the United States often contain four to eight or more plotted shorelines and can span 150 years. Erosion rates are typically calculated from the maps by plotting or generating a line perpendicular to the multiple shorelines and measuring the amount of movement over a period of time defined (and constrained) by the dates of the plotted shorelines. In many cases, subsets of the historical shorelines are used, particularly in areas where prolonged and perhaps permanent physical changes to the beach system have occurred (e.g., inlet openings) or where the construction of man-made structures (e.g., groins, jetties, and seawalls) makes older data unrepresentative of the long-term trend.

Various statistical methods have been proposed to calculate long-term erosion rates, but because of the paucity of data and uneven sampling, higher-order statistical methods have thus far proven no better at predicting future shoreline positions than "simple" methods, such as linear regression. The selection of appropriate shorelines to use in predictions is critical in obtaining a reliable long-term erosion rate. Some have suggested using only the more recent shoreline position data, erroneously assuming that older, historical maps are not sufficiently accurate. However, Crowell *et al.* (1991) have shown that historical maps known as "T" or topographic sheets, produced as far back as the mid-1800s by the United States National Ocean Service (NOS) (and predecessor agencies), are of sufficient accuracy for determining long-term rates of beach erosion. In addition, Crowell *et al.* (1993) and Galgano *et al.* (1998) demonstrated the importance of using data sets spanning 60–80 years or more to determine the long-term trend of erosion for forecasting future shoreline positions. Such long data spans are needed because the erosion/recovery cycle associated with severe storms can obscure the underlying trend of erosion for decades.

The principal steps involved in developing and analyzing historical shoreline change maps are as follows:

- Data selection: select appropriate map and imagery source data for the area to be studied;
- Data preparation: determine shoreline change reference feature to be monitored (usually the HWL or top edge of the bluff line); establish geographic control on source data and annotate features (i.e., shoreline segments and control points) to be digitized;
- Data correction: correct air photo distortions and identify and correct map distortions and errors;
- Data digitization: digitize and combine shorelines and plot them onto a suitable medium;
- Data analysis: calculate erosion rates from shore-perpendicular transects.

Sources of historical data

There are three principal data sources used in the production of historical shoreline change maps: maps, aerial photography, and GPS surveys. In the United States, the primary historical map data source is NOS T-sheets. The first T-sheets date back to 1835, but maps of 1835–45 vintage sometimes show inaccuracies in longitude. In 1846 NOS surveyors began using the telegraph as part of field mapping. This significantly improved longitudinal accuracy to the point that maps of post-1846 vintage are usually accurate enough for use in modern historical shoreline mapping studies.

NOS has periodically remapped coastal areas every 20–60 years. As such, two or three pre-1940s and one to two post-1940s T-sheets are generally available for most of the US East and Gulf Coasts (Anders and Byrnes, 1991). NOS T-sheets are an invaluable data source that expands the temporal range of the historical shoreline data from about 60-years (using aerial photography and GPS ground surveys) to approximately 150 years. A major prerequisite, however, is that the accuracy of each map be verified by analyzing current or “known” geo-positions of recoverable triangulation stations mapped on the historical NOS T-sheets. As an example, analysis of the accuracy of NOS T-sheets for a historical shoreline mapping project for Massachusetts demonstrated that 120 of 141 (85%) T-sheets were of sufficient accuracy for use in a study of long-term shoreline change (Crowell *et al*., 1991). Map scale is obviously a major consideration—1 : 10,000 or larger is preferred, although maps at scales as small as 1 : 20,000 are often usable (Anders and Byrnes, 1991; Moore, 2000).

Vertical aerial photographs date back to the 1920s; however, aerial photography produced prior to the late-1930s is typically overly distorted and of insufficient resolution for use in historical shoreline mapping studies. Moreover, it was not until after World War II that air photos on the US coasts were taken with any degree of regularity. Many of the air photos were taken to document storm impact and consequently are of questionable use for determining long-term rates of beach erosion (Douglas *et al*., 1998). Fortunately, however, several sets of post-World War II aerial photographs suitable for historical shoreline mapping studies are often available for a given area (Crowell *et al*., 1997).

Field-based surveys using GPS have been increasingly used within the past seven years (Morton *et al*., 1993). Shoreline position data are collected by driving a GPS-equipped off-road vehicle directly along the HWL. Geo-coordinates are collected at specified intervals, enabling real-time digitization of the HWL (Byrnes and Hiland, 1993; French and Leatherman, 1994). Table E7 provides a list of milestones in historical shoreline mapping.

Shoreline change reference features

A number of potential geomorphic features can be used to monitor historical shoreline changes. However, in many situations the HWL has been demonstrated to be the best indicator of the land–water interface for historical shoreline comparison studies. It is easily recognizable in the field (it was the boundary line mapped by early NOS topographers), it can usually be approximated from air photos (Stafford, 1971), and it represents a shoreline feature that has been accurately mapped (albeit sporadically) since the mid-1800s. Morton *et al.* (1993), however, notes that the HWL is not always the most diagnostic of long-term shoreline movement, particularly in areas with gently sloping beaches or where rates of erosion are low. In these and other situations, Morton argues that other morphological features, such as erosion scarp, crest of washover terrace, or vegetation line are more diagnostic of long-term change than the HWL. Use of these other indicators, however, severely limits the temporal span of source data. While these shoreline indicators are sometimes depicted on the historical NOS T-sheets (the only good source of pre-aerial photo shoreline position information), only the HWL was delineated with enough accuracy to be useful for temporal position comparisons.

For cliffed situations, the top edge of the bluff (employing the terms cliff and bluff interchangeably) is commonly used as a shoreline change reference feature. Unfortunately, historical maps depicting accurate bluff positions are rare, thereby limiting historical source data to the temporal span covered by aerial photographs (e.g., 1930s to present).

Table E7 Significant milestones in the development of historical shoreline change mapping

Lucke (1934)	Cartographically traced historical and current T-sheets to produce shoreline change maps showing temporal changes for Barnegat Inlet, New Jersey.
Plusquellec (1966)	Produced shoreline change maps compiled from vertical air photos for an area between Brigantine and Beach Haven Heights, New Jersey. The air photos were not corrected for tilt distortion.
Stafford (1971)	Took point measurements from aerial photographs in a study that documented coastal erosion along the Outer Banks of North Carolina. In this study, Stafford developed procedures that minimized scale and tilt distortions inherent in air photos. In addition, Stafford and Langfelder (1971) demonstrated that the mean high water line was the best indicator of land–water contact, and most subsequent (non-bluff) mapping studies have used this interface as the shoreline marker for comparative purposes (Leatherman, 1983).
Morton (1974)	Produced historical shoreline change maps for the entire coast of Texas. These maps were produced by cartographically tracing T-sheets and aerial photograph mosaics.
Dolan *et al*. (1978)	Developed a computer storage and retrieval system, called orthogonal grid address system (OGAS), that incorporated manually produced, unrectified aerial photography in erosion studies.
Leatherman (1982, 1983)	Developed a computer program, called metric mapping, that corrected T-sheets for scale distortion and rectified air photos for scale, tilt, tip, and yaw distortions. Metric mapping computer routines automated much of the data compilation and analysis. The program was used to generate historical shoreline change maps for large sections of the US east coast.
Everts *et al*. (1983)	Used cartographic and computer mapping techniques to compile historical shoreline change maps for a number of US mid- and south-Atlantic states.
Morton et al. (1993) Byrnes and Hiland (1993) French and Leatherman (1994)	Used GPSs in shoreline analyses and historical shoreline change mapping.
Overton *et al*. (1996) Moore *et al*. (1999) Coyne *et al*. (1999)	Used softcopy photogrammetry to measure shoreline change. The technique significantly improves upon earlier computer methods for rectifying aerial photography. For example, fewer ground control points are required, and the shoreline is digitized on-screen.

Other features are sometimes used to monitor historical bluff change. The State of Wisconsin, for example, has experimented with the mid-bluff contour, with the rationale that the middle of the bluff is typically the most stable portion of the slope because it is located below areas subject to frequent failure and above the associated debris or talus pile. A computer program selects the mid-bluff contour from a digi-tal elevation map, in theory, removing the effects of operator error when delineating the shoreline change reference feature. However, the temporal limitations of using the mid-bluff contour are even more restrictive than for using top edge of the bluff, as the quality of 1930s and 1940s aerial photography may prevent their use in determining the mid-bluff contour.

In summary, the HWL is generally the preferred shoreline indicator for use in documenting historical shoreline changes. However, certain beach characteristics (e.g., gently sloping beaches) or situations where the HWL is unavailable or meaningless (e.g., bluff situations in the Great Lakes) may require use of other shoreline indicators. Use of the HWL allows shoreline change comparisons that includes maps, aerial photographs, and ground surveys, thereby expanding the historical limits to the mid-1800s. Use of other shoreline indicators limits shoreline comparisons to aerial photographs and ground surveys, thereby constraining the historical bounds to the last 60 years.

Accuracy of source data

Accuracy of source data has been discussed in a number of papers (Morton, 1974; Anders and Byrnes, 1991; Crowell *et al.*, 1991; Gorman *et al.*, 1998; Moore, 2000). In general, most researchers acknowledge that historical and current aerial photographs provide an important source from which to monitor shoreline change and calculate rates of change. Questions regarding accuracy of older source data, particularly historical NOS T-sheets, spurred Crowell *et al.* (1991) to devise a way to determine the maximum errors one would expect to find using historical and current aerial photography and historical NOS T-sheets. The authors estimated "combined" errors by estimating error for each individual step in shoreline data compilation, including survey, digitization, mapping, and correction of photographic distortion. The individual estimated errors were combined using the theory of propagation of errors to obtain estimates of expected error in the digitized location of the interpreted shoreline (in this case, the high-water line). Expected errors were calculated for the following data sources (all at 1 : 10,000 scale): 1846–1930 T-sheets prepared prior to the use of aerial photography: 8.4–8.9 m; post-1950s T-sheets compiled using aerial photography: 6.1 m; non-tidal coordinated aerial photography: 7.5–7.7 m. These figures were based on analysis of T-sheets from the northeast coast of the United States. Importantly, short-term process variability factors, such as daily and monthly tidal changes and storm effects, were not included in the error estimates.

Preparation, rectification, and compilation of source data

In order to compare mapped, aerial photographed, and field surveyed shorelines, a common coordinate system must be chosen so that all source data can be properly aligned to ensure the most accurate determination of shoreline movement. Modern computer techniques have automated much of the compilation process, but a certain amount of manual preprocessing must completed prior to data digitization. The preprocessing varies by the type of input data.

Historical maps

To align historical maps to a specific coordinate system, one must identify a number of permanent and stable points or features on the map for which accurate and current geographic coordinates are known. The features are known as primary control points. For computer applications, a minimum of four primary control points are required, although six to eight points are commonly used to improve accuracy and aid in error analysis. These points are used to calculate the transformation necessary to change from one coordinate system to another and to correct for error factors such as scale differences, rotation, and uneven map shrinkage. Selection of primary control points is trivial if the source map contains current geo-coordinates, such as latitude and longitude tick-marks. However, historical maps often have latitude–longitude lines based on obsolete data. For example, latitude–longitude coordinates for the US maps produced prior to 1927 must be updated to better standards such as the North American Datum of 1927 (NAD27), or preferably the more recent and accurate NAD83. Several Geographic information system (GIS) programs are currently available that automatically transform the pre-1983 digitized map data to the 1983 standard. If latitude–longitude coordinates are not available for the map, or if the coordinates are present but with an unknown datum standard, then other techniques must be used to update the map. One very useful technique is to search the map for survey stations or hard permanent features for which modern coordinates are known. In the case of NOS T-sheets, several *triangulation stations* are usually mapped for which current coordinates can be obtained.

Aerial photography

Since 1927, aerial photography and photographic methods have been used to provide topographic information along the coast, creating an important dataset for use in historical shoreline change studies. Air photos, however, are not map projections; corrections for distortion due to tilt, tip, and yaw (and sometimes relief) must be made prior to and/or concurrent with the compilation process so that shoreline positions obtained from air photos can be compared with those compiled from planimetric maps and ground surveys. Several computer programs are now available that automate air photo rectification in a process called "soft-copy photogrammetry" (Moore, 2000). The process involves creating photomosaics prepared from scanned and rectified aerial photographs. A series of ground control points are used to spatially reference the imagery to geo-coordinates. Pass points, which are identifiable landmarks common to two or more photographs (but not ground controlled), are supplemental and serve to reference the photos to each other (Coyne *et al.*, 1999). In summary, the rectification process transforms the imagery to a map projection and corrects or minimizes map distortions, such as tilt, scale differences, relief displacement, and radial lens distortion.

GPS surveys

Field-based shoreline surveys using GPS has been increasingly used since the early 1990s (Byrnes and Hiland, 1993; Morton *et al.*, 1993; French and Leatherman, 1994). Shoreline position data are collected by driving an off-road vehicle equipped with a GPS unit directly along the HWL. Geo-coordinates are collected at specified intervals, allowing real-time digitization of the HWL. GPS measurements are so accurate (within a meter) that measurement error is usually insignificant compared with the ambiguity inherent to a shoreline change reference feature.

Shorelines digitized from maps and air photos along with GPS digital surveys are combined and referenced to a common geo-coordinate base. The resultant hardcopy product is referred to as a historical shoreline map or historical shoreline change map. Most such maps usually contain a minimum of four shorelines, although six to eight shorelines are commonly displayed.

Calculation of long-term erosion rates

The primary reason for calculating long-term erosion rates is for land-use planning, ranging in purpose from providing information to property owners to establishing regulatory setback lines for coastal construction. Usually building setbacks are based on the average annual erosion rate (AAER) for the area, multiplied by a specified number of years, commonly 30 and 60 years. The computed setback is then measured landward from an erosion reference feature, whose movement would have the most impact on the structural integrity of a building. As such, the erosion reference feature is typically the top edge of a bluff, dune escarpment, vegetation line, or beach scarp. If none of these are present, then the HWL is often used. If the erosion rate at a site is, for example, 5 feet (approximately $\approx$1.5 m)per year, then the 30-year setback is 150 feet ($\approx$45 m) and the 60-year setback is 300 feet ($\approx$90 m) both of which would be measured landward from, for example, the top edge of the bluff.

The high valuation of coastal property in many countries underscores the importance of developing coastal erosion data that are both accurate and appropriate. Accurate rates of erosion can be determined in many ways, using all or subsets of shoreline data, but not all of the rates would necessarily be appropriate for the situation. Assuming that the source shoreline data are accurate, there are three additional important issues to consider prior to calculating appropriate long-term rates of change: (1) what temporal span of shoreline data should be used in determining the rate (i.e., should short-term, medium-term, or long-term data be used); (2) should post-storm shorelines be included; and (3) what statistical method should be used to determine the rate? Insight into the answers to these questions can be gained from the following example of an actual history of shoreline positions.

Consider the data shown in Figure E9 (Douglas and Crowell, 2000). The graph shows 10 shoreline positions from 1845 to 1997. The shoreline location data are from the Atlantic coast of Delaware, just south of the Indian River Inlet near a location called Cotton Patch Hill. The 1929, 1962, and 1963 shoreline positions were photographed or mapped immediately following major storms and are shown as open circles on Figure E9. Note that these three post-storm shoreline positions are inconsistent with the long-term trend line determined from the other seven shoreline positions. During a large storm, more erosion can occur in a few days than in the previous 50 years, which is often followed by an extended period of beach recovery. Note that accretion continued after the 1962 Ash Wednesday nor'easter for at least a decade (Figure E9). Therefore, determination of the long-term rate of beach erosion should not be undertaken without consideration of the role of severe storms on shoreline position.

The example above also serves to illustrate the proper statistical approach to the shoreline position forecasting problem. A correct methodology requires that the forecast model be in reasonable agreement with the actual physical situation. Figure E9 shows that there was a long-term trend of beach erosion, superimposed with episodes of severe erosion followed by extended periods of recovery. Use of post-storm shoreline positions in determination of the long-term trend will yield aberrant results. Unfortunately, the most common method used by researchers to calculate rates of erosion is the "end-point-rate" method. In this method, the analyst selects two representative shorelines, often the earliest and the most recent, to calculate the amount of shoreline movement. This distance is then divided by the time elapsed between successive shoreline positions. The advantages of this technique include simplicity in application, and two shorelines suffice to obtain a rate. A major disadvantage is that the position of one or both of the endpoint shorelines may be aberrant, and so the rate of change can be misleading for use in determining future shoreline positions. Moreover, data between the end points, of value in determining the rate of change, are not used and hence potentially useful information is ignored.

Another method becoming increasingly popular among researchers (see Crowell and Leatherman, 1999) is linear regression. With this method, a best-fitting straight line is determined that minimizes the sum of the squares of the lengths of vertical line segments drawn from the individual data points to the fitted line. The advantages of this method are that: (1) all data points (except for post-storm shorelines) are used in the rate calculation, thereby reducing the influence of spurious data points; (2) linear regression is an easily understood statistical analysis tool that can be performed with most spreadsheet programs and scientific pocket calculators, and (3) summary and related statistical techniques are available to test and measure the quality of the straight-line fit and estimate the variance of the data (Kleinbaum and Kupper, 1978). However, careful attention must be paid to the influence of severe storms on shoreline position when selecting the data to be used in the regression analysis. Douglas and Crowell (2000) present a methodology for evaluating shoreline position data and computing predicted shoreline positions and their uncertainty. Furthermore, only summertime data should be used because of large seasonal fluctations in beach width; combining summer and winter shorelines is almost like comparing apples and oranges— one can obtain nearly any answer that you wish, ranging from accretionary to a highly erosional trend.

A method for determining rates of erosion known as the minimum description length (MDL) criterion (Rissanen, 1989) was proposed by Fenster *et al.* (1993). This technique uses a type of complexity-penalty model criteria to determine the straight or curved line (polynomial) to fit the data set. While conceptually interesting, the MDL method de-emphasizes historical data to the extent that short-term shoreline perturbations unduly influence the data set, thereby hindering useful long-term (30- to 60-year) forecasts. Crowell *et al.* (1997) demonstrated that simple linear regression consistently gives better long-term forecasting results than does the MDL or the end-point rate technique.

Conclusions

Many difficulties can be encountered in accurately determining the long-term behavior of shorelines based on sparse data sets. The complexity increases if engineering changes (such as construction of groins or jetties) have been made to the shoreline, or if tidal inlets are opened as a result of a large storm. In addition, capes and spits often display a complex episodic cycle of erosion and accretion that is unrelated to storms. Thus, the highest-quality forecasts of long-term shoreline position need to consider meteorological and geomorphic factors and the role they play in the evolution of the shoreline position.

EROSION PROCESSES

Erosional processes along coastlines include: (1) the direct effects of hydraulic action, wedging, and cavitation by waves; (2) abrasion (corrasion), using sand, gravel, and larger rock fragments as tools; (3) attrition of the rock particles themselves during this abrasive action; (4) salt weathering or fretting; (5) erosion by organisms (bioerosion); and (6) chemical attack, or corrosion, which weakens the rocks and accelerates erosion. The rates of erosion by these processes are a function of the exposure of a coast to wave attack (wave energy and length of time of exposure), and the resistance of the materials to erosion and weathering.

Waves are the most dominant force causing coastal erosion. Ocean waves typically break at depths that range from about 1 to 1.5 times wave height. Because waves are seldom more than 6 m high, the depth of vigorous erosion by surf is usually limited to from 6 to 9 m below sea level. This theoretical limit is confirmed by observations of breakwaters and other coastal structures that are only rarely affected by surf to depths of more than 7 m. The change in water level caused by tides, however, allows waves to attack a greater range of elevations on the coast.

Wave impact directly exerts great pressure and can be a highly effective agent of erosion. The pressures produced by breaking waves have been measured by dynamometers, with reported values as high as 250 kg/m^2 (6,000 lb/ft^2). These measurements agree with theoretical estimates (Gaillard, 1904) based on wavelength and celerity. When the waves are long and their celerities are correspondingly high, the greatest pressures are generated.

When waves break against a cliff face, water is driven into cracks and joints and the air within the cracks is greatly compressed. The compressed air acts as a wedge, widening the fractures and loosening blocks of rock. As the wave recedes, the compressed air expands with explosive force (a process called cavitation), effectively quarrying out large blocks (Barnes, 1956). Such quarrying action has provided enough energy to move blocks weighing many tons. There are many reports of the movement of large blocks by wave action, including a 2,500-ton piece of concrete at Wick (Scotland), and a section of a breakwater weighing 1,700 tons that was completely overturned at Bilbao (Spain).

Another method of marine erosion is abrasion, the mechanical wearing and grinding away of rock surfaces by the friction and impact of rock particles. Also called corrasion, this process involves the action of sand, gravel, and large rocks picked up by the waves and driven back and forth against the exposed shore. Potholes can develop where large clasts are rotated by swirling water in the surf or breaker zone. The abrasion process includes dragging (friction), rolling, bouncing (saltation), and the artillery action of large fragments, which can shatter solid rock when hurled against a cliff. At Tillamook Rock on the Oregon coast, for example, rocks weighing as much as 297 kg have been picked up during severe storms and thrown through the windows of the lighthouse, 44 m above mean high water. Similarly, the windows of the Dunnet Head Lighthouse on the north coast of Scotland, more than 100 m above the high water mark, have been broken by rocks propelled by wave action.

Concentration of wave attack at the cliff base accelerates erosion and notches the base, permitting collapse or movement of the overlying material (Sunamura, 1992). Seepage of ground-water (especially along seams and fractures), frost action, and wind combine with the undercutting to produce cliff recession (Nott, 1990). Differences in the resistance of the rocks being eroded and episodic collapse may produce an irregular cliff face, subject to mass movements (Duperret *et al.*, 2002; Benumof *et al.*, 2000). The debris produced by cliff collapse is subsequently used in abrasion of the cliff base, and/or removed by wave action, allowing the wave attack to continue. Thus, cliff erosion is generated by two processes: notching at the base of the cliff by marine processes, and collapse and denudation of the entire cliff face by a combination of subaerial and marine processes (Duperret *et al.*, 2002).

The rate of cliff retreat, combined with rock type, climate (especially rainfall) and vegetation will determine the nature of mass movement down the cliff face. An extensive examination of Japanese cliff erosion, found that long-term cliff retreat is logarithmically related to rock strength and unrelated to cliff height (Sunamura, 1977, 1992). Benumof *et al*. (2000) also found that rock strength, rather than wave energy or slope, is the critical factor in coastal cliff retreat.

Mathematically, the major factors of basal erosion have been summarized in Sunamura's equation:

$$x = f(F_w, S_r, t),$$

where x is the basal cliff erosion rate, F_w is the wave induced force, S_r is the cliff material resistance, and t is the time. Belov *et al*. (1999) developed a mathematical erosion function (the so-called Belov–Davies–Williams (BDW) equation) which accounts for erosion forces and the strength of the rocks, and also for the exponential decrease in wave erosion intensity with height. Numerical models have been quite successful at simulating basal cliff erosion (Belov *et al*., 1999).

The level of planation of the cliff base will usually lie immediately above the level of permanent rock saturation, where continued wetting and drying weakens the rock, allowing accelerated wave erosion. This level will, however, vary depending on wave energy, rock type and structure, platform width, and accompanying atmospheric processes (Stephenson and Kirk, 2000). The abrasion along the shore works horizontally to form a wave-cut cliff and a wave-cut platform. Exposure may be an important factor, as studies of shore platforms in Japan have shown that the mean platform width is about 40 m on the sheltered Inland Sea, 50 m on the more exposed Japanese Sea, and 60 m on the exposed Pacific coast (Trenhaile, 1997).

Attrition is the process of wearing down by friction, involving the abrasion, impact, and grinding together of clasts in motion, resulting in smaller and usually better-rounded particles (in Europe, abrasion is used as a synonym for attrition). The impact and rubbing together of the rock fragments during wave action, as well as the grinding of the blocks that fall as the cliff is undercut, cause the tools themselves to wear down to smaller sizes and become rounded. Studies of attrition of beach clasts include experiments and observations in natural settings. Kuenen (1964) experimentally correlated rate of attrition with relative resistance and median clast size. Early comparisons of natural sediment distributions were done by Landon (1930), but lack of control makes the conclusions questionable. The observed diminution of grain size along a coast could be also due to change in source material or to sorting by longshore transport.

Salt weathering or fretting takes place when salt crystals grow within pore spaces in rocks; the crystal growth expands the pore and may lead to fracturing of the rock (Wellman and Wilson, 1965; Mottershead, 1989). This may be the result of strong evaporation that draws salt solutions to the surface by capillary action. The salt-weathering process is most effective in areas exposed to salt spray and subject to alternative wetting and drying. Salt weathering can also produce a honeycomb pattern in the rocks called tafoni, which is most characterisitic of tropical and subtropical semiarid to moderately arid climates. In chalk cliffs, basal notching has been attributed to salt weathering and repeated wetting and drying cycles (Duperret *et al*., 2002).

The chemical and solvent action of seawater may be especially important along limestone and chalk coasts. On some atolls, solution may be responsible for 10% of total erosion of the coast (Trenhaile, 1997). However, even non-calcareous rocks may weather more rapidly as a result of the chemical action of seawater. In some cases, chemical dissolution and salt fretting may act together.

Additional factors that may contribute to mechanical weathering in certain areas include large diurnal temperature variations and biological activity. Weathering due to temperature variations mainly affects the surface layers. The temperature distribution in rocks is non-uniform, and differences in rock composition yield thermal conductivity contrasts and large temperature gradients. This can cause thermal cracking of blocks, resulting in displacement along existing joints and fractures.

Biological erosion is especially important in tropical or subtropical areas having limestone coasts. Algae are probably the most important bioerosional agent on rocky coasts. The substrate under algal mats is exposed to the products of metabolism and organic waste, which can directly etch the rocks. Algae also support grazing organisms such as gastropods and echinoids, which abrade rock surfaces. Bioerosion, combined with the chemical solution of limestone by algae, produces the intricate scalloping known as phytokarst (Bromley, 1978). Boring and browsing organisms erode rocks most effectively in the inter-tidal zone, and bioerosion can eventually weaken the framework of reefs to the point where collapse takes place. Rates of bioerosion on horizontal and vertical limestone surfaces have been estimated at about 0.5–1 mm per year (Trenhaile, 1997).

In cold regions, where unconsolidated but frozen, ice-bonded sediments are exposed to wave erosion, convective heat transfer between seawater and the melting surface of the frozen cliff sediment (thermal abrasion) combines with erosive wave action and slope failure to undercut cliffed coasts (Kobayashi *et al*., 1999). Wave erosion removes the unfrozen sediment, which would insulate the frozen sediment from further melting. The combined thermal and mechanical processes can lead to rapid erosional retreat (>1 m per year) during periods of open-water conditions. Tidally induced frost action occurs in the inter-tidal zone where rocks freeze when exposed to air and thaw when covered by the rising tide. This mechanism is particularly effective because of the frequency of freeze–thaw cycles. In coastal Maine, for example, there are an average of 133 freeze–thaw cycles each year in the inter-tidal zone versus only 30 or 40 cycles inland (Trenhaile, 1997).

ESTUARIES, ANTHROPOGENIC IMPACTS

Introduction

Estuaries are highly stressed, physically controlled ecosystems characterized by wide variations in environmental conditions. A multitude of anthropogenic activities also affects these coastal ecotones and can significantly impact their water quality, habitats, and biotic communities. These activities are closely coupled to accelerated population growth and development in coastal watersheds. By the year 2025, the coastal population worldwide is expected to approach six billion people (Weber, 1994; Hameedi, 1997). Poorly planned human settlement in the coastal zone will lead to greater stresses on estuarine systems worldwide.

Much human activity is concentrated near estuaries because of their great commercial, recreational, and aesthetic value. Estuaries support multibillion dollar commercial and recreational pursuits, such as tourism, fisheries, mariculture, transportation, shipping, electric power generation, oil and gas recovery, and other endeavors (Kennish, 2000). Estuarine and coastal marine fisheries alone generate more than $20 billion annually for the US economy (Pirie, 1996). However, an array of environmental problems has arisen in response to greater human use of estuarine resources, most notably related to pollution inputs and habitat degradation.

Pollution and habitat impacts

Enrichment

Day *et al.* (1989) have identified five categories of estuarine human impacts: (1) enrichment; (2) toxins; (3) overfishing; (4) introduction of exotic species; and (5) physical alteration. Kennish (1992, 1997, 2000, 2001) has provided an overview of them. Enrichment refers to impacts primarily associated with the input of excessive amounts of nutrients, organic matter, and heat (calefaction or thermal loading). The overfertility of estuarine waters, particularly large inputs of nitrogen and phosphorus from point and nonpoint sources, promotes rapid algal growth (e.g., phytoplankton blooms) and biomass accumu-lation which can lead to hypoxic or anoxic conditions and reduced phytoplankton species richness. The eutrophication of estuarine waters often has devastating consequences, occasionally culminating in heavy mortality of benthic and finfish populations, including commercially and recreationally important forms, and causing significant changes in estuarine community structure and trophic dynamics. Phytoplankton blooms (including toxic and nuisance algal blooms) stimulated by nutrient enrichment usually decrease light attenuation, and the shading effect commonly reduces the production and areal distribution of submerged aquatic vegetation (Valiela, 1995; Valiela *et al.*, 1997; Livingston, 2001). This habitat change often results in the shift from a sea grass-dominated system to a phytoplankton-dominated system in shallow coastal bays (Kennish, 2000).

Estuarine eutrophication is an escalating problem worldwide because of increases in nutrient inputs from a burgeoning human population in the coastal zone. Influxes of nutrients from farmlands, stormwater runoff, wastewater discharges, groundwater seepage, atmospheric deposition, and other sources have contributed to nutrient loading concerns in numerous estuaries. Examples of such impacted US systems include Long Island Sound (New York), tributaries of Chesapeake Bay (e.g., Patuxent, Rappahannock, and York Rivers), Waquiot Bay (Massachusetts), Perdido Bay (Florida), and Barataria Basin (Louisiana). In the conterminous United States, Bricker *et al.* (1999) have documented 44 highly eutrophic estuaries and another 40 estuaries with moderately eutrophic conditions.

Organic carbon enrichment in the form of wastes from sewage and wildlife inputs, livestock and fish processing operations, and industrial effluents not only exacerbates eutrophication problems by raising inorganic nutrient concentrations but also compromises water and sediment quality by increasing pathogen concentrations. Overenrichment of sewage wastes is linked to elevated biochemical oxygen demand and reduced dissolved oxygen levels in estuaries. Sewage wastes can have significant impacts on estuarine and marine organisms (Costello and Read, 1994). For example, such chronic organic carbon enrichment degrades benthic communities, typically reducing species richness and favoring the proliferation of a few opportunistic forms, which frequently dominate the communities.

The calefaction of estuarine waters by the release of waste heat from electric generating stations influences the physiological and behavioral responses of organisms in near-field regions of outfall sites. Biotic impacts typically observed in these receiving waters are decreased primary production, failed reproduction, increased mortality (e.g., heat- and cold-shock mortality of fish), and altered community structure (Kennish, 1992, 1997, 2001). Behavioral adjustments may be dramatic, with many nektonic organisms exhibiting avoidance or attraction responses to the effluent. Significant changes in the species composition, abundance, and diversity of biotic communities commonly occur in outfall canals of electric generating stations.

Toxins

Most chemical contaminants enter estuarine environments from land-based sources via agricultural and urban runoff, municipal and industrial discharges, riverine inflow, and atmospheric deposition. Many have either acute or chronic adverse effects on organisms. Chief among these contaminants are halogenated hydrocarbon compounds, polycyclic aromatic hydrocarbons (PAHs), and heavy metals. All pose a potential threat to organisms, especially in hot spot areas of urbanized estuaries where more elevated concentrations of the contaminants are found (Daskalakis and O'Connor, 1995; O'Connor, 1996). Halogenated hydrocarbon compounds, PAHs, and heavy metals are particle reactive substances; they tend to rapidly sorb to fine-grained sediments and accumulate on the estuarine seafloor, which serves as a repository for the contaminants (Kennish, 1997). In bottom sediments of estuaries, the contaminants resist degradation and may persist essentially unaltered for many years. While it is important to monitor the absolute concentrations of the contaminants, their bioavailability must be considered when assessing biotic impacts (Hamelink *et al.*, 1994).

The halogenated hydrocarbons originate mainly from agricultural and industrial sources and include an array of biocides (e.g., insecticides, herbicides, and fungicides), low-molecularweight compounds (e.g., chlorofluorocarbons), and high-molecularweight chemicals (e.g., chlorinated aromatics and chlorinated paraffins). Some of the most notable synthetic organic compounds of this group (e.g., PCBs, DDT, and non-DDT pesticides) rank among the most toxic constituents in estuaries, and consequently are a high priority concern. They are suspected etiologic agents which have been linked to a number of disorders in estuarine animals such as reproductive abnormalities, altered endocrine physiology, aberrant developmental patterns, skin and liver lesions, and cancer (Kennish, 2001). DDT and PCBs are particularly hazardous substances because they biomagnify in food chains; therefore, they pose a potentially serious threat to humans who consume contaminated seafood products.

Polycyclic aromatic hydrocarbons are widely distributed contaminants that largely derive from fossil fuel combustion, land runoff, municipal and industrial wastewater discharges, and oil spills. Natural processes (e.g., volcanic activity) also generate PAHs, but their inputs to estuaries are low relative to human sources. PAHs are a problematic class of contaminants because the higher-molecularweight forms are predominantly carcinogenic, mutagenic, and teratogenic, and the lower-molecularweight varieties can be acutely toxic. PAHs, when readily bioavailable, produce hepatic neoplasms (e.g., hepatocellular carcinoma, hepatocellular adenosoma, and cholangiocellular carcinoma) and other disorders in demersal fish and shellfish. They also are responsible for a range of sublethal effects manifested as biochemical, behavioral, physiological, and pathological aberrations in organisms that can contribute to changes in the structure of estuarine communities.

Heavy metals likewise are deleterious to estuarine organisms, causing reproductive and developmental abnormalities when present at elevated concentrations (Kennish, 1992, 1997). Orga-nometals (e.g., tributyl tin, alkylated lead, and methylmercury) are particularly toxic to these organisms. Riverine inflow, wastewater discharges, and atmospheric deposition deliver a large fraction of the total heavy metal burden found in estuaries. The combustion of fossil fuels and wastes from mining, smelting, electroplating, and refining operations are important sources. The concentrations of heavy metals in bottom sediments of estuaries are three to five orders of magnitude greater than those in overlying waters (Bryan and Langston, 1992; Kennish, 1998). Thus, benthic organisms may be most vulnerable to the harmful effects of these contaminants.

Overfishing

Fisheries overexploitation depletes estuarine fish and shellfish stocks and often cause their collapse, which simultaneously can generate dramatic ecosystem changes. For example, the collapse, of a major (piscivorous) fish population may lead to the rapid increase in its prey species, creating potential imbalances in community structure and the alteration of ecosystem function (Jennings and Kaiser, 1998; Pinnegar *et al*., 2000). Many commercially important marine species are now overfished, and the exploitation patterns of others are unsustainable (Pauly *et al*, 1998). As a result, the trend has been to "fish down" marine food webs, rendering affected ecosystems impoverished and less valuable (Williams, 1998). Because the marine fisheries harvest worldwide has increased fourfold since 1950, the global catch has shifted from large piscivorous species to smaller planktivorous forms (Boehlert, 1996).

Examples of overexploited estuarine fisheries include the striped bass (*Morone saxatilis*), chinook salmon (*Oncorhynchus tshawytscha*), and delta smelt (*Hypomesus transpacificus*) in San Francisco Bay. The sea trout fishes (*Cynoscion arenarius and Cynoscion nebulosus*) in Sarasota Bay, Florida, also appear to be overfished, with landings having declined by 50% since 1960. Several fish and shellfish species likewise appear to be overfished in the Albemarle-Pamlico Sound system of North Carolina (Kennish, 2000).

Introduced species

The accidental or purposeful introduction of exotic species to an estuary increases the probability of change in the native species assemblages (Moyle, 1986). When the introduced species become overwhelmingly successful in their adapted environment, they can outcompete and exclude the native species, promoting shifts in the structure and trophic organization of communities. In extreme cases, the ecological balance of the system may be threatened, as evidenced by acute reductions in biodiversity. The adapted habitats of the introduced species commonly lack natural controls, enabling these forms to rapidly dominate the native plant and animal communities.

One of the most heavily "invaded" estuaries in the world is San Francisco Bay, where nearly 250 species of plants and animals have been introduced (Cohen and Carlton, 1998). More than half of the fish species in the delta region consist of exotic, non-native forms, and most macroinvertebrates along the inner shallow water habitats of the system are introduced species (Kennish, 2000). Among the prominent introduced species in this estuary are the striped bass (*M. saxatilis*), oyster drill (*Urosalpinx cinerea*), and smooth cordgrass (*Spartina alterniflora*). The Asian clam (*Potamocorbula amurensis*), an introduced bivalve that has outcompeted native clam species (e.g., *Macoma balthica* and *Mya arenaria*), has seriously decimated the phytoplankton community of Suisun Bay.

Other examples of the detrimental effects of introduced species include the invasion of a parasitic protozoan (*Haplosporidium nelsoni*) in Delaware Bay, which has nearly destroyed the American oyster (*Crassostrea virginica*) fishery. Major fouling problems have developed in Corpus Christi Bay, Texas, due to the introduction of the brown mussel, *Perna perna* (Kennish, 2000). Rapid expansion of the nutria, *Myocastor coypu*, a South American mammal introduced into the Gulf of Mexico, may have contributed to the loss of coastal wetlands habitat in Louisiana (Day *et al*., 1989).

Physical alterations

Some of the most damaging impacts of human activities on estuaries are those that acutely modify or destroy habitats. They may occur within the estuarine basin (e.g., dredging and dredged material disposal, shipping operations, and mariculture) or along the estuarine shore (e.g., bulkheading, riprap, docks, piers, and marina facilities). However, many serious impacts also originate in coastal watersheds, particularly bordering wetlands. For instance, increased development and construction of impervious surfaces facilitate erosion and land runoff which can significantly alter water quality, hydrology, and salinity in the estuary. Sprawled development accelerates the fragmentation of natural habitats, thereby forming an impediment to the feeding and migration of wildlife.

Historically, habitat destruction and hydrological alteration have been pronounced in coastal wetlands. For example, the construction of canals, levees, and impoundments, as well as the diking and ditching of wetland surfaces, have destroyed marsh plant communities and have greatly modified drainage to estuaries. These effects have been conspicuous in Atlantic and Gulf Coast salt marshes. The impounding and drainage of wetlands habitat for agriculture and other purposes have eliminated ~50% of the original tidal salt marsh habitat in the United States (Kennish, 2001). In Puerto Rico, human activities have destroyed more than 70% of the mangroves fringing the coast (Alongi, 1998).

Activities in upland areas also can have a devastating effect on estuarine habitats. Mining and silviculture usually raise the concentrations of contaminants (e.g., metals), sediments, and other particulates transported to the coast. However, dam construction lowers these inputs as well as the downstream flow. The channelization of streams and rivers for flood control generally enhances freshwater discharges to estuaries. In contrast, the diversion of freshwater for agriculture, municipal, and industrial uses reduces freshwater inputs. This is exemplified by conditions surrounding San Francisco Bay, where more than 50% of the freshwater inflow is diverted elsewhere, mainly to satisfy agricultural demands (e.g., irrigation) which account for ~85% of the diverted water volume (Kennish, 2000). This freshwater diversion has significantly altered the salinity regime and the distribution of organisms in the upper estuary.

The withdrawal of groundwater, oil, and gas from subsurface formations has been responsible for the subsidence of coastal areas, the local retreat of estuarine high-tide shorelines and the loss and alteration of wetland and estuarine habitats. Such is the case at Galveston Bay and the lower Chesapeake Bay area. Acute subsidence also occurs along the northern Gulf of Mexico (i.e., Louisiana Coast) where sediment compaction, downwarping of the underlying crust, and eustatic sea-level rise are contributing to rapid coastline retreat.

Conclusions

Estuaries rank high on the list of the most heavily impacted aquatic systems on earth. This is largely attributed to accelerating population growth and development in the coastal zone and escalating use of estuarine resources. Most specifically, nutrient enrichment, chemical contaminant inputs, overfishing, introduction of exotic species, and physical alteration of habitats have adversely affected many estuarine systems. In some cases, the structure and trophic organization of biotic communities have been greatly altered. Ecological imbalances have raised concerns regarding the long-term health and viability of these critically important coastal environments.

New management strategies are being formulated and implemented in numerous estuaries and coastal watersheds nationwide to mitigate point and nonpoint sources of pollution and to mollify habitat impacts that threaten estuarine resources. Efforts are underway to restore damaged habitats in estuarine systems, including the revitalization of sea grass, salt marsh, and mangrove biotopes (Zedler, 2000). A major goal is to effectively manage estuaries to ensure sustainable exploitation of renewable resources while protecting the long-time health and viability of the systems. Such a program will help to maintain the ecological integrity of these invaluable coastal waterbodies.

ESTUARIES

In the now voluminous coastal literature, the definition of "estuary" is highly variable, and frequently reflects the standpoint of the author. Pethick (1984) states that: "estuaries are among the largest and most complex of all landforms, so complex in fact that attempting to provide a basic definition has proved extremely difficult."

Indeed one writer describes the definition of an estuary as rather like pornography—difficult to define, but you know it when you see it!

Central to the concept is that *estuaries are the tidal mouths of rivers* (Pethick, 1984). The French geomorphologist Guilcher (1958) pointed out that the word estuary comes from the Latin *aestus*, meaning tide, but that in France it has a popular synonym, *etier*, and the two words denote that part of the river system where the tides (water level rise and fall) and tidal currents make themselves felt. This is essentially the definition adopted by Fairbridge (1980) who defined an estuary as: "an inlet of the sea reaching into a river valley as far as the upper limit of tidal rise." This concept is also accepted by Caspers (1967) who argues that "the upper limit of the estuary is determined not by salinity but by tidal forces. In other words it is determined hydrodynamically rather than hydrochemically."

Thus, in principle an estuary can be defined from several different perspectives, including from the point of view of the geomorphology, sedimentation processes, tidal influences, the physical oceanography/salinity structure, or the ecology. In simple terms the definition is perhaps best considered from the standpoint of either "form" or "function."

From the geomorphic perspective, an estuary is defined in the general sense as: "the mouths of rivers, widening as they enter the sea" (Bird, l972). On a global scale they typically form in drowned river valleys. The Webster Dictionary (2nd edn) describes an estuary as "a passage, as the mouth of a river or lake, where the tide meets the river current; more commonly, a narrow arm of the sea at the lower end of a river." However, the authoritative Glossary of Geology, edited by Jackson (1997) defines an estuary variously as:

> (a) the seaward end or the widened funnel-shaped tidal mouth of a river valley where freshwater mixes with and measurably dilutes sea water and where tidal effects are evident; e.g. a tidal river, or a partially enclosed coastal body of water where the tide meets the current of a stream. (b) A portion of an ocean, as a firth or an arm of the sea affected by freshwater; e.g. the Baltic Sea. (c) a drowned river mouth formed by subsidence of land near the coast or by the drowning of the lower portion of a non-glaciated valley due to the rise of sea level.

In physical geography terms the *Webster Dictionary* (2nd edn) defines an estuary as: "a drowned river mouth, caused by the sinking of the land near the coast." Stamp, in his *Glossary of Geographical Terms* (1966), defines an estuary as a "tidal opening, an inlet or creek through which the tide enters; an arm of the sea indenting the land," but Stamp states that this definition is rare in modern use.

Cameron and Pritchard (1963) provide a definition of estuaries perhaps the most widely accepted by coastal scientists, as: "a semi-enclosed coastal body of water which has a free connection with the open sea and within which sea water is measurably diluted with fresh water from land drainage." This definition appears in most of the modern textbooks such as Pethick's (1984): "*An Introduction to Coastal Geomorphology*" and Black (1986): "*Oceans and Coasts.*" Such a definition leads to a classification of estuaries as a function of their salinity structure, focusing on the oceanographic properties determined by the physical dimensions in relation to river flows, salinity distribution, and tidal conditions. Another influencing factor is the Coriolis effect which becomes important for wide estuaries. Based upon these physical characteristics, estuaries may be classified as follows (Bowden, 1967): (1) *Salt wedge estuaries* occur where river flows dominate the salinity structure. In such cases, the river waters flow seawards as a layer of freshwater separated from the underlying saltwater by a sharp density interface. This reduces the turbulence and mixing between the two separate water bodies, and the saltwater extends as a down-sloping wedge along the bottom into the head of the estuary. (2) *Two layer flow with entrainment*. Again two distinctive water bodies of different salinity and density are apparent in the vertical, but when internal waves at the interface break, saltwater is entrained upwards into the surface freshwater, thereby increasing its salinity. To compensate for this entrainment there is an upstream directed residual flow along the bottom. It is this current that facilitates transport of fine suspended material upstream into the upper reaches of the estuary. (3) *Two layer flow with vertical mixing*. In relatively shallow estuaries the turbulence generated by the tidal flows generates mixing through a greater proportion of the water body. Fresher water is mixed downwards and saline water upwards, but there is no sharp density interface boundary. However, there are still two layers of flow and a bottom landwards residual current. (4) *Vertically homogeneous estuaries*. When tidal currents are strong in relation to the freshwater input, or in shallow estuaries where form drag induces turbulence throughout the flow, the vertical mixing becomes complete throughout the water column, and there is no measurable variation in salinity from the surface to the bottom. There is, of course, a horizontal gradient of salinity from the estuary head to the mouth.

Wind may have an important influence on the estuarine density driven circulations. Wind stress on the water surface produces a net transport of surface water, and the waves generated increase the intensity of vertical mixing. These processes on occasions can override the normal estuarine density circulation.

Physiographically estuaries are of four identifiable types (Healy and Kirk, 1982). These are: (1) *Fiords*, characterized as former valley glaciers in mountainous terrain, with steep sides, a deep basin, and in many cases a sill at its mouth. Such features occur in Norway, Scotland, southern Chile, and southwest New Zealand. But there are also more complex lowland fiords of the Baltic type, formed originally as meltwater depressions under the Pleistocene ice sheet, and flooded with the postglacial sea-level transgression. (2) *Drowned river valleys* or *rias* occur widely along mid-latitude coasts, and occur in their purest form as meandering river valleys along coasts with hard crystalline basement rocks with low sedimentation rates. In many cases, complete valley systems were drowned resulting in a dendritic pattern of arms. Along active sedimentation coasts the rias are often modified as they connect with the open sea, typically exhibiting sediment infill of the drowned river valley to form modern tidal flats (Figure E10) and low alluvial plains developed over the estuarine sediments. They may possess barriers across the mouth of the embayment, such as occurs on the Oregon and New Zealand coasts (Figure E11). Where major faulting occurs the rias may become fault-aligned as in New Zealand's Marlborough Sounds. (3) *Barrier enclosed estuarine lagoons* occur along the low sandy barrier coasts of the world, such as the Atlantic seaboard of the United States or the eastern coast of Australia (Figure E12). The older term "bar built" estuaries is genetically misleading, and should be avoided, as few barriers originate from "bars." The enclosing barriers typically comprise Holocene dune barrier-islands and spits as is typical along the

Figure E13 The down faulted structural graben of the Firth of Thames, New Zealand, into which flows the large Waihou River. The name "Firth" is a geomorphic misnomer, as this structural estuary did not originate from ice scour (photo: T. Healy).

Atlantic and Gulf coasts of the United States, but that is not always the case. Some enclosing barriers may comprise high (up to 200 m) Pleistocene dunes, as for the very large harbors on the west coast of the North Island of New Zealand, and sometimes the enclosing barriers may be of gravel, and even boulders, as for example at Nelson, New Zealand. These lagoonal-type estuaries are characterized by shallow depths and frequently broad expanses of intertidal flats become exposed at low tide. Where they occur along littoral drift coasts the entrances are characterized by narrow tidal inlets with ebb and flood tidal delta systems. Because of the overall shallow lagoon, the estuaries are well mixed in terms of their salinity structure, although there may be salinity variation from the mouth to the head of the lagoonal estuary. In arid coasts, the lagoonal waters may become hypersaline. (4) *Structural and tectonically induced estuaries* are typified by downthrown grabens (San Francisco Bay), tectonic depressions (Botany Bay, NSW), or flooded calderas (Banks Peninsula, New Zealand). These tend to be large-scale features (Figure E13).

Clearly, there is a geomorphic gradation both within and between large estuaries. For example, a large barrier-enclosed estuarine lagoon may possess arms in its upper reaches that exhibit the geomorphic characteristics primarily of a drowned river valley, and salinity characteristics of a salt wedge and two-layer flow. Conversely, a drowned river valley estuary with overall dendritic outline may possess barriers across its mouth (e.g. Chesapeake Bay, or Raglan Harbour in New Zealand).

However, all of these geomorphic categories of estuaries feature an element of "drowning" from rise of the postglacial sea level, which reached its approximate present level some ~6,000 years ago (Russsell, 1967). However, continued drowning of an estuary is rarely identified in modern times, despite the present global warming and its consequent sea-level minor rise.

On the contrary, active sedimentation within estuaries overall outweighs any modern sea-level rise effect. This is especially so for high sediment load major rivers such as the Amazon, the Yellow River of China, and the Mississippi, where rapid sedimentation and the growth of deltas has greatly modified the estuary over the past ~6,000 thousand years. Indeed, estuaries are well recognized as natural sediment traps, and are ephemeral features of the geological record. As Russell notes, most estuaries have changed considerably from the active sedimentation during the past few millenia, and many estuaries are headed for extinction. Rapid sediment input into estuaries from the inflowing river catchments, acts to fill them up from the land. But (especially for lee coast estuaries) diabathic onshore transport across the shelf provides sediment at the coasts that sweeps into the estuary mouths, and acts to infill estuaries from the sea. In addition, the saline density circulation within estuaries and mixing of mud-laden freshwaters from the catchment with the saline marine waters, leads to flocculation of fine particles, which residual bottom currents tend to transport toward the head of the estuary, where the muds deposit and accumulate.

Within most estuaries tides are the major energy source for mixing fresh and saltwater, and for resuspending sediment from the bed and transporting those sediments seawards or landwards. Frictional effects dissipate the tidal wave energy within the estuary, and deform the tidal wave. But this is offset by convergence of the tidal wave as it progresses up the estuary. Depending upon the balance between tidal wave convergence compared with frictional dissipation effects, the tidal range within an estuary can be larger than at the open sea before decreasing landwards toward the river (a hypersynchronous condition), or the frictional effects can dominate and the tidal amplitude decreases landward from the mouth, a hyposynchronous condition. Most ria type estuaries are a hypersynchronous and attain maximum current strength in middle or landward reaches, whereas for the barrier enclosed estuaries the maximum current strength occurs at the narrow tidal inlet.

In many estuaries, there exists an essentially closed circulation system for fine suspended particles, which causes them to become entrapped. This occurs due to the formation of "turbidity maxima" and from the "settling lag" effect. In the latter process, there is a time lag between the turn of the tide (when current velocity is zero) and when the concentration of fine suspended particle concentrations become minimum. This settling lag is due to the time it takes for the fine material to settle through the water column after the reduction in flow velocities (and reduction in turbulence), and thus the particle is carried some distance beyond the point where it starts to sink. Thus for a flood tidal current near high water, a certain amount of fine sediment settles toward the landward areas. The lag effect can explain why in many estuarine tidal flats there is a much greater proportion of mud particles than in the adjoining open sea, and why moving landwards up the estuary the particle size gradually fines (Postma, 1967).

A "turbidity maximum" of suspended sediment concentration often occurs in the upper reaches of many estuaries, particularly in the partially mixed types, where suspended sediment concentrations may reach 10 to 100 times greater than either seaward or further up the river, and may reach 1–10 g/L. This feature occurs in a wide variety of estuaries over the world, and occurs because fine particle settling is trapped in the null zone where river current converges with the landward estuarine flow near the bottom (Nichols and Biggs, 1985).

The formation of highly concentrated fluid mud layers at the bottom may also be part of the sediment dynamics. Fluid mud is a highly concentrated sediment suspension with a sediment concentration of between 10,000 and 300,000 mg/L, and can originate from the turbidity maximum at slack water. It may take the form of mobile or stationary suspensions (Kirby, 1988). But fluid mud can also form from wave action (Healy *et al*., 1999).

A typical feature of shallow estuaries is the estuarine "turbid fringe." This is generated by the wave action as the tide rises over the intertidal flats and reagitates the fine particles into suspension. Thus even in days of very light wave action a zone of brown turbid waters is observed around the shore of the estuary. Fine sediment transport in the estuary is also affected by specific processes such as aggregation of the fine particles, deposition, erosion, and consolidation. Classically, the aggregation of fine sediment particles was explained by the so-called electric double-layer theory. In recent decades, additional mechanisms have been identified including organic aggregation, bioflocculation, and pelletization.

EUSTASY

Eustasy refers to a globally uniform change in sea level. Suess (1888) originally attributed eustasy to crustal subsidence and sediment deposition. Removal or addition of water to oceans during glacial/interglacial cycles was another proposed cause. Fairbridge (1961) summarized these theories as follows: (1) *tectono-eustasy* (tectonic deformation of the ocean basins), (2) *sedimento-eustasy* (loading of crust by sediments), and (3) *glacio-eustasy* (removal/addition of water to the oceans by expansion or contraction of polar ice sheets). Another process is *hydro-isostatic* loading of the seafloor by glacial meltwater (Walcott, 1972; Clark *et al*., 1978). Worldwide compilations of Holocene sea-level curves, however, revealed major regional differences, thus challenging the concept of eustasy (Pirazzoli, 1991).

Seismic reflection profiles on continental shelves, collected during petroleum exploration in the 1970s, showed similar patterns of "sequence boundaries," or regional unconformities, in passive margin

Table E8 Summary of processes affecting global sea level

sedimentary deposits from many parts of the world (see *Sequence stratigraphy*). Sequence boundaries have been widely interpreted as marking major episodes of synchronous eustatic sea-level falls, which are summarized in global sea-level curves (e.g., Vail *et al*., 1977; Haq *et al*., 1987). Although widely used, these curves have been criticized on grounds that sequence boundaries are uncritically accepted as eustatic, that magnitudes of sea-level fluctuations are largely speculative, and that boundaries have not been accurately dated (for good overviews, see Christie-Blick *et al*., 1990; Miall, 1997). However, curves from various sources show certain common features, suggesting that at least some of these proposed sea-level events could be worldwide in scope.

Causes of eustasy

Sea-level integrates the effects of diverse geological and meteorological phenomena, such as glacio-eustasy, glacio-isostasy, plate motions, etc., which operate on differing spatial and temporal scales (Table E8). The relative magnitudes of these processes vary from place to place, thus tending to obscure any globally coherent sea-level signal. As a result, the search for a universal "eustatic" sea level curve has turned toward obtaining improved regional and local ("relative") sea-level curves (Tooley, 1993). Yet, as shown below, improved modeling of glacio-isostatic adjustments and detailed, accurately dated sea-level data from areas of known uplift enable reconstruction of global sea-level rise over the last 18,000 years and the past century.

Table E8 outlines processes affecting global sea level over various geologic timescales. These processes involve: (1) changes in the volume or mass of ocean water, (2) changes in the volume of the ocean basins, and (3) dynamic changes of the ocean surface.

Changes in the volume or mass of ocean water

Glacio-eustasy. Melting or accumulation of continental ice sheets during the last 2.5 million years has produced large changes in ocean water volume and global sea level. These oscillations of sea level over timescales of tens to hundreds of thousands of years are caused primarily by changes in solar radiation arising from periodic variations in the earth's orbit around the Sun (the "Milankovitch" cycles, Imbrie *et al*., 1984).

Changes in sea level during glacial cycles have been analyzed indirectly using fluctuations in the ratio of ^{18}O to ^{16}O in deep-sea microorganisms, such as foraminifera from ocean sediment cores, and also by dating emerged coral reefs on tectonically rising islands (see *Geochronology*, *Coral Reefs, Uplifted*). Variations in the oxygen isotope ratio serve as a proxy for alternations in global ocean volume, and hence in sea-level, linked to changing masses of continental ice. Sea level curves for the past several hundred thousand years have been constructed from well-dated raised coral terraces on Barbados and Papua New Guinea (Gallup *et al*., 1994). These data show highstands of sea level at approximately 193,000, 125,000, 100,000, and 83,000 years ago.

The post-glacial marine transgression of the last 18,000 years has been plotted by careful radiometric dating (^{14}C, and ^{230}Th-^{234}U) of corals from three widely separated oceanic islands with known tectonic trends and minimal glacio-isostatic influence. These three areas show a remarkably consistent and uniform rise in sea level of around 120–125 m, which therefore represents a true eustatic curve (Figure E14, Fairbanks, 1989; Bard *et al*., 1996). Two periods of accelerated sea level rise are detected: the older at around 14,000 years BP (labeled MWP-1A) and the younger at 11,500–11,000 years BP (MWP-1B). These two events correspond to two major meltwater pulses associated with rapid breakup and melting of the ice sheets.

The process of glacio-eustasy is now well established for the late Cenozoic, but less certain is the extent to which Milankovitch cycles have operated in the more distant geologic past. Antarctica has been glaciated for at least 14 million, and possibly as much as 35 million years. The late Paleozoic Gondwana glaciation led to a major marine regression. A late Ordovician glaciation was centered on the Sahara Desert in north Africa. Beyond these, other glacial episodes are less well established, and the presence of 10^4–10^5-year frequencies in the stratigraphic record are not necessarily conclusive proof of Milankovitch cycles (Miall, 1997).

Hydro-eustasy. Redistribution of water among the major terrestrial hydrological reservoirs, in response to major climate shifts, can also affect the ocean's level. A potentially significant terrestrial reservoir on timescales of tens to hundred of thousands of years resides in groundwater (Hay and Leslie, 1990). Sediments may contain enough pore space to hold the equivalent of 76 m of sea level (or 50 m with isostatic adjustment).

Steric changes. Over timescales of decades to centuries, changes in ocean water density become important contributors to sea-level change. Warming, cooling, or changes in salinity of ocean water affect its volume (but not its mass content). Thermal expansion of the upper layers of the oceans, as the earth's climate warmed approximately 0.6°C during the last hundred years, could account for 0.3–0.7 mm/yr of the observed sea-level rise of 1–2.0 mm/yr during this period (Houghton *et al*., 2001).

Changes in volume of ocean basins

Tectono-eustasy: On geologic timescales of tens to hundreds of millions of years, major factors controlling sea level include changes in seafloor spreading rates, cooling of oceanic crust, and passive margin thermotectonic subsidence (Rona, 1995). At times of rapid seafloor spreading, a comparatively larger volume of younger, warmer, more buoyant basaltic crust is created at mid-oceanic ridges. This displaces water, raising sea level on the continental margins. Slow seafloor spreading rates produce the opposite effect. Plate collision, thrusting, and terrane accretion can also cause changes in sea level on timescales of 10^7 years. Continental collision reduces land area due to compression, producing a corresponding increase in ocean area which can lead to a

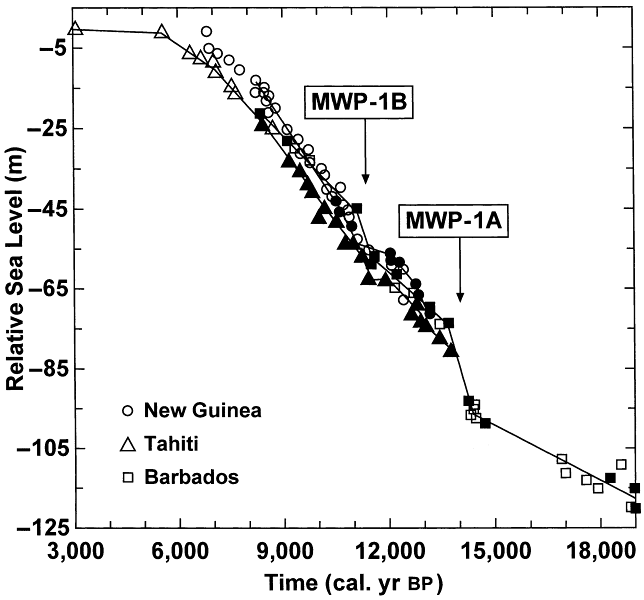

Figure E14 Sea-level curve of the post-glacial marine transgression. Based on radiocarbon and U-Th dating of corals from Tahiti, Barbados, and New-Guinea (modified from Bard *et al.*, 1996).

drop in sea level of up to 100 m (Table E8). Other tectono-eustatic mechanisms include hot-spot activity and deep mantle upwelling (Hallam, 1992).

Sedimento-eustasy: Displacement of water by sedimentation on continental margins and ocean basins displaces water, causing an apparent rise in sea level.

Glacio-isostasy Loading and unloading of ice masses during major glacial cycles induce non-uniform glacio-isostatic adjustments of the earth's crust (Table E8). Resulting changes in coastal elevation strongly affect the location of the earth's coastlines and local sea level. For example, much of Canada and Scandinavia, formerly covered by ice, are still rebounding isostatically and local sea level is falling. Conversely, eastern United States and the low countries of Europe, at the southern edge of the ice, are still subsiding, with locally rising sea level (Peltier, 1999). Subsidence accounts for close to half of the observed recent sea-level rise along the United States east coast (Gornitz, 1995a;b).

Geophysical models calculate the redistribution of mass accompanying the latest deglaciation (Peltier, 1999; Lambeck and Nakada, 1992). These models can be used to filter residual glacio-isostatic movements which contaminate the 20th century sea-level records based on tide-gauges. This has allowed an estimation of the climate warming-induced "absolute" or eustatic sea-level change (e.g., Peltier and Tushingham, 1989). An alternative approach employs late Holocene paleosea-level indicators to remove long-term geologic trends (Gornitz and Lebedeff, 1987; Gornitz, 1995a).

Dynamic changes

Atmospheric and oceanographic processes are responsible for fluctuations in sea level that last from 1 to 2 years to a decade or more, and are coherent over long distances. These fluctuations arise from ocean currents, and closely coupled oceanographic–atmospheric phenomena, such as the Northern Atlantic Oscillation (NAO), or the El Nino-Southern Oscillation (ENSO) in the Pacific Ocean (see *ENSO*; Table E8). During the El Nino phase of the ENSO cycle, anomalously warm water propagates eastward, splitting into north and south poleward-propagating Kelvin waves, causing sea level to rise (for several months) along the west coasts of the Americas (Komar and Enfield, 1987).

Conclusions

Sea-level change is a complex phenomenon, varying considerably over space and time. Nonetheless, considerable progress has been made in modeling of glacio-isostasy and in accurate dating of Holocene sea-level proxies, far removed from glacial influences. This information will enable separation of the present-day eustatic (global) sea-level signal from regional to local geological factors.

EUROPE, COASTAL ECOLOGY

Introduction

Europe occupies a little less than 7% of the total area of the world land surface. For its size its coastline is long, estimated at 143,000 km (Stanners and Bordeau, 1995). The European figure is derived from a map of 1 : 3 million scale and represents a conservative figure. The coastlines of Great Britain and Greece, for example, are 18,838 and 15,000 km, respectively, when the many islands are included. Though the figure for Great Britain is taken from measurements made at a scale of 1 : 50,000 and not directly comparable with the European figure they give an indication of the scale of the resource.

Europe's landmass is bounded by the Atlantic Ocean in the west and includes several enclosed seas (Figure E15). The basic fabric of the coast is formed from rocks which span the whole of the geological timescale from the Precambrian period (3,000–570 million years ago) to the rocks laid down in the Cretaceous–Tertiary period (140–2 million years ago). Superimposed on this structure, in the north, is the effect of the ice-ages of the Quaternary period (2 million to 10,000 years ago) and the glacial deposits, which were left behind as the ice melted. In the south, tectonic activity associated with volcanoes and earthquakes has also had an impact, though on a more limited geographical scale.

A combination of oceanographic factors (such as tides and sea-level change) as well as climatic effects, force the landward or seaward movement of sediments derived from erosion of the land or seabed. This provides opportunities for new coastal areas to develop as the material is deposited on or adjacent to the land. A variety of other variables, including the ameliorating effect of the warm Atlantic waters and westerly winds help to define a west to east climatic gradient, which is most clearly seen in the nature of the vegetation. Human activities have also been important, though more recent in their impact, causing modification or loss of habitat and "squeezing" the coastal zone (Doody, 2001).

The description that follows provides an overview of the nature of Europe's coastline from Norway to the eastern Mediterranean and the flora and fauna which occur there.

The "nature" of Europe's coast

The coastline and marine waters of Europe are areas of great contrast with a high diversity of wildlife and landscape features. The underlying geology helps to define the coast and its landscape. Today, in many areas where the coastline is composed of "hard" rocks resistant to erosion, it may appear unchanging. However, during the 2 million years or so of the Quaternary Period the growth (and retreat) of the ice sheets eroded mountains and scoured river valleys. In the north and west from Norway to the Atlantic coasts of Ireland and western Britain, the combined effects helped to mold the landscape, exposing some underlying structures and covering others. This glaciated northern landscape exists today as a highly indented coast with exposed sea cliffs, coastal inlets (including fjords, fjards and firths, and a few, usually small estuaries), rocky shores, and pocket beaches. By contrast, the coasts of southern England, France, northern Spain, and Portugal include "softer" though resistant limestone molded by more recent events (such as erosion from the sea and land slip) to form cliffs and headlands. Hard igneous rocks of Precambrian age and resistant granites also abound in the northern Baltic. Here, the lie of the land is gentler and cliffs are much less evident. Isostatic rebound continues to create small flat offshore islands.

At the southern limits of the ice sheets, in the southern North Sea and the Baltic Sea particularly (Figure E15), major deposits of glacial sediment left behind as the ice retreated northwards have helped to create the present low-lying landscapes. These provided abundant soft sediments for reworking during the Holocene epoch of the last 10,000 years. Today eroding glacial till cliffs, sand dunes, salt marshes and tidal sand, and mud flats are abundant. These combine to form large estuaries in the meso- to macro-tidal southern North Sea and deltas on the micro-tidal shores of the southern Baltic. Within the matrix of sandy spits and bars and tidal flats, promontories of harder limestone rocks help form embayments in a few locations. Sub-tidal areas also tend to be dominated by softer sediments on the sea bed.

The Mediterranean Sea has both hard and soft rocks, the former predominating as karstic limestone cliffs, and more gently sloping rocky shores. Generally, the land rises uninterrupted from the sea. Where cliffs occur these can reach a height of over 150 m, as on the southern coast of Spain. Over the last 4,000 years or so erosion of the mountains has also helped to create large coastal plains as their river catchments have delivered sediment to the coast. In the micro-tidal areas of both the Mediterranean and Black Seas large deltaic systems such as the Ebro Delta in Spain, the Po Delta in Italy, and the Danube Delta in the Black Sea have grown partly in response to deforestation in the hinterland.

Sea-level change, tidal range, and wave action

Long-term sea-level change is a major determining factor in the development of the coastline and coastal habitats. From around 7,000 years ago, when sea level began to stabilize at its present level, many of the coastal formations that are present today began to develop. Their evolution then and now depends on a combination of factors, including the availability of sediment and the influence of sea-level change, tidal range, and wave action.

With global sea levels rising today at about 1–2 mm per year (Warrick, 1993) there appears to be a general trend towards erosion and mobilization of sediments. Exceptions occur where isostatic rebound of glaciated areas is rising faster than sea level, causing a general rise in the land relative to the sea in areas such as Norway, the Gulf of Bothnia and around the margins of the Central Highlands of Scotland. Where the land continues to sink or is stable, relative sea-level rise tends to push coastal habitats toward the land. When this migration is restricted by resistant, rising landforms or artificial structures built to defend the land from erosion and/or flooding, the shore is squeezed into an ever narrower zone. This has important implications not only for the habitats themselves, but also the ability of the coastal landforms to provide a flexible response to storms and extreme tidal events. It may also impact on human use and infrastructure at the coastal margin.

Tides and tidal range provide a further mechanism for change. Where large amounts of material are available for transport extensive sedimentary habitats can be created. In the macro-tidal areas (spring tidal range >4 m) of the west, including the Celtic Seas, the Bristol Channel (where the tidal range, at 12 m is the second highest in the world) and the Atlantic coast of France, sediments are moved inland to fill inlets and bays, creating estuaries. In meso-tidal (spring tidal range 2–4 m) or micro-tidal areas (spring tidal range <2 m) the tides have progressively less influence. At the lower end of the tidal range the sediment movement is offshore, with rivers tending to exert a more dominant role. Waves and wave energy help determine the final configuration of the deltas as in the Baltic and the Mediterranean.

Climate

The coasts and seas of Europe encompass a wide range of climatic conditions from the Arctic Circle to the deserts of north Africa. Summer temperatures rarely rise above 10°C in most northern latitudes. This gradient is further influenced in the west by the marine waters, which are warmed by the Gulf Stream, creating an extreme maritime climate, which helps to define the Atlantic biogeographical zone encompassing much of northwest Europe (Polunin and Walters, 1985).

Unlike the areas further north the climate of the Mediterranean is very different. The winters are warmer (averaging 6°C) and the summers dry and hot. The range of temperature is much greater than on the Atlantic coast. The combination of thin limestone soils, dry climate and the long history of grazing and burning of the natural vegetation, has helped to create low-growing shrubby, drought and grazing resistant vegetation, which covers large areas of the Mediterranean. Since storms and waves are generated over a smaller sea area than the Atlantic, extreme exposure to gales is less evident than on the Atlantic coast.

Elevated landscapes—sea cliffs

Sea cliffs help to create some of the most spectacular and remote landscapes in Europe. They may have vertical or sloping faces, and in exposed locations are often drenched in salt spray, especially where they face the full extent of the Atlantic Ocean, and in the northern North Sea. Their orientation (and hence degree of exposure) and the nature of the underlying rock helps to determine the type of vegetation growing there. Although not considered in detail here stability is also an important factor helping to perpetuate shallow skeletal soils.

Sea cliff vegetation

Three main types of vegetation have been identified in the European Union Habitats and Species Directive, (European Com-mission, 1999). A brief description of the first two is given below.

Vegetated sea cliffs of the Atlantic and Baltic coasts. In exposed areas with hard rock cliffs, some of the best examples of maritime cliff vegetation in Europe are to be found. These include communities dominated by roseroot *Sedum rosea* and Scot's lovage *Ligusticum scoticum*, on the salt-spray drenched cliffs. Above this spray zone, the cliffs support communities that include arctic-alpine plants including purple saxifrage *Saxifraga oppositifolia*, moss campion *Silene acaulis*, mountain avens *Dryas octopetala* and in Scotland the endemic Scottish primrose *Primula scotica*. In some areas, the extent of the truly maritime zone can be small. In sheltered locations, such as the east coasts of Ireland and Scotland, the cliffs are only marginally exposed to the full power of the wind, breaking waves and salt spray. Here, the maritime influence is reduced and plants less resilient to exposure and salt spray grow in communities more typical of inland locations. Further south from south west Ireland, Wales and south west England to southern Portugal, spectacular west facing cliffs also occur. These are less resistant than the harder rocks further north and in some areas rapid rates of erosion (1 m or more per year) can be measured as, for example, in the chalk cliffs of the Channel coast. Although still exposed to the Atlantic Ocean and its gales, climatic amelioration also allows a richer flora to develop. In limestone areas of south west Britain, northern France, and Spain the cliffs provide important refuges for warm loving species, such as spider orchid *Ophrys sphegodes*, formerly typically found in inland grasslands. In some areas, cliffs provide the most spectacular natural rock gardens, as at Cape St. Vincent in Portugal, where the endemic *Cistus palinhae* is one of the many species present.

Vegetated sea cliffs of the Mediterranean coasts with endemic Limonium *spp.* Unlike the corresponding cliffs in the north and west, the incidence of exposure and hence the maritime nature of cliff vegetation in the Mediterranean is much reduced. Exceptions include the megacliffs of Croatia (Velebit) which represent a coastal habitat of exceptional biological importance. The habitats present range from emerging rocks with a calcifying algal community to sea water-drenched hyper-saline communities, including *Arthrocnemum glaucum* and *Atriplex portulacoides*, to exposed windswept cliff tops from 460 to 1,200 m high. Interspersed in more sheltered areas are woodlands and scrub. There is little elsewhere in the literature concerning these habitats though reference is made to similar cliffs in Albania and southwest Turkey (van der Maarel, 1993). These areas should probably be considered alongside the Atlantic woodlands of the northwest and the laurel forests of the Canary Islands for their conservation importance. The vegetation of all of these is to one degree or another dependent on its presence of moisture-laden air derived from strong onshore winds.

Sea cliffs and seabirds

Because of the close proximity to the rich waters of the Atlantic Ocean and the North Sea, coastal cliffs often support large colonies of nesting seabirds. The most common and conspicuous species are guillemot *Uria aalge*, kittiwake *Rissa tridactyla*, fulmar *Fulmarus glacialis* and razorbill *Alca torda*, which nest on ledges. Steep-sided granite cliffs may support large populations of gannet *Sula bassana*. On sloping cliffs where soil has accumulated, species which prefer to nest in burrows are found in high numbers such as puffin *Fratercula arctica* and manx shearwater *Puffinus puffinus*. Sea cliffs also provide nesting sites for a rare birds of prey such as the peregrine *Falco peregrinus* and the raven *Corvus corax*.

Seabird colonies do occur on cliffs and islands on more southerly coasts, though the populations, especially of cliff-nesting species are much smaller. Birds of prey are important and of these Eleonora's falcon *Falco eleonorae* is of special significance. It is a small falcon feeding mostly on small birds. It migrates northwards from Madagascar where it is widely dispersed feeding on a range of insects and in a wide variety of habitats. These include coastal cliffs and cultivated areas, rice fields, lightly wooded slopes or coastal plains. It breeds in colonies on steep rocky coastal cliffs and islands, mainly in the Mediterranean. The breeding season is later than other species and timed to coincide with passerine migrations, ensuring a supply of food for its young.

"Soft" rock landscapes—unconsolidated cliffs

Cliffs derived from unconsolidated deposits of clay (including glacial material), loam or other easily eroded sediments occur throughout the area. Landslip is common in sand and clays in the southern North Sea, southern Baltic Sea and on the south coast of England and in the sedimentary deposits of the Black Sea. Continuous erosion can result in the formation of high sloping unstable cliffs with little or no vegetation other than ephemeral communities. Where erosion is more episodic, the slopes can support scrub and even woodland on ledges remaining stable over periods of one hundred years or so. In these situations, some of the least "maritime" of the coastal cliff vegetation is found and may be indistinguishable from inland types.

The release of sediment during periods of erosion is an important factor in the development of coastal systems elsewhere. Preventing erosion in order to protect buildings or other human land uses can have consequences for habitats along the shore. As less sediment is available for movement by longshore drift opportunities for the creation of new beaches, themselves a form of coast protection, is restricted. In extreme cases adjacent habitats may be so deprived of sediment that they begin to erode.

Complex sedimentary systems

In contrast to cliffed landscapes, sedimentary landscapes are characteristically low-lying (Figure E18). They can include a variety of very different habitats and are often highly unstable. Tidal flats and salt marshes, sand dunes, and gravel are the main formations that help to define the ecosystem. Coastal wetlands may include some or all of these habitats though the tidal habitats, especially sand and mud flats, have a special significance and are described first. The short- to medium-term influence of tides and waves, freshwater inflows and sediment movement, or longer-term trends associated with sea-level change can result in the systems being very complex both spatially and temporally. Included within this section are the other components that make up the complex coastal sedimentary habitats, including the more terrestrial sand dunes and gravel structures.

Coastal wetlands

Coastal wetlands occur throughout Europe (Figure E19). Wolff (1989) estimates that intertidal areas cover 9,300 km^2, excluding small wetland areas in Iceland, Russia, Norway, Spain, Portugal, and Italy where little or no information is available. This implies that intertidal wetlands cover only 0.09% of Europe's land surface, a figure clearly highlighting the scarcity of the habitat type. They are most extensive in the major estuaries of the southern North Sea and the deltas of the southern Baltic and Mediterranean Seas. The Wadden Sea in Holland, for example, has approximately 123,900 ha and the Ebro Delta in Catalonia, one of the five biggest in the Mediterranean/Black Sea area has some 350,000 ha of tidal and former tidal land.

Estuaries. Estuaries, deltas, and lagoons lie within a range of coastal wetlands which have specific characteristics defined partly by the geographical location and degree of sediment input. In the north and west fjords and fjards, usually considered to be a special form of estuary, are specifically associated with glaciated areas and have limited inputs of sediment. The former are drowned glacial troughs, often associated with major lines of geological weakness. They have a close width–depth ratio, steep sides and an almost rectangular cross section. Sediment deposition is mostly restricted to the head of the fjord where the rivers usually discharge. The latter are glacial relicts on lowland coasts; ice-scoured rock basins, bars and small islands are characteristic features. Rias also have limited sediment and are formed when river valleys were inundated at the end of the last glacial period. They occur on the exposed western shores of Europe in macro- or meso-tidal areas. They are characteristically steep-sided with wooded slopes and occur in south west England and northern France, Spain, and Portugal.

Estuaries usually have major inputs of sediment. They are "partially enclosed bodies of water, open to saline water from the sea and receiving fresh water from rivers, land run-off or seepage" (Davidson *et al.*, 1991). They are complex systems, subject to a usually twice daily tidal rise and fall, they may have sand dunes or gravel structures enclosing sheltered shallow mud and sand shoals and salt marshes. They are particularly extensive in lowland areas with abundant sediment and a macro–meso-tidal range. Particularly large sites occur in the southern north sea, (in and around the Thames Basin, the delta region of Holland and in the Wadden Sea).

Estuarine fauna. A key component in the development of the ecological value of coastal wetlands, especially tidal estuaries, is their high productivity. This is derived from *in situ* primary production of salt marshes and in estuarine waters, as well as inputs from the land and the sea. This abundant source of food can result in very large numbers of a few dominant organisms. Typical densities on muddy shores of the mud snail *Hydrobia ulvae* can be up to 120,000 individuals present per square meter. The burrowing amphipod *Corophium volutator* is also numerous with up to 60,000 individuals per square meter. The segmented worms *Nereis diversicolor* (a ragworm) and on more sandy shores *Arenicola marina* (lugworm), are also often abundant and of particular importance as prey for wintering wading birds. In this context, estuaries in north west Europe are especially valuable and frequently support nationally and internationally important numbers of water birds (wildfowl and waders). Some indication of the significance of these estuaries can be gleaned from the location of the main wintering populations of the knot *Canutus canutus islandica* (Figure E20).

While these wintering bird populations are often the most obvious visible manifestation of the productivity of a wetland system a range of other species occur. These include sea fish using the shelter of the

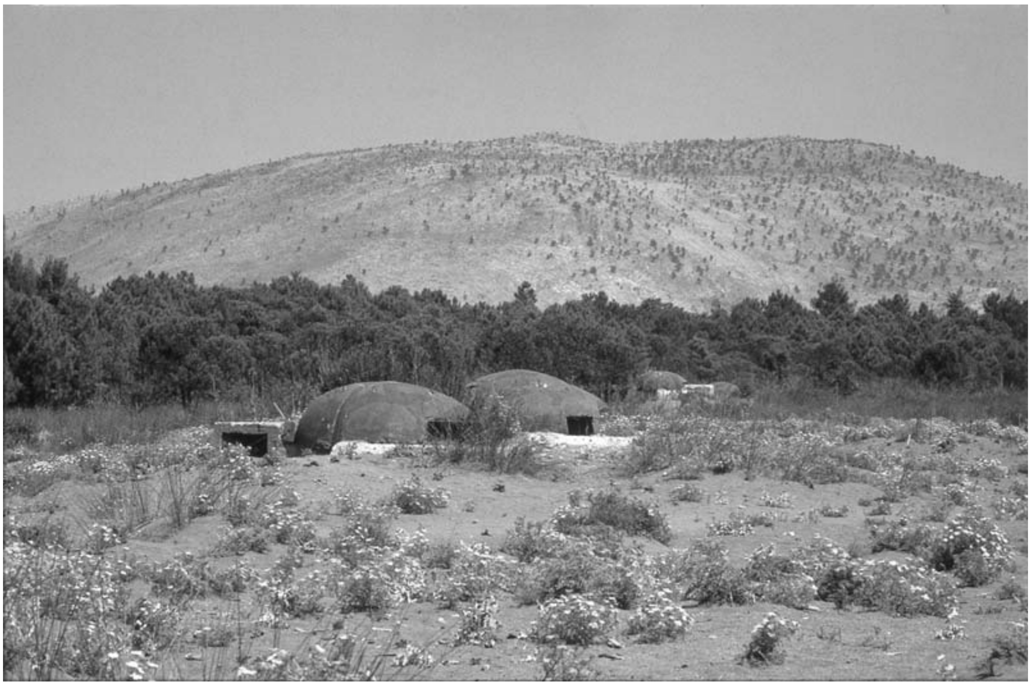

Figure E18 Low-lying sedimentary coastal plain derived from sediments eroded from the hills of northern Albania.

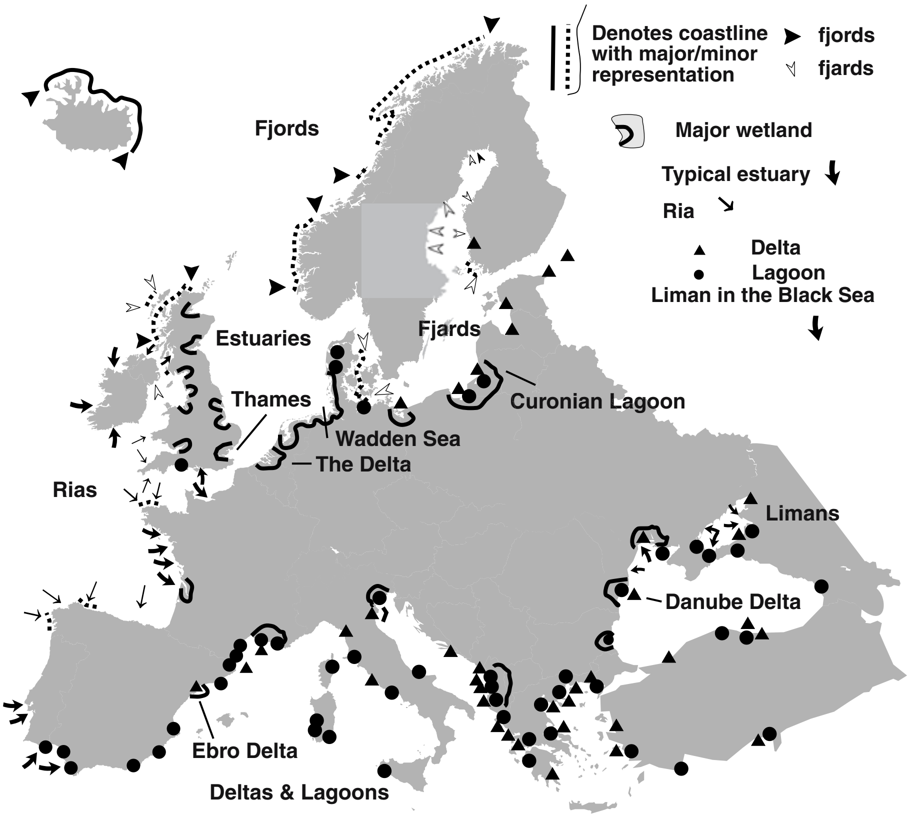

Figure E19 Distribution of coastal wetlands in Europe (adapted from Doody, 2001).

estuary to spawn, or as nursery areas. Diadromous fish are specialists of the estuarine environment. Catadromous species such as *Anguilla anguilla* (the common eel) move from freshwater to the sea where they spawn, passing on the way the salinity gradients in the estuaries and deltas. In contrast an andromous species such as *Salmo salar* (salmon) develops from eggs shed upstream in rivers. A major part of its life is spent outside the home rivers at sea. Important feeding areas are in the Atlantic along the west coast of Greenland, above the Faroe Islands, in the Norwegian Sea, and possibly in the Barents Sea. In the Baltic, the Curonian Lagoon has 46 freshwater, migratory, and marine fish including the Baltic salmon, reflecting its importance for these species.

Deltas and lagoons

Coastal deltas and lagoons are most characteristic of micro-tidal regions (with a tidal range <2 m), and hence in Europe are particularly abundant around the shores of the Baltic, Mediterranean, and Black Seas. Deltas are sedimentary coastal plains built up from material brought down by rivers to cover shallow offshore areas creating sedimentary features which protrude beyond the normal limit of the coastal margin. They are best developed in micro–meso-tidal areas where wave action is the dominant force in building the sand dunes, barrier islands bars, and salt marshes. Lagoons are shallow, virtually tideless, pond- or lake-like bodies of coastal salt or brackish water that are partially isolated from the adjacent sea by a sedimentary barrier, but which nevertheless receive an influx of salt water from that sea (Barnes, 1980; Guélorget and Perthuisot, 1992). Although they are mostly found in micro-tidal seas, they are also present on some macro-tidal coasts—such as the northern North Atlantic—where offshore deposits of gravel are to be found. Gravel then replaces the sand of micro-tidal seas as the barrier material. Europe possesses the smallest proportion of lagoonal coastline of any continent, with only 5% of its coast in this category (Cromwell, 1971). Several deltas, for example that of the Danube (and Nile), have developed within—and have now largely or completely obliterated—former lagoons enclosed by barrier-island chains. The limans of the Black Sea coast receive their salt input via seepage.

Fauna. Deltas and lagoons are also important for a variety of water birds. They support waders, wildfowl, grebes, and similar marshland birds many wintering or on passage, as well as a considerable number of nesting species. Among these black-winged stilt *Himantopus himantopus*, avocet *Recurvirostra avosetta* and herons, including purple heron *Ardea pururea* and large populations of a few species of breeding duck are significant. However, it is the spectacular flamingo *Phoenicopterus ruber roseus*, which is most readily appreciated by anyone visiting the Camargue or the Ebro Deltas in the western Mediterranean. Numbered in thousands in the Camargue it is a species dependent on wetlands which periodically dry out and become hypersaline. These conditions naturally occur in North Africa and the Mediterranean but it is the juxtaposition of "natural" lagoons with "artificial" salinas which provide especially suitable nesting conditions (Sadoul *et al*., 1998).

The lagoons also support invertebrate and fish faunas. These may include essentially freshwater or marine/estuarine species capable of withstanding a degree of brackishness as well as specialist lagoon species. Among the marine fishes are sea bass *Dicentrarchus labrax* and sole *Solea vulgaris* while carp *Cyprinus carpio* and pike *Esox lucius* live in freshwater. Eel *A. anguilla* and mullets (Mugillidae) bridge the salinity gap.

Salt marshes

Salt marshes include all halophytic plant communities and their associated animals, which are influenced by sea water. Typically they are regularly inundated by the tide, have sometimes rapid accumulations of fine sediment and in the absence of enclosure, include transitions to nontidal vegetation. They are at their most extensive on flat tidal plains in sheltered locations where abundant sediment is deposited and wave action restricted (estuarine marshes). These conditions are most favorable to the establishment of the pioneer salt marsh plants such as *Salicornia* spp., *Suaeda* spp. and *Spartina* spp. which are among the most frequent colonists in northern latitudes. Lagoonal marshes occur in association with lagoons and are most extensive in the micro-tidal areas. Salt marshes also occur on beach plains behind exposed or partially protected beaches and in the lee of barrier islands. In some areas where sediment is restricted or (as is the case on some rocky shores and cliff tops) absent, inundation is intermittent and dependent on storms or extreme high water levels. In these situations, "perched" salt marshes on exposed cliffs and narrow saltings of rocky shores "beach head" and

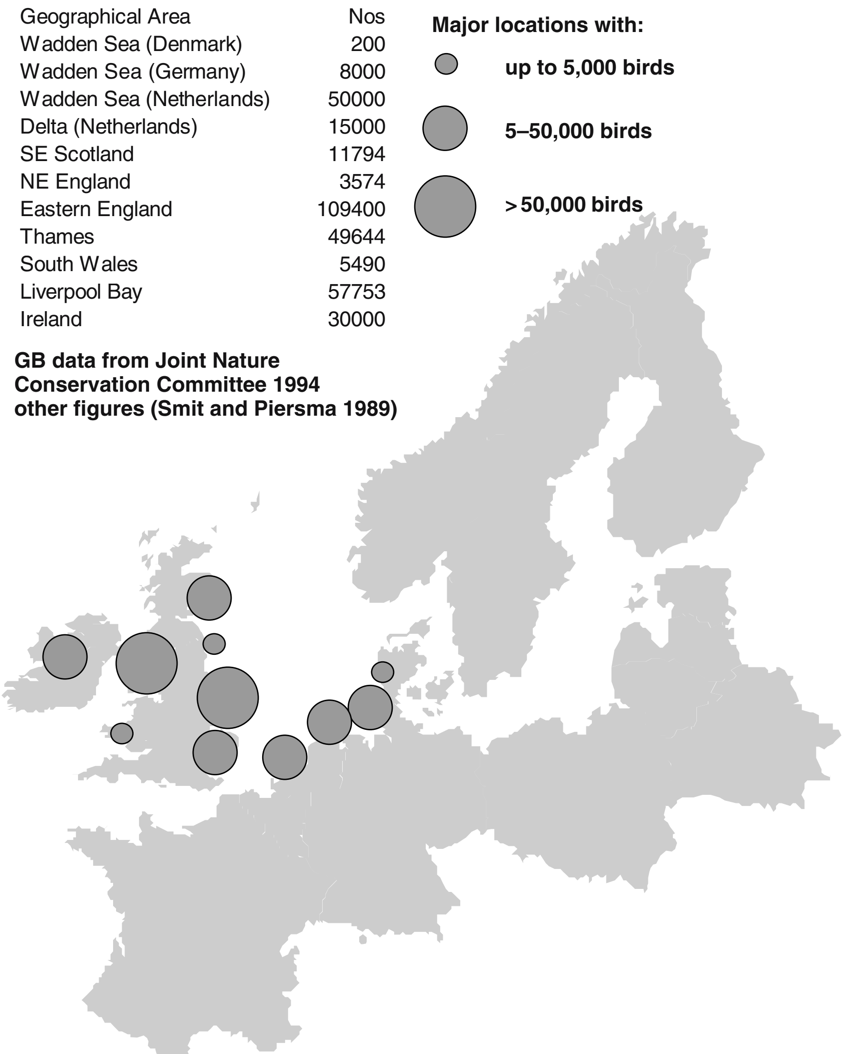

Figure E20 Distribution of the main wintering sites of the knot *Canutus canutus islandica* (adapted from Doody, 2001).

"loch head" salt marshes have vegetation similar to the typical salt marsh but without their rapid sedimentation (Doody, 2001a).

Distribution in Europe. Salt marshes occur throughout Europe and are particularly associated with the major macro-tidal estuaries of the southern North Sea and south and west England (Dijkema, 1984). Elsewhere in the northwest they occur as scattered small sites associated with rocky coasts. In the Baltic, they are more restricted, partly because of the very low salinity within this sea (Dijkema, 1990). In the Mediterranean, all the major deltas have extensive salt marsh communities. Elsewhere they again occur as scattered sites, though here less frequent than in the north. Their distribution is closely related to that of the coastal wetlands.

Vegetation succession. A key element in the development of salt marshes in sediment rich areas is the process of succession. A sequence of communities tolerant of different degrees of tidal submergence may develop, together with transitions to other, terrestrial vegetation. Transitions may be to reed swamp sand dune, gravel, freshwater, or woodland. This natural transition may be truncated by the construction of sea walls or other coastal defenses, with the loss of these upper salt marsh transitions and their associated wildlife. In some areas where a saline influence continues landwards of sea walls on enclosed unimproved salt marshes, coastal grazing marshes with brackish ditches may develop.

The early stages of colonization are represented by two main community types (European Commission, 1999), namely: ***Salicornia* and other annuals colonizing mud and sand** and ***Spartina* swards (*Spartinion maritimae*)**. These are typically referred to as pioneer marsh colonizing the lower levels of the tidal flats, most frequently inundated by the sea. Under these conditions, areas of mud, exposed for several days, are required for the early colonizers to become established. The communities which develop are composed of a few, mostly annual species occuring in mono specific stands, or in simple combinations. These typically include *Spartina* communities, most frequently *Spartina anglica* or stands of *Salicornia* spp., *Suaeda maritima* and *Aster tripolium* with *Puccinellia maritima* dominant. They are most frequently found in the macro–meso-tidal areas of the northwest.

The next stage in the successional process is typically refer-red to as mid-marsh. The distinction between low and mid-marsh is blurred but as the tidal height of the marsh increases additional species occur. These are dominated by the shrub *A. portulacoides* in the absence of grazing with increasingly *Festuca rubra* on grazed marshes. There is a wide variation in the composition of these communities and *Juncus gerardii* is another characteristic species. The presence of abundant *Armeria maritima* gives many marshes in the northwest a visually distinct appearance with a close-cropped, pink sward in summer.

The development of upper-marsh in the absence of enclosure provides some of the richest plant communities. Mid-upper marshes in the northwest are collectively classified within community type. **Atlantic saltmeadows (*Glauco-Puccinellietalia maritimae*)**. The presence of a number of species such as *Suaeda vera*, and *Frankenia laevis* in south-east England, more frequently found in Mediterranean regions suggest an overlap in distribution with. **Mediterranean salt meadows (*Juncetalia maritimi*)** and **Mediterranean and thermo-Atlantic halophilous scrubs (*Sarcocornetea fruticosi*)**. Transitions to swamp also occur in the absence of enclosure and are usually dominated by *Scirpus maritima* and *Phragmites australis*, which can be extensive in the upper reaches of estuaries. These communities form important transitions and may be particularly rich, especially where freshwater seepages or transitions to other habitats such as sand dunes occur. In the Baltic, the low salinity and micro-tidal range of the sea restricts the presence of the pioneer communities and extensive swamps dominated by *Phragmites* are more prevalent (Dijkema, 1990). Similarly in the Mediterranean the extent to which a true succession develops is restricted and narrow zones of a few mid-marsh species quickly merge into more extensive swamp. Some of the best examples of these occur in the still relatively undeveloped coastal deltas of northern Albania.

Fauna. Salt marshes present difficult environments for colonization by invertebrates due to changes in salinity and humidity caused by periodic tidal immersion. The fauna is a mixture of marine, freshwater and terrestrial species, which are adapted in various ways to the stressful environment. Marine species tend to occur lower down the marsh and often burrow to avoid desiccation. Terrestrial and freshwater species occur mostly in the upper marsh and transition zones, and have adapted to, or avoid immersion in saline water. The presence of individual invertebrate species is often closely associated with the type of vegetation which occurs.

Successful breeding by a variety of birds occurs on the upper levels of unenclosed salt marshes following the high spring tides in April and May. Although early nests may be destroyed by high tides, at least one brood is usually possible. The structural diversity of the marsh is also of crucial importance to some species such as redshank *Tringa totanus* and particularly high populations may be present in the best habitats. In winter, many of the most numerous species of wader feed almost exclusively on the invertebrates in the mud flats at low tide and are not dependent on the salt marshes as their main food supply. However, some also use the salt marsh for roosting at high tide, or as supplementary feeding around the pans and bare areas on the marsh (e.g., dunlin *Calidris alpina* and knot). Only the redshank and snipe, of the wading birds, use salt marsh in preference to the exposed tidal flat, probably because they like to be sheltered from view by the cover of vegetation. For these species the salt marsh represents the primary feeding location throughout most of the tidal cycle.

Other species, mainly grazing ducks and geese use the salt marsh as a source of food. The geese seek out open areas with close-cropped or low vegetation. Even here there are distinct preferences, and while the brent goose feeds on Eel-grass (*Zostera* spp.) in the low marsh, the stronger grey-lag goose feeds on the tougher grasses of the marsh itself. Of the ducks the wigeon feeds on both low and high marsh, normally at the waters edge. For most of these species the more palatable grasses favored under high stocking densities of cattle and sheep, are important to the continued use of the salt marsh by the grazing ducks and geese.

Sand dunes

Sand dunes develop wherever there is a suitable supply of sediment (within the size range 0.2–2.0 mm) which is moved onshore by the tide and then blown inland to form accumulations varying from a few centimeters to 40 m or more thick. The type of sand dune which develops depends on the underlying topography and climate. In most locations in the temperate regions of the world, vegetation plays an important role in the growth of the typical dune landscape, facilitating the accumulation of sediment (Ranwell and Boar, 1986). Bay dunes are the most common form and are associated with indented coastlines, often between headlands. Backshore dunes can be large and occur when both dominant and prevailing winds blow sand inland. On especially exposed sites, coastal cliffs may be covered with a veneer of sand blown up over the cliff to create "climbing dunes." Barrier islands tend to occur in exposed locations and may be built on gravel bars. Ness dunes, including cuspate forelands, occur where prevailing and dominant winds are in opposition. Sometimes progradation may be quite rapid and a series of low dune ridges form, interspersed with wet hollows. These are also found in areas where sea level is rising relative to the land as in southeast Norway, northeast Scotland, and Northern Ireland. Spit dunes occur when sediment is deposited at the mouth of an estuary. They take a variety of complex forms depending on the action of waves (longshore drift) and the force of the river flows to the sea. These also include the dune forms associated with deltas in micro-tidal seas.

Distribution in Europe. Sand dunes are distributed throughout Europe (Figure E21). In the areas where sediments are restricted there are a relatively large number of small sites, as in northern Norway and on the rocky, cliffed coasts of the exposed shores of the Atlantic from western Ireland to Spain, the karst coasts of the Mediterranean, and in the Black Sea. In the west where there are abundant coastal sand deposits, prevailing westerly winds blow the sand grains onshore to create large

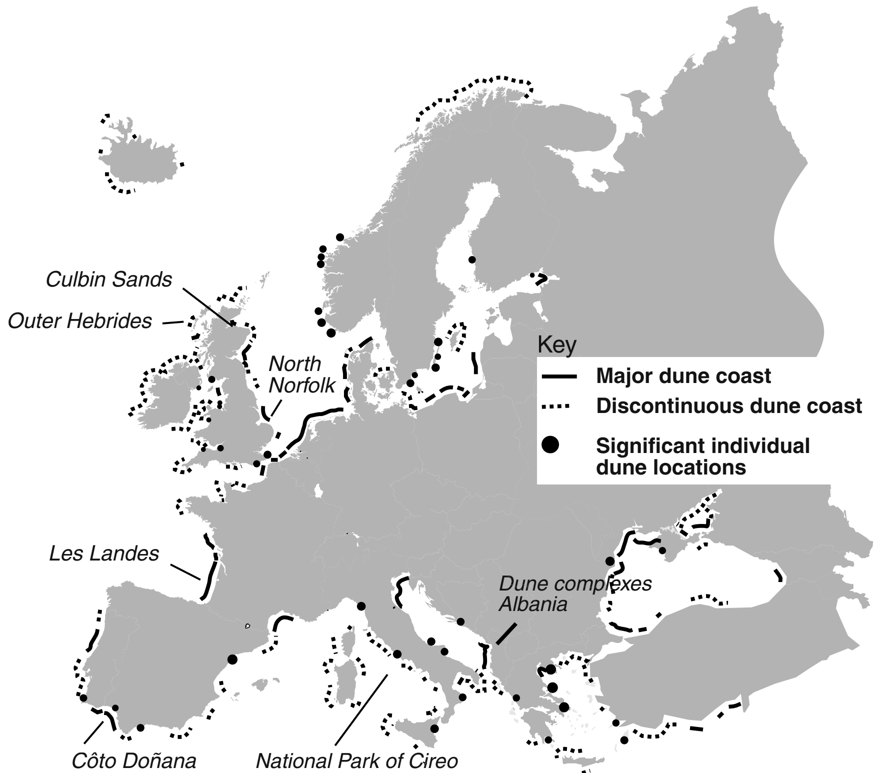

Figure E21 Distribution of sand dunes in Europe (adapted from Doody, 2001).

backshore systems such as those of the Outer Hebrides in Scotland. These include some of the best and largest examples of the extensive cultivated sandy plain or machair, also present in the west of Ireland. In northern Denmark massive accumulations of sand are forced onshore under the action of the prevailing winds from the North Sea. In France on similarly exposed coasts the dunes stretch many kilometers inland. Here, the area known as "Les Landes" has a special significance, and is one of the most extensive dunes in Europe.

On the North Sea coast and in the northern Baltic, dunes develop on a coastline, which is rising relative to sea level. Here, they are generally prograding with ridges becoming established as a sequence lying "parallel" to the coast. They are sometimes interspersed with damp hollows in which dune slack vegetation develops. In eastern Scotland some large examples occur, as at Culbin Sands a system with in excess of 4,000 ha, one of the largest areas of blown sand in Great Britain.

In the southern Baltic and southern North Sea where glacial sediments are particularly abundant, sand dunes are also extensive, for example, they make up 80% of the coastline of Poland. The predominant dune type is represented by sand bars and spits, which lie parallel to the coast (Poland and Wadden Sea). In southern Portugal and Spain, the dune systems also include barrier islands and spits. Rivers bring the sediment to the sea, which is then reworked by wave and tidal action and blown onshore. One the most important dune systems in Europe, lies within the Doñana National Park in Southern Spain. The park consists of beaches, foredunes, high mobile dunes (up to 30 m), and stabilized dunes which enclose a major wetland.

On the Mediterranean and Black Sea coasts dunes are often found in association with deltas. In Italy, dunes probably originated during the thermal optimum after the last glaciation (5,000 years ago). They have since been broken by rivers and their subsequent development has been a product of natural erosive forces and human activity. Today dunes are present around the whole coastline but only in a few protected areas, like the National Park of Circeo, can natural development be seen. Along the Greek coast there are many places where sand dunes cannot develop because the hills or mountains outcrop as rocky coastlines near to the sea. Sand dunes tend either to occupy a narrow fringe bordering flat areas of land or exceptionally form extensive dunes up to 10 m height, as in Western Peloponnesus.

Vegetation succession. The vegetation of sand dunes in temperate regions such as Europe can be grouped according to the successional sequence from the beach inland. These have been defined for the north west coastal areas as follows:

Strandline: This includes vegetation along the high tide line. It is usually ephemeral, salt tolerant and composed of a limited number of species;

Foredune: The first stage in sand deposition occurs here. The vegetation is limited in species diversity, dependent on its ability to withstand the influence of salt spray and trap moving sand;

Yellow dune: This represents the main and usually most rapid phase of dune growth. *Ammophila arenaria*, the main dune forming species, is able to withstand rapid burial by sand;

Dune grassland: Stabilized dune vegetation dominated by species of grass and herbs develops under the influence of grazing and in a moist climate. It is mostly found in northwest Europe;

Dune heath: Occurs on sand dunes where the calcium carbonate content of the soils is low, either because the original sand has a high proportion of silica or where leaching has taken place;

Scrub: Areas with low shrubs. These include woodland understorey species in the northwest and the "maquis" and other similar vegetation in the Mediterranean;

Dune slacks: Vegetation which develops under the influence of high water table and is often completely flooded in winter;

Woodland: Natural forest with various pine species or deciduous trees such as oaks. In most areas natural woodland is scarce.

The European Habitats Directive recognizes three major types of vegetation (European Commission, 1999). Of these the dunes of the "Atlantic, North Sea and Baltic" include at least 11 distinct types and those of the Mediterranean coast, 7 Most of the sand dunes described for northwest Europe appear to have a sequence of vegetation types which potentially includes all the more important successional communities from strandline (driftwalls) to yellow and grey dune, dune pasture and scrub, described above. (In areas where beach erosion is occurring some of the early stages of succession may be absent.)

The sequence of vegetation on the mid-Atlantic coast is similar to that occurring in the northwest. In the north of France, some of the botanically richer areas occur where dunes are composed of calcareous sand and lie against to chalk cliffs. The further south the dunes are formed, the more the southern elements of the flora appear.

On the Mediterranean coast the zonation described above is much less obvious. While *A. arenaria* still plays and important part in dune establishment, communities with dry grasslands and scrub are more prevalent. The following are recognized from the Manual of European Union Habitats (European Commission, 1999).

Crucianellion maritimae fixed beach dunes
Dunes with *Euphorbia terracina*
Malcolmietalia dune grasslands
Brachypodietalia dune grasslands with annuals
Coastal dunes with *Juniperus* spp.
Cisto-Lavanduletalia dune sclerophyllous scrubs
Wooded dunes with *Pinus pinea* and/or *Pinus pinaster*

Fauna. The dune fauna is not especially rich or abundant though the variety of slope, aspect and vegetation structure, coupled with the dynamic nature of many systems, make dunes one of the most suitable habitats for a range of invertebrates requiring open conditions. They are also frequented by warmth-loving species, which bask on the dry warm slopes even in the more northern latitudes. Hymenoptera (especially wild bees, digger wasps, spider wasps, and other solitary wasps) are able to build nests easily in the soft sand and are often found dwelling in sand dunes (Haeseler, 1989, 1992).

The dune avifauna includes breeding colonies of terns such as the sandwich tern *Sterna sandvicensis* and the little tern *Sterna albifrons* which nest on open sand. Other species such as the eider duck *Somateria mollissima* and the shelduck *Tadorna tadorna* nest in the ground vegetation in the north. Further south (including eastern Spain) tree nesting species of heron, such as the squacco heron *Ardeola ralloides* and the purple heron *Ardea purpurea* can be found.

Rabbits *Oryctolagus cuniculus* occur in abundance in all areas and are stock food for fox *Vulpes vulpes* populations of which inhabit mainland dunes. Polecat *Mustela putorius*, weasel *Mustela nivalis*, several species of bats, voles, mice, and shrews also occur in most of the areas, while the roe deer *Capreolus capreolus* and red squirrel *Sciurus vulgaris* are less frequent. Among reptiles and amphibians are sand lizard *Lacerta agilis*, natterjack toad *Bufo calamita* and the edible frog *Rana esculenta*.

Gravel

Gravel is the term applied to sediments larger in diameter than sand but smaller than boulders. A predominant particle size of over 2 mm separates gravel from sand (King, 1972) whereas at much over 200 mm diameter, boulders approximate to cliff habitat. Four environmental factors are responsible for the growth of a gravel beach. There must be an available supply of sediment in the size range mentioned above. At the same time waves, wind, and tidal currents should be favorable for its movement. Since this coincidence is unpredictable, considerable periods of time may exist when no movement takes place, these are interspersed by times of marked activity resulting in stable and mobile gravel habitats varying both in time and space.

Geomorphologists and ecologists have recognized five categories of gravel structures which vary in their oceanicity and therefore in their ecology. The simplest and commonest type is the fringing beach forming a strip in contact with the land along the top of the beach. Gravel spits form where there is an abrupt change in the direction of the coast. They often contain recurved hooks and a recurved distal end, a result of deflection of waves by refraction. Bars or barriers are effectively spits which have formed across estuary mouths or indentations in the coast. These three structures are basically foreshores, regularly washed by spray and storm waves and therefore possessing only limited or ephemeral vegetation over much of their area. Cuspate forelands and offshore barrier islands, on the other hand, are larger structures and are more terrestrial in nature. The former develop when gravel is available in large quantities and piles up in front of fringing beaches or spits and is then driven landwards by storm waves to form a series of roughly parallel ridges. Where wave approach can from two directions only, such apposition beaches will form into cuspate forelands (Figure E22). Large masses of gravel may also form offshore barrier islands under

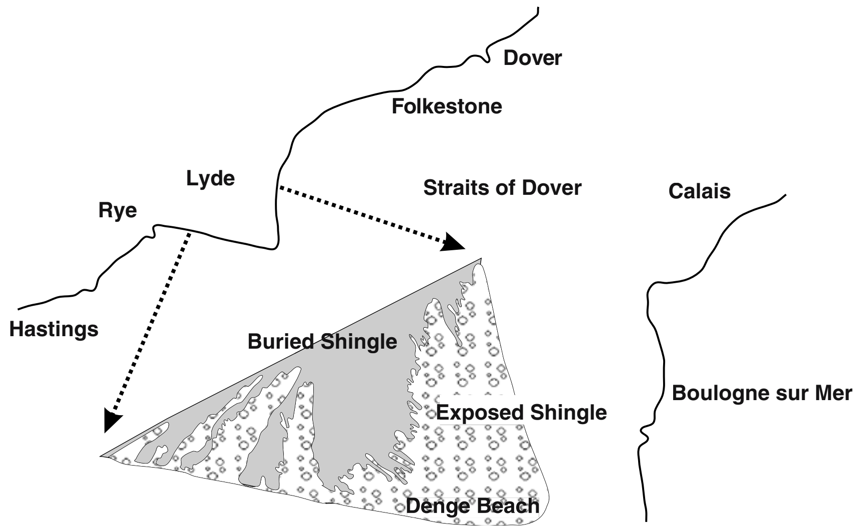

Figure E22 Dungeness southeast England—a cuspate foreland.

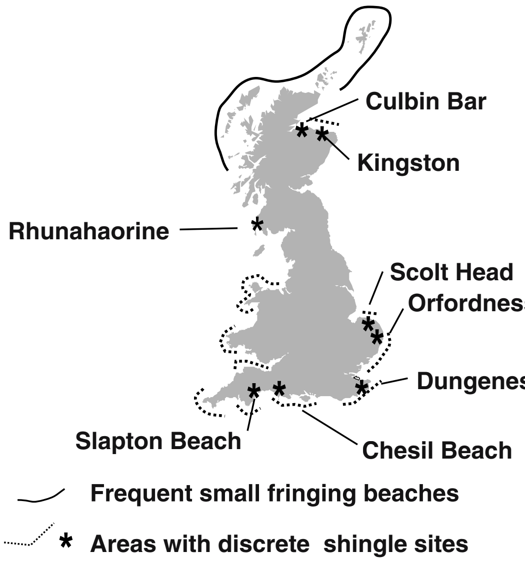

Figure E23 Distribution of gravel shores in the United Kingdom, some key sites are named.

conditions of shallow water and low-energy environments such as in the North Sea and the Baltic.

Distribution. Gravel deposits occur throughout Europe, especially in the north and west. Fringing beaches are widely distributed, though often small and narrow. Larger gravel structures occur as isolated and discrete entities. (Doody, 2001b). In the north, the fjords and sea lochs in both the meso-tidal and micro-tidal areas of the Atlantic, North Sea, and Baltic Sea support long stretches of gravel foreshores. Individual, more substantial structures are scattered throughout the area. The situation in the United Kingdom illustrates the nature of this occurrence (Figure E23). This is derived from extensive surveys undertaken in the 1990s and organized by the statutory conservation body, the Nature Conservancy Council.

Vegetation. Two plant communities identified in the European Union Habitats Directive (European Commission, 1999) help to define these formations: **Annual vegetation of drift lines** and **Perennial vegetation of stony banks**. Gravel shore vegetation includes *Mertensia maritima* prevalent in the north and *Glaucium flavum* and *Matthiola sinuata* in the south. Mobility is an over-riding consideration and the species which colonize are able to withstand periodic disturbance. These include *Lathyrus japonicus* and *Crambe maritima* colonizing the gravel just above the high water mark where the shore may remain stable for periods of 3–4 years. *Crambe maritima* is constant in the three sub-types of **Perennial vegetation of stony banks**, for the Baltic, Channel coast, and the Atlantic, respectively. Besides stability (or its converse mobility) beach composition and especially the amount of fine material present in the gravel matrix is another principal factor influencing the type of vegetation namely:

(1) gravel without matrix (relatively uncommon)—vegetation is limited to encrusting lichens and the most tolerant angiosperms such as *L. japonicus*;
(2) gravel with a sand matrix—dry yet stable conditions, contains species such as *Lotus corniculatus* and *Honckenya peploides*;
(3) gravel with a silt–clay matrix—ecologically related to salt-marshes but with freer drainage. The vegetation is similar to that of salt-marsh levées with *A. portulacoides* or *Glaux maritima*;
(4) gravel with an organic matrix—rotting seaweed is nutrient rich and supports populations of species that arrive as seed within tidal debris. Species include *Beta maritima* or *Atriplex* spp. where there is little drainage from the land, or with more humic soils reed *Phragmites communis* or *Iris pseudacorus* swamp may be present.

Fauna. The fauna associated with gravel structures largely consists of invertebrates (Shardlow, 2001) and avifauna. In the case of the former large numbers of species, such as bumble bees are found. Gravel beaches and structures provide suitable habitat for a small number of other species. These are generally ground nesting birds (Cadbury and Ausden, 2001) which make a simple scrape where they lay their camouflaged eggs. The importance of gravel as a habitat for breeding terns has led to the conservation of several sites and the need to create areas protected from human trampling affects. Few vertebrates other than domestic herbivores are found on gravel sites except hares and rabbits, though in some places foxes are important predators of ground nesting birds.

Human influences

This entry along with many text books describe coastal habitats in terms of their ecological or geomorphological development. Salt marshes and sand dunes, in particular are described as exhibiting primary succession. Classic studies in Great Britain covered salt marshes and sand dunes on the North Norfolk coast. All emphasized the natural status of the vegetation in areas where ecological processes appear to have been relatively free from human influence. The vegetation was thus described as a series of community types progressing from the early pioneer stages to more complex forms related to the physical factors influencing their development. While this is in part true, it is also the case that much of Europe's coastline has been influenced in one way or another by human activity. A few examples are discussed below.

Sea cliffs and slopes

Apparently inaccessible steep-sided sea cliffs and slopes are often seen as virtually unaffected by human activity. Certainly difficulties of access, low productivity, associated with a harsher climate mean that the harder rock of the north are less built on than their counterparts in some parts of the Mediterranean. However, grazing is and has been a traditional activity and even cliffs on more inaccessible islands have been and in a few cases continue to be plundered for sea birds and their eggs.

Sand dunes

Major tourist development, especially along the Mediterranean coast, has destroyed many sand dunes. Building directly onto the beach in some cases has completely obliterated some areas while sand extraction for use nearby has also taken its toll. Another activity is planting with non-native trees, especially conifers, to stabilize them. This has affected many systems throughout Europe and while the dune form is retained most of the dune plant and animal species are lost. One exception to this general picture is the large dune systems which have developed in association with major deltas on the coastline of Albania and in some parts of south east Turkey. Here, many different dune forms are present with a maximum height of about 50 m and width of up to 4.3 km, including huge beach plains with embryo dunes, parabolic dunes, blowouts, dune slacks, lakes, secondary barchans, and dune fields. They also include complete transitions to pine woodland with native *P. pinea* and *Pinus halipensis* as the forest tree. They are among the most important dune areas in Europe.

Secondary habitats coastal grazing marsh and salinas

The partial enclosure of salt marsh by the erection of a small earthen bank was probably one of the first human activities directly affecting coastal habitats. The aim was to extend the period of summer grazing by livestock (cattle and sheep), by preventing over-topping on spring tides. As the early techniques of enclosure improved, larger clay or earth banks were constructed enclosing consolidated salt marsh excluding the tide from larger areas. Historically the land was subsequently used as pasture, with little or no further "improvement". These areas of coastal grazing marsh are defined by the presence of permanent and semi-permanent grassland, drainage ditches, and enclosing earth dikes. The wildlife interest has developed alongside the traditional use of the area for agricultural.

The production of salt is one of the oldest industries known to man. Industrial salinas are large, artificial, and complex lagoon systems and a major source of salt produced today. The principal aim of any salt company is to produce a maximum tonage of salt per annum to meet the demands of commerce and industry. However, these artificial ecosystems are in fact, wetlands of international importance and areas with a rich and diverse flora and fauna, vertebrate and invertebrate communities. They host important breeding populations of aquatic birds, besides rare and endangered species. The special nature of Mediterranean salinas make them vitally important resting and refuelling sites for many thousands of shorebirds migrating between the Palearctic breeding grounds and their winter quarters in Africa (Sadoul *et al*., 1998).

Grazing and other management

A key feature of many habitats throughout Europe is the long history of exploitation by human kind, including grazing by domesticated stock. This has had a profound influence on the type of vegetation which has developed. In the northwest grazing (by rabbits cultivated in warrens) helped to create species rich calcareous dune grassland and heathland, preventing the natural progression to scrub and woodland. In areas formerly used for grazing by domestic stock a reversion is taking place to secondary mixed scrub, broad-leaved woodland and pine forest. This is particularly prevalent in Finland today where invasion of open land by pine forest with *Pinus sylvestris* is common. Prior to this, open vegetation was maintained by the grazing of domestic animals.

Grazing and burning are intimately bound up with the development of the low, thorny scrub vegetation which predominates in the Mediterranean. It is also clear that many of the major deltas would not be as extensive without the influence of deforestation in the hinterland. Thus it can be seen that the rich diversity of habitats and associated species, which exist along the coastline of Europe are influenced to a greater or lesser extent by human activities. At the other extreme major developments including tourist growth in the Mediterranean has greatly reduced the ecological and landscape diversity of many areas to the detriment of wildlife and cultural heritage. The way in which this has altered the coastline of Europe and the approaches being adopted to monitoring the impact of development and policy initiatives designed to protect it is the subject of the entry on Monitoring, Coastal Ecology.

EUROPE, COASTAL GEOMORPHOLOGY

The coastlines of Europe cover a latitudinal range of 45° reaching from 80°N in Spitsbergen to 35°N in southern Crete, Greece. Thus, nearly all coastal types except for mangroves and coral reefs are present in Europe (Bird and Schwartz, 1985; Kelletat, 1995), including arctic ice coasts with calving glaciers, drifting sea ice contact and permafrost decay along cliffs on Spitsbergen or young volcanic coastlines on the Aeolian islands of Italy or Santorini/Greece. Processes of salt weathering associated with tafoni can be observed at the Costa Brava in Spain and the islands of Corsica and Sardinia or SW-Turkey, biogeneous coastal forms (Laborel, 1987) including vermetid boiler reefs and micro atolls are characteristics on Crete islands (Greece) as well as coastal cementation like aeolianites and beachrocks. Because of the rather long and complicated geologic and tectonic history of the European continent, the coastlines are greatly differentiated. Their total length in natural scales is several 100,000 km. Many of the scientific terms in coastal sciences derive from European examples, like ria, fjord, canale, tombolo, or Thyrrhenian, Sicilian, Calabrien for Pleistocene sea level highstands.

The framework of coastal forming in Europe

The geology of Europe varies from very old structures, the proterozoic shields of granite and gneiss in Scandinavia, to rather young like the vivid neotectonic areas—even in historical times—in the eastern Mediterranean (Pirazzoli *et al.*, 1996). The orogenic belts of the Caledonids are still visible in the coastal configuration of Scotland, the Varistids in southern England, and the imprints of the alpidic orogenesis can be observed along nearly all coastlines of the Mediterranean. Areas of longer subsidence are marked by large embayments like the North Sea basin, the Gulf of Biscaya or the intra- continental sea of the Baltic and the intercontinental sea of the Mediterranean. Extremely resistant silicate rocks survived thousands of years of wave attack, whereas Pleistocene moraines or Holocene dunes suffer from strong erosion and abrasion. Vertical movements influence coastal development in many regions, but by different causes: long lasting and ongoing glacio-isostatic uplift in Scandinavia (nearly 300 m, with a modern maximum of 9 mm/year, acc. to Åse, 1980), Iceland and Scotland (both with more than 120 m), salt intrusion in small places of the North Sea basin (e.g., Heligoland) active horst and graben structures in the eastern Mediterranean (Figure E24), sediment load in large deltas (Rhône, Ebro, Po, Figure E25) or local subsidence by gas and water drilling in the Venice area. All processes cause their respective characteristic coastal shape.

Furthermore, exogenic factors of coastal forming are manifold, and here in particular the climate and its influence on the ocean. The spectrum ranges from frost climates of average annual temperature below −2°C and sea ice cover of nine months to nearly 30°C of surface water temperature in summer. Extreme humid conditions with far over 1,000 mm of precipitation are typical for NW-Europe, but then again less than 200 mm/year of precipitation is measured in eastern Crete (Greece), where evaporation exceed precipitation by a factor of 10. The salt content of sea water ranges from nearly 0% in the inner Baltic Sea to at least 3.9% in the eastern Mediterranean. Moreover, wind and wave spectra are very different: in the west strong winter storms may cause severe destruction and flooding, while in small bays of the Baltic or the Mediterranean wave action is insignificant. Tidal range and the strength of tidal currents differ also along a west–east gradient: spring tide range is highest around southwestern England and the Britanny coast of Western France (Figure E26), reaching more than 10 m, but in the Baltic and the Mediterranean it usually is less than 0.5 m to zero. Nevertheless, low air pressure and extreme winds may cause storm surges up to 3 m above datum even in these enclosed basins. Even tsunami impacts can be detected such as along the Algarve coast of southern Portugal, southern Atlantic Spain, Mallorca island, Apulia, Cyprus (Kelletat and Schellmann, 2002), or in marshes in Scotland and in coastal lakes of western Norway (Bondevik *et al.*, 1997).

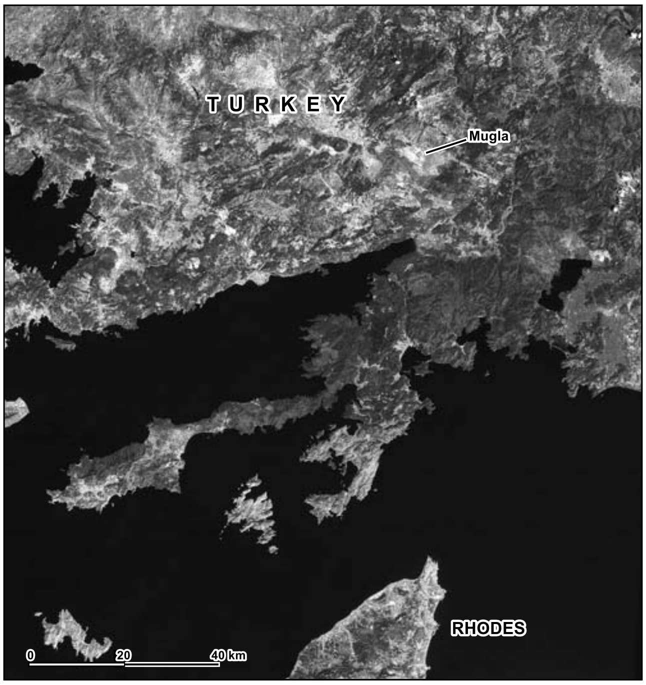

Figure E24 Satellite image of the Mugla-area in southwestern Turkey with ingressive coastal forms as horst and graben structures with straight fault coastlines as well as partial drowning of a terrestrial fluvial and denudational relief (© SI/ANTRIX/Euromap 1996, GAF 1997).

Specific coastal regions

European coastal regions with a specific environmental or geomorphic factor are illustrated in Figure E22: northern Europe including Scotland and Iceland present coastlines of emergence by glacio-isostatic uplift between near 0–285 m (Klemsdal, 1982; Lambeck, 1993; Kelletat, 1994; Steers, 1973). Neverthe-less, those coastal forms are predominantly marked by ingression, so that fjords (Figure E27), fjärds, bodden, förden (Figure E28) or partly submerged roches moutonnées as skerries (Figure E29) as well as partly drowned eskers, end moraines, or drumlins, the latter particularly in Denmark and southern Finland are characteristic (Granö and Roto, 1993; Duphorn *et al.*, 1995). Here, glacial erosion has carved bedrock far below sea level and therefore the late- and post-glacial transgression was not compensated by late- and post-glacial uplift. The area of glacio-isostatic uplift mostly corresponds with glacially sculptured coastal landscapes, in which the forms from the last glaciation are much clearer than those from the penultimate glaciation, which are smoothened by periglacial processes during the Weichselian. Another specificum of the northern sections in Europe is frost action along the coast including drifting sea ice contact, in particular in the inner and eastern Baltic as well as in the Barents Sea and in some inner parts of northern Norwegian fjords (Figure E26), where Gulf Stream influence is minimal and freshwater input is important.

Pleistocene glaciations have left behind specific materials along the coasts: moraines are washed out and now show boulder beaches as in the Aaland archipelago between Sweden and Finland or along the southern Baltic coastline, partly pushed into ridges by drifting sea ice (Philip, 1990). These boulders are an important natural protection against surf beat and erosion. Glacial outwash and fluvioglacial deposits are characterized by gravel and sand, which dominates the southern coasts of Iceland as well as the west coast of Denmark or the northwestern coast of Germany and the Netherlands. If sand supply from the ice ages is abundant, extended beaches are developed, sometimes accompanied by coastal dunes. These conditions may also be found along the southern Baltic coastlines (Baker *et al.*, 1990).

Figure E25 Satellite image of the delta of River Po, Italy. The progradation mostly is a young Holocene feature (© ESA, Eurimage 1989, GAF 1989).

In contrast to formerly glaciated landscapes, fluvial formed landscapes are dominant in the south of Europe, where rivers have carved into older bedrock during low sea levels. Postglacial transgression has transformed these valley mouths into rias as in Southern Ireland, England (Steers, 1976), Britanny in France and in NW-Spain, some of them widened by tides and waves into estuaries as in the mouth of the rivers Elbe (Germany), Thames (England), or Seine (France).

A third representative coastal area in Europe is formed due to faulting processes associated with horst and graben structures such as southern Greece including the Aegean Sea and western Turkey (Figure E24). A vivid neotectonic is still dislocating coastal sections vertically (Lambeck, 1995; Pirazzoli *et al*., 1996, see also Figure E30). In more downward moved parts coastlines of ingression with drowned medium-to-steep slopes are common. Here, canale (Figure E31), short rias, transformed by karst and erosion processes into calas of different shapes are developed and as well drowned karst features like dolines or poljes dominate (Kelletat, 1995). In contrast, cliffs (Figure E32) and coastal terraces are typical for the uplifted parts of the landscape. The areas of (Pleistocene) uplift in southern Europe often correspond with young orogenic structures, representing excellent examples of Pleistocene marine terraces up to several 100 m above sea level today (Kelletat *et al*., 1976).

As limestone is the predominant rock type in the Mediterranean area, coastal bioerosion with notches (mostly by grazing *Patella*) and rock pools (by grazing *Littorina neritoides*) as well as bioconstruction by calcareous algae (e.g., *Neogonio-lithon notarisii*) and vermetids (e.g., *Dendropoma petraeum*, Figure E33) are widely common in this part of the European coast (Kelletat, 1997). Another specification is the extended distribution of younger Pleistocene aeolianites along the Mediterranean coasts, whereas Holocene beach rocks are mostly restricted to the hot and dry sections of thek eastern Mediterranean (Briand and Maldonado, 1997).

There is only one area of medium to high tides in Europe, located between southern England and the Britanny coast of France where the spring tide range reaches around 10 m (Figure E26), diminishing to the inner German Bight and Scotland to medium values of 2–4 m. These areas may show extended tidal flats, with a sandy matrix where wave action and tidal currents are strong, and muddy in regions of weaker water movements (Figure E34; Verger, 1968; Ehlers, 1988; Hillen and Verhagen, 1993; Kelletat, 1998). The growth of green and brown macro algae (*Fucus* sp., *Laminaria* sp. and others) along the rocky shores is characteristic for the cooler European coastlines from northern France including the British Isles and Iceland to northernmost Norway (but excluding the Baltic). They partly give protection against strong surf beat, whereas in the Mediterranean sea grass may form a thick carpet on beaches after winter storms. Along parts of the Swedish, Finnish, Polish, or German coastline with a low salt content of seawater, coastal freshwater swamps with *Phragmites* sp. occur.

Coastal forms and sediments

The differentiation of coastal forms along the European coastlines is visualized in Figure E35 giving an impression of the general form of bays (rias and estuaries by fluvial action, fjords, fjärds, förden, and bodden by glacial sculpturing, canale by folding and faulting control, cala by karst and abrasion, or lagoons with barriers and spits up to 90 km in the eastern Baltic by longshore drift). The map also represents the different coastline types: rocky coastlines with cliffs (and sometimes intertidal platforms), sandy shores with beaches (Guilcher and King, 1961; King, 1972, including areas with beach rocks), muddy ones in tidal flats, deltaic by fluvial progradation (as in the areas of low tides and surf of the Mediterranean), or biogenic structures along limestone coasts with poor sediment supply.

Deeply incised fjords are the main coastal features of northern Iceland, northwestern Scotland and nearly all of Norway except of the easternmost parts where cliff sections around the North Cape and the Barents peninsula occur. In Scotland and the central north coast of Iceland wider rocky embayments in a low and hilly landscape smoothened by Pleistocene glaciation reveal more aspects of fjärds, which are typical for the Swedish coastline along the Baltic and some parts of Finland. Here, an old peneplain is slowly dipping seaward. Numerous skerries decorate all rocky Scandinavian coastlines, whereas to the periphery of former glaciation morainic sediments and fluvioglacial deposits dominate. Thus, the landscape is either characterized by partly drowned eskers, drumlins and end moraines, which are mostly well preserved in areas with low surf energy conditions, such as in the island archipelago of southeastern Denmark, or fast receding cliffs may have been developed like along the southern shores of the Baltic. As a rather unusual feature in the Scandinavian coastal landscape the so-called strandflat exists as an undulating rocky plain surrounding most of the coasts of Norway, but occurring likewise in northwestern Iceland. The form originates from a glacially smoothed very old peneplain now situated around sea level with a medium width of 16 km and a maximum one of 40 km. Roches moutonnées are the dominant features, and old inselbergs may rise from the peneplain to several 100 m of relative height. Outwash plains (sander), fed by meltwater and glacial-burst

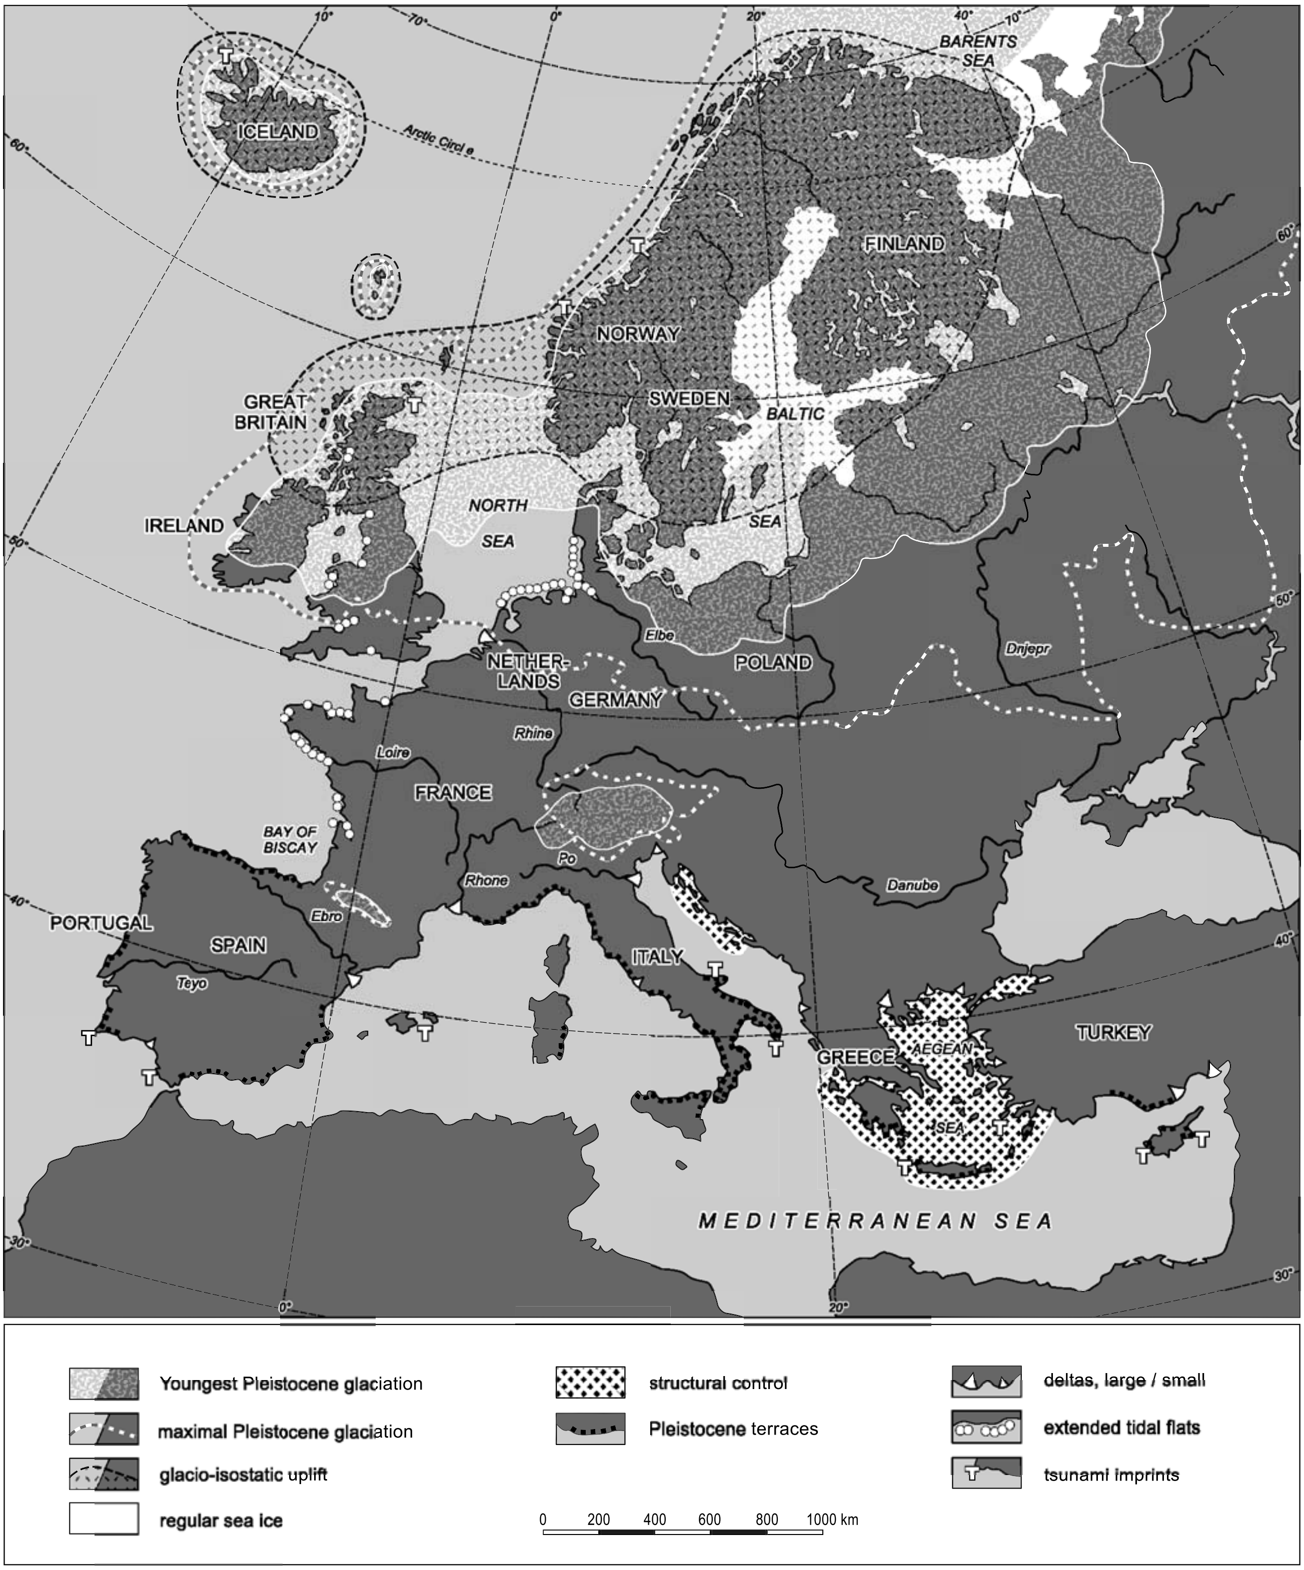

Figure E26 Map of the European coastlines showing special environmental parameters.

floods from the huge glaciers are typical for the southern part of Iceland. Therefore, the coasts show beaches and even barriers and lagoons. Along the southern shores of the Baltic very long spits fed by longshore drift from the west, large lagoons and intercalated cliffy sections occur. Along the Polish coast 52% are sandy beaches, 28% are fresh-water swamps, and only 20% show cliffs. At the German Baltic coastline this type gradually changes to ingressive forms from glacial and fluvioglacial origin like bodden and förden (Figure E34).

The longest section of muddy and sandy tidal flats in Europe with barrier islands and spits can be found from western Denmark all along

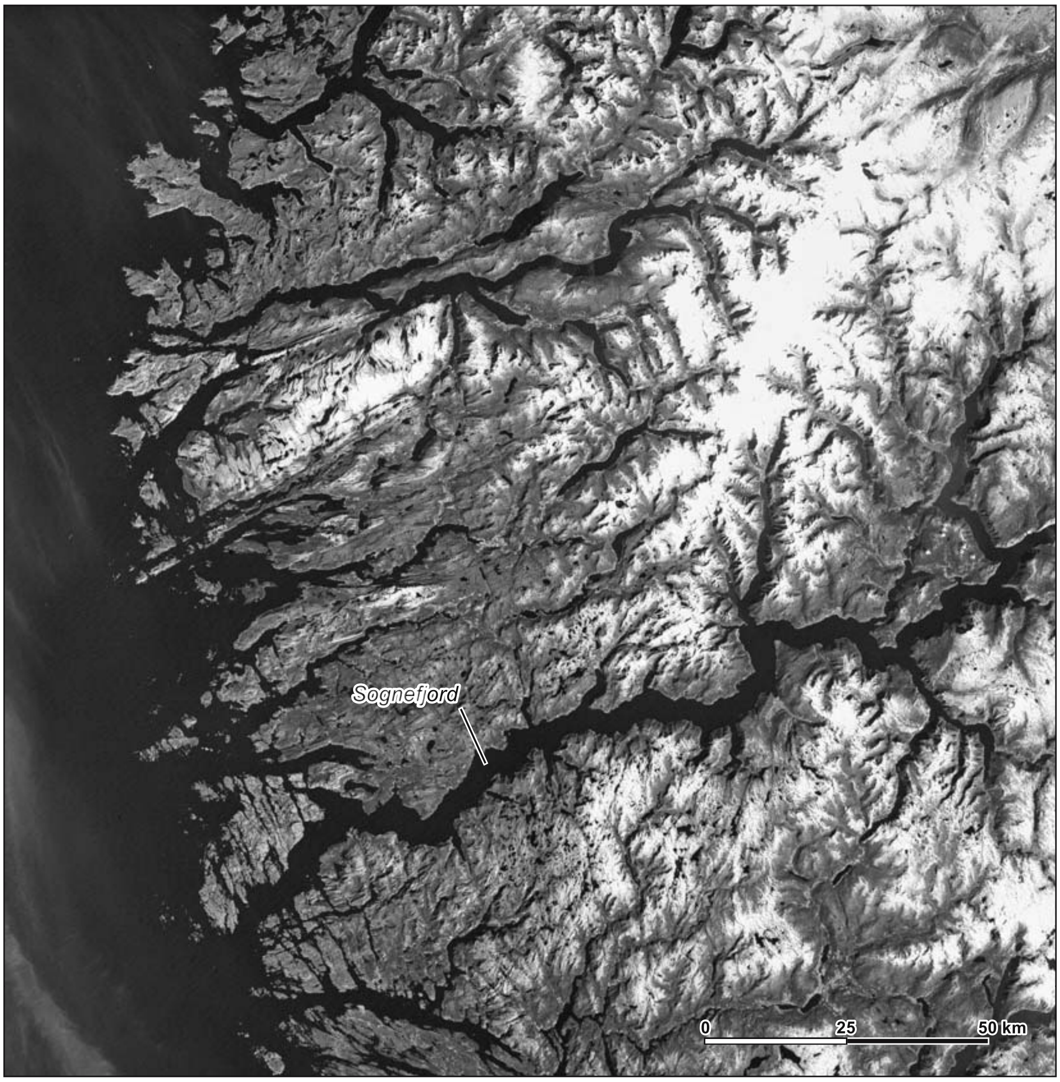

Figure E27 Satellite image of Sognefjord in western Norway, the deepest (more than 1,200 m) and longest fjord in northern Europe with about 200 km of length and a width of 1–8 km. Around the mouth of the fjord structural control of the coastline in very old crystalline rocks, worked out by several glaciations, can be identified (© EOSAT, GAF, AAF 1985).

the German North Sea coast and the Netherlands to Belgium and northernmost France. Further-more, inland marshes are typical (Dijkema, 1987), and along broader sandy beaches coastal dunes are well developed. Other areas of tidal flats are present in many ria embayments from Ireland to Great Britain and western France. They partly are rocky, exhibiting a rich variety of algal belts and hard encrustations of barnacles, mussels, etc. Northern England shows a great variety of spits, marshes, tidal bays, bars, and uplifted coastal terraces, whereas the southern part is dominated by the world famous high chalk cliffs along the English Channel and rias of different length and steep rocky headlands to the southwest. The southwestern coast of France along the Bay of Biscay shows the longest coastal dune belts of Europe with shifting sands of more than 100 m height.

The coastline of Northern Spain along the Bay of Biscay is rocky with cliffs and caves cut into the limestone. To the west narrow and deep rias can be observed, which change to the Portuguese coast into wider and shallower fluvial embayments. The coasts of Portugal, however, are mostly sandy with dune belts and lagoons, except of some rocky headlands and the high and steep cliffs developed in the hard limestone at the southwestern most point of Europe. They are constituted of soft rocks with numerous small landslides at the south-facing Algarve coast. Continuing to the Strait of Gibraltar the eastern Portuguese coastline and the Spanish one are mostly low and bordered by lagoons and dune belts along sandy beaches. Only the last 50 km exhibit rocky coastlines, headlands, and cliffs with smaller sandy beaches.

The volcanic archipelagos of Madeira, the Azores, and the Canary islands are mostly steep, some with mega cliffs up to more than 500 m height. They are not singularly formed due to abrasion, but in addition they represent head scars of huge submarine slides from the collapse of the high and growing volcanic edifices.

The coastlines of the Mediterranean are limited in their coastal forms because tides are nearly absent, and longshore drift is less efficient because of the smaller ocean areas. Thus, the limited tides and wave energy conditions are responsible for many deltas, among them the very large ones of Ebro, Rhône, or Po, and numerous others along the Italian and Turkish coasts. Headlands with cliffs in limestone including bioerosive notches alternate with longer beach sections at the Spanish Mediterranean coastline, whereas in southern France the western section consists of beaches, barriers, beach ridges plains, and the Rhône delta, and of rocky steep coastlines in the east with calanques and calas, which are dominant on the Balearic islands, as well. The most extended granitic coastal landscapes decorated by huge boulders from deep weathering during pre-Pleistocene times and Holocene tafoni can be found around the islands of Corsica and Sardinia. Here, also longer sections of coastal barriers and lagoons exist. Except for the young volcanic Aeolian islands peninsula Italy has beaches along nearly 70%

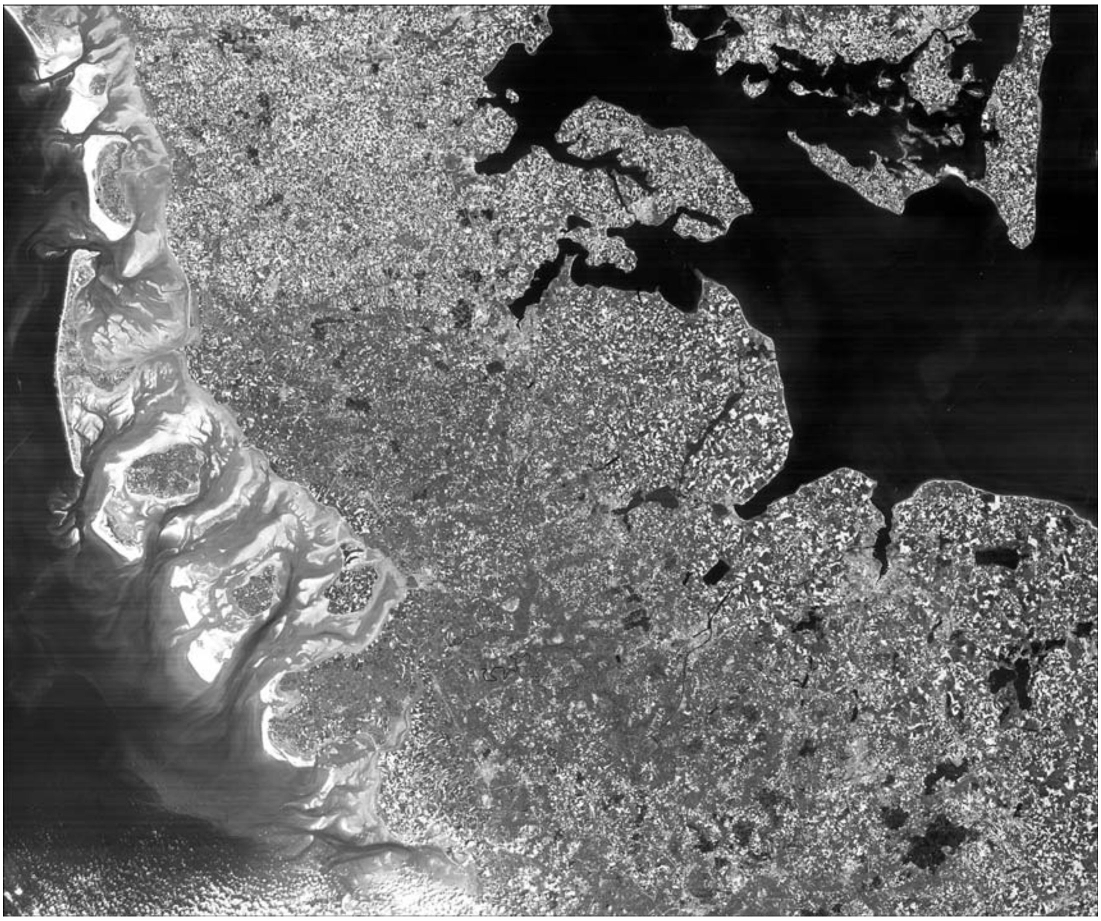

Figure E28 Satellite image of northern Germany and southern Denmark. To the west tidal areas with different types of islands (Pleistocene morainic hills, Younger Holocene marshes, very young spits and dunes), sandy bars and muddy flats with tidal rivers and ebb deltas can be seen. To the east at the Baltic coastline ingression into morainic and fluvioglacial relief on the Danish islands or into ria like förden is typical in an environment without tides (© ESA, Eurimage 1992, GAF 1995).

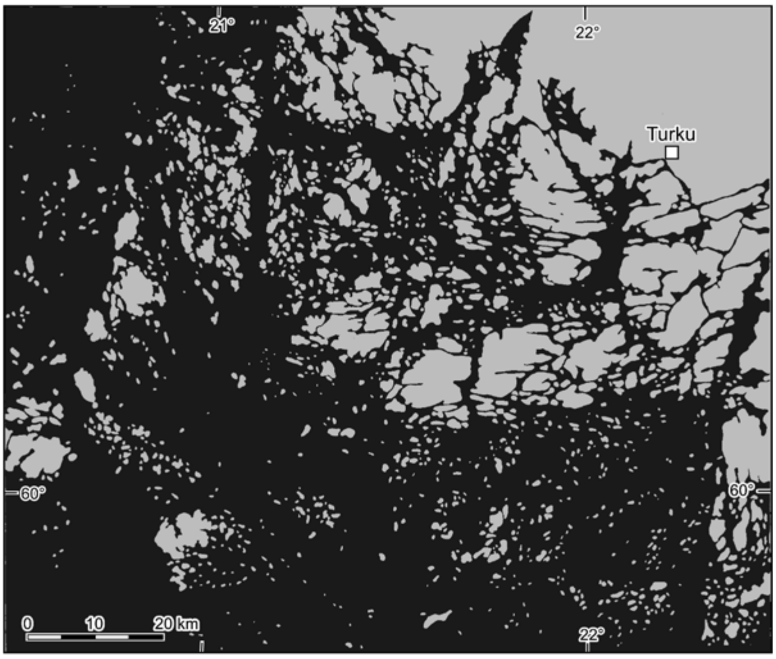

Figure E29 Numerous skerries are typical for the coastlines between Finland and Sweden in the northern Baltic Sea.

Figure E30 Bioerosive notches in limestone at the east coast of Rhodes (Greece) show step-like neotectonic uplift during the last 2,000 years with a maximum of about 2.5 m.

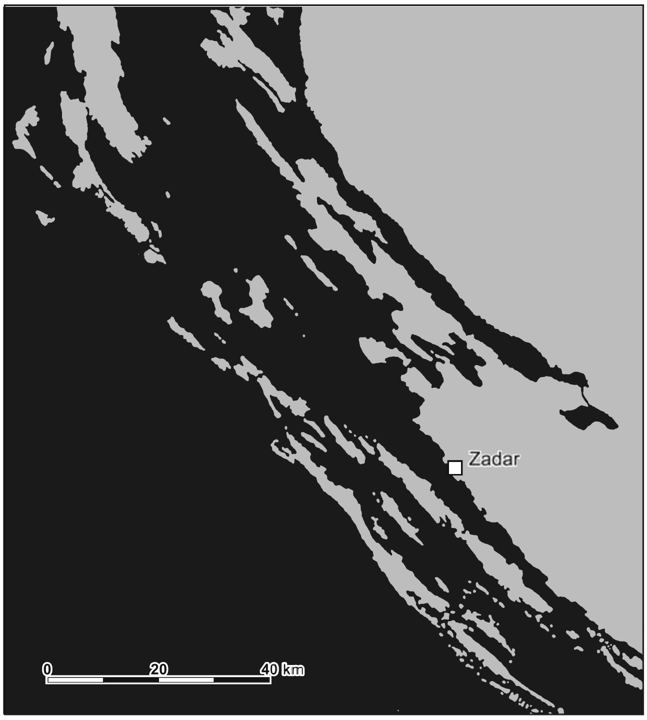

Figure E31 The Adriatic coast along Croatia is a typical area of parallel mountain ridges from Mesozoic folding, drowned by subsidence and post-glacial sea-level rise to form canale coastlines.

of its coastline, whereas in the southeast and on Sicily cliffs and Pleistocene coastal terraces are widespread. From Istria to northern Albania drowned landscapes with the typical parallel canale features occur (Figure E31), beaches are very rare. Another type of an ingressive coastal landscape can be found along the Greek and Turkish coasts. It is the various change of structural embayments as grabens and horst like long peninsulas (Figure E24), mostly showing drowning as the predominant process with medium to steeper slopes but a less amount of real cliffs. Limited sections of uplifted coastal terraces alternate with beaches along barriers and deltas. The islands of the Aegean Sea again are drowned remnants of an older land bridge. Due to the absence of longer rivers and the rather dry climate beach material is scarse. Neotectonics are an important process in coastal forming, as well as bioconstruction at the warmest easternmost parts of the Mediterranean, where many of the small beaches are cemented by Holocene beachrocks.

The maps do not show areas of artificial coastlines mostly due to the need for protection against storm floods in winter by groins, beach nourishment, sea walls, dikes, or land reclamation, most widespread around the North Sea (Figures E34 and E36) as well as along Mediterranean bathing beaches and harbors.

Many of the European coasts are endangered (Kelletat, 1988; Caputo *et al*., 1991; Tooley and Jergersma, 1992; French, 1994; Bartolini and Carobene, 1996;). The primary cause hereby is the accelerated erosion along beaches—at least 75% of all European beaches suffer from this process—marshes and coastal dunes, which as a consequence costs billions of Euro/year for maintaining bathing beaches, coastal settlements, or farmland. The reason is a small general sea-level rise and a local accelerated one caused by deltaic sedimentation, down warping of a ring-like structure around the glacio-isostatic uplifted areas, or pumping of oil, gas, or groundwater from below the sea. Some of the reasons of the accelerated erosion may be located not directly along the coasts but far inland. The predominant cause is the increasing number of reservoirs holding back sediment, and the mining of sand, gravel, and cobble from river beds, in particular in the Mediterranean area. Consequently millions of tons of sediment are not transported to the coasts any longer. This is in striking contrast to a period of progradation and delta build up during late Holocene and historic times, in particular during the Greek and Roman antiquity and the early Middle ages, in some places even starting during the later Neolithic (Erol, 1983; Brückner, 1998). For several 1,000 years progradation was in particular responsible for the development of barriers, spits, or marshes in spite of the still slowly rising sea level. The reason was the ongoing extension of agriculture and deforestation, resulting in soil erosion and denudational processes apart from the coast. Coastal protection against the increased frequency of storms is another problem, which leads to the design of continuous new and

Figure E32 Chalk cliffs along the French coast of Normandy with stack and sea arch.

Figure E33 Living bioconstructional micro atoll by vermetids (*D. petraeum*) giving a very reliable sea-level indicator along the west coast of Crete, Greece.

higher dikes. It can be stated that overall the shape of some thousands of kilometers of coastline in Europe are the result of anthropogenic structures. However, beside that, heavy pollution due to tourist settlements or rivers bringing pulp mill sewage to the sea and oil spillage from the heavy road traffic additionally are causing severe problems in coastal areas. Another important negative effect is caused by the cleaning of ship tanks associated with tar pollution, in particular in the eastern Mediterranean.

Pleistocene and Holocene sea levels

In Northern Europe, glaciation has eliminated all traces of sea levels from former interglacial high stands, and those are mostly missing in areas without significant uplift like around the North Sea Basin and the English Channel. In contrast evidences of higher interglacial sea levels as sediments with marine fossils (e.g., the foram *Hyalinea balthica* for colder events in the older Pleistocene, or the tropical gastropod *Strombus bubonius* for the younger interglacials in the Mediterranean)

Figure E34 Satellite image of the tidal areas and islands along the west coast of northern Germany (© ESA, Eurimage 1992, GAF 1995).

or even as geomorphic features like coastal terraces are widespread in the geologic young environments of the alpidic orogenesis. Côte d'Azur between France and Italy, northern Sicily, or Apulia, and Calabria in southern Italy are world famous sites for the discussion of higher interglacial sea levels. At some places, such as in SW and NE Peloponnesos, Greece or southern Italy, terrace sequences reach several 100 m above sea level. Unfortunately, the absolute dating determination remains still rather difficult. The coasts and as well the islands of the eastern Mediterranean exhibit remnants of higher sea levels, but mostly in short sections, bordered by faults and areas of significant subsidence. The differentiation of substages within the same interglacial (like oxygen-isotopic stages 5e, 5c, 5a) is still under research. Nevertheless the study of high (or uplifted) interglacial sea level evidence has contributed greatly to the understanding of Mediterranean neotectonics.

Holocene sea level is still a topic of intensive discussion in the scientific community (Binns, 1972). In northern Europe, a very good

Figure E35 Forms and sediments along the coastlines of the European continent.

Figure E36 Land reclamation outside the marshes at the northern German North Sea coast, mostly as a tool for protection of dikes and farmland.

dating of glacio-isostatic rebound by the analysis of uplifted beach ridge sequences exists (Figure E33), whereas along the marshy German, Danish, Netherlands, and English coastlines of the North Sea geo-archaeology has much contributed to the identifying of former Holocene sea levels (Behre, 2001). Here, the sea-level curve of the last 6,000 years is characterized by at least two transgressions and regressions of 1–3 m. Some archaeological remains of the Bronze Age below high water level in the high tide range area of western France point to a sea-level rise of more than 3 m in this geologic stable region. Along the Mediterranean coastlines archaeology as well contributes to the identification of the Holocene sea-level curve: drowned ruins and quarries from Greek antique times, the position of Roman fish tanks, and even relics of early Christian times can be found below sea level. Beside these man-made structures, natural sea level indicators are very suitable for relative dating approaches, among them bioerosive notches (Figure E26) or bioconstructive elements like trottoirs or algal and vermetid rims (Figure E32 and Kelletat, 1997). They are much more reliable than beach ridge sequences, beachrock or terraces along deltas. In spite of literally hundreds of dated and measured sites, there is no general agreement about the eustatic sea-level movements in the Younger Holocene in the Mediterranean. But nevertheless these studies have led to a much better understanding of the ongoing and vivid neotectonics in this part of Europe, reaching a maximum of 9 m on western Crete (Greece) since the year AD 365 (Kelletat, 1996).

FAULTED COASTS

Faulted coasts are chiefly associated with active continental margins where tectonic plates are colliding. They often correspond to bold coasts, characterized by continuously steep and straight scarps. However, terraced coastal areas dislocated by faults as well as fiord or estuary coasts controlled by faults have also to be included into the broad category of faulted coasts.

Sea cliffs and fault scarps

In some instances, coastal cliffs may be identified as fault scarps of direct tectonic origin which separate raised blocks of land from dropped ones that have been depressed below sea level. Plunging cliffs, cliffs which are not fronted by shore platforms or beaches and plunge abruptly into deep water, can be the product of recent faulting if down-thrown blocks have subsided to appreciable depths. In that case, and not only in sheltered waters and even if the resistance of rocks is not considerable, plunging conditions could persist long after faulting and the initial profile of the coast may long remain practically unaltered (Johnson, 1919). Cliff recession is very slow since erosional processes are inhibited by the reflection of incoming nonbreaking waves against vertical or nearly vertical walls rising out of deep water. Furthermore, deep waters at the cliff base prevent accumulation of sediment derived from alongshore transport or subaerial scarp weathering, resulting in the lack of abrasive materials which could increase the erosive power of the waves. However, in the course of time, hydrostatic pressure and hydraulic quarrying caused by the rise and fall of standing waves, and the compression of air in rock fractures eventually are able to produce notches and caves. Narrow erosional platforms may subsequently develop, allowing breaking waves to attack the cliff and destroy the plunging condition (Trenhaile, 1987).

Several coastal cliffs in New Zealand are thought to be actual fault scarps (Cotton, 1916). For instance, the cliffs along the Wellington fault, on the northwestern shore of Port Nicholson have been explained in this way. They slope at about 55°, show little evidence of marine modification at the shore level, and descend to a depth of about 20 m, close and parallel to the shoreline. In Russia, on the Murmansk coast, to the west of the White Sea, Archean granites and gneisses are faulted along a line which almost coincide with the present coastline. The foot of the cliffs extends to a depth of several tens of meters without alteration of slope. During storms, waves are reflected from the scarp wall and there are no wave-cut notches or fragments of benches (Zenkovich, 1967). In the United States, some steep cliffs along the coast of California are attributable to fault scarps. For example, a down-thrown block has dropped below sea level on the northeastern side of San Clemente Island, forming a straight cliff with no intervening shelving bottom (Shepard and Wanless, 1971). The Gulf of California, Mexico, gives nice examples of recent faulted coastlines, especially in the islands next to its western side where straight, continuous, and precipitous escarpments display facetted spurs and truncated structures, are not bordered by shelves, have deep water at their base, and show angular contact with the adjacent submarine basin (Shepard, 1950). All these features are evidence of no marine erosion after faulting that is probably recent. For instance, the sea cliff on the southwestern side of Angel de la Guarda Island corresponds to a fault scarp which steeply plunges to the bottom of a trench located at a depth of about 1,000 m. In volcanic areas, cliffs can be directly produced by faulting induced by vulcanicity. Sea cliffs devoid of a bordering shelf on the southern flank of Kilauea Volcano, in Hawaii, can be identified as direct normal fault scarps although, at least in some cases, they may correspond to gigantic slump scars.

Sea cliffs and fault-line scarps

Most tectonically controlled coastal cliffs correspond to fault-line scarps that are scarps produced by structurally induced erosion at ancient faults. As a matter of fact, on the one hand there has been little time for important faulting since the postglacial rise of sea level, on the other hand older original tectonic features are not retained for long because of the erosional effects of subaerial geomorphic processes during periods of low sea level. For example, along the steep Santa Lucia Mountain coast of central California, the continental shelf is in some parts less than 0.6 km wide, suggesting that this is a fault-line coast since a retreat of a relatively short distance, due to marine erosion, has followed faulting. In Japan, the straight montainous coastline which characterizes the northwestern part of Shikoku stretches along the so-called Median Tectonic Line. In the Malta archipelago, the coastline pattern of the main island is mainly controlled by faulting. Here, in the northern part, bays correspond to downthrown blocks that were partially submerged. In the southwestern part, spectacular cliffs which can be more than 200 m high are erosionally derived from a major northwest trending fault, known as the Maghlak fault that has been displaced vertically by at least 230 m and probably moved during the Quaternary (Paskoff and Sanlaville, 1978).

In northernmost Chile, where the oceanic Nazca plate is subducted under the continental South American plate, the extremely arid coast is characterized, over more than 800 km, by a striking, precipitous, northward trending cliff which is 700 m high on average. Because of its length and height, this scarp represents a major geomorphic feature at a worldwide scale. From Arica (18°S lat.) to Iquique (20°S lat.) the cliff is almost vertical and its top can reach 1,000 m above sea-level. At present, it is an active feature, dropping into the sea and receding under marine action. As a result, ephemeral streams of wadi type are cut by the scarp and hanging above sea level (Figure F1(A)). Landslides, triggered by earthquake shocks and affecting rock masses previously loosened by intense tectonic facturation, are also contributing to the cliff retreat. From Iquique down to 27°S lat., the cliff remains very high but not so steep. As a matter of fact, it is no longer an active one since

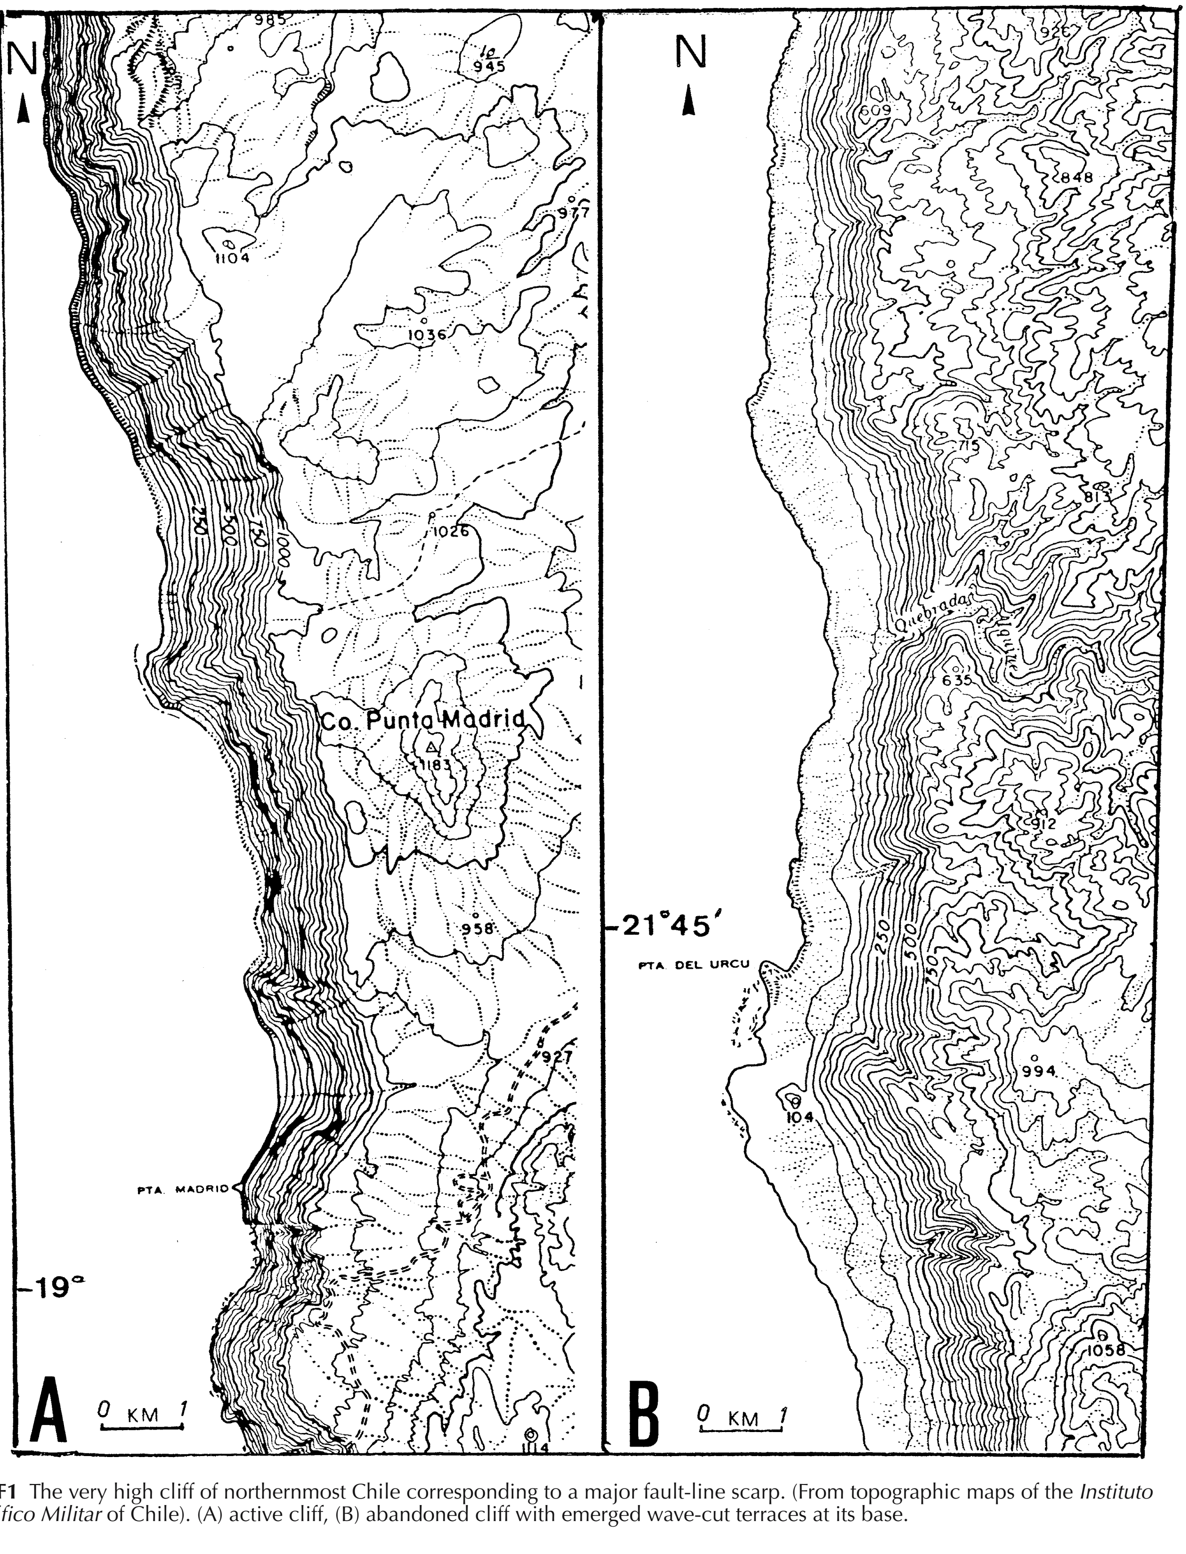

Figure F1 The very high cliff of northernmost Chile corresponding to a major fault-line scarp. (From topographic maps of the *Instituto Geográfico Militar* of Chile). (A) active cliff, (B) abandoned cliff with emerged wave-cut terraces at its base.

a belt of emerged wave-cut platforms, several hundred meters wide, extends at its base, indicating a relative fall in sea level (Figures F1(B) and F2). The cliff of northernmost Chile is a typical fault-line scarp (Paskoff, 1978). Detailed geological mapping failed to reveal faulting at the foot of the cliff whose lack of straightness is also inconsistent with a direct tectonic origin. Actually, the cliff results from an important faulting phase which generated major, north–south trending, *en échelons*, normal faults at the end of the Oligocene Epoch and uplifted the continental block which constitutes the present Coastal Cordillera. Subsequently, these faults retreated under marine erosion, over about 10 km which is here the width of the continental shelf, mainly during a major middle to upper Miocene transgression. Later differential crustal movements occurred. This explains why the cliff is an active one in its northern part where subsidence may be related to a collapse of the continental margin toward the Chile-Peru trench, and an abandoned one in its southern part where, on the contrary, an uplift motion has been taking place.

Coastal terraces and faulting

Former wave-cut platforms that have become emerged because of a fall of sea level due to some combination of eustatic and crustal processes are not unusual on coastal belts. When located on active margins, these elevated marine terraces generally show evidence of active faulting which has occurred in Quaternary time (Pirazzoli, 1994).

Figure F2 The very high cliff of northernmost Chile near 21°25′S lat. The toe of the scarp is covered by thick screes which are the result of salt-weathering and seismic shocks. Wave-cut platforms extent at its base. (Photo R. P. Paskoff).

In north-central Chile, the 110-km-long coast of the Talinay Heights area, between 30°S and 31°S lat., is characterized by a flight of several emerged Plio-Quaternary marine terraces which has been densely and strongly faulted, uplifted, and tilted (Ota *et al.*, 1995). Dip-slip normal faults, which are early Pleistocene in age, have a clear topographic expression, forming conspicuous scarps. The most significant one is the Quebrada del Teniente fault (Figure F3). Distinctively straight, NNW–SSE trending, it runs parallel to the present shoreline and crosses the entire area over a length of about 60 km, dislocating the terraces and generating a striking east-facing scarp. The maximum amount of vertical displacement reaches 52 m.

In eastern Tunisia, the Monastir surroundings (36°N lat.) are well-known for their Tyrrhenian (name used in the Mediterranean for the last interglacial marine episode, i.e., oxygen isotopic stage 5) deposits and for the term Monastirian which was incorporated to the standard Mediterranean terminology for Quaternary marine shorelines early in the 20th century. For a long time Monastir was the type locality for the 18–20 m terrace. This classic, widely quoted term was finally and definitely dropped when it was established that crustal deformation had occurred near Monastir (Paskoff and Sanlaville, 1981). The area is characterized by a triangular wave-cut platform (Figure F4) which dates back to the late Quaternary (oxygen isotopic substage 5e) and has been affected by two main faults. The Wadi Tefla fault which trends northeast is a normal fault which dislocates the platform in two levels and has a maximum vertical throw of 15 m. It was erroneously considered to be a former sea cliff separating two distinct marine terraces. The NNW–SSE Skanes– Khniss fault is a major fault of regional signficance which displays a vertical displacement that reaches 50 m. It also shows a sinistral strike-slip component characterized by an horizontal movement of at least 500 m. The fault has been active in historical times since it cuts a Roman mosaic on a floor of a house which was built in the 2nd century AD.

Fiord or estuary coasts and fault control

In plan view, coasts developed on intrusive and metamorphic terrains may show intersecting linear patterns of fiords or estuaries, depending on the latitude, marking former glacial or fluvial erosion exploiting the structural weakness of faults. For instance, in southernmost Chile, especially between 44°S and 55°S lat., fiords regionally named *canales*, penetrate inland. They correspond to glacial troughs which were eroded and overdeepened during the last Pleistocene glaciation by active Andean glaciers, mainly in Jurassic granitic rocks. The fiord pattern is strikingly controlled by fault lines which are mainly oriented N–S, NE–SW, and NW–SE. Fault lines were selectively exploited by eroding glaciers. Fiords form a dense network of long marine arms, characterized by straight stretches and right angles (Paskoff, 1996).

As already stated by Mclean (1982), the concept of faulted coast has now to be used in a broader sense than initially defined by the pioneers of coastal geomorphology. It encompasses not only cliffs controlled in some way or other by faulting, but also landforms found in the coastal

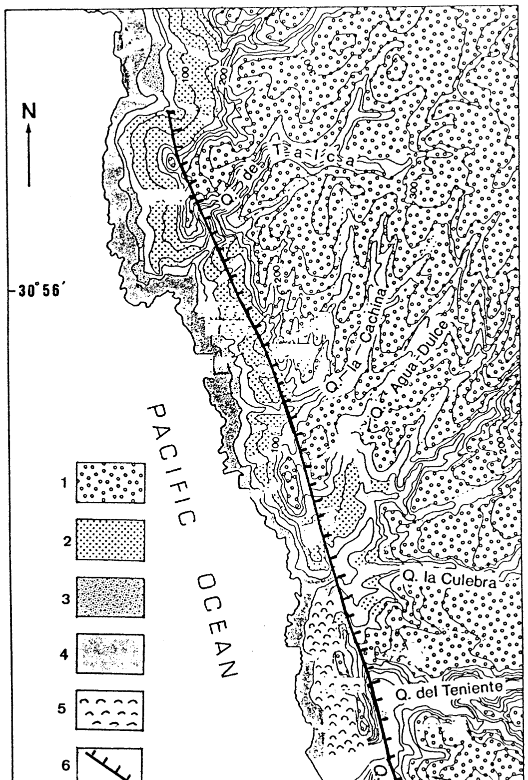

Figure F3 Geomorphological sketch of the southern part of the Talinay Heights coastal area in northcentral Chile (modified from Ota *et al.*, 1995). G

GEOCHRONOLOGY

In coastal research, the terms "geochronology" or "geochronostratigraphy" are used to determine timescales for coastal processes and coastal evolution utilizing relative stratigraphic techniques (morpho-, pedo-, bio-, lithostratigraphy) and absolute dating methods. Relative and absolute temporal scales and dating methods complement each other.

In the 1980s and 1990s, applications of the absolute dating of coastal forms, sediments, and processes were improved, new dating methods were established, and the precision and accuracy of existing age determination methods were considerably increased. Numerous texts describe dating techniques in Quaternary sciences in detail (e.g., Smart and Frances, 1991; Wagner, 1998).

Conventional and mass spectrometric radiocarbon dating methods, as well as ^{230}Thorium/^{234}Uranium isotope, and Electron Spin Resonance (ESR) age determination methods are the most commonly used absolute dating techniques in coastal research (Table G1). The applicability of Thermal and Optical Stimulated Luminescence dating to coastal geochronology is currently being tested. The commonly used Amino Acid Racemization (AAR) method is a relative chronostratigraphic method. The paleomagnetic dating method has proven useful for differentiating marine and littoral sequences between the Middle and Early Quaternary.

Radiocarbon (^{14}C) dating

The importance of this method for the dating of Holocene and late Pleistocene marine terraces, beaches, and other coastal features cannot be overestimated. It is the most common and widely applied dating method in geochronology.

Carbon-14 (^{14}C) is a radioactive carbon isotope with a half-life of 5,730 ± 40 years. The isotope originates from the upper atmosphere, where nitrogen atoms are bombarded by cosmic rays. The isotope ^{14}C is chemically converted to CO_2. This $^{14}CO_2$ mixes with atmospheric CO_2, which contains the stable isotopes ^{12}C and ^{13}C. The natural concentration of radioactive carbon in the atmosphere is approximately $1:10^{12}$. In living organisms, the ^{14}C content is in equilibrium with the CO_2 of their environments (atmosphere, freshwater, saltwater).

The CO_2 exchange between the organism and its environment discontinues with death, and ^{14}C decays to ^{14}N with a half-life of 5,730 years. The upper dating limit of this conventional technique lies at approximately 30,000 years ^{14}C BP (approximately five times the half-life of ^{14}C). Radiocarbon ages are expressed in years ^{14}C BP, with BP referring to the time before AD 1950. Human induced nuclear detonations in the 1950s and 1960s have changed the atmospheric ^{14}C composition.

There are two laboratory methods of radiocarbon dating: The conventional decay counting method which measures beta rays from the ^{14}C decay process; and the Accelerator Mass Spectrometry (AMS) technique which determines the ratio between the number of ^{14}C to ^{12}C atoms in a sample. The AMS technique requires only small samples (less than 1 mg). Dating is limited to 50,000 years due to sample or laboratory contamination.

Since the 1960s, the radiocarbon method has been used successfully for dating Holocene and Late Pleistocene samples. The ^{14}C method delivers reliable results for wood, charcoal, and plant matter (e.g., peat, seeds, leaves). However, the dating of humus, speleothems, caliche, bones, and teeth is frequently inaccurate. In coastal research, the ^{14}C dating method is widely applied to the dating of marine fauna (e.g., mollusk shells, coral) and microfauna (e.g., foraminifera, ostracods). It is an excellent tool for geoarchaeological research in coastal settings where it can be cross-checked with stratigraphies from artifacts (Brückner, 1997).

Variations in the production of atmospheric ^{14}C may be caused by sunspot activity, changes in the intensity of the earth's magnetic field, or variability in cosmic radiation. This atmospheric source of error can be reduced by calibrating ^{14}C dating results (at present the calibration table covers the last 20,000 years) with a dendrochronologic tree ring calendar (dendrochronology: an absolute dating method based on the counting of tree rings). In addition, marine samples may be influenced by the so-called "marine reservoir effect," which is caused by the variability in the ^{14}C concentration in seawater. Deep ocean water has a lower ^{14}C content than the atmosphere. The ^{14}C dating of marine fauna (mollusks, coral, microfauna) from shores influenced by upwelling deep ocean water results in ^{14}C ages that are too old. The global mean reservoir effect for marine carbonates is approximately 400 years and varies spatially and temporally.

Case study: ^{14}C dating of beach ridges

The littoral zone of northern Andréeland (northern Spitsbergen) is characterized by more than one hundred beach ridges ranging in elevation from present sea level to 70 m. They represent uplifted former coastlines (Brückner and Halfar, 1994; Brückner, 1996). Two conditions led to their formation: (1) The West Spitsbergen Current, the northernmost continuation of the Gulf Stream extending up to 80°N, created seasonally ice free conditions in fjords. This allowed wave action which caused the formation of beach ridges. (2) The current elevation of these beach ridges is a result of coastal uplift due to the glacio- isostatic rebound following the last deglaciation.

The radiocarbon dating results of mollusk shells (Figure G1) illustrate: (1) the onset of deglaciation and the beginning of beach ridge formation in the Allerød Interstadial (11,970 ± 60 years ^{14}C BP minus

Table G1 Some important dating methods in coastal research

Dating method	Dating material	Time scales to be dated	Major problems influencing dating results
Absolute dating methods			
Isotope dating methods			
Radiocarbon (^{14}C)	All carbon containing material, for example wood, charcoal, peat mollusk shells*, coral*, foraminifera*, ostracods*	Holocene up to Late Pleistocene conventional ^{14}C method: 20 to 30 ka ^{14}C BP; AMS ^{14}C method: approximately up to 50 ka ^{14}C BP	Variability in atmospheric ^{14}C (cosmic, Suess and nuclear bomb effects); contamination of samples by younger C bearing material; *marine reservoir effect
Thorium-230/ Uranium-234 ($^{230}Th/^{234}U$)	coral, mollusk shells^{+}, bones^{+}, teeth^{+}, speleothems^{+}, travertines^{+}	Holocene up to Late Middle Pleistocene Coral: approximately up to 200 ka BP moullusk shells; approx. up to 130 ka BP (less reliable)	Isotope mobilization, especially uranium migration (radiometric system may not be closed); variability of $^{234}U/^{238}U$ ratio in sea water
Radiation induced dosimetric dating methods			
Thermal and optical stimulated luminescence (TL, OSL)	dune sands, loess, littoral sands+	Holocene up to Late Pleistocene at least up to 70 ka bp	Incomplete bleaching; istope mobilization, especially uranium migration
Electron Spin Resonance (ESR)	coral, mollusk shells, foraminifera, some gastropods	Holocene up to Middle Pleistocene coral: up to 400–600 ka BP mollusk shells, foraminifera, gastropods: up to 200–300 ka BP (upper dating limit still unknown)	Istope mobilization, especially uranium migration; recrystallization of sample
Relative dating methods			
Paleomagnetic dating	all material with stable magnetic remanescence, for example fine grained coastal sediments	Middle and Early Quaternary, limited to paleomagnetic reversals and events	Destruction of primary magnetic signal and acquisition of secondary magnetization
Amino Acid Racemization (AAR)	mollusk shells	From several 100 to several 100 ka BP	Results require calibration through absolute dating techniques; racemization rates may vary between genera; diagenesis temperature histories may differ between geographic regions

+ frequently used, but little suited for dating method
* see remarks in the right column

reservoir effect of approximately 400 years) due to the arrival of the West Spitsbergen Current; (2) that fjords were blocked by sea-ice during the Younger Dryas cold phase. This period of no beach ridge formation ranged approximately from 11,100 to 10,600 ^{14}C BP (minus reservoir effect of approximately 400 years); (3) that the major glacio-isostatic uplift occurred between 12,000 and 9,200 years ^{14}C BP (minus reservoir effect of approximately 400 years) and amounted to more than 140 m. In approximately 12,000 ^{14}C BP, eustatic sea level was at least 70 m lower than today. Since then the oldest beach ridges have been uplifted from less than 70 m below up to 70 m above present sea level.

Thorium-230/Uranium-234 isotope ($^{230}Th/^{234}U$) dating

The Thorium-230/Uranium-234 ($^{230}Th/^{234}U$) dating method is the most frequently used uranium isotope age determination technique. In coastal research, this method is utilized for dating Middle and Late Quaternary coral and mollusk shells.

This method is based on the fact that coral and mollusk shells take up the mother nuclide Uranium-234 without its daughter nuclide Thorium-234. Uranium-234 decays to Thorium-230, which has a half-life of 75.4 ka. Therefore, the upper dating limit of this method is reached at approximately 350 ka BP (as a rule of thumb: dating limit equals five times half-life).

The uranium and thorium isotope content can be determined α-spectrometrically or mass spectrometrically (Thermal Ionization Mass Spectrometry = TIMS). The mass spectrometric method requires smaller sample sizes (approximately 0.5–0.2 g) and is more precise (analytical error is approximately 1%).

The precision of the Th/U dating method has significantly improved due to advances in analytical techniques, however, numerous sources of error still limit the accuracy of the Th/U dating results. One key assumption in Th/U dating is that neither the mother nor the daughter nuclides relocated after the uranium accumulation in the coral structure or mollusk shell (a closed system). However, uranium is easily soluble in an oxidation environment and may have been added or removed. The resulting error in age determination can amount to tens of thousands of years and more. Partially recrystallized coral samples are neither suited for Th/U dating, since uranium and thorium may be mobilized in the process of the formation of calcite through the recrystallization of the aragonitic coral structure.

Mollusk shells are more prone to uranium and thorium migration than coral. Therefore, they are less suited for Th/U dating (Kaufmann *et al.*, 1971). While coral absorb approximately 3 ppm uranium from seawater, mollusk shells take up most of their uranium (approximately 0.2–4 ppm) after death from ground and seepage water. The majority of this uranium is taken up within the first few centuries and millennia after their death (Schellmann and Radtke, 1997). However, later isotope exchanges with the surrounding environment are possible. The variability of the $^{234}U/^{238}U$ ratio in seawater can also cause errors in the Th/U dating of Pleistocene coral and mollusk shells (Bard *et al.*, 1992).

Despite all potential sources of error, mass spectrometric Th/U dating of coral was utilized for the extension of the ^{14}C calibration curve to up to 30 ka BP (ka = 1000 years; Bard *et al.*, 1990). The current knowledge of Last Interglacial sea-level changes (between 75 ka to 130 ka BP) is largely based on α- and mass spectrometric Th/U dating of fossil coral. Even the Th/U dating results of Penultimate Interglacial coral reefs (around 200 ka BP) can reach considerable accuracy. The Th/U dating of Middle Pleistocene and older coral samples is not reliable due

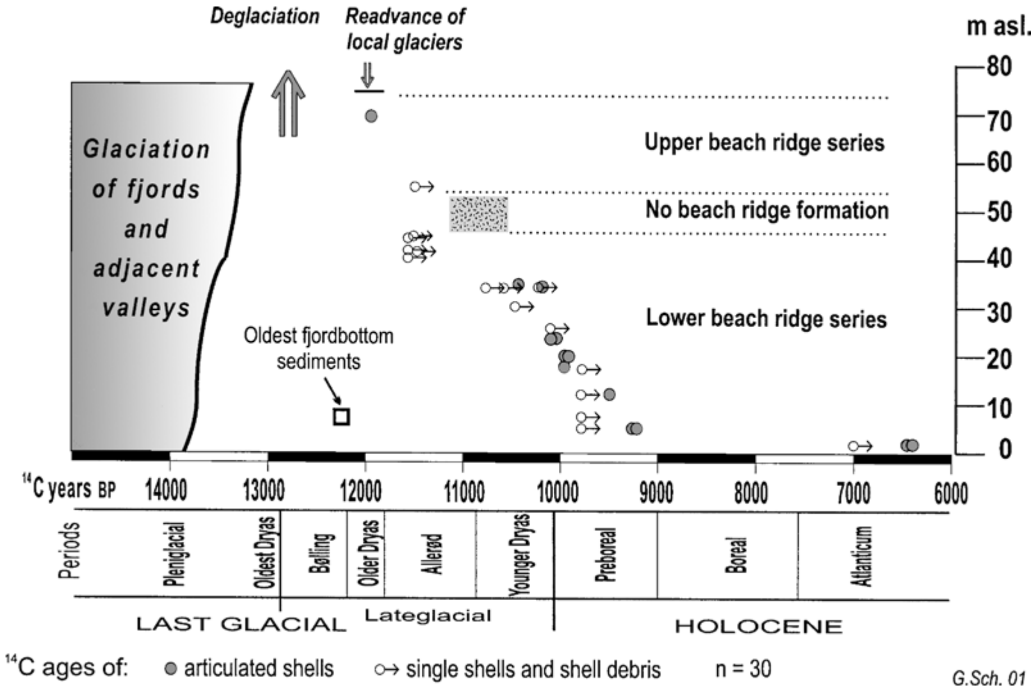

Figure G1 Deglaciation and evolution of beach ridges in Northern Spitsbergen (Woodfjord, Wijdefjord) based on ^{14}C datings. Beach ridges [in m asl] are represented by circles. All ages are uncalibrated ^{14}C years BP. The average reservoir effect for marine carbonates (approximately 400 years) needs to be considered for the correlation of the ^{14}C ages to geologic time periods (e.g., Younger Dryas). Articulated shells give reliable ^{14}C ages for beach ridge formation. The ^{14}C ages of coastal features based on single shells and shell debris are frequently overestimated since this material may have been relocated.

to their increased weathering and the still unknown $^{234}U/^{238}U$ ratio in seawater during those times.

To summarize, Th/U dating of fossil coral produces accurate results up to 200 ka BP, while the Th/U dating of mollusk shells is less reliable.

Thermal and optical stimulated luminescence (TL, OSL) dating

Luminescence dating techniques determine the time period that has elapsed since a charge population trapped within natural crystalline minerals was last reset. The fundamental concept of this method (Prescott and Robertson, 1997; Wintle, 1997; Aitken, 1998) is the use of naturally occurring semiconducting crystalline minerals, such as quartz and feldspars, as natural dosimeters. These minerals record their exposure to naturally occurring ionizing radiation generated by the decay of uranium, thorium, potassium, and to a minor extent, by rubidium and cosmic rays. Ionizing radiation energy moves electrons from their stable state in a crystal lattice to electron traps. Luminescence techniques measure the signals that are related to the relocation of these electrons.

The luminescence signal is the light emitted from crystals when they are stimulated by heat or light after having received a radiation dose (natural or artificial radiation dose). The number of electrons migrating to traps increases with time and dose of natural radiation. The traps are linked to a variety of defects within the crystal structure. These "trapped" electrons are attached to defect sites, where they are stable until a further amount of energy is thermally or optically introduced. For sedimentary material, such as dune or littoral sands, the resetting event (called "bleaching") is the exposure of the material to daylight prior to sediment deposition. After bleaching, the process starts all over again. Luminescence techniques date the time that has elapsed since the last exposure to daylight (during transport) or heating of the sediment.

Luminescence emissions are called thermoluminescence (TL) or optical stimulated luminescence (OSL) depending on the type of energy used to release the trapped charge during measurements. Infrared stimulated luminescence (IRSL) and green light stimulated luminescence (GLSL) are OSL techniques. The OSL signal is more sensitive to light than the TL signal. Exposure to daylight resets the OSL signal within a few minutes and the TL signal within several hours.

Luminescence techniques measure the ionizing radiation dose (equivalent dose, D_E) that has accumulated in the sample since the last reset of charge. One of the three methods is generally applied to determine D_E: (1) additive dose method, (2) regeneration method, (3) partial bleach method. Lumi-nescence techniques can be conducted on many aliquots of a sample (multiple aliquot approach), or on one aliquot of a sample with multiple measurements (single aliquot approach), or on one grain of a sample (single grain approach).

Measurements of the environmental ionizing radiation rate (dose rate or annual dose, D') are required for the age determination of a sample. The sample age is calculated by dividing D_E [in Gy] by the annual dose D' [in Gy/ka]. Luminescence methods have been successfully used for the generation of deposition chronologies up to at least 70 ka with precisions of 5–15%.

Luminescence methods are applied to a wide range of depositional environments. Aeolian sediments, including loess or coastal dune sands, are best suited for luminescence dating since the transport prior to their deposition guarantees their exposure to light. Littoral, lacustrine, or fluvial sediments were subject to transport mechanisms not necessarily ensuring exposure to light. However, these sediments may be suited for luminescence dating since light penetrates into the water column depending on water depth and the concentration of suspended sediment. The complete bleaching of sediments during their deposition is likely in shallow marine environments that are located in regions with intense insolation. Sediments cannot be dated using TL or OSL when a radioactive disequilibrium exists (e.g., uranium uptake or excess).

Electron spin resonance (ESR) dating

The first systematic studies and applications of Electron Spin Resonance (ESR) dating of coral and mollusk shells were conducted in the 1980s. Since then, a large number of Pleistocene coastal features and sediments have been dated using ESR.

ESR dating as well as luminescence techniques (TL, OSL) are radiation induced dosimetric dating methods. They are based on the radiation damage in minerals that increases with their age and is caused by natural radioactivity and cosmic rays. These damages generate paramagnetic centers and radicals that can be measured using ESR.

An ESR age derives from the ratio of the accumulated radiation dose D_E to the antecedent natural dose D'. The accumulated radiation dose D_E (equivalent dose) is determined by an "additive dose method." For this method, 20 or more aliquots of the same sample are stepwise irradiated with increasing γ-doses. Trapped electrons increase in number causing the amplitude of the ESR dating signal to increase. The D_E is determined by extrapolating the resulting dose response curve to zero ESR intensity. The former natural dose D′ is estimated based on the content of radioactive sources (e.g., uranium, thorium, potassium) in the sample and its environment, the intensity of cosmic rays, and present moisture conditions. D′ is determined through laboratory analysis or through field measurements using a portable γ-spectrometer. The correct determination of D′ and D_E is essential for any ESR age estimate. Rink (1997) describes ESR dating techniques in Quaternary sciences and discusses their accuracy and precision.

Recently, both precision and accuracy of ESR dating of fossil coral and mollusk shells have improved due to the higher resolution of ESR measurements and due to new techniques for the determination of D_E (Schellmann and Radtke, 1997, 1999, 2001a). However, ESR ages can deviate by several thousand years if the natural radiation dose (D′) the sample was subject to in the past was altered by uranium or thorium mobilization or by changing moisture conditions. Problems arise (1) from the heterogeneity of the surrounding sediments, and (2) since shells are systems open to uranium migration.

ESR dating results of mollusk shells that were embedded in heterogeneous beach sediments are most affected by these sources of error. Dating errors can reach more than 15%. Therefore, ESR dating results for mollusk shells from littoral deposits are frequently limited to the mere differentiation between Holocene, Last Interglacial, Penultimate Interglacial, and older sediments (Schellmann and Radtke, 2000).

The dating of coral originating from relatively homogeneous reef limestone can generally be accomplished with errors of approximately 10%. Substages of sea-level highstands (e.g., Last Interglacial Oxygen Isotope Substages 5a, 5c, and 5e) can be dated due to improvements in the determination of the accumulated radiation dose D_E.

ESR datings of coral from the Late Pleistocene are now as accurate as those dated using the Th/U method (Figure G2). Therefore, the application of both methods simultaneously is recommended for the dating of coral up to 200 ka BP.

The ESR method allows for the dating of coral and mollusk shells for a larger time span than any other Quaternary dating method. The lower dating limit lies at a few thousand years BP. The ESR method should theoretically allow for the dating of coral and mollusk shells that are several million years old. However, numerous ESR dating results for mollusk shells and coral illustrate that the upper dating limit lies at 200–300 ka and 400–600 ka, respectively.

The upper dating limit is largely dependent on changing conditions due to diagenesis and weathering. For example, the recrystallization of the aragonite coral structure or mollusk shell can cause considerable underestimates of ages, since it eliminates previously stored radiation.

ESR has been widely applied to dating sequences of raised coral reef terraces with ages of up to 500–600 ka, for example, terraces on Sumba island (Pirazzoli *et al*., 1991), and on Barbados (Radtke and Grün, 1988). Mollusk shells with ages ranging from 200 to 300 ka were also dated using ESR, for example, mollusk shells at the Patagonian Atlantic coast (Schellmann, 1998; Schellmann and Radtke, 2000). Most recently, Late Pleistocene gastropods in Aeolianites on Cyprus were accurately dated using ESR (Schellmann and Kelletat, 2001).

Case study: ESR dating of Pleistocene coral reef terraces in southern Barbados

The ESR dating of the fossil coral reef terraces on Barbados delivers an impressive example for the application of this method (Figure G3). In southern Barbados, these terraces rise up to 121 m above present sea-level. The ESR ages increase with height up to 361 ka. The age–height relationships allow for the calculation of neotectonic uplift in Barbados and of paleo- sea-level changes (Radtke, 1989).

Amino Acid Racemization (AAR) dating

The Amino Acid Racemization (AAR) dating technique is a relative age determination method for marine mollusk shells (Miller and Brigham-Grette, 1989). AAR values are applied to timescales ranging from hundreds to hundreds of thousands of years. The method is based on the rate of racemization and epimerization of indigenous amino acids preserved in mollusk shells. The temperature history during diagenesis and the rate of hydrolysis of residual proteins influence the protein degradation processes.

Several uncertainties in the applicability and reliability of AAR remain, since (1) racemization rates may vary between genera, and (2) diagenesis temperature histories may differ between different geographic settings. The AAR method seems to be reliable for distinguished regional aminostratigraphic units only. Since AAR is a relative dating technique, its results need to be calibrated using absolute dating methods.

Paleomagnetic dating

Paleomagnetic dating determines the natural remanant magnetization of sediments and correlates it to the known paleomagnetic polarity stratigraphy. Permanent magnetism is carried by ferromagnetic minerals that are minor constituents of almost all rocks. Magnetic minerals align to the earth's magnetic field and keeps that orientation when they are deposited or precipitated in the sedimentary matrix during early diagenesis. Thompson (1991) lists criteria for the application of this method.

The paleomagnetic reversals at the base of the so-called Brunhes and Matuyama chrons at 0.78 Ma (normal to reverse) and 2.6 Ma (reverse to normal), respectively, are the most important polarity changes of the earth's magnetic field in recent geological history. The Jaramillo and Olduvai subchrons are two timespans within the normal polarized Matuyama chron. At least 18 short-lived polarity events occur within the Brunhes and Matuyama chrons. The most prominent short-lived event is the "Blake Event" (approximately 117 ka), which seems to be a worldwide reversed interval (Langereis *et al*., 1997; Worm, 1997).

Sample applications of the paleomagnetic method include the dating of marine terraces in southern Italy (Brückner, 1980), and the dating of a sequence of beach ridges and coastal dunes at the Moroccan Atlantic coast (Brückner and Hambach, unpublished data). The paleomagnetic method requires a continuous sequence of coastal formations and a narrow sampling strategy. Paleomagnetic dating allows to differentiate within the Middle and Older Quaternary, where other dating methods fail.

GEODESY

According to the traditional classical definition, attributed to F. R. Helmert in 1880, geodesy is *the science of the measurement and mapping of the earth's surface*. Nowadays, this definition is deemed to encompass determination of the topography of the earth's landmasses, the bathymetry of the seafloor, the shape of the surface of the ocean, and form and nature of the earth's internal and external gravity field.

History

The origins of modern geodesy can be traced to antiquity. The ancient Greeks speculated on the shape of the earth with Pythagoras, and later Aristotle, introducing the concept of a spherical earth. The first scholar to make a scientific estimate of the shape of the earth was Eratothenes of Alexandria (276–195 BC) who obtained a value for the circumference of earth to within 2% of modern estimates. A later estimate by Posidonius (135–51BC) was used by Ptolemy (AD 90–168) to produce the monumental eight volume *Guide to Geography*, which contained maps of the world destined to be the definitive work for the next 15 centuries. Columbus, based on such maps, was to underestimate the distances from Europe to India and Asia and, in turn, discover the Americas. Advances in astronomy, instrumentation and physics in the 16th and 17th centuries led to Isaac Newton (1643–1727) and Christian Huygens (1629–95) proposing that the earth was not spherical, but flattened at the poles. This proposal led to some controversy and, it was not until the late 18th century, following increasingly accurate measurements on the earth's surface, that an ellipsoidal model for the shape of the earth was universally adopted.

Essential geodetic concepts

Definition of the size and shape of the earth does not usually involve surface topography or the bathymetry of the oceans, but the surface of mean sea level and its theoretical continuation under the continents. Topographic heights and bathymetry are measured relative to this hypothetical surface which is known as the geoid. By definition, the geoid represents an equipotential surface and is therefore a direct representation of the earth's gravity field. The geoid is a mathematically complex surface, its shape being strongly influenced by irregular mass distributions below the earth's surface. It is thus unsuitable as a reference surface for a geometric figure of the earth. For further details on the earth's gravity field and the geoid, the reader is referred to Heiskanen and Moritz (1967).

For geodetic calculations, such as computing geodetic latitude and longitude and defining map projections (e.g., Bugayevskiy and Snyder, 1995), an ellipsoid of revolution (a three-dimensional surface generated by rotating an ellipse 360° about its minor axis) is defined. This simple figure is known as a reference ellipsoid and is defined by a semimajor axis (equatorial radius) and semiminor axis (polar radius). The earth's semimajor axis is about 21 km greater than the semiminor axis, with the flattening being approximately 1/300. A commonly used reference ellipsoid is that associated with the World Geodetic System 1984 (WGS84) (NIMA, 1997).

For geodetic measurements, the concept of geodetic datum is introduced. A geodetic datum is a three-dimensional representation of the surface of the earth through a framework of discrete points whose coordinates and elevation (either above mean sea level or a reference ellipsoid) are accurately known. In individual regions, datum coordinates and computations are based on a local reference ellipsoid, which corresponds closely to the shape of the geoid in that area. Modern satellite techniques, such as the Global Positioning System (GPS) *(q.v.)*, rely on geocentric reference ellipsoids which have the center of the earth as the origin. To ensure compatibility between GPS coordinates and coordinates in the framework of the local geodetic datum, a mathematical function defining the transformation of the coordinates between the two systems must often be computed. A geodetic datum forms the basic structure for densification surveys which, in turn, can be incorporated into maps or Geographic Information System (GIS) *(q.v.)* databases. The concepts of geodetic datums and reference systems are covered in detail by Torge (1991).

Applications of Geodesy

Space geodetic measurement techniques (descriptions of very long baseline interferometry (VLBI), satellite laser ranging (SLR), and GPS are given in Seeber (1993)) are used to define international geodetic datums, such as the International Terrestrial Reference Frame (ITRF), which provide the basic infrastructure for positioning and navigation on the surface of the earth. These reference frames are used for global and regional plate tectonic studies, measurement of isostatic rebound, and connection of *tide gauges (q.v.)* for monitoring the levels of the world's oceans (see also *Sea-level datum (q.v.)*). They are also critical for satellite orbit tracking required for such applications as satellite *altimetry (q.v.)* and *SAR (q.v.)* studies. Global geodetic measurements are also used to derive parameters that can describe variations in the rotation of the earth (e.g., length of day, polar precession, and nutation), and the dynamics of the atmosphere, oceans, and solid earth (Lambeck, 1988).

Local geodetic measurements rely on survey instrumentation such as electronic distance meters (EDM), precise levels and *GPS (q.v.)* receivers. Such measurements are primarily used for mapping purposes, providing local control for *photogrammetry (q.v.)* and *remote sensing (q.v.)*, and for engineering applications such as monitoring physical changes in man-made structures and ground surfaces. For a complete appraisal of geodesy and terrestrial surveying, the classic text is Bomford (1980).

GEOGRAPHIC INFORMATION SYSTEMS

Introduction

Geographic Information Systems (GIS) are computerized spatial decision-making tools that coordinate place-based information and allow users to manage, analyze, and display geographic data. Since coastal features are typically spatial, coastal managers and scientists have incorporated this technology from its beginnings. However, coastal data often represent dynamic, multi-dimensional systems that present problems to this historically land-based technology.

History

The concept of a GIS originated from non-computerized decision-making techniques. One classic example is a decision-making technique developed by Ian McHarg, a landscape architect and author of *Design with Nature* (McHarg, 1969). McHarg's method for identifying suitable locations for development was based on defining the most favorable characteristics of various sets of information such as slope, soil type, geology, land use, and accessibility and then combining the layers into a composite map. Although McHarg's technique may be carried out in an analog fashion, it is a popular example of the power of applying digital computer technology.

The beginning of the modern, digital, GIS began in the late 1960s. Several efforts in developing digital spatial systems began concurrently and involved applications for urban planning, transportation, natural resources, and the US Census. The first use of the term GIS was the Canada Geographic Information System, implemented in 1964 to identify marginal agricultural lands for rehabilitation (Star and Estes, 1990; DeMers, 1997; Foresman, 1998; Wright and Bartlett, 2000).

Data models

A data model represents the spatial entity and its relationship to the real world (Goodchild, 1992). There are two primary data models in wide use today: raster models and vector models.

Raster models generally depict continuous data by representing data points in a regular pattern of cells. The size of the cells, for example, 10 m by 10 m, defines the geometric resolution and a series of row and column coordinates define the spatial extent. Continuous data commonly depicted with a raster model include surface elevation, precipitation, and satellite image data such as land cover (Bernhardsen, 1992).

Vector models are topological, representing discrete data with nodes and lines (Bernhardsen, 1992). The node may define a starting point, an intersection, an end point, or any point along a line. The topological model retains the relationship and connectivity between and among points, lines, and polygons. For example, a series of nodes and lines may define two adjacent counties; the shared border is captured and stored only once in a vector model and that relationship remains intact even when the geometry is changed.

A third type of data model may represent continuous or discrete data as a network and is most often applied in hydrology and transportation applications (Goodchild, 1992). A fourth model, the object model, follows a new era of object-oriented programming and overcomes some of the deficiencies of the common models (Neves *et al*., 1999).

Functionality

A GIS typically uses hardware and software that allows the following functionality:

- Data input/capture
- Data storage/management
- Data manipulation
- Data analysis
- Data output and display

If data are not already in a digital form, data capture may be a time-consuming component of building a GIS. Data capture techniques include hand-tracing maps with a digitizing puck (mouse) and tablet, electronic scanning that converts points and lines, Global Positioning Systems (GPS) that digitally record surveyed locations, and manual entry of geographic coordinates. Acquiring digital spatial data from secondary sources typically requires a data conversion process, that is, converting from one proprietary format to another or converting from one coordinate system or map projection to another. Once geographic entities are digitally captured, assigning attribute identities is typically required. For example, a river (the entity) may be hand digitized and its name would be assigned separately as an attribute.

Data storage and management is conducted using the database management system (DBMS) component of a GIS. Users create, update, and store the geographic entity files and their associated attributes. Metadata, information about the history and extent of the spatial data, may similarly be stored and managed. Once collected and stored in a GIS database, spatial data may be manipulated (queried, classified, and edited) using tools inherent in GIS software packages.

The ability to analyze spatial data is the component that differentiates GIS from desktop mapping software. GIS software provides tools to analyze distance, direction, connectivity, and proximity through the use of spatial and attribute queries. The movement of humans or natural features through linear networks such as roads and streams may be modeled. Furthermore, data modeling tools allow the depiction of two-and three-dimensional characteristics of the earth's surface, subsurface, and atmosphere. Map overlay analysis involves combining two or more layers of information through logical operations. McHarg's suitability analysis is a perfect example of the use of map overlay analysis.

Finally, data output and display capabilities allow the GIS user to prepare graphic images of their products. The images may be output as paper maps or stored as electronic files for computer screen display or for use in web-based applications.

Coastal GIS

We use our coasts for food, minerals, waste disposal, industry, transportation, leisure, and tourism. With as much as 50% of the US population living on or near a coast, the economic and aesthetic importance of the coastal zone to humans is obvious. Coastal zones are also hazardous places with the threats of flooding, erosion, hurricanes, earthquakes, or tsunamis. The environmental movement of the 1960s and early 1970s highlighted the need for coastal stewardship and by 1972, the Coastal Zone Management Act was passed. With a focus on stewardship and multi-stakeholder management, coastal scientists sought new ways to implement their management directives. Since coastal data are spatial, GIS technology was recognized as a useful tool for coastal management decision-making.

In the early 1970s, coastal literature began to address the need for coastal zone management tools and GIS technology was implicated. The first GIS coastal applications were developed for particular tasks such as development permitting or tourism planning along coasts (Bartlett, 2000). Early efforts to apply GIS were thwarted by limited availability of software, hardware, and trained personnel. And still, with availability of proprietary GIS packages that are easier to use and to maintain, the built in functionality still lacks for coastal applications that require three-dimensional and temporal analysis.

Bartlett identified several primary issues in the "challenge of applying GIS to the coast" including data availability and data models (Bartlett, 2000). It is rare to find available and accessible data and collecting primary data is costly and time consuming. In acquiring secondary data one must ensure data quality issues such as completeness, accuracy, currency, and lineage. In developing a coastal GIS, as in any GIS development, primary and secondary data will most likely be required.

The structure of the data model has also been a limitation in coastal GIS applications. Raster-based models hold the typical advantages of simple programming and high volume storage, however, spatial resolution is compromised. Conversely, vector systems portray finer resolution but inappropriately portray boundaries that are "fuzzy." Dynamic segmentation (network models), object models, and others "hold considerable potential for advancing the utility of GIS within the coastal and marine environment" (Bartlett, 2000).

To date, a number of large coastal GIS-based projects have been implemented and the efforts were largely collaborative between federal governments, academic institutions, non-profit organizations, and local governments. In the United States, federal agencies such as the National Oceanic and Atmospheric Administration (NOAA), the US Geological Survey (USGS) and the Federal Emergency Management Agency (FEMA), have led national case studies. FEMA with a mandate from the National Flood Insurance Reform Act of 1994, has conducted case studies to determine the feasibility of mapping erosion hazards throughout the US coastal zone (Daniels *et al*., 1998). FEMA contracted the Washington State Department of Ecology (with support from USGS, NOAA, and local agencies) to calculate a 60-year erosion hazard area for Pacific County, Washington. Pacific County is located north of the Columbia River and includes 60 km of dynamic shoreline, with both high erosion and high accretion rates. The data collection included digitizing historical coastlines from historical topographic sheets, determining contemporary high-tide shorelines from recent aerial photography, and digitizing the average high water line and vegetation line. They used GIS analysis methods to analyze the past, current, and future high-tide shorelines. The results show that from 1950 to 1995 the rates of change varied within the county from 28.3 m/year of accretion to 27.0 m/year of erosion; the mean rate was 0.9 m/year of accretion. The study determined that 626 structures were within the projected 60-year hazard area.

Future

Despite current limitations, GIS remains an important tool for coastal applications. As collaborative projects and research on the use of GIS in coastal applications continues, Bartlett offers that the key to a successful GIS is planning:

> It is essential to establish the user-base for whom the coastal zone GIS is intended, and the view of the coast and its component elements that is relevant to this constituency, since this operational context will have a direct bearing on the more technologically-oriented questions of hardware and software selection, and the overall architecture of the system. It will also define the information products expected from the system, and hence the types of data, and the processes performed on these, that are required in order to produce the desired output (Bartlett, 2000, p. 18).

One measure of the importance of GIS to coastal scientists is the increasing number of user-groups, web pages, and conferences organized around the theme. Examples include, the International Geographic Union's Commission on Coastal Systems and the Working Group on Marine Cartography of the International Cartographic Association collaborative international symposium known as CoastGIS and a web page devoted to maintaining a bibliography of coastal zone application of GIS (Fell *et al*., 1997).

GEOGRAPHICAL COASTAL ZONALITY

The term "coastal zone" has been misleadingly used, even in scientific papers to describe the coastal environment or the region between the foreshore and the upper supratidal along a coastline. "Zones" in geoscience, however, should be named only for more or less latitude-parallel belts between the equator and the poles, which have been established in the first order by the different radiation of sunlight on our globe.

Nearly all macro-patterns on earth, which depend on climatic influences, like vegetation, soil formation, or forms of relief and inherent processes show a zonal distribution. For the latter, including both relic and contemporary systems, this has been accepted for decades (Murphy, 1968; Büdel, 1977); and the term "climatic geomorphology" has therefore been established. Regarding coastal features and processes, however, these have been looked upon for a long time mostly as azonal, because cliffs, beaches, lagoons and barriers, deltas, etc. can be found in all latitudes; and rock-depending forms are azonal, as well.

It was only in 1964 that Davies established a deductive classification of zonal coastal patterns based on prevailing wave and surf types, and in 1972 Davies introduced his pioneering book on "*Geographical Variation in Coastal Development*," giving an overview of the zonal coastal forms and processes, all inductively identified. Other authors then studied the global distribution of single features and their differentiation according to latitude, or the influence of humid or arid tropical climates on coastal landforms.

Almost two decades ago a "system of zonal coastal geomorphology" was developed by Valentin (1979). This system is limited to the definition of 51 types of non-coastal landforms which were characteristic of the Wisconsin (Würm) glacial climato-morphogenic zones. Many of these areas were in part drowned during the postglacial sea-level rise. The glacio-eustatic drowning is in fact the only "littoral" and global factor in this system, but it is not a zonal process since it can be observed worldwide. In his "Atlas of Coastal Geomorphology and Zonality" Kelletat (1995), however, applied the question of zonality in a strictly inductive sense, that is, interpreted from field evidence and areal distribution patterns, in contrast to previous deductive models. This is only one of the first steps and a complete system of geographical coastal zonality will remain an unsolved problem, so far as the general features of coastal evolution have been firmly established, and we are still far from this aim today. Some examples of zones and sub-zones on selected meridional transects may elucidate the problem (see Figure G4).

The zonality of the coasts of Europe and the Middle East is particularly influenced by two special conditions: the warming effect of the Gulf Stream in the north and the semi-enclosed oceanic basin of the Mediterranean Sea. Thus, it is only north of the Arctic circle in the fresh or brackish waters of fiords that reach far inland and into the Baltic Sea, where the coastal influence of sea ice becomes recognizable. Between coastal freezing of the Baltic and permanent sea ice around the North Pole another zone can be found without shore and sea ice contacts because of the warming of the Gulf Stream around northernmost Norway. In hard rocks, there are only fiords and skerries affected by contemporary coastal processes.

The next important morphodynamic boundary marks the equatorial limit of frost weathering which reaches 54°N and comprises parts of the German coasts and eastern coasts of the British Isles. Thick medium-sized algae are found in the rocky littoral (*Fucus, Laminariae*, and others) that extends to about 46°N in France. South of 44°N latitude in the Mediterranean, calcareous algae and encrusting vermetids create youthful organic rock formations, which sometimes grow together to form trottoirs and even miniature atolls, particularly south of 36°N latitude. South of 38°N latitude, the occurrence of beachrock increases as do coral reefs south of 30°N in the Red Sea; while south of 28°N, the northernmost outposts of mangroves can be found at the Sinai Peninsula.

The Mediterranean may be used to illustrate problems inherent in the field methods that are commonly applied. Davies (1972, p. 183) classified coasts within the zone of the "lower latitudes" and so did Valentin (1979), specifying them as "subtropical." Davies puts the Mediterranean as well as the whole of Australia into the same zone; whereas in Valentin's system, Australia is divided into a tropical and a subtropical zone. Both authors use the same major elements for classification, that is, the distribution of corals, mangroves, and beachrock. But it was only the existence of beachrock that caused the inclusion of the Mediterranean into the subtropical zone or into the zone of the lower latitudes, respectively. In the southern parts of the Australian coast beachrock does not exist, and the subtropical zone would be erroneously shown to extend beyond the beachrock distribution area. On the other hand, the boundary of the coral reef distribution area is practically the same as that of beachrock at the east coast; whereas, mangroves are found in some areas of the south coast far beyond the usual areas of the subtropics in the Northern Hemisphere. This is an important anomaly.

Along the east coast of North America, the zonality of presently active coastal processes is more closely spaced (Kelletat, 1989). The effects of sea ice on rock and beach coasts extend as far south as 46°N,

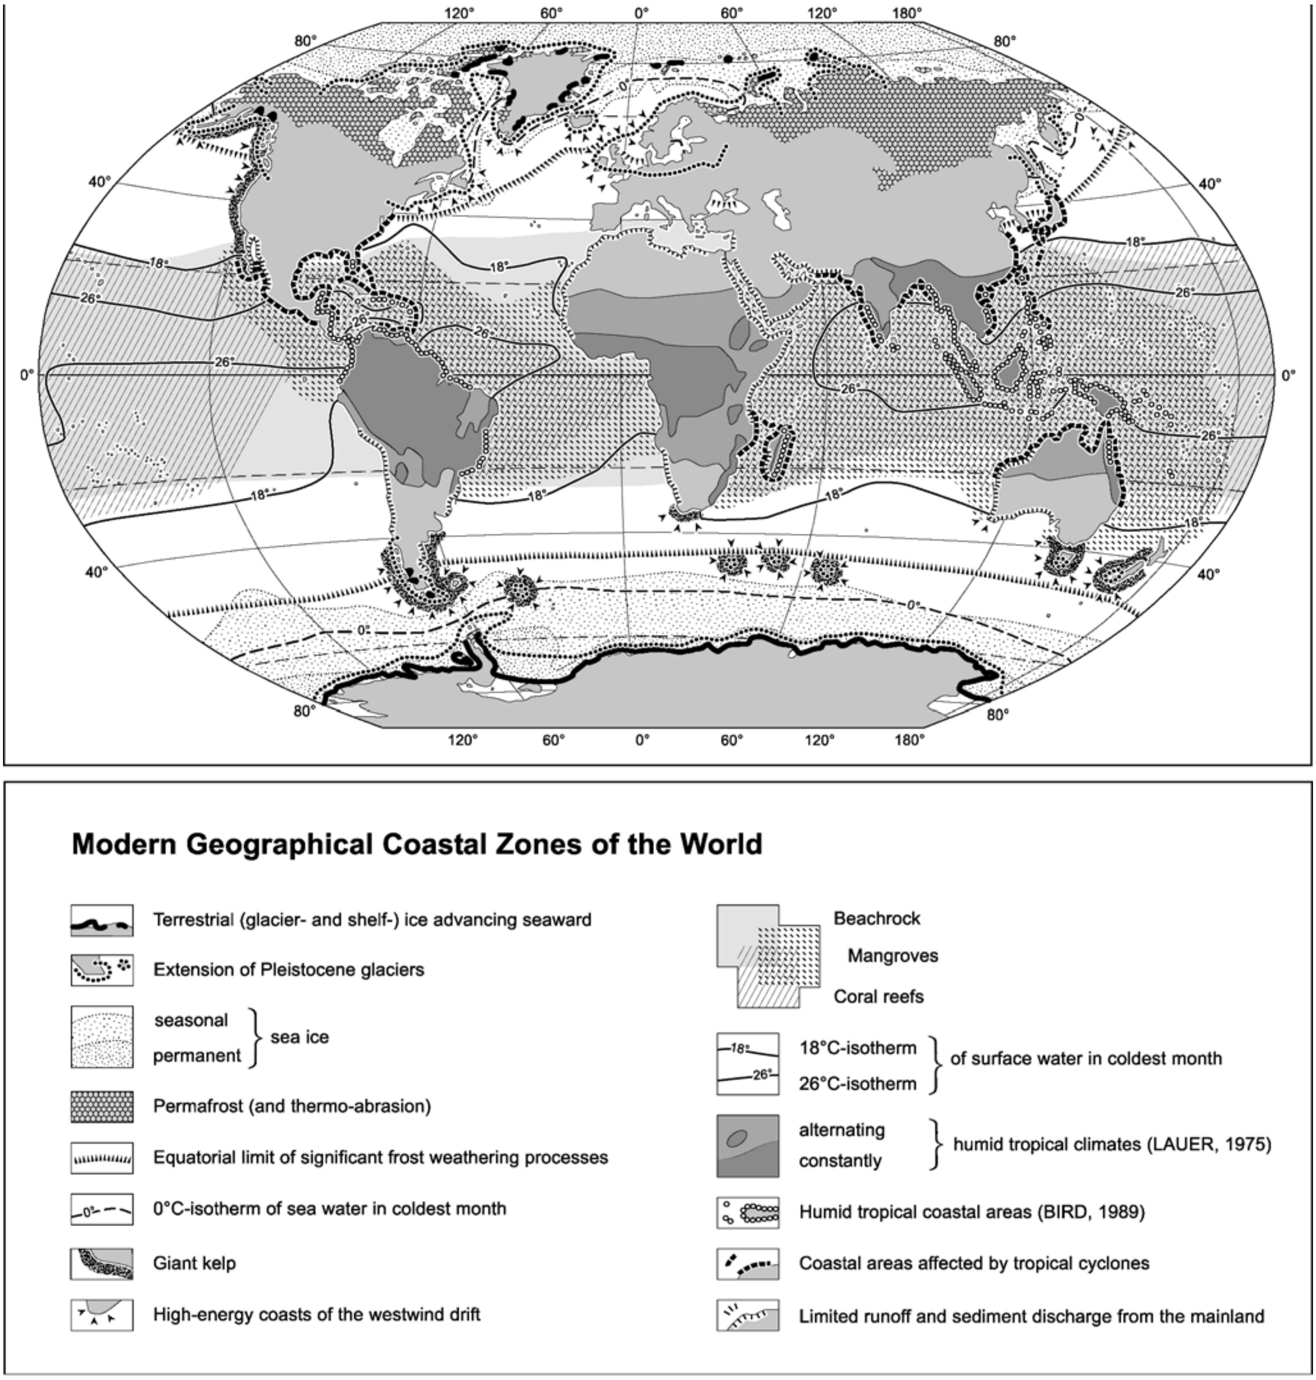

Figure G4 Modern geographical coastal zones of the world. (After Kelletat, 1995.)

and to around 40°N significant frost weathering processes can be observed. South of 35°N there are compound oyster reefs, that is organic rock formations, together with an increasing number of beaches with massive shell deposits. From 34°N to 30°N, hypersaline tidal flats occur in places almost completely free of vegetation (or only with microscopic plant material present), especially around the highest spring tide level. Latitude 28°N marks the poleward boundary of mangroves, 26°N that of the coral reefs. In total, there is only a separation of 20 latitudinal degrees between the coral reefs of the tropical zone and the sea ice effects of the subpolar zone, in comparison to at least 38° on the European side of the Atlantic Ocean. These findings may be contrasted with those on the coasts of eastern Australia and New Zealand; this region is the only one where the problems of zonality have been carefully studied (e.g., Kelletat and Seehof, 1986; Kelletat, 1988). Here, the morphological impact of both sea ice and frost on the coastal environment is missing. Giant kelp (*Durvillsea, Macrocystis*, and others) can be found as far north as 41°S, thus, effectively protecting the rocky coasts from heavy surf. Serpulids and sabellariae form solid organic substrates as far north as 38°S (eastern Australia) and 37°S (New Zealand) respectively, whereas oyster reefs reach as far south as 33°S (Australia) and 37°S (New Zealand).

Within tidal limits, hypersaline tidal flats almost free of vegetation are found as far south as 42°S in New Zealand and south of 28°S in eastern Australia. Latitude 38°S is the southern boundary of mangroves. Just south of the limit of massive coral reefs, that is 25°S, is the change from the tropical to the extratropical species in the rocky littoral.

The zones of giant subpolar algae and mangrove communities commonly reach within 3° latitude and sometimes even overlap. In contrast, the distance between them being 14° on the North American east coast and at least 18° in Europe. In Florida, the northern boundary of the mangrove zone is 2° north of that of the coral zone, whereas in Australia/New Zealand it is 13°, but in North Africa/Middle East (e.g., Sinai Peninsula) the coral reefs extend 2° farther north than the northernmost mangrove, *Avicennia marina* being the species in all areas. These differences cannot properly be explained yet, mainly because the extreme and mean values of both air and water climates differ significantly at these boundary lines.

Thus, both zonal and azonal features at the coasts are manifold, zonal aspects are mainly given by climatic and biogenic parameters (at least the latter partly depends on the first) and geodynamic, structural, petrographic, or sedimentological properties dominate the azonal aspects.

Most authors have tried to define a rather simple system of coastal zonality, either by separating tropical (including subtropical) and extratropical areas or by dividing the Earth's coasts into high-, mid-, and low-latitudes. In his synthesis of 1977 (pp. 181/182) Davies characterizes these zones as follows:

High-latitude coasts: They are frozen part of the year and seasonal ice is active on the beach. Characteristics are: low wave energy because of freezing and limited fetch, many pebbles at the beaches due to former glaciation and frost weathering, barriers developed well and widespread, dunes rather limited and tidal flats dominated by grassy vegetation. Cliffs are mainly formed by frost action, mass wasting is common, often due to permafrost decay. Further categories within high-latitude coasts may be determined by the duration of the sea-ice cover.

Mid-latitude coasts: They show high wave energy and frontal storm maxima, frequent cliffs in hard rock with quarrying and abrasion, sloping intertidal rock platforms, weaker developed barrier systems but with partly very extensive dune areas. Biogenic effects are believed to be insignificant, except for dunes and tidal flats. A differentiation of this broad zone may be made by the limit of Ice-Age glaciers deeply influencing the types of sedimentation along the coastline.

Low-latitude coasts: They are exposed to a relatively permanent approach of wind, waves, and swell and only reduced wave energy is active. Algae and corals contribute to coastal forming, and lithification of dunes and beaches may occur. The widespread coastal sediments are of fine-grain deposits. Dunes exist in limited areas only, and rocky coasts with horizontal rock platforms are restricted. Perpendicular cliffs are very rare (except in arid areas), salt weathering is typical as well as extensive tidal woodlands (mangroves). A differentiation should be made regarding the more humid and the more arid environments.

Although the spatial distribution of some important coastal phenomena is generally known, it is difficult or nearly impossible to define the zonal limits by means of climatic data (although radiation/climate are the main sources of the zonal patterns of the earth).

The 18°C-isotherm of surface water in the coldest month of the year is the thermal factor which sets limits for the coral reef zone. For other coastal features a definition is much more complicated; mangroves occur in very humid to extremely arid regions (e.g., precipitation nearly zero to thousands of millimeters per year) and within limits of low to high evaporation. Mean annual air temperatures at mangrove sites vary from about 28°C to nearly 15°C, those of the coldest month from more than 25°C to only 7°C, and coldest water temperatures from more than 25°C to nearly 6°C. As thermal limit for mangroves (*Avicennia* sp. or *Kandelia* sp. in Japan), several frost days with air temperatures of −4°/−5°C may be defined; whereas the number of months with mean temperatures below 20°C may reach from 12°C to zero (as well as the number of arid months).

The climatic data for beachrock are at least as heterogeneous as for the polar limits of mangroves (i.e., annual precipitation from nearly zero to several thousands of millimeters, low to high evaporation, zero to 12 arid months, mean annual air temperature between 15°C and more than 27°C, mean temperature of the coldest month down to 7°C, as well as water temperature, which may never reach 20°C during the year as in Namibia). When comparing the beachrock distribution on the islands of Oahu (Hawaii) and Madagascar, a clear relationship to the arid areas cannot be detected; microclimatic aridity may be more important than high water temperature. Both islands are situated in the core zone of beachrock distribution. In its marginal fringe like the Mediterranean Sea, beachrock in higher frequency and quality is clearly restricted to the warmer and more arid southern and eastern parts. It is only sporadic and poorly developed in its more humid and colder north and west.

In higher latitudes, the equatorial limits of giant kelp at the coasts show a similar and rather high differentiation (i.e., annual precipitation from around 300 to more than 1,300 mm, mean annual temperatures from 7.5°C to at least 17°C, and the coldest month even from 13°C down to −5°C). The limiting factor seems to be the air temperature, not exceeding a monthly average of 20°/21°C. The average water temperature may vary from below zero to more than 15°C. Twenty degrees centigrade seems to be lethal.

All features discussed here belong to the younger Holocene or even to contemporary decades, that is, an extremely short geologic period under a stable climatic regime. It is, however, difficult and till now partly impossible to commit to a satisfactory definition of limiting climatic conditions for most of the coastal features. In this respect, the related sciences are far from a consensus.

As a synthesis, a complex world map (Figure G4) may show the state-of-the-art in inductive coastal zonality.

For example, it is difficult to define zones and subzones by coastal forms because of their multi-temporal origin, that is from very different climates and, therefore, inherent with aspects of other zones. It may be prudent to restrict a consensus to the distribution of actual coastal processes (or those of the younger Holocene, when sea level was roughly at its present position). This will show a more homogeneous picture, comparable for all zones. A difficult, time-consuming problem that remains is: detecting and evaluating processes. Due to the present state of research, we usually attempt to infer the process itself from its result (i.e., we infer cementation from the occurrence of beachrock and horizontal rock platforms from the process of salt/frost weathering or water-layer leveling, etc.). A fundamental question is, whether we should define a zone or sub-zone by the dominant process (if one exists) or by a combination of more than one process. Does a zone or sub-zone need to show only adequate processes or their forms? Or should they be dominated spatially, or should a zone be characterized by a process even if its geomorphological effect and importance is minimal? Additional problems include insufficient or inadequate knowledge of coastal forms and processes worldwide as well as regionally and thematically.

In reference to coastal features, one is faced with problems that are dominated by azonal geodynamic, geological, structural, tectonic, petrographic, or sedimentological factors, and by seawater or surf conditions, by climatic parameters, or by biospheric processes, etc. Integration of all these categories into only one model of coastal zonality seems not to be acceptable.

Knowing that contemporary coasts were formed during the last 6,000 years, an extremely short timespan in geological and geomorphological times, the question arises as to whether the morphodynamic patterns now detected are representative of the last interglacial. Has the Holocene reached its climax conditions or is it still in process? An ancillary question regards zone shifts when climatic conditions changed. If it is true that coral reefs have their lethal winter temperature limit at 18°C and giant kelp at about 20°C in summer, a general change of 0.5 to 1.0°C (that may occur within decades) would transfer their zonal limits for hundreds of kilometers. Singular and azonal events like changing ocean currents or El Niño effects may re-inforce this tendency.

Being aware of the delicate balance of geomorphological zones and sub-zones during a given geological or climatic condition, it may be interesting to reconstruct those zones and sub-zones valid for former geological periods (which might have been longer lasting once they had reached their climax with certainty) and to learn from these results. On the other hand, by detecting coastal zones of former periods, it sometimes may be possible to deduce their environmental (i.e., paleoclimatological) parameters.

GEOHYDRAULIC RESEARCH CENTERS

Introduction

Several geohydraulic research centers specialize in coastal science and engineering research. Among the largest are current or former government research facilities that have been partially or completely privatized. The centers have laboratory facilities used for both research and scale-model studies to aid in project design. In recent years, most centers have developed numerical models for project design. The following summarizes capabilities of the major geohydraulic research centers.

WL/Delft Hydraulics, Netherlands

WL/Delft Hydraulics located in Delft, the Netherlands, is one of the world's oldest and largest geohydraulic research centers. It was founded in 1927 and is one of the five large technological institutes in the Netherlands. These institutes were originally established by the Netherlands' government but are currently independent consulting and research organizations. WL/Delft Hydraulics provides advice and technical assistance on water-related projects that range from applied research and consultancy to multidisciplinary policy studies.

WL/Delft Hydraulics has a staff of about 400 with expertise in hydrology, hydraulics, morphology, water quality, and ecology. It addresses both construction and design issues related to the offshore, coasts, harbors, estuaries, rivers, and canals and also related environmental impact assessments. Research and development constitutes about 40% of the income of WL/Delft Hydraulics with 10% provided by the Netherlands' government for basic research, 5% for national research programs, 15% for joint research projects with the Rijkiswaterstaat of the Netherlands' government, and 5% related to research projects of the European Union. About 25% of income is for technical assistance in studies around the world.

WL/Delft Hydraulics has extensive coastal and hydraulic laboratory facilities with some designated since 1989 as large installations available for use by European Union members. Its Delta flume is 240 m long, 5 m wide, and 7 m deep and 1–5.5 m water depths are used in testing. The flume's wave generator can produce wave periods from 1 to 12.5 s and a 2.5 m regular wave height or a 1.9 m random wave height. Its Scheldegoot facility is a wave flume that is 0.55 m long, 1 m wide, and 1.2 m deep with a 1.2 m-high wave generator that can operate with water depths of 0.25–1.0 m and produce both periodic and random waves. The wave generator board is equipped for active wave absorption to avoid spurious long-period waves, and a second wave board is located at the flume's end for active wave absorption. The flume has a pump system allowing simulation of currents. The Vinje basin is a multidirectional wave basin with a variable length up to 60 m, a width of 26.4 m, and a maximum depth of 0.75 m. It has a directional spectral wave generator that can produce a maximum wave height of 0.3 m, a significant wave height of 0.15 m for a Pierson–Moskowitz spectrum, and wave periods between 0.4 and 3.0 s. The Schelde basin is a three-dimensional (3D) basin for studying wave attack on structures. The wave basin is 30 m long, 22.5 m wide, and 1.2 m deep with a maximum water depth of 1.0 m. The wave generator can produce waves with a maximum height of 0.4 m and a maximum significant height of 0.2 m.

WL/Delft Hydraulics has an oscillating water tunnel constructed to study sediment transport under controlled full-scale simulated wave conditions. The tunnel has a length of 14 m with an inner width of 0.3 m and an inner height of 1.1 m. Wave periods can be produced with periods between 5 and 15 s, maximum velocities of 2 m/s, and maximum acceleration of 2 m/s^2. WL/Delft Hydraulics also has a rotating annular flume with a mean diameter of 2.1 m, channel width of 0.2 m, and depth of 0.3 m. A circular lid on the surface drives flows, and the channel can be rotated in the opposite direction to minimize secondary currents at the bottom. Then too, there is a sand flume 98.7-m long including a 50 m flow section and 35 m-long testing section that is 1.5 m wide, and 1 m deep. The maximum depth with sand is 0.4–0.5 m. The maximum flow discharge is 0.8 m^3/s and maximum sediment flow is 0.3 m^3/h. In addition, WL/Delft Hydraulics has a dredging flume for testing of cutting and suction devices, trenching equipment, anchors, and jets. It has a variable length up to 50 m, width of 9 m (5.5 m research flume and 3.5 m settling basin), and a depth of 2.5 m.

The tidal flume at WL/Delft Hydraulics is 130 m long, 1 m wide, and has a depth of 0.1–0.9 m. Tides, water depth, salinity, and silt concentration can be controlled at the sea boundary, whereas freshwater discharge and silt concentration can be controlled at its river boundary.

Delft3D is a numerical modeling system developed by WL/Delft Hydraulics that can simulate 2D and 3D flows from tides, winds, density gradients, and waves. It has a central hydrodynamics module that drives ecological, sediment transport, wave, water quality, and morphological modules.

Coastal and Hydraulics Laboratory, United States

The Coastal and Hydraulics Laboratory (CHL) located in Vicksburg, Mississippi, USA, was formed in 1996 through a merger of the Hydraulics Laboratory (HL) founded in 1929 (HL was the original Waterways Experiment Station—WES) and the Coastal Engineering Research Center founded in 1930 (predecessor organization was the Beach Erosion Board). CHL is part of the seven-laboratory complex of the Corps of Engineers Research and Development Center (ERDC) that includes four laboratories at WES (Geotechnical and Structures, Environmental, and Information Technology Laboratories in addition to CHL) and the Construction Engineering Research Laboratory in Illinois, Cold Regions Research Laboratory in New Hampshire, and the Engineering Topographic Laboratory in Virginia. The ERDC has 2,100 employees with 1,200 at WES including 250 mostly engineers and scientists in CHL.

CHL has the largest coastal and hydraulic laboratory complex in the world with over 150,000 m^2 of laboratory facilities under roof. About a quarter of these facilities are used for coastal engineering research and scale modeling with the remainder used for hydraulic-engineering research and scale modeling. CHL has several wave flumes all with spectral-wave generators including the following: 105 m long, 2 m wide, 1.4 m water depth, 0.45 m wave height; 80 m long, 3.5 m wide, 1.4 m water depth, 0.45 m wave height; 65 m long, 3 m wide, 1 m water depth, 0.5 m wave height; 65 m long, 1.5 m wide, 1 m water depth, 0.5 m wave height; 60 m long, 0.6 m wide, 1 m water depth, 0.6 m wave height; 45 m long, 1 m wide, 0.6 m water depth, 0.2 m wave height; and 45 m long, 1 m wide, 0.6 m water depth, 0.2 m wave height. CHL's L-Shaped facility tests 3D stability of structures such as breakwaters and is 75 m long, 15 m wide at the wave generator, 25 m wide at the testing end; operates with water depths up to 1.5 m, and uses a wave generator with a wave board that is 4 m high and 15 m wide and produces waves 0.6 m in height.

CHL has about 30,000 m^2 of building space for 3D wave basins used for studying waves in harbors, movable-bed modeling, coastal processes, wave interaction with ships and other floating structures and other coastal-engineering applications. Large remote-controlled scale model ships (e.g., container ships, submarines, aircraft carriers) measuring about 7 m in length are employed to test ship maneuverability in directional-spectral seas with currents and wind. Long-wave harbor resonance is tested in a facility with a wetted area of over 4,000 m^2 and 14 spectral-wave generators each approximately 5 m long that can generate waves with periods from 1 to 10 s. CHL has two numerical ship and tow simulators for design of navigation channels that include a complete full-scale ship bridge and real-time visualization.

CHL's Long Shore Transport Facility is a unique 30-by-50 m (expandable to 80 m) and 1.4 m deep wave basin used to study longshore currents and sediment transport. Wave makers generate regular or irregular waves with heights up to 0.4 meters, periods of 1.0 to 3.5 seconds, and angles up to 20 degrees from shore normal. A longshore current re-circulation system has 20 independent upstream and

20 downstream flow channels each with a turbine pump that discharges up to 75 L/s. The system accurately controls cross-shore distribution of wave-driven longshore currents and re-circulates currents from downstream to upstream. Downstream flow channels have sediment traps that record sand accumulation and a dredging system that re-circulates sand collected in the traps to the upstream end.

CHL's new ESTEX Hyperflume facility used for conducting unsteady, nonuniform flow and sediment transport research has a 15 m by 18 m and 3 m deep basin connected to an 18 m by 107 m and 1.2 m deep basin and a parallel 3 m by 122 m and 1.2 m to 3 m deep basin.

CHL has software that it distributes at no cost, such as the Automated Coastal Engineering System (ACES). ACES includes well-known models such as the shoreline change model, GENESIS, and the cross-beach and dune model, SBEACH. CHL also has developed the Groundwater/Surface Water/ Watershed Modeling System (GMS, SMS, WMS), integrated modeling systems that are distributed by commercial vendors. These systems have about 9,000 users around the world. The CH3D model developed by CHL is a 3D modeling system for hydroenvironmental and sediment-transport problems.

DHI—Institute of Water and Environment, Denmark

The Danish Hydraulics Institute (DHI) located in Horsholm, Denmark, and VKI Institute for the Water Environment, merged January 1, 2000, to form DHI—Institute of Water and Environment. The VKI Institute for the Water Environment was an independent self-governing institute for water environment affiliated with the Danish Academy of Technical Service that specialized in environmental chemistry, environmental technology, and ecology. Annual funding by the Danish Agency for Development of Trade and Industry provided part of research and development at VKI. DHI specialized in management of the aquatic environment including hydrodynamic and environmental modeling, coastal hydraulics, and port and coastal structures. DHI—Institute of Water and Environment has 460 employees, 75 of whom are employed in international subsidiaries and branch offices, and 230 of whom were employed by the DHI prior to the merger.

DHI—Institute of Water and Environment operates shallow- and deep-water experimental basins for testing of wave agitation in harbors, stability of breakwaters, loads on offshore structures, response of floating structures, and wave hydrodynamics. One basin is 30 m by 20 m including a 3 m deep offshore basin (with 12 m deep pit) for 3D waves, currents, and wind. This basin is equipped with a 60-flap directional-spectral wave generator. Three other basins have dimensions of 32 by-30 m, 0.45 m deep; 30 by-30 m, 0.75 m deep; and 62 by-30 m, 0.45 m deep. It has three flumes, one 35 by-1.8 m; 1.8 m deep; 35 by-5.5 m, 0.8 m deep; and 28 by-0.74 m, 1.2 m deep. Other facilities also are available for use at the nearby Technical University of Denmark.

DHI—Institute of Water and Environment markets a wide variety of 1-D, 2-D, and 3-D numerical models including models of current and water levels to simulate tides, storms, cyclones, and tsunamis. Its 3D ocean circulation model (MIKE3) is used to simulate the coastal ocean when stratification is important. Other models are used for wave hindcasting, advection—dispersion, sediment transport, morphology, and water quality. In collaboration with the Technical University of Denmark, DHI developed the noncohesive sediment transport model STP that can simulate sand transport due to waves and currents including surf-zone transport. The model LITPACK is used to evaluate changes of a coast due to human activities. DHI's model, MIKE21, solves the Boussinesq equations and is used in port planning. DHI studies ship maneuvering using a numerical ship simulator that is driven by numerical hydrodynamic models.

HR Wallingford, United Kingdom

HR Wallingford located in Wallingford, United Kingdom, was founded in 1947 as the United Kingdom's Government's Hydraulics Research Organization, but was privatized in 1982. It has large-scale experimental facilities used for basic and applied research with 29,000 m^2 of covered laboratory space. Its UK Coastal Research Facility consists of a directional spectral wave generator in a basin with tidal and longshore current generating capabilities. It is 36-by-22 m with a depth range of 0.3–0.8 m. Its Flood Channel Facility is a large flume for investigating sediment transport in rivers and flow interactions with flood plains. This facility is 56-by-10 meters with a maximum discharge of 1.1 m^3/s. A Sloping Sediment Duct is used for investigating flow and sediment transport on flat to very steep slopes (up to 33 degrees). The working section is 6-by-0.6 m and is 0.25 m deep with a maximum flow of 0.15 cubic meters per second. The High Discharge Flume is for studying flow and sediment transport or equipment testing and has a working section of 25-by-2.4 m with depth up to 1.2 m and a maximum flow of 1.2 cubic meters per second. The Tilting Flume is for measurements of flow and sediment transport or surface runoff testing with a working section of 25-by-2.4 m, a depth of up to 0.6 m, and with a maximum tilt of 1 in 30 and maximum flow of 0.25 cubic meters per second. HR Wallingford is a partner with Electricité de France in the development and application of TELEMAC, a finite-element modeling system for flows, sediment transport, and water quality in two and three dimensions. Its model SeaWorks calculates wave and beach processes.

Canadian Hydraulics Centre

The Canadian Hydraulics Centre (CHC), located in Ottawa, Canada, is a government agency and a unit of the National Research Council, Canada's leading scientific research organization.

The CHC has extensive laboratory facilities in an 8,400 square-meter building. Its multidirectional wave basin is 50-m long, 30-m wide, and 3 m deep with a 15 m deep central pit with a 6-m diameter. The directional spectral wave generator can produce waves up to 0.7 m. CHC's shallow wave basin is 47 m long, 30 m wide, and 0.9 m deep. Wave generators produce long-crested waves up to 0.2 m high. Currents and tides also can be generated in the facility. Its coastal wave basin is 63-m long, 14 m wide, and 1.5 m deep and is equipped with a single wave generator that is 14 m long and can produce irregular long-crested seas. CHC's large wave flume is 97 m long, 2 m wide, and 2.7 m deep, and its wave generator can produce waves up to 1.1 m in height. A smaller wave flume is 63-m long, 1.22 m wide, and 1.22 m deep, its wave generator can produce waves with heights up to 0.25 m, and it has a pumping system that can produce flows up to 0.2 cubic meters per second.

CHC markets a variety of coastal-process software. Its wave-agitation software can be used for wave-climatology prediction in the open ocean, wave transformation into shallow water, waves in harbors, and waves produced by ships. It has 1D, 2D, and 3D hydrodynamic models for water levels and currents in lakes, rivers, estuaries, and coastal areas. Its sediment modeling includes modeling of beach evolution and erosion and deposition of cohesive and noncohesive sediments. CHC's environmental modeling can be used to predict the fate of oil or chemical spills.

Flanders Hydraulics, Belgium

Flanders Hydraulics, Antwerp, Belgium, is a research institute of the Belgium government that was established in 1933. Flanders Hydraulics advises the government on harbor and waterway design, coastal engineering, and storm surges and other floods. It also provides consultancy to private organizations.

Flanders Hydraulics has two wave flumes for breakwater stability and beach-profile- change research that are equipped with spectral wave generators with active wave absorption to eliminate wave reflections. A wave basin is used to study wave transformation and equilibrium studies. Its spectral wave generator can be moved to generate waves with angles of up to 30 degrees from normal, and longshore currents can be generated by pumping water in a closed circuit. Flanders Hydraulics has a circulating mud-erosion water tunnel used to study the erosion and deposition of cohesive sediments. The tunnel is closed with a measuring section 3-m long, 0.4 m wide, and 0.4 m high. The measuring section is followed by an introductory section 20 m long and 0.4-by-0.4 m square and an outlet section 3 m long.

Flanders Hydraulics operates a ship handling and maneuvering simulator used to both train pilots as well as to design hydraulic structures, harbor entrances, access channels, harbor turning basins, and other aspects of navigation channel design. Flanders Hydraulics also has facilities to study hydraulic structures that block upstream fish migration.

Kajima Research Institute, Japan

The Kajima Research Institute (KRI) was established in 1949 and is located in Tobitakyu, Chofu, Tokyo, Japan. It is a research institute of Kajima Corporation, a private-sector construction company. KRI has a laboratory facility built in 1975 that is in a 2,870 m^2 building. KRI has a wave basin that is 58 m long, 20 m wide, and 1.6 m deep, and its directional spectral wave generator can produce waves up to 0.6 m in height with wave periods from 0.5 to 5 s, and it can actively absorb reflected waves. The basin is equipped to generate tides. The KRI has a large wave flume 62 m long, 2 m wide, and 2 m deep, and its wave generator can produce waves up to 0.6 m in height and it can absorb reflected waves. It has a medium-size wave flume that is 60 m long, 0.7 m wide, and 1.5 m deep, and its wave generator can produce spectral waves with maximum heights of 0.5 m and absorb reflected waves. There is a 30 m section of glass windows. Currents with maximum discharge of 0.2 m^3/s can be generated in the flume.

Then too, KRI has developed a beach evolution predictive model, COASTLINE, that can evaluate waves and wave-induced currents, the effects of coastal development on sediment transport, wave-induced scour around a structure, and the efficacy of beach nourishment and shore protection.

Manly Hydraulics Laboratory, Australia

The Manly Hydraulics Laboratory is located in Manly Vale, a suburb of Sydney, Australia. It has 2,230 square meters of covered experimental space and 3,530 square meters of open-air experimental space. It has a 35-by-1 m and 1.4 m deep wave flume with adjustable floor and a random wave generator, an 11-by- 0.6 m and 0.8 m deep tilting flume with glass panels, and a 30-by-30 m and 1 m deep wave basin with a random wave generator.

Hydraulics and Maritime Research Center, Ireland

The Hydraulics and Maritime Research Center established in 1979 is a semi-autonomous unit within University College Cork, Ireland, and a part of the Coastal Zone Institute. Its Ocean Wave Basin is 25 m long, 18 m wide, and 1 m deep. There is a 9 m square pit in the center of the facility with a depth of 2.5 m. The basin has a directional spectral wave generator that consists of 40 flaps along the 18 m side of the basin. It has an active absorption system for reflected waves.

University of Delaware, United States

The University of Delaware's Center for Applied Coastal Research located in Newark, Delaware, USA, has an Ocean Engineering Laboratory that is among the largest university laboratories in the United States with a two-storey 30-by-38 m facility for laboratory experiments in coastal and ocean processes. Its directional wave basin is 20-by-20 m and 1.1 m deep and has a directional spectral wave generator with 34-flap wave paddles. Its precision wave tank is 33-by-0.6 m and 0.76 m deep with approximately 60% of its length with glass walls. Its wave generator can produce regular and irregular waves and water can be recirculated in the tank and produce a current of 30 cm/s. The facility has a spiral wave basin 8.5 m in diameter for small-scale coastal process studies where an 'infinite' beach is required. A recirculating Armstrong flume is 0.4 m wide and 0.6 m deep is used to generate hydraulic jumps. The Center also has a Sand Beach Wave Tank, a towing and wave tank with a cross section of 2-by-1 m and a piston wave generator.

Scripps Institution of Oceanography, United States

The Scripps Institution of Oceanography located in La Jolla, California, USA, has a hydraulics laboratory with facilities to address coastal and oceanographic research. The facility is in a building 31-by-24 m. Its wind-wave tank is 44.5-by-2.39 m and 2.44 m deep and has glass windows, the largest being 5.5 m long. The wave generator can produce a maximum wave height of 0.6 m. An open-circuit wind tunnel produces variable wind velocities ranging from 0 to 16 m per second. The laboratory has a wave basin with dimensions of 15.2-by-18.3 m and a water depth of 0.61 m. A unidirectional spectral wave generator can produce waves with heights as great as 0.22 m. A glass-walled wave tank is 33 m long, 0.5 m wide, and 0.5 m deep. The wave generator produces waves up to 0.25 m in height and there is a reversible flow system that can pump 0.041 cubic meters per second. A granular fluid mechanics test facility is 12.2 m long, 6.1 m wide, with a maximum depth of 3 m. An adjacent basin is 10 m long with a fluidizing channel that is 1 m^2 in cross section with a high-flow slurry pump used for sand transport. A stratified flow tank with a length of 30 m and a glass-walled test section 16 m in length, 1.1 m in width, and a depth of 1.1 m is used to study stratified flows with flow velocity uniform or in two separate layers flowing at rates from 0 to 1.3 m per second. The laboratory has an oscillatory flow tunnel tank with an overall length of 16 m and a test section 0.39-by-0.4 m. Maximum oscillatory peak-to-peak water particle displacement is 2 m. The maximum sinusoidal velocity is 1.8 m per second. A steady bi-directional flow up to 0.2 m per second can be superimposed on the oscillatory flow. There are sediment traps at both ends, and the tank can be tilted up to 9.1 degrees to simulate a sloping beach.

Queen's University, Canada

The Coastal Engineering Research Laboratory of Queen's University is located in Kingston, Ontario, Canada. The Laboratory is in an 1,860 square-meter building in the west campus of Queen's University. The Laboratory has a coastal model basin that is 21-by-21 m and equipped with a spectral wave generator. Tides and currents can be reproduced in the basin and a sand bed can be used in experiments. The Laboratory has an oscillating water tunnel for research on boundary layers, forces on structures, and other problems. It has three 61-m long wave flumes, two of which are equipped with spectral wave generators and one with a monochromatic wave generator. The Laboratory has a 1D model for simulating long-term beach morphology and is developing a quasi-3D model for study of shore processes.

Catalonia University of Technology

The Maritime Experimental and Research Flume was built in 1992 at the Maritime Engineering Laboratory of the Catalonia University of Technology for experimentation in maritime harbors and coastal engineering. The flume is 100 m long, 3 m wide, and 5 m deep. The facility has a spectral wave generator, a variety of instrumentation, and a bottom profiler for morphodynamic tests. The generator can produce maximum regular wave heights of 1.6 m. The facility is a part of the European Union large infrastructure program that makes facilities available for member-country use.

GEOTEXTILE APPLICATIONS

The technological term "geotextile" has now come to stay in the context of coastal engineering. Perhaps, the original term "filter fabric" is more expressive, but it has fallen into comparative disuse. Geotextiles are really fabric materials used in a "geo," that is an earth-related, engineering context. These fabrics may be based on natural fibers or man-made synthetic fibers. The latter type of geotextiles are referred to as "geosynthetics." Geosynthetic materials are generally nonbiodegradable, whereas natural geotextiles are often biodegradable. Biodegradability would be an advantage or a disadvantage, depending upon the user needs and use contexts.

Most of the man-made geotextiles (i.e., geosynthetics) are made from polymers of various chemical types. Some common polymers used are polyethylene (PE), polypropylene (PP), polyvinylchloride (PVC), nylons, polystyrene (PS), and polyesters. Natural geotextiles are made from natural fibers, which are also polymers, largely based on cellulose and lignin.

Historical development

Pioneers of coastal engineering introduced the use of geosynthetics in the 1950s in the United States. According to Bruun (2000), some of the first coastal geotextile research in the United States was carried out at the University of Florida, Gainesville, where plastic filters were tested. Work on the use of nonwoven fabrics for soil reinforcement was done at the Rhone-Poulence textiles in France. Early development work on geotextiles was also conducted in the Netherlands, Britain, Germany, and the United States. Currently, the geotextile industry is quite active in research and development in the United States, through the establishment of the

Geosynthetic Research Institute at Drexel University. Additional details on the history of geotextiles can be obtained from Heerten and Kohlhasse (2000).

Material types and chemistry

Geotextiles are only a sub-family in the larger family of "Geosynthetics." Other sub-families include geogrids, geonets, geomembranes, geosynthetic clay liners (GCL), geopipes, and geocomposites. Geotextiles are woven or nonwoven fabrics. Geogrids are plastics formed into open grid-like configuration. Geonets are formed by continuous extrusion of sets of polymeric ribs which when opened give rise to a net-like configuration. Geomembranes are very thin sheets of polymeric materials. GCL's are thin layers of bentonite clay sandwiched between geotextiles or geonets. Geopipes are simply buried plastic pipes and represent one of the oldest members of the family of geosynthetics. On the other hand, geocomposites are the newest member of the family and are composed of either geotextiles and geonets, or geotextiles and geogrids, or geogrids and geomembranes, etc.

The material used for fabricating geotextiles is invariably some kind of polymer. A "polymer" is a giant molecule of high molecular weight, obtained by polymerizing one or more smaller units called "monomers." For example, the simple chemical "ethylene" is a monomer. When it is polymerized under suitable conditions, we get "polyethylene" (PE, or polythene). Similarly, the polymerization of simple monomers such as propylene, vinylchloride, or styrene produces PP, PVC, or PS, respectively. In some cases, two monomers are involved in polymerization. Thus, nylons are polyamide polymers formed by the polymerization of diamines and dicarboxylic acids (e.g., hexamethylene diamine and adipic acid). Polyesters such as polyethylene terephthalate (PET) are formed by the polymerization of ethylene glycol and terephthalic acid or derivatives or analogues of these monomers. Polymers commonly used in the geotextile industry include PE, PP, PVC, PET, PS, PA (nylons), and cellulose. Cellulose is a naturally occurring polymer based on glucose as the monomer.

Another recent development is the use of natural geotextiles, which include fabrics formed using coir, the natural fiber from the husk of coconuts. These geotextiles have exceptional strength due to the high content of a cellulose lignin polymer in them. Besides, they are naturally degradable, which may be attractive in certain applications such as natural stream bank restoration. Other natural fibers include jute, sisal, mixed coir-jute, and mixed sisal-jute.

Geotextile applications

Barrett (1966), in his well-known and classic paper, discusses the use of fabric materials as reinforcements behind precast concrete seawalls, and under precast erosion control blocks. At present there are several application domains for geotexiles, as discussed below (Heerten and Kohlhasse, 2000): (1) filters in erosion control structures (revetments, coastal dikes, etc); (2) separators in the foundation of groins and breakwaters, (3) fabric forms for sand filled bags or tubes as construction elements for groins, dikes, and dunes; (4) flexible scour protection mats at different offshore or coastal structures; (5) reinforcement in dredged material sites; (6) membranes for use in landfill caps; (7) bags for disposing dredged material from navigation channels; and (8) dikes for river training and coastal structures.

Koerner (1998) classifies the applications into six broad categories: (1) *Separation*—is the usage of geotextile to provide physical separation between two material types, while retaining their individual integrity and functions; (2) *Reinforcement*—involves using the geotextile to improve on the inherent strength of the system; (3) *Filtration*—is the use of the geotextile to retain the soil behind it while providing an outlet for dissipation of hydraulic forces; (4) *Drainage*—involves the concept of using the geotextile to provide sufficient fluid movement through it without much loss of the soil behind it; (5) *Containment*—is the concept of providing isolation between two surfaces with the aid of an impervious geotextile; and (6) *Combined uses*—which is the use of the geotextile for any combination of the above listed uses.

Design considerations

Important general considerations include the following: (1) *Function*—the type of use the geotextile should provide; (2) *Specifications*—the engineering properties that would be needed to satisfy that function; (3) *Availability*—the supply versus demand of that particular type of geotextile in the region; and (4) *Cost*—the price of obtaining and installing the geotextile in place. For small projects with financial constraints, design by cost and availability is used, which tries to obtain an optimal balance between funds available, area to be covered with geotextile, and unit price of the geotextile.

Key design properties of interest include the following: (1) *Physical properties*—includes specific gravity, mass per unit area of the geotextile, thickness, and stiffness; (2) *Mechanical properties*—includes compressibility, tensile strength, seam strength, burst strength, and elongation; (3) *Hydraulic properties*—includes porosity, percent openings in the geotextile, an equivalent opening size, permeability, and soil retention; (4) *Endurance properties*—includes potential for damage during installation, long-term strength loss, abrasion potential, and clogging potential; and (5) *Degradation properties*—includes potential for degradation from sunlight, temperature, oxidation, biological action, and hydrolysis.

Various international organizations provide standards for estimating the above properties, with the American Society for Testing and Materials (ASTM, 2000) providing the lead. Other leading organizations include the International Standards Organization (ISO), Permanent International Association of Navigation Congresses (PIANC), Geosynthetic Research Institute (GSI) and British Standards Institution (BSI).

Koerner (1998) discusses key aspects of design considerations for the many functional uses of geotextiles, a brief summary of which is presented here

- *Separation design criteria*: Separation function is primal to all geotextiles. Indeed many other functions depend, in their turn, on separation. The use of geotextiles as separators is illustrated by their placement between a soil subgrade (beneath) and a stone base (above). The important criteria here are burst resistance, tensile strength requirements, puncture resistance, and impact resistance.
- *Soil reinforcement design criteria*: Reinforcement of soil is another cardinal application of geotextiles. Seawall reinforcement, reinforcement of embankments, foundation reinforcement and *in situ* slope reinforcement are the important specific cases. Key properties include tensile strength, puncture resistance, and impact resistance.
- *Filtration design criteria*: Geotextile filters are used behind retention walls, around underdrains, beneath erosion control structures and as silt fences. Adequate fluid permeability and soil retention are the main requisites.
- *Drainage design criteria*: The two main design variations here are gravity drainage design and pressure drainage design. Various manufacturing textiles such as woven silt film, woven nonfilament, nonwoven heatbonded, nonwoven resin-bonded, nonwoven needle-punched, and hybrid systems, are used. Nonwoven needle-punched geotextiles are suited for drainage of fine-grained soil masses such as clays and silt. A high permeability and high soil retention are essential to this application.
- *Containment design criteria*: Application of geotextiles in containment include coastal landfills and other waste barriers. Key properties include low fluid permeability and high soil retention.

Summary

The use of geotexiles in coastal areas has been practiced for a very long time for shore protection needs. However, advances in manufacturing and marketing has led to innovative uses of geotextiles in the coastal zone in recent years. These include the use of sand filled geobags as the core of dunes, sand filled geobag breakwaters and reefs, geobag spur dikes, and deep ocean placement of contaminated sediments in geobags. The future of the geotextile seems limited only by human imagination.

GLACIATED COASTS

Introduction

There are a wide variety of glaciated coasts, usually with both erosional and depositional features. Coasts may be actively glaciated systems, such as Antarctica, southeastern Alaska, and Greenland, or formerly glaciated regions such as Scandinavia, Scotland, northeastern Canada and New England, the Pacific Northwest, and southern Chile. Formerly glaciated, or paraglacial coasts (FitzGerald and van Heteren, 1999) are modified by modern coastal processes, and by changes during deglaciation such as permafrost action, outwash, isostatic rebound, and proglacial lacustrine and marine deposition and erosion. Glaciated coasts characteristically have moderate to high relief, with abundant bedrock outcrop. They occur in cold temperate to polar regions where modern glaciers and ice sheets are stable, or where perennial ice was stable down to sea level in glacial climates. Formerly glaciated coasts are found as far as 40° south and north as a result of the Wisconsin (Würm) Last Glacial Maximum (LGM) 20–22 ka ^{14}C (Denton and Hughes, 1981; Andersen and Borns, 1994). Earlier Quaternary glaciations as well as Precambrian and Paleozoic glaciations may have extended even farther from the poles. At present, outlet glaciers from ice sheets meet the coast in Antarctica, Svalbard (Figure G5) and Greenland, extending to a maximum of 63°N (southern Greenland) and 63°S (Antarctic Peninsula). Valley and piedmont glaciers extend to the sea in Alaska (Brady Glacier, 58°N), Baffin Island (71°N), and Chile (47°S). This variability in latitudes demonstrates that relief, precipitation, ocean currents, and other climatic factors must be considered in evaluating changes in extent of ice sheets.

Study of the former extent of ice sheets and valley glaciers on coasts such as Antarctica, New Zealand, Chile, Alaska, and northeastern Canada provides an important proxy for climate change. Of particular interest are the relationships of events in the Northern and Southern Hemisphere (Moreno *et al*., 2001), and to potential driving forces for climate change such as the Milankovitch theory of variations in insolation due to Earth orbital parameters. Other theories of climate forcing include dust, atmospheric CO_2, ocean currents, solar variability, internal ice-sheet dynamics, and deglacial freshwater flooding into the oceans (e.g., Broecker *et al*., 1968; Berger, 1988; MacAyeal, 1993; Denton and Hendy, 1994; Broecker, 1997; Denton and Hall, 2000; Clark *et al*., 2001).

Glaciated coast erosional features

Some characteristic erosional landforms include glacial troughs and fjords. Glacial troughs are immense channels cut by ice streams across the continental shelf in formerly glaciated areas, such as the Laurentian Channel off the Gulf of St. Lawrence and the Northeast Channel off the Gulf of Maine. Other troughs representing greater extent of present ice sheets are found around Antarctic, such as in the Ross Sea and Amundsen Sea. Besides the major ice-stream erosional features, ice sheets also channel flow around resistant rock outcrops and into less resistant valleys, creating characteristic streamlined hills and linear valleys. Erosional resistance is controlled by rock type (igneous and metamorphic versus sedimentary), grain size, weathering, spacing, and frequency of fractures and bedding planes, and structural orientation relative to ice flow. Small-scale streamlined outcrops, roches moutonnées, may form islands (Figure G6). These and less regular small islands are known as skerries. Large-scale streamlining of hills and valleys creates a rolling coastline of complex peninsulas and embayments, known as fjard coasts, as in Maine, Sweden, and other formerly glaciated regions (e.g., Andersen and Borns, 1994).

The classic coastal glacial erosion feature is the fjord. Fjords are steep-walled embayments hundreds of meters deep, tens of kilometers long, and kilometers wide. Their mouths are often restricted by a lip composed of bedrock and/or till. This lip may lead to a salinity density stratification in the fjord, and also acts as a dam that contains abundant proglacial and glaciomarine sediments within the deeper basins. Fjords are formed by valley glaciers, where streaming flow incises more efficiently vertically than laterally, and are subsequently drowned by glacial retreat and rising post-glacial sea level. Sedimentation in fjords is strongly controlled by geometry of the glacial erosion, degree of continuing glacial inflow, and by circulation effects of stratification. Commonly there are coarse deltaic sediments and morainal banks at the head, with fine muddy basins in the remainder of the system. Rapid sediment influx creates instability. Slumps, subaqueous fans, and channels created by sediment-gravity flows are common (Prior *et al*., 1981; McCann and Kostaschuk, 1987).

Glacial depositional features

Glaciers deposit sediments at their bases, sides, and front. Landforms created by these deposits may form important coastlines on their own, such as Cape Cod, Martha's Vineyard, and Nantucket, or may anchor littoral drift systems, such as the southern coast of Long Island. Moraines and outwash plains core the outer and inner portions of the well known "flexed arm" of Cape Cod (Oldale, 1992). Reworking of till and stratified outwash from these sources provides abundant sand and gravel to the modern beach and barrier systems (Fisher, 1987; Leatherman, 1987). Drumlins are less continuous than moraines, often scattered in fields. Johnson (1919) describes a model for evolution of Boston Harbor and the Massachusetts Bay coast as erosion of drumlins supplied coarse sediment for barriers, until the drumlins were consumed. The coastline system then jumped back to the succeeding sets of drumlins and their sediment sources. This coastal evolution of drumlin fields is also found in Clew Bay, western Ireland. In settings where bedrock topography is more important for forming embayments, but glacial sediment sources such as drumlins, moraines, eskers, and kames

provide the sediment for beaches and barriers, a similar saltating coastline mechanism may prevail. Boyd *et al.* (1987) and Forbes *et al.* (1991) show that the southern coast of Nova Scotia has retreated in this manner during Holocene transgression. Newfoundland has outstanding examples of drumlins and moraines sourcing baymouth barriers (Forbes *et al.*, 1995) (Figure G7). Pocket beaches and extended coastlines near these proximal glacial deposits are dominated by boulders, gravel, and sand (Kelley *et al.*, 2001). They may form pure gravel beaches, or mixed sand and gravel systems.

Sediment is also brought to the coast as glacial outwash, in valley-train deposits, in deltas and subaqueous outwash fans. These are generally sand and finer gravel, but may include outsized clasts carried by floods and ice rafts. The southern coast of Iceland contains numerous sandurs (outwash fans) that provide the basis for barrier and beach systems (Nummedal *et al.*, 1987). The southern coast of Alaska contains a rich variety of glaciated coastline types, including outwash plains, direct deposition from the Malaspina piedmont glacier into the littoral zone, and fjords with retreating valley glaciers (Molnia, 1980; Powell, 1983). The finest material is glacial rock flour: silt and clay particles carried primarily in suspension. Abundant rock flour causes rapid infilling of lagoons and embayments (up to several meters/yr) in proglacial and glaciomarine environments. The rapid accumulation of proglacial and glaciomarine fine sediments creates a concentric drape over underlying bedrock or previously deposited glacial sediments, resulting in a distinctive signature in seismic reflection profiles (Piper *et al.*, 1983; Belknap and Shipp, 1991). Later slower sedimentation and reworking produces ponded, flat-lying accumulations. Uplift of the glaciated coastline exposes glaciomarine mud, deltas and outwash fans, as well as moraines and drumlins to wave attack. Much of the coast of Maine, Puget Sound, the Baltic Sea, and similar locations consist of eroding bluffs of these materials. Clay bluffs in particular may be highly unstable, tending to fail as retrogressive slumps.

Glaciomarine deltas form where abundant coarse sediment causes progradation into the sea. On glaciated coasts, especially during deglacial phases, isostatic rebound, and relative sea-level change must be in balance for short periods in order to allow deltas, and other coastline indicators, to stabilize. Glaciomarine deltas are commonly of the classic Gilbert delta type (Figure G8). Topsets are braided stream deposits at the top of the section. These streams incised and reworked underlying units while the delta was prograding. Foresets are avalanche deposits at the terminus of the traction conveyor, the mouth of the stream. Sometimes it is possible to find the "roll-over" point where the process changed from traction to avalanching, allowing confident reconstruction of coastline position and relative sea level at that point (Figure G8). The third component is bottomsets, the suspension and sediment-gravity flow deposits found basinward of the foresets.

Glaciomarine environments

There are two major types of glaciomarine environments, tidewater glaciers and ice shelves (Powell, 1984). Tidewater glaciers have ice fronts in seawater in restricted embayments, fjords in particular, and produce smaller icebergs. Tidewater glaciers terminate in the ocean at an ice cliff, which is a calving front at or near grounding line (the position where the ice floats out of contact with the bottom) (Figure G9), either in the open ocean (Pfirman and Solheim, 1989) or in protected embayments (Powell, 1983). Many Alaskan coastal glaciers, such as in Glacier Bay, are presently retreating rapidly through this process of calving of icebergs. There are several lithofacies found in this environment seaward of the grounding line. Morainal banks are composed of diamicton, gravel, and marine sand and mud. Stratified sand and gravel subaqueous outwash fans interfinger with till and distal glaciomarine mud. These fans may be narrowly restricted in fjords, or broad composites under continental ice-sheet margins (Ashley *et al.*, 1991). Fans also are commonly channeled through traction under density underflows, and may be sites of active slumping. Active ice push can deform and override morainal banks and stratified deposits. Iceberg drop and dump deposits are a common admixture to this and more distal environments. Laminated sand and mud are characteristic of basins farther from the grounding line. These are produced from density overflows, interflows, and underflows. In the marine environment, however, the latter are rare, localized close to the source because of the lower density of fresh meltwater, unless charged with very high concentrations of sediment (2–3 gm/L). Laminated deposits are easily characterized as glaciomarine when they contain abundant ice-rafted detritus.

Ice shelves terminate in the ocean, with the ice edge distant from the grounding line. Ice shelves are broad and flat, and are restricted primarily to Antarctica today. Ice shelves calve immense tabular icebergs hundreds to thousands of square kilometers in area. Polar ice shelves are cold and do not produce abundant sediment. The Ross Sea and Amundsen Sea, for example, are blanketed by marine biogenic sediments draped over glacial deposits left by Holocene grounding-line retreat (Anderson *et al.*, 1983; Kellogg and Kellogg, 1988; Jacobs, 1989). Ice shelves that were abundantly productive of sediment were found during deglaciation after the Wisconsin (Würm) LGM, in particular where fed by ice streams such as the Scotian Shelf and Gulf of Maine (Bacchus *et al.*, 1997; Schnitker *et al.*, 2001).

Glacioisostatic rebound

The release of the immense weight of ice sheets causes rapid isostatic readjustment. As a consequence, raised beaches can be found preserved around many formerly glaciated regions such as Hudson Bay (Fairbridge and Hillaire-Marcel, 1977), Newfoundland (Liverman, 1994), Spitsbergen (Boulton *et al.*, 1982), and Scandinavia (Andersen and Borns, 1994). In Maine, raised beaches formed on the outer edges of glaciomarine deltas (Figure G10) and were raised to elevations 60–130 m above present sea level (Thompson, 1982). Understanding isostasy through study of deformed glacial coastlines has important implications for deep Earth structures such as viscosity of the mantle, thickness and elastic/plastic properties of the lithosphere. These reconstructions also help constrain poorly understood properties of former ice sheets, in particular their thickness.

Figure G7 Drumlins sourcing gravel barriers, Holyrood Bay, Newfoundland (D.F. Belknap photo 5/27/2000).

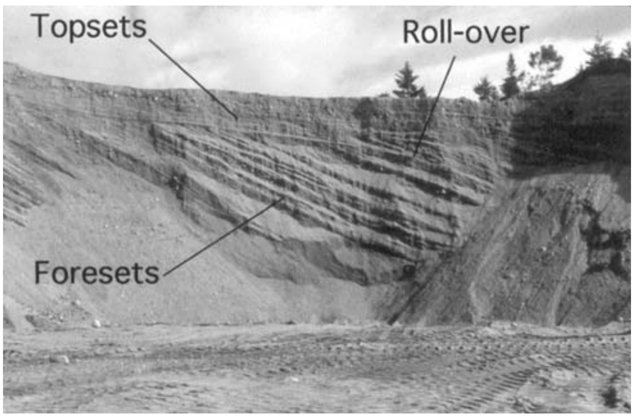

Figure G8 Gravel pit exposure into a glaciomarine highstand delta, Lamoine, Maine, USA. Top of exposure is approximately 70 m above present sea level (D.F. Belknap photo 10/12/1982). Topset–foreset contact approximates contemporaneous sea level. The "rollover" shows the preserved delta front in transition from near-horizontal topsets to foresets inclined near the angle of repose (30–33°).

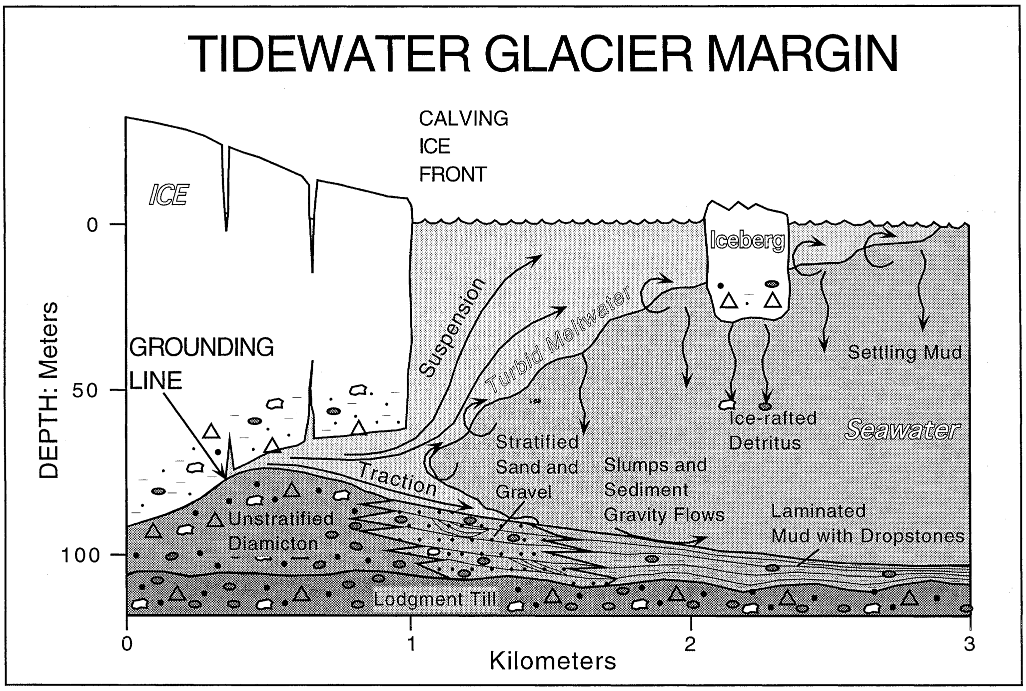

Figure G9 Model of a tidewater glacier calving margin, with morainal bank, stratified subaqueous fan, and distal mud and dropstone facies, after Thompson (1982, figure 3, p. 215; and Pfirman and Solheim, 1989).

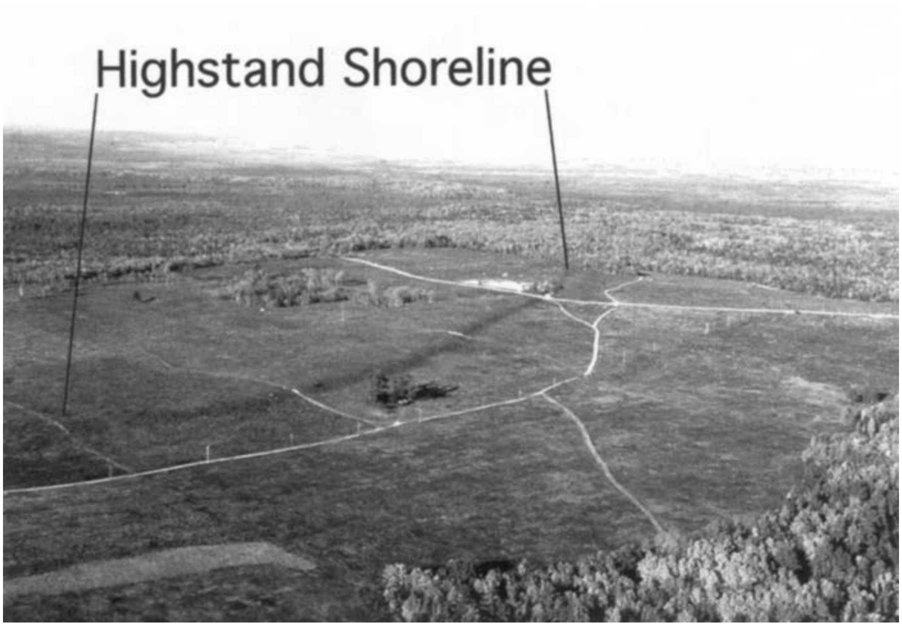

Figure G10 Highstand shoreline formed ca. 13 ka in sand and gravel at the front of a glaciomarine delta on East Base, 75 m above present sea level (D.F. Belknap photo 10/12/1982).

Summary

Glaciated coasts are heterogeneous in morphology and sediment type. They occur in higher latitudes today, but the influence of former episodes of glaciation imposes a strong control on coastal evolution through preserved erosional and depositional landforms, and the variety of sediment types. One association that typifies the glaciated coastline is coarse gravel beaches adjacent to muddy embayments. Lack of long-term stability is another important characteristic, driven by isostatic changes, laterally variable sources of fine and coarse sediment, and a complex, deranged landscape upon which coastal environments form and migrate. Glaciated coasts are not only a widespread littoral environment in the modern and during glacial times, but study of changing distributions and types can supply critical proxy information for reconstruction of global climate change.

GLOBAL POSITIONING SYSTEMS

Developed and operated by the US Department of Defense (DOD), the Global Positioning System (GPS) is a satellite-based navigation system that allows the determination of precise location anywhere on earth. The major components of the GPS consist of the space segment, the control segment, and the user segment (Leick, 1994). Coastal scientists may use GPS techniques to collect field measurements for later implementation into a *Geographic Information Systems* (GIS) database.

The space segment includes a constellation of as many as 27 high altitude satellites complete with computers and atomic clocks. As of September 2000 there were 27 satellites (GPS World, September 2000). A full constellation consists of 24 satellites; the others serve as backups. The satellites orbit the earth in 12 h from an altitude of 20,286 km (12,600 miles).

The control center monitors the satellite system from five stations around the world: Hawaii, Ascension Island, Diego Garcia, Kwajalein, and Colorado Springs. A control center compiles an ephemeris that includes advance calculations of the satellite's orbit; forecasts of the ionospheric and atmospheric conditions are also uploaded to each satellite's computer. A control center additionally monitors the functioning of each satellite and can readjust the clock and locational offsets.

The user segment consists of portable receivers and the community of more than four million GPS users worldwide (Clinton, 2000). Although GPS receivers vary in their components and thus their capabilities, any receiver will determine location as X, Y, or Z coordinates, typically expressed as longitude, latitude, and altitude.

Satellite ranging

Both the receiver and the satellite generate an identical pseudo-random code that is transmitted simultaneously and allows the determination of signal travel time from the satellites. There are two types of pseudo-random code: C/A code and P code. Civilians use the lower frequency C/A code and the P code is reserved for the DOD (Hurn, 1989). When the receiver picks up a transmission from one satellite, it computes the distance by multiplying the velocity (speed of light) by travel time. The geometric principle of trilateration allows one to accurately measure a position with just three distance measurements (Figure. G11). Calculating the distance from the first satellite narrows the possible location to the intersection of a sphere (with a radius of the distance) and the sphere of the earth. A second distance measurement identifies a second intersecting sphere that further reduces the possible location. A third distance measurement produces a sphere that intersects the others at two possible locations: the points where the third sphere intersects the circle of the first two spheres. In three-dimensional space, trilateration requires a fourth measurement to positively identify one location and its altitude. One of the two locations identified with three measurements is often so obviously wrong, however, that a fourth measurement is not needed (Hurn, 1989).

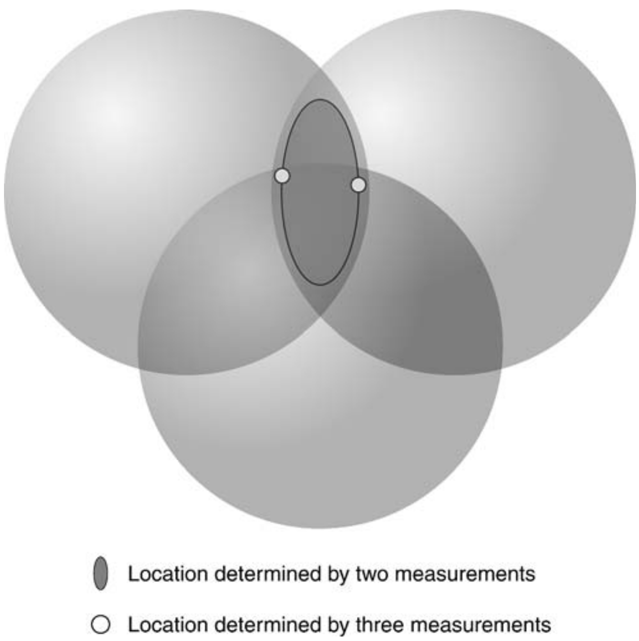

Figure G11 Trilateration with three distance measurements.

Sources of error

There are several types of error that can influence the accuracy of a typical GPS measurement by as much as 100 m (Steede-Terry, 2000). If the task requires accuracy better than that produced by standard GPS methods, differential GPS (DGPS) methods may provide accuracy to within a few centimeters.

Although the satellites carry atomic clocks that keep very accurate time, minimal clock error is still possible and will influence travel time calculations. Additionally, the less accurate receiver clocks may introduce error as well.

A second type of error occurs because radio signals only travel at the speed of light in a vacuum; the ionosphere and atmosphere can therefore slow down the GPS signals. A control center relies on the fact that the GPS satellites transmit signals on two frequencies thereby allowing for dual frequency error correction (Hurn, 1989). Modeling of ionospheric and atmospheric conditions provides another method of correction.

The assumption that the signals will travel in a straight line creates a third potential for error. Multi-path error is caused when a signal is reflected or bounced before reaching the receiver (Leick, 1994). GPS receivers are capable of processing the signals and determining that the earliest signal to arrive is the best choice.

A fourth type of error, geometric dilution of precision (GDOP), is related to the angle between the satellite and the receiver. Since a wider angle between the satellite and the receiver allows for more precise measurement, good quality receivers analyze the positions of the satellites and choose the best four satellites (Hurn, 1989).

Selective availability (SA), the DOD's reduction of the C/A code accuracy for military defense, is an intentional degradation of orbital and atomic clock data. In May of 2000, after determining that permitting an accurate C/A code had little effect on national security, President Clinton eliminated the practice of SA (Clinton, 2000). With SA turned off, GPS measurements, depending on the type of receiver, may provide a horizontal accuracy of 10–15 m (Steede-Terry, 2000). Vertical accuracy is more difficult because satellite signals are not detected below the visible horizon of the earth.

Differential GPS

Differential GPS provides a simple solution that corrects for many sources of error and can provide accuracy from 5 m to a few centimeters, depending on the type of receiver. DGPS relies on two receivers: one receiver is stationary (the base or reference station) and transmits from a known location; the second receiver is the roving device that collects locational data in the field. The receivers both transmit or receive pseudo-random code from the satellites but, since the base station location is already known, it uses that information to compute the travel time that each satellite signal should take. It then measures the actual travel time (if the satellite signal traveled in a straight line with no interference) and that difference becomes the error correction factor. Base stations are often established by government agencies, such as the US Coast Guard or the Federal Aeronautics Administration, and the receivers continually compute correction factors as the satellites orbit overhead. The correction factors are encoded in a computer file that users may download at a later time for post-processing. If a user requires "real time" correction because they are navigating, for example, some receivers are designed to receive radio signals or corrections directly. Real time correction is typically less accurate than post-processing because the correction occurs by averaging a number of readings in a few seconds, versus the potential for averaging several minutes of data collected by a stationary, roving, receiver (Steede-Terry, 2000).

Future

As GPS technology improves and becomes less expensive, the number of potential applications will continue to increase. The US government has estimated that by 2003 the GPS user community will double to more than eight million users and the market will increase to more than US $16 billion (Clinton, 2000). Despite its continuing importance for determining accurate location in navigation, surveying and recreation, the potential for GPS to supply very accurate time, that is, Universal Coordinated Time, will further it's usefulness.

GLOBAL VULNERABILITY ANALYSIS

Introduction

Climate can have great influence on our lives as shown by the great damage and loss of life in events such as Hurricane Mitch in Central America, the 1999 cyclone in Orissa, India, and the flooding in Mozambique in 2000. Such events could be intensified by climate change, making this issue a major challenge for the 21st century. This widespread concern has generated a global policy response including the Intergovernmental Panel on Climate Change (IPCC) and the United Nations Framework Convention on Climate Change (UNFCCC), whose signatories are committed, among other things, to "avoid dangerous climate change." The key policy issue is the relative merits of reducing greenhouse gas emissions (usually termed mitigation) and/or adapting to the impacts of climate change, with a mixed response being most realistic.

A major consequence of climate change is global sea-level rise that could cause serious impacts around the world's coast. In the context of coastal zones, the goal of vulnerability analysis for sea-level rise (and other coastal implications of climate change) is to assess the potential impacts on coastal populations and the related protection systems and coastal resources, including the ability to adapt to these changes. A range of methods for such analyses has been developed and these have been extensively applied at the national and sub-national level (e.g., IPCC CZMS, 1992; Klein and Nicholls, 1999). These varied studies are often based on different assumptions and scenarios, so they are difficult to synthesize to the larger scales most pertinent to the policy debate outlined above. Therefore, there have also been efforts at vulnerability analysis at the regional and global scale.

The first global vulnerability analysis was completed in 1992 and evaluated: (1) increased flood risk and potential response costs; (2) losses of coastal wetlands; and (3) changes in rice production, assuming a 1-m global rise in sea level (Hoozemans *et al*., 1992). This was rapidly updated with a second edition (Hoozemans *et al*., 1993). Here, only results for this second edition are discussed and henceforth this analysis is termed GVA1. The IPCC Common Methodology (IPCC CZMS, 1992) was followed throughout. These results influenced the United Nations Conference on Environment and Development (Rio de Janeiro, Brazil, 1992) (IPCC CZMS, 1992), and the World Coast Conference (Noordwijk, the Netherlands, 1993) (WCC '93, 1994), and are included in the IPCC Second Assessment Report (Bijlsma *et al*., 1996). Subsequently, Nicholls *et al*. (1999) made a major improvement relative to GVA1 for the flood and wetland analysis. This was upgraded to a dynamic form, including improved impact algorithms, which can consider variable sea-level rise scenarios, the implications of growing coastal populations, and rising living standards (this analysis is henceforth termed GVA2). It is widely cited within the IPCC Third Assessment Report and has also contributed to a series of impact studies based on common climate and socioeconomic scenarios (e.g., Parry and Livermore, 1999).

This following description first outlines the key concepts of global vulnerability assessment. It then presents some selected methods of analysis, considering coastal population and flood risk, adaptation to increased flood risk and wetland loss. The results together with their validation and use are then considered, including the differences between the methods used. Lastly, possible developments in the near-future are considered.

Concepts, constraints, and approaches

In the present context, *vulnerability* is defined as the degree of capability to cope with the consequences of climate change and sea-level rise (Klein and Nicholls, 1999). As such, the concept of vulnerability comprises:

- the susceptibility of a coastal area to the physical and ecological changes imposed by sea-level rise;
- the potential impacts of these natural system changes on the socio-economic system;
- the capacity to cope with the impacts, including the possibilities to prevent or reduce impacts via adaptation measures. (This last factor is often termed "adaptive capacity").

However, there are four main barriers to the comprehensive vulnerability assessment, irrespective of the scale of assessment (Nicholls and Mimura, 1998):

- incomplete knowledge of the relevant processes affected by sea-level rise and their interactions;
- insufficient data on existing conditions;
- difficulty in developing the local and regional scenarios of future change, including climate change;
- the lack of appropriate analytical methodologies for some impacts.

For the global assessments, the availability of consistent and complete global databases on (1) the distribution, density and present status of the impacted resources and (2) the nature and probability of the impacting hazardous events was a major constraint. Coverage at a global scale was sometimes incomplete due to regional gaps, or only coarse resolution data was available.

All these problems necessitate careful consideration of what can realistically and usefully be assessed. After considering these limitations, global assessments have evaluated fairly simple parameters to date, with the main focus on impact assessment rather than adaptation assessment. GVA1 was limited to an assessment of the potential impacts on three distinct elements in the coastal zone and one possible adaptive response:

- *risk to population (and adaptation potential)*—population at risk of flooding and also potential protection upgrade costs;
- *ecosystem loss*—coastal wetlands of international importance at loss;
- *agricultural impacts*—rice production at change (in south, southeast, and east Asia only).

GVA2 refined the methods and results for the first two elements, but the underlying data is the same. Only these elements will be considered here.

In order to assess the vulnerability of a coastal zone to sea-level rise we need uniform procedures to compare and to integrate national and regional studies. To determine impacts in measurable and objective terms, the concept of *values at risk, values at loss*, and *values at change* were used. The concept of risk is defined as the consequence of natural hazardous events multiplied by the probability of the occurrence of these events, *excluding* the system response. The concepts of loss and of change are defined as the consequences of natural hazardous events multiplied by the probability of the occurrence of these events, *including* the system response. The "risk"-approach is considered appropriate to assess the consequences of sea-level rise on the probability of episodic hazards such as flood impacts on the coastal population and economy. System response is excluded because it is difficult to predict how flood events may change the behavior of the population in the long term. The concepts of "loss" and "change" are appropriate for impacts on ecosystems and agricultural production, respectively, because it is the long-term consequences of sea-level rise that are the most important factors influencing the magnitude of the impacts.

To examine the capacity to cope with flooding, a set of protection measures was developed with these impact studies to enable the comparison of the impacts of sea-level rise "with- and without increased protection measures." While one may be susceptible to increased flooding, if one can easily afford to upgrade defenses, there is little cause for concern and overall vulnerability is low.

Lastly, the scale of assessment needs to be considered. Much of the available data for these studies was only available at national resolution and was of uncertain quality. Therefore, some of the underlying data as well as the assumptions about physical processes, physical and socioeconomic boundary conditions, limit the accuracy of the national-scale results. This is especially true since the last major revision of the underlying databases was in 1993. However, the errors appear to be unbiased so regional and global estimates are expected to be more robust (Nicholls, 1995). Therefore, all the results are aggregated to 20 regions and the global scale, and this is the output of the analysis that has been utilized elsewhere. The national data and results are available in Hoozemans *et al.* (1993) for reference purposes, although the limits of the accuracy and validity of these detailed results should be born in mind.

Some of the methods are now considered in more detail.

Coastal population and flood risk

Storm surges are temporary extreme sea levels caused by unusual meteorological conditions. The resulting coastal flooding is a major issue damaging livelihoods, causing great distress and in the extreme, loss of life. As many as two million people may have been killed by storm surges in the last 200 years, mainly in south Asia (Nicholls *et al.*, 1995). Sea-level rise will raise the mean water level, and hence allow a given surge to flood to greater depths and penetrate further inland. Changes in storm tracks, frequencies, and intensity would also change surge characteristics, but in the absence of credible scenarios, this factor is considered constant in time within this analysis.

The concept of risk is considered appropriate in the context of assessing the consequences of sea-level rise on flooding for the population in the coastal zone. As rising sea levels intensify flood hazards, some human response might be expected. However, this response is not considered as such a prediction was considered unrealistic given that it involves human choice (ranging from migration to increased protection). Therefore, a high Population at Risk (PaR) indicates the need for some kind of a response. Possible protection costs against flooding are considered in the next section.

Based on the definition of risk, PaR is defined as the product of the population density in a certain risk zone and the probability of a hazardous flooding event in this risk zone. The resulting number is interpreted as the average number of people expected to be subject to flooding events per time unit (/year). Hence, PaR has also been termed "average annual people flooded" (Nicholls *et al.*, 1999). The "risk"-value is able to reflect changes in:

- the population living in the risk zone (coastal flood plain);
- the flood frequency due to sea-level rise;
- the protection standard of defenses.

As a general approach, the following steps were undertaken in GVA1 to determine the PaR for the various scenarios:

- Assessment of the height of the maximum flood level theoretically threatening the low-lying coastal zone, taking into account present and possible future extreme *hydraulic and geophysical conditions*.
- Determination of the *flood-prone area* and calculation of the area contained between the coastline and the maximum flood level.
- Assessment of the *present state of protection* against flooding.
- Determination of the coastal *population densities* for the present and future state.
- Determination of the PaR with and without measures, with and without sea-level rise, and for conditions in the years, 1990 and 2020.

To estimate global PaR with a reasonable accuracy, the world's coast was divided into 192 coastal zones based on the 181 coastal countries (as existed in the early 1990s). For each of the 192 coastal zones, a database was developed and an identical stepwise calculation scheme was followed to arrive at a coastal zone-specific PaR-number for each scenario (e.g., Figure G12). The database contained the following elements:

(1) the maximum area of the coastal flood plain after sea-level rise;
(2) the flood exceedance curve for storm surges from a 1 in 1 year event to a 1 in 1,000 year event;
(3) the average coastal population density in 1990;
(4) the occurrence or absence of subsidence; and
(5) the standard of coastal protection.

Three fundamental assumptions are that (1) the coastal flood plain has a constant slope; (2) the population is distributed uniformly across the coastal zone; and (3) if a sea defense is exceeded by a surge, the entire area behind the sea defense is flooded.

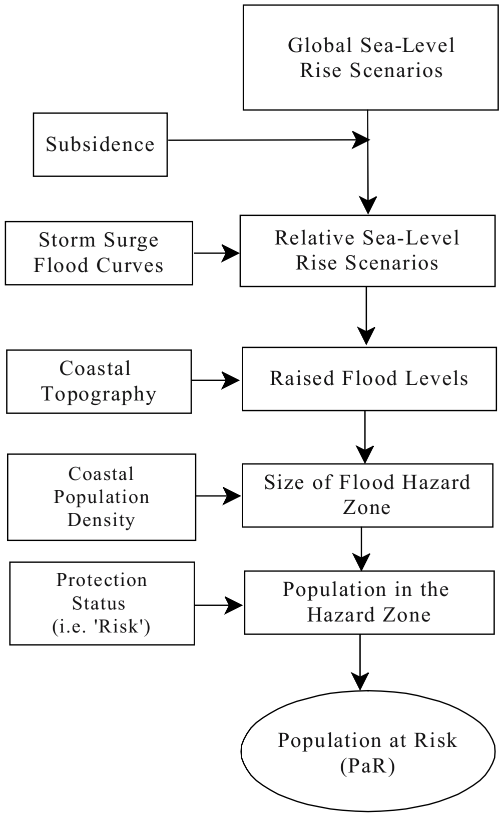

Figure G12 The flood model algorithm as used in GVA2 (modified from Nicholls, 2000).

Calculations proceed as shown in Figure G12. Estimates of four storm surge elevations (1 in 1 year, 1 in 10 years, 1 in 100 years, and 1 in 1,000 years) are raised by the relative sea-level rise scenario and converted to the corresponding land areas threatened by these different probability floods assuming a uniform coastal slope. These areas are then converted to people in the hazard zone using the average population density for the coastal area. Lastly, the standard of protection is used to calculate PaR. These national estimates are then aggregated to regional and global results.

In GVA1, a 1-m rise in sea level was imposed on the 1990 (and 2020) world. Coastal population density was estimated and used directly. In subsiding coastal areas, 15 cm of subsidence was assumed. Protection standards were estimated indirectly as discussed below. Lastly, only impacts of the expansion of the flood plain were considered, although this was amended by Baarse (1995).

In GVA2, a more dynamic approach was followed in which climate and socioeconomic scenarios both reflect realistic timescales. The 1990 coastal population density was increased (or decreased) at twice the rate of national growth. This is simply projecting present trends (Bijlsma *et al.*, 1996). In coastal areas subject to subsidence, a uniform subsidence of 15 cm/century was applied to the entire coastal area, although it is recognized that this is only a first approximation.

There are no global databases on the level of flood protection. Therefore, GVA1 adapted the World Bank classification of less developed, middle and high developed nations to estimate this parameter indirectly and used the GNP/capita in 1989 as an "ability-to-pay" parameter (Table G2). GVA2 used the same concept, but the algorithm was improved to reflect: (1) existing defense standards; (2) the greater costs of protecting deltaic areas against flooding; and (3) the increasing risk of flooding within the coastal flood plain as sea levels rise. The minimum standard of protection in 1990 was assumed to be 1 in 10 years, reflecting that people do not choose to live in highly flood-prone areas. Deltaic areas have a longer land–water interface than elsewhere, and a greater need for water management within the extensive low-lying areas that are protected, substantially raising protection costs. Based on expert judgment, the protection classes shown in Table G3 were

Table G2 Protection Classes used in GVA1

GNP/capita (US$) (or ability-to-pay)	Protection class (PC)	Protection status	Design frequency
<600	PC 1	low	1/1 to 1/10
600–2400	PC 2	medium	1/10 to 1/100
>2400	PC 3	high	1/100 to 1/1000

Table G3 Revised protection classes used in GVA2, allowing for deltaic and non-deltaic coasts

GNP/capita (US$)				
If deltaic coast	If non-deltaic coast	Protection class (PC)	Protection status	Design frequency
<2400	<600	PC 1	low	1/10
2400–5000	600–2400	PC 2	medium	1/100
>5000	2400–5000	PC 3	high	1/1000
—	>5000	PC 4	very high	1/1000

selected. Lastly, the increase in flood risk within the existing flood plain produced by sea-level rise is estimated by reducing the protection class as sea-level rises.

In GVA2, two protection scenarios are considered:

- constant protection (i.e., constant 1990 levels); and
- evolving protection in phase with increasing GNP/capita.

The evolving protection scenario is more realistic based on observed trends during the 20th century. It should be noted that evolving protection only included measures that would be implemented *without* sea-level rise—that is, there are no proactive adaptation measures to anticipate sea-level rise. These two protection scenarios allow us to examine how such evolving protection might reduce vulnerability to sea-level rise.

Adaptation to flooding

To estimate realistic first order national-scale protection costs within the constraints of the GVA1, a simple modular approach was adopted (Hoozemans and Hulsbergen, 1995). This assumed that the protection class is upgraded by one class (e.g., PC 1 increases to PC 2—Table G2). Then the revised PaR is calculated together with the protection costs as outlined below. The regional protection costs are compared with the regional GNP to quantify their relative cost, and hence the relative capacity to implement such measures.

The method aims to address the wide range of existing coastal defense types and their related costs. The following factors were used:

- the lengths of low-lying coastline (or coastal areas) to be protected,
- a set of six standardized coastal defense measures to be applied,
- standard unit costs for each type of defense measure,
- individual national cost factors, to take account of local cost factors.

For each country, the national costs (C_N) were found by applying the following summation at the national scale for all partial stretches of coastline in that country or coastal area which need protection:

$$C_N = \sum l_c \cdot c_m \cdot c_f \qquad \text{(Eq. 1)}$$

where l_c is the coastal length, c_m is the unit defense measure cost, and c_f is the national cost factor.

Regionally and globally, the aggregated cost is found by summing the respective national costs. This approach does *not* produce a basis for national coastal defense planning. However, the modular setup provides a realistic and practical framework for subsequent, more detailed analyses, to improve the accuracy and local relevance of the individual modules.

For each coastal country, an evaluation was made of the present types of sea defenses. It was assumed that new or upgraded defenses will be based on this experience, and hence the preferred type of defense options were selected by expert judgment. This selection should also account for matters like soil conditions, elevation and wave-exposure of the shore, the availability of construction materials, and the value of the direct hinterland.

The length of coastline vulnerable to flooding was determined from the earlier World Coast Estimate (WCE) study by adding the length of low coast, the length of city waterfronts, and the length of low coast of islands. Because there were no suitable global databases on geomorphology/defense status (e.g., dunes, dikes, salt marshes) within each country, a typical coastline was selected, based on the dominant coastline type per country.

Six types of defense measure were considered:

(1) *Stone-protected sea dike*;
(2) *Clay-covered sea dike*;
(3) *Sand dune*;
(4) *Tourist beach maintenance (beach nourishment)*;
(5) *Harbors and industrial areas (upgrade)*;
(6) *Elevation of low-lying small islands*.

Defense measures 1, 2, and 3 apply in most cases. However, the effective implementation of any measures requires a well-functioning technical and organizational infrastructure (as this is a key element of adaptive capacity). More demanding coastal defense works like those used to close off large estuaries were deliberately omitted from the standard list, although their application will be the most economical solution in some cases, as experience in England, the Netherlands, and Japan illustrates.

Cost estimates for the standard protection measures were established in 1990 US dollars. They are based on the following assumptions and conditions, which draw strongly on Dutch technical experience:

- Standard defense constructions are defined for each situations, including dimensions, construction material, and construction methods.
- The schematized designs are based on well-established procedures.
- Standard unit costs are derived from the Dutch situation, including provisions for all the costs, including design, execution, taxes, etc.
- Construction methods and cost estimates are based on the assumption of construction in one continuous operation per project.
- The hydraulic regime determined in the flood analysis is considered in design, increasing adaptation costs in areas with large surges.

Coastal wetlands and loss

Natural systems may also be impacted by sea-level rise. Coastal wetlands are defined as salt marshes, mangroves, and associated unvegetated intertidal areas (and here exclude features such as coral reefs and shallow-water sea grasses). Wetlands are not impacted by short-term fluctuations in sea level such as tides and surges, but they are susceptible to long-term sea-level rise and show a dynamic and nonlinear response (Nicholls *et al.*, 1999). Therefore, we are considering potential losses. In this case, it is important to consider the wetland response to sea-level rise to make credible impact estimates.

All the evidence shows that coastal areas with a small tidal range are more susceptible than similar areas with a large tidal range. Loss of coastal wetlands due to sea-level rise can be offset by inland wetland migration (upland conversion to wetland). However, in coastal areas without suitable low-lying areas, or in low-lying areas protected against flooding, wetland migration cannot occur, producing a coastal squeeze.

A database of the type, area, and location of most coastal wetlands of international importance was created as part of GVA1. It mainly comprised sites recognized by the Ramsar Treaty. It is missing data for certain regions such as Canada, the Gulf States, and the former Soviet Union.

GVA1 identified those wetlands that might be threatened by a 1-m rise in sea level, but did not project actual losses. These threatened wetlands were identified based on coastal geomorphology, tidal range, and local population density.

A nonlinear model of coastal wetland response to sea-level rise was developed in GVA2 (Figure G13). The modeling effort is split into two parts (1) vertical accretion and (2) wetland migration. To model vertical accretion, the availability of sediment/biomass for vertical accretion is parameterized using critical values of non-dimensional relative sea-level rise (*RSLR**):

$$\text{RSLR}^* = \text{RSLR}/\text{TR} \qquad \text{(Eq. 2)}$$

where RSLR is the relative sea-level rise scenario and TR is the tidal range on spring tides. Hence, wetlands in areas with a low tidal range are more susceptible to sea-level rise than wetlands in areas with a higher tidal range. (The rate of relative sea-level rise was implicit being defined by the 95-year period of interest). A critical value of RSLR*

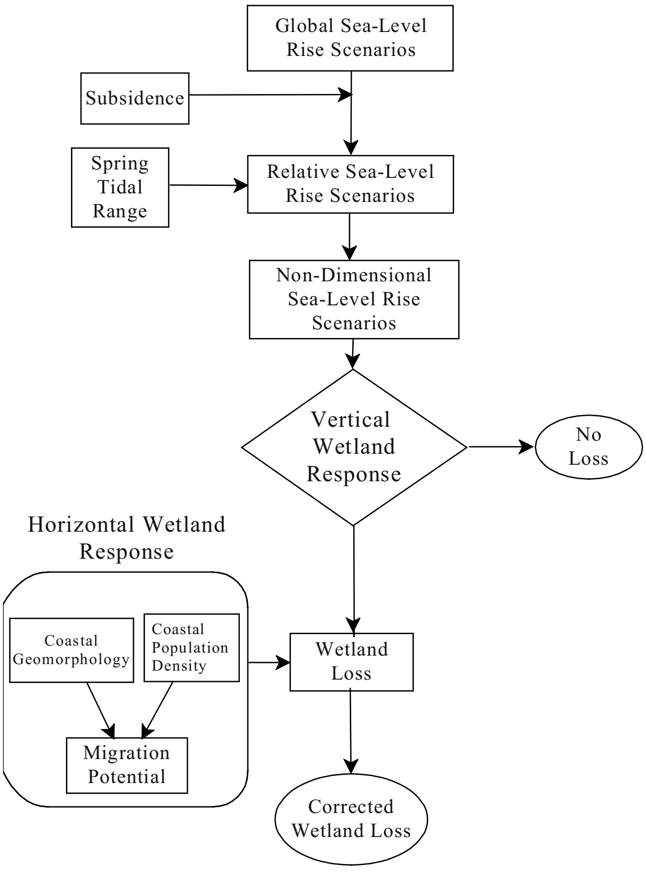

Figure G13 The wetland loss model algorithm used in GVA2 (modified from Nicholls *et al.*, 1999).

($RSLR^*_{crit}$) distinguishes two distinct wetland responses to sea-level rise in terms of vertical accretion:

(1) $RSLR^* \leq RSLR^*_{crit}$, no wetland loss as wetland accretion ≥ sea-level rise; and
(2) $RSLR^* > RSLR^*_{crit}$, partial or total wetland loss as wetland accretion < sea-level rise.

If wetland loss occurs, it is modeled linearly using the excess sea-level rise up to $RSLR^* = RSLR^*_{crit} + 1$. Above this rise, (near-) total loss is assumed and wetlands will only survive if there is inland wetland migration. This simple model captures the nonlinear response of wetland systems to sea-level rise and the association of increasing tidal range with lower susceptibility to loss. The literature stresses the large uncertainties concerning quantitative wetland response to sea-level rise, so a range of values for $RSLR^*_{crit}$ which encompasses the available information were selected (Nicholls *et al.*, 1999). The wetland sites are aggregated to the 192 coastal areas defined in the flood analysis, except for eight continuous national coasts that were subdivided because of a large variation in tidal range.

To model wetland migration, the same approach as GVA1 was used. The natural potential for the migration of the coastal wetlands under sea-level rise was evaluated for each wetland site using the global coastal geomorphic map of Valentin (1954) (showing the limited work on global-scale coastal typology in the last 40 years!). Three classes of migration behavior are recognized: (1) migration is possible; (2) migration is impossible; and (3) migration is uncertain. In the latter cases, losses were calculated assuming both migration and no migration and this contributes to the uncertainty between the low and high range of the results. In areas where migration is possible, the population density was estimated for the 2080s in a consistent manner to the flood analysis. If this population density exceeded 10 inhabitants/km^2, it was assumed that wetland migration would be prevented by flood protection structures. In areas where wetland migration is possible, wetland losses are assumed to be zero (i.e. wetland migration compensates for any losses due to inundation).

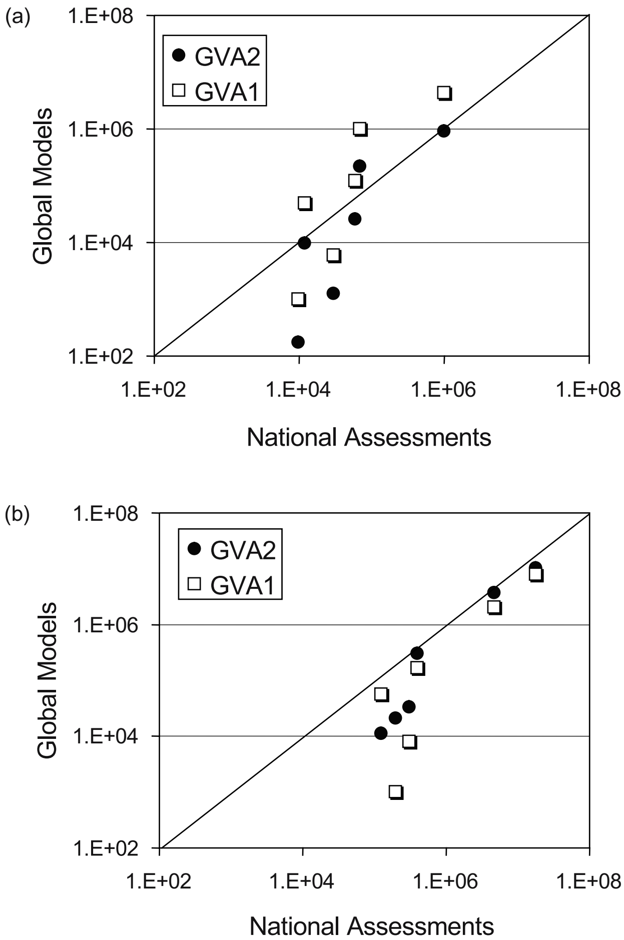

Figure G14 National PaR-estimates from GVA1 and GVA2 against independent national-scale vulnerability assessments for six countries (Egypt, Germany, Guyana, the Netherlands, Poland, and Vietnam): (a) no sea-level rise in 1990, and (b) 1 m sea-level rise in 1990 (modified from Nicholls *et al.*, 1999).

Validation/interpretation of the GVA

Validation of any model is a critical step, which increases confidence in the absolute quality and interpretation of the results. However, global assessments can also be interpreted as relative impact measures. Given that global assessments provide internally consistent results, the relative impacts may be more reliable than the absolute impacts. Therefore, it is suggested that users interpret the results from both an absolute and a relative perspective.

For the flood analysis, an independent data set of the impact parameters was developed via national-scale vulnerability assessments (Nicholls, 1995, 2000). While these national-scale results consider the impacts of sea-level rise on the 1990 world without any socioeconomic changes, the results can be used to validate the global flood model for these scenarios. In broad terms, the results for GVA2 are of the right order of magnitude for the three parameters assessed, and are also an improvement over the results in GVA1 (e.g. Figure G14). Therefore, the changes to the methods in GVA2 are justified.

Validation of the protection cost estimates suggested that they are broadly reasonable (Nicholls, 1995). The validation of the wetland loss models remains limited due to a lack of suitable calibration data.

Results

Globally, about 200 million people live in the coastal flood plain (below the 1 in 1,000 year flood elevation). GVA1 estimated that PaR is 50 million people/year in 1990. Most of these people live in deltaic areas in the developing world. The expansion of the flood plain due to a 1 m sea-level rise will increase PaR to 60 million people/year based on 1990 population. Allowing for the additional factor of increased flood

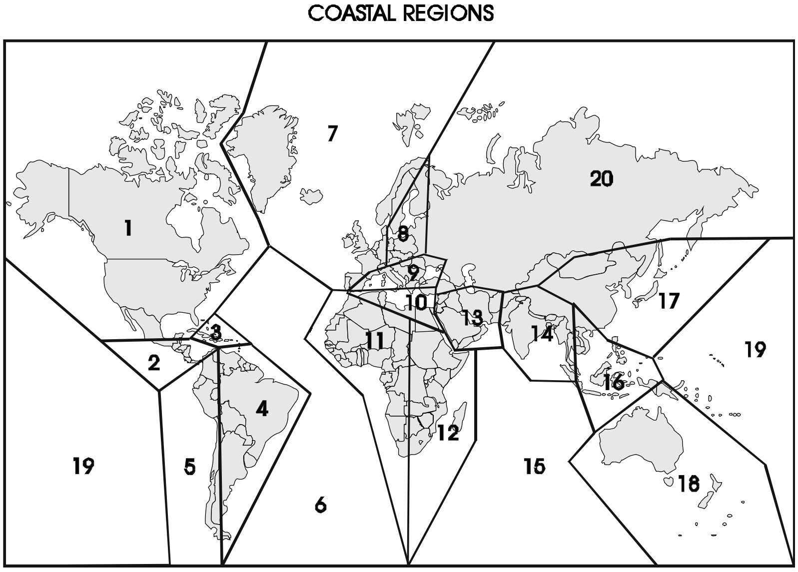

Figure G15 The 20 regions used in the GVA (from Hoozemans *et al.*, 1993).

frequency within the existing coastal flood plain, PaR doubles to 120 million people/year (Baarse, 1995). Upgrading coastal protection infrastructure against a 1 m rise in sea level as outlined above could collectively cost US $1,000 billion (1990 dollars), or 5.6% of the 1990 Global World Income. In this case, PaR is reduced from 60 to 7 million people/year, so there would be substantial benefits to coastal inhabitants. As these cost estimates assume an instantaneous rather than a progressive response and do not consider erosion in non-tourist areas or the costs of water management and drainage, they are more useful as a relative cost rather than an absolute adaptation cost.

Coastal wetlands are already declining at 1%/year to indirect and direct human activities. They would decline further due to a 1 m rise in sea level: more than half of the world's coastal wetlands could be lost.

The coastal regions defined in Figure G15 have different problems in the GVA1. Six regions are vulnerable to the loss of coastal wetlands: North America; Central America; South America Atlantic Coast; north and west Europe; northern Mediterranean; and Pacific large islands (GVA regions 1, 2, 4, 7, 9, and 18). Nine regions were considered to be vulnerable with respect to both flood impacts/response costs and loss of coastal wetlands: the Caribbean islands; west Africa; the Indian Ocean small islands; east Asia; the Pacific small islands; the southern Mediterranean; south Asia; southeast Asia; and east Africa (GVA regions 3, 11, 15, 17, 19, 10, 14, 16, and 12). Relative flood impacts are significant for small island settings, but the absolute impacts are highest in south, southeast, and east Asia.

The improved and validated approach of GVA2 suggests that under the 1990 situation, PaR is 10 million people/year. Even without sea-level rise, PaR is likely to increase to the 2050s due to increasing coastal populations. A 1 m rise in sea level produces a 14-fold increase in PaR given the 1990 world, rather than a 3-fold increase as found by Baarse (1995). Therefore, in the absence of adaptation, the impacts of sea-level rise on flooding are much more dramatic than previously realized. Evolving protection reduces the magnitude of flood impacts, but the relative increase in people flooded given sea-level rise is still dramatic. Under a lower sea-level rise scenario of 38 cm by the 2080s, the global increase in flooding will be seven-fold compared with the situation without sea-level rise. Most of these people will be flooded so frequently that some response seems inevitable. The most vulnerable regions are similar to GVA1, comprising large relative increases in the small island regions of the Caribbean, Indian Ocean, and Pacific Ocean small islands (GVA regions 3, 15, and 19), and large absolute increases in the southern Mediterranean, west Africa, east Africa, south Asia, and southeast Asia (GVA regions 10, 11, 12, 14, and 16).

Wetland losses given a 1 m rise in sea level could approach 46% of the present stock. Taking a 38 cm global scenario by the 2080s, between 6% and 22% of the world's wetlands could be lost due to sea-level rise. When added to existing trends of indirect and direct human destruction, the net effect could be the loss of 36–70% of the world's coastal wetlands, or an area of up to 210,000 km^2. Therefore, sea-level rise is a significant additional stress which makes the prognosis for wetlands even more adverse than existing trends. Regional losses would be most severe on the Atlantic coast of North and Central America, the Caribbean, the Mediterranean, and the Baltic. While there is no data, by implication, all small island regions are also threatened due to their low tidal range.

The major change in flood impacts from GVA1 to GVA2 reflects the more realistic assumptions in GVA2 concerning the present protection status, and its degradation as sea-level rises. The most important effect on PaR is the increased risk of flooding in the existing flood plain, rather than the expansion in the size of the flood plain as sea levels rise. Wetland losses in GVA1 and GVA2 are difficult to compare, but results for the common 1 m scenario are similar. The main benefit of GVA2 is its more flexible form.

What have we learned/next steps?

The analyses described here have proven the concept and utility of global vulnerability assessment for policy analysis. The results confirm that global sea-level rise could have a range of serious impacts on the world's coasts if we fail to plan for these changes. Further, these impacts will be greater in some regions than others with parts of Asia, Africa, and small island regions most adversely impacted. This is an important result to be considered by the UNFCCC policy process. However, what to do is not evaluated by the existing analyses.

In scientific terms, the rigor of developing such models gives improved insights into the functioning of the integrated (i.e., coupled natural-human) coastal system from the local to the global scales. For instance, this work explicitly considers the relationship between local wetland accretion and elevation change rates and potential regional and global wetland losses. It also explores how increased protection of human activities in low-lying areas may exacerbate wetland vulnerability under a scenario of rising sea level. Continued research efforts will provide important insights that will be useful to research programs such as the International Geosphere–Biosphere Programme, Land–Ocean Interactions in the Coastal Zone Project (IGBP-LOICZ) (Holligan and de Boois, 1993) and more generally improve the scientific basis of long-term coastal management.

Policy analysis for climate change requires flexible tools, which can link different emission scenarios all the way to potential impacts and adaptation potential. This will allow exploration of a wide range of sea-level rise (and other climate change) and socioeconomic scenarios, including different mixtures of mitigation and adaptation options. The experience with developing GVA1, and its improvement to GVA2 provide the basis to develop such tools. Important needs for future models include operation at a finer resolution, a better description of impact processes, and the facility to include different response and adaptation pathways, among other improvements. A European Union research project called Dynamic and Interactive Assessment of National, Regional, and Global Vulnerability of

Coastal Zones to Climate Change and Sea-level rise (or DINAS-COAST) is exploring these issues and will report in 2004.

GRAVEL BARRIERS

Definition

Gravel barriers are morpho-sedimentary units comprising beach face and rear landward-sloping unit whose surface sediment size ≥3ø. Surface sediment may be swash sorted by particle size and shape to form zoned facies. Internal structure shows matrix-supported as well as open-worked clast-supported stratification. Thus fine sediment (≤0ø) is an element of most gravel barriers. The type concept of sand, mixed sand and gravel, and pure gravel barriers (Kirk, 1980) is simplistic. Gravel barriers comprise sediment mixtures, the surface is but one coarse-clastic dominated facies set, as a function of incident wave energy, swash dynamics, and tidal range. Carter and Orford (1993) consider "coarse-clastic" a more appropriate descriptive term than "gravel."

Location and type

Most gravel (including shingle) literature concerns mid- to high-latitude barriers (mainly northern latitudes) associated with paraglacial coasts. These barriers tend to be transgressive and sediment depleted (Orford *et al.*, 1991). There are also gravel barriers, predominantly regressive and sediment abundant, in southern latitudes formed from mega-river supply or from reworked fluvial gravel fans associated with mountains. Gravel accumulations constructed from storm-generated coral reef debris can occur on tropical atolls.

Morphology

Transgressive barriers show a classic barrier morphology: narrow (<100 m), elongated longshore, and comprising one ridge crest up to 14 m high above mean sea-level. Ridge height is a function of sediment shape and size and breaking wave height. Breaches in transgressive barriers are usually initiated by cross-barrier hydraulic gradients, forced either landward by storm surges or seaward by terrestrial flood impoundment. A reduction in the fine-sediment component is likely in transgressive barriers. Regressive barriers show multiple beach ridges often with seaward trends in ridge elevation. Internal sediment facies variation reflects the importance of cuspate and berm morphology superimposed on prograded ridge sedimentation. What controls multiple ridge development is still widely debated: extreme storms, storminess phases, extreme tidal elevation, sediment supply and textural mix, and stochastic processes.

Essential concepts

Relative sea-level (RSL) change sets paraglacial barrier development tempo. Forbes *et al.* (1995) argued that longshore supply is controlled by RSL rise. Jennings *et al.* (1998) suggest that RSL rise controls types of gravel barrier development: spatial stability exists between 2 and 8 mm a^{-1} RSL rise. Below 2 mm a^{-1}, RSL rise is too slow for sediment replenishment and allows longshore reworking of a barrier. Above 8 mm a^{-1}, the high-tide shoreline is moving too fast for barrier concentration. Orford *et al.* (1995) identified barrier retreat rate as 1 m a^{-1} for each millimeter per annum RSL rise.

Barriers are defined as drift or swash-aligned, based on sediment supply. Paraglacial barriers related to till-covered basements are often fed from supply-limited sources of sediment (e.g., drumlins). Early to middle stages of drumlin erosion (high longshore supply) lead to associated longshore drift-aligned barriers (forced regression). As sediment supply reduces, the barrier becomes swash-aligned with both longshore cannibalization of shoreline barrier sediment and onshore movement of remnant sediment by overtop and overwash. Spatial fluctuations in sediment supply are not as important for barriers fed from unlimited supply sources.

Gravel barrier development is related more to storm wave than fair-weather conditions. Beach crest height is proportional to past breaker heights recorded at high water, hence the storm connection. Extreme run-up may flow over the crest top, transporting gravel to the crest (=overtop). Overtopping builds up the crest elevation, reducing the rate of subsequent overtopping and preventing barrier retreat. Extreme volumes of overtopping water can wash sediment down the barrier back-slope (=overwash). This lowers the crest height and allows smaller breaking waves to overwash. Consistent overwashing leads to landward migration of the gravel barrier. Quiescence and storminess periods may regulate short-term barrier retreat rates, but RSL rise controls long-term retreat.

Basement structure defines the barrier's accommodation space. When sediment supply is scarce then a crenulate coastal configuration is essential to define both shoreline hinge points and offshore bathymetric variation that causes refraction of incident wave by which barriers can accumulate sediment. Crenulate coastlines help transform drift-aligned gravel spits into swash-aligned gravel barriers as supply dwindles.

Conclusions

Swash-aligned barriers cannot rollover indefinitely so barrier breakdown will occur (Orford *et al.*, 1996). Sediment may come from rollover incorporation but this is outweighed by sediment loss to the barrier's extending length. Where sea level is rising the reducing return period associated with extreme water levels means that the barrier is more liable to overwashing and multiple phases of barrier-breaching. Wave refraction around the breaches forces the barrier remnants to fall back on themselves, with sediment moving onshore along transverse shoal lines to act as a source for new landward barrier construction. It is possible that swash-aligned barriers in rollover mode may be "scalped" in extreme storms (=overstepped). The upper barrier is swept onshore to form a new barrier leaving the old basement as a relict feature on the foreshore (Forbes *et al.*, 1991). The 20th century has seen a trend for fixing gravel barriers by artificially maintaining the crests, allowing urban development in their lee. The coastal squeeze is very pronounced behind such modified barriers with no space for rollover. The high likelihood of catastrophic gravel barrier failure is a salient problem for 21st century coastal zone management.

GRAVEL BEACHES

Introduction

Gravel beaches are accumulations of shore material formed into distinctive shapes by waves and currents and containing lithic particles in the gravel size range. The beach form is a generally seaward-sloping boundary between a water body and mobile sediment, and a flat or landward-sloping surface at the upper limit of the beach. One or more gravel ridges may exist in the subaerial profile. A bar might be present on the submerged profile. Figure G16 describes beach features to be discussed. Natural beaches composed of coarse material are common in high latitudes where much coastal sediment has a glacial transport history. They also occur at other latitudes, especially near eroding cliffs, platforms, and reefs (Carter, 1988, p. 130).

Terminology

Gravel beach is a term that includes shingle beach and mixed beach. Various investigators refer to gravelly beach material as having a median diameter between 5 and 75 mm, and shingle larger than 2 mm. The composition of the gravelly surface results from winnowing of finer sediments from the original material, or from active sorting of material during transport both onshore and alongshore. A shingle beach contains no or negligible amounts of sand and finer material. Mason *et al.* (1997) identified two categories of mixed beach. One is a broadly homogeneous mixture of sand and gravel, with some grading across shore and alongshore. The distinctly sandy region, if present, is usually exposed only during low spring tides. The second category is a composite beach, characterized by a wide, sandy, intertidal terrace flanked by a gravel ridge. The division between the two sediment types in this second beach category is marked by an abrupt change in slope. As the water level changes, beach reflectivity changes rapidly. Both types of mixed beaches may have complex stratigraphy. The surface layer of pebbles and cobbles is often underlain by gravel and pebbles of mixed sizes supported in a sand matrix. Surface material of the berm crest might not be wave-sorted gravel where the back beach or berm crest is quite narrow and fronts an eroding cliff, but composed of colluvium derived from the cliff face with particle size unrelated to the washover process.

Significant studies

The interactive influences involving beach material size, sediment transport, profile characteristics, and evolution of beach profile in response to changing wave energetics mark gravel beaches as different from sand beaches. Literature of shore processes contain fewer studies of gravel beaches than studies of sand beaches, possibly because sand beaches occur in parts of the world where their economic value to upland property and demand as a recreational asset are relatively greater. Chesil Beach in Dorset, United Kingdom stands out as a shingle beach with a long history of study of processes relating wave energetics to particle sorting and profile characteristics, one as early as 1853 (King, 1972, p. 307). Bluck (1967) and Orford (1975) reported studies of the control by particle shape and size on zonation of beach surface gravels. Van der Meer and Pilarczyk (1986) developed mathematical relationships between profile features and incident wave characteristics from tests of variable wave conditions and beach material sizes in a wave flume. Approximately 200 km of the Black Sea coastline has been reconstructed

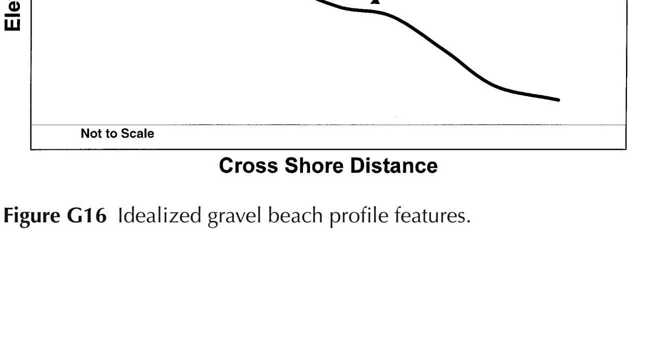

Figure G16 Idealized gravel beach profile features.

with designed gravel beaches (Zenkovich and Schwartz, 1987; Kiknadze, 1993). Kirk (1992) reported monitoring results of a mixed sand and gravel renourishment project, and developed a method for estimating the fill life.

Essential concepts

Gravel beach profile shape and particle size are hydraulically related. Beach morphology results from the near balance of forces acting on the beach material delivered to the nearshore zone. Hydraulic forces are directed onshore during wave advance. Opposing forces are weight and mechanical resistance of the particles being moved. Seaward directed forces are downslope component of weight and hydraulic forces associated with wave downrush, percolation flow in the beach face, and return flow in the surf zone. The mode of transport corresponding to predominant particle size and predominant form of wave energy reaching the nearshore zone influence beach morphology and wave energy dissipation rate across the profile. Gravel beaches are usually dominated by plunging breakers with no surf zone, with longshore transport occurring as bedload in the swash zone, and display higher reflectivity of the low-frequency wave energy (compared with that of a dissipative foreshore of a sandy beach).

Nearshore mechanics

The forms of energy dissipation and the modes of sediment transport make a gravel beach different from a sand beach. Wave energy is dissipated on a sand beach through turbulent dissipation in the wave breaking process through the surf zone, bottom friction, and work expended in suspending sediments. Swell wave reflection is lower for sand beaches and water infiltration into the beach face is relatively insignificant, compared with gravel beaches. Wave breaking at a gravel beach is closer to the high-tide shoreline, with the Irribarren Number well into the plunging breaker range. Gravelly beach material is moved as bedload or in close contact with the bed under most transport conditions. Bedload is a much less efficient mode of transport than suspended load. Plunging breakers at the shore confine longshore transport of gravel to the swash zone. Measurements of Mason *et al.* (1997) showed that swell wave reflection increased with beach gradient for gradients exceeding 0.06 (3.5°), but for lower gradients no relationship was observed. Reflection of wind waves showed no relationship with gradient, and never exceeded 40%. Powell (1988) determined from laboratory studies that wave energy reflected by a shingle beach was about 10% for all values of sea steepness greater than 0.02, but reflection increased rapidly as sea steepness decreased below 0.02. Greater energy reflection diminishes the energy available to create high runup.

Swash mechanics

Wave energy loss in runup and rundown is mainly through frictional loss on a sandy beach surface (Damgaard *et al.*, 1996, p. 11). With highly porous beach material, percolation of the swash into the surface accounts for most of the energy loss that would otherwise be available for producing higher runup. The greater porosity of the gravelly beach material creates a greater asymmetry of shear stress applied to swash zone surface material in wave uprush and downrush. As water from the advancing wave percolates into the beach face, the water table locally is raised and the volume of water available for transporting material seaward is diminished. Van Wellen *et al.* (1997) reported measurements on a shingle beach during a high-energy wave event of shore-normal runup, in which the average sediment transport rate in uprush was over three times that of the backwash.

Morphology

The resulting equilibrium slope of a gravel beach face is steeper, and the transport asymmetry is responsible for the creation of the berm that often is present at a gravel beach. Typical cross-sectional shape of a gravel beach includes a bar seaward of the break point, a step in the profile at the point of wave breaking, and a berm built near the limit of uprush. Laboratory tests of Powell (1988) showed that generally less than 2% of runups of random waves exceed the wave-formed beach crest, regardless of shingle size or wave conditions. Simpson (1995) determined that the elevation of the berm crest on a semi-protected gravel beach approximately matches the runup elevation having the 33% exceedance probability based on combined probability of tide levels and runup distribution of the two-year return period storm. Figure G17 describes the profile geometry and pertinent elevations. The inset shows the particle size distribution of that beach surface material. Figure G18 is a photograph of the upper beach at the transect described in Figure G17. The plan shape of gravel beaches often includes cusps. Cusps are associated with steep, reflective beaches and are more prevalent on shores composed of coarse material than fine material.

Application

The interest in developing quantitative prediction of geometry and transport rates for gravel and shingle beaches is increasing as their value is recognized for support of aquatic habitat and for shore protection, and as more development pressure has potential to disrupt balances that maintain gravel beaches. The features of a gravel beach that are of interest to the engineer, coastal planner, and beach management decision-maker are the elevation of the beach crest (or berm height), the beach slope (or beach gradient), and the location and dimension of the submerged bar. The designer is interested as well in particle size distribution and its effect on hydraulic conductivity. These elements determine the rate of wave energy dissipation, wave reflection, and wave runup height. Processes of interest are sorting, depth of disturbance, and cross-shore and longshore transport. These processes determine suitability of a constructed protective beach, the longevity of a beach nourishment project, and the potential impact of a littoral barrier in a gravel beach system. Artificial gravel beaches can create shore protection that is environmentally compliant and acceptable to the recreational user. More research is needed to fully specify the effect of sand content in mixed beaches during varying levels of wave attack. Quick and Dyksterhus (1994)

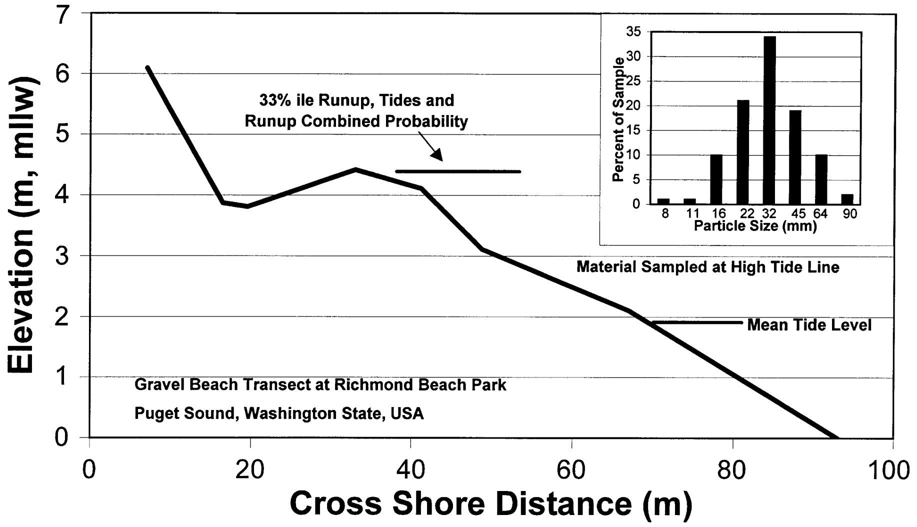

Figure G17 Gravel beach profile, particle sizes, and water level characteristics, example from moderate wave environment.

Figure G18 View of upper profile of gravel beach plotted in Figure G17 (Richmond Beach, Puget Sound, Washington, USA).

experimented with different heights of incident waves and beach material composed of sand and gravel. The same high level of wave attack that produced a steep, bermed profile with gravel caused strong offshore movement and flattening of the slope when the beach was a gravel mixture containing only 25% sand. Under medium wave attack, the mixed beach behaved generally as a gravel beach. This change in behavior with waves is important to designers who intend to design a beach to be dynamically stable in higher wave events. Generally, adding sand to a shingle beach can lower the beach gradient, and adding gravel to a sandy beach has no effect.

GREENHOUSE EFFECT AND GLOBAL WARMING

Most of the coastal processes examined in this volume depend on climate, sea level, or both. Over long periods of time, climate has always fluctuated. The next century, however, may see unusually rapid changes because humanity is adding gases that absorb infrared radiation to our planet's atmosphere, and thereby enhancing the "greenhouse effect." This entry examines the greenhouse effect, the trends in climate, and expected future changes.

Greenhouse effect: the earth's changing energy balance

Any planet's temperature depends mainly on (1) the amount of sunlight received, (2) the amount of sunlight reflected into space, and (3) the extent to which the atmosphere retains heat. Figure G19 shows our

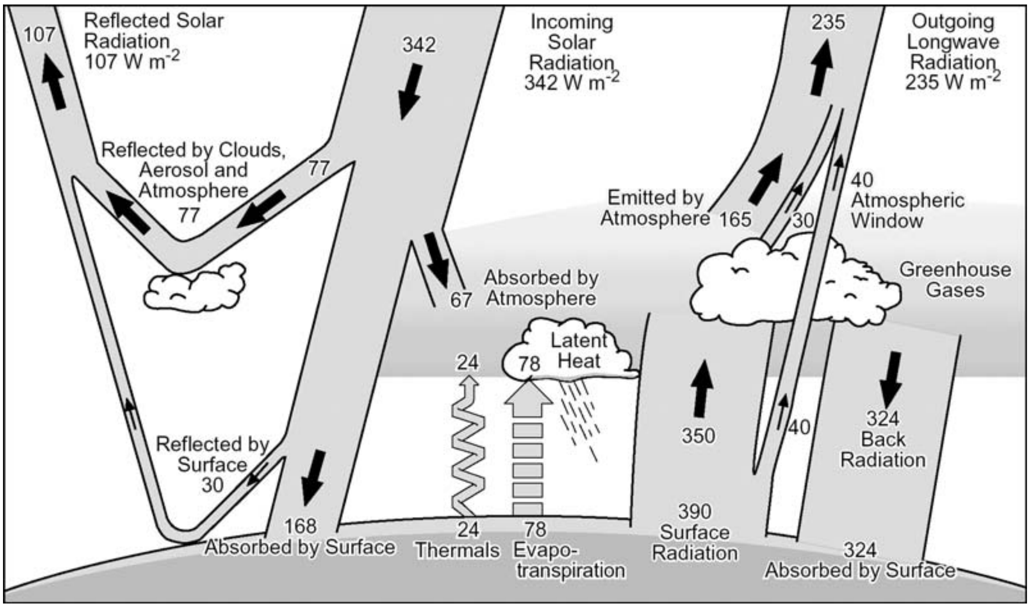

Figure G19 The earth's average annual energy balance.
Source: Kiehl, J.T., and Trenberth, K.E., 1997. Earth's annual global mean energy budget. *Bulletin of American Meterological Society* **78**: 197–208.

planet's annual energy balance, measured by watts of energy for each square meter of the earth's surface. Of the 342 W/m^2 reaching the atmosphere, 107 W/m^2 are reflected back into space by clouds, ice, and other reflective surfaces. Another 168 W/m^2 of sunlight is absorbed by the earth's surface, which re-radiates the energy toward space in the infrared part of the spectrum. But the water vapor and carbon dioxide found naturally in the atmosphere absorb all but 40 W/m^2 of this infrared radiation. This absorption warms the atmosphere, and the warmer atmosphere then re-radiates energy upward into space and downward back to the earth's surface. This feature of the earth's energy balance has long been known as the "greenhouse effect" (Arrhenius, 1896) because the atmosphere—like the glass panels of a greenhouse—allow sunlight to penetrate but retain heat. The importance of the greenhouse effect is apparent from Figure G19. The downward radiation from the atmosphere (334 W/m^2) is twice the energy received directly from sunlight. Without the greenhouse the effect, the earth's surface would be about 33°C (60°F) colder than it is currently.

A second important impact of the greenhouse effect, albeit less widely discussed, is the cooling of the stratosphere. The more a substance absorbs energy, the more rapidly it radiates away its energy, which means that greenhouse gases radiate energy more rapidly than other gases in the atmosphere. Therefore, higher concentrations of greenhouse gases create both a warming effect (increased ability to absorb infrared radiation) and a cooling effect (increased ability to radiate energy away). The warming effect is more important in the lower part of the atmosphere than the upper atmosphere. In the lower atmosphere there is more infrared radiation to absorb, because it is coming from the surface and gases below, and from the gases above, whereas in the upper atmosphere, infrared is only coming from below. Because the gases radiate energy away in all directions throughout the atmosphere, the increased greenhouse gases have a fairly uniform cooling effect. With uniform cooling, greater warming below and less warming aloft, the net effect is warming near the surface and cooling in the upper atmosphere.

Over the last two million years, changes in the timing and amount of sunlight striking the earth have induced ice ages and interglacial warm periods. During ice ages, global temperatures were about 5°C colder than today, and much of the Northern Hemisphere was covered with ice; during interglacial periods, temperatures have often been about 1°C warmer than today. Many scientists believe that cyclical fluctuations in the earth's orbit around the sun, and the tilt and wobble of the earth's axis slowly alter the amount and timing of sunlight received by the earth. The resulting long-term shift in climate is sometimes called the "Milankovich effect." (Milankovich, 1930; Hayes *et al*., 1976).

The direct effects of changes in solar irradiation appear to have been substantially amplified by several climate feedbacks (IPCC, 1996).

- *The albedo feedback*: Warmer temperatures caused glaciers to retreat, exposing land and open seas, both of which reflect less light into space than snow and ice.
- *The water vapor feedback*: Warmer temperatures increas the absolute humidity of the atmosphere, which in turn increases the greenhouse effect from water vapor.
- *Carbon-cycle feedback*: Warmer temperatures reduce the solubility of CO_2 in water, leading to higher atmospheric concentrations of CO_2, enhancing the greenhouse effect.
- *Cloud feedbacks*: There is no data on how clouds behaved during previous interglacial cycles, and scientists are unsure whether clouds amplify or dampen the global warming from other factors.

Although changes in solar irradiation have been important in the past, changes in the greenhouse effect will probably be more important during the 21st century. Humanity is adding gases that absorb infrared radiation to the atmosphere, and thereby strengthening the greenhouse effect. Figure G20 provides estimates of the impact of these gases and other human activities on the amount of energy absorbed by the earth's surface. The first three bars in the chart are concerned with greenhouse gases, most of the remaining bars focus on activities that increase the extent to which sunlight is reflected or absorbed.

Greenhouse gases

The chief greenhouse gases are CO_2, methane, and nitrous oxide. Whenever oil, coal, gas, or wood are burned, carbon dioxide is released into the atmosphere. Approximately half of this CO_2 is soon absorbed by the oceans or by increased plant photosynthesis. The other half remains in the atmosphere for many decades. As a result, the average concentration of carbon dioxide has increased from around 275 parts per million (ppm) before the industrial revolution, to 315 ppm when precise monitoring stations were set up in 1958, to 368 ppm in 1999. This change has increased the amount of energy striking the earth's surface by about 1.5 W/m^2.

The remaining gases released by human activities appear to be adding about 1.0–1.5 W/m^2. Increased methane and halocarbons are both adding about 0.5 W/m^2. About two-thirds of the current emissions of methane into the atmosphere result from cattle farming, rice paddies, landfills, coal mining, oil and gas production, and several other human activities. Radiation from methane has increased by about 0.5 W/m^2 since the Industrial Revolution. Nitrous oxide is released by the use of nitrogen fertilizers, the burning of wood, and some industrial processes. Some of the most important halocarbons are the fully halogenated chlorofluorocarbons once used in aerosol spray cans, refrigerators,

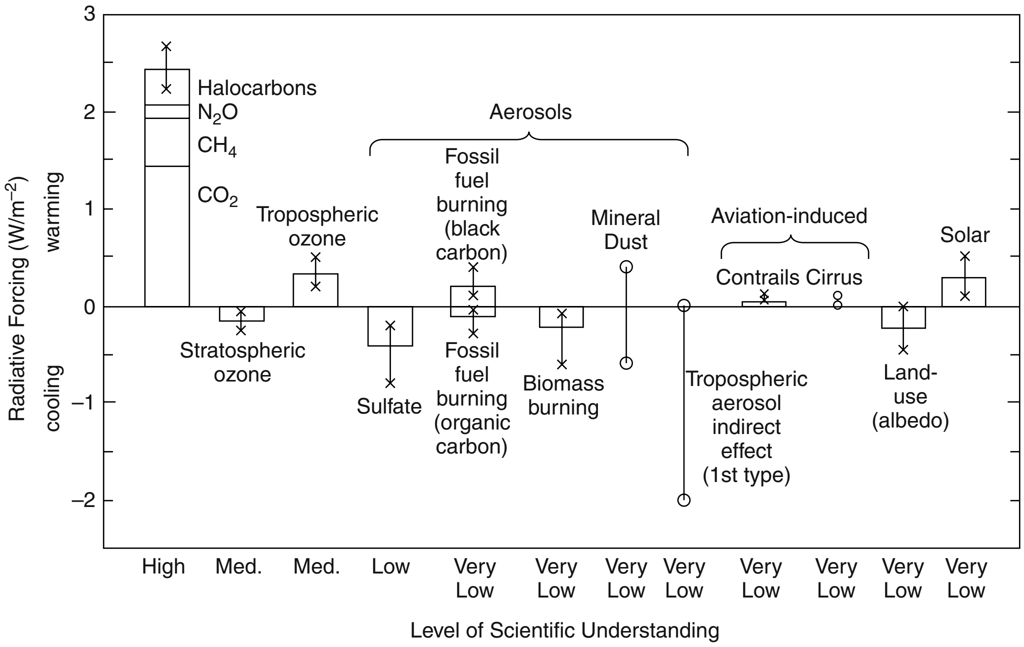

Figure G20 Estimates of changes in global annual average radiative forcing from various causes, 1750 to the Present. *Source*: IPCC (2001).

air-conditioners, electronics cleaning, and foam-blowing. The production of those gases is being phased out under the terms of the Montreal Protocol on Substances that deplete the Ozone Layer. Nevertheless, the gases will remain in the atmosphere for several decades.

Aerosols

Humanity is also increasing the extent to which the atmosphere and the surface of the earth reflect light back into space, which tends to cool the earth. Land uses can alter the reflectivity of the earth's surface; tropical deforestation appears to be the most important change, but it has only reduced the amount of sunlight absorbed by about 0.1 W/m^2. Changes in the reflectivity of the atmosphere, however, may be altering the earth's radiative balance as much as carbon dioxide, albeit in the opposite direction. Most importantly, society is adding very fine particles and droplets known as aerosols.

Aerosols have three different impacts on the global energy balance. First, they tend to reflect light back into space (the *direct cooling effect*). Second, large particles absorb sunlight and radiate infrared radiation in all directions, including toward the surface (the *direct warming effect*). Finally, aerosols can increase the density of clouds (the *indirect effect*).

The most important aerosols are sulfates and smoke particles. Power plants that burn coal, as well as copper, lead, and zinc smelters, release sulfur dioxide, which reacts with water vapor in the atmosphere to form sulfates. Sulfates currently reflect enough light back into space to reduce the amount of energy striking the earth's surface 0.2–0.8 W/m^2. Unlike most greenhouse gases, which remain in the atmosphere for decades or longer, precipitation removes most sulfates within a few weeks. As a result, sulfates tend to be concentrated in the areas immediately downwind of major industrial areas.

Smoke from oil and coal has an ambiguous impact: black carbon particles absorb sunlight and heat the atmosphere, while organic particles behave more like aerosols and reflect light back into space. IPCC (2001) estimates that black carbon provides a positive forcing of 0.1–0.4 W/m^2 with 0.2 the most likely value, and that organic carbon has a forcing of about -0.1 W/m^2. It is not clear whether mineral dust has a warming or cooling effect. A final confounding factor is the so-called indirect effect of aerosols on clouds. Aerosols appear to increase the concentration of droplets while decreasing the size of the typical droplet, which leads clouds to scatter more light back to space. Sulfates alone appear to have an indirect effect of -0.3 to -1.8 W/m^2, which may be greater than the direct cooling effect from sulfates.

Trends related to global climate change

Data on a wide variety of environmental indicators are consistent with the consequences that scientists generally expect to result from increasing concentrations of greenhouse gases. This section summarizes data reported in IPCC (2001).

Temperatures

Global temperatures are rising. Reasonably good data from thermometers are available for land surface temperatures from approximately 1860 to the present. These data suggest that the average land surface temperature has risen 0.3–0.8°C (0.6–1.5°F) in the last century (IPCC, 2001). Studies that combine land and sea measurements have generally estimated that global temperatures have warmed 0.4–0.8°C (0.7-1.4°F) in the last century. As Figure G21 shows, about two-thirds of this warming took place during 1900–1940. Global temperatures declined slightly from the 1940 to 1975, but rose more rapidly during the last 25 years than in the period before 1940.

Surface temperatures are not rising uniformly. The winters between 50°N and 70°N (the latitude of Canada and Alaska) are warming relatively fast, while summer temperatures show little trend. Urban areas are warming somewhat more rapidly than rural areas, because of both the changes in land cover and the consumption of energy occurring in densely developed areas (the latter is known as the "urban heat island" effect). All of the contiguous United States warmed during the last century, except for a portion of the southeast. No one has adequately explained why this region cooled while other areas warmed.

Nighttime low temperatures appear to be rising about twice as rapidly as daytime highs. This decreased diurnal temperature range is generally occurring in areas where cloud cover is increasing. Unfortunately, the data required to analyze the diurnal temperature range are available only for the period 1950–1993, and only about half the world's land areas.

The temperature trends for the atmosphere vary by altitude. For the period 1979–1999, satellite observations and weather balloons show very small warming trends of 0.04–0.05°C/decade in the lower troposphere (surface to 8 km), even though the earth's surface warmed about 0.15°C per decade over the same period. By contrast, during the period 1958–79, there was almost no change in the average surface temperature, while the lower troposphere warmed close to 0.2°C/decade. There seems to be no trend in the upper troposphere (8–18 km). Finally, the stratosphere is cooling: Observations from weather balloons suggest that the lower stratosphere (15–23 km above the surface) cooled about 0.1–0.3°C/decade from 1959 to 1979, and 0.5–1.2°C/decade from 1979 to 1999. The more comprehensive satellite observations available since 1979 suggest a cooling of about 0.5°C in the lower stratosphere.

Scientists are still debating the importance of the various atmospheric temperature trends (or lack thereof). Although some nonspecialists are confused by cooling in the upper atmosphere, climatologists have long expected that greenhouse gases would cool the stratosphere, as discussed above. Moreover, in addition to the expected greenhouse

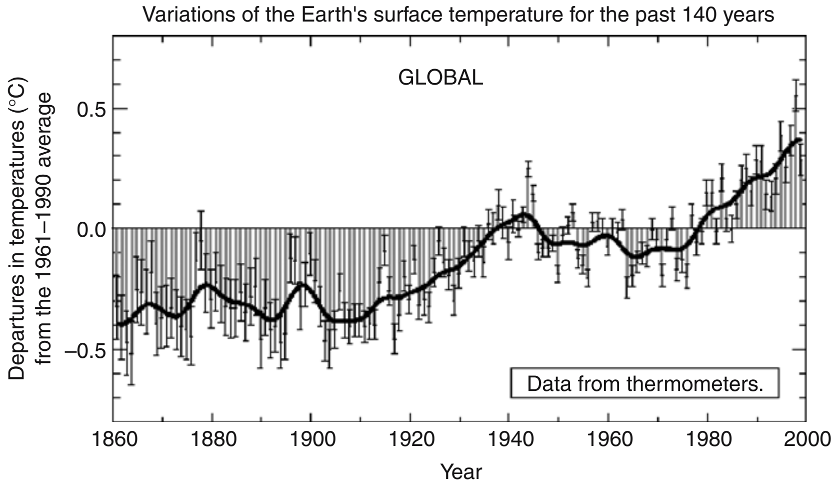

Figure G21 The temperature at the earth's surface based on thermometers, 1860–2000. The solid line is a 20-year moving average. Error bars for annual observations represent two standard deviations.
Source: IPCC (2001).

cooling, ozone depletion from chlorofluorocarbons probably cool the stratosphere: ozone absorbs incoming ultraviolet radiation and thereby warms the stratosphere, but less ozone means less warming from ultraviolet.

The lack of a recent warming in the troposphere is harder to explain. Climate models generally have projected that the lower atmosphere would warm by about the same magnitude as the earth's surface. The Intergovernmental Panel on Climate Change (2001) believes that about half of the discrepancy can be explained by "observation biases" caused by differences in coverage and the timing of volcanic eruptions and the El Nino cycle. The other half of the discrepancy may represent a real difference over the 20-year period. Because the surface and the troposphere are two different entities, it is not necessarily surprising that they are following different trajectories.

The world's oceans are also warming. The average sea surface temperature has risen approximately 0.6°C in the last century. One would expect the lower layers of the ocean to warm more slowly, because of the great heat-absorbing capacity of the oceans. The upper 300 m appear to have warmed at a rate of approximately 0.3°C/century. Around Bermuda, at the 1,500–2,500 dbar depth, temperatures warmed 0.05°C/decade from 1922 to 1995. Between 800 and 2,500 m below the surface, ocean temperatures have warmed about 0.5°C in the area bounded by 52–66° W and 20–32°N (IPCC, 2001).

Is the last century's warming the start of a new trend, or simply part of a natural cycle that has always caused temperatures to rise and fall? Because thermometer data is sparse before 1860 outside of a few countries, scientists must rely on tree rings, corals, ice cores, pollen, deposits from mountain glaciers, and—in some cases—historical documentation. These sources are much less precise than thermometers, and in some cases they are able to show direction of change but not the actual temperature. Nevertheless, their estimates have been validated by comparisons with the instrumental record. Figure G22 shows the best available reconstruction of temperatures over the last one thousand years. These data suggest that Northern Hemisphere temperatures fluctuated within a 0.4°C range from AD 1000 to 1900, before warming approximately 0.8°C in the last century. The final decade of the second millennium appears to have also been the warmest. Because this warming is more than twice the standard deviation of previous fluctuations, it is probably not simply a random fluctuation.

The hydrologic cycle

Precipitation has increased by about 2% over the world's continents since 1900. Based on over 20,000 data stations, this estimate is statistically significant, but geographically variable. Precipitation increased 9–16% on average over the land areas between 30°N and 85°N, but only about 3% in the areas between 30°S and 55°S. Overall, precipitation declined between 10°N and 30°N.

Throughout most of the United States, precipitation has increased 5–10% in the last century. Along the northern tier states and in much of Canada, rainfall has increased 10–15%. Much of this increase has taken place between September and November; in the southeast, rainfall has actually declined between June and August. Rainfall is also tending to be more concentrated in heavy downpours. At the beginning of the 20th century, only 9% of the nation experienced a storm each year in which more than 2 in. of precipitation fell in a 24-h period. In recent decades, such a severe storm has occurred each year over close to 11% of the nation (see Figure G23). The trend toward more concentrated rainfall is apparent in Canada and much of Europe as well.

Humidity is also increasing. In the United States, both relative humidity and the dew point have been rising, particularly at night. There is some evidence that absolute humidity is increasing worldwide at several different altitudes.

Clouds, by contrast, may offset this warming. Because clouds reflect sunlight back into space and absorb outgoing infrared radiation, and increase in clouds can tend to limit daytime warming but increase the warming at night. Observations indicate that cloud cover has increased over the United States and Soviet Union. These increases are highly correlated with the decline in the diurnal temperature range.

Snow and ice cover

The world's ice cover can be divided into five categories: polar ice sheets, small glaciers, snow cover, ice shelves, and sea ice. The polar ice sheets of Greenland and Antarctica contain enough ice to raise sea level about 70 m. Most of those ice sheets are in areas that are too cold for ice to melt even if temperatures warm a few degrees. No one has demonstrated that greenhouse gases are responsible for any trends in the mass of these ice sheets.

The world's small glaciers and ice caps retreated enough to raise sea level about 5 cm since 1900. In the tropics, where snow is only found at high altitudes, the freezing line is about 100 m higher than two decades ago and glaciers are retreating in all areas. The European Alps glaciers have retreated enough to expose areas that have been covered by ice for several thousand years, revealing, for example, the 5,000-year-old Oetzal "ice man" and various ancient artifacts.

Snow cover in the Northern Hemisphere has decreased about 10% since 1966. Satellite records show that snow cover has retreated earlier in the spring and summer, but it has not changed during fall and winter. Assessments based on weather station records suggest that the area covered by snow on average over the course of a year during the last decade was less than any decade during the last century. During winter and fall, the amount of snow cover may have increased slightly.

Between 1978 and 1996, the area of sea ice has decreased in the Northern Hemisphere, according to satellite data, especially during summer. Over the last century, sea ice has declined about 15% during summer, 8% during spring, and very little during autumn and winter. The seasonality of the decline contradicts the calculations of most climate models, which project greater reductions of sea ice during winter. Sea ice appears to have *increased* about 3% in Antarctica in the last two decades; but the data are insufficient for estimating a longer-term trend.

The large Ross and Filchner-Ronne ice shelves in western Antarctica, hundreds of meters thick, do not have a discernible trend. Several smaller

ice shelves around the Antarctic Peninsula, however, have been retreating, possibly as a result of the 2°C warming in that region over the last 40 years. Climate models have not attributed this region's warming to greenhouse gases.

Sea level

Table G4 summarizes the various contributors to sea level rise. During the 20th century, sea level rose 10–20 cm, about half of which can be attributed to global warming. Approximately 2–4 cm resulted from the melting of small glaciers and ice caps, which most researchers attribute entirely to global warming; and models estimate that global warming should have caused ocean water to expand enough to raise the sea another 3–7 cm. Global warming appears to have had a negligible impact on the polar ice sheets. However, the long-term adjustment of the Antarctic ice sheet to the warming since the last Ice Age may have caused a contribution up to 5 cm. Changes in terrestrial water storage have both added to (e.g., groundwater depletion, runoff from urbanization, and wetland loss) and subtracted from sea level (e.g. dams, infiltration from irrigation), but the net effect may still be significant. The best estimate of the contributions to sea-level rise (7 cm) is about half the best estimate of observed sea-level rise (15 cm), implying either that one of the contributors is substantially underestimated, or the true value of most of the contributors is near the high end of the uncertainty range.

Projections of the future

Emissions, concentrations, and radiative forcing

The extent and speed at which humanity changes the climate will depend to a large extent on the rate at which society adds additional greenhouse gases to the atmosphere. If we continue to use today's technology, then as populations and the economy grow, emissions of CO_2 will continue to increase. Until a few decades ago, energy consumption grew at about the same rate as the Gross National Product. After oil supplies were disrupted in 1973 and 1979, however, people made substantial efforts to decrease energy consumption, including better insulation, smaller cars, and more energy efficient appliances. More recently, relatively low gasoline prices, economic growth, and demographic trends have led Americans to buy larger cars, minivans, and light trucks that consume more gasoline than the compact cars that were more in vogue a decade ago. Nevertheless, many businesses are continuing to institute energy conservation measures. As a result, US emissions have grown 1.2% per year since 1990, while the economy grew 3.1% per year.

Worldwide, emissions have grown approximately 1.7% per year since 1900, but only about 1.0% since 1990. CO_2 has increased several percent per year in some developing nations, but remained roughly stable in Western Europe, and declined due to the economic contraction in the nations comprising the former Soviet Union. Japan, Canada, and Australia experienced roughly the same emissions growth as the United States.

Will CO_2 emissions continue to grow in the next century? The answer depends both on the evolution of our way of life, and on whether governments take measures to reduce emissions. The IPCC (2000) has developed a large set of scenarios for analyzing emissions trajectories assuming that no policies are enacted to reduce CO_2 emissions. Table G5 illustrates some of the key aspects of four of the most commonly cited scenarios.

Higher economic growth does not necessarily mean higher CO_2 emissions. In IPCC's Scenario "A1T," world population increases from

Table G4 Comparison of observed sea-level rise with estimated rise in sea level attributable to various causes

	Presumed cause	Source of estimate

5.3 billion today to 8.7 billion by 2050, before declining to 7 billion in 2100. The gross world product grows by about 3.7% per year from 1990 to 2050, but only 2.2% from 2050 to 2100, leading to a 20-fold increase in per capita income. But in this scenario, increased wealth and stabilizing population comes along with increased reliance on non-carbon based energy, from 18% today to 85% in 2100. As a result, emissions of CO_2 increase from 6 Gt/yr in 1990 to 12.3 Gt/yr in 2050, but decline to 4.3 Gt/yr in 2100.

Emissions increase to 30 Gt/yr under scenario A1T, which assumes a similar amount of economic growth, but continued reliance on fossil fuels. Scenario A2 leads to similarly high CO_2 emissions, under very different assumptions. In this scenario, per capita income only doubles over the next century, because world population increases to 15.1 billion, while the gross world product only increases 2.3% per year. In spite of the seven-fold difference in year 2100, the major differences do not emerge until the middle of the 21st century. Therefore, the cumulative emissions from 1990 to 2100 are only about twice as great for the high-emissions scenarios for the low-emissions scenarios.

How will atmospheric concentrations change? Both the oceans and plants remove CO_2 from the atmosphere, through a number of processes that themselves depend on climate. Carbon dioxide dissolves into the upper layers of the ocean. Solubility, however, declines as temperatures increase. Moreover, the ability of the upper layers to take up CO_2 is limited, and is maintained by ocean circulation in which water with high CO_2 concentrations sinks while deep water with low concentrations of CO_2 is brought to the surface. If global warming decreases ocean circulation, then the oceanic removal of CO_2 would be slowed. The terrestrial biosphere can store some of the CO_2 released into the atmosphere, both because climate warming lengthens the growing season in cold regions and because CO_2 itself enhances photosynthesis. However, if insufficient water is available, warmer temperatures could also enable soils to release carbon dioxide into the atmosphere.

The models that have been developed to calculate how much CO_2 will remain in the atmosphere imply that CO_2 concentrations will increase throughout the next century for all of the IPCC emissions scenarios. IPCC models suggest that concentrations are likely to increase from the current concentration of 367 ppm to somewhere between 540 and 970 ppm, that is anywhere from 2 to 3.5 times the preindustrial concentration of CO_2. Today, the concentration of 367 ppm is about 90 ppm greater than the preindustrial concentration. Thus, IPCC's scenarios imply that in the next century humanity will increase atmospheric CO_2 by 2–6 times as much as we increased CO_2 in the last century.

The scenarios all imply somewhere between 1.5 and 2 W/m^2 additional radiative forcing through the year 2050, and anywhere from 2 to 5 W/m^2 through the year 2100. The IPCC undertook similar assessments for the other greenhouse gases, and the key aerosols. Considering all the greenhouse gases and aerosols, the next century seems likely to see an increased radiative forcing somewhere between 2 and 7 W/m^2,

[a] IPCC uses slightly different categories for describing historic and future radiative forcing from black carbon and organic carbon. Table 6.11 reports values for historic fossil fuel black carbon, fossil fuel organic carbon, and the net effect from biomass, which includes both types of aerosol carbon. The projections in table 6.15 report total black carbon and total organic carbon, a convention that this table follows.
[b] Ozone depleters include CFC 11, 12, 113, 114, and 115; carbon tetrachloride, HCFC's 22, 141b,142b, and 123; halons 1211 and 1301, and Ch_3CCl_3.
[c] Includes HFC23, 125, 32, 134a, 143a, 152a, 227ea, 245ca, and 43-10mee.
[d] Includes carbon tetrafluoride, ethyl fluoride, butyl fluoride, and sulfur hexafluoride.

compared with a historic contribution of approximately 2 W/m^2 (Table G6). Carbon dioxide will continue to be by far the most important contributor, responsible for 70–80% of the anthropogenic greenhouse warming.

Future climate

Global temperatures. Since 1979, scientists have generally agreed that a doubling of atmospheric carbon dioxide increases the earth's average surface temperature by 1.5–4.5°C (3–8°F). More recent studies have suggested that the warming is likely to occur more rapidly over land than the open seas. Moreover, the warming in temperatures tends to lag behind the increase in greenhouse gases. At first, the cooler oceans will tend to absorb much of the additional heat and thereby decrease the warming of the atmosphere. Only when the ocean comes into equilibrium with the higher level of CO_2 will the full warming occur.

As a result of the delay induced by the oceans, climate scientists do not expect the earth to warm by the full 1.5–4.5°C (3–8°F) during the next century, even though the level of CO_2 is expected to more than double and other greenhouse gases would add to the warming. In 1995, the Intergovernmental Panel on Climate Change projected a warming of 1.0–3.5°C (1.8–6.3°F) by the year 2100; the more recent IPCC (2001) estimated a range of 1.4–5.8°C, largely due to the inclusion of a few emissions scenarios that seem very unlikely. Wigley and Raper (2001) estimated a 90% confidence interval that global temperatures will rise 1.7–4.9°C from 1990 to 2100.

Sea level. The warmer temperatures are expected to raise sea level by expanding ocean water, melting mountain glaciers, and melting parts of the Greenland Ice Sheet. Warmer temperatures also increase precipitation, as described below. Snowfall over Greenland and Antarctica is expected to increase by about 5% for every 1°F warming in temperatures. Increased snowfall tends to cause sea level to drop if the snow does not melt during the following summer, because the water will either be on land or in the ocean. (The amount of water in the atmosphere is less than the water it takes to raise the oceans by 1 mm.) Considering all of these factors, the IPCC estimates that sea level will rise 20–86 cm by the year 2100. Environmental Protection Agency (EPA, 1995) estimated that global sea level has a 50% chance of rising 45 cm (1.5 ft) by the year 2100, but a 1-in-100 chance of a rise of about 110 cm (over 3.5 ft).

Over the longer run, more substantial changes in sea level are possible. Some scientists believe that the West Antarctic Ice Sheet could slide into the oceans after a sustained warming, or if other factors raised sea level. The vulnerability of this ice sheet is poorly understood. It contains enough ice to raise sea level 6 m (20 ft), and coastal scientists generally agree that sea level was 20 ft higher than today during the last interglacial period, which was only slightly warmer than today. While some scientists have suggested that there is fossil evidence on the polar ocean floor that this ice sheet collapsed during the last interglacial period, there is no scientific consensus on this question.

Two risk assessment studies involving panels of experts (EPA, 1995; Vaughan and Spouge, 2002) have sought to quantify the potential magnitude of unlikely-but-possible scenarios under which west Antarctica makes a substantial positive contribution to sea level. Almost all of the experts have concluded that Antarctica is most likely to have a negligible contribution to sea level over the next century. Nevertheless, they all agreed that there is some risk that a catastrophic collapse of the ice sheet could occur over a couple of centuries if polar water temperatures warm by a few degrees, with a contribution of about 30 cm in the next century but more than a meter during each of the following centuries. Most of the scientists estimated that such a risk had a probability of between 1 and 5%, Because of this risk, as well as the possibility of a larger than expected melting of the Greenland Ice Sheet, the EPA study estimated that there is a 1% chance that global sea level could rise by more than 4 m (almost 14 ft) in the next two centuries. Although the IPCC (2001) did not include these extreme scenarios, they did acknowledge their scientific basis.

Glaciologists generally agree that a sustained warming of Greenland could cause an irreversible loss of the ice sheet there. Even in today's climate, the temperature at sea level is too warm for an ice sheet to persist; but most of the ice sheet is well above sea level and hence colder. IPCC (2001) reviews several modeling studies that suggest that 3°C and 5.5°C warming of Greenland temperatures would lead Greenland to contribute 1 and 3 mm/yr, respectively, over the next 1,000 years.

The rates of sea-level rise at specific locations will diverge from the global average rise, for two reasons. First, land movements caused by a variety of factors currently cause relative sea-level changes to vary from a drop of several millimeters per year in parts of Alaska and Scandinavia, to rises of more than 1 cm in a few areas where groundwater pumping has accelerated the rate of sea-level rise. Second, global warming may not have a uniform effect on sea level: Changing climate may alter local sea level through changes in winds, currents, and pressure. Within estuaries, changes in rainfall and evaporation may cause the mean tide level to diverge from the trends in the open ocean. Moreover, the earth's center of gravity would migrate away from the polar ice sheets if their ice was discharged into the oceans.

Regional climate change: climate models. Projecting the change in climate for particular regions is more difficult than estimating global warming. There is a general consensus that temperatures will warm throughout the United States. However, scientists are unable to say whether particular regions will receive more or less rainfall; and for many regions they are unable to even state whether a wetter or a drier climate is more likely.

Virtually all published estimates of how the climate could change in the United States are the results of computer models of the atmosphere known as "general circulation models." These complicated models are able to simulate many features of the climate, but they are still not accurate enough to provide reliable forecasts of how the climate may change; and the several models often yield contradictory results. For the time being, however, these models are about all we have to say how the climate may change in particular areas. This leaves many researchers with a rather unsatisfactory situation: the climate models have been reviewed as acceptable descriptions of global climate with explicit provisos that one should not use their results to protect regional climate change; but those who want to analyze site-specific impact of greenhouse gases invariably use them anyway.

Given the unreliability of these models, researchers trying to understand the future impacts of climate change generally analyze different scenarios from several different climate models. The hope is that, by using a wide variety of different climate models, one's analysis can include the entire range of scientific uncertainty. Even this assumption probably overstates the extent to which existing scientific understanding has been quantified. *The projections of climate change in specific areas are not forecasts but are merely reasonable hypothetical examples of how the climate might change.*

Regional temperatures

The historical temperature record shows that a rise in the global average temperature does not automatically imply that every part of the world warms. The cooling from sulfates may offset the warming in some areas. Moreover, natural fluctuations in the jet stream and other factors often can cause some areas to be unusually cool when others are warm. During the summer of 1988, for example, when the eastern United States suffered severely hot and dry weather, cold relatively deep ocean water began to flow to the sea surface off the mid-Atlantic Coast, keeping the coastal zone unusually cool. Scientists have not ruled out the possibility that global warming could induce such shifts, which could lead to little or no warming in some areas while other areas warm by much more than the 1.0–3.5°C (3–8°F) expected for the world as a whole.

One of the most seriously discussed regional shifts in climate concerns the Gulf Stream, which keeps northern Europe much warmer than the parts of Canada, United States, and Russia at similar latitudes. The current is largely propelled by the sinking water in the North Atlantic off the coast of Greenland. The warm Gulf Stream waters evaporate more, and have higher salinity levels, than the surrounding ocean. At the middle latitudes, the warm saline water remains at the surface because the higher temperature more than offsets the density increase caused by high salinity. At higher latitudes, however, the cold polar climate cools all the water to within a few degrees of freezing. With all the water at approximately the same temperature, the more saline Gulf Stream water sinks. Many climate models, however, predict that warmer temperatures will increase rainfall over the Gulf Stream enough to reduce its salinity, which may reduce the amount of sinking water, and weaken the current. The possibility of a sudden shutdown of this deepwater formation cannot be ruled out. Such a shutdown would cause Europe to cool even while the rest of the earth warmed!

The region of the United States that has been the most thoroughly examined is the area from 35°W to 50°N and 85°N to 105°W. Climate model results suggest that if global temperatures warm 2.6°C, the combined impact of aerosols and greenhouse gases is likely to warm this region approximately 1.5–3.5°C (3–6.5°F) during winter. The same models suggest, however, that summer temperatures will warm between 0°C and 0.5°C (less than 1°F). Our actual uncertainty for future temperature change is probably at least twice as great as these ranges suggest, because global warming is also uncertain.

Regional and hydrology

Water resources are sensitive both to rising temperatures and changes in precipitation. Although scientists expect global temperatures to rise approximately 0.5 to 1.5°C (1–3°F) by the year 2050, most climate models suggest that warming over land will be greater than the warming over the sea. Because higher temperatures increase evaporation and plant transpiration, rainfall would generally have to increase just to maintain current levels of water availability. Holding other factors constant, the potential for evaporation and transpiration increases about 5–10% per degree (C) throughout most of the United States (Waggoner and Revelle, 1990).

There is a general consensus that annual worldwide precipitation and evaporation will increase a few percent for every degree of warming; this prediction is consistent with current trends. But there is considerably less certainty about rainfall in particular locations, and whether the rainfall will increase enough to offset the increased evaporation. Many scientists, however, believe that middle latitudes such as that of the United States will see drier summers. Assuming that the land warms more than the sea, evaporation over the land will increase by more than the evaporation over the sea that produces rainfall. Thus, summer rainfall may not increase by as much as evaporation.

For specific locations, however, it is currently impossible to confidently project even the direction, let along the magnitude or timing, of the seasonal or even annual changes in precipitation. In the Central North American region, most models estimate that rainfall will increase approximately 10% during winter, but the models disagree about whether summer rainfall will increase or decrease. The scenarios that show an increase in precipitation also project warming of 4–5°C (7–9°F), which would generally cause evaporation to increase by 20–50%. Thus, the models generally suggest that summers in the United States will be drier.

Whether or not annual or seasonal rainfall increases, many climate models project that rainfall will occur in a smaller number of heavier storms. The intensity increase would result both because the warmer atmosphere holds more water vapor, and because greenhouse gases increase the radiative cooling in the upper atmosphere, which induces intense rainstorms. Several models project that even if summer rainfall in the mid-western US declines slightly, heavy rainstorms would occur about twice as often. The National Center for Atmospheric Research also expects fewer but heavier rainstorms. Data on existing trends are consistent with this general prediction.

Climate modelers have long suggested that drought may also become more severe in the mid-latitudes. Scientists at NASA have suggested that in the long run, a worldwide expansion of deserts is likely (Rind *et al.*, 1990). Today, deserts tend to be found at latitudes between 20° and 32°, where potential evapotranspiration is generally greater than the average rainfall. The NASA study showed that with a 4°C warming, the potential evapotranspiration would increase 30–40%, while precipitation would only increase 10–15%. Even in the nearer term, deserts may expand. Land areas are likely to warm more rapidly than the oceans; so evaporation on land is likely to increase more than evaporation from the oceans. Because oceanic evaporation ultimately drives precipitation, it follows that evaporation would be likely to increase by more than precipitation in most continental areas. Most of the recent model studies have confirmed this early NASA result (IPCC, 2001).

Storms

Hurricanes require water temperatures of at least 79°F (26°C) to form. They often gain energy when they cross warm currents such as the Gulf Stream, and lose energy when crossing cooler waters. Therefore, scientists and popular accounts of global warming have long suggested the potential for global warming to increase both the frequency and intensity of hurricanes. Nevertheless, hurricane experts seeking to verify this risk have generally questioned such a presumption. First, there is no evidence that hurricane frequency or intensity has been increasing as global temperatures warmed during the last century. Second, hurricanes also require that wind sheer be minimal. Wind sheer tends to be high in the Atlantic and low in the Pacific during El Nino years, which many models suggest will occur more frequently as global temperatures warm. Finally, hurricanes tend to occur more frequently when the Gulf

Stream and other major ocean currents are strongest; as mentioned above, many scientists expect these currents to weaken as the earth warms. Putting all of these factors together, IPCC (2001) concluded that we simply cannot say whether hurricanes will become more or less frequent; but that a modest intensification from those that do occur seems likely.

Extratropical storms such as northeasters seem likely to decline in frequency, because of the reduction in the temperature difference between the poles and the equator that is generally expected to occur. But the intense storms caused by deep low-pressure may become more severe, because these lows are exacerbated by the latent heating associated with increased evaporation at higher temperatures.

Implications for the coastal zone

The foregoing discussion suggests that global warming is likely to alter many of the environmental conditions in the world's coasts. Warmer temperatures will lead plant and animal species to move into what are now cooler areas. Such migrations will be relatively easy for migratory birds and fish that swim along the oceans; but it may be more problematic for corals which require a particular substrate, or fish that inhabit the northern Gulf of Mexico and thus are unable to swing any farther north. People whose vacation habits are motivated largely by climate may be among the most rapid species to adapt. Intense rainstorms may increase pollution runoff, while longer droughts may increase salinities in estuaries. The changing storm patterns may increase or decrease wave-driven beach erosion. The many impacts of sea-level rise are discussed in *Sea-Level Rise, Effect*.

Will these changes be rapid enough to matter to most people who inhabit the coastal zone, or do they merely constitute a changing background condition that must be considered by scientists and engineers but not the public at large? The available research suggests that sea level is already rising rapidly enough to matter to those who inhabit the most vulnerable areas, and so the accelerating rise is bound to be relevant to an increasing fraction of the world's coastal inhabitants. Rising temperatures are starting to have some effects, but it is far from clear what—if anything—people can do about them. The big unknown remains the possible changes in hydrology and storminess. No one knows whether those changes will be good or bad, or whether they will be gradual like sea-level rise or so sudden that by the time we know for sure what to expect, it will have already happened.

GROSS TRANSPORT

Gross transport refers to the total movement of sand approximately parallel to the shoreline over a specified period, often one year (see entries on *Cross-shore Sediment Transport* and *Longshore Sediment Transport*). Waves approaching the shore at an oblique angle, such that the crests of the breakers are at an angle to the shoreline, generate longshore currents that convey the mobilized sand along the shore. In many locales, the wave approach direction varies over time such that this transport can be in either direction relative to the shoreline (see entry on *Waves*). Consequently, sand may move upcoast for an interval and then, as wave conditions change or the lesser effects of tidal or wind-driven currents intervene, reverse direction and move downcoast. Gross transport amounts or rates account for all transport regardless of direction. The units of gross transport are typically volumetric rates (cubic meters per year).

There are difficulties associated with estimating gross transport. First, an estimate requires comprehensive sets of data collected over long periods. These would typically include the height and the direction of breaking waves measured for long enough intervals to average out the randomness and often enough to include the real variation in waves brought about by changing atmospheric forcing. No autonomous method for measuring either the height or the angle of breakers has been developed. However, a technique for making autonomous measurements outside the surf zone and converting them to equivalent values for calculating longshore transport has been developed (Seymour and Higgins, 1978). Finally, the models for longshore transport are rudimentary and can result in estimates with very large errors, even when quality wave data are available. Only occasionally, special conditions exist that will allow direct measurement of gross transport (Seymour *et al.*, 1981). One such condition is the construction of a jettied entrance that will function for a sufficiently long period as an effective trap for longshore transport in both directions.

The significance of gross transport to coastal engineers is related to understanding the fate of beach sand in the presence of some mechanism for sequestering or otherwise removing sand from the system. In other instances, the coastal engineer is usually concerned with the difference between the upcoast and downcoast transport (see entry on *Net Transport*). Entrances to tidally influenced bays or lagoons along sandy coasts will typically form shoals offshore and inshore of the entrance channel. These shoals can impound very large quantities of sand. If a new entrance is constructed (see entry on *Navigation Structures*) coastal engineers must be concerned with the impact on the adjacent beaches during the formation of these shoals. The availability of sand to form shoals is a function of the local gross transport so that this value is useful in determining strategies for remediation. Further, dredging of shoals in natural or constructed inlets may be required before they reach their equilibrium extents in order to maintain safe navigation channels. Again, the rates at which these channels will refill are a function of the gross transport. These data are useful in estimating the frequency and cost of dredging operations

Narrow continental shelves often contain submarine canyons (see entry on *Continental Shelf*). These underwater valleys often extend from close to the shore to great depths beyond the shelf. It is generally agreed that these canyons have been formed over geological time by erosion from episodic sand-laden gravity-driven flows (Heezen and Ewing, 1952). The presence of huge depositional fans at the canyon outlets indicates that these features can function as significant loss mechanisms for beach sand. The canyon head, near the shoreline, fills with sand delivered by longshore transport. Typically, the canyon will fill during strong longshore transport events regardless of their direction. Thus, gross transport rates provide an indication of the potential for losses at submarine canyons, which could have significant effects on the c ondition of associated beaches.

GROUND-PENETRATING RADAR

Originally designed for the purpose of environmental and geotechnical investigation of the shallow subsurface, the ground-penetrating radar (GPR) is a high-resolution geophysical technique which is being successfully used in stratigraphic research of sedimentary sequences. GPR was instrumental in imaging the internal architecture of a variety of recent geological settings: fluvial (Leclerc and Hickin, 1997; Roberts *et al.*, 1997), glaciofluvial (Beres *et al.*, 1995, 1999), periglacial (Jol *et al.*, 1996a; Busby and Merritt, 1999), aeolian (Schenk *et al.*, 1993; Harari, 1996; Jol *et al.*, 1998), and lake deltas (Jol and Smith, 1991; Smith and Jol, 1997). The application of GPR to coastal research has led to significant advances in our understanding of mesoscale (centimeters to 10's of meters) stratigraphy of marginal marine sequences and has already resulted in several radar facies models (Baker, 1991; FitzGerald *et al.*, 1992; Jol *et al.*, 1996b; van Heteren *et al.*, 1996, 1998; Smith *et al.*, 1999; Buynevich and FitzGerald, 2000; FitzGerald *et al.*, 2000). Knowledge of the principles and limitations of the GPR technique in coastal settings is essential if accurate and complete models of large-scale coastal development are attempted. A general introduction to the GPR method and discussion of its applications to coastal stratigraphic research are presented here.

Theoretical background and methodology

Ground-penetrating radar method is in many ways similar to seismic-reflection profiling, except that it uses electromagnetic (EM), rather than acoustic, waves with the frequency range of 10–2,000 MHz. The behavior of the EM waves, governed by Maxwell's equations, is controlled by such factors as the material's electric conductivity, magnetic permeability, and dielectric permittivity. The first two parameters control the attenuation and ultimately the penetration depth of the EM signal. Highly conductive (less dielectric) materials resulting in signal dissipation and loss. Sensitivity and frequency of the antenna, as well as the gain setting on the control unit also control the penetration and resolution of the GPR record (Figure G24; Davis and Annan, 1989; Conyers and Goodman, 1997; van Heteren *et al.*, 1998).

Dielectric permittivity is the ability of a material to become polarized and respond to incoming EM waves (von Hippel, 1954). Relative dielectric permittivity (ε_r) is a dimensionless constant which is obtained by comparing the permittivity of a particular material with that of a vacuum (which is one). This parameter controls the velocity of EM waves and is inversely related to it:

$$v = \frac{c}{\sqrt{\varepsilon_r}}, \qquad \text{(Eq. 1)}$$

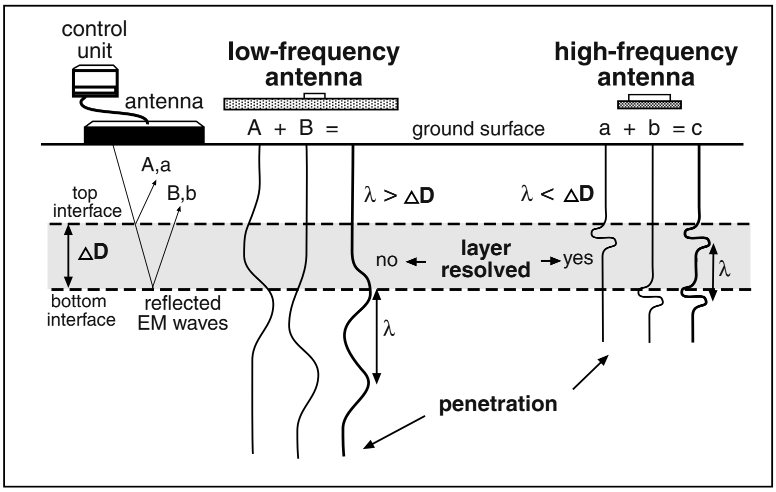

Figure G24 Generalized diagram depicting the differences in resolution and penetration depth for the low- and high-frequency antennae. Low-frequency wave (A) defines the top interface, but the distance between the interfaces (ΔD) is less than the wavelength (B). The relatively long wavelength (λ) of the resulting EM signal (C) does will not resolve both interfaces. A high-frequency EM wave defines both the top (a) and bottom (b) interfaces. The resulting wave (c) is shorter than the distance between the two interfaces. The penetration in this case, however, is less than with a low-frequency antenna (modified after Conyers and Goodman, 1997).

Table G7 Relative dielectric permittivity (ε_r) of common earth materials

Material	ε_r
Air	1
Ice	3–4
Freshwater	80
Seawater	81–87
Sand	
Unsaturated	3–7
Saturated	20–32
Unsaturated, with gravel	3.5–6.5
Saturated, with gravel	15.5–17.5
Silt	
Unsaturated	2.5–5.0
Saturated	20–30
Clay	
Unsaturated	2.5–5.0
Saturated	15–40
Bedrock	4–15

where v is the velocity measured in nanoseconds (1 ns $= 10^{-9}$ s) and c is the speed of light (0.2998 m/ns). Typical values of relative dielectric permittivities for common geological materials are presented in Table G7. The magnitude of a particular subsurface reflection is directly related to the difference in dielectric properties of the two subsurface materials. From equation 1, the velocity of EM waves ranges from about 3 cm/ns in water to 30 cm/ns in air. Therefore, the groundwater table commonly appears as a strong sub-horizontal reflector on the radar trace. Above it, the unsaturated portion of the sedimentary sequence with lower permittivity values will be penetrated more readily by the radar signal. Consequently, a greater thickness of dry sediments can be represented on a particular record, compared with the part of the sequence below the water table, and will have a lower vertical exaggeration than the saturated portion. Once the velocities of EM waves or dielectric constants of specific lithologies (both saturated and unsaturated) are established and the time (t, ns) is obtained from the record, the approximate depth (D) to a particular target layer may be calculated using the two-way travel time between the ground surface and the layer in question, or between two layers as:

$$D = \frac{vt}{2} = \frac{ct}{2\sqrt{\varepsilon_r}}. \qquad \text{(Eq. 2)}$$

Sediment characteristics that affect the subsurface behavior of EM waves include pore-water and clay mineral content and their chemical composition, as well as magnetic properties of constituent minerals (Topp *et al.*, 1980; van Heteren *et al.*, 1998). High concentrations of ferromagnesian ("heavy") minerals (e.g., magnetite, ilmenite, garnet) that form as storm-lag deposits on beaches often produce prominent reflectors on GPR records. In some cases these sedimentological anomalies, as well as thick iron-stained horizons, may have high enough magnetic permeability values such that they attenuate the magnetic portion of the EM signal and preclude further penetration (Topp *et al.*, 1980).

Ground-penetrating radar profiles taken over areas with substantial relief need to be topographically corrected. This arises from the fact that the ground surface on the time-record output is represented as the horizontal surface. For example, on a profile taken over a dune, the dune surface will be depicted as a horizontal reflector and (sub-)horizontal layers of the under-lying sequence (e.g., dune/beach contact, washover deposit, peat horizon) will appear as concave-upward reflections (i.e., the mirror images of dune topography). For short segments of the trace, groundwater table, if present, may be assumed (or determined) to be nearly horizontal and thus aid in correcting the record.

The radar data are commonly collected in either step mode or continuous mode. In the step mode, the source of the signal (transmitter) and the receiver are placed on the ground, and after the reading is obtained, moved to the next location. Continuous mode involves the unidirectional movement of both transmitter and receiver (usually housed within one antenna box). The cart-mounted GPR system allows rapid collection of continuous traces over large areas and has proven to be an effective method of subsurface data collection. In recent years, the advances in radar technology and software have improved the resolution and processing of the field data. Using a series of parallel, closely spaced transects, a three-dimensional image of the subsurface, as well as plan-view time slices that correspond to various depths, can be obtained (Beres *et al.*, 1995, 1999; Conyers and Goodman, 1997). Most recently, a combination of time-domain reflectometry and sediment peels have been used by Van Dam and Schlager (2000) to identify the reflector-producing horizons and construct synthetic radar traces analogous to synthetic seismograms. Because the description and analysis of sedimentary facies on GPR records are similar in many ways to seismic-stratigraphic attributes (e.g. reflector configuration, frequency, continuity, etc.), the onshore records of the barrier lithosome can be integrated with the available nearshore and offshore seismic reflection profiles (van Heteren *et al.*, 1998).

Limitations of the techniques

The most obvious limitation of a specific GPR system setup are the penetration depth and resolution. Both of these attributes depend on the choice of the antenna, which is in turn governed by the research objectives (Jol, 1995; Smith and Jol, 1995). Figure G24 shows that the top and bottom interfaces of a subsurface layer can only be resolved if these are separated by at least one wavelength of the radar signal (cf. Davis and Annan, 1989). High-frequency antennae (500–2,000 MHz) are smaller in size and provide high resolution at the expense of relatively limited penetration (commonly less than 8–10 m). Antennae with frequency range of 12.5–50 MHz have poor resolution, but allow for a maximum probable penetration of 45–65 m (Smith and Jol, 1995). The optimal antenna frequencies for stratigraphic research are 100 MHz or 120 MHz, which allow penetration of 15–20 m (deeper in unsaturated sequences), while still providing high-resolution images.

One of the important considerations in GPR research is the attenuation of the EM signal by brackish to salty groundwater due to its high conductivity. As a result, sections of many profiles adjacent to a beach or backbarrier margin, or deeper portions of profiles affected by saltwater intrusion are often reflection-free (van Heteren *et al.*, 1998). In some locations, the barrier is wide enough such that most of the stratigraphy can be imaged by GPR without attenuation. Besides seawater, increase in clay content drastically increases conductivity thereby reducing or precluding signal penetration. The top of the clay unit itself, however, often appears as a strong reflector on the radar trace. As mentioned above, sedimentary deposits with high magnetic permeability may also limit signal penetration, while themselves providing strong reflectors. Aside from sedimentological characteristics, the distortion and amplitude change of the EM waves as they propagate into the earth may reduce the accuracy of the final depth/distance calculations.

Due to inherent differences in sediment properties from site to site, the velocity of EM waves may also vary (Davis and Annan, 1989; van Heteren *et al.*, 1996). The velocity values for a particular site may be calibrated through common mid-point analysis (Jol and Smith, 1991) or by measuring the depth to specific marker horizons in sediment cores and calculating velocity values from equation 2. In general, unless the geology of a study site is well known, sediment cores should be taken along the GPR profile to interpret the major reflectors. In turn, the radar images of dipping subsurface horizons (e.g., buried marsh layer, sloping bedrock surface, tidal inlet channel) may be used to maximize the coring effort by planning a core site in the area where the depth to a target reflector is minimal.

Examples of GPR images from coastal environments

Styles of barrier progradation

Many coastal areas have experienced progradational (seaward) growth. Geomorphic expression of this process, such as a series of beach ridges is often used to determine the origin, magnitude, orientation, and chronology of barrier growth (Tanner, 1995). However, in many cases dense vegetation, parabolic dune migration, or human development have modified or obscured the surface expression of barrier growth (Figure G25(A)). In such areas, subsurface records, complemented with sediment cores, may provide the only means of analyzing the erosional–depositional history of a barrier. In many instances the progradational of a barrier may be punctuated by erosion and shore retreat. At these sites, there may be no distinct morphological evidence of an erosional event, except occasional washovers or dune and berm scarps confined to the youngest portion of the barrier. These features, particularly in the earlier constructional history of the barrier, are often preserved as buried accumulations of coarse-grained sediments or heavy-mineral horizons that are rarely detected in the field. Such lithological anomalies may be observed in sediment cores, but their

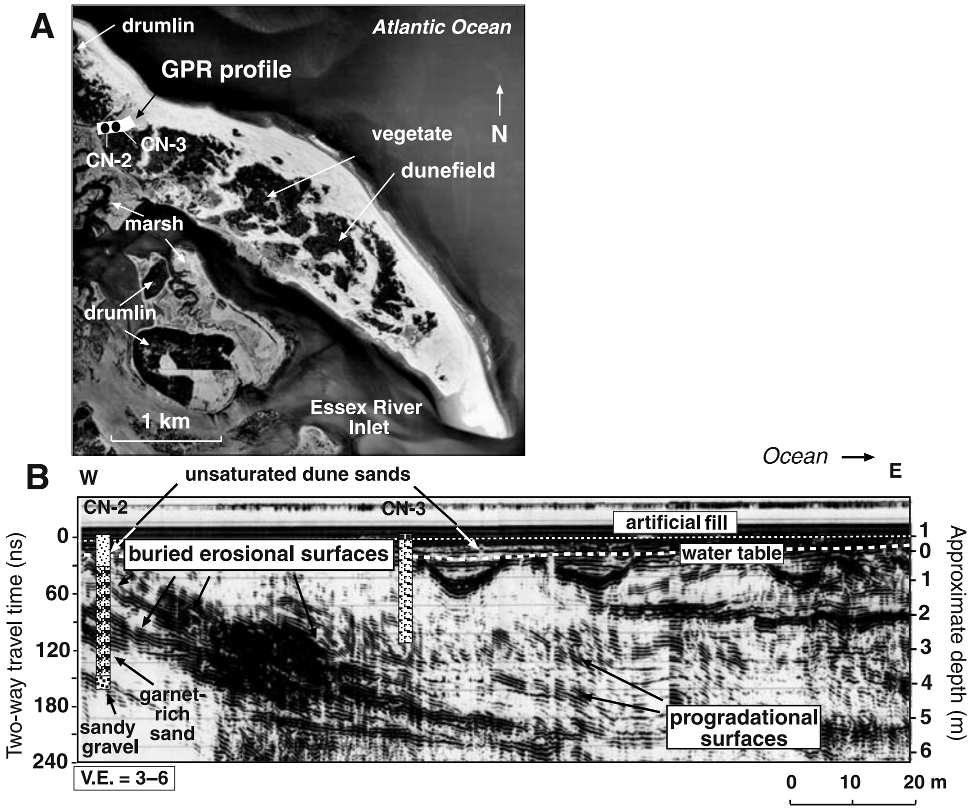

Figure G25 (A) Vertical aerial photograph of Castle Neck Barrier, Massachusetts, dominated by vegetated parabolic dunes. Note the absence of beach ridges. (B) Shore-normal GPR transect taken across a parking lot reveals a series of strong seaward-dipping reflectors in the landward segment of the GPR trace giving way to a sequence of less prominent, nearly uniformly spaced reflectors in a seaward direction. Sediment core CN-2 penetrated several layers of concentrated garnet-magnetite sands interbedded with quartz-rich units. All records are taken as a continuous trace with a 120 MHz antenna. See text for discussion.

geometry and continuity can only be confirmed in geophysical records (Figure G25(B)). For example, the GPR profile in Figure G25(B) illustrates a series of prominent tangential-oblique reflectors that represent buried erosional beach face and berm scarps. They grade into uniformly spaced sigmoidal-oblique reflectors in a seaward direction, which mark a period of increased sediment supply (Buynevich and FitzGerald, 2000).

Geometry of tidal inlet paleo-channels

Channel-fill sequences of tidal inlets may comprise a significant portion of the barrier lithosome and, in some instances, the locations and dimensions of former inlet channels can be detected with GPR. Mixed-sediment barriers are ideal for the recognition of inlet-fill structures. Due to large contrast between the coarse-grained channel lag and finer-grained channel-fill deposits, the outline of the channel often appears as a prominent concave-upward reflector. Figure G26 shows a paleo-inlet channel that has migrated along a retrograding, sand-and-gravel barrier as evidenced by a series of northward-dipping reflectors. Eventually, the inlet stabilized in one location and was infilled by sediment from a seaward source recorded as subhorizontal reflectors within the paleo-channel. Using GPR profiling, the locations of the former inlets can be mapped and compared with historical maps, where available. At least 18 historical inlets were mapped along Duxbury Beach, Massachusetts, where none exist today (FitzGerald *et al.*, 2000). In addition, such elements of inlet channel geometry as depth, width, and approximate length (using a series of records) can be determined. The elevation of the paleo-inlet channel relative to present sea level can also be estimated.

Stratigraphy of coastal lakes

Freshwater lakes and ponds of various origins (closed lagoons, glacial depressions, dune swales, deflation basins, etc.) are common features along many coasts. Their sedimentary fills serve as archives of depositional events that result from climatic, oceanographic, and geomorphic changes in coastal regions. Shifts from organic- to clastic-dominated deposition result in a sequence of interbedded layers with distinct lithological and dielectric properties, making these systems suitable for GPR research. Figure G27 shows a shore-normal transect taken across an ice-covered coastal lake. A steeply dipping reflector representing the bedrock surface can be traced to a depth of over 7 m below the lake surface. The seaward portion of the trace shows the margin of the barrier dunefield as a landward-dipping surface with several basinward-dipping internal reflections. Below the flat lake-bottom reflector, a sequence of wavy reflectors can be traced across the profile. These represent muddy, organic-rich lake-bottom sediments interbedded with aeolian sands. A prominent convex-up reflector with a transparent core is indicative of a buried dune. This interpretation is based on similar reflector configuration observed on the lake bottom adjacent to a recently migrating dune.

Summary

Ground-penetrating radar has proven to be a valuable tool for high-resolution imaging of antecedent geology, stratigraphy, and hydrogeology of coastal systems. Although saltwater attenuation presents a significant limitation in coastal lowlands, areas with moderate to high rainfall and relatively good sediment permeability often contain considerable freshwater lenses (5–20 m) which ensure good penetration of EM signal. Varying degrees of textural and compositional heterogeneity of sediments in many coastal sequences produce the lithological contrast necessary to generate subsurface reflections. These systems provide excellent natural laboratories for effective and detailed stratigraphic analysis using GPR profiling supplemented with sediment cores. Such studies have already significantly improved our knowledge of coastal development over a wide range of temporal (years to millennia) and spatial (centimeters to 10's of kilometers) scales and served to emphasize the complexity of coastal processes and resulting stratigraphic records.

HEADLAND-BAY BEACH

A headland is defined in common language as: (1) a point of usually high land jutting out into a body of water: promontory; (2) high point of land or rock projecting into a body of water. Therefore, a headland-bay beach is a beach whose shape is mainly conformed by the fact that it is located between such headlands, or at least adjacent to one. Some of the synonymous terms that can be found in literature to describe a headland-bay beach are: bay-shaped beach, pocket beach, zeta bay, bow-shaped bay, and half-heart bay. This type of feature shows a gradually changing curvature which Krumbein (1944) noted resembled that of a logarithmic spiral curve.

Johnson (1919) gave an incisive description of wave refraction caused by headlands along an embayed coastline, and Krumbein (1944) showed a simplified diagram of wave refraction into a bay lying to the lee of a headland. According to Yasso (1965), a headland was considered to be any natural or artificial obstruction that extended seaward from the coastline and caused a change in some element of the coastal wave pattern because of its presence.

Historical development

Observations of headland beach morphology in nature

Krumbein (1944) was the first author to describe a beach planshape—Halfmoon Bay, California (USA)—as being similar to the increasing radius of curvature found in the logarithmic spiral, although the restricted classification was removed some years later and the paper was reprinted in 1947. Yasso (1965) selected four US beaches for testing goodness of fit to the logarithmic spiral approximation. Poles for three of the best- fitting logarithmic spirals were located in close proximity to the seaward end of each headland. The spiral angle α was found to range between 41.26° and 85.64°. Berenguer and Enríquez (1988) reviewed data from 24 beaches around Spain and derived empirical correlations between geometrical characteristics of the layout of the offshore breakwaters and beach planshape. Moreno and Kraus (1999) performed fittings of analytical planshapes to a data set of 46 beaches in Spain and the United States and derived preliminary engineering design guidance including the proposal of a new functional shape.

Observations of headland beach morphology in the laboratory

Silvester (1960) tracked the time evolution of a beach in a physical model and observed that the beach between headlands tended to reach an equilibrium shape—logarithmic spiral shape—in response to persistent swell directions under a certain wave angle of attack. The model coastline was allowed to erode without replenishment of sand at the updrift end. Yasso (1965) pointed out that the conditions of Silvester's physical-model test (lack of continuous sediment supply to the updrift end of the model and close spacing of the headlands) suggested that the equilibrium form achieved in the model may not be identical to that achieved under natural conditions of sediment supply and wider separation of headlands.

Silvester (1970) performed additional model tests in which three different wave conditions were generated at three different angles of incidence to the alignment of a headland on an initially straight sandy beach. It was observed that the coastline developed three distinct curvature zones: first, a near circular section in the lee of the upcoast headland; second, a logarithmic spiral; and finally, a segment tangential to the downcoast headland. The time evolution of the spiral constant angle was plotted for the three incident wave angles tested, but only one wave condition was run long-enough as to see an asymptotic trend. A graphical linear relationship between the logarithmic spiral constant angle α and the wave angle β was provided based on the three angles tested.

Spătaru (1990) studied Romanian Black Sea beaches subjected to normal wave incidence by means of physical models. Equilibrium beach planshapes were considered to be described by arcs of circumferences, and provided design guidance based on geometry.

Numerical model approaches

Mashima (1961) constructed wave-energy diagrams from wind-rose diagrams and studied the configuration of stable coastlines based on energy considerations. When the wave energy is a semi-ellipse, the configuration of the stable coastline is approximately parabolic on which the tangent direction at the apex of the parabola coincides with the direction of the major axis of the wave-energy diagram.

LeBlond (1972) attempted to study how wave-induced longshore currents in the presence of a headland could erode a linear beach by developing a numerical model. LeBlond (1972) stated that if there existed a planimetric shape which the headland beach asymptotically approached, it must have the following properties: (1) it should be concave outwards, near the headland, and then convex outwards. (2) the sand transport should increase monotonically along it. (3) erosion, by causing the beach to be displaced normal to itself, should not qualitatively change the shape of the beach. LeBlond also pointed out that the logarithmic spiral did not satisfy the first condition because it is always concave outwards, and that there may be other curves satisfying all of the above three conditions, and one could not decide "*a priori*" which one will be the equilibrium one.

The main modification implemented by Rea and Komar (1975) with respect to previous numerical modeling efforts, was the combination of two orthogonal one-dimensional grids to simulate beach configurations, so that beach erosion could proceed in two directions without the necessity of a full two-dimensional array. Testing of the model in a hooked beach coastline configuration indicated that the coastline would always attempt to achieve an equilibrium configuration governed by the pattern of offshore wave refraction and diffraction and the distribution of wave-energy flux.

Walton (1977) presented an analytical model to describe the equilibrium shape of a coastline sheltered by a headland using a continuous wave-energy diagram consisting of representative offshore ship wave height and direction observations. It was found to produce coastline shapes similar to the logarithmic spiral shape for sheltered beaches in Florida. The model worked by establishing that the coastline orientation at a certain point was normal to the average direction of the so-called energy of normalized wave attack—that is, the energy which is allowed by the headland to reach the shore.

Yamashita and Tsuchiya (1992) constructed a numerical model for three-dimensional beach change prediction to simulate a pocket beach formation. The model consisted of three modules to calculate waves, currents, and sediment transport and beach change. The wave transformation module was based on the mild-slope equation of hyperbolic type; the current module was horizontally two-dimensional with direct interaction with sea-bottom change, which was evaluated by the sediment transport model formulated by Bailard (1982) in the third module.

In a theoretical work on the subject of headland-bay beaches, Wind (1994) presented an analytical model of beach development, where the shape of the headland-bay beach remained constant with time and expanded at a rate according to a time function. Wind's (1994) conceptual framework was based on knowledge of the existence of a headland-bay beach shape centered around a pole and that evolved in time in a more or less constant shape. If the position of the coastline is described by the radius r, the angle δ, and time t, the evolution of the coastline with a constant shape implies that the coastline might be described as

$$r(\delta, t) = r_0 f(\delta)\, e(t) \qquad \text{(Eq. 1)}$$

where r_0 is the constant, $f(\delta)$ is the shape function, and $e(t)$ the evolution function of the coastline in time. With respect to the time function, it was shown that in the diffraction zone it should follow a $t^{1/3}$ law, whereas for the refraction zone a $t^{1/2}$ law was found. This implied that the evolution of a headland-bay beach in the diffraction zone should initially be faster and on the long term, slower than the evolution in the refraction zones. With respect to the shape, the function shape $f(\delta)$ is expressed in terms of functions representing the diffracted wave field. The logarithmic spiral is obtained by taking the functions for the group velocity and the geometrical part for the driving force as constants.

Equilibrium planshapes of headland-bay beaches

Three functional shapes have been proposed to describe the equilibrium planshape of headland-bay beaches, namely the logarithmic spiral shape, the parabolic shape, and the hyperbolic tangent shape.

The *logarithmic spiral* (also named equiangular, or logistic spiral), first described by Descartes, was described as the curve that cuts radii vectors from a fixed point O under a constant angle α (Figure H1). The equation of the logarithmic spiral can be written in polar coordinates as

$$R = R_0\, e^{\theta \cot \alpha} \qquad \text{(Eq. 2)}$$

where R is the length of the radius vector for a point P measured from the pole O, θ is the angle from an arbitrary origin of angle measurement to the radius vector of the point P, R_0 is the length of radius to arbitrary origin of angle measurement, and α the characteristic constant angle between the tangent to the curve and radius at any point along the spiral. The pole of the spiral is identified as the diffraction point (Silvester, 1960; Yasso, 1965), and the characteristic angle of the spiral is a function of the incident wave angle with respect to a reference line. For headlands of irregular shape and for those with submerged sections, the diffraction point cannot be specified unambiguously, a problem entering specification of all equilibrium shapes. The reference line extends from the approximate location of the diffraction point to a downdrift headland. This shape is extremely sensitive to variations in the characteristic angle α because the angle enters the argument of an exponential function (Moreno and Kraus, 1999), being the practical consequence that α has to be accurately defined. For engineering application four unknowns must be found: location of pole (two coordinates), characteristic angle α, and scale parameter R_0. The shape of the log spiral is controlled only by α, with the parameter R_0 determining the scale of the shape. In fact, the functioning of R_0 is equivalent to setting a different origin of measurement of the angle θ. In other words, graphically the log spiral may be scaled up or down by turning the shape around its pole.

Values of α for headland-bay beaches reported in the literature range from about 45° to 75°. As α becomes smaller, the log spiral becomes wider or more open. There are two singular values for α: if $\alpha = 90°$, the log spiral becomes a circle, and if $\alpha = 0°$, the log spiral becomes a straight line.

Various authors have noted that fitting of the log-spiral shape is difficult in the downdrift section of the beach. It is a particular concern in attempting to fit to long beaches or to beaches with one headland. However, even in these situations, a good fit could be achieved for the stretch near the headland (Moreno and Kraus, 1999).

The *parabolic shape* of a headland-bay beach was proposed by Hsu *et al.* (1987) and is expressed mathematically in polar coordinates by equation 3 for the curved section of the beach and by equation 4 for the straight downdrift section of the beach (Moreno and Kraus, 1999),

$$\frac{R}{R_0} = C_0 + C_1\left(\frac{\beta}{\theta}\right) + C_2\left(\frac{\beta}{\theta}\right)^2 \quad \text{for } \theta \geq \beta \qquad \text{(Eq. 3)}$$

$$\frac{R}{R_0} = \frac{\sin\beta}{\sin\theta} \quad \text{for } \theta \leq \beta \qquad \text{(Eq. 4)}$$

where R is the radius to a point P along the curve at an angle θ, R_0 is the radius to the control point at angle β to the predominant wave-front

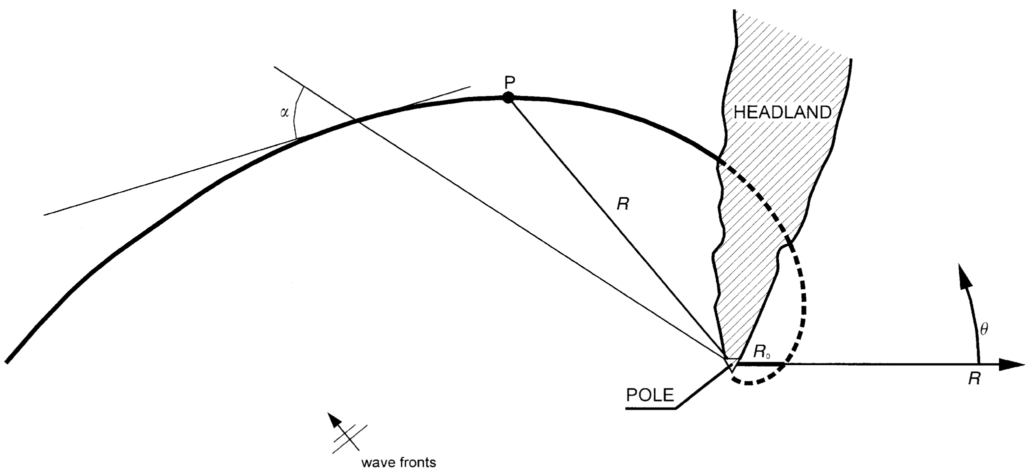

Figure H1 Definition sketch of the log spiral planshape.

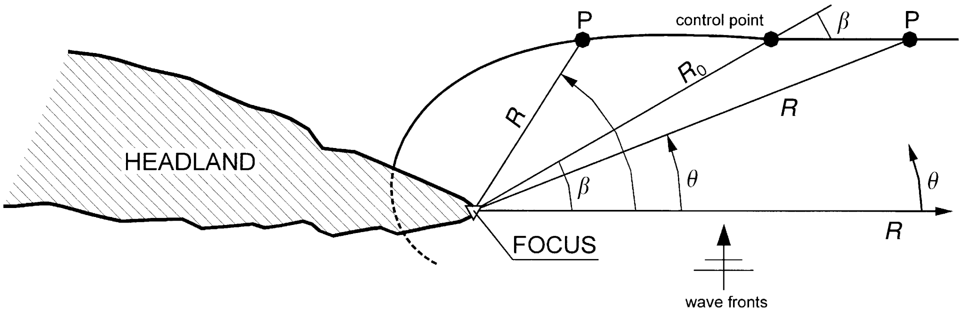

Figure H2 Definition sketch of the parabolic planshape.

direction, β is the angle defining the parabolic shape, θ is the angle between line from the focus to a point P along the curve and predominant wave-front direction; and C_0, C_1, and C_2 are the coefficients determined as functions of β—the coefficients C_0, C_1, and C_2 are listed in Silvester and Hsu (1993) form from β = 20° to 80° at a 2°-interval (Figure H2).

For this parabolic shape, the focus of the parabola is taken to be the diffraction point. The three coefficients needed to define the shape (see Silvester and Hsu, 1991, 1993) are functions of the predominant wave angle with respect to a control line. The control line is defined similarly to the case of the log-spiral shape as the line that extends from the diffraction point to a reference point, at an angle β between the control line and the predominant wave crest orientation. Downdrift of the reference point, the coastline is assumed to be aligned parallel to the incident wave crests. This shape pertains to that of a long straight beach with shape controlled by one headland. Values of β ranged in prototype beaches from 22.5° to 72.0°, whereas the variation in model beaches was from 30° to 72°.

Sensitivity tests were performed (Moreno and Kraus, 1999), where the response of the parabolic shape to a change in the value of the characteristic angle β and of R_0 was analyzed. The results proved that R_0 is a scaling parameter—the length of the control line, the alongshore extent of the shape decreases as β increases because the parabolic shape is defined only for θ ≥ β. In summary, the angle β controls the shape of the parabola, and R_0 controls its size. Because the control line intersects the beach at the point where the curved section meets the straight section of the beach, the sensitivity of the parabolic shape to errors in the estimation of the control point was examined. This was done by jointly changing R_0 and β while keeping the distance from the headland to the straight coastline constant. This observation means that the control point is not well-defined, that is uncertainty in selection of the control point and hence the corresponding joint combination the radius R_0 and β has little influence on the final result.

According to Moreno and Kraus (1999), the parabolic shape provides good fits for beaches with a single headland, because they consist of a curved section (well described by the portion of the beach protected by the headland) and a straight section (well describes the downdrift section).

González (1995) provided an improvement in the lack of definition of the location of the control point on the formulation of the parabolic shape by developing a relationship between β and the geometry of the beach and the incident wave climate according to the following equation:

$$\beta = \frac{\pi}{2} - \tan^{-1}\left[\frac{(0.1 + 0.63\,y/L)^{1/2}}{y/L}\right], \qquad \text{(Eq. 5)}$$

where y is the offshore distance from diffraction point to coastline, L the average wavelength in the lee area (between coastline and diffraction point).

For practical use of the parabolic shape, five unknowns need to be solved for: location of focus (two coordinates), characteristic angle β, scaling parameter R_0, and the orientation of the entire parabolic shape in plan view.

The *hyperbolic tangent shape* was developed by Moreno (1997) and proposed for engineering design of equilibrium shapes of headland-bay beaches by Moreno and Kraus (1999) to simplify the fitting procedure and to reduce ambiguity in arriving at an equilibrium coastline shape as controlled by a single headland (Figure H3). As mentioned above, it can be difficult to specify the location of the pole or focus, and the characteristic angle (angle between predominant wave crests and the control line) for developing a log-spiral shape or a parabolic shape. In addition, the log-spiral shape does not describe an exposed (straight) beach located far downdrift from the headland, so that another shape must be applied.

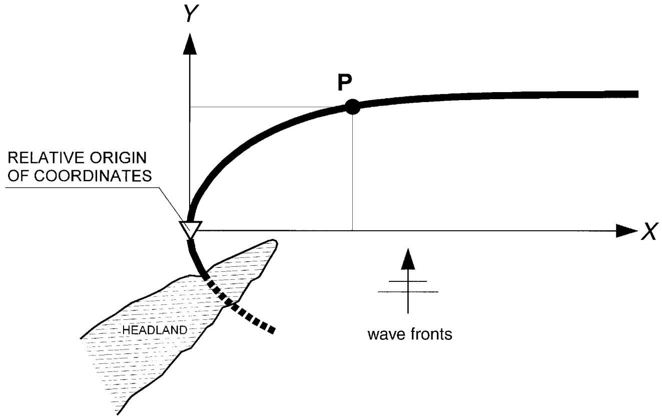

Figure H3 Definition sketch of the hyperbolic tangent planshape.

The hyperbolic tangent functional shape is defined in a relative Cartesian coordinate system as:

$$y = \pm\, a \tan \mathrm{h}^{m}(bx) \qquad \text{(Eq. 6)}$$

where y is the distance across shore, x is the distance alongshore; and a (units of length), b (units of 1/length), and m (dimensionless) are empirically determined coefficients.

This shape has three useful engineering properties. First, the curve is symmetric with respect to the x-axis. Second, the values $y = \pm a$ define two asymptotes; in particular of interest here is the value $y = a$ giving the position of the downdrift coastline beyond the influence of the headland. Third, the slope dy/dx at $x = 0$ is determined by the parameter m, and the slope is infinite if $m < 1$. This restriction on slope indicates m to be in the range $m < 1$.

According to these three properties, the relative coordinate system should be established such that the x-axis is parallel to the general trend of the coastline with the y-axis pointing onshore. Also, the relative origin of coordinates should be placed at a point where the local tangent to the beach is perpendicular to the general trend of the coastline. These intuitive properties make fitting of the hyperbolic-tangent shape relatively straightforward as compared to the log-spiral and parabolic shapes, making it convenient in design applications.

Sensitivity testing of the hyperbolic tangent shape was performed (Moreno and Kraus, 1999) to characterize its functional behavior and assign physical significance to its three empirical coefficients: a controls the magnitude of the asymptote (distance between the relative origin of coordinates and the location of the straight coastline); b is a scaling factor controlling the approach to the asymptotic limit; and m controls the curvature of the shape, which can vary between a square and an S-curve. Larger values of m ($m \geq 1$) produce a more rectangular and somewhat unrealistic shape, whereas smaller values produce more rounded, natural shapes.

To fit the hyperbolic tangent shape to a given coastline, we must solve for six unknowns: the location of the relative origin of coordinates (two coordinates), the coefficients a, b, and m, and the rotation of the relative coordinate system with respect to the absolute coordinate system. Because of the clear physical meaning of the parameters, fitting of this shape can be readily done through trial and error.

Moreno and Kraus (1999) found the hyperbolic-tangent shape to be a relatively stable and easy to fit, especially for one-headland bay beaches. According to their work, the following simple relationships were obtained for reconnaissance-level guidance:

$$ab \cong 1.2 \qquad \text{(Eq. 7)}$$

$$m \cong 0.5 \qquad \text{(Eq. 8)}$$

The physical meaning of equation 6 is interpreted that the asymptotic location of the downdrift shoreline increases with the distance between the coastline and the diffracting headland. Equations 6 and 7 are equivalent to selecting one family of such hyperbolic tangent functions for describing headland-bay beaches, and these values are convenient for reconnaissance studies prior to detailed analysis. Equation 6 could be more precisely written as:

$$a^{0.9124}\, b = 0.6060 \qquad \text{(Eq. 9)}$$

Headland-control concept of shore protection

The headland-control concept of shore protection was first proposed by Silvester (1976) and further discussed by Silvester and Ho (1972), and was described as a combination of groins and offshore breakwaters at alongshore and seaward spacings such to create long lengths of equilibrium-bay beaches (Silvester and Hsu, 1993). The structural dimensions in proportion to beach length are much smaller, and headlands are spaced much farther apart than offshore breakwaters. Therefore, it is intended to be a “regional” means of shore protection. Because headlands form pocket beaches, they might best be applied in a sediment-deficient area or for stabilizing an entire littoral reach of coast.

Headland beaches compartmentalize the coastline and reorient it in the local compartments to be parallel to the wavecrests of the predominant wave direction. If a coast has a substantial change in wave direction annually, the headland-bay beach might not be as stable as beaches behind traditional detached breakwaters, or shorter headland-bay beach compartments would be required.

A headland-bay beach design requires that a tombolo forms or be created (as by beach fill) behind the anchoring headland. If this connection is lost, the pocket beach is destroyed, and sediment can move alongshore, between adjacent compartments. Headland-bay beaches function and have their main attribute in creating independent pocket beaches, for which there is little or no communication of sand alongshore. Therefore, a headland beach presents a total barrier to littoral drift and can only be considered as a shore-protection alternative if such a barrier would not pose a problem to adjacent beaches.

The assumption that there is a single predominant wave direction which controls the final coastline shape is questionable where long distances are involved. If the design goal is to stabilize a regional extent by multiple pocket beaches, the headland-control concept might be appropriate.

HEALTH BENEFITS

Introduction

Alternative, or parallel, medicine has been steadily gaining followers and its merits have been discussed in conferences held at traditional colleges of medicine. Osteopathy, chiropractic, naturopathy, naprapathy, acupuncture, Chinese traditional medicine, aromatherapy, thermalism, thalassotherapy, and others have entered the common vocabulary for some time, some celebrating their 100th anniversary on the scene. The latter two make use of ocean algae in packs, powders, and other forms.

Thalassotherapy and thermalism are medical approaches known for thousands of years and have gained access to hospitals, private practitioners’ offices, and the hallowed halls of some universities’ faculties of medicine. Sea products are also used in balneotherapy and aromatherapy. The first is a treatment technique based on bathing—and used in both thalassotherapy and thermalism—in which plant extracts, oils, marine products (mainly salts and algae) are added to the water. Aromatherapy is more controversial; it is based on the use of organic substances (essences) with massages or in bath and steam treatments;

centers are not numerous but it is seemingly *à la mode* in Great Britain where it is offered in 24 sites; a volume handling the topic in America has been published in 1999. Thonon-les-Bains is the only French center with a comprehensive program. (Valnet, 1995).

Thalassotherapeutics [θαλασσα, sea; θηραπεια, *care, treatment*] and thermalism [θερμοσ, warm, heat] got a boost in the 19th century when tourism lifted out of its infancy. The enthusiasm displayed by prestigious visitors to "health" centers—particularly of thermalism at the time—made it possible for "*cure*" stations to associate cultural, leisure, and even gambling activities with a treatment program. Napoleon III and his empress Eugénie contributed much, albeit mostly unintentionally, to the new fashion. A journey to a "*cure*" station took on a double aspect: a visit to a place to improve or restore one's health, the avowed aim of a trip, and of tourism and discovery, the hidden aim of the voyage, because a voyage it often was: roughly 7 h by railway from Paris to Plombières or to Deauville. Today the *curist* and *tourist are commonly* both one and the same person.

Tourism has become a full-fledged activity. Both the "treatment" and the desire to know a region and its cultural traits motivate the visitor. And for a modern person in search of his "better-being" simultaneously with his "well-being" marketing specialists play it from both sides: tourism uses thalasso/thermalism as a travel theme, while the cure-station uses tourism to diversify its offer. The aim is to "twin," to link, the medical quality of "cures" to the tourists' and curists' quality of life. An effort that has also to be directed toward children who may find relief, cure, or improvement of ailments related to breathing, skin, and developmental troubles, such as enuresis, growth, and fracture healing. *Mens sana in corpore sano*: the body will heal the better if the mind is kept away from the problem: tourism may thus in some cases become a component of the curative process.

It has been often said, lately, that the tourist is increasingly in search of a "return to the sources"; this is not a legend, but fact, and water, pure clean water that is, is commonly equated with health and well-being. A concern that has not escaped the attention of the European Union's Commission (Anonymous, 1996; Charlier, 1999). Hence an increased interest in "water centers" whether Tatabanya, Baden-Baden, Mangalia, Varna, Djerba, or Le Touquet-Paris-Plage. The blossoming of the "social tourism" as a consequence of paid leave, the explosion of mass tourism and a trend to spend holidays at considerable distance from one's home-base are powerful factors in making "exotic" destinations popular and sites, such as the Black Sea, both easily conceivable in vacation planning, and also very accessible. In Brussels for instance separate offices offer exclusively "health and tourism" products: *Thalasso* for one, *Thermalism* for another, are thriving on the fashionable Avenue Louise yet are patronized by a clientele from every social and income level.

The concept of health tourism

Efforts have been made for decades in Romania to develop tourism and seawater therapeutics along the Black Sea coast. Other coastal countries in the area—Bulgaria, Russia, Ukraine—have not been lagging either. The success, in France for instance, of thalassotherapy centers has been heralded by economists, tourism officials, and many health practitioners.

Thalassotherapy, and also thermalism, is thus certainly not new. What can be new is the updating of the facilities and the introduction of new technological advances. Health tourism is a powerful development tool and is undergoing an in-depth change. Where balneotherapy and exposure to coastal climate have been essentially a re-adaptive and convalescence treatment, a constantly growing segment of the clientele is made up of younger—and middle aged—people who seek an effective approach to reshaping, the *remise en forme*, encompassing not only physical reshaping but also a health restorative process.

This involves demands on computers, equipment, personnel qualification, research, thus also retooling and refurbishing, and a fresh outlook on approach and problem-solving. Marine muds have an economic potential in muds export to other countries, for example, the Italians provide muds to Bourbonne- les-Bains, France and the Israelis ship their Dead Sea muds to Plombières-les-Bains, France.

Competitive, concurrent or concomitant?

Thermalism, thalassotherapy, and lately aromatherapy, all claim scientifically proven curative effects. An abundant literature has been published recently, for instance in France, but often strongly publicity-slanted (François, 1999). Which does not mean that several treaties have not been written long before (Jacob, 1570, Russell, 1720). Boulangé (1995, 1997a and b; Boulangé *et al.*, 1989) of the University of Nancy, and others, like Collin (1995) and Constant *et al.* (1995), have made important contributions to the field [Larivière, 1958, Lance, 1988, Hérisson, 1989, Valnet, 1995]. Both thermalism and thalassotherapy use waters, muds, and thermal gases.

If thalassotherapy is sole in using algae (but not algal mud), seawater and its "aeration," techniques, however, appear to be quite similar in thermalism and thalassotherapy. They associated at the *Thermalies* of the 17th *Salon de la Santé* at Versailles in March 1999, a congress twinned with MEDEC *Salon de la Médecine*. As for aromatherapy it has not really wrought its place in the panoply of alternative medicines; it uses a variety of oils, extracted from plants; care with aromatherapy is not thus far eligible for benefits from the social security system in France, though included in "putting back into shape" treatments in some centers, including well-known ones such as for instance Thonon-les-Bains. With the notorious exception of Belgium, thermal and thalassotherapy cures are reimbursable medical expenses in most countries of the European Union and in some others as well.

There are more than a hundred thermal cure centers in France alone not counting those of overseas departments (La Réunion and Guadeloupe); thalassotherapy centers are a least a good fifty.

France with 50 centers, leads in numbers, with Germany in second place. Other stations surround the Black Sea, and are also located in Denmark, The Netherlands, and Belgium (Ostend, Knokke). Belgium (Spa, Limelette), and Luxembourg (Mondorf-les-Bains) have famed thermal centers and it is Spa that gave its name to the cure centers. The practice of "taking the waters" is far less common in the United States where it rather faded away during the in-between World Wars period, though Saratoga Spa is still "on the map."

Historical perspective

The map of Europe is literally strewn with places where the Romans tapped thermal waters and built their famous *thermae* from *the Baths of Caracalla* to those of Trier (Trêves), Lindesina (today Bourbonne-les-Bains), or Plombières dating from before the year 100. Roman Emperor Augustus was there, and so were scores of other leading figures of history such as writers Diderot, Chateaubriand, and rulers or their relatives like Laetitia Bonaparte (Napoleon I's mother), Napoléon III, Louis XV of France, German Emperor Wilhelm II to name but a very few.

Buchet (1985), describing medicine and surgery during the 1st century in Gaul, focuses on the role of thermal waters, but use of seawater for therapeutic aims was known in what are contemporary Egypt, France, Italy, and Greece as far back as 3000 BC. Nor was thalassotherapy a stranger in the medical arsenal of classical times. The knowledge and practice was spread by Celts, Gauls, and especially Romans (Grenier, 1960; Kretzschmer, 1966; Rameau, 1980; Buchet, 1985; Anonymous, 1991; Malissard, 1994). Bath, in Britain (the Romans' Aqua Sulis) got its name from the Romans' custom. Ancient Greeks placed considerable faith in the healing power of the sea. Greek poet Euripides (480–460 BC) wrote "The sea restores man's health," Greek philosopher Plato (428–437) "The sea washes all man's ailments," and 20 centuries later historian Jules Michelet (1798–1874) opined "*La terre vous supplie de vivre; elle vous offre ce qu'elle a de meilleur, la mer, pour vous relever . . . .*" But thalassotherapy faded away in the Western world imbued with Aristotelian logic, later nurtured by Gallileo (1568–1642) and Descartes (1596–1650), more recently by Pasteur (1822–95) and physiologist Claude Bernard (1813–78) (Larivière, 1958).

Springer traces it back, in modern times, to the Margate Royal Sea-Bathing Hospital, and famed Blackpool, England, has its spot in sea-water therapy history (Springer, 1935; Charlier, 1975). Russell (1720) of England, Barelli of Italy, Perochaud (and closer to us Rivière) of France, Benecke of Germany are credited as founders of the contemporary seawater therapy while Boulangé and his coauthors act as contem-porary spokesmen for French thermal-therapy (1995a,b). Thalassotherapy is, however, no longer limited to utilization of the maritime climate, but involves administration of seawater orally and by injection, use of the spray of water, of the pounding effects of waves, of heated seawater baths, and such even newer approaches as combining electroacupuncture and sea-water therapy. The 1935 four hundred seashore sanatoria and preventoria have multiplied during the second half of this century.

While centers of marine cures are numerous in France, Germany, Belgium, Russia, Ukraine, Romania (Eforie, Mangalia), Bulgaria (Varna), Israel, little or no interest has been shown for decades in the United States and is at best stagnant in Great Britain. In intense use before the 1920s, seawater injections though credited with healing nervous and blood diseases in children, fell in disuse (Larivière, 1958).

In the late 1930s near miraculous cures of nervitis, lumbagos, cellulitis, and obesity focused anew attention on the healing effects of sea-air and seawater (Gruber, 1968). Today injections and oral administration of seawater, even in minute quantities (in wise opposition with the Russell prescriptions of large quantities!) can claim serious therapeutic effects.

Rebirth

The resurgence of interest is coupled with new concepts. One hundred fifty years ago a report ventured that "therapeutics draw good results, every day, from the use of seawater and from salt springs; and although its use in baths and tubs is often not as advantageous as when taken in the surf, when the mechanical action of the fluid is added to its chemical action, one can still expect much of this (thalassic) therapeutic application . . ." (Translation, 1856).

In the 20th century, under the influence of Freudian writings and the psychosomatic philosophical movement, medical thinking split into a traditional scientific approach and "enthropological medicine" which includes acupuncture and thalassotherapy (Range, 1958). The coincidence of timing between the renewed interest in marine cures and the growing disenchantment with current ways of life in an ever increasingly technological society may be underscored. The return to the sources' desire is, of course, part of that trend.

Thalassotherapy is neither limited to nor solely based upon use of seawater: part of the treatment is the change of lifestyle, the new surroundings, the freeing of the individual from modern life's stresses, embodying aerosol- and helio-therapy. The tiny salt particles contained in sea-air (aerosols) work their way into the deepest parts of pulmonary alveoles and settle on their walls with a probably not negligible physiological effect (Woodcock and Blanchard, 1957). The high proportion of ultraviolet seaside sun rays influences favorably calcium metabolism. That natural oligo-element and others such as magnesium, manganese and cobalt, which buttress the organism's natural defenses, are also absorbed through warm seawater baths. Its biochemical properties make it a successful side-effect-free substitute for comfort medications.

Heated seawater causes a dilatation of cutaneous vessels and under water jet streams has the same beneficial effects as the pounding of the waves against the body and its spraying by sea foam. The initial shock of cold water in swimming pools has been looked at as a potential negative factor, particularly for older persons. However, most centers swimming pools are now adequately heated and wave machines provide the beneficial pounding.

Physiological effects of marine climates are reflected in a slowing down of the rates of breathing and heartbeat. The amplitude of the respiratory movement and pulmonary ventilation are increased, and so are the hematites in the blood and hemoglobin ratio, while heart contraction is reinforced; the body is thus better prepared for the beneficial impact of sea-water baths due to an increase of cutaneous exchanges. Many physicians recognize such additional symptoms as neuroendocrinic and growth stimulation, and an increase of diuresis and of basic metabolism.

Showers prior and after baths, overall or localized, exert a dual thermal and mechanical action on vessels and nerve endings; alternating of short cold- and warm-water sprays may well have the same tonifying effect as the Finnish sauna. Gynecological irrigations favor seawater's hypertonic action upon mucous tissues and penetrative ability. Nasal irrigations, aerosols, gargles help with sinus problems, ear-, nose-, and throat-ailments (Arehart, 1969).

The medical and pharmaceutical value of marine "products" has of course been proven. Didemnin-B, diazonomide-A, dolastin-10, and discodermolide are all potential cancer-fighting compounds derived from marine organisms, dwellers of the coral reefs ecosystems. Marine organisms produce chemical compounds—and over 6,000 unique compounds have been isolated with hundreds providing "drug leads"—with antiviral, antibacterial, and antifungal properties. The bryozoan *Bugula neritina* produces bryostatin-1, a potential anticancer agent, *Pseudopterogorgia elisabethae*, a soft-bodied coral known popularly as the Caribbean sea whip, produces anti-inflammatory pseudopterosins.

French and German pharmaceutical firms market vials of seawater tapped at 50 km offshore at depths of up to 20 m. It is claimed that such waters when purified provide cures for gastric troubles. With a reduced salinity the water remains nevertheless rich in magnesium and other oligo-elements, and free of chlorides, closely resembles blood plasma. Bread, crackers, and pasta made using seawater are marketed in France, Germany, and The Netherlands. Seaweeds play a significant role in cosmetology (DeRoeck, 1991).

Algae

Algae have been alternatively, and concurrently, praised and damned along coasts (Charlier, 1990; Charlier and Lonhienne, 1996) including the Black Sea (Bologa, 1985/86; Petrova-Karadjova, 1990; Bologa *et al*., 1999). The European Union under its COST-48 program has encouraged research into their use and their eradication (Morand *et al*., 1990; Guiry and Blunden, 1991; Schramm and Nienhuis, 1996). They have a role among others in food and feed, in cosmetology, methane- and fertilizer-production, and in therapy (Găstescu, 1963; Pricajan and Opran, 1970; Cotet, 1970).

The passage of algae components such as iron and cobalt through the skin is controversial for several physiologists. On the other hand, biomedical applications of *Lyngbya majuscula* are recognized by oncologists; this reef dwelling blue–green alga produces curacin-A which functions as an anti-proliferative that inhibits cell division, the mechanism by which cancer grows and spreads. Algae powder has been added to seawater baths and algae creams are sold in pharmacies and cosmetology stores.

They are present in some marine muds, and in some treatment centers their proportion is increased. German physicians had already in 1929 collected muds in a remote corner of Wilhelmshafen harbor. Romania has advertised them widely. French "marine cures" use an alga jelly mixed with wet sand heated in a double boiler. The mixture applied to the body slowly releases its heat. The ionic displacement of marine electrolytes and algal constituents through the skin is however, not universally agreed upon. Challenged 15 years ago, the practice is continued both in centers and on shores. German centers provide *pelotherapy* using silt packs rich in vegetal and mineral substances, rather similar to the moor-silt.

A mineral spring discovered in the royal residence of Ostend (Belgium) launched a thermalism and thalassotherapy center (1856) at one time catering to as many as 80,000 "curists." The vegetal marine mud, also in use here, is principally made up of compacted peat carried at strong high tides to the beach area. Dried, it is turned into a powder and mixed with a marine clay powder. For use in local applications the peloid is mixed with seawater and heated in a double boiler.

Some of the hyper-saline lakes of the Romanian Black Sea coast, according to the season have temperatures that may reach 27°C with an alkaline pH. The microfauna is abundant and at least 30 species of algae have been identified. The water level may fall to 14 cm of the adjoining Black Sea. The bottom muds, rich in amino acids and carcinoids, have a high rate of natural radioactivity. Some muds are sapropelic, with phyto-remains, particularly algae which are putrefied in an anaerobic environment. Lake Techirghiol, once a bay of 1,170 ha, now separated by a sand bar, is the source of the mud but irrigation of surrounding land caused a salinity decrease with resulting ecosystem changes.

Black Sea centers ring its shores; originally catering especially to their own nationals, they have increasingly drawn foreign visitors. Mangalia, southernmost resort, has attracted seamen since classical times; it forms with Eforie and Neptun, artificial creations, the Romanian cure complex. Blessed with a balmy climate, the center offers a therapy based on seawater and sapropelic mud use, sulfurous mesothermal springs; mud baths and application of mud poultices, it acquired some international reputation. The black, pasty, sapropelic mud comes from Lake Techirghiol, with a mineralization of 80 g/L. Concentrated mud extracts have been shipped to distant locations. At 150 m from the sea, the beach facilities follow the Egyptian method of open-air treatment. An air rich in iodine, magnesium, bromine, and sodium chloride creates an ambience particularly favorable for aero-ionization and insolation.

As in Germany, pelotherapy is also practiced with peat mud found in Lake Mangalia. Bicarbonated, hypotonic, mesothermal (26°C), radioactive, sulfurous water sprouts from springs on or near the Mangalia and Neptun beaches. The sapropelic mud rich in carbonaceous or bituminous matter has a plasticity value of 250 g, a thermal metric capacity index of 20.99. It is enhanced by bacteriostatic, bactericidal, and antiallergic qualities due to its high vitamin (C, E, B2 and B12), nicotinic acid, hormones, and organic content.

Economics

Setting aside the savings aspects in hospital days and pharmaceuticals consumption which benefit state and private insurance systems, and the individual, and considering the tourism aspects, it appears that thalassotherapy and thermalism are large earners and big employers. Taking, for example, the sole thermalism in France, in 1998 centers hosted 548,003 curists representing 9,864,054 "visitors" days for insured parties and 527,629 days for other curists, for a year's total of 10,391,683.

Many did not come by themselves but were accompanied by non-curists, representing an additional 300,000 persons.

A low-priced cure costs an average FRF 1,000 (€ 150) for a six-day stay, with a per person FRF 2,200 (€ 320) tab for food and accommodations (thus exclusive of such additional expenses as beverages, entertainment, sundry purchases). The income for the French centers, besides payment for medical services, exceeds thus by far 13,400,000 "days" × FRF 2200 = FRF 29,480,000,000 or approximately US$5,781,000,000, about EUR 4,494,000,000 [Exchange rates used in the calculations are FRF6.3 = US$1; Euro 1 FR = F 6.56]. It is furthermore estimated that the 100-plus thermal centers provide employment to at least 100,000 people.

Examining these numbers for a developing economy as for instance in Romania, one one-hundredth of this is 1,000 jobs and an income of US$46,740,000 for a single low-priced center. *Thermae* income amounts to, using the same formula, FRF 104,000,000 or about US$16,508,000 or EUR 15,857,000 [Exchange rates used in the calculations are FRF6.3 = US$1; EURO1 = FRF6.56]. An adjustment factor is naturally needed as wages and prices are clearly higher in France than in Romania. Nevertheless, thalassotherapy (and of course thermalism) are not to be looked at as an insignificant economic player (Guillemin *et al*., 1994; Boulangé, 1995; Anonymous, 1997; Collin, 1997).

Revenues are generated by use of facilities, hotels, restaurants, but also by pharmaceuticals and cosmetics: the University of California has received in royalties for patented pseudopterosins over US$1,200,000, and the cosmetics firms have collected several millions more. Algae and muds can thus be "earners."

Treatment centers

Thalassotherapy stations have a long history with the largest number of stations in Germany and France. Most of the 22 German stations grew in importance during the last half century. They have attracted a large clientele and contributed substantially to the growth and expansion of touristic sites. France remains the leader with the largest number of stations, some catering to the well-to-do. Of over 40 hydro-linked health resorts found in Great Britain, the birthplace of sea-bathing hospitals, only Springs Hydro at Packington, Ashby de la Zouch in Leicestershire propose thalassotherapy; algae baths or seaweed body wraps are offered in Scotland (St. Andrews, Kingdom of Fife) and in London and balneotherapy at Newport Pagell (Buckinghamshire). Thalassotherapeutic facilities sprung up principally around the Mediterranean in Spain, Monaco, Greece, and Tunisia, and in Israel. Black Sea facilities acquired a solid reputation over the last decades. The development of a therapy *de pointe*, free from extravagant claims in up-to-date facilities can nurture a sustainable and rational growth of Romanian Black Sea resorts.

One may recall the medications developed some decades ago—and still in use—by Romanian Dr. Aslan (Gerovital, Aslanvital) against antioxidant (ao) ageing. Her work remained highly controversial to the point that some considered her therapy charlatanism. Is a similar risk conceivable with thalassotherapy and its sister cure thermalism? Indeed development must be considered on a long-range scale.

The introduction of new technologies such as the combination of electro-acupuncture with thalassotherapy is due to win over a new clientele. Thalasso-electro-acupuncture brought back from China relatively recently, has rapidly gained *droit de cité* and garnered enthusiasts in French centers.

Comparisons have been made among European centers and a critical analysis of the recent relevant bibliography published (Collin, 1995; Constant *et al*., 1995; Graber-Duvernay, 1999). A study conducted by the French National Health Insurance System (*Caisse Nationale d'Assurance Maladie*) observed 3,000 persons who took a thermal cure during a span of three years and found a health improvement dealing with various ailments, for example, rheumatism, back pain, arterial problems (Morand *et al*., 1990; Guiry and Blunden, 1991), in two-thirds of the group and a concomitant decrease in the length and frequency of hospital stays. Furthermore, the use of medicines dropped or was cut for 72.4% of the patients while the disbursements of the Health System for thermal care represent barely 0.22–0.43% and "*cures*," stays at thermal centers, represent 0,89–1% of the total medical "consumption." It is not preposterous to extrapolate these observations to the domain of thalassotherapy.

In fact, a thorough scientific project has been conducted by the department of hydrological and climatological medicine of the University of Nancy medical faculty and results made public in July 1999. The conclusions are positive and doubts as to the value of thermal cures seriously challenged. The congress (*assises*) of thermalism held in Toulouse, France in May 1999 (*Proceedings* were published in June 1999) confirms the medical dimension of thermalism. Positions held since 1996 seem thus appropriate. Furthermore, statistics show a substantial sustained drop in the frequency of hospital stays and the consumption of medicines.

The venture is foreseeably valid and sustainable. Boulangé in his 1989 and 1995 papers examining the scenario, both in the framework of the European unification and of the next century, for French thermalism—and there is no reason for not extrapolating these views to thalassotherapy—sees a bright future (Boulangé *et al*., 1989).

With France and Germany still the leaders in centers, facilities and techniques, a noticeable increase in treatment centers has taken place in Tunisia and Morocco. One center in Austria, another in The Netherlands, import marine muds so it can claim thalassotherapy care. Marine muds of Israel are used in the Plombières (France) thermal center (Anonymous, 1999). A unique case is that of Ein Bokek, Israel on the Dead Sea. There is virtually no town but a cluster of hotels catering to patients seeking treatment mainly for (arthritic) psoriasis. The treatment commonly combines helio- and thalassotherapy; solar rays are filtered by an extra 300 m of atmosphere than elsewhere on earth and seawater here has a tenfold higher salt content. Results of treatments have been repeatedly commented in the *Journal of the American Academy of Dermatology* (1985) and the *International Journal of Dermatology* (1995, 1997).

HISTORY, COASTAL ECOLOGY

Introduction

The history of the investigation of the way in which coastal habitats and species interact with each other and respond to human intervention is relatively recent. Studies of the distribution of individual species populations, pattern and process in species and groups of species, and the relationship with the physical environment, has mostly taken place during the last century. An ecosystem approach which embodies all of the above and lays stress on the complexity of the interactions, is the most recent manifestation of the developing science. Nowhere is this more obvious than in the study of the ecology of coastal habitats, species, and coastal systems.

Some of the earliest work involved quantitative descriptions and successional studies of vegetation. These were undertaken around the end of the 19th century, and included work on the Dutch Wadden Sea islands and on sand dunes in Germany. Studies in Denmark also took place on dunes and were the forerunners of the study of plant ecology (van der Maarel, 1993).

This early work was carried out on habitats which were mostly, apparently free from human interference. Thus, coastal salt marshes and sand dunes with seemingly simple successional sequences were amongst the first to be studied in relation to the way they responded to natural forces. Understanding of the role of human activity was not considered to be a priority. This situation changed dramatically in last half of the 20th century as human populations put increasing pressure on marine and coastal ecosystems throughout the world. This entry attempts to describe some of the ecological principles which have been developed over the last 100 years or so, and discusses how they are applied to coastal systems today.

Early work, unravelling complex coastal systems

Studies of the autoecology and ecophysiology (of plants) dominated early coastal ecological work. Salt marshes and sand dunes were obvious candidates for studying ecological change because of their seemingly regular patterns of succession and their dynamic nature. Some of the best known British ecologists of the first half of the 20th century, for example, included detailed work on these coastal habitats (Tansley, 1949; Salisbury, 1952).The early descriptions were concerned both with the pattern of plant communities and also the process through which these patterns developed (e.g., chapman, 1976). Thus, coastal vegetation became recognized as a series of types progressing from early pioneer stages to more complex forms which could be related to the physical parameters affecting their development. The role of animals in this process was not considered and studies of animal populations continued along a largely separate path.

Plant zonation and succession

Zonations of seaweeds can be related to tidal influence and/or wave exposure, and on rocky shores these can be very pronounced (Stephenson and Stephenson, 1972). Similar patterns can be discerned for many coastal, terrestrial habitats, though the reasons for them may be less easy to interpret. Early studies looked at the role of individual plants in overcoming the rigors of what was considered to be a hostile environment, in an attempt to establish whether there were recognizable factors determining the sequence of development. *Suaeda fruticosa*, a plant of gravel shores, for example, was shown to be able to establish itself over time by slowing down the landward movement of the beach (Oliver and Salisbury, 1913). On sandy shores pioneer plants and other obstacles do the same by arresting the movement of sand grains (Figure H4). The growth habit of the plant itself, including its root system, soil water, and mineral nutrient relationships were the subject of classic studies on sand dunes (Salisbury, 1952) and helped to define the adaptations of individual species in overcoming environmental perturbations. Similar studies were carried out by others on sand dunes and salt marshes (e.g., Chapman, 1934).

The mechanism through which succession took place was perhaps most clearly elucidated for salt marshes. Primary colonizers such as *Salicornia europea* or *Suaeda maritima* (in north-west Europe) become established on accreting sedimentary tidal flats. The pioneer plants, tolerant of immersion in seawater, were shown to be dependant on periods in the early stages of plant establishment when they are free from tidal

Figure H4 Strandline and pioneer sand dunes, Magilligan Point, Northern Ireland.

Figure H5 Parallel zones on a salt marsh. *Spartina* expansion following erosion, Severn Estuary, England/Wales.

movement. As sediment height increases, the marsh is subject to progressively fewer tidal inundation, less sediment is deposited and a richer complement of plants and animals replaces the specialist salt-tolerant species (Ranwell, 1972). Thus, from an ecological point of view salt marshes provided evidence of primary succession, with the development of a parallel spatial zonation (Figure H5) which could be related to tidal inundation. The fact that this occurred apparently "largely without human interference" made them ideal for studying the processes associated with "natural" vegetation development.

By 1972 when Ranwell published his book on the ecology of salt marshes and sand dunes recognition of the importance of understanding the complex relationships, which determined the nature of salt marshes and sand dunes, was much more clearly understood (Ranwell, 1972). These and other early studies showed that there are zonations attributable to environmental gradients in coastal vegetation. Anyone looking at the early stages in salt marsh or sand dune growth will need little convincing that this is so. However, unravelling the precise relationships was much more difficult than it at first appeared.

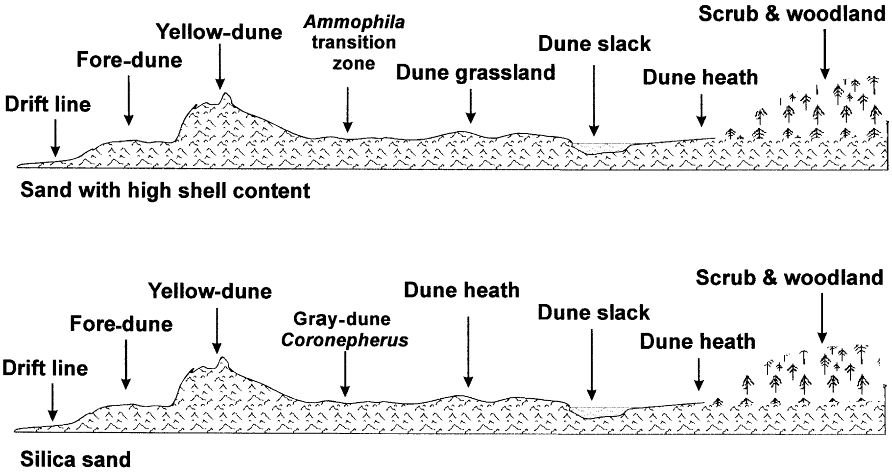

Figure H6 A sequence of sand dune succession on calcareous and acidic sand. Notice the dune building phase (high dune) followed by deflation and the development of more stable communities.

Salt marshes not only respond to tidal movement, but also to relative sea-level change. The fact that these operate over very different temporal scales is an important factor in understanding the mechanisms involved. The movement of estuary channels, which may cause erosion operates over yet a different timescale. The development of salt pans or the effects of rotting seaweed cause changes to the surface vegetation. Added to this is the fact that succession may be cyclical as sediments are exposed when erosion takes place.

Sand dunes also show forms of successional development in the early stages of growth by the accretion of sand, aided by specialist plants. However, once the main body of the dune is formed other processes come into play and the change from mobile foredunes and yellow dunes to grassland, heath, scrub, and woodland is rarely a straight forward progression, though it may be depicted as such (Figure H6). Blowouts occur with or without the intervention of man and can be the precursors of dune slacks. Similarly, the reprofiling of dune ridges under the influence of changing wind patterns bring an infinitely variable topography, the origins of which may be difficult or impossible to unravel.

Coastal networks

As the mechanisms through which the habitats developed were unravelled, so the sheer complexity of the relationship with the "natural" environment became more apparent. Individual species relationships, to some extent, provided only a first level in understanding of the way in which coastal systems and their biological components operate. The physical conditions in which plants and animals exist provide powerful controls on populations, especially where there are major perturbations in these conditions. Superimposed on this are the various natural cycles involving predator–prey relationships and intra- and inter-specific competition. Thus, it is not surprising that as the study of ecology developed, these complex relationships came under scrutiny. These interactions are the "stuff" of ecology and the studies have been many and various. Nowhere is this more apparent than in coastal wetlands.

Nutrient cycles and energy flows within wetland communities are key and often quoted examples. Attempts to describe the complex interactions between detritus, nutrient inputs, primary producers, detritus feeders, predatory fish, and birds are usually presented as "generalized" food webs. However, these pictures can only represent a very simplified view of the systems involved. A detrital food chain in a mangrove forest alone, for example, may include 11 different groups of animals with untold species involved.

The importance of geomorphology

Engineers were perhaps amongst the first to appreciate the interaction and complexity of whole coastal ecosystems. Writings early last century described the way the coast responded to natural conditions such as sea-level rise, tides, storms, wave action, wind, and rain and how these affected the shoreline (Wheeler, 1903; Carey and Oliver, 1918). Later studies were concerned with coastal erosion and land reclamation (Du-Plat-Taylor, 1931; Matthews, 1934). These helped lead the way to unravelling the relationships between the physical and biological components of the coastal environment, including an appreciation of the dynamic nature of the habitats involved.

The description of coastal landforms and the factors which have helped to shape them come under the general heading of geomorphology. Some of the most important texts, which have helped secure a better understanding of the coast and its management needs come from these studies. In Great Britain, during the 1940s and 1950s, a survey of the geology and history of change on the coast was undertaken and described in two classic works (Steers, 1946, 1972). These provided a much better understanding of the coastal landscape and its conservation needs and helped lay the foundation for much of the subsequent coastal policy. In America, comprehensive accounts of the development and the processes by which coastal systems came into being were led by geologists (e.g., Johnson, 1919). More recent academic publications look at examples from around the world and provide more detail, not only of the way in which the coast responds to the many natural driving forces, but also the influence of human use in shaping its condition (Bird, 1984; Carter, 1988; Carter and Woodroffe, 1994).

Human occupation and use

As has already been intimated above, from an ecological perspective, coastal habitats are often considered amongst the more natural ecosystems. This has led to the impression that the process of succession takes place in a sequence which is determined largely by natural forces. The classic studies of the salt marshes and sand dunes on the North Norfolk coast (Chapman, 1938, 1941, 1959) or the Dovey Estuary in west Wales (Yapp *et al.*, 1917) emphasized the natural status of the vegetation. However, this hides a long history of human use. On the sedimentary shorelines of the Wash, for example, artificial embankments to enable salt-making were present in some numbers in Roman times (Simmons, 1980). Hay making, oyster cultivation, turf and reed cutting, and samphire gathering all take place or have taken place on upper marshes throughout Europe (Dijkema, 1984). The deliberate planting of *Spartina anglica*, itself a hybrid fashioned from the interaction of a native and an introduced species in southern England (Marchant, 1967), has been a major influence on salt marshes throughout the world.

Occupation of sand dunes probably dates back several thousand years as archeological studies have shown. Many sites have examples of middens with the remains of shell fish in them. An analysis of flint tools suggests that settlers of Torrs Warren, a sand system in south-west Scotland, may have appeared between 5,500–7,000 years ago (Coles, 1964). It seems that cultivation has taken place since then and in 1572 three farm houses were recorded on the Warren. As long as 4,500 years ago a small settlement existed on the shores of Skaill Bay in Orkney. The Neolithic people which inhabited the site, known today as "Skara Brae," seem to have been agriculturists as well as hunters/gatherers (Ritchie and Ritchie, 1978) living on the coast until their village was overwhelmed by a sand storm. Since Medieval times, dunes have been used extensively as rabbit warrens and are grazed by domestic stock to the present day. Research on the origins of the deltas of the

Mediterranean show a link between population growth and decline, deforestation in the hinterland, and the growth and retreat of the deltas themselves.

This knowledge has altered our perception of coastal habitats. Far from being natural, many coastal systems are highly modified by human activity. Their ecology and conservation thus depends both on understanding the "natural" processes by which they develop and the impact of human action (Doody, 2001).

Conclusion

Unravelling the ecological interactions of species and their environment has been the main thrust of ecological studies for most of the last century. It has been suggested that this has been largely undertaken without any direct investigation of the human factor and its impact on the individual elements in the coastal environment, whether they are concerned with vegetation succession or change in animal populations. As our understanding of the relationship between the physical and biological components of the coastal environment has grown, so has concern for the impact of human use both on the coast itself and its ability to sustain human uses. This has brought into sharp focus the need for a more integrated approach to the study of coastal ecosystems. At the same time the role of ecology has moved substantially from the study of systems "apparently" free from human interference, to one where socioeconomic forces are equally, if not more important, to understanding how coastal landscapes function.

Sustaining coastal habitats

The study of ecology has also formed the basis for the identification, protection, and management of areas of nature conservation importance. Indeed, it was the preeminent ecologists of the day who helped develop the present approach to the protection and management of nature reserves. In the United Kingdom, for example, in 1942 the British Ecological Society established a Nature Reserves Committee under the Chairmanship of Sir Arthur Tansley (Sheail, 1987). It was this committee which provided the foundation for the series of Nature Reserves and other protected areas that are so important to the conservation of the remaining areas of natural and seminatural habitats today.

In the early postwar period, the understanding of successional processes, the concept of climax vegetation, and the notion of zonation, helped to lead conservation managers toward a preoccupation with the protection of existing interests, identified when the sites were first assessed. To many the "naturalness" of the system was the prime reason for its conservation. However, as has been argued above, many so called "natural" systems are not natural at all. Most if not all, in temperate regions at least, have in some way been modified by human activity. The extensive unmodified lagoons and deltas with their apparently natural salt marshes and sand dunes in Albania and eastern Turkey, grow rapidly today because of deforestation in the hinterland. Even here drainage and land "improvement" for agriculture has destroyed large areas of transitional vegetation and pollution is a major consideration.

This understanding has important consequences both for the development of conservation policy and the ecological principles upon which it is based. Agenda 21, a program for action agreed at the United Nations, Earth Summit in Rio in 1992, aims to help achieve the twin goals of sustainable human development and the maintenance of biodiversity. The statements clearly point the way toward recognition of the interrelationship between the so called "natural environment" and human economic and cultural activity. If policies are to be developed which fulfill the aspirations both the politicians and the traditional conservationist, future ecological studies must include human use as a key component of the "natural" system.

The coastal squeeze. An important component of human use centers around the loss of coastal and tidal land. The process by which this affects the margin between the land and the sea can be described as "coastal squeeze." Here human action pushes the limits of intensive use of the land (for agriculture, industry, and the like, or land claim of tidal areas), toward the sea. At the same time, where sea level is rising relative to the land, the upper limits of tidal influence are pushed landward (Figure H7). Taken together, these effects cause a narrowing of the shore and the loss of coastal habitats. In its turn this can result in a reduction of the capacity of the shore to withstand, and recover from, episodic events including major storms. In low-lying coastal areas, for example, coastal properties are put at greater risk from flooding and/or erosion, as the protection afforded by a wide beach is reduced, as it becomes steeper and narrower.

The cumulative effects of habitat loss may also reduce the ability of the coast to recover from major environmental perturbations. This may include difficulties in replenishing living and nonliving resources. In their turn these result in an inability to sustain the economic fabric of some areas.

A question of sediments. Other factors, which have been increasingly recognized as being important to the sustainable use of the coast, include the nature and availability of sediments. In this context, there is also an increasing recognition that the reduction in availability of sediments, whether due to offshore exploitation, damming of rivers, or reducing the flow from longshore drift, has a predicable outcome. Many deltas have grown through the transport and deposition of sediments eroded from the hinterland following deforestation. Studies suggest that this situation has been reversed as the damming of rivers has reduced the available sediment supply. As a result, today the outer margins of many deltas are eroding as they become wave-dominated rather than ones where freshwater river flows exert the major force. This pushes the margins of the delta landward and with it increases saline water intrusion into the underground aquifer. The implications for the continued economic use of these areas for agriculture (e.g., rice cultivation), ground water abstraction, or problems associated with erosion are largely ignored by the political and economic forces, which continue to dictate land use policy and coastal management.

Ecological change as a healing force, a new paradigm?

Change is an important part of the development of coastal systems. This was most dramatically revealed by major events, such as the landslip between Axmouth and Lyme Regis (Devon, Dorset, southern England) on Christmas Day 1839, which created a chasm 1 km long and up to 122 m wide, taking with it a small village. The steady erosion of the cliffs at Dunwich (Suffolk, England) has now thrown all seven of the Medieval churches of this once-important port into the sea. At the same, time saltmarsh erosion and accretion are relatively natural phenomena, taking place in response to changes, for example, in the location of the tidal channels or, over a longer time period, in sea level. Recognizing these changes as factors to work with rather than against, may provide a more sustainable approach to coastal development.

In this context, the alliance between the ecologist, geomorphologist, and coastal engineer in re-creating new coastal habitats may be a first step toward accepting change as a means of securing more sustainable living on the coast. For example, the re-creation of salt marshes, or other tidal wetlands from land given back to the sea may not only secure new nature

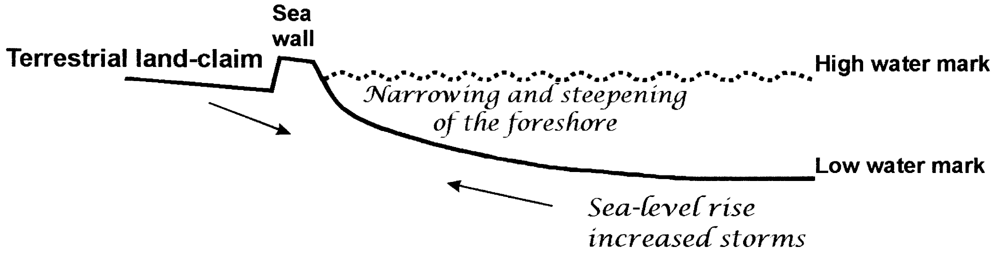

Figure H7 "Squeezing" the coast.

conservation opportunities, but also provide a more sustainable sea defense. Perhaps, ultimately we will emulate our ancestors, and in some areas initiate major change and then step back and let nature take its course. Under these circumstances the role of the ecologist may be paramount in predicting the outcome of a particular management option. This will require a marriage between the traditional approach which sees the ecological process as natural, and a more pragmatic one where human factors play a significant role. This will not reduce the importance of the "natural" succession, but set it in a wider human context. In the same way that our ancestors helped fashion the present coast and its biological and non-biological resources by accident, we can do it by design!

HISTORY, COASTAL GEOMORPHOLOGY

> I am only too painfully aware how increasingly difficult it is to find time for a careful study of the work of our predecessors . . .
>
> (Geike, 1897)

The coast has been of primary concern to man since he first set foot upon it, and will undoubtedly continue to be so long into the future. It must have been "studied" by the earliest dwellers in their quest for food and also by later inhabitants for other reasons, such as a need of harbors or for defense. Men learned early about cliffs, rocky shores, and sandy beaches; they must also have discovered the operation and importance of tides, currents, and waves upon the shore. In light of man's long-continued interest in the coastal zone, it is surprising that its scientific study lagged so far behind that of many of the earth's other environments.

One explanation may well be that the shoreline, like so many of nature's other boundaries, failed to attract the attention of scientists. Scientifically, it was long a no man's land—neither "ocean nor land." Oceanographers were reluctant to tread where their ships would not go, and geologists were equally reluctant to tackle the sea near the shore.

Early observations and theories

Although the actual beginnings of coastal study are shrouded in the haze of history past, some of the speculations of the early Greeks and Romans have been preserved. They were aided by having a keen practical interest in things coastal; as early as the 4th century BC they were well acquainted with Mediterranean and Black Sea littorals. Their knowledge of coasts was advanced greatly by such men of action as Alexander the Great. The anonymous Greek *Periplus of the Erythraean Sea*, which described the coasts of the western Indian Ocean and even, albeit hazily, the coast east of India, was used by sailors during the days of Pliny. Although based on direct observation and unhindered by religious teachings, early theories about coasts were nonetheless tempered by the superstitions, legends, and myths that were in the heritage of all Mediterranean peoples at the time.

The presence of marine fossils far from the sea led Aristotle (384–322 BC) and others to conclude that the sea had previously occupied higher levels. Strabo (54 BC–AD 25) even went so far as to write that it frequently changed levels—rising at times, falling at others. The role of rivers in altering the landscape also attracted the attention of these natural philosophers, and, although they had several ideas about where and how river water originates, there seems to have been little doubt in their minds about what happens when it enters the sea. Aristotle, Strabo, and others recognized deltaic and alluvial plain deposits. They knew that river-carried sediment first shallows the sea, then converts it into marshland, and changes it eventually into dry, farmable land. Erosion as a coastal phenomenon was not ignored. Strabo, for example, noted that the ebb and flow of tides prevent deltas from advancing continuously outward into the sea.

The role of man as coastal agent was also studied. Strabo cited an example of the attempt to improve the harbor of Ephesus in the 2nd century BC:

> The mouth of the harbor was made narrow by engineers, but they, along with the king who ordered it, were deceived. . . . He thought the entrance would be deep enough for merchant vessels. . . . But the result was the opposite, for the silt, thus hemmed in, made the whole of the harbor . . . more shallow. Before this time the ebb and flow of the tides would carry away the silt and draw it to the sea outside (Russell, 1967, p. 299).

Such was the state of knowledge and theory during those Greek and Roman times at about the beginning of the Christian era. Although these notions persisted in Europe only until the fall of the Roman Empire, they were nonetheless preserved and nurtured in the Arab world during much of the time leading up to the European Renaissance.

The Renaissance

The translation of Ptolemy's *Geography* in the early 15th century was a major step toward the great discoveries of the 15th through the 18th centuries. Much of the actual knowledge held by the Greeks, Romans, and Arabs about coasts came from navigators, and so it was to continue for many centuries. Many of the voyages during this period (such as those of the Cabots, Verrazano, and Gómez along the northeast coast of North America) were strictly coastal; there was no attempt at colonization or at exploration of the interior. Penrose (1955, p. 147) wrote: "A fair coastal survey was the sole result—nothing more. . . ."

Such surveys added rapidly to the body of knowledge that was beginning to accumulate, and influenced those who would put their minds to coastal problems. Most of the material was pure description, and just what influence it actually had on the development of coastal morphology as a science is uncertain. Nonetheless, it was available for such thinkers as Leonardo da Vinci (1452–1519), who recognized terraces for what they are, and for Steno (1631–87), who established a depositional sequence in explanation of the strata he observed.

Bernhard Varenius (1622–50), because he successfully merged description with theory, has been credited with laying the foundations for geography as a science (Mather and Mason, 1939). These foundations are recorded in his *Geographia Generalis*, a book that was used as a text in British universities for a century by such notables as Isaac Newton. On the topic of coastal morphology, Varenius wrote, "The ocean in some places forsakes the shores, so that it becomes dry land where it was formerly sea" (Mather and Mason, 1939, p. 25). He reasoned that many factors may be involved in such a change, including those of erosion and deposition, ocean currents and tides, texture and structure, river flow, and wind. Process was very real in his science.

The influence of scripture

Nearly all "scientists" of the 17th, 18th, and much of the 19th centuries were influenced to greater or lesser degree by the Bible and the Church. In some cases, this acceptance was probably not unlike that of the Greek philosophers, influenced unknowingly as they were by mythology. The biblical quotations of greatest significance, as found in the King James version of the Bible are:

> Let the waters under the heaven be gathered together unto one place, and let the dry land appear . . . (Genesis, 1: 9). Let the waters bring forth abundantly the moving creature . . . (Genesis, 1: 20). And . . . the flood was forty days upon the earth; . . . and the waters prevailed exceedingly upon the earth; and all the high hills, that were under the whole heaven, were covered (Genesis, 7: 17, 19).

Because, according to the Bible, the separation of land from sea occurred two days before animal life in the sea was created, the utilization of *fossils* in explaining the history of the earth, as the Greeks had done, was heresy. However, the Bible offers the universal flood of Noah's time as a possible out, one that was used in many explanations. A major difficulty was time. Because of the strict application of scripture, time was unavailable as a basis for applying observable processes to earth history. The major challenge was how to present the facts as offered by landscape observations without running counter to theological precepts.

Theories of landscape development and coastal morphology

Within such a Church-dominated intellectual environment, it is not surprising that a number of theories were proposed to explain the earth and its surface forms. During the 18th and 19th centuries many were proposed, accepted, modified, merged, and abandoned. Contemporary and subsequent history has labeled many of these theories by their predominant theme, and some also by the name of their principal proponent. Examples include neptunism (Wernerism), plutonism, diluvialism, and fluvialism (Huttonism). These theories and their major advocates are treated at length in volume one of *The History of the Study of Landforms*, by Chorley *et al.* (1964). Basically, most of the earlier theories were catastrophic in approach, reflecting a high degree of biblical influence; later ones tended toward uniformitarianism, although there was much overlap. In any event, each theory in its own way has played a role in the development of coastal geomorphology.

The neptunists, of whom Werner (1749–1817) was the principal spokesman, invoked a primeval universal ocean in accounting for both stratigraphic sequence and landform types. The earth's rocks were formed, according to the neptunists, through the successive accumulation of chemical precipitates within the ocean. Although some surface forms were caused by submarine deposition and erosion during the presence of the universal ocean, most forms resulted from erosion during a rapid recession of oceanwater. From this viewpoint, every landform originally was coastal—at least, in the sense that it was formed by turbulent oceanic currents and waves.

The diluvialists, as exemplified by Buckland (1784–1856), held a theory that was similar in some ways to that of the neptunists. The catastrophe they invoked, however, was Noah's flood. In the pure form of diluvialism, the flood was more a destructive than constructive agent. Again, it was rapidly receding water that carved the landscape. Some of the many types of otherwise unexplained phenomena that were accounted for by the flood were erratics, underfit streams, and terraces both river and marine.

Most of the catastrophists recognized that coastal and riverine erosion and deposition did occur but at such a slow pace that they had no place in earthly or "Godly" schemes. Nonetheless, even before and especially during the dominance of catastrophism, uniformitarian ideas surfaced and by the mid-19th century were dominant.

The uniformitarians were united on the concept that currently operating processes were capable of creating present-day landscapes. They were not united, however, as to which processes were most important. In general, there were two camps: one, represented by Hutton (1727–97) and Playfair (1747–1819), believed that the river was the most important agent in landscape development; the other, represented by Lyell (1797–1875) and Ramsay (1814–91), advocated marine abrasion as dominant.

Form and process: 17th–19th centuries

Although it is basically correct to conclude that the dominance of the catastrophic schools during their heyday retarded the study of geomorphology, the study of *coastal forms and processes* actually progressed to some extent. Because such forms and processes were considered insignificant from the standpoint of the overall scheme of landscape development, they could be looked at without fear of countering religious dogma if one did not try to conclude too much. Coastal cliff erosion and deposition are so conspicuous, especially in parts of the British Isles, that they did not escape the consideration of layman, geologist, and engineer alike. Hutton and Playfair, although mainly fluvialists, recognized coastal processes. Hutton, for example, wrote, ". . . we never see a storm upon the coast, but that we are informed of the hostile attack of the sea upon our country" (1788; quoted in Chorley *et al.*, 1964, p. 39). Playfair, in the same vein, emphasized the obviousness of coastal erosion when he wrote, "If the coast is bold and rocky, it speaks a language easy to be interpreted." He also noted that once fragments of rock are detached they "become instruments of further destruction . . ." (1802; quoted in Chorley *et al.*, 1964, p. 60). Thus, throughout the period of, and subsequent to the Renaissance, statements appeared that indicated some relatively advanced thoughts about coasts, some of which did overstep the bounds of Church dogma.

For example, John Ray (1627–1705), a keen observer, went so far as to propose that the combination of subaerial erosion and coastal cliff retreat would eventually reduce all land to a level below the sea. Guettard (1715–86), famous for his geological maps, believed the sea to be the major agent in land erosion, and that cliff coasts were the remnants of former extensive hill systems. He observed that sediments brought to the sea by rivers mixed with material eroded from adjacent cliffs and submerged rocks. However, he tempered this view by noting that the action of the waves would have little effect beneath the surface of the sea. Lavoisier (1743–94) adopted the Guettard idea that littoral beds are composed of materials from varied sources, but went a step further and noted that the coarsest materials are highest on the shore, and are followed downslope by coarse sands, fine sands, and clay. The width of each band, he maintained, varies with the steepness of the slope.

One of the most perceptive of the natural historians of this period was the little-recognized John Walker (1731–1803). He was the first effective teacher of geology at the University of Edinburgh where he held the chair of natural history from 1779 to 1803. His students included the geologists Playfair, Hall, and Jameson. His lecture notes—not published until 1966—contained many advanced notions that must have guided much of the thinking of the geologists of the early part of the 19th century. Some of Walker's notions, of relevance to coastal geomorphology, dealt with: continental drift—". . . why not America from Europe and Asia and indeed every one continent from another"; coral reefs—he was apparently the first geologist to actually describe the growth of coral reefs; subsidence—he not only described the processes of alluviation but wrote that sediments ". . . are found in great quantity and to considerable depth, being the sediment of rivers. . . ." (Walker, 1966, pp. 178, 183) anticipating R.J. Russell's work of 150 years later. Unlike most geologists of the time, Walker believed that sea sand was formed by the weathering (his term) of rocks rather than by chemical precipitation from the sea (Walker, 1966).

Marine planation

With Ray's 17th-century and Guettard's 18th-century views of marine erosion, coupled with the fact that even the most dedicated of fluvialists placed great importance on marine processes, it is not surprising that some men in the 19th century considered the sea as being more powerful than the river. Lyell was one of them, although he had not always been so. During his career he gave increasing importance to marine erosion, finally considering it to be the major modifier of the landscape. His ideas were modified by Ramsay, and eventually evolved into the theory of marine planation. Ramsay's concepts included two ideas: one, that the sea is capable of planing surfaces over which it moves, regardless of rock composition; the other, that unequal hardness in cliffs will result in differential erosion and the creation of an irregular coastline. He also maintained that marine planation accompanies shifts in sea level, using as evidence the presence of plains at different elevations above sea level. The escarpments between these levels he explained as old sea cliffs.

The importance of planation theory is emphasized by Chorley *et al.* (1964, p. 313): "Even when the idea of universal marine erosion had been discredited, the planation part of the theory lived on in Davis's cycle of erosion and in the writings of mid-20th-century geomorphologists."

As far as the coastline is concerned, Ramsay and others emphasized increasing irregularities because of differential erosion, a view that was not difficult to accept in the British Isles. However, Dana (1813–95), a confirmed fluvialist, disagreed. He believed that: ". . . waves tend rather to fill up the bays and remove by degradation the prominent capes, thus rendering the coast more even, and at the same time, accumulating beaches that protect it from wear" (1849; quoted in Chorley *et al.*, 1964, p. 363). These conclusions were based on observations made during Dana's four-year voyage in the Pacific Ocean.

During this period, thought was being given to a number of agents previously little considered. Hutton, it is true, had recognized the importance of chemical action in soil formation, and others had discussed the transport of matter being carried to the sea in solution. Nonetheless, it was von Richthofen (1833–1905), a staunch follower of Ramsay, who applied such ideas to coasts. He wrote:

> The weathering and loosening of rock by sea salts, carbonic acid, the formation of ozone, and the gripping of plants and animals—to which must be added the action of frost in higher latitudes—aids the mechanical action of the striking billows (1882; quoted in Mather and Mason, 1939, pp. 515–516).

Gilbert and Lake Bonneville

It is somewhat curious that the western explorations in the United States, especially those during the last half of the 19th century, should be important from the standpoint of the history of the study of coastal morphology. This importance is even more surprising when one realizes that much of the western field work combined with the studies being made on the Ganges (Everest, 1793–1874) and the Mississippi (Humphreys, 1810–83) rivers and in the heavy rainfall areas of the tropics in helping to reestablish the notion that the river is the dominant agent in geomorphology.

Especially significant are the coastal concepts presented by Gilbert (1843–1918) in *Lake Bonneville* (1890) and *The Topographic Features of Lake Shores* (1885). He treated a variety of shore-related topics, including beaches, cliffs, terraces, barriers, lagoons, waves, currents, undertow, backwash, and sorting, among many others. His deductions, based on intensive fieldwork, were lucidly presented. The main limitation to their usefulness was that, having been derived from work on lakes, they are not always applicable to oceanic situations. A major case in point is the concept of the bottomset, foreset, and topset bed composition of delta terraces, a concept that has little value when dealing with major oceanic deltas. Nonetheless, by describing coastal landforms in terms of physical processes, Gilbert set the style for present-day research in coastal geomorphology.

Gilbert, like most of the other geologists involved in the western explorations, was not tradition-bound and thus was able to distinguish between the relative importance of subaerial and marine processes, as he did in his Lake Bonneville research.

Possibly his most important contribution in the development of geomorphology is Gilbert's concept of grade, a concept that he used in the development of his ideas on beach equilibrium. He wrote: ". . . in order that the local process be transportation only, and involve neither erosion nor deposition, a certain equilibrium must exist between the quantity of the shore drift on the one hand and the power of the waves and currents on the other" (1885, p. 101).

Gilbert utilized lake shorelines and lake deposits as indicators of past climates and tectonic history. For example, he was able to correlate lake-terrace width with rock type in a lake's discharge channel and the lack of horizontality and parallelism of shores with orogenic movement.

Davis, Gulliver, and Johnson

The role of William Morris Davis (1850–1934) in the development of geomorphology has been analyzed many times (most thoroughly by Chorley *et al.*, 1973). Davis influenced in some way nearly every aspect of geomorphology, including coastal geomorphology. This influence was realized in several closely linked forms, including his own research and publications on coastal topics, the wide adoption of his concepts of the cycle of erosion, and the work of his students (especially Gulliver and Johnson) who emphasized the study of coasts.

Much of Davis's research on coastal problems was related to reestablishing support for Darwin's subsidence theory of coral-reef growth. By writing some three quarters of a century after Darwin, Davis was able to incorporate in his writings data about sea-level changes during the glacial period. He believed that the only way to properly understand coral reefs was through an examination of the ". . . physiographic features of the coasts, either insular or continental, that are bordered by fringing reefs or fronted by barrier reefs . . ." (1928; quoted in Chorley *et al.*, 1973, p. 592) and not from the reefs themselves.

Another example of Davis's contributions in coastal geomorphology is his *The Outline of Cape Cod* (1896). It illustrates an attempt at geomorphic reconstruction: "Let the activities of the sea be resolved into two components: one acting on and off shore, the other along shore; and let the effects of the first of these components be now examined alone, . . ." (Davis, 1896, p. 700).

Davis incorporated the ideas of Gilbert's beach equilibrium within his cyclic concepts: "Here the sea is able to do more work than it has to do. Its action is like that of a young river. . . . When a graded profile is attained, the adolescent stage of shore development is reached" (Davis, 1896, p. 701). This paper also presents numerous diagrams, a Davisian hallmark, illustrating the development of graded profiles (both normal and longitudinal) and of bars and spits.

The cyclic concepts presented in the Cape Cod paper preceded by three years the publication of his most famous and influential paper, *The Geographical Cycle* (Davis, 1899). The Cape Cod paper is only one example of the fact that the cyclic concept had been in Davis's mind for many years before the turn of the century. The influence of this concept in coastal geomorphology is further evidenced in the dissertation by Gulliver (1865–1919) that was entitled simply *Shoreline Topography* (1899) and was published in the same year as *The Geographical Cycle*.

Davis was continuously working with the cycle, and considered that it is ". . . not arbitrary or rigid, but elastic and adaptable. . . ." For example: "Like the processes of surface carving, the processes of shoreline development are subject to variation with climate, from the work of the ice foot in polar regions to the work of coral reefs and mangrove swamps in the torrid zone" (Davis, 1905, p. 290).

The most influential of Davis's disciples was Douglas Johnson (1878–1944). Despite Gulliver's early coastal work under Davis's direction, it remained for Johnson to publish the first inclusive book dealing with coastal morphology, a book that Zenkovich (1967) considered to be the most complete theoretical study of coasts available. Entitled *Shore Processes and Shoreline Development* (Johnson, 1919), it was aimed at presenting an analysis of the forces operating along the shore together with a systematic discussion of the cycles of shoreline development. This book had a major influence on the study of coasts for at least 40 years, an influence that must be considered to have been detrimental in some regards. Johnson's emphasis on the importance of submergence and especially emergence in shoreline development, as well as the incorporation of these aspects of shore profile development in his classification scheme, delayed more meaningful approaches to coastal understanding for several decades. Nonetheless, much of his material is still useful, and should be consulted by any serious student.

Coastal geomorphology: World War I to World War II

Although the Davisian and Johnsonian evolutionary and qualitative approaches to geomorphology dominated coastal research from World War I to World War II, there were nonetheless a number of important developments that occurred during this period of time. One of the most significant of these developments was that coastal research became a respectable research endeavor after Johnson's book was published. Earlier most coastal research was of a practical nature—harbor construction, coastline defense, coastal mining, and the like. Few university scholars studied coasts for their own sake. Geologists, for example, often resorted to coasts, but only because coastal cliffs provided them with good exposures of the rocks they were studying, not because of any interest in their existence as coastal forms.

A second and concurrent development was the rapid rate at which human utilization of the coast developed. The increase resulted directly from increases in coastal populations and indirectly from man's increased mobility, desire for coastal vacations, and use of coastal resources. Fortunately, this increased utilization of the coast was accompanied by an increase in its study, although not to the extent that might have been desirable.

The sponsorship by the United States National Research Council of separate studies on tides and sea-level changes in the 1920s, the creation of the Commission of Coastal Studies in the USSR and the Coastal Engineering Research Center in the United States, and the publication of such volumes as *Recent Marine Sediments* (Trask, 1939) are examples of the organized endeavors that began between the two World Wars.

Despite a number of technical advances, there were surprisingly few actual substantive developments. In a very real sense, this period of time was transitional and set the stage for the rapid rise in coastal research that began after World War II. The way in which this transition proceeded might be illustrated by considering the way in which depositional landforms came to be recognized as significant elements of the landscape. One of the pioneers of depositional geomorphology was R.J. Russell (1895–1971). Trained in the Davisian School with its emphasis on erosion, Russell had to develop a completely new perspective in order to understand the depositional landforms he found when he moved to Louisiana. He utilized the thousands of cores taken during the drilling for oil in the Mississippi River delta, sets of detailed topographic maps (the drafting of which was prompted by a severe flood in 1927), and aerial photography (Russell, 1936). This research of Russell and his co-workers over a 20-year period led to the acceptance of the importance of three-dimensional studies in geomorphology, a clarification of the different types of subsidence, a reevaluation of Johnson's concepts of emergence and submergence and of Davis's concept of old age, and to new notions about sea-level fluctuations.

World War II and the impetus it gave coastal research

By the end of the 1930s, research on coastal problems, as well as that on other scientific topics, was beginning to recover from the difficult times that accompanied a worldwide depression when World War II erupted. Many scientific and engineering activities such as those being planned by the revitalizing Beach Erosion Board (BEB) of the United States had to be redirected toward war efforts. An even more extreme response to wartime demands was the dissolution of the Commission of Coastal Studies in the USSR mentioned above. Before its demise; however, the Commission sponsored a number of coastal engineers and geomorphologists (such as Vesolod Zenkovich) many of whom became very productive after the war.

In the case of the BEB, wartime coastal research efforts were focused on gathering information on foreign beaches. W.C. Krumbein (1944) of the United States and W.W. Williams (1947) from England, along with their associates, concentrated on those coastline characteristics that could impact beach landings including beach slope, sediment texture, wave climate, and tidal parameters. During the War, the BEB produced more than 50 reports on beaches around the world including some in the little previously studied tropical zones.

More important from the standpoint of coastal research than the descriptive details of many of the world's beaches that came from these efforts, were the war-generated developments that impacted virtually all of science. The developments included (1) the assemblage of scientists into research groups including those that became known as Research and Development Laboratories, (2) many technological advances in equipment useful to coastal research, (3) specialized educational opportunities at universities, (4) the spread of both scientists and scientific research around the world, (5) the multiplication of regional, national, and international organizations devoted to geomorphology including coastal morphology, (6) an increasing emphasis on scientific conferences, workshops, and symposia, and (7) an increase in opportunities to publish on basic, as well as applied, topics.

Coastal research during the third quarter of the 20th century: a period of expansion

One of the major advances that blended many of these developments was the creation, in 1952, of the Commission on Coastal Sedimentation within the International Geographical Union (IGU)—a commission whose name was changed a few years later to the Commission of Coastal Geomorphology (Schou, 1964). The senior members of the Commission— A. Schou (Denmark), J.A. Steers (England), V. Zenkovich (USSR), R.J. Russell (USA), and A. Guilcher (France)—were among the most productive geomorphologists during and immediately following World War II. With the diverse topical and regional backgrounds they and numerous corresponding members represented, they recommended a very diverse set of topics that needed research (Schou, 1964).

A couple of years earlier (1950) coastal engineers began holding biennial conferences from each of which stemmed proceedings volumes on coastal topics. By 1996 more than 2,300 papers had been produced, most of which have relevance to coastal geomorphology.

Whereas the 1950s showed much progress, some coastal geomorphologists still considered the subject immature. For example, Williams (1960) observed that:

> . . . theories of coastal behaviour have been based on the most simple visual observations, and there is no doubt that some of these observations have been misleading . . . [however, he added further that] today new techniques are being developed which should lead to a more certain knowledge of the subject (p. xi).

Similarly, as late as 1968, Russell still considered ". . . the subscience of coastal morphology as one in relative infancy . . ." but, like Williams, one with great promise. During the 1950s and 1960s, a number of coastal scientists began to base their research on the concept of process and response. They in general followed the procedure advocated by Strahler (1952) for fluvial morphologists. Strahler stated that:

> . . . dynamic-quantitative studies require, first, a thorough morphological analysis in order that the form elements of landscapes may be separated, quantitatively described, and compared from region to region (p. 1118).

Such a procedure proved to be especially valuable for morphologic research in the coastal zone because of the great number of forms and processes present there and because of the complex nature of the interrelationships that exist between them. The process-response models that resulted from such studies proved of value in both the production of specific types of coastal behavior and the provision of a clearer understanding of the integrated nature of the coastal system.

During the period of the 1950s and 1960s, such varied techniques as radioactive tracers, aqualung diving, satellite imagery, electron microscopy, and high-speed computers began being used to provide data and analyses about coastal forms and processes at scales both larger and smaller than had been possible during prewar years (Walker, 1977).

Although the scientific study of coasts had traditionally been in the hands of western Europeans and Americans, during the years following World War II it truly became international. Evidence of this development is indicated by: the frequency with which international symposia were being held; by the increasing numbers of research papers being produced in non-Western countries (Walker, 1976); and by the increasing frequency of research along arctic, desert, and tropical coasts.

In the third quarter of the century the number of publications in coastal geomorphology increased dramatically. Some of the books, like that of Douglas Johnson 40 years earlier, were broadly based. Included were Guilcher's *Morphologie Littorale et Sous-Marine* (1954), Zenkovich's *Processes of Coastal Development* (1967), Bird's *Coasts* (1969), King's *Beaches and Coasts* (1972), and Davies' *Geographical Variation in Coastal Development* (1973). Others such as Ippen's *Estuary and Coastline Hydrodynamics* (1966), Shepard and Wanless' *Our*

Changing Coastlines (1971), and Komar's *Beach Processes and Sedimentation* (1976) deal with special aspects of coastal science.

Also, during this period of time, collections of papers began to become common. Many of them were special issues of standard periodicals, such as *Dynamics and Morphology of Sea Coasts* edited by Longinov (1969) as Volume 48 of the *Transactions of the Institute of Oceanology*; Tedrow and Deelman's *Soil Science* (1975), which is devoted to soil formation in sediments under water; and Fairbridge's *Contributions to Coastal Geomorphology* (1975), and Kaiser's *Küstengeo- morphologie* (1968), as special issues of *Zeitschrift für Geomorphologie*. Yet another category of volumes that resulted from symposia include: *Estuaries*, edited by Lauff (1967); *Waves on Beaches and Resulting Sediment Transport*, edited by Meyer (1972); *Coastal Geomorphology*, edited by Coates (1973); *Nearshore Sediment Dynamics and Sedimentation*, edited by Hails and Carr (1975); and *Research Techniques in Coastal Environments*, edited by Walker (1977). Still, a third type of compilation was developed toward the end of this period. Especially valuable from the standpoint of the development of coastal concepts, its volumes brought together the key papers representing the development of particular topics. A prime example is the *Benchmark Papers in Geology*, of which *Spits and Bars* (1972) and *Barrier Islands* (1973), both edited by Schwartz, and *Beach Processes and Coastal Hydrodynamics*, edited by Fisher and Dolan (1977) are especially appropriate.

Contemporaneous with the publication of volumes such as those listed above was the development of a number of concepts that modified the focus of many coastal researchers. In 1962, Per Bruun, in response to the emerging concern over sea-level rise, proposed what is now known as the *Bruun Rule* (Schwartz, 1967). In essence, it states that a beach will maintain equilibrium through concurrent erosion and deposition as sea level rises. Criticized and modified subsequent to its proposal, the *Bruun Rule* nevertheless continues to be the focus of numerous studies on into the 21st century.

Although coastal sediment transport had been the subject of discussion for decades, the coastal circulation cell concept in relation to the compartmentalization of erosion, transport, and deposition of sediment along coasts was proposed in the 1960s. Bowen and Inman (1966) applied the concept in California while Stapor (1971) used it in connection with a Florida study.

Probably the most innovative development to appear during the third quarter of the 20th century was the scheme proposed by Inman and Nordstrom (1971) in which plate tectonics was used as the basis for classifying coasts. With this scheme coastal morphologists were forced into giving ". . . more thought to long-term but continuing processes in their attempts at explaining present form and location" (Walker, 1975, p. 4).

The last quarter of the 20th century: a period of sophistication and diversification

Whereas the third quarter of the 20th century was one of rapid expansion in coastal research, the last quarter might be considered as one in which research became more sophisticated and diversified. Improved equipment, expanded multidisciplinary cooperation, modified methodologies, and enhanced funding contributed to a number of new research avenues in coastal geomorphology. Possibly one of the most important realizations, following from the cell concept, was the recognition of the interrelationships that exist between different parts of coastal systems.

Even though coastal research became more diversified during the 1980s and 1990s, the research dedicated to beach morphology and processes continued to receive the most attention. Much of this attention is devoted to small-scale hydrodynamics and sediment transport as it occurs in the surf/swash zone. During the 1980s, several large-scale field experiments were conducted on and in the surf zone. Included were the *Near-shore Sediment Transport Study* (Seymour, 1987), the *Duck Experiments* (Mason *et al*., 1987), and the *Canadian Coastal Sediment Study* (Willis, 1987), among others (Horn, 1997). Not surprisingly, considering the complicated nature of such a dynamic zone, different views as to the nature of swash dynamics developed. One group, as exampled by Guza *et al*. (1984), holds that swash is dominated by low-frequency infragravity motions and can be attributed to standing long waves; whereas, another group, represented by Hibberd and Peregrine (1979), holds that swash motion is mainly driven by incident waves that collapse at the shoreline and propagate up the beach face.

For the geomorphologist the value of these hydrodynamic studies is in their help in predicting sediment transport and beach morphology. New instruments, such as the optical backscatter sensor (OBS) and the acoustic backscatter sensor (ABS) are enabling the measurement of suspended sediment concentrations in the surf zone and are being used in conjunction with acoustic doppler velocimeters (Downing *et al*., 1981).

As noted above much of the research along the shoreline has been concerned with the contact zone of the beach and surf. Nevertheless, increasing attention, especially during the past two decades, has been given to mudflats and coastal dunes and especially to their marsh/mudflat and beach/dune systems (Viles and Spencer, 1995). Although mudflats, like the marshes and mangroves behind them, traditionally were considered wasteland and thus prime areas for reclamation, their importance ecologically, once recognized, has served to bring them into the research spotlight.

In China, where mudflats have been reclaimed for millennia, basic research into their characteristics was initiated primarily by the Coastal and Estuarine Research Laboratory (later one of China's Key Laboratories) in Shanghai under the leadership of J. Chen, and the School of Geoscience, Nanjing University. Much of the earlier mudflat research was on mudflat distribution but by the late 1980s it included examination of how tidal currents influence grain size distribution (Wang, 1989) and mudflat sediment exchange (Tang-Yinde, 1989). The stability/ erodibility of mudflats during tidal cycles and in response to mudflat biotic activity have also been the subject of recent research (Viles and Spencer, 1995). During the 1990s, several investigators began dealing with the effects of sea-level rise on muddy coasts (El Ray *et al*., 1995; Han *et al*., 1995).

The seminal research on sand dunes by Bagnold (1941) served as the rationale for dune research for more than 30 years following World War II. It was not until the late 1970s that some researchers began to emphasize the distinctions between interior and coastal dunes. An increased appreciation for the facts that the presence and stability of dunes are important in coastal protection, that human activity can impact heavily on dunes, and that coastal dunes play an important role in the beach/dune system led to an increase in the quantity and variety of research on coastal dunes during the last quarter of the 20th century.

Much of the new research on coastal dunes has been devoted to the determination of vertical velocity profiles across beaches and within dune fields and to the measurement of sediment transport by winds (Carter *et al*., 1990). Included is the basic research by Hotta (1988) and by Hsu (1977) who examined the boundary-layer conditions in both sand dunes and coastal ice ridges along an arctic coastline. Hydrodynamic research, which has become so important in many aspects of coastal research, has been applied to coastal dunes by Hesp (1988) and his colleagues. For example, Hesp used morphodynamics as a basis for classifying foredunes by linking vegetation and morphology to nearshore processes. Other factors that have received attention recently are the importance of beach wetness to sediment transport (Jackson and Nordstrom, 1998) and large-scale budgeting in the beach/dune system (Illenberger and Rust, 1988).

Dune research, like that on beaches, has become very international in scope. Some of the most important morphologic research on coastal dunes has been conducted in Australia, South Africa, The Netherlands, Japan, the United Kingdom, and the United States.

Among the other coastal topics that have recently attracted increased attention are shore platforms, sea-level rise and coastal erosion, extraterrestrial coastal geomorphology, and humans as geomorphic agents.

The focus in shore platform research has been on morphology and processes (Stephenson, 2000). For example, Trenhaile and Byrne (1986) concentrated on tides and sea-level change, Sunamura (1992) emphasized wave dynamics, and Viles and Naylor (2002) investigated the role of biogeomorphic processes on platform development.

Along with the proliferation of research on global warming and sea-level change since the 1970s, has come a surge in the investigations devoted to the impact of sea-level change on the coastline. Because all types of coasts are affected when sea level changes, it is not surprising that research of such impacts has been done on beaches, reefs, estuaries, deltas, and even coastal cliffs (Viles, 1989). Morphological and ecological changes in coastal marshes have been intensively examined by Reed (1995), mangrove response by Woodroffe (1995), foredune erosion by Carter and Stone (1989), and, as mentioned above, mudflats by Han *et al.* (1995). This kind of research is destined to intensify even more so long as sea level continues to rise as it has been doing the past few decades.

Extraterrestrial geomorphology is one of geomorphology's newest subdisciplines (Baker, 1993). It, like most other themes in geomorphology, has a long history (see e.g., Gilbert, 1893). Not surprisingly, the field of extraterrestrial geomorphology also has a coastal component (Baker, 2001). Parker *et al.* (1993), after examining high-resolution images of Mars, concluded that that planet not only had liquid water in the past but also possessed lakes and even oceans. Recent studies have identified relic lake sediments, deltaic deposits, and eroded "massifs" (resembling the wave-eroded headlands in Lake Bonneville) (Parker and

Currey, 2001). It is believed that other extraterrestrial bodies such as Venus and Titan, the moon of Saturn, may also support such features and thus provide research opportunities for additional coastal geomorphologists well into the future.

The importance of humans as agents of geomorphologic change has long been recognized and documented (Thomas, 1956; Turner, 1990). The coastal zone, as one of the world's unique landscapes, has been impacted intensively along much of its extent. Indeed, along the coastline of some of the world's most densely populated coastal zones, the bulk of the shore is now artificial. This provides an opportunity and challenge to coastal geomorphologists because, as Viles (1990) noted:

> Studies on coastal landforms, processes and change are becoming more and more relevant as human intervention (at scales ranging from sand mining on a single beach to global warming) increases (p. 238).

The rapid increase in human intervention in the coastal zone is intimated by the fact that in the year 2000 the number of coastal dwellers was equal to the global population of 1950 (Haslett, 2000). It is not surprising then that many coastal geomorphologists as well as coastal engineers are heavily involved with coastal research.

Much of this research has been focused on coastline protection (Walker, 1988; Pilarczyk, 1990), beach nourishment (Finkl and Walker, 2002), beach stabilization (Silvester and Hsu, 1991), beach management (Bird, 1996), and wetland restoration (Mitch and Gosselink, 2000). Sherman and Bauer (1993), referring to this trend, predict that:

> . . . human altered coastal systems will be a major focus of research for coastal geomorphologists over the next twenty years . . . [and, equally as relevant] that coastal scientists will have less choice and less input to what their subject of study will be . . . (p. 240).

Organizations, conferences, proceedings, journals, and books: 1975–2000

The fourth quarter of the 20th century saw the number of organizations, conferences, proceedings, journals, and books dealing with coastal geomorphology continue to increase. In addition, the coastal component of a number of geomorphology organizations also increased in prominence. For example, at the First International Conference on Geomorphology (1985) more than one fifth of the papers presented dealt with fluvial and coastal topics. Coastal geomorphologic papers have continued as an important ingredient of subsequent conferences. Recently established journals (i.e., those founded since 1975) that publish coastal papers of interest to geomorphologists include: *Applied Ocean Research* (1979), *Coastal Society Bulletin* (1977), *Earth Surfaces Processes and Landforms* (1976), *Geomorphology* (1987), and the *Journal of Coastal Research* (1985). In addition, many long-established journals have recently published special numbers devoted to coastal topics. They include: *The Geographical Review* with a number called *Coastal Geomorphology* (1988); *Catena* with a number on *Morphology and Sedimentation in Fluvial–Coastal Environment* (1997); *Marine Geology* with numbers on *Beach Ridges* (1995) and *Large Scale Coastal Behavior* (1995); and *Physical Geography* with a number on *Coastal Dunes* (1994).

One of the most extensive series of special numbers devoted to coastal topics is that published as Special Issues by The Coastal Education and Research Foundation (CERF). Since 1986, more than 30 such special issues have been published under such titles as *The Effects of Seawalls on the Beach* (1988), *Impacts of Hurricane Hugo: September 10–22, 1989* (1991), *Coastal Hazards* (1994), *Sediment Transport and Buoyancy in Estuaries* (1997), and *Tidal Dynamics* (2001).

In addition to such special numbers are the numerous review articles that have recently appeared detailing the advances in coastal geomorphology. *Progress in Physical Geography*, for example, has had a number of status reports including: *Coastal Landforms* by S.B. McCann (1982), *Coastal Depositional Landforms; a Morphodynamic Approach* by L.D. Wright and B.G. Thom (1977), *Coastal Geomorphology* by H.A. Viles (1990), *Sea-level Rise as a Global Geomorphic Issue* by D.R. Stoddart and D.J. Reed (1990), *Beach Research in the 1990s* by D.P. Horn (1997), and *Mid-Holocene Sea-Level Change and Coastal Evolution* by A. Long (2001).

Possibly the most revealing characteristic in the development of coastal research subsequent to World War II is illustrated by the articles appearing in what must now be considered the bellwether journal of coastal science, the *Journal of Coastal Research* (JCR). Since its foundation in 1985 as an "International Forum for the Littoral Sciences" it has published some 1,400 articles in more than 18,000 pages. Although published in the United States, JCR reflects the international character of today's coastal research in that more than half of the articles stem from countries other than the United States. Of the total, the United Kingdom is represented by more than 80 articles; New Zealand, Australia, and South Pacific Islands by 116; Canada by 57; Latin America by 73; Scandinavia and The Netherlands by 63; the Orient by 51; and Russia by 24 (Finkl, 2002, personal communication).

Equally as revealing of the trend in research in coastal geomorphology is the specialized nature of the books that have appeared since 1975. Although prior to that date, as noted above, conference proceedings were often quite topical, books tended to remain inclusive. By 1980, however, coastal books began to reflect the maturation of coastal geomorphology in two significant ways. First, details about coastal environments had developed to a point where specialized volumes became justified and second, theories of coastal science had been enhanced sufficiently to lead to new approaches in considering the field especially in those portions of coastal geomorphology relevant to human activities.

The first category of books is well exampled by a series, edited by E.C.F. Bird for John Wiley & Sons, that includes *Coral Reef Geomorphology* (1988) by André Guilcher; *Coastal Dunes: Form and Process* (1980), edited by K. Nordstrom, N. Psuty, and B. Carter; and *Geomorphology of Rocky Coasts* (1992) by T. Sunamura. The second-type approach is represented by three books recently published by UK authors, namely: *Coastal Problems: Geomorphology, Ecology and Society at the Coast* by H. Viles and T. Spencer (1995); *Coastal Systems* by S.K. Haslett (2000); and *Coastal Defences* by P.W. French (2001).

Conclusion

Although, as noted in the introduction of this History of Coastal Morphology, the coast was late in attracting the attention of scientists, it eventually became one of the major subdisciplines in the field of geomorphology. The rapidity with which it has developed during the past few decades might have pleased R.J. Russell who, even as late as 1968, considered the field in its infancy. Since World War II, a number of conditions evolved to place coastal geomorphology on a sound footing. Advancements in monitoring systems, development of new theories, increased funding opportunities, broadening the scales of investigation, inputs from other disciplines, and debates of controversial conclusions have all played a part in the maturation of coastal geomorphology.

As has been true throughout the history of science each new discovery rewards investigators with intriguing questions. Coastal geomorphology is no exception. The variety of the earth's coastal forms coupled with the dynamics of the forces operating on them will tax the expertise of coastal geomorphologists far into the future.

Sea-Level Rise, Effect

HISTORY, COASTAL PROTECTION

Though the claim of the Frisians to have been the first to devise an embryonic system of coastal defense is probably appropriate for the northern European area, others may equally assert their right to first place; the history of coastal engineering can be traced back in China to the East Han dynasty era. Indeed large coastal defense projects were initiated between about 25 and 220 before our era (Xu Qiwang, 1993). In the Mediterranean, likewise, coastal engineering had an "early start" particularly among Greeks, Etruscans, and Romans, and also Carthaginians, Minoans, Phoenicians, Sumerians, and Egyptians.

Classical times

Dikes were built under the reign of Apollonios Ptolaemeus II Philadelphis, Egyptian ruler, during 259–258 BC. He donated to his employee Stothoaetis, a large section of land in Ghoram, Fayoum (Philadelphia); where the owner decided to exploit the embankments by establishing a network of canals and dikes, well before "westerners" drained land in more northern areas. A cursory examination of a picture of the Alexandria Lighthouse, one of the seven wonders of the world of the classical times that crumbled to the bottom of the sea due to a 14th-century earth tremor, shows rather sophisticated dikes around Pharos Island. A French expedition funded by the Electricité de France brought back to the surface, in 1998, the colossal statue of Ptolaemeus II that stood in front of the lighthouse.

Coastal defense history is, naturally, closely linked to harbor creation and development. Primitive breakwaters were put in place occasionally with ramps allowing the top of the waves to pass over them. The Phoenicians had devised wave catchers by excavating holes and establishing trenches in the rocks lining the shores (Raban, 1988). Carved breakwaters were cut out of bedrock: a suitable wave-absorber profile was created which had a gentle grooved slope at the waterline. The classical example dating from the 2nd century BPE is still visible at Ventotene (Italy), it had an overspill. One may see in it an early version of today's Fontvieille breakwater (Principality of Monaco).

Greek and Etruscan breakwaters and seawalls consisted of rubble mounds topped by cut rocks; though no mortar was used, neighboring blocks were sometimes held together by clamps and joints made out of metal. With the discovery of pozzolanic ash hydraulic-cement, solid breakwaters could be built underwater, and several vertical composite concrete walls have been preserved from the 2nd century to the 5th century before our era. There are illustrations of a vertical breakwater made *in situ* within a wooden frame and tie-rods. Toe protection against scouring was provided occasionally by a bronze slab (Oleson, 1988).

Not only had these engineers mastered the art of erecting cofferdams for construction "in the dry," but they also thought of caissons, forerunners of contemporary building methods. Watertight wooden cellular caissons were used to cast large concrete breakwaters, for example, at Caesarea. "Permeable" breakwaters and "arched moles" were installed in various sites (Franco, 1996a). Apparently well before the Dutch dykebuilders thought of sinking old ships, the Romans sank old hulls, filled them with concrete and had a breakwater placed in no time, under Claudius' reign, Caligula's "monster" ship was sunk at Ostia (50) to provide a breakwater (Testaguzza, 1970). Remnants are still visible at 4 km from the Fiumicino airport.

Trajan built a rubble mound breakwater on an "island," reshaped by nature and workers leading to a subsequent mild slope profile (Franco, 1996b).

Medieval times and Renaissance

Grillo (1989) reports that the earliest written document dealing with shore protection dates back to 537 when fagines, wicker faggots, supplemented by timber piles and stones, held up earthen dikes adding their protection to that of the dunes.

"Timber and rock revetments and groynes have been used (in the Venice area) until 1700 to halt beach erosion and silting" notwithstanding a lengthy transport for rocks and short life span of wood (Franco, 1996b). Strict environmental regulation governing shore protection can be traced back to legal documents of 1282 and 1339: prohibition to cut or burn trees from coastal forests, to pick mussels from rock revetments, to let cattle walk the dikes, to remove sand, and vegetation, from beach or dune, and to export materials used in coastal defense (Grillo, 1989). The *Magistrato alle acque*, created in 1501, invited suggestions to reduce the high cost of the coast defense, so, in the 18th century, there appeared rip-rap revetments, gabions, staircase-placed limestone blocks, and the use of mortar and steel links and flexible steel strips became common.

Whereas beaches protect the littoral, they had to be maintained, and artificial nourishment with offshore dredged sand was initiated as early as the 17th or 18th century, hence long before California used the method (1919).

Massive *murazzi*, devised by Zentini and his team were constructed from 1741 on; with an average width of 12 m (39 ft), their crest peaked at 5 m (16 ft) above mean sea level. It took 40 years to construct a protective seawall 20 km (12.4 miles) long (Charlier and De Meyer, 1998). *Murazzi* have withstood the test of time, though storms took their toll and toe protection was eventually provided by a rubble mound structure and, more recently, jet-grouting diaphragms. Commenting on the Genoa breakwater, an actual fortification with a superstructure, Franco (1996b) underscores its importance as in 1245 it was proclaimed a "pious work" thereby compelling every citizen of the Republic of Genoa to provide in his will for the breakwater's maintenance.

Of course no Renaissance technology review can pass over Leonardo da Vinci whose talents included hydraulics and is the father of a proposed triangular-shaped island breakwater. He as well championed the credo of "working with Nature," rather than against it: *ne coneris contra ictum fluctus: fluctus obsequio blondiuntur (Nature should not be faced bluntly and challenged, but wisely circumvented)*.

Franco (1996b) has virtually provided a catalog of Italian designed breakwaters: use of irregular blocks with pozzolanic concrete crown and large rock armor porosity, (Crescentio in 1607), a monolithic superstructure over a leveled rubble mound foundation; (De Mari in 1638), armored with precast blocks (San Vincenzo mole at Naples, 1850), vertical composite structures (1896), and caisson construction (1915, 1931, 1936, 1938, 1995).

Contemporary approaches

If new approaches to coastal defenses were slow, and little new technology was introduced during the centuries—though improvements and refinements were often made—the pace of change accelerated considerably in the 20th century, even more so during the last decades. The large beach nourishment achievement in Belgium (1980s) has been surpassed, profile nourishment and berm feeding have been implemented—aimed simultaneously at restoration and protection—not less than 40 alternative methods have been proposed and tried out. But the problem has not been solved; for instance, all 30 of the US coastal states suffer from erosion and some see Hawaii's tourist industry in jeopardy.

At the turn of the 20th century, the response to coastal erosion remained the construction of hard defense structures: groins, jetties, breakwaters, revetments, gabions, placement of tetrapods, and the like. However, the groins placed at Miami Beach and Long Island N.Y. did not stall retreat of the shore. The same situation prevailed in Europe where beaches were shrinking in Denmark, Germany, The Netherlands, Belgium, and France. The Mediterranean beaches were not spared either. The problem is worldwide. Variants were tried out, sometimes meeting limited success, that is, floating, permeable, offshore breakwaters. If hard structures do protect or extend beaches on one face, the downdrift side is starved.

Beach planners, engineers and geologists proposed to artificially renourish beaches and the approach was tried on northern California beaches in the early 1920s. Since then the "re-charging" of beaches has been carried out around the globe, wherever there were sufficient funds to undertake an operation that is not inexpensive. Major schemes were undertaken in the United States, Belgium, and France. The beaches require regular additions of sand and in some cases a major storm may carry back to sea a major part of the artificial deposit.

Artificial beach nourishment entails many operations among which selection of the materials and of the source spot, method of material transportation, study of the waves and weather climate, of the physical and biological impacts. Improvements on the simple method of direct material dumping have been sought and thus appeared profile feeding, establishment of a feeder berm (e.g., De Haan, Belgium), and combinations of hard and soft defenses. Beach dewatering has been presented as a new alternative (e.g., Carolinas in the United States) but in fact it is more a complementary than an alternative method. At any rate it helps a beach retain the nourished material for a longer span of time. Sand backpassing and by-passing have proven valuable approaches (Hillsboro Inlet, Florida; Durban, Republic of South Africa); sand is transferred from one side of a structure or formation to the other which is starved. In compensation dredging, a somewhat similar method, the material is dredged and carried to another site that needs to be nourished.

There are over 40 methods that have been proposed and/or patented to halt coastal erosion. Though most have merits, most also have objectional side effects or hard-to-accept environmental impacts. Two of them, Berosin® and Beachbuilder®, apparently are free of them but are, at least temporarily, unaesthetic. The latter of the two attempts to promote beach accretion by using the power of the erosive waves to build up the beach.

Still other approaches have been tried: artificial reefs, artificial or restored dunes, fields of algae or synthetic fronds, creation of inlets for seawater. However, one should not lose sight of the fact that shore landward migration is inexorable, that people can only slow down the inland progress of the sea, and that only nature can definitely reverse the trend.

Conclusion

In the 19th and 20th centuries, coastal protection against an advancing sea has been centered on a variety of hard structures (groins, breakwaters, seawall, tetrapods, etc.) and artificial nourishment. Environmental concerns have steadily played a more important role. Some 40 types of alternative schemes have been proposed over the last decades, with a large number of them faulted for negative environmental impacts. As the economic consequences of the landward migration of the shore are often disastrous, the search of solutions remains.

HOLOCENE COASTAL GEOMORPHOLOGY

Normally forming processes on the earth need time measured in geological scales (i.e., many thousands to millions of years) to show adequate results with mature forms. In contrast to this general rule all coastal forms we can see along the world's coastline are not older than 6,000–6,500 years, because the oceans had not reached this level before this date; coming from a lowstand near −100 m during the last cold phase with extended glaciers (last Ice Age). The Holocene as a geological epoch, however, started about 10,000–11,000 years ago with the shifting to modern climate and temperatures, but it took several thousand years to melt the extended ice sheets and fill the oceans again. Therefore, the coastal forms we see today belong only to the last phase of the Holocene. There might be some inherited features incorporated in them, formed during former sea-level highstands in the warmer periods of the ice ages, the last time being about 100,000 years ago.

The world's coastlines are the most extended geomorphological features on earth, measuring several 100,000 km on small-scale maps, but more than 1 million km in nature. They are developed in all the different geotectonic and geodynamic situations, along all petrographic units of hard rocks and sediments and in all climatic and biogeographic regions of the world. Therefore, their geomorphological inventory and the amount of forming processes are numerous. Besides the tectonic situation (stable, subsiding, rising) and the type of rock (more or less resistant, massive or stratified, limestone or silicate, hard rock or loose sediments) the kind of wave impact along a certain coastline is the most important factor, itself depending on other facts like depth of nearshore water, strength of wind, tidal range, and others. These elements all have a wide range; in particular the tides, from microtidal (less than 1 m), to macrotidal (with spring-tide ranges exceeding 10 m as in southern England or along the French coast, or even more than 15 m in the Fundy Bay of eastern Canada). These tides distribute wave energy and currents on a wide horizontal area, resulting in tidal flats exposed during low water, marshes from high water and storm deposition, or mangrove fringes in warmer latitudes. Surf beat, with effects on coastal abrasion, depends—besides the water depth—on strong winds from one direction over a long time and on a wide ocean area (called fetch), and the availability of particles as abrasive agents in the surf. Nearly zero energy coasts in calm climates may change to those with gale forces and surf waves more than 10 m high around the southern parts of South America, South Africa, or Tasmania/New Zealand, but even in warmer latitudes hurricanes may occur with similar geomorphological effects. They usually are accompanied by storm surge, that is, rising water driven by strong wind against the coastline and rising additionally by very low barometric pressure. This has the same effect of

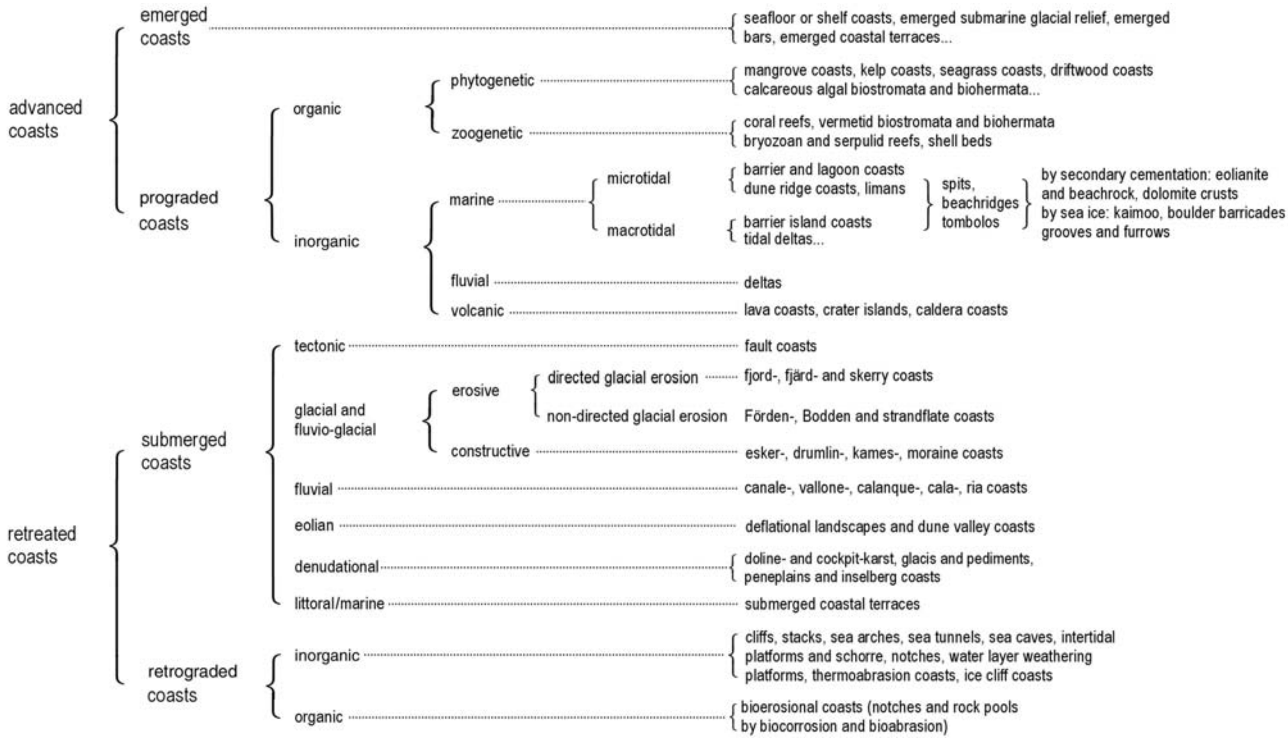

Figure H8 Genetic classification of the world's coastlines (based on Valentin,1952; and modified by Kelletat, 1999).

flooding on low-lying coastal lands as winter storms in higher latitudes. In the highest latitudes, however, sea-ice cover may suppress wave action during many months of the year, but this ice may have geomorphological effects when moving along a coastline during breakup in spring time. Beside the influences of the lithosphere, atmosphere, and hydrosphere the biosphere at the coastlines of the world will promote growth, as well. There are mangrove coasts, coral reef coasts, or those with dominant kelp, sea grass, or driftwood.

All in all, the world's coastlines show a latitudinal zonality (Kelletat, 1995) from sea-ice belts to coral reefs, depending on climate and water temperature in the first order, and on aridity or humidity, in the second order. Even small secular sea-level variations (by neotectonic or isostatic movement of the land, or eustatic changes of the water body itself) have a strong influence on coastal forms: relative rising sea levels lead to more erosion or drowning, falling sea levels to emergence and accumulation. Congruent with the ongoing sea-level rise during the last 1–2 centuries on the order of 1–3 decimeters (maybe partly caused by the anthropogenic greenhouse effect with global warming) a significant erosion of beaches and coastal dunes as well as wetlands has been observed. Holocene sea-level variations, however, are still under debate. It seems that there are a large number of different sea-level hypotheses depending on geotectonic factors as well as eustatic ones, sediment load, compaction, and more (Pirazzoli, 1991).

The prehistory of all modern coastal forms is a rising sea level (i.e., about 100 times faster than today's rising) from the last glacial maximum to the present warm phase. This steady transgression on formerly terrestrial environments could not leave marked forms but reworked the weathered mantle on the drowned landscapes, thus generating abundant coastal sediment. The transformation of the landscape by waves, however, was minimal, and the type of "primary coasts" with partly submerged terrestrial forms dominated nearly everywhere. After reaching the modern level about 6,000 years ago, the balance between marine and littoral processes on one side and terrestrial ones on the other side was concentrated along a fixed level, leading to a significant transformation and sculpturing the many types of "secondary coasts," dominated by littoral processes. The most striking evidences for abrasion and coastal destruction are cliffs, sea arches, sea caves, or stacks. Their amount of recession depends on surf energy and rock resistance but can reach several 100 m during Holocene times, leaving slightly inclining rock platforms in front of the cliffs. There is not only surf that destroys the coasts, but salt weathering or bioerosion may be important in certain environments, as well. Advancing coasts show beaches with accompanying coastal dunes (possibly cemented into beachrock or eolianite in more arid environments), sometimes formed into spits or barriers (or chains of barrier islands in regions with higher tidal range), or marshlands, whereas deltas can develop even along submerging coasts, if sediment discharge is strong enough. Beside the destructive and constructive coastal forms the category of ingressive features is very variable, representing many relief forms of the earth in a partly drowned status (fjords, rias, tropical karst, etc.).

A fully genetic classification of the world's coastlines is presented in Figure H8: All belong either to the class of advanced or retreated coasts, advancing may be caused by emergence or progradation, retreating by submergence or erosion. Next categories point to organic or inorganic processes or types of partly drowned terrestrial relief, tidal range, etc. (Figure H8). The coasts—in particular the accumulative ones—are important archives for even small environmental changes, because their ecosystems are very sensitive. They more and more fill the gap between terrestrial proxies (from inland ice, peat, lakes) and oceanic ones (from deep-sea sediments).

On a worldwide scale, the coasts are more and more often being transformed by human beings, either directly (land reclamation, coastal protection with seawalls and dikes, mining of beaches, aquaculture in mangrove areas, and others), or indirectly, by drilling oil or water from the ground, with the consequence of subsidence (Mississippi Delta, Venice), trapping river sediments in reservoirs far from the coast with the consequence of starving beaches, polluting nearshore waters by pesticides or sediment suspension from deforestation and agriculture, with the consequence of coral reef destruction, etc., or by global warming by emission of greenhouse gases. Textbooks on coastal geomorphology mostly give the impression of a consecutive, slow development in coastal environments. New research brings into discussion, whether sudden events of extreme energy (such as tsunami) may be as important or more important for the development of some coastal forms and deposits. All in all many questions remain to be solved in coastal geomorphology, and the coastlines of the world are by far not adequately investigated.

Further reading on this subject may be found in the following bibliography.

HOLOCENE EPOCH*

The Holocene, or "wholly recent," Epoch is the youngest phase of earth history. It began when the last glaciation ended, and for this reason is sometimes also known as the post-glacial period. In reality, however, the Holocene is one of many interglacials which have punctuated the late Cainozoic Ice Age. The term was introduced by Gervais in 1869 and was accepted as part of valid geological nomenclature by the International Geological Congress in 1885. The International Union for Quaternary Research (INQUA) has a commission devoted to the study of the Holocene, and several International Geological Correlation Programme (IGCP) projects have been based around environmental changes during the Holocene. A technical guide produced by IGCP Subproject 158B ("Palaeohydrological Changes in the Temperate Zone") represents a comprehensive account of Holocene research methods (Berglund, 1986). Since 1991, there has also existed a journal dedicated exclusively to Holocene research (*The Holocene*, published by Arnold).

During the Holocene, the earth's climates and environments took on their modern, natural form. Change was especially rapid during the first few millennia, with forests returning from their glacial refugia, the remaining ice sheets over Scandinavia and Canada melting away, and sea levels rising to within a few meters of their modern elevations in most parts of the world. By contrast, during the second half of the Holocene, human impact has become an increasingly important agency in the modification of natural environments. A critical point in this endeavor was when *Homo sapiens* began the domestication of plants and animals, a process which began in regions like the Near East and Mesoamerica very early in the Holocene, and which then spread progressively to almost all areas of the globe. For short histories of the Holocene, see Roberts (1998) and Bell and Walker (1992).

Although there are different schools of thought about how the Holocene should be formally defined (see Watson and Wright, 1980), the most common view, and one which is supported by INQUA, is that the Holocene began 10,000 radio-carbon (^{14}C) years ago. But ^{14}C chronologies count AD 1950 as being the "present day" and also underestimate true, or calendar, ages by several centuries for most of the Holocene. Nonetheless, there is evidence of a global climatic shift remarkably close to 10,000 ^{14}C yr BP (years before present), often involving a sharp rise in temperature (see Atkinson *et al*., 1987).

Various attempts have been made to subdivide the Holocene, usually on the basis of inferred climatic changes. Blytt and Semander, for instance, proposed a scheme of alternating cool–wet and warm–dry phases based on shifts in peat stratigraphy in northern Europe. Some researchers believe there is evidence of a "thermal optimum" during the early-to-mid part of the Holocene. During the 1980s, the Cooperative Holocene Mapping Project (COHMAP) members established a comprehensive paleoclimatic database for the Holocene (Wright *et al*., 1993), and showed that variations in the earth's orbit were the principal cause of differences in climate between the early Holocene and the present day. For this reason, the early Holocene is unlikely to provide a good direct analog for a future climate subject to greenhouse-gas warming (Street-Perrott and Roberts, 1993).

HONEYCOMB WEATHERING

Honeycomb weathering produces extensive networks of small cavities that form on rock surfaces. These patterns initially develop as many shallow depressions, but continued development produces deep chambers that are separated by thin septa of unweathered rock (Figure H9). Individual cavities are typically several centimeters in width and depth, the shape often being controlled by bedding planes, foliation, or other structural features of the rock in which they occur. In many localities the holes occur in association with a hardened surface layer formed when dissolution of ferruginous minerals has been followed by precipitation of ferric hydroxides near the outcrop surface. The thickness of this hardened layer may range from a few millimeters to several centimeters.

Honeycomb weathering has worldwide distribution, typically found in coastal outcrops and inland deserts. The most-studied occurrences are those of Australia, the western United States (Figure H10), and South Victoria Land, Antarctica. This type of weathering is most commonly observed in sandstone, but it also occurs in granite, gneiss, schist, gabbro, and limestone. The mode of formation of these cavities is not well established, and several hypotheses have been advanced. Possibly more than one type of mechanism may be involved.

In formulating any explanation it is necessary to account for the extremely selective nature of the erosion. One possibility is that the rock possesses internal variations in hardness, composition, or porosity. This conflicts with the fact that honeycomb weathering commonly occurs in rocks that have a high degree of physical and chemical homogeneity. Thus,

Figure H9 Honeycomb weathering in sandstone near Baku, Azerbaijan on the west coast of the Caspian Sea. (Photo, M.L. Schwartz.)

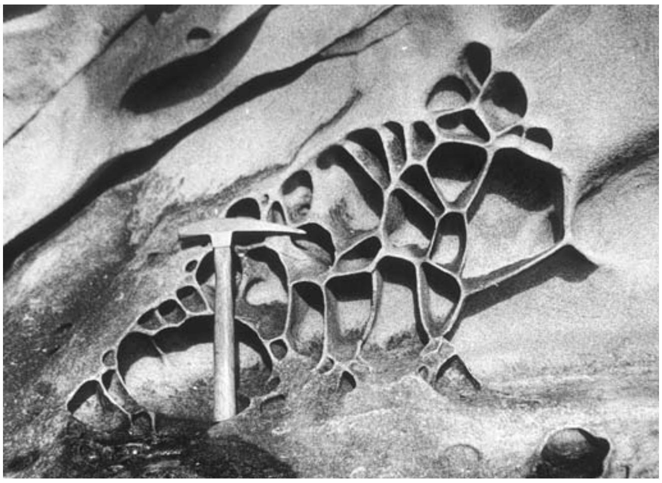

Figure H10 Honeycomb weathering in sandstone at Larrabee State Park, near Bellingham, Washington, USA. (Photo George Mustoe.)

it is more likely that attack by the weathering agents occurs in a differential fashion. Early investigators invoked a diverse variety of geomorphic processes to explain honeycomb weathering, but these cavities are now generally accepted to be caused by salt weathering, where evaporation of wave splash or saline pore water produces salt crystals that wedge apart mineral grains (Evans, 1970). Chemical dissolution of silicate minerals may also play an important role (Young, 1987). Just how these process works to produce a delicate honeycomb pattern remains an enigma. Mustoe (1981, 1982) believed that coatings of lichens and algae on the rock surface control the pattern of cavity development. Laboratory experiments by Rodriguez-Navarro *et al*. (1999) suggest that erosion may be related to variations in wind currents flowing over the rough outcrop surface.

HUMAN IMPACT ON COASTS

Introduction

Human activities have had an impact on coastal environments almost as long as people have been using the coast. It was not long before attempts to control erosion resulted in various types of structures such as jetties, groins, and seawalls. Access to the beaches of barrier islands resulted in fill-type causeways. Development of barrier islands accessed by these causeways resulted in various types of construction that have negatively impacted on the coastal zone. Harbors and the navigational channels leading to them have resulted in some problems for estuaries. Overall, there are many ways whereby human activities have caused problems for a broad spectrum of coastal environments. Some of these are a result of direct acts of development and others are indirectly the result of these activities. The following discussion will consider some of the more obvious and problematic human impacts. Many of the examples will come from Florida where such development-related activities have been underway for several decades and where we can learn from our experiences.

Direct impact

Hard protection

Among the first, the most widespread, and the most problematic human impacts on the coast is the erection of hard structures: those that are immobile and that are not modified by coastal processes. This category includes seawalls, groins, breakwaters, and jetties. Their primary purpose is to protect the coast from erosion and to stabilize tidal inlets. The variety of such structures is tremendous (CERC, 1984), and a comprehensive discussion of them would fill a book. The basic characteristics of each general type and some examples will be provided to acquaint the reader with such structures.

Figure H11 Rip-rap in front of concrete seawall. This is one of the most common types of erosion protection on the open coast environment.

Seawalls of various types have been around for more than a century. The basic situation is protection of the open coast landward of a beach from wave attack. Such structures may be poured concrete, metal sheet piling, pressure-treated wood, or various types of rip-rap; well-placed boulders. Sometimes longard tubes or other sand-filled plastic or cloth tubes are used as temporary protection. Such an approach is viewed as a semi-hard type of protection.

There are problems with these types of structures. Regardless of their type, they tend to be temporary. Eventually, time or severe storms will cause them to fail or become useless for various reasons. Some of the problems associated with seawalls are the scouring that occurs at the base. In many cases, these walls are vertical which takes the full impact of the waves. Rip-rap placed in front of the seawall dissipates wave energy but continued wave attack will eventually result in failure (Figure H11).

Groins are placed perpendicular to the shore in an attempt to keep sediment from being carried away by longshore currents. Most of these are overdesigned and act like dams along the beach causing downdrift erosion (Figure H12). The best performing groins, also among the largest, are along the North Sea coast of The Netherlands and Germany (Figure H13).

Jetties and stabilized inlets are also a problem for beach erosion. They act as large dams, prohibiting longshore transport from moving across the inlet. This is, of course, their purpose because they are constructed in order to stabilize the inlet and maintain its navigability. The downdrift erosion produced by such jetties is chronic (Figure H14) and can only be avoided by some type of sediment or bypass system. Another problem with jetties is that many leak sediment or are short enough to allow sediment to pass around the end so that regular dredging becomes a necessary procedure for maintenance of inlet navigation. Attached breakwaters also have similar problems.

Detached breakwaters (Figure H15) are probably the most benign of the hard open coast structures. These are typically parallel to the shore and are designed to provide some combination of protection from shore erosion and safe mooring for small boats. The negative effects are that they commonly cause a salient to form in the lee of the structure that in many cases forms a tombolo. This connection between the structure and the shore is an unwanted occurrence, which can sometimes be eliminated by lowering the breakwater to permit some wave action and therefore, longshore currents to keep sediment from accumulating. In some cases, the shore erodes even in the presence of these structures leaving them in place but without function. Removal is generally very expensive; commonly more than their emplacement.

Figure H12 Groin showing a significant amount accumulation on the updrift side.

Soft protection

More recently there has been a dramatic and nearly total shift to soft protection for erosion control along the open coast. This has come in two basic approaches: (1) beach nourishment, and (2) vegetation and protection of dunes. These approaches have received the endorsement of the engineering and the environmental community alike. The result is much more esthetic shore protection, however, these techniques are not permanent solutions to coastal erosion. The only permanent solution is abandonment of the barrier islands and open coast shores.

Beach nourishment. Although not new as a method of erosion control, beach nourishment became a standard beginning in the early 1980s (NRC, 1995). The basic scheme is to artificially rebuild the beach that was removed by erosion, and to do it as close to the original, natural beach as possible. The most important factor for such a construction project is the location of a sediment source that is similar to that on the natural beach and that is of sufficient volume to do the job. Most of these projects require an average of about 1 million m^3 of beach quality sand being placed on the eroding shore area. Some are smaller and a few have been much larger.

For a variety of reasons, the borrow site for such beach sand is typically seaward of the beach rather than landward, although a few upland sources have been used. Most of the offshore sources have been the ebb-tidal deltas associated with tidal inlets, and large sand bars or old beach deposits from the present shoreface. Some projects have been nourished using beach quality material dredged from inlets but these are typically at the smaller end of the spectrum. In addition to the limitations posed by the availability of beach quality sand, the distance of transport is a major consideration because this is what comprises most of the cost of the project.

The design of the nourishment project is undertaken by coastal engineers and requires considerable input of coastal processes, storm surge levels at the site in question, desired protection, and historical characteristics of beaches at the site. Commonly, the elevation of the construction berm is associated with the surge level of a 10–20-year storm. In many parts of the Gulf Coast of the United States that would be at about 1.5–2 m above mean sea level. Some extreme elevations along the Atlantic Coast have been constructed at 3–3.5 m above mean sea level.

Figure H16 Construction of a new beach using a conveyor belt to offload sand from a large barge.

Figure H17 Pumping and spreading nourishment sand in the construction of a new beach.

Width is also variable but is almost always at least 15–20 m and sometimes will be up to 50 m.

Once the borrow material has been located, all of the permits are obtained, contracts let, and pre-nourishment surveys completed, then dredging and construction begins. The typical approach is to use a large suction dredge to remove the sand, pump it through pipes or onto barges and eventually be pumped onto the subject shore. Barges are used for transport when the borrow site is more than a couple of kilometers from the construction site. Large tractors are then used to spread the new beach into the specifications in the construction plans (Figures H16 and H17).

Such nourishment projects typically cost from about \$3/m^3 up to \$15/m^3 meaning that many of these projects are over US\$10 million. Overall, this has been a very successful approach. Some areas such as in New Jersey and parts of North Carolina have not been uniformly successful but others such as the Florida Gulf Coast have been successful beyond predictions (Trembanis and Pilkey, 1998). We are still learning about the best way to conduct such protection activities but the cost/benefit ratio on most of them has been high on the benefit side. Probably, the most successful of these projects, and the largest, is the one at Miami Beach (Figure H18). It was completed in 1980 at a cost in excess of US\$60 million but is performing very well and is protecting billions of dollars of upland properties.

Dune protection and stabilization. The other environment that is critical to protection of the upland environment and properties is the dunes that are immediately landward of the beach. Destruction of dunes for development purposes has been eliminated along most coasts and preservation of these dunes is a high priority. In many places dunes have been rebuilt, vegetation has been established, and other measures have been put in place to stimulate dune growth and to preserve those that are there.

Actual construction of dunes is not a widespread practice although small dunes are commonly built to initiate dune development. This approach is most effectively used after a severe storm has caused removal of all or portions of foredunes or if there have been no dunes along a backbeach area. Most commonly, the approach for stimulating dune growth is through planting of appropriate vegetation. This vegetation provides a very efficient mechanism for trapping wind-blown sand from the beach, and dunes form very quickly (Figure H19). These plantings are even irrigated in some areas. Other efforts to enhance dune growth are various types of fencing that will trap sand. Originally, the same type was used that has been used in northern climates for trapping snow along the highways but that has now given way to various types of biodegradable material that will deteriorate when buried for some time. In some countries such as The Netherlands, rows of twigs and shrubbery are planted to trap the wind-blown sand.

Once established, there are methods of preserving the dunes. The most common and most effective is construction of walkovers to prevent foot erosion from people. This is widespread along coasts where there is considerable development and traffic to the beach. In more remote areas, the paths to the beach are simply developed so as to be in opposition to the prevailing and predominant wind directions. The paths also may have multiple changes in direction to prevent wind from blowing along them and eroding the sand.

Soft shore protection is now the standard due to its compatibility with the natural coastal environment and its esthetically pleasing appearance. Although costs are high and maintenance is mandatory, this approach has prevailed for about two decades and will likely do so in the future.

Indirect impact

There are numerous ways in which human activities along the coast can indirectly impact the behavior of coastal environments. These range from the obvious situations where jetties at an inlet may impact beach erosion kilometers down the beach to more subtle situations where activities in an estuary can influence open coast morphodynamics. The discussion here will focus on the activities that impact on tidal inlet stability. All of these activities are involved, one way or another, with coastal development.

Before proceeding farther in the discussion it is important to briefly consider the important factors in inlet morphodynamics. First, the volume of water that passes through an inlet during a given tidal cycle is the tidal prism, a water budget. The prism is the product of the area of the back-barrier area served by the inlet and the tidal range. It is the tidal prism that determines the size and stability of the inlet. Large prisms tend to maintain stability in the inlet position and cross-sectional area whereas small tidal prisms lead to instable inlets that migrate and often close. It is the latter condition that is a main reason for the construction of jetties as considered in an earlier part of the discussion.

There are various types of human activities in the back- barrier/estuarine environments that can impact on the tidal prism and therefore, on tidal inlets. In nearly every case the result of these activities is a decrease in tidal prism and a lack of stability in the tidal inlet(s) involved.

Figure H19 Artificially planted vegetation that is designed to trap sand and promote growth of dunes.

Figure H22 Finger canal development on the back-barrier area as the result of dredge and fill construction.

Construction of fill-type causeways

One of the first major activities of barrier island development is the construction of roadways to access these recreational and resort areas. This was typically accomplished by dredge and fill construction of causeways (Figure H20), many of which were built in the United States in the early 1920s. This was the time that many private vehicles were on the road and people wanted to "drive to the beach."

Such causeways acted like dams in the area between the mainland and the barrier islands. They became efficient tidal divides because, except for navigational passages, there was essentially no tidal flux across these ribbons of fill. As a consequence, there was significant change in the tidal prism of the tidal inlet(s) that served this back-barrier area. The result was change in the inlet stability, typically a reduction in the size and commonly the tendency for migration. As an example, Dunedin Pass in the Clearwater area of the Florida Gulf Coast (Lynch-Blosse and Davis, 1977) showed a major reduction in its cross-sectional area shortly after construction of the Clear-water Causeway in 1922 and then after construction of the Dunedin Causeway in 1964 it was reduced substantially again (Figure H21). This same phenomenon has also taken place on the coasts of Texas, New Jersey, and North Carolina.

Another type of human activity that has had a major influence on inlet stability is the dredge and fill activity that has taken place on the landward side of the barrier islands. The typical situation on this side of a barrier island is domination by some type of wetland environment; either salt marsh or in the low latitudes, mangrove communities. As pressures of development increased and space on barriers became limited these wetlands were included. Such lands brought only a small price because they were deemed worthless. The potential for development was, however, very good. These wetlands were converted to buildable uplands by dredge and fill techniques. Finger canals were dredged through the wetland and the spoil was cast to the side thus producing a supratidal finger of land which when stabilized by seawalls, was suitable for building houses. These finger canals and their associated small peninsulas of land are widespread along many back-barriers but are most common in Florida (Figure H22).

Obviously such development practices have terrible negative impacts on the wetland environments, essentially destroying all of them. Fortunately, they were stopped in the 1960s. The impact of such activities on the tidal prism is also significant. These practices of dredge and fill construction reduce the area of the back-barrier which in turn reduces the tidal prism (Davis and Barnard, 2000). A comparison of two examples from the west-central coast of Florida shows the contrast. Caladesi Island is a virtually pristine barrier island that is about the same size and shape as Long Key, a fully developed barrier. The outlines of these barriers display how the area of the back-barrier has been reduced (Figure H23). An extreme example of this has occurred in Boca Ciega Bay in the St. Petersburg area of Florida (Davis, 1989). This large back-barrier estuary has had its surface area reduced by more than 25% since the 1920s.

Construction of the intracoastal waterway

The Intracoastal Waterway (ICW) is a dredged and maintained navigational channel that extends from Brownsville, TX across the Gulf Coast and then continues along the east coast of the United States up to New England. It was originally constructed for commercial traffic to protect vessels, especially barges, from severe weather and energetic wave conditions. Through most of its extent, the ICW has a design width of 50 ft (~15 m) and a depth of 8 ft (~2.5 m). This channel cuts through some land areas but mostly follows along the open water, back-barrier areas. Along most of its extent the spoil from dredging was cast alongside in piles forming small islands. Aerial photos along many stretches show dozens of these islands that have become valued for fishing and as bird rookeries. The negative side of this dredge spoil is that in many places it was dumped on wetlands and destroyed the area covered. Now a few decades old, the ICW is in need of major maintenance dredging in many locations. Whether or not this happens depends on plans to dispose of the dredge spoil. It is unlikely that disposal of this spoil will be permitted along the channel for environmental reasons. This spoil is not suitable for beach nourishment because of its high mud content and its toxic content at some locations. The cost of disposing it in deep-water offshore is probably too high to be a viable solution. A solution is still not forthcoming.

Another important impact of ICW dredging is its impact on the tidal prism. In narrow back-barrier areas where the prism is comparatively small, such a channel can divert the tidal prism from a natural inlet, along its path up and down the channel. Such a circumstance took place

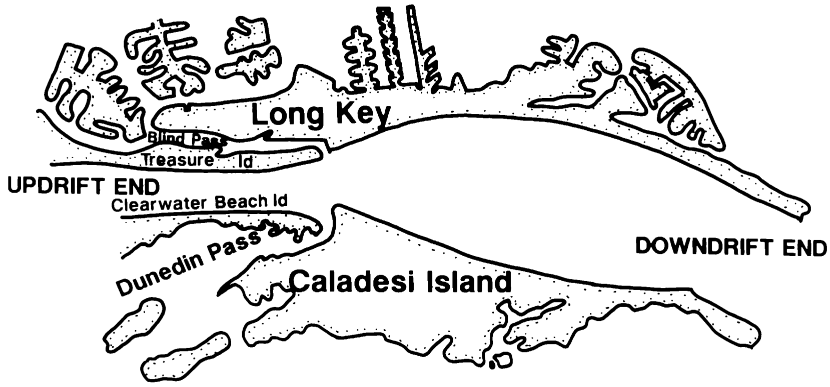

Figure H23 Comparison of the natural shore of Caladesi Island and the drastically modified shore of Long Key, two originally similar barrier islands on the Gulf Coast of Florida. (From Davis, 1989.) Reproduced by permission of the ASCE.

in Little Sarasota Bay, FL in conjunction with the ICW dredging and some other construction practices. The result was closure of a natural tidal inlet that had been open throughout historical time (Davis *et al.*, 1987).

Coincidently with the dredging of the ICW was the dredge and fill construction over several elongate oyster bars that were covered with mangroves. Dredge material was placed on these features and sheet piling was used to contain it. These areas now have several houses on each one. The result is that all circulation within Little Sarasota Bay is now channeled through the ICW and the natural inlet that served this bay, Midnight Pass, has been closed due to its greatly reduced tidal prism (Figure H24).

Summary

Human impacts along the coastal zone are numerous, widespread in kind, and typically detrimental to the environments where they take place. This discussion has focused on the open coast impacts emphasizing the beach and inlet environments. Other types exist, especially in various coastal bay environments.

In general, the impacts on these environments are the result of development pressures for more space to be occupied by residential or commercial properties. Because the land along the coast is so expensive, the pressures are great; both economical and political. The consequences have been disastrous in nature. Fortunately, most governmental jurisdictions have taken action to prevent such activities in the future; at least in the developed countries. Many of the developing countries are still way behind in their planning and management of the coast. Unfortunately, there are indications that too many of them are not learning from the many mistakes that have already taken place and that are well-documented. The other unfortunate circumstance is that even though we have rules and ordinances in place, there seem to be too many exceptions that are granted to violate these regulations.

HYDROLOGY OF THE COASTAL ZONE

Concepts and definitions

In the broadest sense, the hydrology of the coastal zone could include the distribution and movement of any water in the coastal zone; however, in practice, this term generally refers to ground water. A few studies have looked at ground water movement in coastal barriers, water table

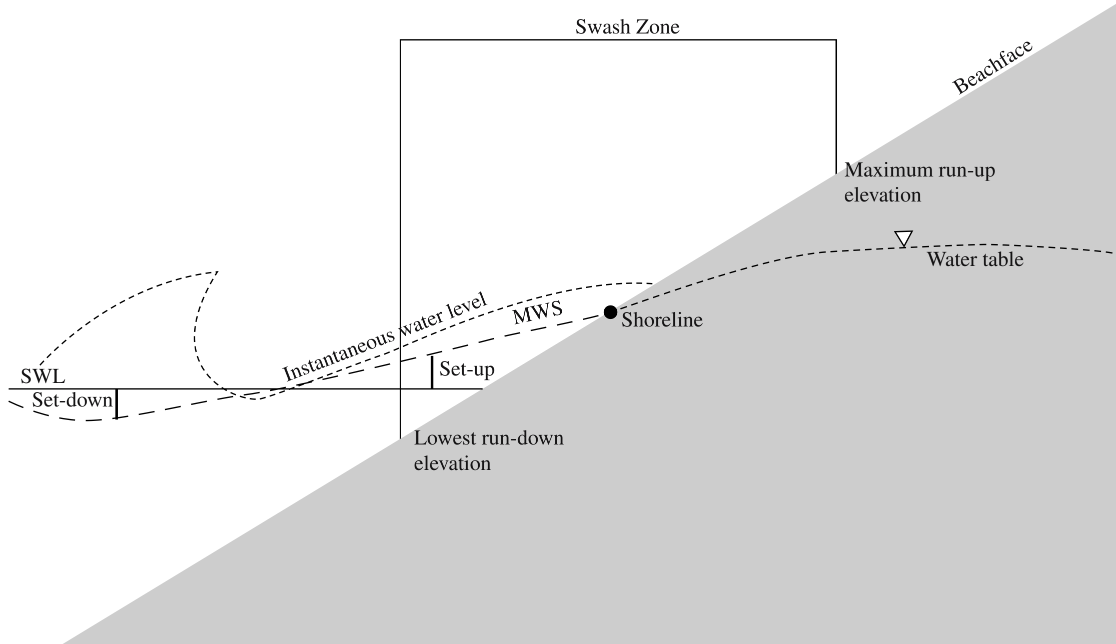

Figure H25 Definition sketch of surface and subsurface water levels in the swash zone.

fluctuations in estuarine environments and gravel beaches, or sand moisture content effects on aeolian sediment transport. However, most studies of coastal ground water dynamics have concentrated on ground water in beaches, and in particular, in the swash zone of sandy beaches. The *swash zone* is the section of the foreshore where final wave-energy dissipation occurs, which is alternately covered and exposed by water motions.

The complex interaction of surface and subsurface water in the swash zone are defined below and illustrated in Figure H25. The *still water level* (SWL) is the water surface in the hypothetical situation of no waves. When the local water-surface elevation is averaged over a time span much longer than incident and infragravity periods but shorter than the tidal period, the result is the local mean water level, which traces the *mean water surface* (MWS). The MWS in the surf and swash zones generally has a gradient which balances the change in the *radiation stress*, defined as the excess flow of momentum due to the presence of waves. Changes in radiation stress are balanced by changes in hydrostatic pressure; in other words, by changes in water level. This difference is known as set-up or set-down. *Set-up* is a wave-induced increase in the MWS, whereas *set-down* is a wave-induced decrease in the MWS. Set-down occurs seaward of the breakers, where radiation stress is at its maximum. The positive gradient due to radiation stress is balanced by a negative water-surface gradient, resulting in a lowering of the MWS to below SWL. Set-up occurs inside the surf zone, where the decrease in radiation stress due to energy dissipation is balanced by the raising of the MWS to above SWL. As long as energy dissipation continues, set-up continues to increase in the onshore direction and is greatest at the shoreline. The concept of set-up is discussed in more detail in the entry on *Surf Zone Processes*.

The *shoreline* is the position where the MWS (including the set-up) intersects the beachface; in other words, the line of zero water depth. The shoreline represents the land–water boundary, which moves across the intertidal beach at a range of frequencies from incident waves (3–15 s) to tides (daily or twice daily for high tide–low tide cycles, and approximately 2 weeks for spring—neap cycles). The limits of shoreline excursion define the boundaries of the swash zone, which migrates up and down the foreshore of the beach over a tidal cycle. The seaward and landward limits of the swash zone are, respectively, the point of collapse of the wave or bore, and the landward limit of wave action. There are two components to the water motions in the swash zone. The first is *swash* (also referred to as *uprush*), which is a landward-directed flow characterized by the upslope transport of water. The second component of the cycle is the *backwash*, which is the downslope movement of the water which follows maximum run-up. The uprush–backwash cycle is essentially an oscillation superimposed on the maximum MWS (including set-up) inside the surf zone. Total wave run-up represents the combined effect of set-up and swash at incident and infragravity frequencies. The *maximum swash height*, or *maximum run-up elevation*, is the maximum vertical height above SWL reached by the uprush. Wave *run-down elevation* is the lowest vertical height reached by the backwash of a wave before the uprush of the next wave begins to run up the beachface. The run-down elevation may be below SWL.

The terminology used by ground water hydrologists to describe subsurface water may not be familiar to coastal researchers; therefore, these terms are defined in some detail here, and are illustrated in Figure H26. The best general reference on ground water hydrology is Freeze and Cherry (1979), from which many of the definitions in this entry are taken.

The beach water table is generally considered to be the continuation of the MWS inside the beach; however, a more physically correct definition of the *water table* is an equilibrium surface at which pore water pressure is equal to atmospheric pressure. The water table may also be referred to as the *phreatic surface*. *Pore water pressure* is the fluid pressure in the pores of a porous medium relative to atmospheric pressure. Below the water table, pore water pressure is greater than atmospheric pressure; above the water table, pore water pressure is less than atmospheric pressure. Hydrologists generally use the term *ground water* to refer to water below the water table, where pore water pressures are positive, and use *soil water* to describe water above the water table where pore water pressures are negative (subatmospheric). However, to equate beach sediment with a soil would be misleading, so in beach hydrology, the term *ground water* is commonly used to mean any water held in the sand below the beach surface. The *phreatic zone* is the permanently saturated zone beneath the water table. The *vadose zone*, which is sometimes called the *zone of aeration* or the *unsaturated zone*, is the unsaturated region of a beach sand body extending from the water table to the sand surface. In the saturated (phreatic) zone, pore spaces are filled with water and pore water pressures are equal to or greater than atmospheric pressure. In the zone of aeration, the pores are filled with both water and air and pore water pressures are less than atmospheric. For this reason, beach ground water zones are better defined by pore water pressure distribution than by saturation levels. A *capillary fringe* develops immediately above the water table as a result of the force of mutual attraction between water molecules and the molecular attraction between water and the surrounding sand matrix. The capillary fringe may also be referred to as the *tension-saturated zone*. (Ground water hydrologists often use the terms *tension* or *suction*—which can be used interchangeably—to describe a pressure which is negative relative to atmospheric pressure). In the capillary fringe, pore spaces are fully saturated, but the capillary fringe is distinguished from the water table by the fact that pore water pressures are negative. The thickness of the capillary fringe in sand beaches may vary between a few millimeters to nearly a meter, and it may extend to the sand surface. Some workers also refer to an intermediate zone which may occur above the capillary zone where the degree of saturation may vary, but remains less than 100%.

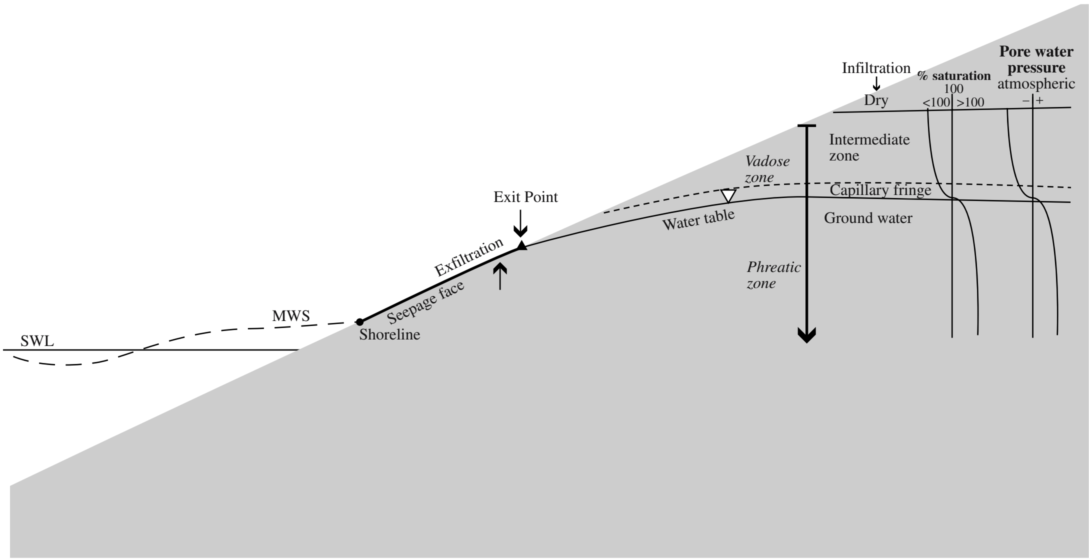

Figure H26 Definition sketch of beach ground water zones when the water table is decoupled from the tide.

Importance of beach ground water and swash zone processes

Swash zone and beach ground water processes are of interest to geomorphologists who wish to determine beach erosion or deposition, or aeolian sediment transport, to marine biologists who are interested in intertidal fauna, and to engineers who require data on run-up, particularly on coastal structures such as breakwaters. Over the past few decades, data on the position of the shoreline, which is directly dependent on swash zone processes, have emerged as one of the principal sources of information for monitoring coastal change. In some cases, the shoreline position (identified as the maximum extent of run-up) is used to establish legal boundaries, setback lines or flood hazard zones.

Marine biologists have an interest in the swash zone, as the distribution and type of macrofauna inhabiting the intertidal zone of sandy beaches appears to be related to the swash climate. Both the interstitial fauna and the macrofauna of sandy beaches are directly affected by swash and ground water processes: the former by infiltration, which is responsible for flushing oxygen and organic materials into the sand, and the latter by swash dynamics and the position of the seepage face, which influence tidal migrations and burrowing (McArdle and McLachlan, 1991). Differences in the spatial distribution and abundance of beach fauna have been explained in relation to sediment size and beach slope, but have not yet been related successfully to swash dynamics.

Coastal engineers have long recognized the need for a better understanding of swash zone processes, largely concentrating on the measurement and modeling of run-up on structures such as breakwaters. Such studies are needed to establish design criteria, particularly the elevation of the structure required to prevent overtopping by the run-up of extreme waves. Recently, the commercial possibility of modifying beach water table elevation to control beach erosion has been recognized, and several studies have investigated the use of beach dewatering as an alternative to hard engineering practices. Beach dewatering works by lowering the water table artificially through a system of buried drains and pumps (see the entry on *Beach Drain* for further details). Other engineering applications where knowledge of beach ground water dynamics is important include water quality management in closed coastal lakes and lagoons, and the operation of water supply and sewage waste disposal facilities in coastal dunes, contaminant cycling in estuaries and coastal water resource management issues such as salt water intrusion into coastal aquifers, wastewater disposal from coastal developments, and pollution control.

An understanding of swash and beach ground water dynamics is also important in the modeling of beach profile evolution. At present, most beach profile and shoreline change models either do not include, or vastly simplify, sediment transport processes in the swash zone. Cross-shore sediment transport models have demonstrated considerable success in predicting eroding beach profiles on relatively fine sand beaches. Predictions of accretionary events and the behavior of coarser sediment beaches are generally less good, particularly in the inner surf zone and swash zone (Schoones and Theron, 1995). Since an accretionary event is defined by the deposition of sediment above mean sea level, the lack of detailed knowledge of swash and beach ground water dynamics is probably an important factor in the inability of beach profile models to simulate accretionary events accurately.

Erosion and accretion of the beach profile, and the resulting movement of the position of the shoreline, are a direct result of sediment transport processes occurring in the swash zone and inner surf zone. Beach ground water—swash dynamics provide an important control on swash zone sediment transport, which affects the morphology of the intertidal beach by controlling the potential for offshore transport or onshore sediment transport and deposition above the SWL. Cyclic erosion and accretion of the beachface as a result of relative elevations of the beach water table and swash have been substantiated by researchers for many years. Most of these studies suggest that beaches with a low water table tend to accrete and beaches with a high water table tend to erode. Recent observations indicate that flows in the swash zone can also affect the beach profile seaward of the intertidal profile, influencing sediment transport in the bar region.

Swash and beach ground water interaction may play a particularly important role in profile evolution and sedimentation patterns on macrotidal beaches. Many macrotidal beaches have two, and sometimes three, distinct beach zones: a flat, dissipative low-tide beach and a steeper, more reflective high-tide beach. There is generally an abrupt decrease in beach slope on macrotidal beaches where the water table intersects the beachface, which may be also marked by a change in sediment size between coarse and fine material. The interaction between beach ground water and swash flows may provide a mechanism for the shore-normal sorting of coarse and fine material that is often observed on macrotidal beaches, with dissipative sand low-tide terraces at the base of steep reflective high-tide gravel ridges. For example, Turner (1993a) surveyed 15 macrotidal beaches on the Queensland coast in Australia, and found that a decrease in sediment size was strongly correlated to an increase in the relative extent of the lower gradient (saturated) lower region of the intertidal profile. Turner (1995) developed a simple numerical model that incorporated the interaction of the tide and the beach water table outcrop. This model predicted the development of a break in slope resulting from landward sediment transport and berm development across the alternately saturated and unsaturated upper beach, while the profile lowered and widened across the saturated lower beach. Hughes and Turner (1999) gave different empirical equations for equilibrium slope on unsaturated and saturated beachfaces.

Common to all these studies is the observation that when the water table outcrops above the tide, two zones are distinguished: a lower saturated zone that promotes downslope (offshore) sediment transport, and an upper region that alternates between saturated and unsaturated conditions, with upslope (onshore) sediment transport potentially enhanced by infiltration. However, the relative importance of infiltration is not yet known, and will be discussed further below in the section on *Mechanisms of surface–subsurface flow interaction*.

Behavior of beach ground water

Turner and Nielsen (1997) identified a number of mechanisms which have been associated with observed beach water table oscillations: seasonal variations, barometric pressure changes associated with the passage of weather systems and storm events, propagation of shelf waves, and infragravity and incident waves. However, the majority of research has concentrated on tide-induced fluctuations of the beach water table.

A number of studies since the 1940s have described the shape and elevation of the beach water table as a function of beach morphology and tidal state. The majority of these studies have been limited to measurements of water table elevations across the beach profile, although limited observations of both longshore and cross-shore ground water variations have been reported. The elevation of the beach water table depends on prevailing hydrodynamic conditions such as tidal elevation, wave run-up and rainfall, and characteristics of the beach sediment that determine hydraulic conductivity, such as sediment size, sediment shape, sediment size sorting, and porosity. Observations of beach water table behavior show that the water table surface is generally not flat. Several authors have showed that the slope of the water table changes with the tide, sloping seaward on a falling tide and landward on a rising tide. The slope of the water surface has been found to be steeper on a rising tide than on a falling tide. Other researchers have measured water table elevations with a humped shape, with the hump near the run-up limit. Water table oscillations have been shown to lag behind tidal oscillations. Observed water table elevations are asymmetrical, as the water table rises abruptly and drops off slowly compared to the near-sinusoidal tide which drives it. For a given geometry, the lag in water table response is due mainly to the hydraulic conductivity of the beach sediment. With increasing distance landward, the lag between the water table and the tide increases and the amplitude of the water table oscillations decreases. However, Raubenheimer *et al.* (1999) found that fluctuations at spring-neap frequencies are attenuated less than fluctuations at diurnal or semidiurnal frequencies. Wave run-up, tidal variation, and rainfall may produce a *superelevation*, or *overheight*, of the beach water table by raising the elevation of the beach water table above the elevation of the tide.

Many researchers have observed that the beach acts as a filter that only allows the larger or longer period swashes to pass. Both the amplitude and the frequency of the ground water spectrum decrease in the landward direction. The further landwards the given ground water spectrum, the narrower its band and the more it is shifted toward lower frequencies. Infiltration into the beach also acts to reduce the amplitude and frequency of the input swash energy. Based on observations such as these, the beach has often been described as a low-pass filter (meaning that only lower frequency oscillations are transmitted through the beach matrix). High-frequency, small waves are damped and their effect is limited to the immediate vicinity of the intertidal beachface slope, whereas low-frequency waves can propagate inland. Comparison of run-up and ground water spectra shows a considerable reduction in dominant energy and also a shift in dominant energy toward lower frequencies.

Decoupling between the tide and the beach water table occurs when the ground water exit point becomes separated from the shoreline (shown in Figure H26). This occurs because the rate at which the beach drains is less than the rate at which the tide falls, so the tidal elevation generally drops more rapidly than the water table elevation and decoupling occurs, with the water table elevation higher than the tidal elevation. The *exit point* is the position on the beach profile where the decoupled water table intersects the beachface. After decoupling occurs, the position of the exit point is independent of the MWS until it is overtopped by the rising tide. Below the exit point, a *seepage face* develops where the water table coincides with the beachface. The seepage face is distinguished by a glassy surface. The seepage face is different from the water table in that its shape is determined by beach topography. However, water on the seepage face is at atmospheric pressure, as is water on the water table. The extent of the seepage face depends on the tidal regime, the hydraulic properties of the beach sediment, and the geometry of the beachface; thus the degree of asymmetry in water table response will vary between beaches. The exit point is generally assumed to mark the boundary between a lower section of the beach which is saturated and an upper section which is unsaturated; however, this assumption is probably an oversimplification.

Modeling beach ground water dynamics

An *aquifer* is a saturated geologic unit that can transmit significant quantities of water under ordinary hydraulic gradients (Freeze and Cherry, 1979). An *unconfined aquifer*, or *water table aquifer*, is one in which the water table forms the upper boundary. Beach ground water systems are generally treated as unconfined aquifers because commonly the upper boundary to ground water flow is defined by the water table itself rather than by some surface layer of impermeable material (Masselink and Turner, 1999). The beach ground water system is underlain by an impermeable boundary at a depth which is often unknown. The rate of flow (or *specific discharge*) of water through unconfined aquifers, u, is given by Darcy's Law:

$$u = -K\frac{\partial h}{\partial z} \qquad \text{(Eq. 1)}$$

where h is hydraulic head (units of length, L), z is the vertical coordinate (L), and K is hydraulic conductivity (LT^{-1}).

Darcy's Law is valid as long as flow is laminar, which is a reasonable assumption for sand beaches; however, this may not be the case for gravel beaches. Darcy's Law shows that the rate of ground water flow is proportional to the hydraulic gradient, or slope of the water table. The *hydraulic gradient* (dh/dz) is the change in hydraulic head (h) over distance; in this case, the change in elevation (z). Water flows down the hydraulic gradient in the direction of decreasing head. The *hydraulic head* (h) is the sum of the elevation head (z) and the pressure head (ψ), and is measured in length units above a datum. There is no standard datum that is used in beach hydrology, but many researchers use the elevation of an impermeable layer beneath the beach sediment, so that the vertical coordinate z is measured from the impermeable base. Some workers have considered the hydraulic head in a beach ground water system to be the elevation of the free water surface, or water table elevation. However, this is only true when there is no vertical component to the flow; in other words, when Dupuit–Forcheimer conditions apply (see below). *Hydraulic conductivity*, K, may be defined as the specific discharge per unit hydraulic gradient. The hydraulic conductivity reflects the ease with which a liquid flows and the ease with which a porous medium permits the liquid to pass through it, and relates the mean discharge flowing through a porous substance per unit cross section to the total gravitational and potential force. Hydraulic conductivity has units of velocity, usually ms^{-1} in the case of beach ground water systems. Hydraulic conductivity should be distinguished from *permeability* (also referred to as *intrinsic* or *specific permeability*), denoted by k, which is the measure of the ability of a rock, soil, or porous substance to transmit fluids and refers only to the characteristics of the porous medium and not to the fluid which passes through it. Permeability has dimensions of L^2.

Ground water hydrologists generally model water flow using Darcy's Law in combination with an equation of continuity that describes the conservation of fluid mass during flow through a porous medium. A common approach to modeling beach ground water flow in response to tidal forcing in sandy beaches uses the one-dimensional (1-D) form of the Boussinesq equation:

$$\frac{\partial h}{\partial t} = \frac{K}{s}\frac{\partial}{\partial x}\left(h\frac{\partial h}{\partial x}\right) \qquad \text{(Eq. 2)}$$

where h is the elevation of the water table (L), t is time (T), K is hydraulic conductivity (LT^{-1}), s is the specific yield (dimensionless), and x is horizontal distance (L). The *specific yield*, which is also known as the *drainable porosity*, is defined as the volume of water that an unconfined aquifer releases from storage per unit surface area of aquifer per unit decline in water table (Freeze and Cherry, 1979).

It should be noted that specific yield, or drainable porosity, is not the same as porosity, and the two terms should not be used interchangeably. *Porosity* is the volume of the voids in a sediment or rock divided by the total volume of the sediment or rock. Porosity is denoted by n, and is usually reported as a decimal fraction or percent. The *volumetric water content*, θ, is defined as the volume of water in a sediment or rock sample divided by the total volume of the sediment or rock. In saturated conditions, where the pores are filled with water, the volumetric water content, θ, is equal to the porosity, n. In unsaturated conditions, where the pores are only partially filled with water, the volumetric water content, θ, is less than the porosity, n.

There is also a difference between specific yield and *specific storage*, which is defined as the volume of water that a confined aquifer releases from storage under a unit decline in hydraulic head (Freeze and Cherry, 1979). The term specific storage refers to a unit decline in hydraulic head below the water table, in an aquifer which is saturated. Releases from storage in unconfined aquifers (such as beach sediments) represents an actual dewatering of the pores, whereas releases from storage in confined aquifers represent only the secondary effects of water expansion and aquifer compaction caused by changes in the fluid pressure (Freeze and Cherry, 1979).

The main assumption in using equation 2 is that ground water flow in a shallow aquifer can be described using the Dupuit–Forchheimer approximation. Dupuit–Forchheimer theory states that in a system of shallow gravity flow to a sink when the flow is approximately horizontal, the lines of equal hydraulic head or potential are vertical and the gradient of hydraulic head is given by the slope of the water table. In effect, the theory neglects the vertical flow components. Using Dupuit–Forchheimer theory, two-dimensional (2-D) flow to a sink can be approximated as 1-D flow, and the resulting differential equation (equation 2) is relatively easily solved. In beaches which are underlain by relatively impermeable material it is likely that Dupuit–Forchheimer theory provides an adequate description of ground water flow, and field studies such as those of Baird *et al*. (1998) and Raubenheimer *et al*. (1999) support this assumption.

Where Dupuit–Forchheimer assumptions do not apply, for example, in artificially drained beaches, the beach aquifer should be considered as a 2-D flow system. One approach is to assume that the water table is a free surface or flow line so that

$$\frac{\partial h}{\partial t} = \frac{K}{s}\left(\frac{\partial H}{\partial z} - \frac{\partial h}{\partial x}\frac{\partial H}{\partial x}\right) \qquad \text{(Eq. 3)}$$

where H is the total or hydraulic head (L) and z is vertical distance (L). As in equation 2, h is the elevation of the water table (L), t is time (T), K is hydraulic conductivity (LT^{-1}), s is the specific yield (dimensionless), and x is horizontal distance (L). Equation 2 is much easier to solve than equation 3 and should be used whenever the assumption of near-horizontal flow through the beach sand is generally met.

Several analytical and numerical models have been developed which are able to predict beach water table fluctuations in response to tides (Nielsen, 1990; Turner, 1993b,c; Li *et al*., 1997a; Baird *et al*., 1998; Raubenheimer *et al*., 1999). These Boussinesq models, based on solutions to equation 2, have been successful in reproducing observed fluctuations of the beach water table at diurnal and higher tidal frequencies, and also reproduce observations such as the shape and slope of the beach water table, the lag and landward attenuation of beach water table oscillations, and seepage face development. However, these models generally underpredict the water table elevations under conditions when wave effects are important. Models of beach water table fluctuations that incorporate wave effects have been developed only very recently. Nielsen *et al*. (1988) proposed the use of a linearized version of the Boussinesq equation (equation 2) with an additional term to model water table fluctuations in the zone of run-up infiltration:

$$\frac{\partial h}{\partial t} = \frac{Kd_a}{s}\frac{\partial^2 h}{\partial x^2} + U_1(x, t) \qquad \text{(Eq. 4)}$$

where d_a is the aquifer depth and $U_1(x, t)$ is the infiltration/ exfiltration velocity per unit area. As in equation 2, h is the elevation of the water table (L), t is time (T), K is hydraulic conductivity (LT^{-1}), s is the specific yield or drainable porosity (dimensionless), and x is horizontal distance (L). Li *et al*. (1997b) and Li and Barry (2000) have developed more complicated models to predict wave-induced water table fluctuations; however, none of the models which include wave effects have yet been tested against field or laboratory data.

Finally, beach ground water models have not yet been linked to swash hydrodynamic and sediment transport models, although Turner (1995) modeled beach profile response to ground water seepage using an equilibrium net transport parameter. In particular, models of swash–ground water interactions do not yet incorporate the physical processes such as infiltration and ground water outflow which are thought to influence sediment transport in the swash zone. The relative importance of these mechanisms is where the greatest areas of uncertainty arise.

Mechanisms of surface–subsurface flow interaction and implications for sediment transport

Several mechanisms have been suggested to explain why beaches with a low water table tend to accrete and beaches with a high water table tend to erode. The mechanisms which are proposed most frequently are infiltration and exfiltration. The terminology used to discuss these mechanisms requires some clarification, as different terms may be used by hydrologists, engineers, and other coastal scientists. The physical process of interest is that of vertical flow within a porous bed and/or through a permeable boundary. Vertical flow exerts a force within the bed called *seepage force*, which is defined as a force acting on an individual grain in a porous medium under flow, which is due to the difference in hydraulic head between the front and back faces of the grain (Freeze and Cherry, 1979). The seepage force, F, is exerted in the direction of flow and is directly proportional to the hydraulic gradient, and is given by

$$F = \rho g \frac{\partial h}{\partial z} \qquad \text{(Eq. 5)}$$

where ρ is the density of the fluid (ML^{-3}), g is acceleration due to gravity (LT^{-2}), and $\partial h/\partial z$ is the hydraulic gradient (dimensionless). In the convention used here, a positive hydraulic gradient represents a downward-acting seepage force and a negative hydraulic gradient represents an upward-acting seepage force.

The vertical flows which produce this seepage force have been referred to in a number of different ways in the literature: bed ventilation, suction and blowing, piping, seepage erosion, ground water sapping, etc. In the case of beach hydrology, however, the terms infiltration and exfiltration are most commonly used. *Infiltration* is the process by which water enters into the surface horizon of a soil or porous medium, such as beach sediment, in a downward direction from the surface by means of pores or small openings. Infiltration is often used interchangeably with *percolation*, which more correctly refers to the flow of water through a soil or porous medium below the surface. Recently, the term *exfiltration* has been used to describe outflow from the bed. Infiltration/exfiltration velocity may also be referred to as seepage velocity.

Grant (1946, 1948) was among the first to suggest a link between beach ground water behavior and swash zone sediment transport, proposing a simple conceptual model which has been highly influential in beach hydrology research. Grant defined a dry foreshore as one with a low water table and an extensive infiltration zone. On a dry foreshore, most of the water infiltrates rapidly into the sand above the water table, which reduces the flow depth of the swash and thus the velocity, allowing sediment deposition. Grant's conceptual model also described conditions on a wet foreshore, one whose water table is high and contiguous with the surface of most of the foreshore. He reasoned that when the beach is in a saturated condition throughout all of the foreshore the backwash, instead of being reduced by infiltration, retains its depth and is augmented by the addition of water rising to the surface of what he called the effluent zone (the seepage face). Grant also noted that ground water outcropping at the beach surface can cause dilation or fluidization of the sand grains, allowing them to be entrained more easily by backwash flows.

The logic of Grant's conceptual model has led many researchers to concentrate on the effects of infiltration losses on beach accretion and erosion, suggesting that infiltration losses during swash provide the main mechanism by which beach accretion occurs above the SWL. Because the swash and backwash are relatively shallow, a small change in water volume due to infiltration could significantly decrease the energy available for sediment transport. Within the swash zone, rapid water table fluctuations due to swash infiltration into the capillary fringe may also influence sediment mobility. Ground water flow at deeper levels within the beach is also influenced by infiltration during swash uprush, although the hydraulic gradients developed tend to be small.

Although most researchers have concentrated on infiltration/ exfiltration and possible effects on swash/backwash asymmetry, Nielsen (1992) suggested that vertical flow within the beach alters the sediment transport characteristics due to a modification of the effective weight of the sediment, which will act to stabilize the bed under infiltration or destabilize under exfiltration. Turner and Nielsen (1997) identified several mechanisms by which vertical flow through a porous bed could affect swash zone sediment transport, including an alteration in the effective weight of the surface sediment due to vertical fluid drag and modified shear stresses exerted on the bed due to boundary layer thinning due to infiltration or thickening due to exfiltration. Turner and Masselink (1998) identified a number of effects of vertical flow through a porous bed: the angle of attack at which the main flow contacts the particles is altered; dead water is flushed out of the top bed layer, increasing the exposed surface area of a particle to the main flow; and the changed wake behind a particle not only affects that particle but others in its lee. Turner and Masselink (1998) summarized the effect of these processes on the boundary layer, with stream lines being drawn closer to the sediment–fluid interface under infiltration and moved away from the sediment–fluid interface under exfiltration. The result is a vertical shift of the boundary layer velocity profile, with an increase of shear stress at the bed under infiltration and a decrease under exfiltration.

Experimental work on the influence of seepage flows within sediment beds provides conflicting results concerning the effect on bed stability. These contradictory results may be because the effects of seepage force and boundary layer thinning tend to oppose each other. While infiltration results in a stabilizing seepage force, simultaneous boundary layer thinning has the opposing effect of enhancing sediment mobility and *vice versa* for exfiltration (Hughes and Turner, 1999). The relative importance of these opposing effects depends on the density of the sediment and the permeability of the bed (Nielsen *et al.*, 2001). Although recent work by Baldock and Holmes (1998) showed that sediment transport over a fluidized bed in the presence of a steady current may be little different from that over a normal sediment bed, they also suggested that a seepage flow might have a significant effect on sediment transport during sheet flow. In their experiments, the bulk motion of a top layer which was many grain diameters thick was sometimes observed during exfiltration or no seepage, but was suppressed by infiltration. Sheet flow conditions are likely to occur during backwash and probably also during the uprush.

Nielsen (1997) proposed a revised Shields parameter that includes the effects of infiltration/exfiltration:

$$\theta_m = \frac{u_{*0}^2(1 - \alpha(w/u_{*0}^2))}{gd_{50}(s - 1 - \beta(w/K))} \qquad \text{(Eq. 6)}$$

where w is the seepage velocity (LT^{-1}, with infiltration negative), u_{*0}^2 is the shear velocity without seepage (LT^{-1}), s is relative density (dimensionless: ρ_s/ρ, where ρ_s is the density of the sediment and ρ is the density of the fluid), K is hydraulic conductivity (LT^{-1}), g is acceleration due to gravity (LT^{-2}), d_{50} is median grain diameter, and α and β are constants, defined by Neilsen *et al.* (2001) as 16 and 0.4, respectively. The factor β is intended to quantify the increase of the particle's weight due to the vertical seepage velocity, and is 1 for particles in the bed but considerably smaller for particles on the surface (Nielsen *et al.*, 2001). The modified Shields parameter in equation 6 was designed to account for the opposing effects of infiltration, as the extra term in the numerator represents the increase in shear stress due to the thinning of the boundary layer and the extra term in the denominator represents the effect of the downward seepage drag on the effective weight of the grains (Nielsen *et al.*, 2001). Equation 6 suggests that for a fixed sediment density, as grain size (and therefore, hydraulic conductivity) decreases, the stabilizing effect will increase. Therefore, finer quartz sands ($d_{50} < 0.58$ mm) are likely to be stabilized by infiltration, whereas the net effect of infiltration on beaches of coarser sediment may be destabilizing (Nielsen, 1997). Nielsen *et al.* (2001) extended this analysis to show that infiltration is likely to enhance sediment mobility for dense, coarse sediment where $\alpha(s-1) > \beta(u_{*0}/K)$ and impede sediment motion for light, fine sediment where $\alpha(s-1) < \beta(u_{*0}/K)$.

Turner and Masselink (1998) also followed this approach, but included the effects of the seepage flow on the bed shear stress. They used their modified Shields parameter, which incorporated an additional through-bed term, to calculate the swash-zone transport rate in the presence of infiltration/exfiltration relative to the case of no vertical flow through the bed. Their modeling showed that altered bed stresses dominated during uprush, indicating enhanced sediment mobility relative to the case of an impermeable bed. They found that altered bed stress effects were also dominant during backwash; however, the net effect of combined seepage force and altered bed stress was less pronounced during backwash than during uprush. Turner and Masselink (1998) concluded that the effects of combined seepage force and altered bed stress enhanced net onshore sediment transport on a saturated beachface.

Nielsen *et al.* (2001) conducted laboratory measurements to investigate the effects of infiltration on sediment mobility of a horizontal sand bed under regular nonbreaking waves under conditions of steady downward seepage, and compared these to measurements without infiltration. Their experiments showed that infiltration had the effect of reducing the mobility of 0.2 mm sand, and they suggested that infiltration effects on sediment mobility in the swash zone would be minor if infiltration rates are in the range reported by other researchers, where $w < 0.15K$.

Although infiltration and exfiltration are the primary mechanisms by which ground water flow is thought to influence sediment transport in the swash zone, the potential of beach ground water fluctuations to cause bed failure due to instantaneous fluidization has also been considered. *Fluidization* of sediment occurs when the upward-acting seepage force exceeds the downward-acting immersed particle weight. In particular, it has been suggested by a number of workers that tidally induced ground water outflow from a beach during the ebb tide may enhance the potential for fluidization of sand, and thus the ease with which sand can be transported by swash flows. However, tidally induced ground water outflow alone is unlikely to be sufficient to induce fluidization, because hydraulic gradients under the sand surface will tend to be relatively small, generally of the order of the beach slope (1 : 100–1 : 10). In addition, Turner and Nielsen (1997) found that, rather than fast water table rise in the swash being the cause of upward flow (and hence potential fluidization), rapid water table rise within the swash zone resulted from a small amount of infiltration of the swash lens. However, upward-acting swash-induced hydraulic gradients which are capable of fluidizing the bed have been measured within the top few centimeters of the beach. Horn *et al.* (1998) presented field measurements of large upward-acting hydraulic gradients which considerably exceeded the fluidization criterion, which occurs when the upward-acting hydraulic gradient is greater than (i.e., more negative than) about -0.6 to -0.7 (in the convention used here). The mechanism responsible for these upward-acting hydraulic gradients is not clear.

Baird *et al.* (1996) argued that fluidization is only generally possible in the presence of swash on a seepage face. As a swash flow advances over the saturated beach surface there will be a rapid increase in pore water pressures below the beach surface. When under swash flow, the beach sediment behaves like a confined aquifer. The sediment is saturated and movement of water into the beach is extremely limited since changes in porosity due to expansion and contraction of the mineral "skeleton" will be minimal. However, water pressures will propagate rapidly through the sediment. As the swash retreats there will be a release of pressure on the beachface, potentially giving large hydraulic gradients acting vertically upwards immediately below the surface. The resultant seepage force associated with these upward-acting hydraulic gradients could be sufficient to induce fluidization of the sand grains at the surface. They showed theoretically how hydraulic gradients in the saturated sediment beneath swash can exceed, or at least come close to, the threshold for fluidization.

Baldock *et al.* (2001) compared field measurements of swash-induced hydraulic gradients in the surface layers of a sand beach to the predictions of a simple (1-D) diffusion model based on Darcy's Law and the continuity equation. The model allows for dynamic storage (within the sediment–fluid matrix) due to loading/unloading on the upper sediment boundary. The model predicted minimal hydraulic gradients for a rigid, near fully saturated sediment which were in accordance with measurements close to the seaward limit of the swash zone. The model also provided a good description of the measured hydraulic gradients, both very close to the surface and deeper in the bed, for the region of the beach where the beach surface is frequently exposed between swash events. These model-data comparisons suggest that the surface layers of a sand beach store and release water under the action of swash, leading to the generation of relatively large hydraulic gradients as suggested by Baird *et al.* (1996). However, the model was not able to predict the very large near-surface negative hydraulic gradients observed by Horn *et al.* (1998), although, for the same swash events, the agreement was good deeper in the bed. Baldock *et al.* (2001) concluded that the very large upward-acting hydraulic gradients observed in the upper part of the bed were not simply due to pressure propagation during swash loading/unloading or swash-generated 2-D subsurface flow cells. Instead, they suggested that these very large negative hydraulic gradients are probably generated by alternative mechanisms; possibly due to non-hydrostatic pressures developing within the sheet flow layer that occurs during backwash.

The implications of these hydraulic gradients for sediment transport are not clear. Vertical seepage forces are not themselves capable of transporting sediment; however, this process may act to provide readily entrainable material which is then available for transport, onshore under uprush or offshore under backwash. Nielsen *et al.* (2001) noted that their experiments indicated only the effect of infiltration/exfiltration on sediment mobility and did not necessary suggest anything about the direction of net sediment transport. This is likely to be affected by other factors such as the phase relationship between infiltration/ exfiltration-induced effects on sediment transport and swash flows. For example, Blewett *et al.* (1999) measured events where large upward-acting hydraulic gradients occurred when the head of water at the surface, and therefore, the uprush or backwash flow, was zero. Under these conditions, even if the sediment were to be fluidized, it would not be transported. However, in other data sets, Blewett *et al.* (1999) reported measurements with upward-acting hydraulic gradients of -1.7, which were more than sufficient to fluidize the bed. These hydraulic gradients lasted for approximately 4 s in waves with a period of 6.3 s under a falling head of water, initially as deep as 40 mm, and under offshore-directed flows of 0.7–1.4 ms^{-1}. This suggests a possible erosional mechanism under backwash. Clearly, the phasing between these potentially destabilizing hydraulic gradients and swash flows is critical to the potential for sediment transport.

Nielsen *et al*. (2001) argued that if the beachface tends to be fluidized during backwash as suggested by Horn *et al*. (1998), a mechanism must exist to enhance sediment transport during the uprush in order to balance this effect—otherwise the beach would rapidly disappear. They suggested that this balancing effect might be delivered by fluidization due to strong horizontal pressure gradients near bore fronts. However, Hughes *et al*. (1997) suggested an alternative mechanism, arguing that onshore transport in the uprush is likely to be significantly influenced by turbulence and sediment advection from bores arriving at the beachface. The lack of a clear mechanism for onshore transport highlights the complexity of sediment transport processes in the swash zone, as the exact nature of the relationship between swash flows, beach ground water, and cross-shore sediment transport is not yet known.

For another aspect of this discussion see Otvos (1999).

ICE-BORDERED COASTS

Introduction

Since the publication of *The Encyclopedia of Beaches and Coastal Environments* (Schwartz, 1982), the term "cold coasts" has come into common use even serving as a chapter title in the book *Coastal Problems*. The authors, Viles and Spencer (1995), use the 1961 definition by R.L. Nichols that cold coasts ". . . are those where there is or has been abundant sea ice, lake ice, water-terminating glaciers or deeply frozen ground" (p. 254). The advantage of such a definition is that it avoids the latitudinal restriction placed by such locational designators as Arctic and Antarctic and thus can accommodate lower latitudinal examples including the tidewater glaciers of Chile and southern Alaska and the presence of sea ice along the Labrador and Hokkaido coasts or even the coast of Spain during the Pleistocene.

This entry treats two of these types of cold coasts: namely, water-terminating glaciers and sea ice. Glacial ice is land-derived and tends to be perennial; sea ice, on the other hand, develops seaward of the coastline and is usually seasonal. They both can serve as erosional, transportational, and depositional agents along coastlines, although the rates and intensities of their action vary greatly between the two and with time and location.

Glacial ice and the coast

One of the conspicuous features of the landscape at present and during much of the past three million years is glacial ice. Although today it is dominant (as a coastal feature) only in Antarctica, Greenland, and a few smaller islands in high latitudes, it is still sufficiently abundant to affect more than 35,000 km of the world's coastline. Glacial ice impacts the coastline in several ways including burying and depressing the coast as it moves across it into the sea, flowing in preexisting valleys into the sea as tidewater glaciers, and replacing the traditional shore with an ice margin that then interfaces directly with the sea.

Ice sheets, such as those in Antarctica and Greenland, serve as the source of ice that moves under its own weight and in response to gravity from inland to sea. Glacial ice is so extensive in Antarctica that only about 5% of the coastline is ice-free (Figure I1). Greenland contrasts with most of Antarctica in that glacial ice does not dominate the coastal zone but flows through relatively few high passes in the coastal mountains (Figure I2). A major exception is where inland ice reaches Melville Bay along a 460 km front.

A further characteristic of ice sheets is that their great weight depresses the landmasses upon which they form. Near the coastline the depressed continental shelf slopes downward inland thereby reversing the general slope of the coastal zone. Large parts of Antarctica and Greenland have been depressed to such extents that their present elevation is below sea level. Although, with rebound, much of this depressed land would be above sea level, large areas beneath the West Antarctic Ice Sheet (which averages 440 m below sea level) would still be a series of islands with lengthy coastlines even after the rebound that would accompany deglaciation (Paterson, 1994).

Ice shelves, which are large ice masses floating on the sea, range in thickness up to several hundred meters. They are especially common in Antarctica (Figure I1), but also occur as small shelves in Greenland, Ellesmere Island, and Franz Josef Land. The ice shelves of Antarctica fill many of the continent's embayments giving the continent a nearly circular form excepting the northward trending Antarctic Peninsula.

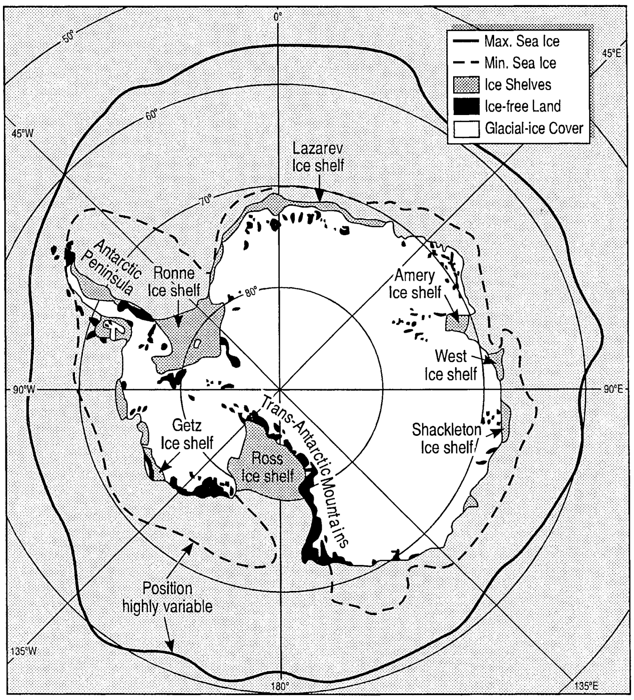

Figure I1 Ice and the Antarctic coastline (modified from Mellor, 1964; Paterson, 1994; and Crossley, 1995).

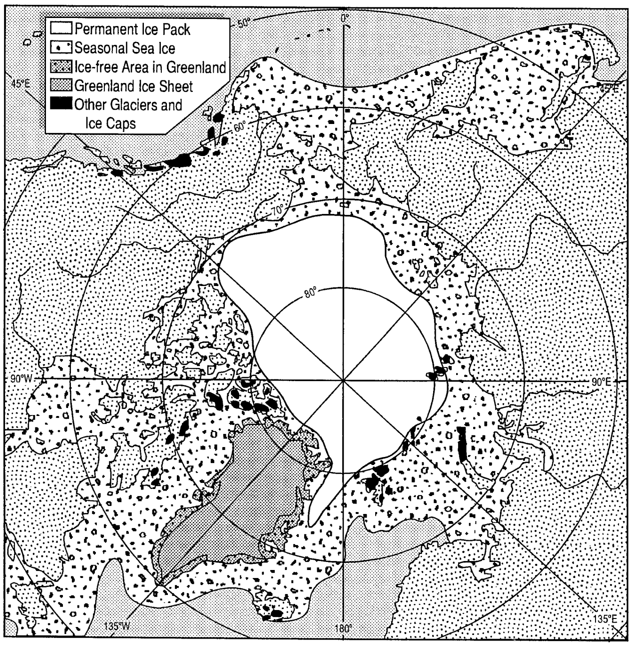

Figure I2 Ice and the Northern Hemisphere Coastline. Note that within the ice-free coastal area of Greenland there are numerous small ice caps (modified from Mellor, 1964; Field, 1975; and Williams and Ferrigno, 1995).

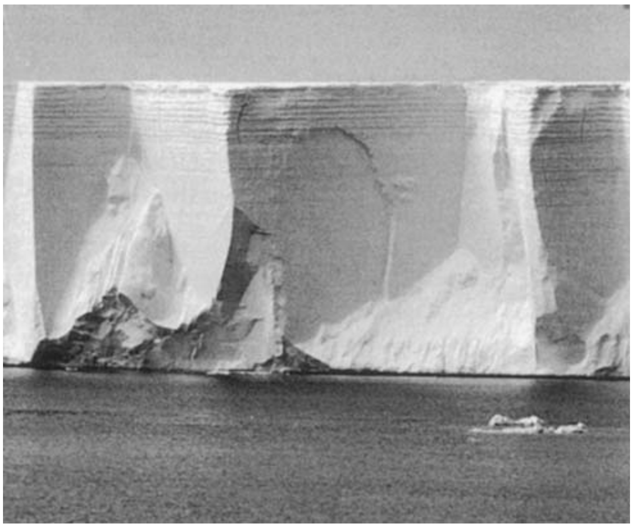

Figure I3 Ice cliff, Antarctica. (Williams and Ferrigno, 1995. Photograph by Charles Swithinbank, courtesy of Richard S. Williams, United States Geological Survey.)

Thus, the 11,000 km (more than one-third of the total) of Antarctica's coastline occupied by ice shelves, possesses ice cliffs (Figure I3) at the ocean interface. These ice cliffs are impressive coastal features as illustrated by the Ross Ice Shelf (Figure I1) where the front edge is more than 200 m thick with a 20–30 m cliff above water. The ice landward of the Ross ice cliff thickens to 700 m at land's edge (Robe, 1980). The exposed ends of these floating glaciers are impacted by the same agents and processes as the coast proper including waves, tides, currents, and sea ice.

Many of the coastal glaciers in Antarctica (~38%) and most in the Northern Hemisphere do not have floating shelves or tongues but are grounded at their termini (Powell and Domack, 1995). For example, part of the west coast of the Antarctic Peninsula has glaciers that have formed ice walls at the shore because of undercutting and calving at the ice front where they override a gravelly beach (Robin, 1979).

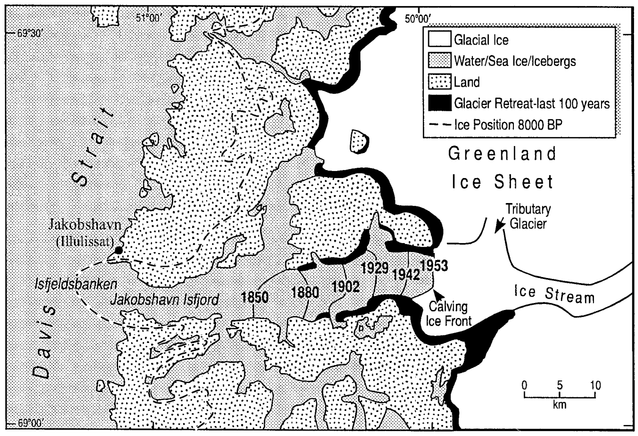

Figure I4 Tidewater glacial retreat (1850–1953) and ice-margin retreat in Jakobshavn Isfjord (modified from Williams and Ferrigno, 1995).

Tidewater glaciers are found in nonpolar areas such as southern Alaska and Chile as well as at higher latitudes. In the Arctic, tidewater glaciers are present in Jan Mayen, Svalbard, Novaya Zemlya, Severnaya Zemlya, Ellesmere, Baffin Island, Bylot Island, and Devon Island as well as Greenland and Alaska (Figure I2). The termini of temperate tidewater glaciers are grounded as are many in higher latitudes (Hambrey and Alean, 1992). Most tidewater glaciers are confined in fjords of variable length and terminate at some distance inland from their mouth. Many are very long, such as the combined 350 km long Nordvestfjord and Scoresby Sund in east Greenland. Such fjords not only have glaciers at their inner ends but also are icebound with icebergs and sea ice. Because of the nature of the coastal mountain rim around the Greenland Ice Sheet the coastal impact is highly varied at the front of outlet glaciers. Although many flow into the sea, others terminate on land (Figure I4) and in glacially created lakes (Warren, 1991).

A major characteristic of glaciers is their changeable rate of advance and retreat. Thus, their position and therefore their impact on the coastlines they border is continuously varying. Jakobshavn Isbrae (Figure I4) in west Greenland, for example, retreated 26 km between 1851 and 1953 (Williams and Ferrigno, 1995) exposing sizable sections of the fjord's shore that it formally bordered.

The most important mechanism for the loss of glacial ice, whether it be the large ice shelves of Antarctica or the smaller tidewater glaciers of Alaska, is calving at their termini. Calving produces icebergs that range in size from very small, as those produced in constricted fjords, to very large such as those tabular icebergs that calve from ice shelves. On March 17, 2000, iceberg B-15, with a length of 295 km and a width of 37 km calved from the Ross Ice Shelf. It broke into two parts a few months later (Lazzara *et al.*, 1999).

Icebergs, once formed, essentially become floating islands. The act of calving increases the number of sides in contact with the sea, hastening their disintegration. Many of them float for years as exampled by those ice islands that have been used as research bases in the Arctic Ocean. Others become trapped, even if temporarily, in sea ice and some become grounded in shallow water. They can also be erosional agents, often in association with the floating pack ice that forms around them, creating deep gouges in the nearshore bottom.

Glaciers, whether they terminate onshore, at the shore, along fjords or at some distance offshore, are major morphological agents. If terminating inland, meltwater drainage carries the sediment formed by the glacial scour that accompanies the advancing ice to the sea creating depositional facies along the shore. Those glaciers that terminate at the shore and those that have overridden the shore leave behind ice-scoured surfaces and depositional forms including a variety of morainal types. Such coasts, once released from their overburden of ice, rebound as is happening in northern Canada, Scandinavia, and many parts of Antarctica especially on the Antarctic Peninsula. Some of the raised beaches on the Peninsula are as much as 60 m above present sea level (Kirk, 1985).

Sea ice and the coast

Sea ice, one of the most variable elements in the oceanic system, varies seasonally in areal coverage by nearly 500% in the Southern Hemisphere but by less than 200% in the Northern Hemisphere (Figures I1 and I2).

These percentages show that sea ice is more strongly seasonal in the Antarctic than the Arctic. It is again a reflection of the nature of the two ocean areas involved. Because the Arctic Ocean is surrounded by land and the Antarctic Ocean surrounds a continent, ice formation and movement and therefore, impact on the coastlines is quite different. Most of the Arctic Ocean sea ice is of the multi-year type whereas most (~85%) of that of the Antarctic is first-year ice.

During the Arctic winter, sea ice not only affects the coasts surrounded by the Arctic Ocean but also extends south to locations such as Hokkaido, Japan in the North Pacific Ocean and New Foundland in the North Atlantic (Figure I2). In contrast, during summer virtually all Arctic coasts are free of sea ice for varying lengths of time. Exceptions include northern Greenland, Ellesmere, and part of the Canadian Arctic Archipelago where sea ice may last throughout the year. Of major interest and concern is the great variability in sea ice cover and thickness. An analysis of satellite passive microwave observations shows those areas exhibiting negative trends in the sea ice season are larger than those exhibiting positive trends (Parkinson, 2000). If such negative trends continue, ice-free periods along Arctic coasts will continue to lengthen.

During the austral winter, sea ice extends north several hundred kilometers from Antarctica even reaching 55°S in the Indian Ocean (Figure I1). During that period of the year, sea ice is present along the entire coastline although nearshore in many locations are polynyas—some maintained by katabatic winds. As summer approaches, sea ice drifts out and away from most of the coast except for a few locations where it remains attached to the shore throughout the summer (Wadhams, 2000).

Sea ice and its impact on coasts during summer

For a few months during summer most of the coasts in both the Antarctic and Arctic are ice-free. However, in the Arctic Ocean especially, the permanent (although highly mobile) pack is often close enough to shore to dampen waves and thus reduce their impact on the coast. During those periods of time when the pack retreats from the coast thereby increasing fetch over coastal waters, storms can cause severe erosion as happened at Barrow, Alaska in October 1986 (Walker, 1991). The shorter the ice-free period and the narrower the shore lead, the more limited the wave action alongshore.

Under certain wind and current conditions pack ice can move onto shore even at the height of the summer season causing some ice scour and sediment transport. This situation is especially true along the Beaufort Sea coast.

Freeze-up and the ice foot

The factors affecting the timing of freeze-up include temperature, wind, snow, waves, tides, and the nature of the shoreline. When the temperature is lowered to the value at which seawater freezes, ice forms on the foreshore and within the interstices of shore sediments. Ice buildup occurs through the addition of the spray, swash, slush ice, and ice floes brought by waves and tides plus the addition of snow. The accumulation becomes the ice foot, a major characteristic of ice-bordered shore (Figure I5). The form, structure, and extent of the ice foot varies with shore gradient as well as tidal range and wave conditions during formation (Taylor and McCann, 1983). A gently sloping shore face and a high tidal range favor the development of a wide ice foot whereas variable wave conditions often produce complex structures (Owens, 1982).

The ice foot, composed of a mixture of sediments, snow and ice, rests on a beach surface that is also frozen. As waves approach the ice foot, they continue to deliver sediment from offshore either as loose particles or as material already incorporated into the pancake and brash ices that are added to the ice foot mix (Evenson and Cohn, 1979).

The ice foot is bottomfast and immobile. At its seaward edge it abuts floating ice that moves vertically with tidal and wave action. They are separated by tidal cracks along a line which has been referred to as a "hinge zone" (Forbes and Taylor, 1994). The degree of roughness of the sea ice at the hinge zone tends to increase with increasing tidal range.

Once freeze-up is complete, wave action on the coast ceases and any sediment transport by longshore currents is confined to locations seaward of the bottomfast ice zone. However, exceptions do occur. In the case of the Beaufort Sea, for example, severe winter storms can produce override with ice being forced over the ice foot high up on the shore. These features are known among the Inuit as "ivu."

Although bottomfast ice usually extends out to water depths of two or more meters, shorefast ice extends out over deeper water to distances of as much as 20–30 km (Taylor and McCann, 1983) where it merges with drifting pack ice. Shorefast ice is relatively immobile especially when present between islands as in the Canadian Arctic Archipelago. However, along open coasts, as those facing the Beaufort and Chukchi Seas, shorefast ice may be subject to occasional drift. The area between the outer limit of shorefast ice and the drifting pack, known as the "stamukhi" zone, is characterized by large pressure ridges some large enough so that they last through the summer.

Ice melt and breakup

Although shore leads in the sea ice may open early during the breakup period, the ice foot is not directly affected. Its ice melts in place. The rate and timing depend mainly on temperature conditions and depending on the amount of ice and snow present, may last into summer (Figure I5). During winter, snow accumulates on the irregular surface and may be quite thick especially if there is a cliff behind the beach. As sea ice begins to move, especially with offshore winds, it breaks apart and floats the outer edges of the bottomfast ice. In the process, much of the sediment that has been incorporated into the sea ice is transported off and alongshore. The last ice to be removed from the coast are the large ice masses that become stranded and often buried onshore. Their melt rate is affected by the sediment that may cover them (Figure I6).

In contrast to the shore ice melt and breakup that occurs along the exposed shore is that occurring out from river mouths. Off river mouths the gradients of subaqueous deltas are usually more gentle than those along other coastlines so that the bottomfast sea ice zone is wider. During river breakup, floodwaters progress out over the sea ice and in the larger rivers beneath it in the subice distributary channels that do not freeze to the bottom. The water flowing over the sea ice deposits much of its sediment on top of the ice before it reaches pressure-ridge cracks or potholes out from the bottomfast/shorefast ice boundary where it drains to continue flowing seaward (Walker, 1974). The drainage through these holes (Figure I7) create in the bottom what Reimnitz has labeled strudel-scour holes (Reimnitz and Bruder, 1972). Most of the sediment deposited on top of the sea ice is later deposited in the delta as the ice melts. However, some of it is transported seaward and alongshore as the offshore ice begins to drift.

Figure I5 Stranded ice-foot at Barrow, AK in June.

Figure I6 Five-meter-high sea ice pileup with accumulated snow onshore during melt season. Note the gradual settling of incorporated beach materials as ablation occurs.

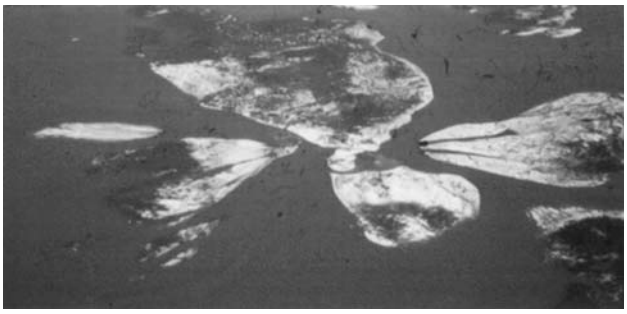

Figure I7 Drainage hole in sea ice at the Colville delta front. The floodwaters from the river drain from the ice creating strudel scour in deltaic sediments.

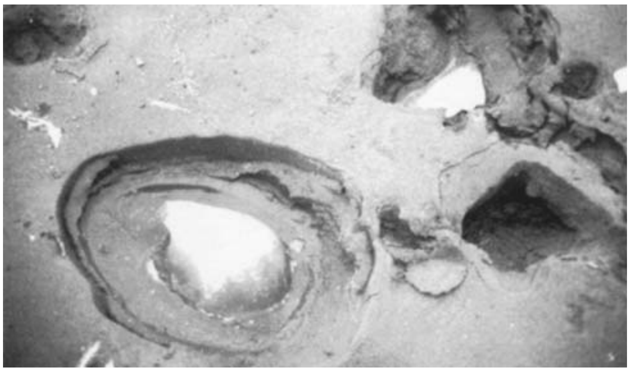

Figure I8 Small kettles forming in the beach at Wainwright, AK as stranded ice blocks melt.

Sea ice: its role in erosion, transportation, and deposition

In addition to the transport of sediment and the development of strudel mentioned above, sea ice is involved in other geologic processes along coastlines. The movement of sea ice on the beach and near the shore can produce scour marks and ridges. The uneven bottom of sea ice and especially when present as pressure-ridge keels gouge bottom materials as the ice drifts along the shore or up to the beach. As sea ice rides up onto the shore it both erodes and transports beach materials some distance above the high-tide shoreline. If the moving ice is impeded, ice pileups develop. They form not only at the high-tide shoreline but also at the hinge-line that joins bottom- fast and shorefast ice and around grounded floes. Such ice pileups impact heavily on both shore and nearshore sediments. Pileup heights of 20 m are common; some grow to double that (Forbes and Taylor, 1994).

The beach which can have a very irregular surface at the end of the melt season because of the presence of ice-push ridges, kettles left by the melting of stranded ice blocks (Figure I8), and a variety of scour forms is generally reworked by waves during the ice-free season. Only those forms that are especially large or that have been produced at the back of the beach may last through the summer.

Sea ice like glacial ice serves as both an agent of erosion and of protection. In the case of sea ice, the period of time it protects the coast from erosion varies from hours or days to year round in some very sheltered locations, whereas in the case of glacial protection the time period may be reckoned in millennia. With the rapid changes taking place in the icescapes of the world (e.g., the 15% reduction in sea-ice cover in the Arctic Ocean in the past 20 years (Krajick, 2000)), the impact on the coastlines of ice-bordered coasts is continually in flux.

INDIAN OCEAN COASTS, COASTAL ECOLOGY

Introduction

The coastal zone is the area covered by coastal waters and the adjacent shore lands, strongly influenced by each other. Coastal lands are some of the most productive and invaluable habitats of the biosphere, including estuaries, lagoons, and coastal wetlands. They are a place of high-priority interest to people, commerce, military, and to a variety of industries. Because it contains a dense population, the coast undergoes environmental modification and deterioration through reclamation, dredging, pollution, industry, and anthropogenic activities.

India has a vast coastline of approximately 7,000 km along the Arabian Sea in the west and the Bay of Bengal in the east. The western coastal plains lie between the Western Ghats and the Arabian Sea, further split into the Northern Konkan Coast and the Malabar Coast. The eastern coastal plains on the other hand, lie between the Eastern Ghats and the Bay of Bengal. Indian coasts have a large variety of sensitive ecosystems—sand dunes, coral reefs, sea grass beds, wetlands, mudflats, and rocky and sandy shores.

As shown in Figure I9, there are number of backwaters, estuaries and coastal lagoons that support the rich and diverse flora and fauna (Figure I10). These coastal habitats are considered to be highly productive areas in terms of biological productivity and one of the "*hotspots*" of marine biodiversity. Over 11,000 faunal (10,400 invertebrates and 625 vertebrates) and over 800 floral (624 algae, 50 mangrove, 32 angiosperms, 71 fungi, 14 lichens, 12 sea grass) species have been identified from Indian coastal areas (Untawale *et al.*, 2000; Anon, 2002). The majority of the shallow coastal and backwater areas form an important spawning and nursery ground for commercially important fishes, molluscs, crustaceans, and various other species that constitute the coastal fishery of India.

Type of marine habitats

Mangroves

Mangroves are woody plants that grow at the interface between land and sea in tropical and subtropical latitudes where they exist in conditions of high salinity, extreme tides, strong winds, high temperatures,

Figure I9 Some of the important coastal lagoons and marine biosphere reserves of India.

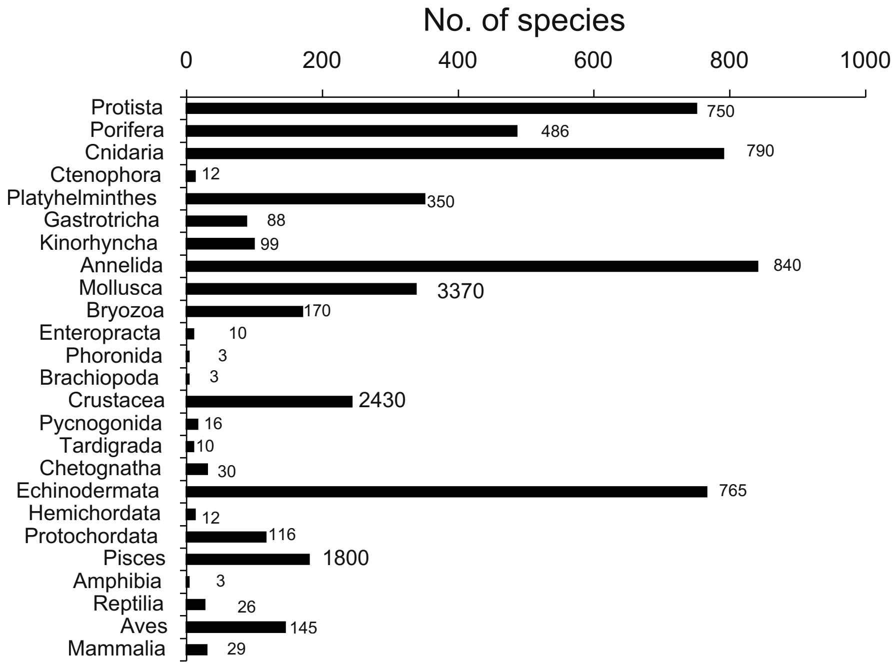

Figure I10 Marine faunal diversity of India. (After Anon, 1997; Untawale *et al.*, 2000; Anon, 2002)

Figure I11 Estuarine mangrove habitat along the Indian coast.

and muddy, anaerobic soils (Kathiresan and Bingham, 2001). Mangroves are usually present in estuarine and muddy shores (Figure I11), but can also be found on sand peat.

They are a complex and highly productive ecosystem that forms the interface between land and sea. The mangroves are widespread along the east and west coast of India. A detail of areas covered by mangrove habitat is given in Table I1.

On the Indian subcontinent, the mangrove ecosystems are distributed within the intertidal or tidal, supra-tidal or subaerial deltaic zones of both the east coast, facing the Bay of Bengal, and the west coast, facing the Arabian Sea. Mangrove flora of India comprises 50 exclusive species belonging to 20 genera, and 37 mangrove-associated floral species (Jagtap *et al.*, 2002; Upadhyay *et al.*, 2002). The maximum species diversity occurs in the Mahanadi delta along the Orissa coast, with 36 mangrove species present. Mangroves in India are estimated to cover about 4,871 km^2 (Upadhyay *et al.*, 2002). The mangrove ecosystem on the Indian subcontinent is of three types.

1. *Deltaic mangroves*: These are found along the mouth of different major estuaries on the east coast, and two gulfs (Gulf of Kachehh and Gulf of Khambhat) on the west coast. However, deltaic mangroves cover up to 53% of the total Indian mangals, which are estimated to be about 2,560 km^2, out of which the Gangetic delta popularly, known as *Sunderbans*, alone covers about 78%. About 48 species of mangroves have been recorded from the east coast (Upadhyay *et al.*, 2002). Mangrove distribution is scattered along the west coast with stunt growth and less species diversity.

Table I1 State-wise mangrove forest cover in India (in 1999)*

	Area (km^2)
States along the east coast	
Tamil Nadu	21
Andhra Pradesh	397
Orissa	215
West Bengal	2125
Andaman & Nicobar Islands	966
Sub-total	3724
States along the west coast	
Karnataka	3
Goa	5
Maharashtra	108
Gujarat	1031
Sub-total	1147
Grand Total	4871

* Source: Forest survey of India (1999)

2. *Coastal mangroves:* These are found along the intertidal coastlines, minor river mouths, sheltered bays, and backwater areas of the west coast. They extend from Gujarat to Kerala, and constitute to 12% of the mangals area of India. Due to less freshwater supply the mangals in the west coast are less, sparse, and show stunted growth. About 41 species have been reported from the west coast (Jagtap *et al*., 2002).
3. *Island mangroves:* They are found along the shallow but protected intertidal zones of bay islands, Lakshadweep and Andamans. These are estimated to be about 16% (800 km^2) of the total mangrove area. About 30 true species of mangroves have been recorded from the island areas.

Species of *Avicennia* and *Aegicera* are dominant vegetation in the Godavari–Krishna and Cauvery deltaic system while *Ceriops decandra, Sonneratia apetala* are dominant on the Mahanadi delta. About 33 species of mangroves have been reported from the Gangetic Sunderbans, with species such as *Heritiera fomes, C. decandra, Xylocarpus* spp., *Lumnitzera* sp., *Sonneratia alba, Kandelia candel, Nypa fruticans*, and *Phoenix paludosa*. The mangroves of the West Bengal are dominated by *Excoecaria agallocha, C. decandra, S. alba, Avicennia* spp., *Bruguiera gymnorhiza, Xylocarpus granatum, Xylocarpus moluccensis, Aegiceras corniculatum*, and *Rhizophora mucronata*.

Species such as *R. mucronata, Rhizophora apiculata, Avicennia officinalis, Avicennia marina, Ceriops tagal, E. agallocha*, and *Acrostidum aureum* are most dominant along the west coast. Mangrove habitats harbor a variety of flora and fauna species (Figures I12 and I13). Until recently, mangroves were treated as unwanted plants and were used largely as a source of timber and charcoal. Therefore, mangrove ecosystems have been severely depleted during the last two decades. According to recent surveys, deforestation has destroyed about 44% and 26% of mangroves along the west and east coast, respectively (Upadhyay *et al*., 2002). It is only in recent years that they have been recognized as ecologically vital. Mangroves play a very important role in protecting the shore from major erosion. The ecosystem forms an ideal nursery for the juvenile forms of many economically important fish and prawn species. A large percentage of the detrital food, which supports a variety of young fish and shrimps, is generated from mangroves.

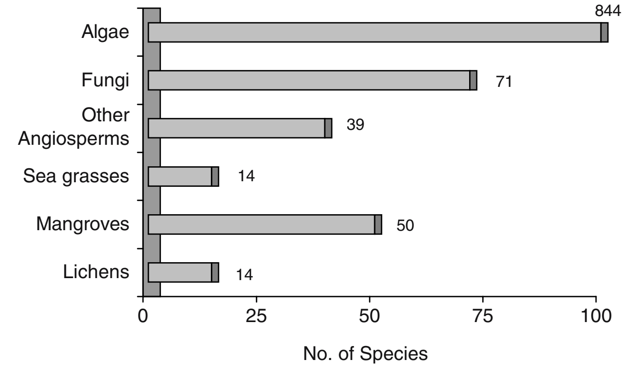

Figure I12 Floral diversity in mangrove habitat. (Compiled from Anon, 2002)

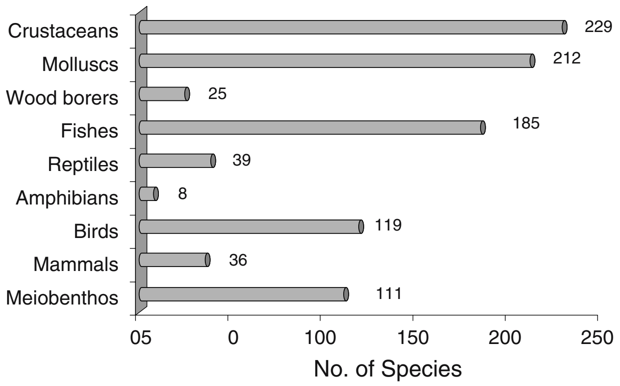

Figure I13 Faunal diversity in mangrove habitat. (Complied from Untawale *et al*., 2000)

Management

Traditionally, mangroves have been utilized for their wood, mainly for construction, fuel, and stakes. The bark of *Rhizophora* and *Bruguiera* spp., are used for tannin extraction. The leaves and fruits of *Avicennia* are used as fodder. *Avicennia* forests in the Gulf of Kachchh are constantly grazed by cattle. Mature fruits of *Sonneratia* as well as young fruits of *C. tagal* are consumed as vegetables in the human diet. Similarly, the young shoots of *A. aureum* and *Salicornia brachiata*, associated fern and an obligate halophyte, respectively, are also used as vegetables (Jagtap *et al*., 2002). Mud from the mangrove regions is used as manure for paddy and coconut fields. The roots and leaves of *Derris heterophylla* are used for narcotizing and stupefying fish. Extracts of *Acanthus* leaves are used for rheumatic disorders, while that of *Bruguiera* species for high blood pressure and *Rhizophora* extracts as a cure for jaundice. The bark and the leaves of *E. agallocha*, though poisonous, are used to cure rheumatism.

Mangrove fisheries

Mangroves have a rich and diverse fish assemblage and the habitat is commercially exploited for capture as well as captive fisheries. The capture fisheries mainly consist of various species of bivalve and gastropod, crabs, prawns, and fishes from the proper mangrove regions and estuarine waterways. The captive fishery includes fish and prawn farming in the mangrove regions as well as mussels and oyster culture in the estuarine region. The salt-affected, water-logged, tidal regions in the vicinity of mangrove environments are commonly used for paddy-cum-prawn farming and salt production.

Lagoons

Coastal lagoons are shallow water bodies lying parallel to the coastline and separated from the open sea by a narrow strip of land or salt bank (Figure I14). They are a very rich and fragile natural ecosystem. As shown in Figure I9, lagoons are distributed all along the Indian coast.

There are eight important lagoons along the east coast; they are the Chilika, Pulicat, Pennar, Bendi, Nizampatnam, Muttukadu, Muthupet. Chilika is the largest brackish water lagoon and Pulicat is the largest saltwater lagoon on the eastern seaboard of India. Chilika lagoon (Figure I15) is spread over 1,100 km^2 while Pulicat lagoon is spread over 350 km^2.

There are nine important lagoons along the west coast of India (Figure I9). They are Vembanad, Ashtamudi, Paravur, Ettikulam, Veli, Murukumpuzha, Talapady lagoon of the Bombay coast, and the Lakshadweep lagoons (Kavaratti and Minicoy). Vembanad and Ashtamudi are the largest coastal and backwater lagoons found in Kerala.

Halophila spp., *Thalassia* spp., *Cymodocea* spp., *A. marina, Acanthus* spp., *Xanthium* spp., *Acacia* spp., *Gracilaria, Asterionella* spp., *Enteromorpha* spp., are some of the floral species found in the lagoons of India.

The benthic fauna of lagoons constitute various species of, foraminiferas, nematodes, gastrotrichs, oligochaetes, polychaetes, calanoids, amphipods, isopods, decapods, tanaids, and molluscs. Among all the lagoons, Chilika has the richest biodiversity. Ecologically, it is

Figure I14 Coastal lagoon at Vadhawan.

Figure I15 Chilika lagoon (Orissa, India).

endowed with a wealth of flora and fauna (Figure I16). A total of 788 faunal species has been reported form the Chilika (Ingole, 2002). The majority of these are aquatic and almost 29% (225) are fish species (Figure I16). About 61 are protozoan species, 37 nematodes, 29 platyhelmenthes, 31 polychaetes, 58 decapods and brachyuran crabs, 37 amphibians and reptile, 136 molluscs, 18 mammals, and 156 bird species.

Chilika Lake contributes to a major portion of the fish catch in the region. The lagoons provide an excellent opportunity for aquaculture and get a good foreign exchange. The rich demersal fishery (especially of prawn, crabs, and molluscs) supports over 80,000 fishermen from 122 villages. The lake supports one of the largest populations of waterfowl during winter season. The area is known as an ideal habitat for crocodile, dolphin, and a variety of birds. An area of 15.53 km^2 of this lake has been designated as wildlife sanctuary. However, Chilika has been facing some natural and manmade problems, particularly frequent shifting of the mouth region, reduced seawater inflow, siltation, and encroachment. With a rise in human population in the lagoon periphery, pollution from domestic sewage, pesticide, agriculture, chemical, and industrial effluent have become major threats to the lagoon ecosystem. The lagoon was rapidly shrinking at the rate of about 2 km^2 per year. According to Ingole (2002) fish catches which used to be about 8,500 tonnes per year in 1980s were dwindling during 1985–2000.

However, due to the timely action taken by the Chilika Development Authority (CDA, Government of Orissa), the lake environment is being restored under the "Chilika Development Plan." Substantial increases

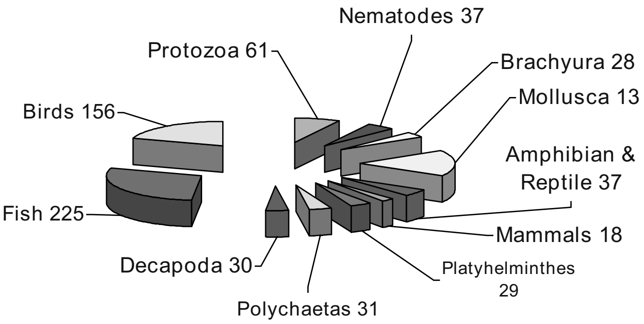

Figure I16 Biodiversity of Chilika Lake ((No. of species); Ingole, 2002).

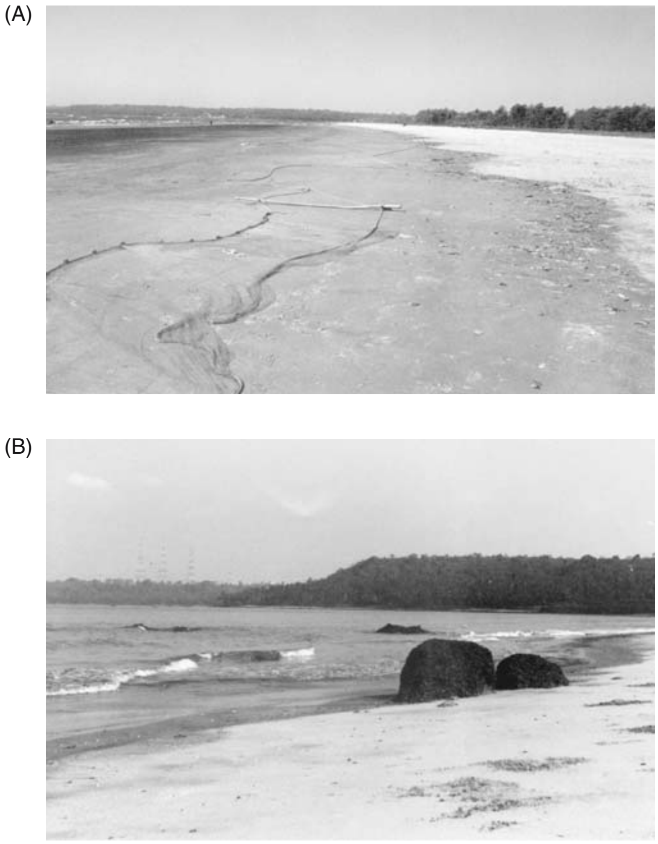

Figure I17 Sandy beaches of Goa (Central west coast of India).

in the fish production (11,989 tonnes) during 2001–02 (Ingole, 2002) clearly demonstrated the efforts of CDA toward the sustainable development and conservation of this important ecosystem. Recently, due to the rapid recovery of the lake ecosystem, the CDA Authority has been awarded the International *Ramsar Award* and Chilika is also included in the list of *Ramsar Sites*.

Estuaries

Estuaries are an integral part of the coastal environment. They are the outflow regions of rivers, making the transitional zone between the fluvial and marine environment. Estuaries are the focal point of studies, and activities. Fourteen important estuaries have been reported along the east coast and west coast of India (Anon, 1997; Qasim, 1999). Hooghly, Rushikulya, Godavari and Krishna, Edaiyur-Sadras, Araniar, Ennore, Cooum, Adyar, Uppanar, Vellar, Kollidam, Kaveri, Agniyar, Kallar along the east coast, and Ashtamudi, Korapuzha, Beypore, Periar, Kadinamkulam, Vembanad, Netravathi and Gururpur, Gangolli, Pavenje, Kali, Narmada Amba, Purna, Mandovi, and Zuari estuary on the west coast of India.

Biodiversity in the estuaries is very impressive. Some floral species are *Oscillatoria* spp., *Enteromorpha* spp., *Spirogyra* spp., *A. marina, Excoecaria* spp., and *Sonneratia* spp. Various species of polychaetes, crustaceans, molluscs, echinoderms, and fish are the faunal component of estuaries.

Estuaries are semi-enclosed water bodies and thus, they provide a natural harbor for trade and commerce. They are also effective nutrient traps and provide a vital source of natural resources for people and are used for commercial, industrial, and recreational purposes. They also act as nursery grounds for a variety of shrimps and finfish and are the best settling places for clams and oysters.

Indian estuarine ecosystems are deteriorating day by day through human activities, and the dumping of an enormous quantity of sewage into the estuary has drastically reduced the population of spawning fishes. It has also caused considerable ecological imbalance and resulted in the large-scale disappearance of the flora and fauna. Introduction of untreated municipal wastewater and industrial effluents into these water bodies has led to serious water pollution including heavy-water pollution, which becomes bio-magnified and reaches people through the food chain.

Mudflats

Mudflats develop in sheltered places of the intertidal area. Twice each day, water flows in and out with the tides, filling or draining the flat. The mudflat receives nutrients from the tidal flow and the nearby marsh, particularly as it decays. This means that mudflats have rich plant and animal communities.

They are important as sedimentation areas and provide a rich source of organic material for the endo- and epibenthic community. Because of this high availability of organic substances, oxygen content in the pore water is rather low and may limit chemical and biological degradation processes.

Phytoplankton and zooplankton are abundant, as are mud snails. Filter-feeding animals such as oysters and clams live in mudflats because of the availability of plankton. Fish and crabs move through the flats at high tide. Birds and predatory animals visit tidal flats at specific times for feeding.

Sandy beaches

The sandy beaches seem to be barren. There is no lush growth of macroalgae and apart from sea grasses there is no obvious plant life. Few animals live on the surface and most of them live below the sand. The organisms found here have suitable burrowing mechanisms, which may take the form of proboscis, parapodia of a polychaeta, and foot of molluscs.

Vast stretches of sand are seen along the east and west coast of India forming the boundary between land and sea. The beaches are subjected to the forces of waves, tides, currents, and winds. Sandy beaches along the Gujarat coast are limited between muddy and rocky shores. Although sandy strips along rocky cliffs are also observed along the Maharashtra and Goa coast, beaches along the central west coast of India are of sandy nature. The sandy shores of Goa and Karnataka (Figure I17) are of limited width, while Kerala has extensive sandy beaches interspersed with coastal lagoons. Tamil Nadu has sand strips along the deltaic shores and rock-bound beaches. Beaches along the Andhra Pradesh coast are of limited width interspersed by the rivers Godavari, Krishna, and their tributaries. Orissa has extensive sand strips at Konark—Puri. The coast of Andaman and Nicobar Islands have sand strips interspersed with bluffs, rocks, or shingle along the coastline. The Lakshadweep atolls have long stretches of coralline sandy beaches with unique vegetation.

Macrofaunal species (benthic organisms having body size >0.5 mm) such as *Donax incarnates, Donax spiculum, Donax faba, Donax scortum, Suneta scriptta, Mactra* spp., *Paphia malabarica, Bullia melanoides, Umbonium* spp., Oliva *spp*., *Emerita holthuisi, Eurydice* spp., *Gastrosaccus* spp., *Ocypode ceratophthalma, Ocypode macrocera, Ocypode platyarsus, Dotilla intermedia, Glycera alba, Lumbriconereis latreilli*, *Onuphis eremita* are some of the common species found on the sandy beaches of India.

Sand dunes

The term “sand dune” reflects the image of vast amounts of shifting sand, barren of plants, and hostile to human habitation. Hot and dry winds shape and arrange the sand in geometric and artistic patterns.

Dunes are of two types. The first type is found in the extremely dry interior desert such as Rajasthan in India and the other type is the coastal sand dune, which occur along the coast of India.

Dunes are composed of wind-blown sand. Fore-dunes are built up at the back of the beaches on the crest of berms and dune ridges where vegetation or other obstacles trap wind-blown sands. During periods of coastline advancement, successful dunes may develop to form a series of parallel dunes (Figure I18).

The common vegetation found in the fore-dune are *Hydrophylax maritima, Ipomoea pes-caprae* (Saurashtra), *Canavalia maritima, Cyperus arenarius, I. pes-caprae, Launea sarmentosa, H. maritima* (Orissa), *H. maritime, I. pes-caprae, C. maritima, C. arenarius, I. pes-caprae, L. sarmentosa, H. maritime, Sporobolus virginicus* and *Zoysia matrella* (Andhra Pradesh), *I. pes-caprae, L. sarmentosa, Dactyloctenium aegypticum, C. arenarius* (West Bengal), *I. pes-caprae, Spinifex littoreus* (Goa). In the parabola dune the following vegetation have been recorded along the west coast of India: *Halopyrum mucronatum, Borreria articularis, Lotus garcinii, Asparagus dumosus, Enicostema hyssopiflorum, Peplidium maritimum, Cassytha filiformis*, and along the east coast of India *Euphorbia rosea, Geniospermum tenuiflorum, Phyllanthus rotundifolius, S. littoreus, Goniogyne hirta, Perotis indica, Brachiaria reptens, Elusine indica, Rothia indica, Trianthema pentandra*.

Sand dunes throughout the world have been recognized for their ecological significance. The coastal dune vegetation acts as shelter belts protecting the inner land. When the dune system and the vegetation are destroyed for short-time benefits in the name of development, disaster occurs. Floods and cyclones on the east coast of India are eye-opening examples. The cause and effect of destruction are not short-termed or locally limited.

Rocky shores

In contrast to sandy beaches where many individuals live unseen in the soil, many of the plants and animals of the rocky shores are conspicuously displayed. Another feature of the rocky shore is the distinctly noticeable zonation of plants and animal communities.

The rocky coast shows a richer fauna than that of the sandy beach and is varied in composition. The rock and crevices give shelter to numerous crabs, molluscs, and fish. *Grapsus grapsus, Tectarius trochoid, Littorina scabra, Littorina angulifera, Littorina undulat, Trohcus* sp., *Cellana radiata, Planaxis sulcatus, Thais bufo, Drupa* sp., *Hemifusus pugulinus, Perna viridis, Nereis* spp., amphipods, isopods, Holothuria, Sea Urchin, nudibranch, *Aplasia* spp., are some of the common fauna of the rocky shores. Common flora of the rocky shore are different species of *Porphyra*, *Gracilaria,* and *Enteromorpha*, *Padina, Ulva*, *Gelidium*, *Sargassum*, and *hypnea*, *Chaetomorpha* spp.

Sea grass

Sea grasses are submerged flowering plants (angiosperms) that have adapted to life in the sea. They differ from what we refer to as "seaweed," in that they are plants with vessels and well-defined root and shoot systems. Sea grasses have been able to successfully colonize the marine environment because of five properties:

- the ability to live in a salty environment;
- the ability to function normally when fully submerged;
- a well-developed anchoring system;
- the ability to complete their reproductive cycle while fully submerged;
- the ability to compete with other organisms under the more or less stable conditions of the marine environment.

Sea grass habitats are mainly limited to the mudflats and sandy regions from the lower intertidal zones to a depth of ca. 10–15 m along the open shores and in the lagoons around islands. The major sea grass meadows in India occur along the southeast coast (Gulf of Mannar and Palk Bay) and along a number of the islands of Lakshadweep in the Arabian Sea and of Andaman and Nicobar in the Bay of Bengal. The largest area (30 km^2) of sea grass occurs along the Gulf of Mannar and Palk Bay, while it is estimated that ca. 1.12 km^2 occurs in the lagoons of major islands of Lakshadweep. A total of 8.3 km^2 of sea grass cover have been reported from the Andaman and Nicobar Islands (Jagtap *et al*., 2003).

The sea grasses of India consists of 14 species belonging to 7 genera. The Tamil Nadu coasts harbor all 14 species, while 8 and 9 species have been recorded from Lakshadweep, and Andaman and the Nicobar group of Islands, respectively. The east coast supports more species compared to the west coast of India. The main sea grasses are *Thalassia hemprichii, Cymodocea rotundata, Cymodocea serrulata, Halodule uninervis* and *Halophila ovata*. Species such as *Syringodium isoetifolium* and *Halophila* spp., occur in patches as mixed species. Gulf and bay estuaries mostly harbor low numbers of species, dominated by *Halophila beccarii* in the lower intertidal region and by *Halophila ovialis* in the lower littoral zones.

Sea grass beds are:

- Major primary producers (food manufacturers) in the coastal environment. Their high primary productivity rates are linked to the high production rates of associated fisheries;
- Stabilizers of bottom sediments; they provide protection against erosion along the coastline;
- Important nutrient sinks and sources, that is they help in the recycling of nutrients.

With root-like stems, which extend horizontally under the sea bottom, sea grasses act to stabilize the sediment. These sediments, that

Figure I18 Typical sand dune found along the east coast of India.

would otherwise settle on coral and prevent contact with sunlight, tend to accumulate and become trapped in the sea grass. Turtle grass, the most common type of sea grass thrives in areas that are protected from wind-driven current and surf. The broad leaves of turtle grass act as huge filters, removing particles from the water and depositing them as fine sediment. These sediments often contain organic matter, which contribute to the high productivity of this habitat. For this reason, the sea grass habitat attracts various species of fish, conch, lobster, turtles, and manatees for feeding and breeding. Numerous species of reef fish use sea grass as a protective nursery, hiding amid the grass from predators. Moreover, adult fish that hide in the coral reef during the day and venture out at night to feed, take advantage of the rich source of food that exists in the sea grass.

The natural causes of sea grass destruction in India are cyclones, waves, intensive grazing, and infestation of fungi and epiphytes as well as "die-back" disease. Exposure at the ebb tide may result in the desiccation of the bed. Strong waves and rapid currents generally destabilize the meadows causing fragmentation and loss of sea grass rhizomes. The decrease in salinity due to extensive freshwater run-off also causes disappearances, particularly of the estuarine sea grass bed.

Anthropogenic activities such as deforestation in the hinterland or mangrove destruction, construction of harbor or jetties, loading and unloading of construction materials as well as anchoring and moving of boats and ships, dredging and discharge of sediments, land filling and untreated sewage disposal are some of the major causes of sea grass destruction of India.

As of yet, there is no specific legislation protecting sea grasses, although generally the Fisheries Department is responsible for this habitat. Green Reef recommends that in addition to controlling the use of pesticides and decreasing run-off, dredging activities need to be strictly monitored and limited. Sea grass beds should be thought of as an indication of the health of the ecosystem; when they begin to disappear, we know there is trouble.

Coral reefs

Coral reefs are among the most biologically productive, taxonomically diverse, and aesthetically important living organisms among all the aquatic ecosystems.

The major coral formation in India is around the Lakshadweep (816 km^2) and Andaman Islands (960 km^2), as well as in the Gulf of Mannar (94 km^2) and the Gulf of Kachchh (406 km^2). Reefs in the Gulf of Kachchh, Gulf of Mannar, and Andaman and Nicobar Islands are mostly of the fringing type, with a few platform, patch and atoll reefs, and coral pinnacles. Lakshadweep Islands on the contrary are mostly atolls with a few coral heads, platform reefs, and sand cays. Coral, though rare in occurrence, are reported at many locations along the west coast.

About 44 species of scleractinian coral and 12 species of soft corals occur in the Gulf of Kachchh (Figure I19). The submerged reefs of these areas harbor 18 species of stony coral and have 45% coverage. *Acropora, Porites, Pseudosiderastrea*, and *Favia*, and one species of soft coral *Juncella juncea* are common. Two species of hard coral (*Pseudosiderastrea tayamai* and *Porites lichens*) have been recorded in patches along the central west coast. Large well-developed hard colonies have also been sighted at Colaba near Mumbai.

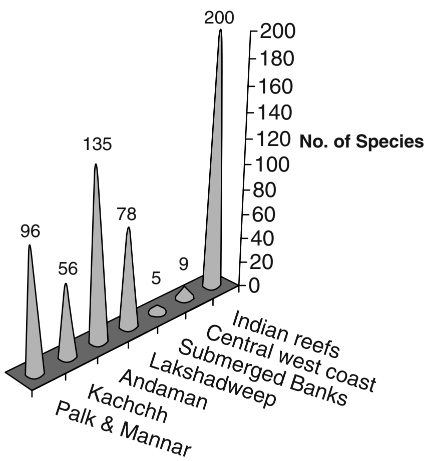

Figure I19 Coral distribution along the Indian coast.

Malvan is considered to have the richest marine biodiversity along the central west coast. *Porits*, a stony coral is most common in Malvan waters. Nine species including a rare coral species belonging to the genera *Coscinaraea*, *Favites, Goniastrea, Synaraea* and *Pseudosiderastrea, Cyphastrea, Turbinaria* have been recorded in this region. Angria bank—a submerged reef off Ratnagiri has stony corals. A few patches of scleractinian corals have been reported in subtidal waters off the Goa coast (Rodrigues *et al*., 1998). Five coral species have been recorded from Gaveshani Bank off Malpe along the Karnataka coast (Qasim and Wafar, 1979; Wafar, 1990). *Pocillopora eydouxi* has recently been reported from Vishakhapatnam on the east coast.

About 96 species belonging to 36 genera of Scleractinian and 7 species of Ahermatypic corals are reported from Palk Bay and the Gulf of Mannar (Figure I19). *Montipora* and *Acropora* represent 40% of the species in the Palk Bay. Thirty species of stony corals are reported from Manauli reef, of which the dominant corals are *Acropora, Porites, Goniastrea, Favia, Pocillopora* and *Montipora*. Krusadai island has a well-developed coral reef and sustains 96 species belonging to 26 genera of hermatypic corals.

Massive occurrences of corals provide much needed protection from waves to the coastline; and coral productivity yields a multitude of flora and fauna dependant on the coral ecosystem. Coral reefs also provide opportunities for skin diving, under-water photography, sport fishing, and shell collection, thus, providing a vital stimulus to the tourist industry. Coral reefs are often exploited for calcium carbonate—a raw material for many lime-based industries. The fishery resources of the reefs are extremely rich and diversified. They are also exploited for their beautiful associated fauna such as molluscs and ornamental fish.

Due to population pressure, most of the coral reefs have become extremely vulnerable to industrial development and pollution along the coastline. Unless protection is offered to the coral reefs, most of them will diminish in size in the future and ultimately die. The reefs that will probably flourish are on the atolls of Lakshadweep and some of the islands of Andaman and Nicobar Islands.

Marine protected areas

There are 26 Marine Protected Areas (MPAs) in India comprised of national parks and wildlife sanctuaries declared as coastal wetlands; especially mangrove, coral reefs, and lagoons, under Wildlife (Protection) Act, 1972. These 26 MPAs are located in 7 coastal states and 2 union territories and cover 13% of the total coastal wetland area of the country. Some of these MPAs are shown in Figure I9 and Table I2. The Gulf of Kachchh Marine Sanctuary and Marine National Park, the Gulf of Mannar National Park, and the Wandoor Marine National Park (Andaman Islands) have been established primarily to protect marine habitats.

Table I2 Marine national parks and sanctuaries along the Indian coast (Anon, 2002).

States	Location	Name of the biosphere
Gujarat	Gulf of Kachchh	National Marine Park, Bird Sanctuary, and coral reef
Maharashtra	Mahaim (Mumbai)	Natural Mangrove Park
	Malvan	Marine Park (coral reef)
Goa	Chorao island	Bird Sanctuary
Lakshadweep islands	Kawaratti, Agatti, Minicoi islands	Marine Park (coral reef)
Tamil Nadu	Gulf of Mannar	National Marine Park, Sanctuary, and coral reef
	Muthupet	Reserve Mangrove Forest
Andhra Pradesh	Coringa	Wildlife Sanctuary
Orissa	Nalaban (Chilika)	National Marine Park and Bird Sanctuary
	Bhittarkanika	Wildlife Sanctuary (Turtle project)
West Bengal	Haribanga	National Marine Park and Bird Sanctuary (Tiger project)
Andaman and Nicobar Island	Wandoor	National Marine Park

Management of coastal ecology

As shown in Figure I20, there is great demand for industrial development along the Indian coast. This in turn amounts to the increase in pressure on the coastal zone due to concentration of population, development of industries and ports, discharges of waste effluents and municipal sewage, and spurt in recreational activities which have adversely affected the coastal environment. Coastal resources are affected by activities far distant from the coast (viz., deforestation, damming of rivers, bunding/barraging of the coastal water bodies, river sand mining, discharge of pesticides, heavy metals, domestic and factory wastes, garbage, and other substances that are harmful to the coastal areas. Lagoons, estuaries, wetlands, and nearshore shallow water areas are particularly vulnerable to these activities. Considering the urgent need for protecting the Indian coast from degradation, the Government of India enacted "Coast Regulation Zone (CRZ) Act, 1991." The area influenced by tidal action up to 500 m from High Tide Line (HTL) and the land between the Low Tide Line (LTL) and the HTL has been declared as Coastal Regulation Zone (CRZ).

Mangroves and coral reef ecosystem

The mangroves are constantly threatened by increasing anthropogenic pressures such as indiscriminate cutting, reclamation mainly for agriculture and urbanization, fuel and construction, and overgrazing by domestic cattle. Mangrove ecosystems along the west coast, particularly in the States of Gujarat, Maharashtra, and Kerala, have been degraded to a large extent. However, West Bengal (Sundarbans), Orissa, and the Andaman and Nicobar Islands still form the best mangrove ecosystems of India. Considering various estimates for the mangrove cover in the country, 30% of the mangrove area was reclaimed for different anthropogenic activities during the period 1975–90 (Jagtap *et al*., 1993).

Realizing the importance of mangroves and coral reefs, the Government of India initiated efforts for their conservation and management. They were declared as ecologically sensitive areas under the Environment (Protection) Act, 1986, banning their exploitation, and followed by a CRZ Notification 1991 prohibiting development activities and disposal of wastes in the mangroves and coral reefs. The Ministry initiated a plan-scheme on conservation and management of mangroves and coral reefs in 1986 and constituted a National Committee to advise the Government on relevant policies and programs. On the recommendations of this committee, 15 mangrove areas in the country have been identified for intensive conservation (Anon, 1997 & 2002; Jagtap *et al*., 2002).

Considering the importance of coral reefs and the factors responsible for their deterioration, Andaman and Nicobar Islands, Lakshadweep Islands, Gulf of Mannar, and Gulf of Kachchh have been identified for conservation and management. Efforts have been initiated to establish Indian Coral Reef Monitoring Network (ICRMN) to integrate various activities on coral reefs through national and international initiatives.

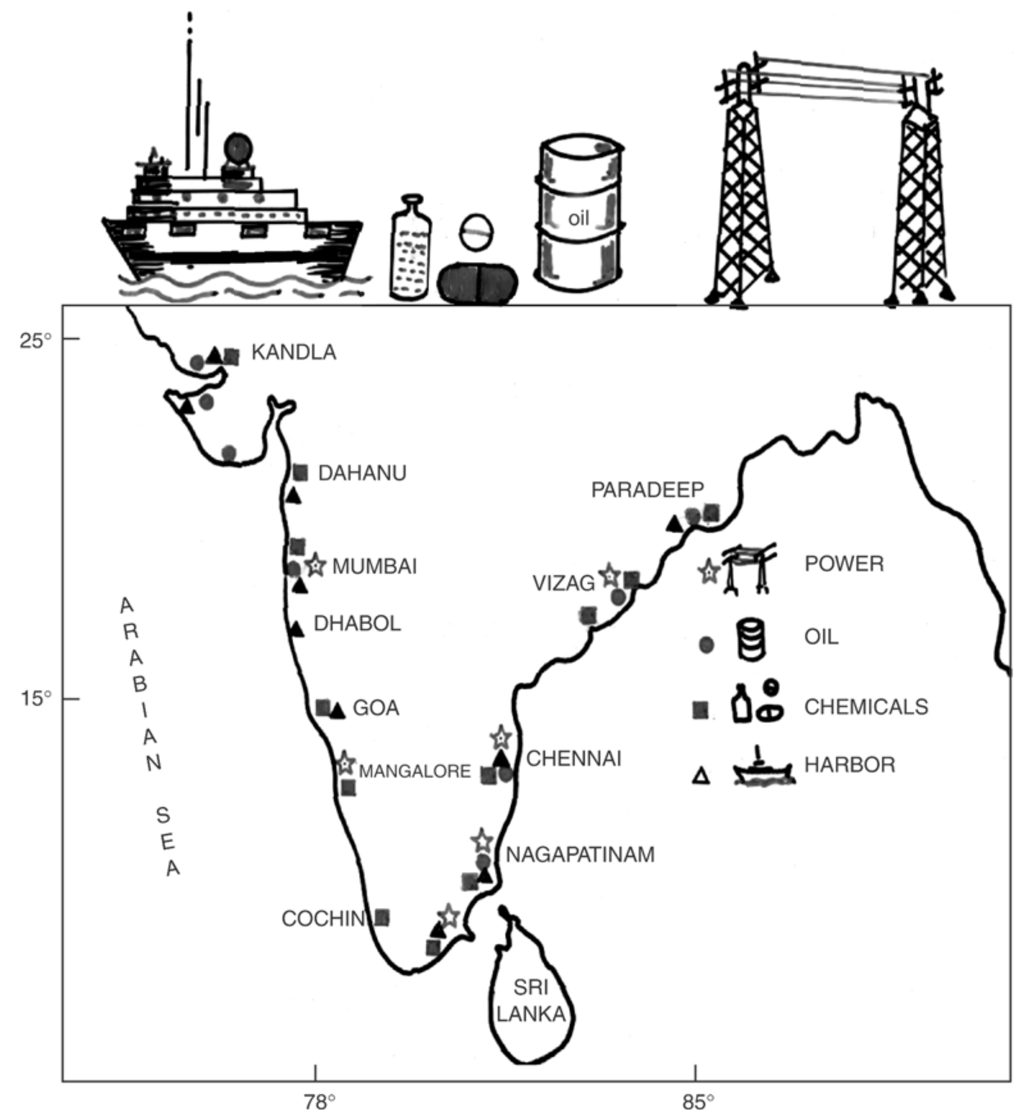

Figure I20 Patterns of industrial development along the Indian coast.

Institutions of database networking and capacity building and training on coral reefs have been identified. With the establishment of the National Mangrove Committee (NATMANCOM), attempts are being made to protect, conserve, and restore the mangrove habitats. Mangrove regions in the country have been categorized presently under the Ecologically Sensitive Zone; vide CRZ Act of the country. As per the CRZ Act, no development in the mangroves or in the vicinity is allowed prior to an environmental impact assessment (EIA) and clearance from the Ministry of Environment and Forests (MoEF), Government of India. Few of the mangrove regions in the country have been conserved as Biosphere reserves for germplasm and wildlife sanctuaries.

Shrimp culture activities

The aquaculture industry is growing at a faster rate than many of the sectors of the coastal zone in India. Socially, its product is seen as a currency. However, if aquaculture expansion is not regulated, its long-term consequences will be felt in the quality of water bodies. In fact some adverse effects of shrimp culture are already seen along the east coast of India, particularly along the coast of Andhra Pradesh.

Sandy shores

Mining of beach sand is a widespread activity in many of the coastal areas. Though sand is an important constituent of construction activities, it has to be borne in mind that it is these sand deposits that provide the natural protection to the coast from erosion. Storms, waves, currents, and wind temporarily displace vast quantities of beach sand that is then held in storage as sand bars. These sand bars then become the protectors of the coasts against those forces, which finally return the sand to the beach. Thus, removal of sand from any part of the beach can aggravate the erosion and recession of the beach front altogether.

For the above reasons and also for the sustainable management of the coastal resources, many countries are now developing Coastal Zone Management (CZM) strategies, and some have already begun to adopt such programs. The CZM has to manage, develop, and conserve natural resources and, while doing so, it has to integrate the concerns of all relevant sectors of the society, economy, and prosperity.

A major thrust in implementing the CRZ notification is in the conservation of coastal resources, to achieve their sustainability, and long-term protection of its natural assets. The criterion for sustainable use is that the resource shall not be harvested, extracted, or utilized in excess of the quantity that can be produced or regenerated over the same period. It is important to learn the acceptable limits of coastal environmental degra-dation and the limits of sustainability of coastal resources. Hence, in order to achieve the goals set forth in the notification, it is imperative to have first-hand-information on the present land use practices and availability of the resources in the coastal zone. Contribution No.3897 of NIO, Goa.

INDIAN OCEAN COASTS, COASTAL GEOMORPHOLOGY

The coastal geomorphology of the Indian Ocean coast, with special reference to coasts of Pakistan, India, SriLanka, Bangladesh, and Myanmar, is mainly governed by the processes associated with monsoons.

Pakistan

The coastline of Pakistan, from the Iranian border on the west to the Indian border on the east is about 990 km long. This coastline is one of the active tectonic regions. The coast here is associated with a narrow continental shelf, except off Indus delta. The coast of Pakistan is divided into the Makran coast, Las Bela coast, Karachi coast, and Indus Delta coast.

The Makran coast, with approximately 473 km length, from the Iranian border to Ras Malan, consists of long sandy beaches associated with either wide coastal plains or valleys landward. These plains and valleys are interrupted by uplifted marine terraces at places. Also the Makran hill ranges, which lie about 32 km from the coast, become part of the coast at Ras Malan with massive headlands. Spits and bars are common seasonal morphologic units along sandy beaches. At places, well-developed beach ridges are seen. Dasht is the only river which brings a small quantity of sediment from land to the Arabian Sea along this coast.

The Las Bela coast, with about 260 km length, extends from Ras Malan to Ras Muari. The Ras Malan range is made up of sandstone and shelly limestone and presents gorges and cliffs as high as 600 m, which drop directly to the sea. Followed by this, on the east, is the Las Bela plain. The coast here consists of a series of beach ridges, sand dunes, bars, tidal flats, and lagoons with mangroves (Bird and Schwartz, 1985). Between the Ras Malan ranges and the Las Bela main valley notable mud volcanoes are present, the largest among them is called Chandragup (Snead, 1964). On the eastern side of the Las Bela valley, promontories of limestone are present. Here marine terraces at different elevations have wave cut sea caves and blow holes (Snead, 1966). Along this coast, the Hab River joins the Arabian Sea at its mouth compound bars, shallow lagoons, and sandy beaches are present.

The Karachi coast, about 48 km in length from Ras Muari to Clifton beach, consists of low rocky cliffs and sandy beaches of almost equal length. Marine terraces, sea caves, and arches are common in the sandstone and shale rocks. Sandy barrier beaches, spits (the longest one 15 km in length), shallow lagoons, tidal flats, and salt evaporation ponds are common along the sandy beaches.

The Indus delta coast is about 200 km long with uniform landforms namely large tidal channels with mudflats in between, barrier bars and spits with hooks, and beaches, and a few small mangrove shrubs. The sand bars and delta channels are dynamic in nature as they change their morphology due to tidal currents, waves and channel floods. The coastal area in this region is very flat and therefore up to 6.5 km from the coastline it is submerged during high tide. The river Indus brings a large quantity of sediment from land to sea and joins the Arabian Sea along this coast.

India

Most of the early literature on Indian coastal geomorphology was essentially of a descriptive nature based on the nature, location, and relationships of the landforms and sea level. Ahmad's (1972) was possibly the first and only book on coastal geomorphology of India, and contains data collected from large-scale maps and inferences drawn on the nature of the coasts. In addition, there are some isolated studies by Vaidyanathan (1987), Baba and Thomas (1999). The Space Application Centre (SAC, 1992) has carried out a comprehensive study on the coast using LANDSAT and IRS data. The information on Indian coastal geomorphology presented in this article is based on these and many more isolated published studies.

India has about a 7,500-km long coastline. The coastline of India has been undergoing morphological changes throughout the geological past. The sea level fluctuated during the period of last 6,000 years and recorded marked regression during the period between 5,000 and 3,000 years before present (Rajendran *et al*., 1989). The present coastal geomorphology of India has evolved largely in the background of the post-glacial transgression over the preexisting topography of the coast and offshore (Baba and Thomas, 1999).

The major rivers that cut across the coast and bring large quantities of water and sediment to the coast from Indian continent are the Ganges, Brahmaputra, Krishna, Godavari, and Cauvery on the east coast, and the Narmada and Tapti on the northwest coast. In addition, there are about 100 smaller rivers, these also supply considerable quantities of water and sediment. While larger rivers have well-developed deltas and estuarine systems, almost all the small rivers have estuarine mouths with extensive mud flats and salt marshes and some of them with estuarine islands.

The continental shelf of India is very wide on the west coast with about 340 km in the north, tapering to less than 60 km in the south. The shelf is narrow along the east coast. The coastline on the west receives southerly winds that bring high waves during the monsoons (June–September). The east coast generally becomes active during the cyclones of the northeast monsoon period (October–November). The tidal range varies significantly from north to south. It is around 11 m at the northwest, 4.5 m at the northeast and around 1 m at the south.

Considering geomorphic characteristics, the Indian coast is divided into two categories, namely coasts on the west coast of India and coasts on the east coast of India. The coast on the west coast of India differs from the east in that there are practically no deltas on the west coast. The coastline here is modified by headlands, bays, and lagoons at irregular intervals. There is distinct evidence of the effect of neotectonics in some sections (Vaidyanathan, 1987). The east coast on the contrary is known for the number of deltas especially along the northern portion, West Bengal and Orissa coast. Deltas in the southern portion have helped in recognizing ancient channels, ancient beach ridges, former confluences, and strandlines.

West coast of India

Though there are a large numbers of small rivers bringing enormous quantity of sediment to the Arabian Sea along the west coast, deltas are not formed, possibly due to the high-energy condition of the coast. Beach morphological changes along the west coast are controlled by the southwest monsoon. The maximum morphological changes occur during early monsoons (June–August). During this period most of the material is transported to the offshore and some alongshore. Most of the material appears to be returned again during the fairweather season.

The west coast of India is further divided into the Gujarat coast, Maharashtra, Goa and northern Karnataka coast, and southern Karnataka and Kerala coast based on their geomorphological distinctions. The coastal area of Gujarat is the largest in the country with about 28,500 km^2. The coast in Gujarat, from west to east, varies from a deltaic coast, the irregular drowned prograded coast, the straightened coast, the spits and cuspate foreland complex, and the mudflat coast. The Gujarat coast is further divided, from west to east, into five regions, namely Rann of Kutch, the Gulf of Kutch, the Saurashtra coast, the Gulf of Khambat, and the South Gujarat coast, based on coastal geomorphic characteristics.

The Rann of Kutch remains saline desert for the larger part of the year and is further divided into the Great Rann and the Little Rann. On the west of the Great Rann of Kutch is the area of the lower Indus deltaic plain which is characterized by tidal creeks and mangroves. The coastline in the Gulf of Kutch has extensive mudflats and is highly indented with a number of cliffed rocky islands (Baba and Thomas, 1999). Migration, joining of different creeks, reorientation of tidal current ridges, and regression of the sea are seen and are related to tectonically activated lineaments. The coast here is fringed by coral reefs and mangroves. Algae, salt marsh, dunes, and salt pans are very common. The Saurashtra coast has numerous cliffs, islands, tidal flats, estuaries, embayments, sandy beaches, dunes, spits, bars, bays, marshes, and raised beaches at some places. The coast, in Gulf of Khambat is indented by estuaries and consists of mudflats, dunes, and beaches. Here mudflats are seen at different levels and paleo-mudflats have been related to regression. The south Gujarat coast is relatively uniform and is indented by a series of creeks, estuaries, marshes, and mudflats. The Gujarat coast, from Great Rann to the south Gujarat coast, presents evidence for both emergent and submergent coasts.

The Maharashtra, Goa, and northern Karnataka coasts are characterized by pocket beaches flanked by rocky cliffs, estuaries, bays, and at some places mangroves. Beaches in southern Goa and some places along northern Karnataka, however, are long and linear in nature with sand dunes. The Mandovi and Zuari estuarine system in Goa is the largest in this part of the coast. Mudflats are found mainly along estuaries and creeks. Rocky promontories on the Maharashtra coast are made up of Deccan basalts whereas in the south they are mainly of granite gneisses. A number of raised platforms can be seen all along the coast. There are a few islands along the southern parts of this coast near Karwar. This coastal stretch is typical of a cliffy coastline with raised platforms and strong evidence of a submergent coast. The beaches in Goa and northern Karnataka are well-studied and classified as stable beaches with seasonal morphological changes and annual cyclicity (Nayak, 1993).

The southern coast of Karnataka is characterized by long linear beaches, estuaries, spits, mudflats, shallow lagoons, islands, and a few patches of mangroves. Satellite image studies revealed northward shifting of the mouth of estuaries along this coast (SAC, 1992). Beach erosion is severe in some areas along this stretch. The Kerala coast is known for the presence of laterite cliffs, rocky promontories, offshore stacks, long beaches, dunes, estuaries, lagoons, spits, and bars. Using Landsat images, three sets of sand dunes have been identified. The mud banks are unique transient nearshore features appearing during monsoons (Mathew and Baba, 1995) at Kerala. They are unique phenomenon occurring at particular locations along the Kerala coast during the southwest monsoon season, which act as natural barriers to coastal erosion. Along the coast, sand ridges, extensive lagoons, and barrier islands (700 landlocked islands) are indicative of a dynamic coast. About 420 km of the 570 km coastline is protected by seawalls and about 30 km of the coast is undergoing severe erosion. Maximum loss of material has been reported along the southern sections. The predominant southwest wave approach during monsoons, result in northerly littoral drift with varying speed. Some parts of the Kerala coast are known for rich heavy-mineral deposits. The characteristic coastal geomorphology provides an ecosystem, which supports both agriculture and fisheries. Evidences of both emergent and submergent coasts are available for the southern Karnataka and Kerala coast.

East coast of India

The deltaic systems of the east coast experience the high sedimentation rate and periodic cyclones which result in extensive floods.

The east coast in the south, along Tamil Nadu and Pondicherry, is straight and narrow except for indentations at Vidyaranyam. The major landform along this coast is the presence of a large delta formed due to the Cauvery River and its tributary system. The other landforms are mudflats, beaches, spits, coastal dunes, rock outcrops, salt pans and strand features. At a few places mangrove systems, and at Gulf of Mannar and Rameshwaram fringing and patchy reefs, are seen. Deposition and erosion have been reported at different beaches along this stretch. Rich heavy-mineral deposits have been reported at Muttam–Manavalakuruchi.

The coastline of Andhra Pradesh, mainly the deltaic coast, is 640 km long and comprised of bays, creeks, extensive tidal mudflats, spits, bars, mangrove swamps, marshes, ridges, and coastal alluvial plains. Inundations are seen in the extreme south of the Andhra Pradesh coast, that is, in the saltwater lagoon of Pulicate lake and also between the Godavari and Krishna deltas. The Kolleru lake, situated in the interdelta, formed due to coalescence of the deltaic deposits of the rivers and later it cut off from the sea (SAC, 1992), is shrinking on the northern side. The deltaic and southern coasts are rich in agriculture and aquaculture production. The deltaic coast is well vegetated with mangroves. The Pulicate lake has extensive tidal flats and a 12 km long spit. In the north, residual hills and ridges are seen close to the sea. Rocky outcrops and bay beaches are seen here. Storm wave platforms, sea caves in rocks, and cliffs are common coastal features in the north. A critical examination of the relief chart off the region around the Krishna River confluence has indicated the presence of extensive banks in the shelf zone (Varadarajulu *et al*., 1985). The islands of the Krishna delta front are intertidal and submerged to a large extent during spring tide. The Krishna delta front has been growing through spits and barrier bars (SAC, 1992).

The Orissa coast is a site of deposition formed and controlled by the Mahanadi and Brahmani–Baitarani deltas. Mudflats, spits, bars, beach ridges, creeks, estuaries, lagoons, flood plains, paleo-mudflats, coastal dunes, salt pans, and paleo-channels are observed all along the Orissa coast. The Chilka lagoon is the largest natural water body of the Indian coast. The inlet mouth of Chilika lake is exposed to high annual northward littoral drift and observed to migrate about 500 m northward per year (Chandramohan *et al*., 1993). The width of beaches at Orissa vary. Littoral transport of sediments in the coastal region is a strong process. The coast is also exposed to severe cyclones. Turbidity in the nearshore as well as in the estuarine region is very high. Progradation of the coastal region in the north of the Devi estuary, and drifting of beaches has been observed. The Bhitarkanika and Hatmundia mangrove reserves are as extensive as 190 km^2. Gopalpur is rich in heavy minerals. Prominent and well-developed sand dune deposits containing monazite, zircon, rutile, ilmenite, and sillimanite occur along the southern coast of Orissa.

The West Bengal coast represents a typical deltaic strip with almost a flat terrain. The Hooghly and its distributaries form the conspicuous drainage system and forms an estuarine delta. The major geomorphic features are mudflats, bars, shoals, beach ridges, estuaries, a network of creeks, paleo-mudflats, coastal dunes, islands like sagar and salt pans. The Sundarbans, one of the largest single block of halophytic mangrove systems about 1,430 km^2, of the world need a special mention.

SriLanka

SriLanka has a coastline of about 1,700 km including that of the Jaffna lagoon. It is a tectonically stable tropical island consisting mainly of Precambrian rocks, and in the northwest, Miocene limestones, and Quaternary sediments. The central portion of the island is a highland surrounded by lowland coasts. Two-thirds of the island's coastline consists of sandy beaches bounded by Precambrian headlands (Swan, 1979). The remaining one-third of the coastline, in the northwest and north, consists of sedimentary rocks. Beach material is predominantly terrigenous. Coastal dunes occur along some sections depending on prevailing energy conditions.

The continental shelf between the Gulf of Mannar and Pak Strait in the northwest and north, respectively, is considerably wide across to India. Elsewhere it is narrow.

The coastline of the island is affected by northeast and southwest monsoons. Wave energy is relatively low in the north and northwest because of shallow seas and barriers. In general, however, beaches are open to seasonal strong wave action. In the north and northwest where energy is low, sheltered lagoons with mangroves, estuaries, barrier beaches, spits, and tidal flats are common. Corals forming fringing and small barrier reefs are also seen. Beaches here are narrow and composed of coarse calcareous material. In the Pak Bay and Gulf of Mannar many depositional morphological units are seen. They include, intertidal barriers, multiple sand bars, dunes, and in the southern part of the Gulf of Mannar a stable sand spit growing toward the northwest. Net sediment movement toward the north along the west coast causes this spit to maintain a stable sand body. From this spit to Colombo in the South, important morphological features that are seen are relict beaches, sand dunes, flood plains, deltas, lagoons, and swamps backed by raised beaches. Dune deposits here overlie limestone. From Colombo, further to the south, lateritized Precambrian rocks form promontories. A sandstone reef offshore, opposite Colombo, acts as a barrier to incoming large waves and the supply of sand material. Raised beaches up to 8 m above sea level are seen at Colombo. Further south the coastline is smooth and sandy, with bays and headlands, backed by raised beaches, flood plains, swamps, and laterite terraces. Along the southwest coast, wave energy is high and sand supply is poor and therefore the coast is undergoing severe coastal erosion. Yun-Caixing (1989) studied coastal erosion and protection using remotely sensed data between Colombo and the southernmost point of the island. The southernmost part of the island consists of low platforms of resistant granitic rocks. The coast here is indented and morphologic units seen are promontories, cliffs, barrier beaches, lagoons, and swamps.

The east coast adjacent to the southern tip, consists of wide coastal plains and low coastlands. Headlands are spaced far apart, and behind long barrier beaches are lagoons, and estuarine deltas. Sand-rich rivers traverse this sector. This change in coastal morphology is in response to a change in geological structure (Cooray, 1967). Further north along the east coast, there are two linear submarine structures, namely the Great and the Little Basses (reef) ridges. These ridges are composed of calcareous sandstone (Throckmorton, 1964). The landforms of bedrock and sand dunes are replaced by broad flood plains, river terraces, and lagoons, further north small barrier beaches are present. A series of large lagoons which are interconnected are called Batticaloa lagoon, a major feature along east coast. Further north, the coastline is made up of bays and headlands of coral, backed by beach ridges and lagoons. Estuaries, deltas, lagoons, and bay-head barrier beaches are common features along the coast. Along the northeast, bays and headlands backed by raised beaches, lagoons, and low residual rises are the common morphological features. Old beach deposits and dunes are seen, which are rich in ilmenite and rutile minerals.

Bangladesh

The coastline of Bangladesh is around 654 km long from the Indian border in the west to the Myanmar border in the east. This excludes tidal channels and delta estuaries. If estuaries, islands, and tidal channels are included it is more than 1,320 km long. The Bangladesh coast is divided into four parts from west to east; Sundarbans, cleared Sundarbans, Meghna, and Chittagong. Except for the last one Chittagong, the coastline is low, swampy, and rapidly changing and composed of sediments of the Quaternary period in large alluvial basins. The source is from two vast river systems, the Ganges and the Brahmaputra.

The Sundarbans are thick mangrove and nipa palms swamps, with a total distance of about 280 km (about 195 km in Bangladesh) from the Hooghly River in India to the Tetulia River in Bangladesh. About 68 km long, sundarban forests have been cut and destroyed. This area, is presently, being used for extensive farming. Tidal estuaries, flat marshy islands, creeks and channels, banks of soft muds and clays with thick mangrove and nipa palms are characteristic features of the Sundarban coast. It represents the older deltaic plain of the Ganges with the presence of old beach ridges in the western swamps. The Meghna is a single main channel which after collecting water and material from the Ganges, Brahmaputra, and Meghna rivers, joins the Bay of Bengal. The characteristic feature is the series of extensive shoals called the Meghna flats developed at the mouth of the River Meghna. These shoals are barren mud and sand bodies. This strongly supports a drowned coastal region.

The geomorphic history of the deltaic plain, which includes Sundarbans and Meghna, is continuous shifting of the river course. In recent times, the Ganges has shifted to the east, resulting in the Meghna as a major course. The shifting is explained as tectonic by Morgan and Mcintire (1956). Sediment supply and tectonic history at the delta with reference to the last glacial period is explained by Chowdhury (1996).

The Chittagong coast extends 274 km between two rivers, namely River Feni in the north and River Naf on the Myanmar border. Small beaches and broad sand flats between headlands along this coast are the common features. There are many islands and shoals found along this stretch of the coast.

Myanmar

The Myanmar coast is about 2,300 km long from the Bangladesh border to the border of Thailand. The coast is divided into three parts namely the Arakan, Irrawaddy, and the Tenasserim.

The Arakan coast runs parallel to a mountain chain of strongly folded Mesozoic and Tertiary rock. Near the Bangladesh border, the coast is elongated with steep-sided rocks and islands, but further south the coast consists of estuarine channels, mangrove forests, patchy coral reefs, and islands. The coast is an example of an emerged coast with many raised beaches and old sea cliffs. Another significant feature of this coast is the presence of mud volcanoes which form temporary islands. With wave action, coming in slowly, they transform to shoals.

The Irrawaddy delta coast runs west to east, and is a large delta with deposition of silt and sand. The delta features a number of shoals, estuarine distributaries, channels, and mangrove forests. From the delta region a large volume of sediment is shifted to the east to the Gulf of Martaban by southwest waves during monsoons.

The Tenasserim coast is composed of rocky promontories, valleys, estuaries, mangrove-fringed creeks, and sand spits. Estuarine lagoons and bays are silted up and transformed into mangrove swamps and saline marshy lands. Beaches are rich in heavy minerals, namely ilmenite and monazite. Some beaches are also backed by coastal sand dunes.

INDIAN OCEAN ISLANDS, COASTAL ECOLOGY AND GEOMORPHOLOGY

Geographically, the Indian Ocean islands (Figure I21) range from oceanic to continental, geologically from volcanic, limestone, granite, metamorphic to mixed, and physiographically from low to high. Most of these types of islands, though, are not sharply separated.

Oceanic islands are those considered never to have been part of, or connected with, any continental landmass. Their biota is commonly poor in diversity, with unbalanced or uneven representation of taxa, compared with those of continents or continental landmasses. Chagos archipelago, Diego Garcia, and Cocos-Keeling are some such examples. Continental islands may vary in dimensions from subcontinental sizes down to small rocky outposts, the essential characteristics being their continental type rocks and their history showing a former land connection to an adjacent continent. Madagascar, the Malay archipelago, Seychelles, Sri Lanka, and Indonesian islands are examples of continental islands. Seychelles in the north-west Indian Ocean is an extreme case that is totally isolated today, but in Mesozoic and possibly early Tertiary time it was connected to Madagascar. Volcanic islands are rather small (1–100 km across) but often very high, ranging in elevation from 500 m to 3,000 m. They occur generally in irregular clusters, in sub-rectangular patterns or in long lines. Coral islands appear either as an accumulation of coral sand and gravel on the surface of coral reefs or as a slightly emerged limestone platform of formerly live coral not more than a few meters above mean low water. Barrier Islands are constructed entirely by the terrigenous or bioclastic sands from barrier beaches and are built up by longshore drift, probably first as offshore bars, and gradually gaining size later by eustatic oscillations, dune building, and colonization by vegetation.

Because of the very high number of the islands within some island groups in the Indian Ocean it would be difficult to describe them all. Instead, salient features of major groups are given below (see also Table I3).

Western Indian Ocean

Gulf of Kachchh islands

The 42 islands of the Gulf of Kachchh (22°15′N–23°40′N; 68°20′–70°40′E) are the northernmost coralline or sandstone based islands in India. Almost uninhabited, the vegetation inland consists only of shrubs. Several of the islands have dense mangrove patches on the coast, 34 islands have fringing reefs (often called as patch reefs) confined to intertidal sandstones or wave-cut, eroded, shallow banks. The region is tectonically unstable and evidence of uplift can be seen in the form of raised reefs near the mouth of the Gulf, not far from extant islands.

The coastal geomorphology and the fauna and flora of the islands are influenced considerably by the sediment depositional regime, high-velocity tidal currents (up to 5 knots), and a large range in environmental parameters (e.g., temperature 15°–30°C, salinity 25–40). The extreme conditions also limit coastal biodiversity to 37 species of corals and a smaller number of other invertebrates. However, algal growth along these coasts can be substantial at certain times of the year. The mangroves already constrained by high salinity and high tidal exposure also have been heavily impacted due to felling for fuel and fodder. Areas around some of the islands have earlier been good pearl oyster and chank fishing grounds, and one of the islands is even called Chank island. However, overexploitation has decimated both these fisheries.

Laccadive–Chagos ridge

Lakshadweep islands. These are the northern-most islands of the Laccadive–Chagos ridge (9°–12°N; 72°–74°E). Located about 200–400 km off the southwest coast of India, this part of the ridge comprises of 12 atolls, 3 reefs, and 5 submerged banks. Of the 36 islands on the atolls, only 10 (Minicoy, Kalpeni, Andrott, Agatti, Kavaratti, Amini, Kadamat, Chetlat, Kiltan, and Bitra) are inhabited. The northernmost Bitra Island is the smallest inhabited island in India. Among these, Minicoy is separated from the rest by the 9° channel. It is culturally and linguistically closer to the Maldivian islands.

Basically coralline, and no more than a few square kilometers in area, all these islands are low-lying with profuse coral growth all around. The only cultivated plant is coconut, besides a few vegetable and horticultural

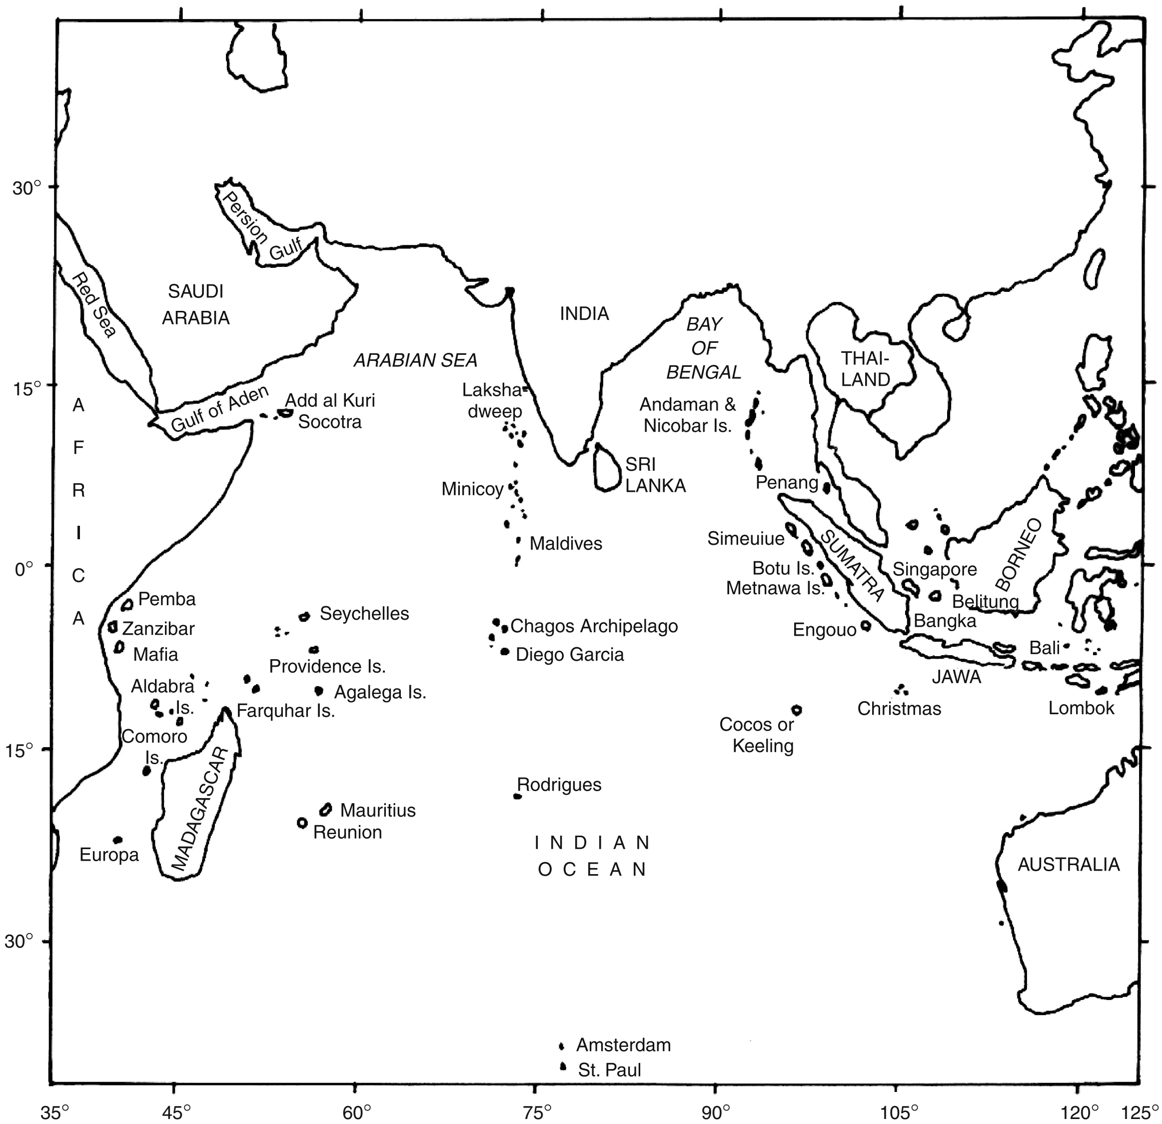

Figure I21 Major islands of the Indian Ocean.

plants introduced from the mainland. The coast toward the lagoon is sandy and habited by sand dune flora *Spinifix* and *Ipomea*. The seaward shore is rocky and typical of all oceanic atolls, with a steep drop in profile. Radiocarbon dating of the storm beach at Kavaratti island gave an age of about 6,000 BP indicating their recent origin. Some of the uninhabited islands are only sand cays; one of them is an important nesting ground for seabirds.

The littoral and sublittoral fauna and flora have been studied reasonably well. The known biodiversity status is as follows: hard corals—104 species, soft corals—37 species, fishes—163 species, invertebrates—about 2,000, and algae—119 species. The bleaching event of 1998 has, however, caused a serious reduction in coral biodiversity. Shore erosion and silting are additional causes for loss of coral cover and reduction in species abundance.

Maldivian islands. The double chain of Maldivian islands (7°N–0.5°S, 73°E) is the largest part of the Laccadive-Chagos ridge that extends southwards from India to the center of the Indian Ocean. The more-than 1,200 islands, clustered in 19 groups of atolls, are entirely low-lying. The geologic history of the island chain is a complicated picture of sea-level changes, reef and carbonate platform development, and erosional events.

As would be expected in the case of small islands on the atolls, the coastal ecology of the islands is reef-dominated. The reefs, though principally atolls, have the unusual features of broken rims that consist of numerous patches or faroes, many of them with islands, and the presence of lagoonal islands which are simply knolls with their emergent surfaces capped with vegetation.

Biological and ecological information on Maldivian islands is rather poor, with stress on only some groups. About 200 species of corals under 60 genera have been recorded so far. No comprehensive checklist of other groups of coastal marine fauna exists; however, the cowry shells and groupers (40 species) are important components of reef biodiversity. Similarly, descriptions of zonations of the reefs are known from some islands but detailed studies of the ecology, either at community or at species level, are scarce.

Islands of Chagos archipelago. The Chagos archipelago (5°–8°S 71°–73°E), the southern part of the Laccadive–Chagos ridge, consists of five coral atolls with islands, besides several reefs that are partially or wholly exposed at low tide. The five atolls are: Great Chagos Bank, Peros Baňhos, Salomon, Egmont, and Diego Garcia. The number of islands on these atolls varies from 4 in Diego Garcia, to 24 in Peros Baňhos. The total land occupied by these islands is about 40 km^2.

Most of these islands are located on the atoll rims with elevation of no more than 2–3 m. Raised reefs with small, uplifted, and vertical cliffs rising to over 6 m occur in two atolls—southern Peros Baňhos and northwestern part of the Great Chagos Bank. Isotopic dating of fossil corals in the emerged beach rock of the islands and some extant corals

Table I3 Indian Ocean Islands

Name of island	Position	Location	Geomorphology	Major disturbance
Barrow islands (Middle Boodie, Pasco & Double islands)	20°40′–20°58′S, 115°18′–115°30′E	West Australia (56 km off Pilbara coast)	Fossiliferous Miocene Limestone	Oil fields
Christmas island	10°35′S, 105°35′E	290 km south of Indonesian islands	Guano deposits	Anchorage and phosphate loading dock
Cocos–Keeling islands	12°00′S, 96°56′E	South east Indian Ocean	Atoll	Storms, earthquakes, red tides
Dampier archipelago (six main and many small islands)	20°20′S–20°50′S, 116°20′E–117°10′E	Eastern Indian Ocean (northwest Australia)	Igneous rock of Archean age	Dredging for shipping
Houtman Abrolhos islands (Total 35 islands)	28°15′–29°00′S, 113°30′E–114°05′E	Eastern Indian Ocean		Oilfield
Kimberley coast reefs		Northwestern coast of Australia	Steep rocky shores	Iron ore mining
Broome	17°58′S, 122°14′E			
Wyndham	15°28′S, 128°06′E			
Holothuria and Lacepede reefs	16°52′S, 122°08′E			
Adele	15°31′S, 123°09′E			
Monte Bello islands and Lowendal islands	20°20′S–20°33′S, 115°27′E–115°37′E	West northwest of Dampier	Vacant Crown islands	Tourism and oil exploration activities Reef damage by *Acanthaster plancii*
Muiron island and Ningaloo island	21°40′S, 114°2′E	Eastern Indian Ocean	Limestone islands. Part barrier and part fringing reefs	Overexploitation of marine resources Petroleum tenements
Rowley shoals		Northwest Australian shelf	Atoll	Fishing, anchor damage
Mermaid reefs	17°7′S, 119°36′E			
Clarke reef	17°10′S, 119°20′E			
Imperieuse reef	17°35′S, 119°56′E			
Scott reef and Seringapatam reef	14°5′S, 121°51′E 13°40′S, 122°00′E	–	Atolls	Exploitation of molluscs and holothurians
Bahrain Mubarraq, Sitra and other islands	26°N, 50°E	Persian Gulf, Saudi Arabia coast	Limestone and deserts	Oil and gas
Lampi island (30 islands)	10°50′N, 98°10′E	Near Burma	Coral reef	Undisturbed
Moscos island	13°50′N–14°20′N	Burma Sea	Rocky shoreline	Illegal logging, collection of turtle eggs
Chagos archipelago				
Blenheim reef	5°12′S, 72°29′E	East Chagos Archipelago	Atoll	Undisturbed
Diego Garcia	7°20′S, 72°25′E	South of Chagos	Atoll	Military presence, dredging and blasting
Egmont atoll (five islands)	6°40′S, 71°20′E	West of Chagos	Atoll	Undisturbed
Peros Baňhos atoll	5°20′S, 71°55′E	Northwest of Chagos	Atoll	Undisturbed
Salomon atoll	5°20′S, 72°15′E	North of Chagos	Atoll	Undisturbed
Speakers bank	5°32′S, 72°25′E	North of Chagos	Submerged atoll	No manmade changes
Victory bank	5°32′S–72°15′E	–	Submerged atoll	Undisturbed
Comoros island	12°S, 44°E	North of Mozambique	Four high islands, fringing reef	Dredging
Mayotte barrier reef	12°30′S, 45°10′E	Southernmost islands of Comoros group	Extinct volcano surrounded by reef	Siltation from erosion, mining of coral rocks
Andaman islands	10°30′N–14°N, 92°E–93°E	Bay of Bengal	Emerged part of mountain chain	Massive siltation due to deforestation
Nicobar islands	6°30′N–9°30′N, 93°E–94°E	Bay of Bengal	Emerged part of mountain chain	Overexploitation of corals and shells for ornamental use
Lakshadweep islands	9°N–12°N, 72°E–74°E	Arabian Sea	Atolls	Dredging, mining, siltation, and *A. plancii* infestation
Indonesian islands				
Kepulauan Aru	0°50′–1°25′N, 131°16′E	Irian Jaya	Coral island	
Pulau Mapia	1°1′N–134°10′E	Irian Jaya	Coral island	
Raja Ampat (proposed wildlife reserve)	0°25′N–130°08′E	Irian Jaya	Coral island	
Sabuda-Tataruga	2°30′N–130°50′E	Irian Jaya	Coral island	

Table I3 (*Continued*)

Name of island	Position	Location	Geomorphology	Major disturbance
Karimunjawa (proposed wildlife reserve)	5°50′N–110°20′E	Java	Coral island	
Pulau Seribu (strict nature reserve)	5°26′–5° 37′S, 106°24′–106°37′E	Java	Coral island	Fishing activities
Karimata	1°30′S, 109°00′E	Java Kalimantan	Coral island	
Pulau Maratua (Karang Muaras proposed strict nature reserve)	1°50′–2°10′N, 118°30′–118°55′E	Java Kalimantan	Coral island	
Pulau Sangalaki (Marine park)	2°05′N–118°15′E	Java Kalimantan	Coral island	
Pulau Semama (wildlife reserve)	2°05′N–118°15′E	Java Kalimantan	Coral island	
Aru Tenggare (proposed marine reserve/marine park)	6°35′S – 7°11′S, 134°12′– 135°E	Moluccas	Coral island	Fishing and exploitation of marine resources
Kepulauan Kai Barat Tayandu (proposed marine multiple use reserve)	5°30′S, 133°0′E	Moluccas	Coral island	
Pulau Angwarmase	7°55′S, 131°20′E	Moluccas	Coral island	
Pulau Banda (marine park)	4°30′S, 130°E	Moluccas	Volcanic origin	
Pulau Pombo (marine park)	3°31′S, 128°22′E	Moluccas	Coral island	Overexploitation
Pulau Renyu–Pulau Lucipara (proposed strict nature reserve)	5°40′S, 127°50′E	Moluccas	Coral island	Overexploitation
Komodo National Park	8°35′S, 119°30′E	Nusa Tenggara	Rocky island	Dynamite fishing
Pulau Rakit	8°35′S, 118°E	Nusa Tenggara	Coral island	
Pulau Satonda	8°10′S, 117°45′E	Nusa Tenggara	Volcanic	
Kepulauan Peleng	1°50′S, 123°14′E	Sulawesi	An archipelago	
Kepulauan Sangihe	3°45′S, 126°35′E	Sulawesi	Islands and reefs	
Pulau Kakabia	6°55′S, 122°30′E	Sulawesi	Islands and reefs

Pulau Smalona	5°10′S, 119°10′E	Sulawesi	Coral islands	
Selat Muna	5°05′S, 122°05′E	Sulawesi	Coral islands	
Spermonde islands	5°30′S, 119°10′E	Sulawesi	Coral islands submerged reef, patch reefs	Dynamite fishing, sedimentation
Tiga island	3°50′S, 123°15′E	Sulawesi	Islands and reefs	
Togian island	0°10′N–0°40′S, 121°32′E–122°12′E	Sulawesi	Extended mountains surrounded by limestone	Dynamite fishing
Tukang Besi	5°35′S, 123°50′E	Sulawesi	Archipelago	
Muara Siberut (five islands)	1°30′S, 99°25′E	Sumatra	Islands with coral reefs	Overfishing
Pulau Weh	6°0′S, 95°30′E	Sumatra	Coral reefs	
Sheedvar island	27°0′N, 53°E	Iran	Coral reefs	
Pulau Paya (group of islands)	6°02′N–6°05′N, 99°54′–100°04′E	Malaysia	Coral islands	Fishing activities
Pulau perak	4°41′N, 98°56′E	Malaysia	Conical rocky islands	
Pulau Tiga	5°44′N, 115°40′E	Malaysia	Volcanic island	Legal protection and management
Sembilan islands	2°03′N, 100°33′E	Malaysia	Volcanic island	
Pulau Bohey dulong Pulau Bodgaya Pulau Tetagan	4° 38′N, 118°46′E	Malaysia	Volcanic island	Domestic pollution, overexploitation of marine fauna
Pulau Sipadan	4°05′N, 118°40′E	Malaysia	Coral reef	
Pulau gaya Pulau Sapi Pulau Mamutik Pulau Manukan Pulau Sulung	6°04′N–5°55′N, 116°E	Malaysia	White sandy beaches with rocky interruption	Coral mining, overexploitation of reef fauna
Maldives (a group of atolls)	7°N–0°30′S, 73°E	Central section of Chagos archipelago	Atolls	Growing urbanization, domestic pollution
Mauritius	20°S, 58°E	180 km northeast of Réunion island	Remains of old emerged coral reefs	
Cargados Carajos shoals	16°23′S, 59°27′E	North northeast to Mauritius	Coral islands	Exploitation of marine products, Guano mining
Île Plate	19°53′S, 57°39′E	–	Volcanic rock	Dynamiting, fishing, anchoring, and boat grounding

Table I3 (*Continued*)

Name of island	Position	Location	Geomorphology	Major disturbance
Rodrigues	19°42′S, 63°25′E	North eastern Mascarene island	Volcanic island	Public interference
Mozambique				
Ilhas da Inhaca e dos Portugueses (Inhaca islands)	26°S, 33°E	Southern most island of Mozambique	Pleistocene dune rock –	Goat overgrazing denudation, public interference
Primeira and Segundo islands	16°S–17°S, 38°E–41°E		–	
Quirimba islands	10°45′S–12°42′S, 41°E		–	
Réunion islands				
Réunion	21°7′S, 53°32′E			
Europa and Basses de India	22°20′S, 40°20′E	In Mozambique channel	Atolls	Undisturbed
Iles Glorieuses	11°30′S, 47°20′E	100 km northwest of Europa	Atolls	Undisturbed
Tromelin	15°52′S, 54°5′E	390 km east of Madagascar	Atolls	Undisturbed
Saudi Arabia				
Al Wajhto Qalib	26°16′N, 36°28′E	Northern Red Sea	Rocky island	Undisturbed
Farasan archipelago	17°40′N, 42°10′E	Red Sea	Coral islands, swamps, and reefs	Undisturbed
Seychelles	5–10°S, 45–56°E	NE of Madgascar		
Platte island	5°50′S, 55°E		Granitic and coralline islands	– –
Doivre island	5°50′S, 55°E			
Aldabra island	9°25′S, 46°25′E	North of Mozambique channel	Atoll, limestone	–
Bird island	3°43′S, 55°13′E	Northern edge of Seychelles	Sandy clay and calcareous	–
Dennis island	3°48′S, 55°40′E	–		Phosphate mining
Cousin islands	4°20′S, 55°40′E	Southwest Seychelles	Granite island	Tourism
Curieuse island	4°05′S, 55°43′E	–	–	–
Singapore		–	–	Growing urbanization
Pulau Hantu	1°20′N, 103°50′E			
Pulau Suelong	–			
Pulau Salu	–			
SriLanka				
Trincomalee and Pigeon island	8°N, 82°E	16 km from Trincomalee	Extended part of Indian mainland (limestone-granite)	Mining for lime, dynamite fishing, tourist pressure, overexploitation of marine fauna
Sudan				
Mukkarwar island	20°50′N, 37°17′E	North of port Sudan	Well-formed reefs	
Sanganeb atoll	19°45′N, 37°25′E	Red Sea	Atoll	*A. plancii* infestation, overexploitation
Suakin archipelago	19°14′N, 37°51′E			Fishing, tourism pollution, and human interference
Sultanate of Oman				
Daymaniyat islands (10 islands)	23°45′N, 58°10′E	Gulf of Oman	Corals	Litter, *A. plancii* infestation
Tanzania				
Latham island	6°50′S, 39°50′E	64 km off Dar es Salaam	Atoll	Undisturbed
Mafia island	7°40′S, 40°40′E	South of Dar es Salaam		–
Maziwe island	5°30′S, 39°5′E	Northern Tanzania		–
Thailand				
Koh Larn	12°55′N, 100°47′E	Northern Gulf of Thailand	Coral reefs	Tourism and pollution
Koh Sak				
Koh Krok				
Koh Phuket	8°N, 98°20′E	Andaman Sea	Rocky extended mountains	Extensive sedimentation, dredging, mining

gave an age not more than 5,200 years BP, indicating that all these islands are relatively recent in origin.

Being coralline islands, the coastal morphology is typically characterized by vast and profuse reef growth. Mangroves and associated flora are absent. The coastal and inland flora consists primarily of native vegetation (*Tournifortia*, *Scaevola*, and *Casuarina*), disturbed by coconut plantations in inhabited islands. None of the 250 species of flora are endemic. Two faunal groups—birds and turtles—are important biological components. The islands provide nesting grounds for over 50 species of seabirds and several species of green and hawksbill turtles.

Seychelles

A total of about 42 granitic and 74 coralline islands, spread over 5°–10°S and 45°–56°E, with a total land area of 455 km^2 comprise the Seychelles. The inner Seychelles islands to the north are granitic, remnants of ancient Gondwanaland, rugged, mountainous, and rise up to 1000 m in the Morna Seychellois on Mahé island. Coralline islands and atolls of the Amirantes, Farquhar, and Aldabra groups, spreading westwards and southwards from the granitic group, constitute the second group. They are composed of numerous low islands or atolls in several clusters, each located on top of volcanic structures of various sizes. Principal granitic islands in the Seychelles archipelago are Mahé, Praslin, Silhouette, La Digue, Curieuse, Felicité, North Island, St. Anne, Providence, Frigate, Denis, Cerf, and Sea Cow island. Among the coralline islands and atolls, Alphonse, Bijoutier, St. François, St. Pierre, Astove, Assumption, Coetivy, and Aldabra are the major ones. Some of the coralline islands, though relatively low-lying by comparison with granitic islands, are often taller, reaching as much as 8 m above sea level. These include Aldabra, Assumption, Astove, Cosmoledo, and St. Pierre. These limestone atolls have formed on top of volcanic structures and rise from water depths of over 2,000 m. The high limestone islands are also characterized by terraces that reflect changes in sea levels during the last glacial cycle. The Amirantes island group is the second largest group after Inner Seychelles and comprises 10 islands and atolls and several shoals and submerged reefs. The major atolls in the Farquhar (or Providence) group are Farquhar and Providence, each rimmed with several islands. St. Pierre Island in this group is a circular, uplifted atoll, with coastal cliffs rising to 10 m. In the Aldabra group, Aldabra and Cosmoledo atolls have several islands on their rims, whereas Astova and Assumption are elevated atolls: in the Assumption island, reef rocks rise to 7 m above sea level, with dunes on the east and south rising to nearly 30 m.

Coastal geomorphology of all the islands is characterized by the presence of reefs. Three major types—fringing, platform, and atoll reefs—are recognized. The granitic islands have well-developed fringing reefs. Among the outer islands, several are raised platform reefs (e.g., Assumption and St. Pierre) and others are atolls (e.g., St. Joseph, St. François).

There are pronounced differences in the coastal ecology of these islands. The northern islands lie in the path of the east-flowing Equatorial Counter Current whereas the southern islands lie in the path of the west-flowing South Equatorial Current. Besides, the granitic islands receive more rainfall and are often forested. As a result, the nutrient regimes in the coastal waters are distinctly different between these two groups. The high nutrient levels around the granitic islands favor dominance of crustose coralline algae and frondose macroalgae whereas nutrient-poor waters around the coralline islands support a hermatypic coral dominance. The raised reefs were used as nesting sites by seabird colonies and have been extensively mined for guano.

Description of coastal ecology has primarily been with reference to coral reefs, though not all have been studied as extensively as Mahé or Aldabra islands. The coral diversity is more or less same between granitic and outer islands, the former with 51 genera and the latter with 47 genera. The total species count is 161, and this does not include those of *Acropora*. Though the coasts with well-developed reefs can be expected to sustain a high faunal and floral diversity, there is still poor documentation from most islands. The recorded forms include 128 species of marine caridean shrimps, 49 species of brachyuran decapods, 150 species of echinoderms, 450 species of molluscs, about 1,000 species of fish, 8 species of sea grasses and 4 species of turtles. Among these the gigantic land tortoise of Aldabra atoll and the double coconut, *coco de mer*, of Mahé Island are unique.

Mascarene islands

Mauritius. Mauritius (20°S, 58°E) represents the southern part of the Mascarene Plateau, which is an arcuate series of banks extending for 2,000 km from the Seychelles Bank. The Mauritius island is volcanic in origin and is composed of olivine basalt and doleritic basalt.

Mauritius, along with several small adjacent islands, spreads over 1,865 km^2. The northern part of the island is a plain while the center is a plateau rising to a peak height of 826 m at Piton de la Rivière Noire and bordered by low mountain remnants of a large volcano. The south of the island is largely mountainous.

The crenulated coastline, exposed to varying wave activity, extends to about 200 km. The southwest coast is made up of basaltic rocks while carbonate sands, the bulk of which is coral debris, largely cover the remaining parts. A large submarine platform with extensive fringing coral reefs that cover three-fourth of its coastline surrounds the island. There are also the remains of old, emerged coral reefs, recalcified to varying degrees, indicating recent uplift.

Sugarcane and tea cultivation are the major revenue sources for the islands. Conversion of forest lands to plantations has, however, reduced the original forest cover to less than 1%. The other important revenue sources for the island are coastal fishing and tourism. Reef fisheries yield about 200 tons per year and reef tourism caters to more than 300,000 visitors a year.

Considering that the entire coastline is reef-rimmed, the corals- and reef-associated fauna and flora are important components of coastal biodiversity. The reefs cover an area of about 300 km^2, with a maximum reef width of 4 km. Mauritius reefs are notable for the absence of reef flats; consequently, sediments accumulate in the lagoon providing a favorable environment for sea grass growth. A total of six sea grass species—*Thalassiodendron ciliatum, Syringodium isoetifolium, Halophila ovalis, Halophila stipulacea, Halodule universis*, and *Halodule* sp.—are known from Mauritius.

A total of about 186 species of corals belonging to more than 50 genera have been reported from the Mascarene archipelago, with 75% of these recorded in Mauritius reefs. The fish diversity, with 263 species, is also high. The molluscan fauna is another important biological constituent of Mauritius reefs. A detailed survey has revealed the presence of more than 3,500 species, with approximately 10% of them being endemic. These include the Imperial Harp shell *Harpa costata* and the cowry *Cypraea mauritiana*, besides species like *Clanculus mauritianus* and *Bursa bergeri*. Diversity of marine macro algae is also high: 127 species, mainly red and green algae, have been recorded from the littoral zone.

Higher freshwater flux, more siltation, and high humidity favor the growth of mangroves on the northeast and east coasts of Mauritius. Dense mangroves dominated by *Rhizophora mucronata* cover an estimated area of 20 km^2.

Rodrigues. Rodrigues island (area 110 km^2; 19°42′S, 63°25′E) and two cays at 10°24′S and 56°38′E (known as Agalega island) are part of the Republic of Mauritius. Rodrigues, the smallest of Mascarene islands, is of volcanic origin and consists of subhorizontal basaltic flows. The northeastern part of the island is mountainous but not very tall, the peak height not exceeding 400 m.

Like Mauritius, Rodrigues island is also reef-rimmed, with a wide expanse of reef platform extending without a break for 90 km around the island, providing a fringing reef cover of about 200 km^2. Presence of reef flats, with a width ranging from a low of 50 m in the east to as much as 10 km in the west distinguishes Rodrigues from Mauritius. The reef flats also provide habitat for large sea grass beds, though the species diversity is much less; only two species—*H. ovalis* and *Halophila balfouri* are known from Rodrigues. Muddy accumulations, hence development of mangroves, are rare.

Coral species diversity is high, with a similar number of species as in Mauritius. Information on other coastal marine fauna and flora are scarce; however, the small islands around Rodrigues are important nesting sites for brown noddy, lesser noddy and white tern.

Réunion. Réunion (21°7′S, 53°32′E) is the most southwesterly of the Mascarene islands. Covering an area of 2,512 km^2, Réunion is a large Hawaiian-type volcano that includes an older part, the massif of Piton des Neiges (peak height 3,069 m), incised by three large cirques, and an active volcano to the southeast. Several small islands—Tromelin to the north of Réunion, Europa and Bassas de India atolls in the Mozambique Channel, Juan de Nova off the west coast of Madagascar, and Iles Glorieuses to the north of the Mozambique Channel, are the other island dependencies of Réunion. These are relatively very small. Tromelin is no more than a cay of 1.1 km^2, Juan de Nova is a raised fossil reef of 9.6 km^2 and the Grande Glorieuse Island covers only 3.9 km^2.

The coast of Réunion is generally rocky, with low cliffs cut in lavas. Sectors of low coast correspond with the three large depositional cones built below the three cirques and show pebbly beaches while the rare sandy beaches are related to embryonic fringing reefs. Because of the relatively young age, reefs are less developed, discontinuous, narrow with their widest part no more than 550 m, and cover only an area of 7.3 km^2. In contrast with Mauritius and Rodrigues, reef platforms are abundant on Réunion but muddy accumulations and mangroves are totally absent. Lack of organic and terrigenous material also limits the diversity of sea grasses and their extent: only one species, *H. stipulacea*, that too not in abundance, has been known from Réunion.

Coastal marine fauna and flora have been better inventoried in Réunion than in the other two islands. This includes 40 species of dinoflagellates, 150 species of macro algae, 120 species of corals, 90 species of hydroids, 2,500 species of molluscs, and more than 650 species of fish. Coastal fisheries, however, are relatively less developed, with no more than 1,500 tons yield per year, of which only 100–150 tons are truly reef fishes, Tourism, likewise, is also less developed compared with Mauritius.

Madagascar

Madagascar is a fragment of a lost continent (Lemuria) and this severance from the ancient land mass is evident from the sheer drop of mountain into ocean depths of 3,000 m or so, especially on the eastern side. The island's rocks, volcanic structure, besides the subsoil formed of granites, gneiss, and crystalline schists, warm water springs and frequent earthquakes also provide evidence for this origin. Paleontological evidence for this comes from the remains of many large prehistoric birds and even the present day fauna of the island has a special individuality. The large number of endemic flora also confirms that Madagascar is an island that has been long since isolated from other regions. Madagascar is also one of the largest islands in the world (5,87,000 km^2) with a coastline of about 4,000 km. The east and west coasts are asymmetrical in physiography. The east coast presents an almost unbroken appearance, with few bays and indentations. The continental shelf here is narrow and coral reefs and mangroves are poorly developed. The west coast, on the other hand, has a broad continental shelf and has the majority of the island's reefs and mangroves.

Reefs and mangroves are important coastal ecosystems of Madagascar. The reefs cover an area of 200 km^2. Most of the west coast has large tracts of tidal marshes (4,250 km^2) of which 3,200 km^2 are populated by mangroves. Sea grass beds are also extensive on the west coast. Emergent fossil reefs up to 10 m above present sea level are found in the far northwest coast. A barrier reef, 10–16 km offshore, also exists at the edge of the continental shelf.

There is an extensive bibliography of the various coastal and marine fauna and flora, synthesized from numerous studies of many French scientists. Most of the information is from Toliera and Nosy-Bé and biodiversity of the whole island could be still higher than what is known—200 species of corals, 1,500 species of fishes, 28 species of sponges, 227 species of echinoderms, 1,158 species of mollusks, 779 species of crustaceans, 121 species of worms, 182 species of ascidians, 108 species of algae, besides 5 species of turtles and 32 species of mammals.

Comoros islands

The Comoros archipelago consists of four major islands—Grande Comore, Anjouan, Moheli and Mayotte—at the northern end of the Mozambique Channel (12°S, 44°E). All these islands are of volcanic origin and mountainous, and are surrounded by numerous coralline and granitic islets. The Grand Comore is the largest island among these, with an area of 1,131 km^2. While three of these islands have fringing reefs, Mayotte is surrounded by a 140 km long barrier reef lying 13–15 km offshore. The coastal features include the mangroves, which, in some islands, are expanding due to influx of terrestrial sediments from hillsides.

Among these islands, only Mayotte has been studied to some extent. These studies are essentially related mainly to the description of the barrier reef and its faunal and floral composition, since it is one of the few barrier reefs in the world, and the best developed in the Indian Ocean. The reef, which had a good live coral cover, was heavily impacted during a bleaching event in 1983 related to El Nino.

Islands off Tanzania

The islands off the coast of Tanzania are Mafia, Pemba, Unguja (Zanzibar), and those of Songo Songo archipelago. Mafia island (7°40′S, 40°40′E), along with the four small adjacent islands, are continental islands off Rufiji delta. The coastline consists of vast stretches of sheltered and exposed fringing reefs and mangroves besides beds of sea grasses, algae, and soft corals. The Unguja island, slightly larger than the Mafia island, as well as the Mnemba island lying to the north, also have coral development all around the coast. The Pemba island is 62 km long and 22 km wide, with a reef area of 1,100 km^2 along its coastline. All these islands show evidence of several terraces, along with indication of a relatively recent subsidence. Another feature common to these is the 3,300–3,400 m of marine sediments, ranging from Miocene to Cretaceous, underlying them.

The Songo Songo archipelago (8°30′S, 39°30′E) consists of a 7 km long island, with four smaller islands in the vicinity. As with other islands off Tanzania, these islands support some of the largest expanses of shallow water coral reefs, with the estimated reef cover of about 40–50 km^2. No other remarkable coastal features are known from these islands.

Islands off Mozambique coast

The islands off the Mozambique coast are grouped into Quirimbas archipelago, Primeiras and Segundas archipelago, Bazaruto archipelago, and Inhaca and Portuguese islands. Besides these, the Mozambique, Goa, and Cobras islands are located just 4 km off the mainland coast.

The Quirimbas archipelago (10°45′–12°42′S) comprises a 200 km chain of 32 islands along with numerous reef complexes. The Primeiras and Segundas archipelagos, located at 16°12′– 17°17′S consists of 10 islands and two reef complexes. The Bazaruto archipelago consists of five islands located between 21°30′ and 22°10′S. All these islands are small, with the largest no more than 25 km^2 in area and all lie close to the coasts.

Coastal morphology of these islands is composed of grasslands, scrubs, and mangroves, with varying degrees of development in the different islands. All of these, however, support good fringing reef growth. As with most islands, it is the coral fauna and fish that were widely studied. About 50 genera of reef building corals and 300 species of fish are known from Quirimbas archipelago. A total of about 155 molluscan forms, with 6 endemic species among them, have been reported from Bazaruto archipelago. The western coasts and the area between the islands and the mainland coast have good sea grass beds.

Socotra island

The Socotra (8°N, 53°E), off the mouth of Gulf of Aden, is an island that has survived the subsidence of the great primeval continent, which embraced present-day Africa, the Middle East, southern Asia, and the Northwestern part of the Indian Ocean. It is a fairly large island (3,582 km^2) with its mountainous interior rising to 1,520 m. The coastline is varied, consisting partly of low-lying plains and partly of steep limestone cliffs, edging an undulating plateau (500–600 m high) that covers much of the island.

Bahrain

This consists of a group of low-lying islands, largely of limestone outcrop and desert, off the Saudi Arabian coast. Ranging from a rocky out crop (Jidda Island) to the large Bahrain Island (660 km^2), these are low and sandy islands, except for clusters of barren rocky hills in the center.

Eastern Indian Ocean

Gulf of Mannar islands

A chain of 20 islands (8°45′–9°16′N, 79°4′–79°29′E) constitutes the coralline islands of the Gulf of Mannar between southeast India and Sri Lanka. None of these Islands is inhabited. Spreading over not more than 2 km^2 individually, most of these islands have only shrubs as vegetation and occasionally some patches of mangroves. The fringing reef growth in profuse all around the islands. The sea grass beds associated with the reefs have been important feeding grounds for the Dugong species.

Geologically, these islands are connected with those of northern Sri Lanka through a series of shallow banks called Adam's bridge between Rameswaram in India and Talaimannar in Sri Lanka. As a consequence, there is a good similarity in island geomorphology, coastal ecology, and fauna and flora among these islands.

Sri Lanka

Sri Lanka lies off the southeast tip of India between 6° and 10°N and 80° and 82°E (65,610 km^2). The island is basically a central mountain mass of Pre-Cambrian crystalline rocks ringed by a broad coastal plain. The highest point is the Pidurutalagala peak (2,700 m). The plains are fairly level in the north but the extensive soft limestone deposits are broken elsewhere by outcrops of the main rock core. The coastal region is characterized by fringing reefs, shallow lagoons, marshes, and many sandy bars, especially in the north. Though not a very large island, three distinct climatic features are evident: the low country Dry Zone that receives low rainfall, the East Coast Plains that experience one monsoon, and the Low Country Wet Zone which receives rainfall from both the monsoons.

Coastline features vary considerably, from sandstone to granite, but detailed studies are scarce. Along the west coast, coral growth is mainly on ancient sandstone and on the east coast, it is on gneiss or granite outcrops. Fringing reefs are found only along 2% of its 1,585 km coastline and not all of these are comprehensively mapped. Surveys have mainly been carried out for reef-building corals and fishes. A total of about 183 species of corals and over 350 species of fishes have been recorded. Though a number of faunal groups occur in these reefs, their systematic records are not known. Mangroves occur along the southwest, northwest, and northern coasts. The total area covered by mangroves is 36 km^2. *Rhizophora, Avicennia, Excoecaria, Lumnitzera, Aegiceras* and *Sonneratia* are the mangrove genera recorded.

Extensive damage to coastline habitats has been recorded where reefs and mangroves are abundant. The reefs are mined for lime manufacture and the mangrove wood is used to fuel the limekilns. Often coastal forests are also exploited for use as fuel in the limekilns. Though detailed information on the impacts are not available, damages to coastal habitats at local scales are considerable.

Andaman and Nicobar islands

These are the emerged parts of a mountain chain that stretches from the Arakan Yoma in Myanmar to the islands of Indonesia. Spread meridionally between 6° and 14°N, and between 91° and 94°E in the Bay of Bengal, these islands number more than 500, of which only 38 are inhabited. All the islands are mountainous, sedimentary in nature, and have fringing reefs towards the east. The total area covered by these islands is 8,293 km^2. The Andaman group of islands is separated from the Nicobar group by the 10° channel which has a heavy tidal flow and difficult to navigate with conventional crafts. As a result, the biogeography of the Andaman has more of Malay affinities whereas that of the Nicobar has Indonesian affinities.

Most parts of these islands are covered with thick forests and the low-lying areas are covered with mangrove swamps. Biodiversity of the islands is quite high, with an abundance of corals, fishes, algae, turtles, and the unique saltwater crocodile. Avifauna is more endemic in nature, with distinct local species of eagles, parakeets, and orioles. The islands have a few land mammals like deer and elephants, which were introduced from the mainland India.

Indonesian islands

Indonesia is an island nation of 13,700 islands having a coastline of about 60,000 km. The islands form a region of tectonic instability, marked by frequent earthquakes and volcanic eruptions. These tectonic movements have also shifted out of the sea some of the numerous coralline reef formations along the island coast.

Typically tropical in climate, the larger islands (e.g., Java, Sumatra, Borneo, and Sulewasi) have varied coastal geomorphology ranging from mangrove-bordered shores through estuarine deltas to coral reefs. Borneo is the third largest island in the world and lies between the Sulu Sea, Java Sea, and South China Sea. It is densely forested, with extensive swampy lowlands in the southern and southwestern coastal areas.

Smaller islands are more coralline in nature. The Indonesian region is known for the highest diversity of corals and mangrove species, in the latter case practically all known mangrove species from the new world are present here.

Cocos or Keeling islands

These islands (12°S, 96°56′E), numbering 27 and covering a total area of 30 km^2, lie about 960 km southwest of Sumatra (not to be confused with Cocos Island, a small uninhabited island of 26 km^2 area off Costa Rica). The largest among them is the West Island, with an area of 3.2 km^2. These are extremely coralline islands but also with a luxuriant growth of land vegetation that includes coconut palms, sugarcane, and banana. No quantitative accounts of other fauna are available but the coconut eating crab *Birgus latro* is an interesting species from these islands.

Christmas island

Christmas island, with an area of 128 km^2, and lying 650 km south of Java Head, is a strongly uplifted island surrounded by high cliffs of coral limestone. It is well-known for its extremely rich phosphate deposits and the coconut crab *B. latro* (another Christmas island is an atoll in the Line islands, central Pacific).

In summary, the major features of Indian Ocean islands are:

- Wide range in size, from sand cays to some of the largest islands in the world.
- Coralline origin in most of the oceanic regions and granitic or sedimentary origin in coastal regions.
- Coasts characterized by fringing reefs in almost all cases, and mangroves and other wet lands in most others.
- Endemism in some islands, with native flora and fauna.
- Most of the smaller islands are uninhabited. Where settlements have taken place, marked erosion in biological diversity and resources are noticeable.

Suggested further reading on this subject may be found in the bibliography listing.

INGRESSION, REGRESSION, AND TRANSGRESSION

A transgression is a landward shift of the coastline while regression is a seaward shift. The terms are applied generally to gradual changes in coast line position without regard to the mechanism causing the change. In addition, these terms usually are applied to changes over periods greater than 10^3 years as can be expected to be recorded by facies distributions in the geologic record or the stratigraphic interpretation of seismic reflection. "Transgressions" and "regressions" are commonly used, for example, to refer to coast line changes due to glaciations, which cause both eustatic sea-level changes and subsidence or rebound. Of particular significance is the "Holocene transgression" which corresponds to a eustatic rise in sea level of between 100 and 130 m and between 18,000 and 6,000 yr BP. The terms also have been applied, however, to changes occurring over shorter time scales in, for example, Lake Chad.

"Ingression" refers to the advance of marine conditions into more-or-less confined areas, like the drowning of a river valley (Schieferdecker, 1959, terms 1260 and 1840, as cited in Jackson, 1997) or to the infiltration of water to an interior low-lying area of land creating an inland body of water. In the former application, at least, neither mechanism or time period is implied although the tendency seems to be to use "ingression" to refer to more rapid, if not catastrophic, transitions rather than to more gradual changes. An example might be the marine invasion of a glacial lake by breeching of a morainal barrier during post-glacial, sea-level rise. A rise in relative sea level will also raise the water table in coastal aquifers causing the appearance of lakes and ponds but the same could be accomplished by changes in recharge (percipitation–evapotranspiration).

Facies relationships and implications

Regressions or transgressions can be due to any combination of (1) eustatic sea-level rise or fall; (2) subsidence or uplift; and (3) sedimentation or erosion. In sedimentology, transgressions are also referred to as "retrogradation" in which a depositional environment due to the rate of creation of accommodation space exceeds the sediment supply (Curray, 1964; Nichols, 1999). This results in a landward shift of coastal facies belts, although it is possible that the advance of the marine conditions had occurred so quickly that sediment deposition could not remain in equilibrium with changing conditions. In this case, relict, subaerial sediments may be found drowned in place or shallow water deposits covered discontinuously by deep water facies. Transgressions are usually associated with a rise in relative sea level due to eustatic sea-level rise and/or coastal subsidence. Even during periods of stable sea level or slowly rising sea level, however, erosion of coastal deposits can result in a transgression.

Regressions are also referred to as "progradations" in which the sediment is supplied at a higher rate than the potential space for sediments to be accommodated is created. In the geologic record, this can be preserved by up-column transitions to distinctly shallow water facies. A regression is usually associated with a falling sea level, but even in the face of a stable or slightly rising local sea level, the shoreline may still be displaced in a seaward direction by the rapid deposition of coastal sediments. Progradation is, for example, associated with delta formation. The relationship between the rate sea level changes and the rate of deposition or erosion was discussed by Curray (1964).

Onlaps and offlaps

The terms seem to have entered the literature associated with "onlaps" or "offlaps." Onlaps are overlapping relationships of shallower water sediments over deeper water sediments, which progressively pinch out toward the margins of a sedimentary basin. "Marine transgressive sequence" is used as a synonym for onlaps. Offlaps occur when progressively younger sediments have been deposited in layers offset seaward, often associated with an upward coarsening. Curray, accordingly, came to refer to the occurrence of a shift in the shoreline independent of the evidence found in the geologic record for these changes.

ISOSTASY

Numerous observations point to a complex and changing relationship between land and sea surfaces throughout geological time. In some localities elevated coral reefs, wave-cut rock platforms, and molluscs embedded in their original marine sediments attest to past sea levels having been higher than present. At other sites, drowned forests and submerged sites of human occupation point to sea levels having been locally lower than present. These observations represent a measure of relative sea-level change which can involve a land-movement signal as well as an ocean-volume signal. The indicators of submerged or elevated coastlines therefore point to one of three occurrences: land has moved up or down, ocean volumes have changed, or both have occurred simultaneously.

Tectonic process operating within the earth have caused uplift and subsidence throughout the Earth's history, resulting in relative sea-level change on a wide range of spatial and temporal scales. They include uplift and subsidence at convergent plate margins where the relative sea-level change is usually episodic and abrupt but cumulative over long periods of time resulting in, for example, the marine mollusc beds high in the Andes of South America that were first described by Charles Darwin. The tectonic processes also include slower and longer-duration events such as the initiation of continental rifting and sea floor spreading with the concomitant changes in the displacement of water by the developing ocean ridge system. Long-term thermal contraction of the cooling outer layers of newly created ocean crust at the ocean ridge results in sea-floor subsidence, creating basins into which sediments accumulate, thereby magnifying the subsidence. Large volcanic edifices stress the earth and cause more local subsidence and deformation of the earth's surface in the vicinity of the load.

At the same time that the tectonics events shape the earth's surface and shift the relative positions of land and sea surfaces, ocean volumes also change, largely because of climate-driven changes in the extent of glaciation of the planet. During extended cold periods large ice sheets form, extracting water from the oceans and lowering sea levels. As the climate warms up sufficiently to melt the ice sheets sea levels again rise. Such glacial cycles have occurred at intervals throughout much of the earth's history but they have been most significant during recent times, the Quaternary period, for which the record has not yet been wholly overprinted by the subsequent tectonic and land-shaping events.

The combined result of the tectonics and glacial cycles is a sea-level signal that has varied significantly in time as well as being geographically variable. The record of this variability is, however, far from complete, and to be able to model and predict the migration of coastlines, an understanding and separation of the underlying causes of sea-level change is essential. Isostatic processes are key elements in this understanding and separation.

The isostatic process

Isostasy is the tendency of the earth's crust and lithosphere—the upper, effectively elastic layer of the earth—to adjust its vertical position when loaded at its surface by, for example, ice, water, volcanos, or sediments. For this purpose, the earth can be represented to a good approximation as a spherically symmetric body with a fluid core of about 3,400 km radius. The upper layer is called the lithosphere and includes the crust. Its thickness is typically between 50 and 150 km, varying with the tectonic history of the region. The lithosphere is characterized by being relatively cold and to behave elastically when subjected to load stresses below a critical failure limit. The mantle, between the lithosphere and core, is at a temperature that is relatively close to the melting point of terrestrial materials. As a result the mantle flows viscously, with characteristic relaxation times of 10^4–10^5 years, when subject to non-hydrostatic stress. It is this zonation of a "rigid" lithosphere over "viscous" mantle that gives validity to the isostatic models.

The simplest representation of isostasy is by "local" response models which are statement of Archimedes' principle: a load of heights h, density ρ, placed on the earth's surface results in a subsidence of the underlying surface of $\delta = h\rho/\rho_m$, where ρ_m, the density of the mantle, exceeds the density of the lithosphere (see Figure I22(A)). This model assumes that the crust or the lithosphere has no shear strength (or has failed under the load) and overlies a fluid mantle. This model, while unrealistic in many respects, is nevertheless useful for estimating magnitudes of crustal deflection beneath loads. For example, under a 3 km thick ice sheet the crust is predicted to deflect by about 1 km. A more reasonable model is one in which the load is supported by both the "elastic" strength of the crust-lithophere and by the buoyancy forces at the base of the layer (Figure I22(B)). In this model, the mantle also behaves as a fluid and it provides a reasonable description of the earth's response to loads with time constants that are longer than the relaxation times of the mantle. These models have been extensively used to represent the response of the earth to sediment loads or to volcanic loads. They are usually referred to as regional isostatic models.

When the load duration is of the order 10^3–10^5 years any load-generated stresses that have propagated into the mantle will not have relaxed and the viscosity of the mantle must be taken into account. In these cases the isostatic models are usually represented by an elastic layer over a viscous or viscoelastic halfspace or, in the case of global problems, by spherical shell models of an elastic lithosphere over a viscoelastic mantle and fluid core. Both lithosphere and mantle may be represented by some degree of layering in physical properties (elastic moduli, viscosity, and density). Formulation of these spherical response models are well developed and solutions for the surface deformation under complex

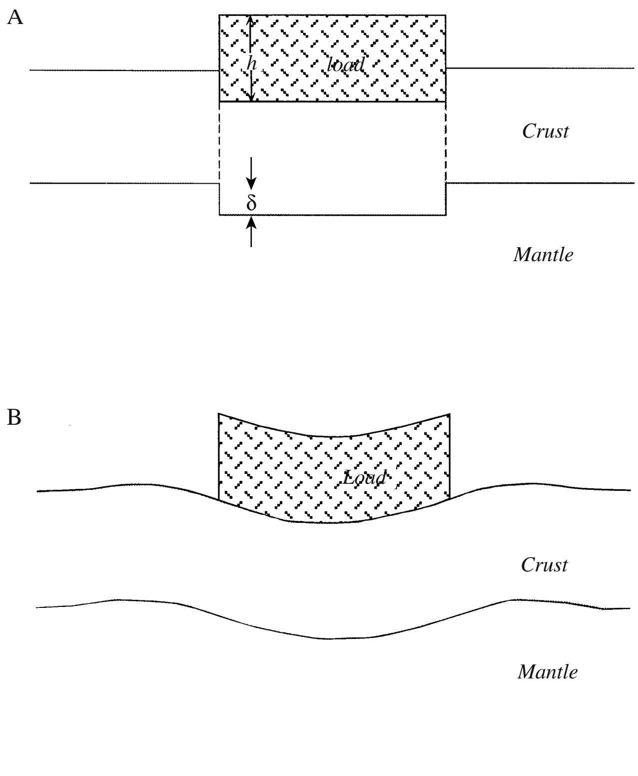

Figure I22 Models (A) local isostasy (B) regional isostasy. In (A) the load is supported by the buoyancy force at the base of the crust or lithosphere, whereas in (B) the load is also supported by the elastic stresses created in this layer. As the load diameter in (B) increases the isostatic response at the center of the load approaches that of local isostasy.

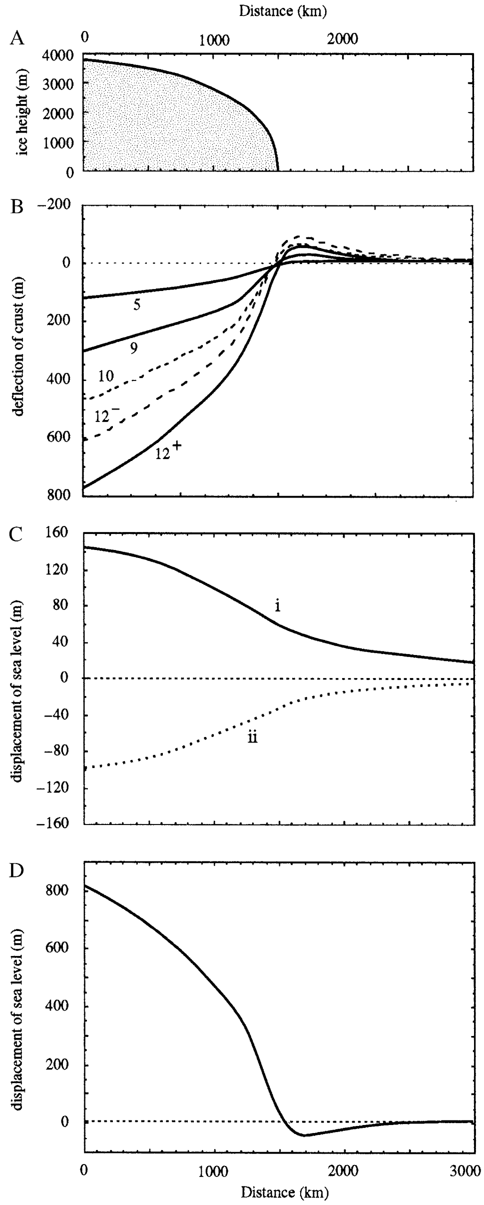

Figure I23 (A) Radial cross section of axisymmetric ice sheet. (B) Deformation of the earth's surface under the ice that has loaded the earth for 20,000 years (curve 12+). At 12,000 years ago the load is removed instantaneously. The initial response is elastic (curve 12−) and this is followed by viscoelastic creep, the surface being shown at 10,000 years (10), 9,000 years, and 5,000 years ago. (C) The gravitational attraction of the ice load, represented as the deflection of the geoid (i), and the change in geiod from the change in the planets gravity due to the deformation of earth under the load (ii). The results are shown for a period before unloading starts. (D) The relative sea-level change, due to the combination of crustal deformation, change in gravitational attraction, and ocean volume change long after the load has been removed. The sea level is expressed with respect to its present position. If the a coastline formed near the center of the load soon after the ice melted, it would now be at nearly 800 m elevation.

surface load geometries exist. Figure I23 illustrates an example of surface deformation where a large-diameter axi-symmetric ice sheet has been instantaneously removed. The rheology (viscosity structure) of the planet is realistic (see Figure I27, below) and the results indicate that the crustal readjustment continues for thousands of years after the unloading is completed.

In addition to the surface deformation, the gravity field of the planet also changes under the load: the shape of the envelope containing the mass is modified by the deformation and material is redistributed within this envelope. At the same time there is a redistribution of the material on the surface: sediments are transported from mountains into basins, or the meltwater from land-based ice sheets flows into the oceans. Surfaces of constant gravitational potential—surfaces on which the gravity vector is everywhere perpendicular—therefore, change with time as the load and planetary response evolve. One such equipotential is the geoid, the shape of the ocean. (If the ocean is not an equipotential surface then the gravity vector has a component along the surface and ocean currents result until an equilibrium state is reached; thus in the absence of winds and other perturbing forces, the ocean will be an equipotential surface. This is called the geoid.) Figure I23 illustrates the change in the equipotential surface resulting from the unloading. It includes a contribution from the surface load itself—the ice "attracts" the ocean water and pulls the ocean surface up around it (curve *ii*)—and a contribution from the earth's deformation (curve *i*). The illustration is for the period while the ice is intact and when melting starts both curves will evolve with time.

The example in Figure I23 illustrates that relative sea-level change resulting from the removal of the ice sheet contains several elements. The crust is displaced radially, the ocean surface is deformed by the redistribution of surface and internal mass, and water is added to the ocean. The rebound resulting from the melting (or growth) of the ice sheet is referred to as glacio-isostasy. The water added to (or withdrawn from) the oceans has its own isostatic effect and is referred to as hydro-isostasy.

The combined glacio–hydro-isostatic processes are of global extent. The melting of an ice sheet in one location modifies sea level globally, not just by changing the amount of water in the ocean but because of the planet's isostatic response to the changing surface load of ice and water. Other loading processes, such as by sediments or volcanic loads, are usually more local in their consequences. Also, these tectonic process generally occur on longer time scales so that the mantle response can usually be approximated as a fluid, and the local or regional isostatic models are mostly appropriate.

Glacio-isostasy

Ice sheets represent surface loads that reach radii in excess of 1,000 km and thickness approaching 3 km. These loads are large enough to deform the earth and to produce substantial changes in sea level as illustrated in Figure I23. Glacio-isostasy is the major cause of sea-level change in areas of former glaciation. When a large ice sheet melts the rebound of the crust is of larger amplitude than the rise in sea level resulting from the addition of the meltwater to the oceans (typically 120–130 m, see Figure I29 below) from all of the ice sheets. If ΔV_i is the change in volume of ice on land and A_o the area of the ocean, then this second signal is

$$-\frac{\rho_i}{\rho_w}\int \frac{1}{A_o(t)}\frac{d}{dt}\Delta V_i(t)dt$$

where ρ_i, ρ_w are the densities of ice and water, respectively, and both A_o and ΔV_i are functions of time. This contribution is referred to as the ice-equivalent sea-level change.

Because of the viscosity of the mantle, the crust continues to rise long after the ice has vanished and sea level appears to have fallen since deglaciation. This is seen in the Gulf of Bothnia and northern shores of the Baltic Sea, as well as in the Hudson Bay area of northern Canada. For these locations near former centers of glaciation the rebound signal dominates and the observed sea-level curves are characteristic relaxation curves (although only the post-glacial part of the change is recorded) (Figure I24 (Angermanälven)). Near the ice margins the rebound is reduced in magnitude and may become comparable to the rise resulting from the increase in ocean volume. Now the time dependence of the sea-level change becomes more complex, with its character depending on the relative importance of the two contributions. In Figure I24(Andøya), for a site just within the ice-sheet margin, the rebound initially dominates but later, because of the melting of other and distant ice sheets, the ocean volume increase becomes the dominant factor and sea level rises until a time when all ice sheets have melted. The remaining signal is a late stage of the relaxation process and sea levels continue to fall up to the present.

The rate and magnitude of the sea-level change is a function of the earth's viscosity and the ice history: of the duration of the ice load, of its areal extend, and of its thickness. The importance of the rebound phenomenon is that it provides a means of estimating the earth's rheology: if climate models and geomorphological observations constrain the ice geometry through time, then observations of sea-level change provide a constraint on the mantle viscosity. If the ice models are not sufficiently well-known then it becomes possible to learn something about the ice sheets as well. Figure I25 illustrates observational results for sea-level change across Scandinavia. Here, the ice sheet reached its maximum at about 20,000 years ago and most melting occured between about 16,000 and 10,000 years ago. As the ice retreated, coastlines formed on the emerging land providing a comprehensive description of the rebound across northern Europe. The rebound did not cease at the time melting ceased and coastlines have continued to retreat in formerly glaciated regions up to the present. This can be seen in tide gauge records across the Baltic, with present sea-level falling locally at rates approaching 1 cm/yr in the northern part of the Gulf of Bothina. Figure I26 illustrates the rate of crustal rebound and to obtain relative sea-level change these values must be increased by about 1–1.5 mm/yr. Coastlines here continue to retreat despite other factors that may contribute to an increase in global ocean volume.

Glacio-isostasy does not cease at the ice sheet margins. Because the mantle flow generated by the changing surface load is constrained within a deformable shell, when some areas are depressed under a growing load others are uplifted. The latter areas form a broad zone or swell around the area of glaciation of amplitude that may, depending on the size of the ice sheet, reach a few tens of meters. When the ice sheet melts this peripheral swell subsides and for island or coastlines on it sea level will be seen to be rising at a rate that is over and above the ice-volume equivalent contribution (Figure I24(Store Bælt)). Beyond the Scandinavian relic ice margins this occurs in areas of the North Sea and as far away as the western and central Mediterranean and here the sea level continues to rise even when all melting has ceased. Beyond the North American ice sheet this zone of recent crustal subsidence and marine flooding occurs as far away as the southern USA and Caribbean.

Observations of sea level within and beyond the former ice margins provide the principal source of information on mantle viscosity. A typical result for northwestern Europe is illustrated in Figure I27 where the rebound phenomenon provides a good constraint on the viscosity of the upper mantle. The main features of the viscosity profile include a lithosphere of thickness 65–75 km, a relatively low value for the viscosity of the mantle immediately below the lithosphere, and increasing viscosity with depth, particularly at a depth of about 700 km. Analyses for different regions produce comparable results although actual values for the viscosity and lithospheric thickness may differ because of the possibility that the rheology is laterally variable. The determination of such variability is one of the important research areas in glacio-isostasy.

While the glacio-isostatic models are well understood, one of the key limitations of their application is the inadequate knowledge of the former ice sheets. The ice margins at the time of the Last Glacial Maximum, some 20,000 years ago, are usually well-defined by geomorphological markers but the timing of their formation is not always known. This occurs particularly where the ice margins stood offshore and left few datable traces of both the time of their formation and of their retreat. Also, the ice thickness cannot usually be inferred from observational evidence alone and is inferred instead from glaciological and climate models. The sea-level observations can nevertheless help constrain the ice models in important ways. Thus, the total ice volumes in the models for all the major ice sheets must yield a global sea-level curve that is consistent with the changes observed far from the ice sheets (see hydro-isostasy). Also, details in the ice models can also be derived from the sea-level data from sites within and near the former ice margins. The shape of the sea-level curve from a near-margin site (Figure I24) changes quite rapidly with distance from the former ice margin, with the signal evolving from that for a central-load site to that for a site on the peripheral swell, and observations across the margin can constrain the former ice distribution within the ice-marginal region. One of the more recent research directions in glacio-isostasy is the use of this sea-level and crustal-rebound evidence to improve models of the ice sheets during the last deglaciation phase.

Hydro-isostasy

As ice sheets melt, the additional water entering the world's oceans loads the sea floor, load stresses are propagated through the elastic lithosphere into the mantle, the newly stressed mantle material flows toward unstressed regions and the sea floor subsides. The shape and holding-capacity of the ocean basin is thereby modified and the ocean water is redistributed, changing sea level. This adjustment of the earth

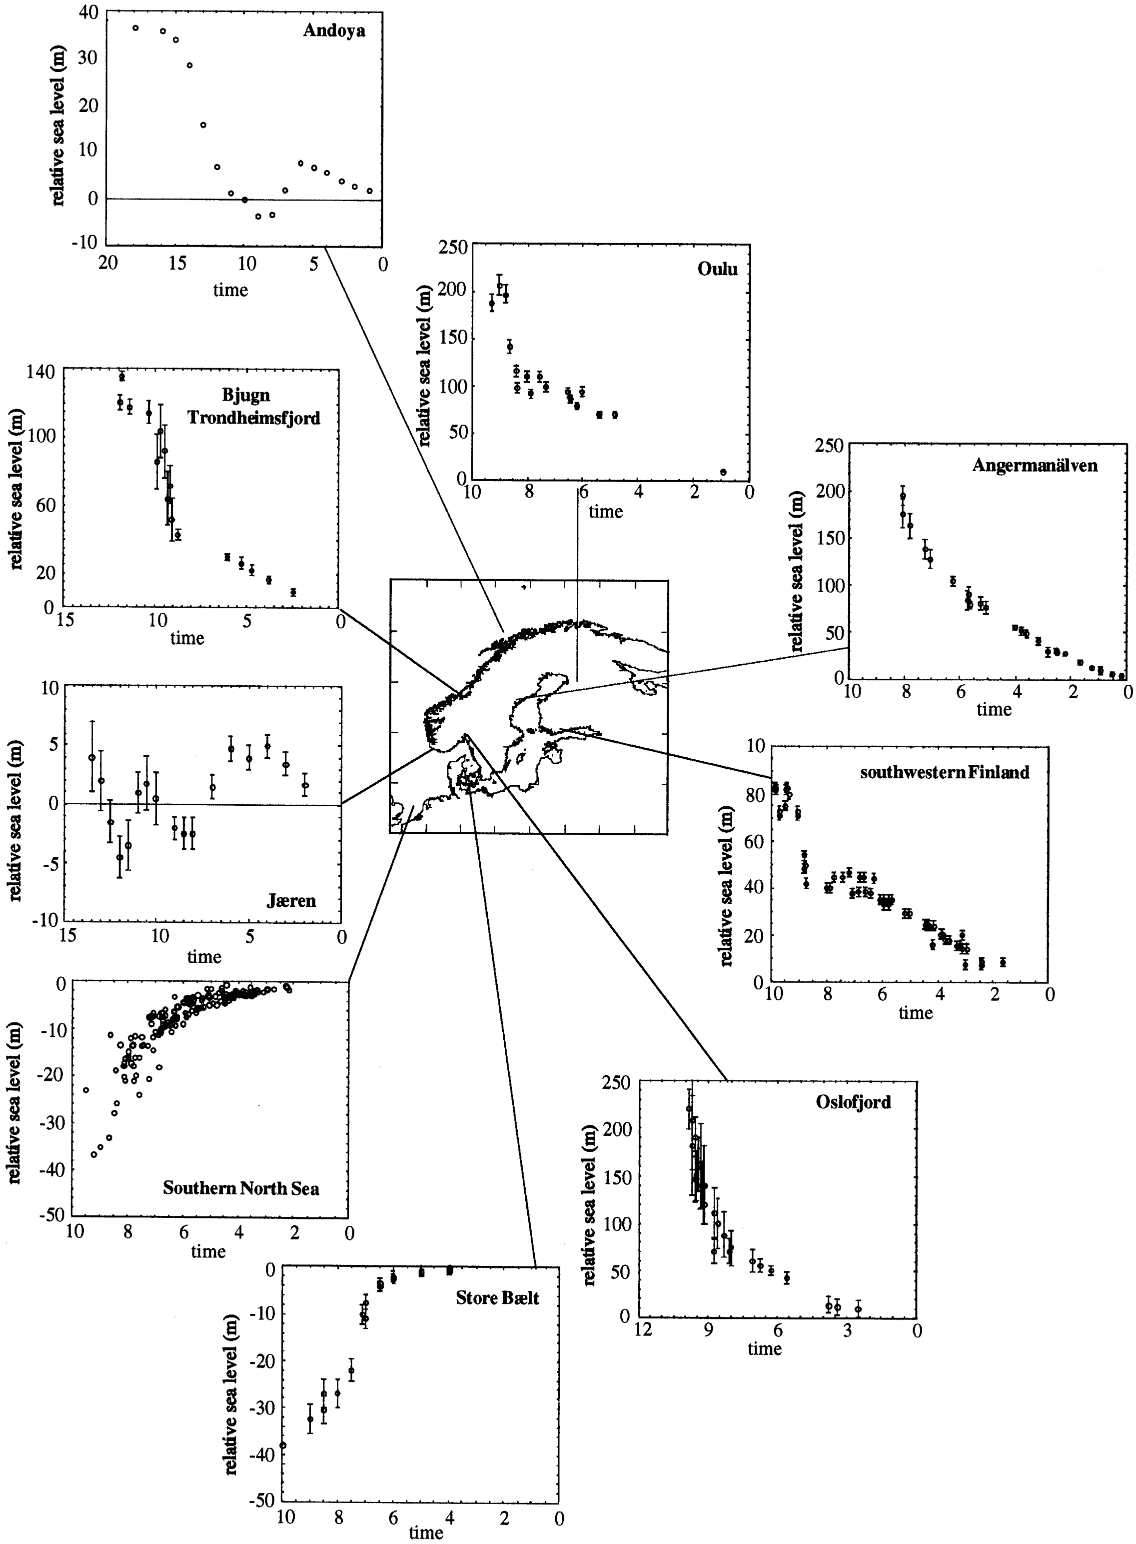

Figure I24 Observed relative sea-level change for sites in Scandinavia illustrating some of the spatial variability in the response. The ice sheet covered all of Scandinavia and spread onto the German, Polish, and Russian plains. Retreat started at about 18,000 years ago and the final disappearance of ice occurred at about 10,000 years ago. The time scale used in these plots corresponds to the radiocarbon time scale which differs from a calendar time scale by about 10–15% for this interval (1 C^{14}years ≈ 1.1–1.15 calendar year).

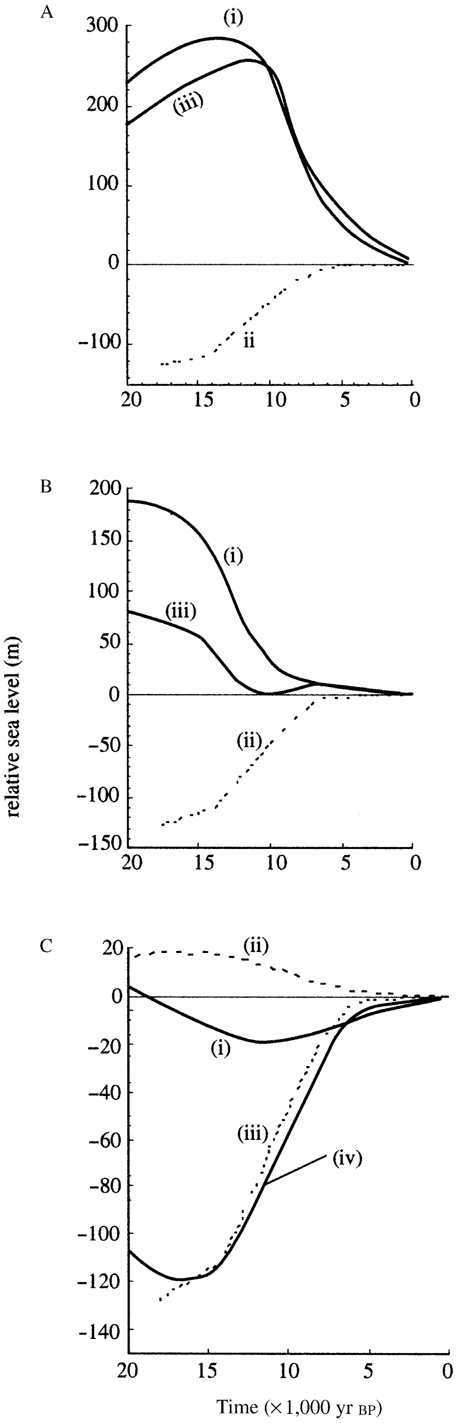

Figure I25 Schematic contributions to sea-level change from the glacio-isostatically driven crustal rebound and increase in ocean volume from meltwater. (A) For a location near a former center of glaciation where the rebound (i) exceeds the rise in sea level (ii) from the added meltwater, (iii) is the total change. (B) For a location near the former ice margin where the two contributions are of comparable magnitude but of opposite sign. (C) For a location beyond the ice margin where the crustal uplift is replaced by subsidence. The effect of the water load (ii) now is important as well as the ice-load effect (i). The meltwater contribution is given by (ii) and the total change by (iv).

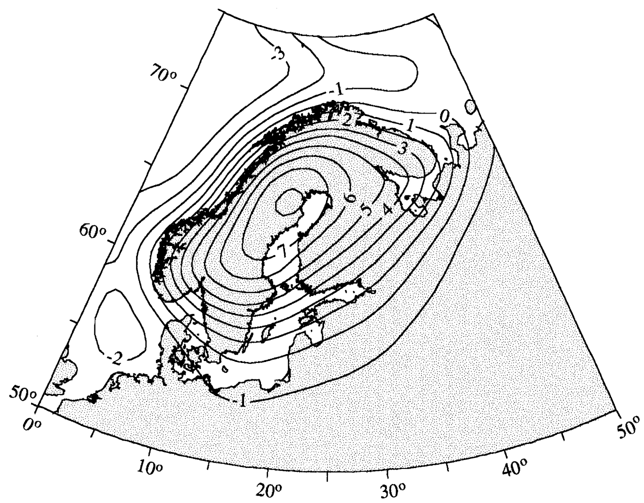

Figure I26 Present rates of crustal uplift (in mm/yr) of Scandinavia based on rebound models and on observed rates from tide gauges across the region (from Lambeck *et al.*, 1998; with permission of Blackwell Publishing).

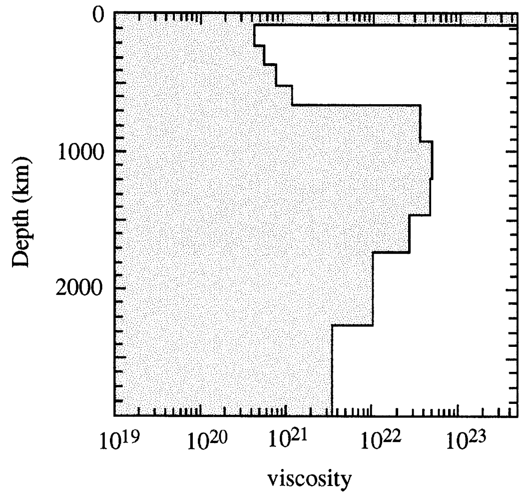

Figure I27 Profile of mantle viscosity (in units of Pa s) inferred from glacial rebound analysis of European sea-level data (G Kaufmann, with permission).

under the time-dependent water load and the concomitant sea-level change is referred to as hydro-isostasy. Since the onset of the last deglaciation, sea levels have risen on average by about 120–130 m and the additional load has been sufficient to modify the shape of the earth. This is a result of the long wavelength nature of the water load. Loads of dimensions less than the thickness of the lithosphere are supported mainly by the strength of the lithosphere and the resulting surface deformation is small. But large-dimension loads effectively see through the lithosphere and are supported by the much more ductile mantle which flows even under small changes in the stress field.

At continental margins the hydro-isostatic deformation of the earth's surface describes quite complex patterns because of the geometry of the load. The lithosphere acts as a continuous elastic layer or shell and the continental margin is dragged down by the subsiding ocean lithosphere but, because of the asymmetry of the load, not by the same amount as in mid-ocean. At the continental coastlines, therefore, the subsidence will be less than it would be in mid-ocean. At the same time, some of the mantle material flowing away from the stressed oceanic mantle flows beneath the continental lithosphere, causing minor uplift of the interior. The net effect of the ocean volume increase is a seaward tilting of the continental margin which will be seen as a variable sea-level signal across the shelf. This effect is clearly seen for tectonically stable continents that lie far from former ice sheets, as in the case of Australia.

While the ice sheets are still melting the dominant sea-level signal here is from the increase in ocean volume and the glacio- and hydro-isostatic effects are second order. But when melting ceases the on-going isostatic effects come into their own. Now sea level appears to be falling at the coastal site as the ocean waters recede to fill the still-deepening ocean. In consequence, small sea-level highstands are left behind with peak amplitudes of 1–3 m occurring at the time global melting ceased (Figure I28). Such highstands are common features along many continental margins and manifest themselves as relic shorelines or fossil corals above the present formation level or habitat. If the coast is deeply indented, sites at the heads of gulfs, being furthest away from the water load, experience greatest uplift while offshore islands experience least uplift. This differential movement provides a direct measure of the viscosity of the mantle across the continental margin.

Like the glacio-isostatic effect, the water load does not only deform the surface of the earth, it also results in a redistribution of mass and a change in gravity and in the shape of equipotential surfaces. The total sea-level changes associated with the hydro-isostasy include, therefore, both the crustal radial deflection and the associated geoid change. Also, the glacio- and hydro-isostatic effects are closely linked when their cause is the deglaciation of the last ice sheets. Near the edge of the ice sheets, for example, the water is pulled up (Figure I23) and the waterload is increased above what would result from a uniform distribution of the meltwater over the entire ocean. Here the hydro-isostatic signal is a function of the magnitude of the glacio-isostatic effects. Elsewhere, the broad zone of crustal rebound surrounding a large ice sheet may occur in an oceanic environment. Then, when the ice sheet melts this swell subsides, increasing the volume of the ocean basin, water is withdrawn from other parts of the ocean, and a further global adjustment of sea level occurs. Thus, the treatment of hydro–glacio isostasy requires a global and consistent formulation that ensures that these various interactions are included.

The hydro-isostatic signal is an on-going one even when major melting of the world's ice sheets ceased about 6,000–7,000 years ago. Thus sea-level change today will contain a small but not insignificant component of hydro-isostatic origin (cf. Figure I28 for the Australian region). This signal must, of course be superimposed upon any other changes, including possible global warming signals. The results indicate that sea levels around the Australian margin are slowly falling under the combined glacio–hydro-isostatic response to the past melting of the large ice sheets (with the possible exception of Tasmania where the glacio-isostatic effect of Antarctic ice volume changes becomes significant, canceling out the hydro-isostatic signal such that little overall change now occurs). Similar isostatic effects will be present at all coastline, increasing in magnitude as the locality approaches the regions of former glaciation.

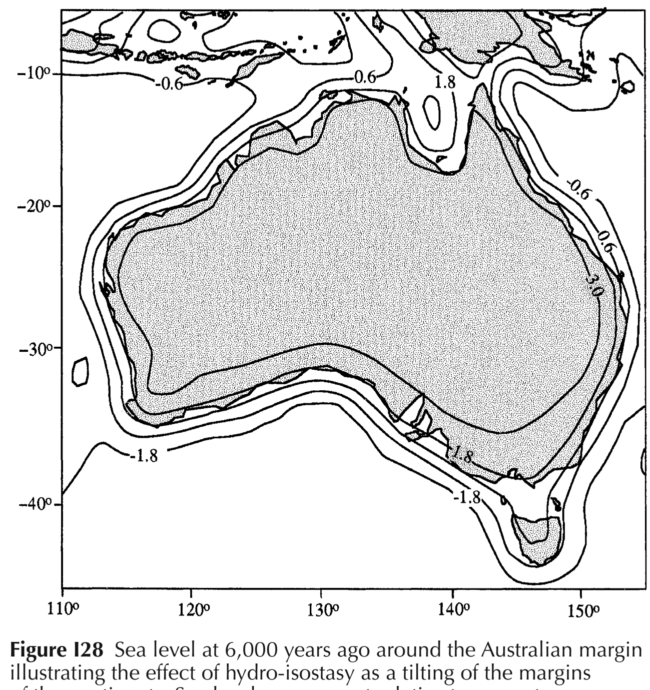

Figure I28 Sea level at 6,000 years ago around the Australian margin illustrating the effect of hydro-isostasy as a tilting of the margins of the continents. Sea levels are present relative to present mean sea level. Contour intervals are 1.2 m. The present-day rate of change in mm/yr given approximately by dividing the contour values by 6 and changing the sign, the resulting negative value for most locations indicating a fall in sea level from isostasy alone.

The importance of the sea-level observations far from the ice margins is that because the glacio–hydro isostatic effects are relatively small (10–15% of the total signal) they provide an estimate of the change in volume of the oceans when corrected for the isostatic effects: the observed sea level, less the isostatic correction yields the ice-equivalent sea level defined above and hence an estimate of the change in ocean volume ΔV_i. Several long records, extending back to the Last Glacial Maximum, of local sea-level change exist which provide evidence for the change in ice volume since this time. They indicate (Figure I29) that maximum ice volumes globally were $(50–55) \times 10^6$ km^3 greater than today but, they do not indicate necessarily where this extra ice was stored. To resolve that issue recourse to the study of the glacio-isostatic process from formerly glaciated regions is necessary.

Sediment and volcanic loading

Large accumulations of sediment occur along many of the continental margins reaching, in some instances, a thickness of 10 km or more. The rate of accumulation is usually slow and continuous, occurring over periods of tens of millions of years with the sources of sediments coming from continental interiors where tectonic processed have caused uplift and erosion processes have carried the sediments to the sea. Examples include the Bay of Bengal, the northwestern margins of Europe, the eastern margin of North America, and the Gulf of Mexico. Thick accumulations of sediments are possible because of the subsidence of the lithosphere under the growing sediment load. With the above model of local isostasy an ocean basin of depth d_o can, with adequate sediment supply, lead to a maximum subsidence of $d_o\rho_s(\rho_s-\rho_m)$ where ρ_s is the density of sediments. This assumes that the basin is ultimately filled to sea level. For $d_o = 4$ km, $\rho_s = 2.5$ g cm^3, $\rho_m = 3.5$ g cm^{3}the maximum thickness of sediment that can be attained is about 10 km. However, in this case the deeper sediments will have been deposited in water depths initially of $d_o = 4$ km, whereas the characteristics of the fauna preserved in the basin sediments usually indicate that deposition invariably occurred in relatively shallow waters. Isostasy alone, therefore, cannot produce thick sediment sequences but it does act as an amplifier of subsidence that is the result of other processes: in this case mostly the thermal contraction of ocean lithosphere as it cools from an initially hot layer formed at the ocean ridges and then moves away from the heat source.

On short time scales, sediment loading can lead to substantial coastal subsidence. This may occur in conjunction with deglaciation cycles where sediments are eroded from the continents during the deglaciation stage and delivered to coastal environments at some later stage. An example of such subsidence occurs along the US coast of the Gulf of Mexico, particularly for the Mississippi delta. Here, coastal subsidence occurs at rates approaching 10 mm/yr and are attributed in part to the isostatic response to recently delivered sediments, but also in part to the extraction of fluids from the sediments and the associated compaction. Here, as in most isostatic problems, several factors will contribute to the observed signal.

Volcanic loading of the crust provides another example of isostasy at work. Large volcanic complexes form on the sea floor, and elsewhere, because of upwelling convection currents in the mantle that lead to an injection of magma into the crust and ultimately onto the surface as volcanos. The mantle source regions for the magma appear to be long-lived and as the lithosphere moves over the earth's surface under the forces of plate tectonics, a trail of volcanos is left on the surface. The Hawaiian chain provides the type example. Other examples include the Society Island chain whose current center of volcanic activity lies to the east of Tahiti. The subsidence of the lithosphere beneath the volcano is adequately described by the regional isostatic model in which the load is supported by the elastic stresses within the lithosphere and by the buoyancy force at the base of the layer (Figure I22(b)). Because of the elastic properties of the lithosphere small peripheral bulges, concentric about the center of loading, develop and any islands located in this zone at the time of volcano development are uplifted by some tens of meters. An example of this is provided by the uplifted atoll that forms Henderson island, southeast of Pitcairn island. This small island about 200 km from the volcanic island of Pitcairn, appear to have been uplifted some 20–30 m at the time of Pitcairn's formation, perhaps 700,000 years ago. The location of the zone of maximum peripheral uplift provides a measure of the flexural wavelength of the lithosphere, a parameter that characterizes the physical response of the layer to loading. With time, some relaxation of the loading stresses can be expected to occur within this layer such that the isostatic state evolves

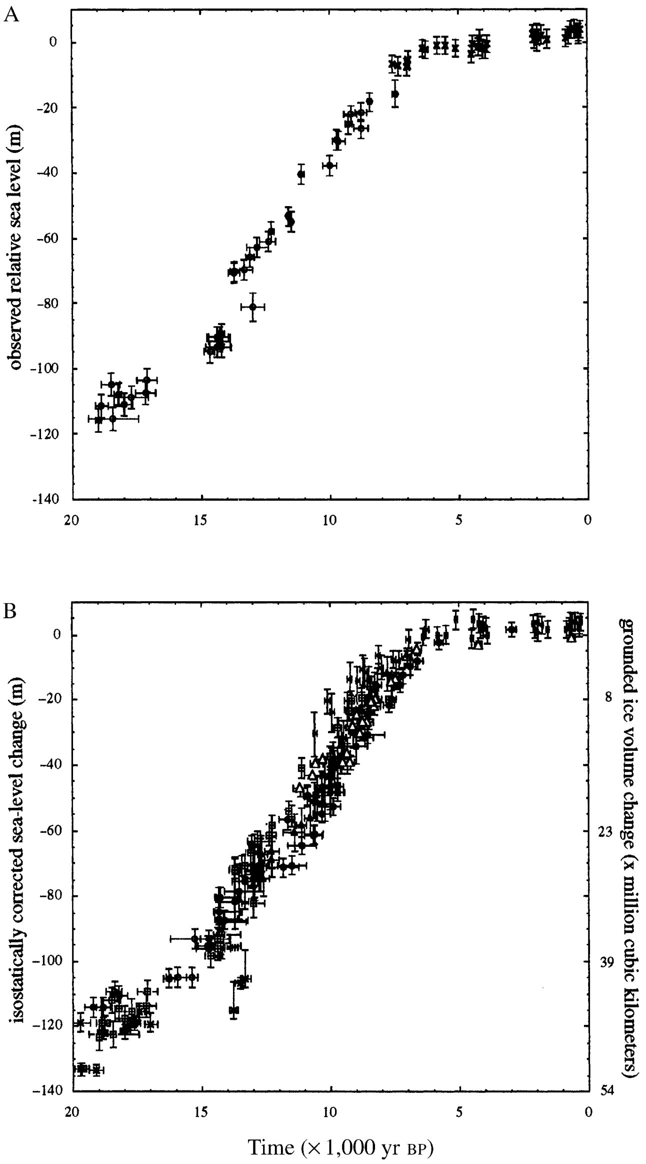

Figure I29 Sea-level change for the past 20,000 years. (A) A record of observed local relative sea-level change from Barbados and other Caribbean sites, and (B) isostatically corrected sea level from a number of sites distributed globally and combined into a single ice-equivalent sea-level curve. Scale on the right hand side gives the corresponding change in volume of ice on land and grounded on shallow sea floor.

slowly from regional to local isostasy and that the volcano slowly subsides. Thus Tahiti, a relative young volcanic load of about 1–2 million years, may be subsiding at a rate of about 0.2 mm/yr or less.

These examples of vertical movements driven by sediment or volcanic loading illustrate the interaction that occur between the various isostatic contributions to sea-level change. To estimate rates of tectonic uplift or subsidence, heights of identifiable coastlines are measured with respect to present sea level. Thus, the fluctuations in sea level of glacio-isostatic origin must be known, but these fluctuations are inferred from the same observational evidence. An important research area is to develop methods for separating out these effects, through observational improvements and through improved modeling of the physical processes.

JET PROBES

Introduction

Jet probes are used for a variety of purposes (e.g., underwater cable routing, marine archaeology, coastal engineering) and are usually deployed in conjuction with other data-collection techniques such as hydrographic surveys (to determine water depths and map existing bottom conditions), subbottom profile survey (to identify near subbottom stratigraphy, 3–7 m depth), side-scan sonar survey (to identify morphological variations, and natural and man-made obstructions on the seabed), and vibratory coring (to acquire direct physical information of nearsurface sediments). Jet probe surveys acquire indirect physical information on subsurface lithology by surveying the thickness and stratigraphic layering of sedimentary covers on land or underwater. A jet of either air or water is used to penetrate the sand cover; the latter, however, is only applicable underwater (USACOE, 2002).

Most jet probe surveys, in the service of coastal engineering for shore protection via beach renourishment, provide a rapid means for determining the nature of unconsolidated sedimentary deposits that occur underwater. Because jet probes have no cutter head and depend only on the power of a water jet to penetrate bottom sediments, they are restricted to use in shallow waters (i.e., the effective range of operating depths is usually from 1 to about 30 m) that overlie unconsolidated (loose) sandy deposits. Clear water is desirable, but not essential, because it facilitates site location, maneuverability of jet probe equipment over the bottom, and visual estimation of turbidity plumes that are created by water-jetted penetration of a pipe down through the sediment (CBNP, 1995). Jet probing finds application in marine archaeology, geotechnical studies that feature searches of seabed deposits for beach-compatible sands that can be placed on degraded beaches, and geological investigations that attempt to determine the thickness of sand covers on the seafloor or on lakebeds. Although widely deployed in many different kinds of environments and for various applications by scientists and engineers, jet probing probably finds most extensive application in coastal sand searches (e.g., Meisburger and Williams, 1981; Meisburger, 1990; Keehn and Campbell, 1997; Finkl *et al*., 1997, 2000, 2003; Andrews, 2002) that require reconnaissance surveys of bottom types or verification of geophysical survey data (e.g., subbottom profiles, side scan sonar surveys).

Grab samples provide information about surficial seafloor sediments, whereas vibracore and jet-probe samples can penetrate down into the sediment layers. Vibracore samples are relatively inexpensive to obtain and can recover the long and relatively undisturbed cores that are required to assess the composition and grain sizes of the materials, as well as to establish the stratigraphy of the deposits (e.g., Meisburger and Williams, 1981). Water jets are less expensive than cores (CBNP, 1995; USACOE, 2002), involving the water-jetted penetration of a pipe down through the sediment in order to determine the layering, as opposed to (undisturbed) core retrieval for splitting and analysis.

Marine archaeology

This tool assists marine archaeologists in determining the nature or presence of materials or features that lie within or underneath bottom sediments (Anon, 1996). On archaeological sites, the jet probe is manually driven through various nonconsolidated sediments on the seabottom where the probing pipe goes through soft strata until it hits bedrock, a cemented stratum, compacted clay, or artifact. This tool provides information regarding the location and elevation of buried ancient waterline features (indicators of previous sea-level positions) and other geomorphological data. Ultimately, the information enables the archaeologist to reconstruct shallow coastal-marine sedimentary environments, local surficial stratigraphic sequences, and other geological features that can then be dated and calibrated with archaeological finds.

Stratigraphic studies

Coastal-marine stratigraphic studies often rely on a range of techniques that are used to compile various kinds of information, that is, related to layering of different kinds of materials on the seabed (e.g., Toscano and Kerhin, 1990; Wells, 1994). Data are commonly derived from several independent studies viz. surface sediment samples, vibracores, and seismic records to compile an assessment of Quaternary stratigraphy, as, for example, in the Paranaguá Bay Estuary in southern Brazil (Lessa *et al*., 2000). Estuarine environments often provide ideal conditions for jet probing because there is a range of unconsolidated materials related to coarse- and fine-grained facies. Fluvial- continental deposits often occur with paleo-valleys as substratum for more recent sedimentation. These kinds of estuarine environments are often characterized by the intercalation of trans- gressive–regressive mud and sand facies that can be effectively studied using jet probes in conjunction with other techniques.

Underwater surveys of lakebeds often use jet probes to assist in reconnaissance verification of sedimentary bottom types, especially where sediment samples and grain-size analyses are eventually required. Lakebed studies often combine jet probing with underwater video investigation as independent lines of inquiry. Jet probe surveys to determine the thickness of sand cover are based on differentiation of the kinds of materials that are penetrated by the jet probing. On the American Great lakes, for example, the presence of diamictites (tills) that have been eroded from truncated drumlins to produce cobble–boulder lag deposits on the lakebed can limit the effeciveness of jet probes, as would any other substantial impediment to penetration of sedimentary layers (e.g., Stewart, 2000).

Assessment of sand resources and mining

Sandy shores occur along about 13% of the world's coastline (Coleman and Murray, 1976) and it is estimated that today about 75% of these shores are eroding (Bird, 1985). Beach erosion is thus a common problem along sandy coastlines and it is necessary to artificially renourish beaches because they provide natural protection from storms and have economic value (Finkl and Walker, 2002). The location of materials that are suitable for beach renourishment becomes an issue for best management practices that have to consider environmental concerns, methods of shore protection, storminess, and impact of exploration procedures to locate sand bodies on the seafloor. Even though sand sources differ from region to region around the world, there is a commonality to the need for good-quality sand and methods of looking for adequate long-term supply, as described, for example, by Anders *et al.* (1987), Conkright *et al.* (2000), and Walker and Finkl (2002).The salient problem then, is how to best locate sand sources that are appropriate for beach nourishment. Although inland sand sources are often suitable from a textural and compositional point of view for beach replenishment, their location away from the coast requires overland transport that can pose significant placement problems along the shore. Offshore sources of beach-quality sand are thus most often sought as geotechnical and economic reserves. Inner continental shelves host a range of coastal (e.g., beach ridges, dunes, nearshore bars, flood- and ebb-tidal deltas, estuarine sands) and marine sediments (e.g., shoals, banks, ridges, terraces, blanket deposits) as well as terrestrial deposits (e.g., glaciofluvial materials on valley floors, winnowed tills, coarse-grained alluvial terraces, and plains), all of which have been drowned and modified by rising sea levels during the Holocene (e.g., Toscano and York, 1992). Offshore sands that are suitable for beach renourishment are a sought-after and coveted commodity because in many regions they are in dwindling supply (e.g., Freedenberg *et al.*, 2000).

Advanced geophysical and geotechnical procedures are often backed up or verified by low tech efforts, such as jet probing, that are essential to the efficiency and economic success of offshore sand searches. General procedures for the exploration and development of borrows were summarized by James (1975) and Meisburger (1990), for example, who emphasized the value of collaborative approaches. Figure J1 shows the main sequential steps in modern data collection that are followed in sophisticated coastal sand searches that integrate diverse techniques. As shown in the figure, jet probe surveys are typically conducted at the reconnaissance level in conjunction with a suite of independent, but related, geophysical and geotechnical survey operations that provide specific kinds of information that collectively elucidate sediment thickness, lateral continuity, structural relationships, and composition. It is important to note that the first step in sand resource assessment is the review of historical data, an effort that is essential to proper appreciation of prior efforts and conclusions. Jet probe logs (Figure J2) are archived because they contain useful information that may be required later. A typical jet probe log, as shown in Figure J2, includes the usual kinds of locational information; date acquired, water depth, top and bottom divers, start- and end-times, etc. Notes in the log include important information that is related to the length of pipe, penetration depth, jet pump capacity, weather conditions, turbidity levels, and characteristics of the sand (grain size, percentage of silt content, color).

Sand searches for beach nourishment and protection commonly employ jet probe surveys (e.g., see Meisburger and Williams, 1981; CBNP, 1995; Walther, 1995; Freedenberg *et al.*, 2000; Finkl *et al.*, 1997, 2000). Usually conducted as a reconnaissance field survey (cf. Figure J1), the procedure is often misunderstood and the least utilized tool in sand

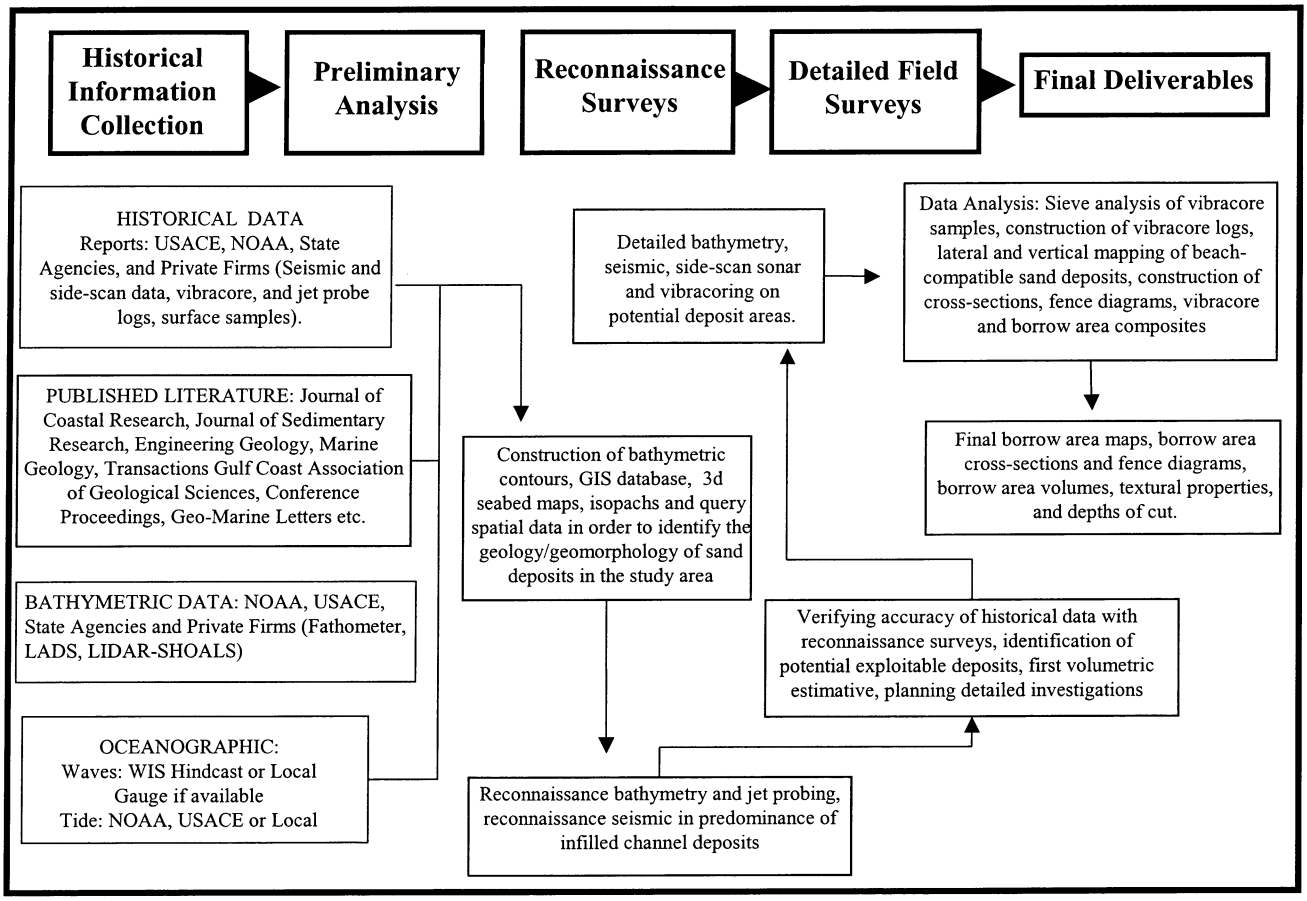

Figure J1 Flow diagram showing the organization, routing, and sequential application of coastal sand searches that are normally deployed on the inner continental shelf. Note that investigations begin with review of historical data, including proprietary reports and works in the public domain, and proceed to the construction of electronic databases that interface with GIS frameworks. Reconnaissance jet probing assists in the verification of historical data and provides focusing criteria for conducting detailed surveys. After review of historical, laboratory, and field data, sand resources with the greatest potential for use as beach sediments are identified as borrow sites. Jet probe surveys provide critical information in the evaluation of offshore sand resources and help identify which deposits are exploitable.

Figure J2 Example of a jet probe log showing the kind of information that is logged in verbal or numerical formats along with graphic displays of sediment composition. These digital logs are part of a GIS framework and the information contained in them can be queried for special purposes. Note that some information is back loaded into the logs because it is obtained subsequent to field logging. Granulometric analyses, for example, report median grain sizes for clasts (e.g., sand grains) and particulate matter (e.g., percent silt content).

search investigations. Usually deployed after preliminary assessment of historical data (e.g., geophysical and geotechnical information), comprehension of the regional geology and geomorphology, and computer aided analysis (including GIS summaries), jet probing should verify previously indicated field conditions. Jet probe surveys thus perform a valuable function in sand searches and their relevance and importance should not be underestimated as a time- and cost-saving effort.

Reconnaissance bathymetric and jet probe surveys are also used to verify hydrographic features with widely spaced bathymetric surveys, historical surface sand samples, jet probes, core sites, and other potential sand features in the study area. Reconnaissance bathymetric surveys groundtruth and verify the National Oceanic and Atmospheric Administration hydrographic data in selected areas of potential sand deposits. The reconnaissance bathymetry should be compared with historical bathymetry to identify areas where sand has accumulated by natural coastal processes or offshore dredge disposal. An example of reconnaissance jet-probe survey is shown in Figure J3 for a portion of the southwestern coast of Florida. Here, on the wide continental shelf of the eastern Gulf of Mexico, a range of sedimentary deposits overlie a karstified limestone peneplain that extends seaward from the Florida peninsula (Evans *et al*., 1985). Although the karst surface is somewhat irregular due to dissolution of the carbonate rocks, drowned valleys are infilled and planar areas are covered by blanket deposits and ridges.

Inlets along this coast, which produce deltaic deposits, show no strong regional trends and are stable in terms of channel width, length, geographic position, and orientation (Vincent *et al*., 1991; Finkl, 1994). The low wave energy regime that influences sediment accumulation at inlets in this region enhances construction of large ebb-tidal deltas, which store enormous quantities of sand (Davis *et al*., 1993). Flood-tidal deltas along the west-central Florida coast are relatively inactive due to small tidal ranges, sheltered lagoons, and ebb-dominated inlets (Davis and Klay, 1989; Finkl, 1994). The wide Continental shelf offshore southwest Florida, described by Davis (1997) and which gently slopes seaward toward the central basin of the Gulf of Mexico, maintains shallow depths to 9 km offshore to the 10 m isobath. Shelf morphologies and coastal (inlet) morphodynamics impact spatia distributions of mineral resources (Wright, 1995), large-scale coastal behavior (Short, 1999), and barrier island evolution (Oertel, 1979).

Various types of sand ridges (linear accumulations of sand bodies) are common on inner shelves along many shores the world over (viz. Duane *et al*., 1972; Swift and Field, 1981; McBride and Moslow, 1991). These topographically positive sedimentary accumulations on the seafloor are recognized as relict sand bodies that formed in response to prior stillstands of mean sea level (MSL) when sea levels were lower than those of today. On the shelf off southwestern Florida, for example, prominent seabed morphologies include linear sand ridges, some of

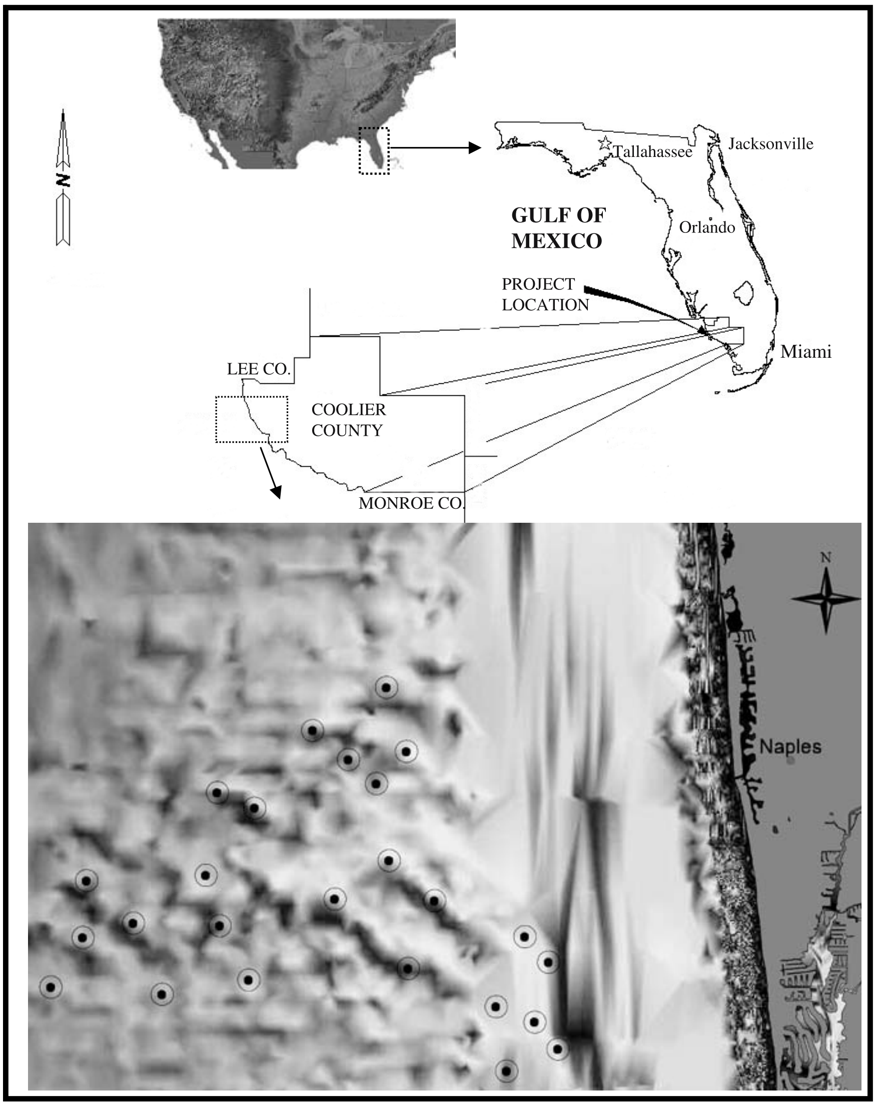

Figure J3 Jet probe location diagram showing bathymetry in terms of a graduated grayscale ramp so that sedimentary accumulations on the seafloor may be inferred from bathymetric highs. Jet probe locations, identified by the circled dots, are strategically placed to provide information related to the deposit thickness. Note the placement of jet probes on sand ridges.

which extend continuously for distances greater than 6 km. These deposits formed during the Flandrian Transgression (most recent Holocene trend in sea-level rise) (Davis, 1997). Depressional (negative topographic) features are incised into the karst surface and some surficial marls. When the continental shelf was exposed to subaerial geomorphic processes during low stands of sea level, streams cut into the karstified surface and persisted as valleys until sea level rose and they became infilled with recent marine and terrigenous sediments.

Figure J3 shows the distribution of reconnaissance jet probe locations of Naples, Florida. The jet probe locations are strategically placed on the basis of hydrographical, geophysical, geotechnical, and geological (including geomorphological) information (cf. Figure J1) that indicates the presence of sand deposits. As illustrated here by the shaded bottom relief on the lower left side of the Figure J3, caused by sedimentary accumulations on the seafloor, jet probes are sited on ridges, inter-ridge depressions, sand flats, and in other areas to verify thickness of sedimentary covers (or lack thereof). Emphasis must be placed on the fact that jet probes are not randomly sited on the seabed just to see what is there; rather, siting is intelligently coordinated with all collateral data that is related to the nature of bedrock surfaces and sedimentary accumulations on the seafloor. Reconnaissance jet probing is a strategy that is conducted as part of an overall coordinated methodology to define the presence of beach-quality sands on the seafloor.

Jet probes are thus taken in areas that show promise for sand deposits and to confirm historical vibracore logs. Jet probes and surface sand samples provide an indication of the thickness and characteristics of the unconsolidated sediment layers. With two dive teams, consisting of a geologist and a support diver, generally 8–15 jet probes can be obtained in a day depending on water depths, weather, and sea conditions (Andrews, 2002).

Geologists who are proficient in SCUBA diving, operate the jet probe by penetrating a graduated 7 m water pressure pipe into the ocean bottom and making observations as it passes through the sediment layers. The geologist is on the bottom and the support diver stays at the upper end of the probe to hold it upright against the current (Figure J4). The support diver also observes the turbidity level changes from above as silt is washed out of the probe hole (becoming suspended in the water column) during penetration of the seafloor. The geologist on the bottom observes the graduated scale on the probe and by the "feel" of the objects it encounters, makes mental notes of the depths of each change in texture, which are afterwards incorporated into the field log (cf. Figure J2). An experienced diver-geologist can distinguish layers such as shell, rubble, sand, peat, clay, and rock. The probe is jetted to the total length of the pipe (usually 7 m) or until it encounters a layer that it is unable to penetrate. On the Florida Gulf coast, karstified limestone formations on the inner continental shelf (e.g., Evans *et al*., 1985; Hine *et al*., 1998) usually limit jet probe penetration because sand deposits are less than 7 m thick. Nearly contiguous offshore sand ridges (described above), which are related to ebb-tidal deltas, and paleo barrier island, beach, and surf zone environments constitute the major source of beach renourishment sand on the central coast of west Florida. Jet probes, which are ideally suited to quickly and economically measure the thickness of thin sand deposits (i.e., <7 m in thickness), are therefore widely used in this geomorphic setting to determine the isopachs of shelf deposits that often occur in the form of sand sheets (shoals) or low ridges.

To obtain sediment samples from various depths, wash borings are obtained by the following methods. The geologist, who directs the jet probe into bottom sediments, takes two sample bags that are labeled "mid-depth" and "bottom of hole." The support diver, near the water surface, takes one sample bag labeled "surface sample." The probe is driven to its total depth of penetration, point of refusal (caused by hard layers, large floater, or bedrock) or maximum length of pipe. If that depth is 6 m, for example, the probe is pulled out and a second hole is

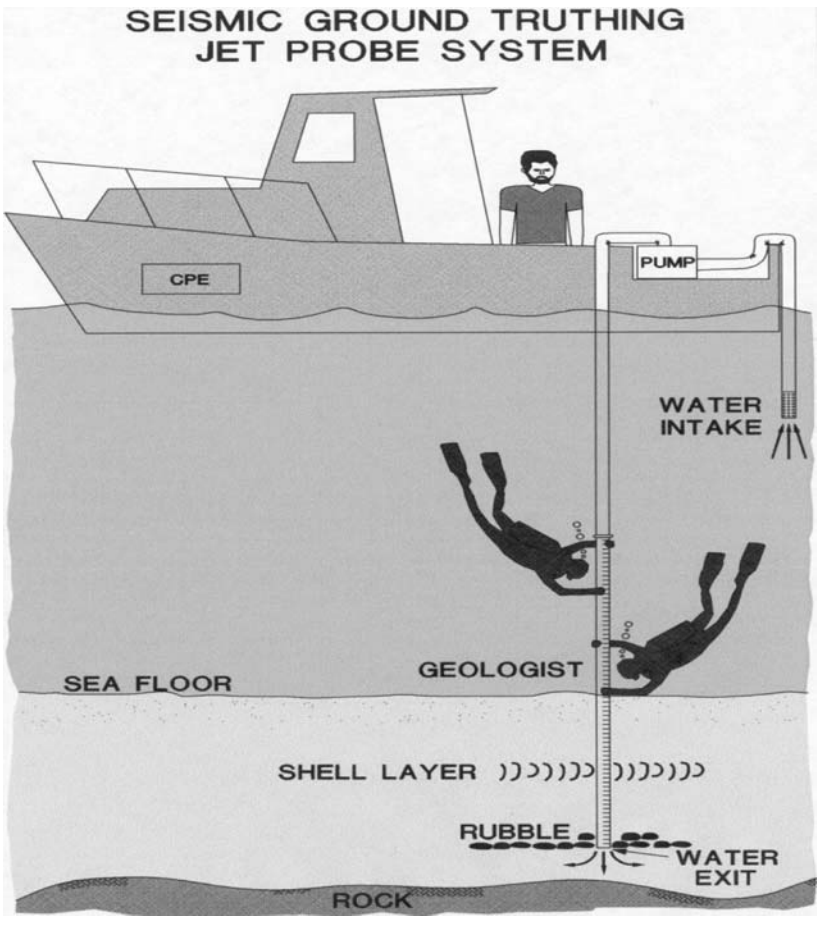

Figure J4 Schematic diagram showing the procedure for jet probing bottom sediments on the seafloor. Note that the portion of pipe that penetrates into the sediments contains graduated marks so that sediment thickness can be accurately determined. The geologist-diver works at the lower level near the seafloor and is proficient at estimating the nature of the materials probed by the "feel" of the pipe as it penetrates to refusal or reaches the end of the pipe.

probed to a depth of 3 m, 2–4 m up current from the first hole. The geologist pulls the first probe and the support diver signals the boat to haul the probe to the surface. The geologist takes a sample of the material that has formed a mound (spoil pile) around the probe hole and places it in the "bottom of hole" sample bag. A subsample of the material forming a mound around the second (shallower) hole is placed in the bag labeled "mid depth." The support diver, after the jet probe is hauled to the surface workboat, swims toward the bottom while moving against the current at about 2 m from the probed area (first two holes) and obtains an undisturbed "surface" sample from the bottom.

The subsamples removed from the washout mounds provide a representative bulk sample of the material that the probe passed through and which was jetted to the surface by the water pressure in the pipe. Materials comprising the washout mounds are deposited in the reverse order of the actual stratigraphic layers in the bottom sediments. Wash borings tend to have inherently low slit contents because the fine-grained particles, which have lower specific gravities than larger grains, tend to remain in the water column as suspensiods. The denser grains thus settle annularly in a mound around the jet probe. Suspension of fine-grained materials (typically silt plus clay and possibly organics) produces turbidity clouds in the water, which are quickly dispersed by currents. It is essential for the near-surface support diver to estimate changes in the turbidity plumes issuing from the jet probe so that the presence of fine-grained sediments is not under estimated from inspection of the heavier wash borings that quickly settle out of the water column. With experience, estimates of fines at different depths can be surprisingly accurate. Even though these samples (spoil from jet probing and estimates of fines) are extremely useful in the selection of areas for additional investigation, they are not meant to supplement or replace vibracores when defining borrow sites.

Upon returning to the surface workboat, both the diver- geologist and support diver immediately relay their underwater jet probing observations (i.e., depths of penetration, nature of the materials in different layers, and levels of turbidity that were associated with different depths) to the second onboard geologist who records this information in a permanent logbook. The descriptions relayed to the logbook should also include information that is relevant to characterization of the seafloor surface viz. sand ripples, algae, sea grass, surface rubble, or other observations. This information is often used to assist in the interpolation of sidescan sonar data. The sand samples are cataloged and notes on the texture (grain size) and color are recorded.

To prepare jet probe data for inclusion in reports, data that were recorded in the logbook are digitally entered into a jet probe log that is formatted in a manner similar to vibracore logs (see *Vibracores*). Sand samples are sieved to determine grain size and compared, in both wet and dry states, with a Munsell soil color chart. Representative samples are archived in small sample bags for presentation, reporting, and review. An example of data compilation for a jet probe survey is summarized in Table J1, which shows the classification of the jet probe, local relief of the surrounding seafloor, penetration of the probe, grain size, turbidity, and other relevant observations. Classification of the jet probe is important to interpretations of the survey because a single probe does not determine the viability of a deposit. The classification reported here is not universal, just an indication of what kind of system might be devised to show the resource potential of a probed area. Categorization of the "area of influence" for a single jet probe is comprehended by the application of "buffers," whereas multiple jet probe penetration defines a deposit. The buffer concept for jet probes represents an area that expands or contracts, depending on local sedimentary and geomorphological conditions. A sand sheet deposit will, for example, have a larger buffer zone around each jet probe because these kinds of deposits tend to be rather uniform over relatively large distances. The buffer around a probe on isolated sand ridges or in valley fills (i.e., drowned fluvial valleys, delta distributaries, tidal channels) will be a smaller zone because these kinds of deposits have limited lateral extents and conditions of sedimentation change in relatively short distances away from the probe. Local relief of the seabed in this area, increased by the presence of sedimentary bodies, is an indication of penetration depth for jet probes. Figure J5 demonstrates the observation with a fairly good correlation coefficient ($R^2 = 0.3935$). Once a survey is completed and the full range of parameters is appreciated and incorporated into an electronic database (see below), each jet probe is back classified so that it indicates the location of potential sand resources to be further investigated by refined geophysical (seismic and sidescan sonar) and geotechnical (vibracore) methods. Each jet probe is thus classified into one of five categories that range from unsuitable to a high potential for use. The categories are defined in Table J1 and it is important to note that application of the buffer concept in a spatial context on maps permits the recognition of sands (and the associated seafloor texture as seen in sidescan sonar images, three-dimensional bathymetric models, or isobathic expression of geomorphic units) that are potentially useful in beach replenishment projects. Grain size is determined by granulometric procedures from the subsamples collected by the geologist manning the jet probe. Turbidity is reported as estimated in the field and is a rough guide to the percent silt in the deposit (which is accurately determined later in the laboratory). Other observations included in Table J1 refer to the presence of rock fragments (e.g., limestone rubble, coral fragments), whether grain sizes fine or coarsen upwards or downwards, or any other property that should be noted.

Modern jet probe surveys are interfaced with advanced navigational software and differential GPS that make it possible to incorporate data into GIS database systems in such a way that reconnaissance-level surveys can be easily updated by new information and to facilitate efforts to groundtruth geophysical and geotechnical surveys. Table J1 is an example of the kind of jet probe-related information that can be extracted from GIS databases or queried for specific purposes. GIS analysis rings also facilitate querying procedures that can locate potential targets for sand mining activities and that can also point to areas where sediment texture and compositional information is insufficient to make reliable conclusions as to the presence of quality-sand sources. On the basis of jet probe data and other information, specific sand deposits are identified for detailed field surveys. Summary reports are usually prepared in a composite GIS framework, that is, in an electronic database and maps that help estimate sand volumes and approximate costs for detailed investigation of each potential borrow area, based on characteristics such as grain size and distance from the beach nourishment site on the shore and dredging suitability.

Conclusion

Jet probes are used to obtain information related to surficial sediment thickness on land and in shallow coastal waters. On land, jet probes may be powered by air or water pressure forced through a length of pipe. Jet Probes represent a good low-cost survey method for reconnaissance surveys on the sea and lakebeds. They are applicable to archaeological investigations and stratigraphic studies of thin sedimentary sequences, but it is in the search for beach-compatible sediments on the inner continental shelf that they find greatest use.

As a coastal resource tool, jet probes are often underutilized because researchers tend to use more sophisticated survey methods in the belief that greater value is received from greater expenditure. Jet probes are, however, an economical way of determining not only the thickness of sedimentary bodies but also their composition, grain size, compaction, and inclusions of rock fragments or other materials. When used collectively with a defined area as a specialized reconnaissance survey method, jet probes provide groundtruthing for geophysical, geotechnical, geological, and geomorphological interpretations of the seabed sediments. The main drawback for jet probing is that operators need to acquire sensitive skills for interpreting the "feel" of probe penetration. With some practice, however, geologist-driver operators can become proficient estimators of the various parameters that are normally associated with jet probe surveys. The most widespread application of jet probing is in coastal sand searches because increased knowledge of offshore sand resources is required for beach nourishment projects. Maximum water survey depths for jet probing are limited to about 30 m and the depth of penetration to the length of pipe that is easily handled underwater, usually about 7 m. For practical considerations, the minimum operating depth in water is about 1 m. As the search for sand resources intensifies, due to increasing erosion of beaches and coastal land loss on protective barrier islands and shoals, jet probes will increasingly serve as comparatively inexpensive procedures for evaluating seabed sediments on inner continental shelves.

Advanced geophysical and geotechnical procedures are essential for the accurate definition and location of sand resources on the inner shelf; however, these resources can be optimized if backed up or verified by low tech and less costly efforts, such as jet probing, that are essential to the efficiency and economic success of offshore sand searches. Advancements in positioning and navigation software and hardware that can be interfaced with GIS systems in the field permit analysis of spatial data associated with the jet probes in a timely fashion that increase survey efficiency and applicability. Although combinations of modern marine exploration techniques have contributed to the cost-effectiveness and success of sand search investigations, they are of reduced value if they are not accompanied by logical and rational planning of surveys in accordance with local geology and geomorphology.

Charles W. Finkl and Lindino A. Benedet

Table J1 Summary of field results for a jet probe survey off Charlotte County, southwestern Florida.

Jet Probe (#)	Category (rank)[a]	Relief (ft)	Penetration (ft)	Grain size (mm)	Turbidity (estimated)	Observations and notes
1	3	N/Av[b]	19	0.18	M to H[c]	Four feet of silty sand with clay balls on top/ no refusal
2	4	N/Av	12	0.24	H; H to M	Three feet of sand with silt/clay on top
3	5	N/Av	14	0.42	L to M	Slightly fining upwards
4	5	N/Av	20	0.31	L to M	Slightly fining upwards/no refusal
5	4	5	5	0.23	L to M	Fining upwards (1 ft layer), rock on bottom
6	4	5	7	0.35	H	Two feet of silty sands on top, 1 ft rubble on bottom
7	3	3	4	0.23	M to H	Fining upwards, rock on bottom, not well-defined ridge
8	2	4	3.5	0.19	M to H	Homogeneous, rock on bottom
9	1	4	3	0.16	H	One-foot thick layer of silty sand on top
10	2	5	7	0.17	L to M	About 4% silt and very fine sand
11	3	4	3	0.33	M to H	Fining upwards, relatively thin
12	1	4	3.5	0.17	H	Silty sands, 0.5 ft of rubble
13	2	5.5	4.5	0.17	M to H	One layer of silty sand on top
14	2	4.5	7.5	0.15	L to M	Fining upwards, very fine sediments
15	3	5	4	0.71	H	Fining upward, shell fragments
16	3	4.5	5	0.19	M	Finer than 0.2
17	2	5	8	0.14	H	Silty sand, too fine and H turbidity
18	4	5	9	0.16	M to H	Finer top, 0.5 mm visual estimate of bottom sand
19	3	6	16	0.14	M to H	Finer top, coarser on bottom (0.23 visual estimate)
20	2	1	3	0.22	H	Finer silty sand in top layer
21	4	6	8	0.23	M to H	Fining upwards, 1′ silty sand on top, 0.5′ rubble bottom
22	4	4	6	0.23	M to H	Fining upwards, at least 4 ft of fine–medium sand
23	3	4.5	4	0.95	M to H	Shell fragments, some silt in top 2 ft
24	4	7	7	0.52	M to H; L to M	At least 4 feet of clean sand, silty sand in top 2 ft
25	3	4.5	6	0.17	L to M	Clean sediments but too fine
26	5	3.5	5	0.23	L to M	Five feet of clean sand
27	5	4	8	0.37	L to M	Eight feet of clean sand, fining upward
28	4	6	6	0.19	L to M; M to H	Somewhat finer-grained than neighbors
29	5	3	5	0.29	M; M to H	Four and one-half feet of clean sand
30	2	2	2	0.41	M to H	Missed the top of the ridge
31	3	3.5	3	0.28	M	Missed the top of the ridge
32	3	3	3	0.22	H	Limited penetration, high turbidity
33	3	4	4	0.19	M to H	Fine sand, M to H turbidity levels
34	1	1	0	—	—	Trough before reef gave a “false-ridge” impression
35	1	3	3	0.16	H	Fine sediments, high turbidity, limited thickness
36	1	2	2	0.22	H	Limited thickness, high turbidity
37	2	3.5	3	0.34	H	Limited thickness, high turbidity
38	2	3	5	0.2	M to H	Silty sand on top, relatively high silt %
39	3	3	4	0.54	M	Shell fragments, 3 ft of clean sand
40	3	3	3	0.6	H	High turbidity, limited thickness
41	1	1	2	0.19	H	Trough after outcrop, limited thickness and silty sediments
42	3	3	4	0.6	M to H	Limited thickness, shell fragments, 1 ft layer of rubble 3 to 4′
43	4	2.5	5	0.57	L to M	One foot of rubble from 4 to 5
44	5	3.5	6	0.5	M	Five and one-half feet of coarse gray sand
45	2	3	2	0.22	L to M	Missed depositional area
46	5	3.5	11	0.25	M	Homogeneous sediment distribution
47	4	N/Av	14	0.17	L	Coarsening upward
48	2	N/Av	15	0.13	L	Sediments <0.15, but coarsening upwards and low turbidity
49	2	N/Av	15	0.13	L	Sediments <0.15, but coarsening upwards and low turbidity
50	2	N/Av	15	0.15	L	Sediments <0.15, but coarsening upwards and low turbidity

Table lists major criteria that are useful for the interpretation of sand deposits. Information that is summarized in tubular form assists in the identification of materials that are suitable for beach replenishment.

[a] Buffers divide jet-probed sedimentary deposit thickness into four categories based on sand quality and dredging capabilities, as follows: (1) Unsuitable: Deposit is less than 0.5 m thick, or mean grain size <0.17 mm, or there are high levels of turbidity during jet probing. (2) Marginally useful: Deposit is less than 1 m thick, or mean grain size is <0.2 mm, or the deposit is thicker with larger grain sizes but there is high turbidity, or the presence of silty sands or rubble layers. (3) Conditionally usable: Deposit thickness is between 0.5 and 1 m with relatively good quality sediments containing a mean grain size greater than 0.2 mm, but there are limiting factors such as limited thickness of sand bodies, or high turbidity levels, or good penetration but sediments analyzed <0.2 mm but visual description on other layers was >0.2 mm mean diameter of sand grains. (4) Potentially useful: Deposits thicker than 1 m but less than 1.5 m and sand grain sizes are between 0.2 and 0.25 mm; there is moderate to low turbidity. (5) High potential for use: Deposit is more than 1.5 m thick and sand grain size is more than 0.25 mm, there is moderate to low turbidity.

[b] N/Av = not available.

[c] The terms low, medium, and high are relative estimates of silt content based on visual interpolation of turbidity plumes.

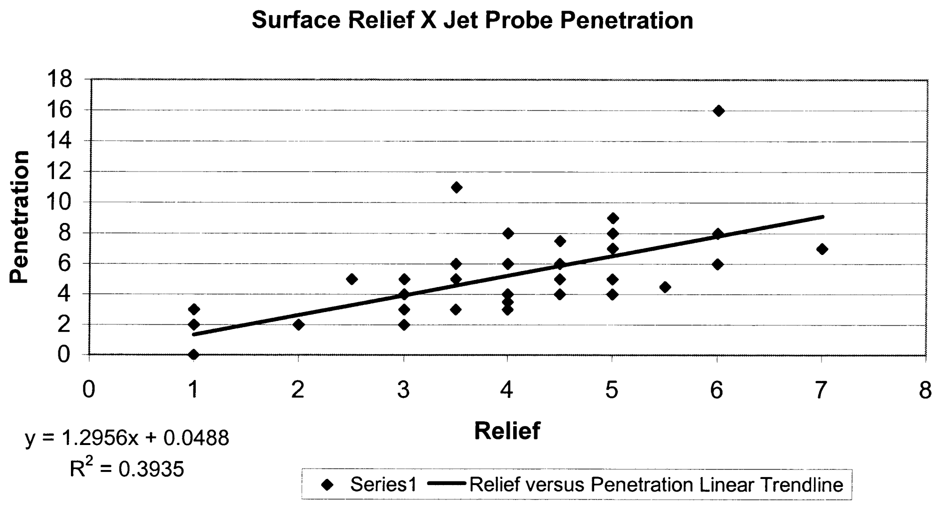

Figure J5 Linear regression analysis for a subset of jet probes collected offshore Naples, Florida, showing that jet-probe penetration increases with increasing local relief of sediments on the seafloor. The survey area included a series of sand ridges with intervening troughs. The troughs contained a thin veneer of sand (generally less than 0.5 m) over limestone bedrock whereas the sand ridges had a local relief up to at least 2.5 m (units on the graph are in feet).

K

KARST COASTS

Karst coasts are defined as coasts made of calcareous rocks and showing distinctive geomorphic characteristics related to their lithologic nature (Jennings, 1985). In some cases, these original features are directly due to seawater action and marine weathering. Halokarst is a word sometimes used to designate such erosion forms (Fairbridge, 1982). In other cases, karst coasts correspond to the exposure by coastal retreat or to the drowning by the postglacial transgression of subaerial or underground karst features, which are actually the result of limestone solution in continental environments (Trenhaile, 1987).

Coastal karstification

Seawater corrosion

The word corrosion, introduced by A. Guilcher, includes different chemical, physicochemical, and biological processes operating on carbonate-rich rocks in coastal environments and resulting in specific erosional features.

The ability of seawater to dissolve calcium carbonate has long been a contentious issue. Nowadays, the most widespread opinion is that no real evidence favoring solution has been produced. It appears that coastal seawater is saturated or oversaturated with calcium carbonate and data-showing solution at night, through emission of carbon dioxide by green algae living in pools, is not wholly convincing. However, recent work seems to indicate that chemical erosion has been underestimated (Miller and Mason, 1994). It is now proved that, at least in tropical environments, undersaturation of inshore waters may occur at night with respect to calcite and at any time with respect to aragonite and high magnesian calcite, accounting for some 10% of the erosion in coralline limestones (Trudgill, 1976).

Bioerosion (*q.v.*), a term for the removal of rock by the direct action of living organisms, is generally acknowledged to play the greatest role in the development of coastal corrosional features, not only in the tropics where an enormously varied marine biota live on calcareous substrates, but also in higher latitudes (Kelletat, 1988). Algae are probably the most important erosive organisms, both in the intertidal and the supralittoral zones. Endolithic cyanophyta are boring organisms that actively contribute to the rock destruction. Fungi and lichens also are effective rock borers. Grazers consuming the microflora, such as the gastropods *Littorina* and *Patella*, can cause mechanical rasping of rock surfaces, which have been weakened by the penetration of endolithic algae. The chiton *Acanthopleura* has hard teeth that enables it to erode resistant limestones. Borers are responsible for excavations into the substratum. Penetrating habits of *Lithophaga, Lithotrya, Cliona* are frequently mentioned. *Lithophaga* acts through mechanical boring facilitated by acid secretion, which causes a softening of the rock. The sponges pertaining to the genus *Cliona*, which are able to bore microscopic to macroscopic excavations in limestones, play a particularly important role in the disintegration of rock substrates. Also worms, such as *Polydora*, may be active borers in calcareous substrates. Biological erosion is of great significance on the limestone coasts, which may justify the term of biokarst which has been proposed for the resulting forms (Spencer, 1985).

In the supralittoral zone, physicochemical processes operate jointly with bioerosion. Spray action, implying wetting and subsequent drying, leads to salt crystallization and causes rock disintegration. Eolianites are especially prone to such kind of weathering.

The rate of sea corrosion in calcareous rocks has been measured in a great number of sites all over the world. A figure of about 1 mm per year may be considered as an average rate.

Shore platforms

Bare erosional platforms (see entry on *Shore Platforms*) may be found on low carbonate-rich rocky coasts where waves are not supplied with clastic tools of allocthonous origin, which enhance their mechanical action. Figure K1 represents a typical profile of a corrosional shore platform from the Mediterranean which can be used as an illustration of a littoral karst in subtropical, low wave energy, and microtidal conditions. There is a general zoning of forms between low water mark and the area reached only by spray. The main feature of the midlittoral (intertidal) zone is represented by a platform, several meters in width, which is called trottoir (*q.v.*), a French word for sidewalk (Figure K2). In its upper part, the platform shows pools with overhanging edges and, lower down, wide shallow pools with flat bottoms, the so-called "vasques," which are separated by low, narrow, continuous, sinuous rims made of residual rock or built by calcareous organisms. Seawards, before terminating abruptly in a small vertical infralittoral cliff, the platform is often characterized by an overhanging ledge made by vermetids (*Dendropoma*) and calcareous algae (*Neogoniolithon*). Sometimes, a fossil trottoir, a few tens of centimeters above the active one, characterized by crater-shaped pools, is found, pointing to a higher relative sea level during the Holocene. Further up, in the supralittoral zone where spray is acting, above an overhanging cliff pitted by alveoles and vermiculations, jagged and sharp lapiés are found (Figure K3). They are separated by deep pools with overhanging rims. In fact, wave energy, tidal range, and mainly seawater temperature are the most important parameters which explain a great variety of shore platforms in carbonate rocks. In cool temperate regions, the trottoir is unknown, whereas in warm seas the presence of deep notches and protruding visors is noticeable (Guilcher, 1953).

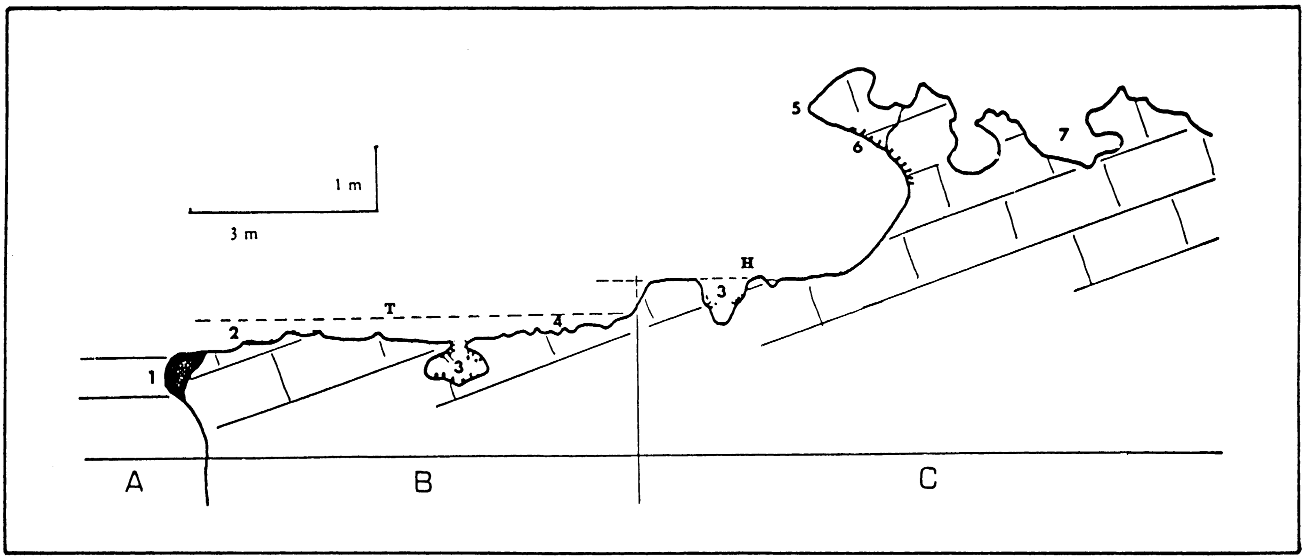

Figure K1 Schematic profile across a limestone shore platform in the Mediterranean, after R. Dalongeville (1977). A, infralittoral zone; B, midlittoral zone; C, supralittoral zone; H, elevated trottoir indicating a Holocene relative sea level higher than the present one; T, trottoir; 1, vermetid ledge; 2, shallow pool of vasque type; 3, pool with overhanging sides; 4, alveoles; 5, overhanging cliff; 6, vermiculations; 7, lapiés and pools.

Figure K2 Typical trottoir developed into an upper Pleistocene eolianite, northern Israel coast. (Photo R.P. Paskoff.)

Notches

Coastal *notches* (*q.v.*) are indentations due to lateral cutting by sea corrosion, which is particularly active on calcareous-rich rocks in tropical waters (Figure K4). Cliffs, low rocky shores, or wave-thrown large boulders on coral reefs may be affected by notches, which are good indicators of sea-level position, especially where the tidal range is low and the coastal environment sheltered. Site exposure is the most important factor and two main types of notches are to be distinguished (Pirazzoli, 1986): (1) tidal notches, in relatively protected sites and cut in the intertidal zone, which are relatively narrow; (2) surf notches in exposed sites and cut above high tide level. In the case of the first type, when the undercutting is well developed, being 2–3 m deep, the notch roof often forms an overhanging rock ledge, called the visor. Deep tidal undercut on low stacks and isolated blocks may result in mushroom-shaped rocks. Surf notches have a distinctive morphology due to water turbulence and spray action. Organic accretion around high tide level by calcareous algae and vermetids protects the substrate calcareous rock and inhibits sea action, meanwhile erosion proceeds above, forming an asymmetric notch with generally a short roof and a developed floor which eventually may form a bench protruding seaward. Simultaneously, bioerosion, is responsible for the development of another notch around low tide level. Consequently, double notches are not necessarily evidence of a relative sea-level change.

Solution pipes in eolianites

Calcareous eolianites or eolian calcarenites are subaerially cemented paleodunes (see entry on *Dune Calcarenite*). They characterize many coastal regions which are semiarid at present and they may also be found in those which were semiarid at some stages during the Pleistocene, a period of important sea-level oscillations and climate changes. They have been described from the Mediterranean, the Canary Islands, South Africa, southern and western Australia, Bermuda. Diagenesis by continental waters of the carbonate-rich sand deposits, largely composed of fragments of marine organisms, took place in a vadose environment and generally includes dissolution of unstable aragonite and high-Mg calcite, and precipitation of relative low-Mg calcite.

Such eolianites may be affected by piping, which produces tubular underground conduits (Figure K5). For instance, in northern Tunisia, conspicuous pipes, 20–40 cm in diameter and a few meters deep have been reported (Paskoff, 1996). They are cylindrical in shape, taper vertically downward, and occur in aggregated clusters. They show a red coat which is a hardened calcitic crust and are filled by red silts and sands, sometimes strongly cemented. In the early literature, it was suggested that pipes represent the pseudomorphs of former tree stumps buried under advancing sand dunes. They were also simply explained as random solutional features corresponding to points where percolating water happened to converge and caused localized subsurface dissolution. A more appealing explanation was recently put forward for the Bermuda pipes by S.R. Hervitz (1993) who suggested that the cylindrical vertical conduits are the products of the stemflow of tree species capable of acidifying intercepted rain water and funneling large quantity of it down their trunks. The result is a subsurface dissolution forming pipes, which extend vertically downward through eolianites.

Exposed and submerged terrestrial karst on coasts

There are coasts where karst landforms can be followed from the land into the sea practically without any substantial modification. A conspicuous example of such a situation is given at Along Bay, near Haiphong, in northern Vietnam, where a typical tower karst, developed in a humid tropical environment, has been submerged and makes up an archipelago of islands and islets in a shallow sea (Figure K6).

Exposed karstic landforms

As a result of coastal erosion, continental karstic features may have been exposed and modified by marine processes. For instance, the nearly vertical chalk cliffs (see entry on *Chalk Cliffs*) of the Normandy coast, in France, show typical solution forms of terrestrial origin, which have been revealed by the shoreline retreat. There are examples of inherited karstic caves debouching in the face of the cliffs. Others have been captured by sea caves developed at the foot the cliffs under mechanical wave attack. Coastal erosion has also exposed deep cylindrical hollows, which originally formed as solution pipes. The famous arch and pillars at Etretat owe their existence to marine action in a highly karstified area. The crest of the Normandy chalk cliffs shows a crenulated appearance,

Figure K5 Vertical section of a solution pipe on an active sea cliff developed into an upper Pleistocene eolianite in northern Tunisia. (Photo R.P. Paskoff).

which is due to dry valleys, locally called *valleuses*, now hanging as a result of coastline recession. Near Cascais, in central Portugal, on a rock coast, bare and deeply developed lapiés are exposed in the upper mid-littoral zone because decalcification red silts which once covered them have been stripped off by swash denudation. In Australia, west of Melbourne, the Port Campbell coast illustrates the effects of marine erosion processes on a highly karstified area of Miocene limestones. Sinkholes and caves have been cut by wave action (Baker, 1943).

Drowned karstic landforms

The interaction between continental processes, sea-level variations, and wave erosion is well illustrated by subaerial or underground features which developed in limestone terrains, such as enclosed depressions or caves, and are now invaded by the sea. In this respect, Malta gives conspicuous examples of what could be called marine sinkholes, originally karstic features developed in coralline limestones (Paskoff and Sanlaville, 1978). On Gozo Island, Dewra Bay is a semi-circular cove, measuring 340 m in diameter, which results from marine erosion breaching a doline wall whose eastern half alone has been preserved and whose bottom is now largely occupied by the sea. An islet, Fungus Rock, is the last remnant of the destroyed western wall (Figure K7). Qwara, an immediately neighboring landform, is an identical circular sinkhole, 400 m in diameter and 70 m deep, bounded by vertical walls, which remained unbreached, but has been nevertheless partially inundated through a karstic gallery now connecting the open sea with the depression. Blue Grotto, in the southern part of the main island, corresponds to another kind of cove which is due to the sea eroding into a large cave system and causing subsequent roof collapse. In Asturias, Spain, different types of periodically or permanently flooded dolines, by salt water, have been described (Schülke, 1968). Marine charts of the subsident Dalmatian coast, in Croatia, clearly show broad enclosed basins of polje type, which are completely submerged (Baulig, 1930). The extended Novigrad Bay is regarded as a polje invaded by the sea. The freshwater lake of Vratna, on the island of Cres, appears to occupy the floor of an uvala, a large depression resulting from the coalescence of sinkholes, which was deepened when sea level was lower than now and became a permanent lake as a result of the postglacial transgression. In the vicinity of Marseille, in France, giant lapiés have been identified at a depth of 40 m in the Veyron Bank. In the same area, the partly submerged Cosquer cave, which was discovered in 1991 and became notorious for its exceptionally nice paintings and engravings dating back to the upper paleolithic period, has only one entrance located at 37 m

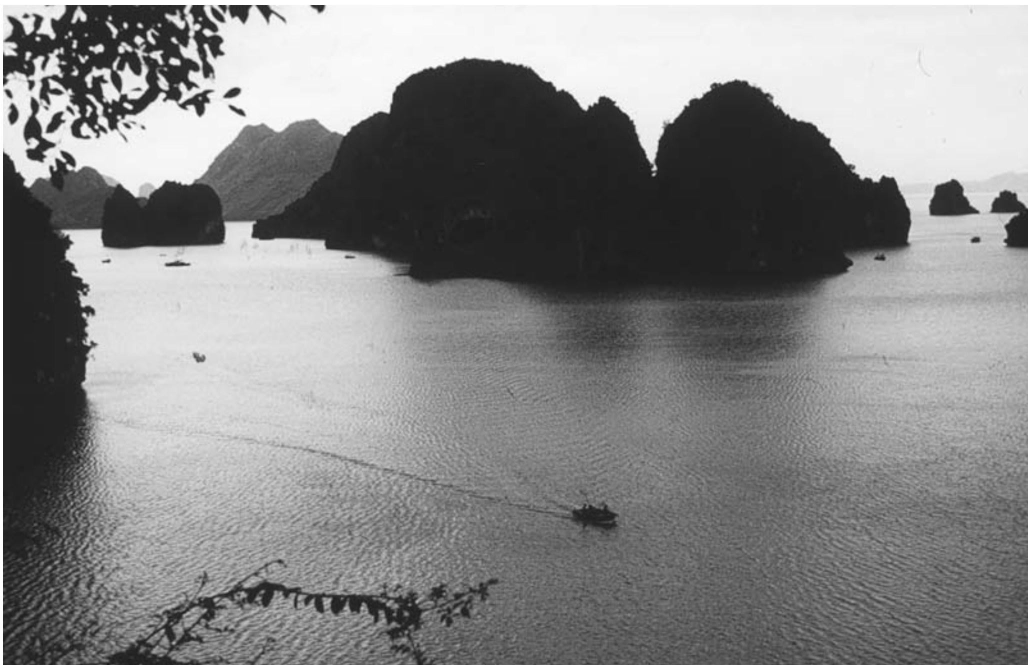

Figure K6 Islands and islets corresponding to a submerged tropical karst, Along Bay, northern Vietnam. (Photo M. Paskoff.)

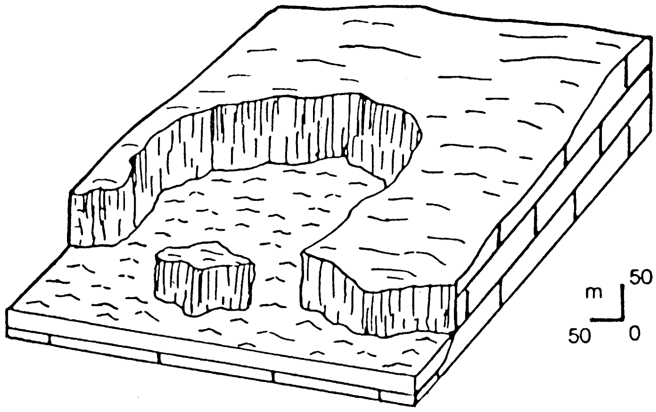

Figure K7 Dweyra Bay and Fungus Rock, Gozo Island, Malta: a semicircular cove created through sea invasion of a doline (after Paskoff and Sanlaville, 1978).

under present sea level. The limestone littoral of Provence, as others calcareous coasts in the Mediterranean, shows many active submarine springs or resurgences, for instance the one at Port-Miou, near Cassis, east of Marseille, located at a depth of 12 m.

Calanques or calas

Calanque from the French coast of Provence or *cala* from the Balearic islands in Spain are words which designate a narrow, short, and drowned valley with steep sides, developed in limestone terrains and continued inland by a dry course. Several types have been identified, as in Malta, for example (Paskoff and Sanlaville, 1978). Some are of ria type. They were deepened during glacial periods of low sea level and pluvial climate, which facilitated the cutting of deep ravines by stream action, subsequently submerged in their lower portion by postglacial transgressions, as it was the case with the Holocene sea-level rise (Figure K8). The amazing pattern of digitate calanques, which makes the site of the capital city, Valletta, one of the finest anchorages in the world, corresponds to a branching valley system whose deeply and extended drowning resulted from a marked subsidence in this area. Other calanques are linked with continental karst processes. They appear, at least partly, related to the formation of subterranean caves and conduits by freshwater solution of limestones along faults. Later on, wave erosion opened these cavities and the rushing of marine water caused the roofs to collapse. Such a case raises an important question about the extent to which karst features can develop below the sea without any change in the relative level of land and sea. If the response is positive, calanques may form without a marine transgression being necessary.

Karstified coral reefs

According to some authors, barrier reef and atoll morphology (see entry on *Coral Reefs*) is fundamentally karst induced (Purdy, 1974). This theory, sometimes called "the karstic saucer theory" (Guilcher, 1988) and still in discussion, states that the shape of such reef forms derives from antecedent and horizontal coralline platforms, which were emerged and modified by subaerial solution processes. It is logical to assume that all reefs which are today at or near sea level were emergent during the glaciation periods. Being emerged, they became karstified. Rainfall and percolating water action is supposed to be more rapid toward the interior of the calcareous platforms than around their steep edges where runoff is rapid. The result is a saucer-shaped surface dissolution with a central depression and a peripheral raised rim interrupted by ravines through which a part of the water escaped, the other part percolating through the limestone. Subsequent submergence of karst-eroded platforms started a revival of coral growth and the ramparts resulting from previous subaerial karstification became barrier reefs or atolls.

The karstic saucer theory, which is not in contradiction with the Darwin's subsidence theory of coral reef formation and can be combined with it, is supported by geomorphic observations. Floors of many lagoons are characterized by numerous upstanding pinnacles or knolls which rise from various depths and have living coral on their surfaces. They are generally interpreted as remnants of karstification during low sea-level glacioeustatic phases and compared with the tower karst developed in rainy tropical environments. Lagoons may also show pits which are considered as submerged sinkholes or blue holes. At Mayotte, a Comoro island, the bottom of the lagoon shows several enclosed depressions with steep sides, 60–70 m deep, lying at approximately 20 m below the surrounding floor. These features are obviously the result of a subaerial karstification. Mataiva, an atoll in the Tuamotu archipelago, has a reticulated lagoon formed by a network of about 70 pools of varying sizes, with an average depth of some 10 m, separated by shallow ridges. This strange honeycombed pattern whose exact conditions of formation remain uncertain is thought to derive from a complicated evolution during which tropical phases of karstification are supposed to have occurred when the structure was emerged. So, it appears that the sea-level lowerings related to the Pleistocene glaciations have in many cases determined a karstification of preexisting coral structures.

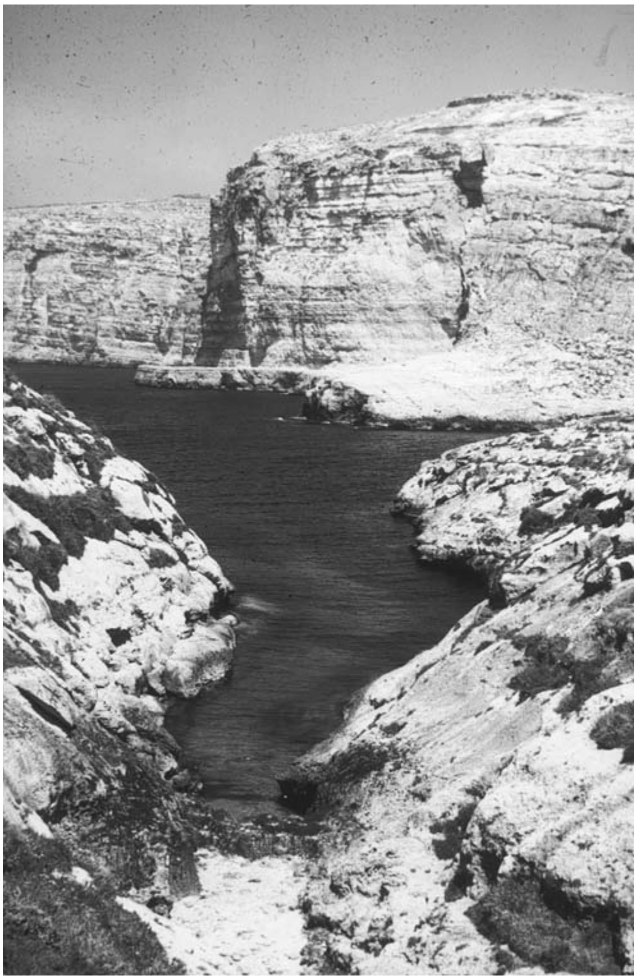

Figure K8 Typical calanque in the island of Gozo, Malta. It corresponds to a partially drowned valley, with steep sides, cut into coralline limestones. (Photo R.P. Paskoff.)

KLINT

The term klint, widely used in countries around the Baltic Sea, was originally a Danish and Swedish word synonymous with *klev*, signifying an escarpment in sedimentary rocks. Usually it comprises a line of marine abrasion or ancient (pre-Quaternary) fluviatile erosion scarps. In Swedish, the word occurs synonymously with *grike*, signifying a type of hollow formed by karst weathering (Martinsson, 1958), and also means mountaintop or bioherm (coral reef) hillock. Also the term *fjällglint* is used for rock formations in a Scandinavian mountain ridge (*fjällkedjan*). In German literature the word *glint* is preferred and in such form was adopted also in Estonia, the classical klint area (Tammekann, 1940). The word in English is often recorded as *clint*, in Russian *glint* (more rarely *klint*), in Latvian *glints* (*klints* in Latvian means *rock*), and in Lithuanian *klintas* is used. The corresponding Estonian word is *paekallas*; for separate klint lobes and promontories the word *pank* is also used.

Distribution and structure

The most well-known klint in the Baltic Sea area is the Ordovician. It consists of an almost continuous, but indented and lobated arc, from the western coast of the Island of Öland (Västra Landborgen) in Sweden over the Baltic Sea via the north coast of Estonia to Lake Ladoga in Russia (Figure K9). This monumental escarpment, up to 56 m high (at Ontika in Estonia) and 1,200-km long, is called the Baltic Klint (Figure K10). Its basal part consists of Cambrian rocks, dominated by sand- and siltstones and soft "Blue clays." The hard crest layers of the klint, however, which primarily cause the steepness of the escarpment, consist of Ordovician limestones (Orviku, 1940). In the westernmost area, on the Island of Öland, the klint crest is developed exclusively in Middle Ordovician limestone beds. A submarine Ordovician klint, as a morphological feature, has been identified on sea charts and with

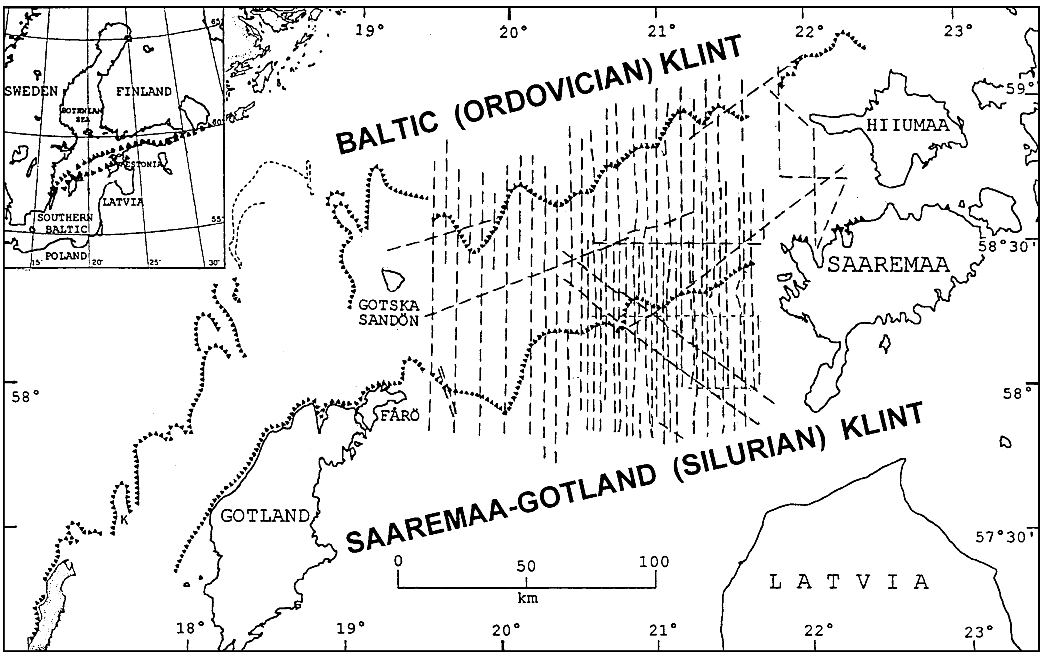

Figure K9 The distribution of klint (black triangles) in the Baltic Sea area. Compiled by R. Vaher, based on the data published by A. Martinsson (1958) and I. Tuuling (1998). Dashed lines mark seismic profiles.

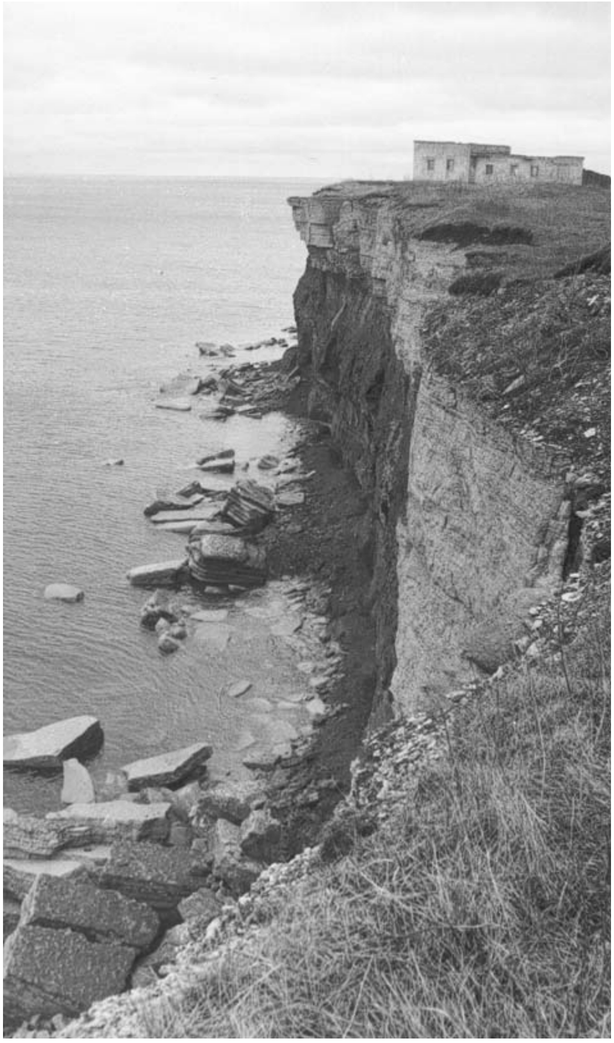

Figure K10 The Pakerort Klint on Pakri Peninsula, northwestern Estonia. (photo by A. Miidel.)

geophysical sounding methods (Figure K9). The Baltic Klint, called North-Estonian Klint in the Estonian mainland, is dissected by river valleys forming over 20 picturesque waterfalls (Aaloe and Miidel, 1967). A submarine Vendian–Cambrian klint line in the scientific literature indicates not only the escarpment line, but also the border between the Fennoscandian Shield and the Russian Platform.

To the north of the Baltic (Ordovician) Klint on the seafloor, Vendian and Cambrian scarps and to the south step-by-step Silurian, Devonian, and Carboniferous klints crop out. The Saaremaa–Gotland (Silurian) Klint in Silurian strata forms an arc of more or less lobed scarps along the northwest coast of Gotland Island in Sweden, on the seabottom and on the north coast of Saaremaa Island in Estonia, following to Central Estonia. The westernmost part of this klint arc limits the shelf on which two Karlsö islands, Store Karlsö and Lilla Karlsö, are situated. The larger part of the klint crest on Gotland reaches between 40 and 50 m above sea level. On Saaremaa, the height of cliffs is up to 22 m at Mustjala and on the Estonian mainland rarely more than 10 m. Devonian and Carboniferous klints in the contemporary topography differ from each other in scarps of different height and length.

Formation

Some klints in the Baltic Sea area began to develop during the Late Silurian and pre-Middle Devonian continental period (Puura *et al.*, 1999). Later the prolonged pre-Pleistocene erosional–denudational processes were of utmost importance, operating upon the main features of structural changes in the Precambrian crystalline basement and the sedimentary cover. The latter has a gentle southward inclination (6–18'). Due to the tectonic uplift, new areas were influenced by the lateral river flows forming questa-like topography with steep northern and gentle southern slopes. The influence of the old drainage systems upon the klint formation is evident. The Ordovician klint system developed throughout the entire length by the erosion of the soft, mainly Cambrian sandstone and clay strata, overlain by much more resistant limestones, which determined the retreat of the klint and caused the relative steepness of the feature. The bottommost part of the Saaremaa–Gotland Klint also consists of softer rocks in mainland Estonia, for example, from marls of the Jaani Regional Stage, overlain by the Jaagarahu limestones, a large part of which consists of reefs, which cause the dissected and lobated appearance of the klint. Zigzag contour lines in many places are dependant on tectonic joints.

During the ice ages the klints were influenced by glacial erosion and, after the retreat of the continental ice, the Ordovician and Silurian klints were strongly changed by wave action of the Baltic Sea. This influence was different, because different parts of the klints rose above the sea level at different times (Orviku and Orviku, 1969). If the Ordovician Klint at Ontika in northeastern Estonia was under the influence of waves during the Baltic Ice Lake more than 11,000 years ago, then the Island of Osmussaar in northwestern Estonia appeared above the sea level only some 2,000 years ago.

The term *klint* is used more and more not only in the Baltic Sea area, but also in North America and western Europe for the mentioning of steep escarpments with monoclinal bedding of sedimentary rocks. There is also a specific type of klint (glint)-line lakes in Norway and Scotland, which were formed between the ice and escarpments.

LATE QUATERNARY MARINE TRANSGRESSION

The total volume of water in the world's oceans exhibits a nearly perfect negative correlation with global ice volume; when one increases the other decreases. This is known as *glacial eustasy* (first proposed by Maclaren, 1842). The balance between global ice volume and ocean water volume is controlled by climate. At the last glaciation maximum some 20,000 radiocarbon years BP large quantities of water were withdrawn from the oceans and accumulated in the form of extensive continental ice caps. We may try to reconstruct past glacial volume changes by the following three means:

(1) the recording of corresponding sea-level positions, which are affected by numerous other variables;
(2) the recording of corresponding oxygen isotope variations, which are affected by other factors, too, not least temperature;
(3) volumetric estimates of corresponding ice caps, which is quite a rough method (presently stored ice in Antarctica, Greenland, and alpine glaciers are estimated in this way).

Though all three methods have their limitations and problems, there is a general agreement that the 20 ka glacial eustatic lowering was on the order of 120 m, as seen in sea level (e.g., Fairbanks, 1989), in oxygen isotope values (e.g., Shackleton, 1987), and in glacial volume (Flint, 1969). According to Chappell *et al.* (1996) there is an excellent agreement between the coral record of the Huon Peninsula in New Guinea and deep-sea oxygen isotope records.

The glacial eustatic rise in sea level as a function of the switch from ice age conditions at about 20 ka to interglacial climatic conditions is known as "the postglacial transgression." It commenced some 20,000 radiocarbon years ago and ended at around 5,000 radiocarbon years BP. This rise in sea level was neither smooth nor globally consistent.

Figure L1 gives the combined view of sea-level changes as established from coral reefs in Barbados, from sea-level data off west Africa, and from the eustatic component as calculated from multiple sea-level records in northwest Europe.

Oscillations were induced both by glacial eustatic variations and by the interaction with others factors acting on sea level. The largest glacial eustatic oscillations were those associated with the high-amplitude climatic changes at around 13–10 radiocarbon Ka ago, that is, the period including the classical climatic oscillations of the Bölling Interstadial, the Older Dryas Stadial, the Alleröd Interstadial, and the Younger Dryas Stadial (Fairbanks, 1989; Mörner, 1993).

Regional variations in amplitude and fine-structures of the transgression were induced by additional variables (Mörner, 2000). Those variables are deformation of the geoid relief (Mörner, 2000), internal adjustment to loading changes (e.g., Peltier, 1998), changes in earth's rotation, and the ocean circulation system (Mörner, 2000). Therefore, the actual sea-level rise after the last glaciation maximum differ significantly from place to place over the globe as illustrated by the atlas of Holocene sea-level curves (Pirazzoli and Pluet, 1991).

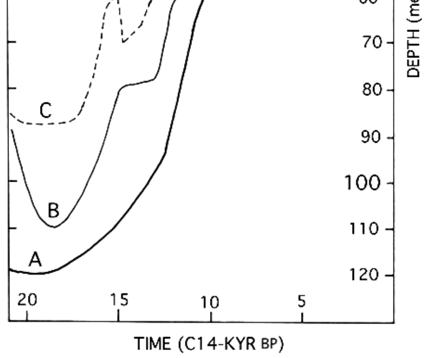

Figure L1 The postglacial transgression illustrated by the sea-level changes recorded in (A) Barbados, (B) west Africa, and (C) northwestern Europe. Depth in meters and age in C14-years BP.

Global sea level was dominated by the glacial eustatic rise in sea level up to about 5,000 radiocarbon years BP. After that, it was dominated by the redistribution of ocean masses.

LIFESAVING AND BEACH SAFETY

Lord, Lord! methought, what pain it was to drown!
What dreadful noise of waters in mine ears!
What ugly sights of death within mine eyes!
Methought I saw a thousand fearful wrecks,
Ten thousand men that fishes gnawed upon.

King Richard III
By William Shakespeare

Beaches are a major attraction for people throughout the world. In the United States, it is estimated that 85% of all tourism revenue stems from visits to coastal areas (Center for Marine Conservation, 2000). Like any natural area, however, hazards exist that can result in injury or death. Managing these hazards is key to ensuring that beaches can be safely enjoyed.

Drowning is the most serious problem related to beach and water use. Annual deaths by drowning, whether from floods, sinking ships, recreational swimming, home accidents, and other causes, easily outstrip deaths from war and terrorism. In 1997, for example, 4,051 Americans died by drowning (National Center for Health Statistics, 1997). According to the Centers for Disease Control and Prevention, drowning is the second leading cause of injury-related death for American children aged 1–14 years (National Center for Health Statistics, 1997). And death is not the only outcome of distress in the water. It has been found that for every child who drowns, 17 or more are treated at hospitals for complications related to near-drowning (Wintemute, *et al.*, 1988).

Beyond drowning, many other hazards exist in the aquatic environment. Spinal injury from shallow water diving occurs with unfortunate regularity, often caused by inadvertently diving into a submerged sandbar or bodysurfing over a wave and striking bottom. Scuba related illness has existed since the inception of scuba and, while the safety of equipment has improved, so has the volume of people scuba diving. Boating accidents, both recreational and commercial, are a source of injury and death. And of course, all of the common ailments related to any other physical activity occur in and around the water. All of these, and many more, have increased attention paid to accident prevention and, in particular, the provision of lifeguards at coastal beaches.

Ocean Beach in San Francisco provides a stark example. In 1998, three persons drowned on the first day of summer at this beach, which is beset by strong surf, consistent rip currents, and relatively cold water. No lifeguards were provided by the federal government, which owns the beach as part of a national park. Instead, strongly worded signs had been used in an effort to warn people away from use of the water. This was clearly not fully effective at preventing drowning.

As the summer of 1998 progressed, further drownings occurred, eventually totaling seven. There was heavy media attention and advocacy by groups like the International Life Saving Federation (ILS) and the United States Lifesaving Association (USLA) for the immediate provision of lifeguards.

Under public and political pressure, the National Park Service ultimately relented and provided preventive beach rescue services beginning at the start of the summer of 1999. During that summer, there were no drownings. Lifesaving services have continued since.

Lifesaving history

In historical terms lifesaving, as an organized response to persons in distress in the water, is young. The rescue of shipwrecked sailors appears to have spurred some of the earliest organized efforts. China's Chinkiang Association for the Saving of Life was established in 1708 as the first of its kind in the world (Shanks *et al.*, 1996). It eventually came to involve staffed lifesaving stations with specially designed and marked rescue vessels.

In the Netherlands, the Maatschappij tot Redding van Drenkelingen (Society to Rescue People from Drowning) was established in Amsterdam in 1767, primarily to address problems of drowning in the numerous open canals in Amsterdam. This society remains in existence today, now promoting a wide variety of drowning prevention initiatives. English lifesaving efforts began in 1774, though boating rescue operations were not initiated until 1824 (Shanks *et al.*, 1996).

In 1787, the Massachusetts Humane Society began what was to become a lifesaving movement in the United States that evolved into the US Life-Saving Service (USLSS). The USLSS was eventually composed of an extensive national network of coastal lifesaving stations staffed by government paid lifesavers, and credited with saving over 170,000 lives. In 1915, this organization joined with the Revenue Cutter Service to become the US Coast Guard.

It was only in the late 1800s that swimming, then known as bathing, began to emerge as a widely popular form of recreation. When ocean resorts were built, in places like Atlantic City and Cape May, New Jersey, drowning quickly emerged as a problem. Various drowning prevention methods were implemented, including the use of lifelines in the water—fixed ropes to which bathers could cling.

When these approaches proved inadequate, police were assigned to lifesaving duties in Atlantic City. Eventually though, police resources became strained by this responsibility. Instead, a corps of lifeguards was employed in 1892. In Cape May, efforts began with rescue rings hung on bathhouses and the provision of dories on the beach that could be used for rescue. By 1865, hotels began hiring persons to staff the surfboats. Later, a municipal lifeguard operation was begun that continues to the present day.

Both the American Red Cross and the YMCA initiated efforts in the early 1900s to teach Americans to swim and to rescue each other when in distress. This grew into nationwide networks of swimming instruction and lifeguard training that exist today, with a focus on pools and inland beaches.

While the need for prevention and rescue services was evinced by drownings, the elemental lifesaving techniques were just that—rudimentary steps that one swimmer could use to rescue another—person to person and often without equipment. The rescue equipment, what there was of it, was adapted from other disciplines, such as the devices that had been used by the USLSS to rescue sailors from the sea.

Surfboats, similar to those used by the USLSS, were adapted for use by lifeguards to row to swimmers in trouble. They remain in use in a few areas of the United States. The predominant method of rescue though, was by swimming to the victim.

One of the greatest difficulties for swimming lifesavers was the struggle sometimes required to overpower a panicked victim before the rescue could be completed. The line and reel (landline), was an early solution. A lifeguard would swim out to the victim while attached to the line, clutch the victim, and would be rapidly pulled back to shore by others.

This method had the advantage of quick retrieval, but there were some disadvantages too. The line produced drag, which could slow approach to the victim; it required two or more persons to operate; it was inadequate in cases of multiple rescues simultaneously occurring at different locations; and, it could become tangled. In Atlantic City, use of the line was discontinued after a lifeguard was strangled by the device. Nevertheless, it was widely used elsewhere for decades and is still in use in a few areas.

As an alternative, lifeguards fastened an eight-foot line and shoulder harness to a life ring. The lifeguard would swim out with the life ring, push it to the victim, and tow the victim to a dory or to shore. This avoided contact with the victim, but like the line and reel, the life ring created significant drag in the water.

Captain Henry Sheffield, an American with a variety of aquatic accomplishments to his credit, was touring Durban, South Africa in 1897 when he designed the first "rescue can," also called the "rescue cylinder," for a lifesaving club there (Brewster, 1995). It was made of sheet metal and pointed on both ends, with the same over-the-shoulder harness and line as had been used on life rings. The advantage was that it moved much more smoothly through the water, providing little drag. A disadvantage was that the heavy metal and pointed ends could cause injury.

In Australia, the first volunteer lifesaving "club" was founded at Bondi in 1906. Prior to that, ordinances had proscribed swimming, but civil disobedience eventually resulted in making swimming permissible and prompting the need for lifesaving services. Surf Life Saving Australia, one of the largest volunteer organizations in the world today, grew out of the Australian tradition that began at Bondi, of voluntarily guarding the beach. Today, some Australian lifesavers are paid, but most are still volunteers.

In 1907, George Freeth was brought from Hawaii to Redondo Beach, California to help promote a seaside resort. Billed as, "the man who walks on water," Freeth was the first person to surf on the American West Coast and is considered by many to be the first California beach lifeguard, as he made many rescues of persons in distress. According to the USLA though, it was not until the legendary Duke Paoa Kanhanamoku visited California in 1913 and introduced his redwood surfboard to Long Beach, California lifeguards, that the surfboard was adopted as a rescue tool. Later, the term "rescue board" would be coined (D'Arnall *et al.*, 1981).

The initiation of lifeguard services has often resulted from drownings and, even today, drownings tend to spur the provision or augmentation of such services. In 1918, 13 people drowned in a single day in San Diego, California, spurring the creation of a lifeguard service that now counts some 240 lifeguards providing response to coastal emergencies 24 h a day, throughout the year.

In 1935, Santa Monica, California lifeguard, Pete Peterson, seeing a need for a device that could be wrapped around the victim for greater security in the surf, produced the first rescue tube as an inflated device. Though it was vulnerable to weather, it became quite popular among lifeguards, and even more so when, in 1964, it was made of foam rubber, hot dipped with a rubber coating. Known to many veteran lifeguards as the "Peterson Tube," or just the "Peterson," it is in wide use today.

The rescue tube is an excellent tool for surf rescue because the victim is less likely to become separated from the rescuer in breaking waves. It is a particularly valuable option for semiconscious or unconscious victims, though it is less useful for multiple victim rescues, since its design is intended for a single victim. Interestingly, it has now become a common tool at pools and waterparks. So a device developed by a single lifeguard for a particular environment has come to be used in all aquatic environments throughout the world.

Captain Sheffield's sheet metal rescue "can" came to be constructed of aluminum in 1946, which lightened it substantially and allowed the ends to be rounded, but it was still heavy and itself presented a hazard. Then, Los Angeles County lifeguard Bob Burnside developed an improved rescue buoy, made of plastic, with handles on each side. It was on the beach in 1972 and greatly improved upon the ability of lifeguards to safely effect rescues, particularly in open water environs.

The "Burnside buoy" continues to be the rescue device of choice in situations where a highly buoyant and hydrodynamic float is needed to handle multiple victim rescues, since several victims can easily hold onto it at once. As a symbol of modern lifeguarding, it may have even come to eclipse the life ring.

The invention of the swim fin has changed lifesaving too. Lifeguards with fins are much faster in their swimming approach to victims and have the power to easily rescue several victims at a time, fighting the very currents that caused distress in the first place. Fins are particularly valuable in areas where the surf breaks gradually offshore and where distress may occur far from the beach. For some lifeguard agencies, swim fins are a required tool for swimming rescues and each lifeguard has a pair available at all times.

Rescue boards, a variation of surfboards and one of the original rescue devices, have been perfected to include handles for extra victims, specially designed decks for knee paddling, and lighter material. The lengths range from 3 to 4 m, with longer boards being more buoyant and faster, but heavier. Using a rescue board, a well-trained lifeguard can move quickly over the water and keep eight or more victims afloat. These devices can also be carried easily atop lifeguard emergency vehicles.

Statistics

The volume of beach use has expanded tremendously, as has the work of lifesavers. For 1998, the USLA reported the following from major reporting beach lifeguard agencies (Table L1).

Rip currents

USLA statistics show that over 80% of rescues at surf beaches are due to rip currents. This phenomenon is caused by a variety of factors. First, wave action pushes water up the slope of the beach. Then, gravity pulls it back to sea level. As it seeks to return, the water takes the path of least resistance, which sometimes causes it to be concentrated in

currents of water moving away from shore. These currents in the ocean are called rip currents.

Rip currents have three major components. The *feeder* is the main source of supply, composed of water that has been pushed up the beach by wave action. The *neck* is a relatively narrow river of water within the ocean moving back to sea. The *head* is typically a mushroom shaped area of water as the rip current disperses outside the surfline.

Wherever there is regular surf, there will be some form of rip currents. These currents vary in intensity according to wave energy, as well as bottom conditions. For example, a rocky bottom with channels can foment the formation of strong rip currents, as can reefs parallel to shore. They can also form due to channeling of water by undulations in the sand bottom, jetties, groins, and piers.

The USLA has identified several different types of rip currents (Brewster, 1995), including:

- *Fixed rip currents*: These are found on sand beaches, and remain in the same place so long as underlying sand conditions remain the same.
- *Permanent rip currents*: These remain in the same area year round and are usually seen on beaches with rocky bottoms, near groins, or piers, where the underlying structure never changes and rip current intensity varies only with swell size and direction.
- *Flash rip currents*: These currents occur suddenly and unexpectedly typically due to sets of waves that are higher in size than other waves and bring unusually high volumes of water ashore quickly. They may form regardless of an obvious differentiation in underlying beach structure.
- *Traveling rip currents*: These currents usually occur on sandy beaches and move along with the prevailing swell direction as longshore currents move water along the beach.

Worldwide, it would appear that the highest volume of rescues by lifeguards, by a significant margin, exists in the southern California counties of Los Angeles, Orange, and San Diego. There, regular and strong wave action and resulting rip currents, combined with high, year-round beach attendance, ensure that many persons will need rescue. In 1998, the USLA reports that lifeguards in these three counties effected 43,882 rescues, which represented 66% of all rescues reported to USLA by American beach lifeguard agencies that year. In contrast, Surf Life Saving Australia reports that a total of 12,948 rescues were effected by Australian surf lifesavers in the 1998/99 season.

Drowning prevention

Another important statistic is "preventive actions." Preventive actions are typically warnings to swimmers and others to avoid areas of hazard that might result in distress or drowning. Not all agencies report these actions to USLA, but USLA statistics show that for every rescue, there are at least 43 preventive actions by lifeguards. Clearly, this is an essential action, without which the number of rescues and drownings might be much higher. As such, the value of lifeguards extends well beyond the reactive service of rescuing someone in need, to active prevention.

According to the USLA

> USLA has calculated the chance that a person will drown while attending a beach protected by USLA affiliated lifeguards at 1 in 18 million (.0000055%). This is based on the last ten years of reports from USLA affiliated lifeguard agencies, comparing estimated beach attendance to the number of drownings in areas under lifeguard protection.

Historically, lifeguards have typically been placed on beaches and the level of lifeguard coverage increased only after drownings have occurred. This may be partially due to a view that swimming and related activities are considered discretionary, recreational activities, and to some, worthy of a lesser level of attention than more common or necessary activities. Nevertheless, the impact of death resulting from drowning, for whatever reason, is the same as that from other causes.

Another problem confronting lifesaving is the lack of standardized systems for rating the ambient hazards at swimming beaches that might dictate specific levels of lifeguard protection. The wide variety of factors that increase the likelihood of distress and drowning are quite complex. Such factors include attendance levels, weather, water temperature, surf, strength of rip currents, swimming skills of users, etc. Recent efforts by Professor Andrew Short on behalf of Surf Life Saving Australia have produced a system to consider these many factors and develop appropriate preventive strategies (Short, 1997). It has been effectively applied in several areas. Further work and testing of this system is underway.

Beach signs

Statistics indicate that the provision of lifeguards results in heightened safety and drowning prevention. In some areas, however, passive warning systems, such as flags and signs, are the only source of drowning prevention measures. This is particularly true at areas with low attendance or relatively benign ocean conditions. However, as was demonstrated at Ocean Beach in San Francisco, where extremely strongly worded signs were initially employed in place of lifeguards, signs alone are of limited value in drowning prevention.

At present, there is no internationally recognized standard for beach signage. Since many beachgoers are tourists, this lessens the likelihood that preventive signs will be read or understood. Regardless of the reason, signs seem of very limited value. One study of beach signs found that 85–90% of beachgoers did not recall having seen the signs posted at beaches where they were recreating.

Modern lifesaving

The major national lifesaving organizations of the world have organized themselves into a single worldwide confederation, known as the International Life Saving Federation. Through this organization, lifesavers exchange information, extend lifesaving aid to countries lacking preventive programs, and meet to vie in lifesaving competition.

Many changes have taken place in lifesaving over the years. Effective modern lifeguarding involves a carefully orchestrated system of drowning prevention in which lifeguards in elevated towers oversee designated areas of water and cross-check the edges of areas of responsibility of neighboring lifeguards. Some areas employ a so-called "Tower 0" system, which involves a permanent, elevated structure with an enclosed observation deck overseeing an entire beach area, sometimes more than a mile in length.

The lifeguard in Tower 0 acts as something of an overseeing traffic controller who coordinates activities of lifeguards in beach level towers, sending backup when they make rescues or need assistance for medical aid. This system depends on mobile backup services from emergency vehicles and boats.

The need for emergency vehicles initially arose as lifeguards were expected to patrol larger areas and were summoned away from their regularly assigned stations to emergencies elsewhere. Lifeguards in emergency vehicles can respond over long distances to deliver rescue personnel and equipment to remote areas or simply to better cover longer beaches. They are now an essential element of backup at major beaches that reduce the need for personnel and increase the rescue equipment that can be transported to assist at a rescue.

Vehicles can also provide emergency backup to other lifeguards stationed a significant distance away. The public address systems on lifeguard vehicles are invaluable for delivering preventive warnings to swimmers and communicating to lifeguards in the water.

Rowed dories continue to be used in a few areas of the world for rescue, but since the advent of motorized vessels with compact engines, motorboats have become the rescue vessel of choice in most areas. The 10 m Baywatch boats of Los Angeles County, with their inboard motors, were some of the first boats designed specifically for lifesaving. They allow lifeguards to rescue multiple victims, as well as to respond to offshore boating emergencies. The only limitation of these vessels is that they must remain outside the breaking surf, where victims are sometimes trapped.

When Australian lifesavers first modified commercially available inflatable vessels to operate effectively as rescue boats in the surf environment and dubbed them IRBs, they pioneered one of the most striking modern advancements in lifesaving. Unlike hard hull vessels, these 4 m boats with small outboards are able to navigate the largest and most powerful surf to rescue distressed swimmers and surfers. Even in the unfortunate event of a capsizing, these vessels are easily righted and their outboards rehabilitated for operation. They have proven their worth time and time again in the most inclement conditions.

It was not long ago that personal watercraft (PWCs; also known by the trade name Jet Ski) were introduced to the waterways. To some they are seen as a noisy irritant, or a water toy more suited to an amusement park; however, personal watercraft have transformed boating recreation, becoming one of the most popular types of recreational boat.

Initially, few saw the PWC as a viable rescue tool. Now however, thanks in particular to pioneering efforts by Hawaiian lifeguards and loaner programs provided by some manufacturers, PWCs are employed by many lifeguard agencies as rescue boats. These boats are extremely quick, powerful, usually unaffected by capsizing, and can be operated by a single rescuer; although they work best when two lifeguards work in concert using a towed rescue sled.

As the boats available to lifesavers have changed and adapted, so have the technologies that make boat rescues more effective. Global positioning systems, for example, can now be found aboard many of the larger and more advanced lifeguard rescue boats. And radio direction finders allow boat operators to hone in on an emergency radio signal from a boat in distress.

The most sophisticated rescue implement used by lifeguards today is aircraft, particularly helicopters. In some areas, lifeguards have made arrangements with a local police or rescue helicopter service to assist them in times of need; but in Rio de Janeiro, Brazil, Durban, South Africa, New Zealand, and Australia, helicopters have long been a basic tool of the lifeguard agencies themselves. They allow quick access to offshore or remote emergencies, unimpeded by traffic or surf conditions. They also allow for rapid evacuation of the injured to hospitals. When not used for emergencies, helicopters are excellent platforms for observation, patrols of remote areas, searches, and dissemination of public information.

Communication has been a perennial challenge for lifesaving. Particularly at beaches, where lifeguards may cover broad expanses of shifting sand, remote areas, and the open sea, there is a need to quickly summon backup or advise others of an emergency in progress. Whistles, megaphones, and flags were some of the first tools used for this purpose, but their value declines rapidly as distance increases. For this reason, two-way radios have become the communication tool of choice.

First aid is another area of tremendous change. Bottled oxygen, suction devices, and one-way masks are all highly recommended pieces of first aid equipment, which many lifesavers have available. So are spinal and cervical immobilization devices. A recent innovation in this area is the floating backboard. Implements to protect against communicable disease have also become a must.

All of these improvements in equipment, technology, and rescue techniques, along with the exploding attendance levels at aquatic areas, now demand training levels among lifesavers that go well beyond the early days. Effective lifesaving has always called for superior resuscitation skills, but with advancements in techniques this has come to require tens of hours of training in both resuscitation and professional level cardio-pulmonary resuscitation. In some areas, lifeguards are trained to the level of paramedics, and many full-time lifeguards are emergency medical technicians.

General rescue skills have been advanced also. In America, lifeguards assigned to coastal beaches typically receive 80 to well over 100 hours of basic training before they are given basic lifesaving duties. Full-time lifeguards, who work year-round in California, Florida, and Hawaii receive many additional hours of training. In the European Union, the minimum standard to become a lifeguard is now some 300 h. Other countries exceed even these levels.

In addition to the responsibility for water rescues, some lifeguards have been called upon to perform specialized emergency services in and around the aquatic environment. This has required special training and equipment appropriate to the task.

Expanding lifeguard services

From the rocky Irish coastline, to the soft sandstone of the California coast, people headed for the beach are sometimes stranded on the cliffs above. Some lifeguards are trained and equipped in high-angle rescue to pluck them from their plight. In San Diego, where over 25 of these rescues are performed each year, a special rescue vehicle with a crane aboard is used to lower rescuers and raise victims to safety.

All lifeguards have some degree of responsibility for controlling the swimmers they protect and regulating activities, but in some places that responsibility has advanced to regular law enforcement power. Lifeguards employed by the State of California and Volusia County, Florida are empowered as police officers, carrying firearms, and enforce even the most serious crimes that occur on their beaches.

Some of the other specialized services provided by lifeguards include marine firefighting and flood rescue. At least two lifeguard agencies, San Diego and Los Angeles County, have expanded upon the emergency callback system used by other lifeguard agencies to staff lifeguards 24 h a day to respond to the many calls that come in to their dispatch centers during nighttime hours.

Lifeguards are also participating in mutual aid networks within their communities. As many lifesaving groups align themselves with police and fire agencies, they are increasingly called upon to act in concert with other public safety providers when natural disasters strike.

Lifeguards around the world are taking their preventive responsibilities one step further through the development of youth programs. Called nipper or junior lifeguard programs, they train youngsters in ways to safely use the waters and encourage their later participation as lifesavers. Many thousands participate in these programs each year.

Lifesaving competition too, has become tremendously popular, involving some 600,000 people annually. Many of the early international exchanges of lifesaving information came through the solidarity brought about through competition and this tradition continues with events sponsored by the International Life Saving Federation and its member federations, as well as other groups. These competitions encourage not only information exchange and international goodwill, but also inspire lifesavers to maintain the high levels of fitness needed to effectively save lives in the water.

With the continually increasing responsibilities, technologies, and training, the role of the lifesaver has been transformed over the years. The lifesaver has acquired an internationally recognized and tremendously positive image of a well prepared, physically fit, and versatile person ready for any emergency that might develop in or near the water. This has benefited water safety, but it has also burnished the image of lifeguards, now more likely than ever to be seen as providing an integral layer of essential public safety protection, allowing safe use of a sometimes hazardous coastline.

LITTORAL

In the vernacular, "littoral" refers to a shore or coastal region from the Latin *litus*, shore. In the technical usage, "littoral" and its associated, derivative nomenclature are variously defined primarily depending on the disciplinary context. Even within a discipline, the terms tend to be used with some elasticity and in a semi-quantitative sense due to the quantitative imprecision of boundaries defined by "high tide" or "low tide," "ordinary surf," etc., or by primary and secondary biotic transitions (Figure L2).

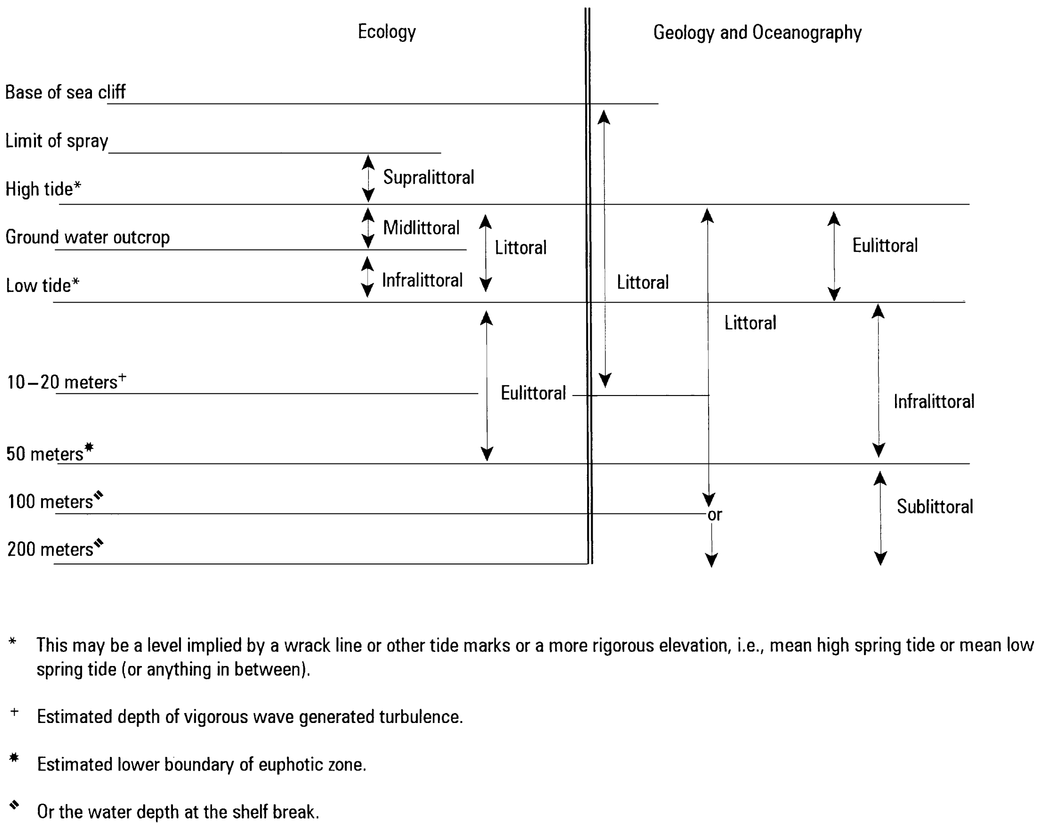

Figure L2 Vertical boundaries for various usage of "littoral" and its derivatives.

The first technical use of "littoral" in English was in a biological context (Forbes and Hanley, 1853, as cited in Hedgpeth, 1957) to designate the space between tide marks, or the intertidal. "Supralittoral" and "sublittoral" were first employed in a similar context (Lorenz, 1863, as cited in Hedgpeth, 1957) with supralittoral being near the shore but above the level of high tide and sublittoral defined by water depth between two fathoms (3.65 m) and fourteen fathoms (25.60 m).

Ecological context

Marine ecologists have used the term to not only include the region between the tides but also the substrate wetted by ordinary surf above the level of high tides or "spray zone." In modern usage, the "supralittoral," or supratidal generally has referred to the spray zone immediately above either the highest high tide (Nybakken, 1993) or the mean high spring tide (Eisma, 1997) where the substrate is commonly, more-or-less, moistened by extreme tides, waves, and spray. This has also been called "extratidal." Ecologists divide the zone between the tide levels, into a "mid-littoral" from highest high tide to the level at which the water table on the beach outcrops at the beach surface; and an infratidal from the level of the water table outcrop to the elevation of the lowest low tide (Nybakken, 1993). "Eulittoral" refers to that part of the littoral zone less than 50 m in depth (American Geological Institute, 1960), 50 m, or between 40 and 60 m, being the lower limit at which "more abundant attached plants can grow" (Sverdrup *et al.*, 1942 citing Ekman, 1935). In practice, these terms are not so much defined by the physical processes controlling the landward distribution of sea salt but by the flora and fauna characteristic of such an influence.

In limnology, "littoral" refers to the zone below the highest reach of typical waves in a calm season (i.e., where the ground is dampened by waves) and above the maximum depth of substrate supporting rooted plants with floating or emergent leaves or flowers (e.g., Pillsbury, 1970; Jackson, 1997). Strictly speaking, it is possible for the littoral zone of a lake to cover the entire submerged area.

Geological and oceanographic context

When applied to the marine environment by marine geologists "littoral" generally refers to the zone between high tide and low tide. Classification of these zones was set forth by Johnson (1919) with reference to earlier investigations and to "legal authorities"; "shore" and "beach" both were synonymous for the intertidal and also referred to as "littoral." More strictly speaking the "littoral" is that region between mean high water spring tide, and mean low water spring tide (Eisma, 1997). Such a definition recognizes the complexity of the tidal signal and vicissitudes of a particular high tide level around some average position. "High tide" (or "low tide") is an imprecise term because these levels vary from one tidal cycle to the next. Harmonic analysis provides dozens of tidal constituents, acting at different periods, which conspire to provide any instantaneous high tide (or low tide). In other geological context, the "littoral" zone has a lower boundary at the depth of vigorous wave-generated turbulence, generally 10–20 m or, in one case, one-third the wave length of storm generated surface waves, and an upper limit at the seaward foot of sand dunes on the shore of the base of beach ridges or sea cliffs (Fairbridge, 1968). In a common usage, where the lower boundary of the littoral zone is at the level of low tide, "sublittoral" is the region below the low tide level to a depth of 100 m (American Geological Institute, 1960) or 200 m (Nybakken, 1993). This has also been referred to as the "shelf zone."

Oceanographers have tended to use "littoral" to designate the broad region from the high tide elevation down to the compensation point, generally between 200 and 400 m in the shelf. Alternatively, it is used as a synonym for "neritic" referring to the region below the low tide level to a depth of 200 m or to the shelf break (Kuenen, 1950, p. 313; Jackson, 1997). In this usage "eulittoral" can be synonymous with "intertidal." "Infralittoral" is the shallow (or inner) sublittoral generally the euphotic zone or between low tide and the depth compatible with the occurrence of phanerograms or photophilous algae (Visser, 1980, term 2839). Alternatively, the lower limit has been cited as about 50 m (Hedgpeth, 1957). "Sublittoral" is the region between water depths of 50 and 200 m.

The terms, without the "intertidal," "supratidal," "subtidal" synonyms of course, may also be applied to the shores of tideless seas where regular water level variations due to, perhaps, storm surges, seiches, etc. are observed. In light of these various usages, these terms are best specifically defined in articles and some care may need to be exercised when reading the literature.

LITTORAL CELLS

A littoral cell is a coastal compartment that contains a complete cycle of sedimentation including sources, transport paths, and sinks. The cell boundaries delineate the geographical area within which the budget of sediment is balanced, providing the framework for the quantitative analysis of coastal erosion and accretion. The sediment sources are commonly streams, sea cliff erosion, onshore migration of sand banks, and material of biological origin such as shells, coral fragments, and skeletons of small marine organisms. The usual transport path is along the coast by waves and currents (longshore transport, longshore drift, or littoral drift). Cross-shore (on/offshore) paths may include windblown sand, overwash, and ice-push. The sediment sinks are usually offshore losses at submarine canyons and shoals or onshore dune migration, rollover, and deposition in bays and estuaries (Figure L3).

The boundary between cells is delineated by a distinct change in the longshore transport rate of sediment. For example, along mountainous coasts with submarine canyons, cell boundaries usually occur at rocky headlands that intercept transport paths. For these coasts, streams and cliff erosion are the sediment sources, the transport path is along the coast and driven by waves and currents, and the sediment sink is generally a submarine canyon adjacent to the rocky headland. In places, waves and currents change locally in response to complex shelf and nearshore bathymetry, giving rise to subcells within littoral cells (e.g., Figures L4–L6).

The longshore dimension of a littoral cell may range from one to hundreds of kilometers, whereas the cross-shore dimensions are determined by the landward and seaward extent of the sediment sources and sinks. Littoral cells take a variety of forms depending on the type of coast. Cell forms are distinctive of the following coastal types: collision (mountainous, leading edge), trailing-edge, marginal sea, arctic, and coral reef. The first three types are determined by their position on the world's moving plates while the latter two are latitude dependent.

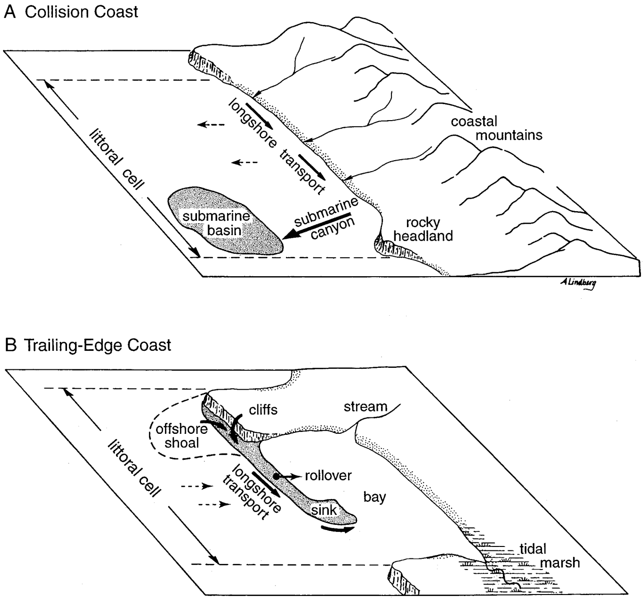

Figure L3 Typical (A) collision and (B) trailing-edge coasts and their littoral cells. Solid arrows show sediment transport paths; broken arrows indicate occasional onshore and offshore transport modes (after Inman, 1994).

Background

The concept of a littoral cell followed from the observation that the southern California coast was naturally divided into discrete sedimentation cells by the configuration of the coastal drainage basins, headlands, and shelf bathymetry. The principal sources of sediment were the rivers, that periodically supplied large quantities of sand to the coast. The sand is transported along the coast by wave action until the longshore drift of sand is intercepted by a submarine canyon that diverts and channels the flow of sand into offshore basins (Figure L3(A)). It was found that littoral cells, because they contain a complete cycle of sedimentation, provided the necessary framework for balancing the budget of sediment. These concepts were first presented at the International Geological Congress, Copenhagen (Inman and Chamberlain, 1960). The littoral cell now plays an important role in the US National Environmental Protection Act (1974) and the California Environmental Quality Act (1974), and it has become a necessary component of environmental impact studies. In the realm of public policy and jurisdictions, the littoral cell concept has led to joint-power legislation that enables municipalities within a littoral cell to act as a unit (Inman and Masters, 1994).

The configuration of littoral cells depends on the magnitude and spatial relations among the sediment sources, transport paths, and sinks. These in turn have been shown to vary systematically with coastal type. Because the large-scale features of a coast are associated with its position relative to the margins of the earth's moving plates, plate tectonics provides a convenient basis for the first-order classification of coasts (Inman and Nordstrom, 1971; Davis, 1996). This classification leads to the definition of three tectonic types of coast: (1) collision coasts that occur on the leading edge of active plate margins where two plates are in collision or impinging on each other, for example, the west coasts of the Americas; (2) trailing-edge coasts that occur on the passive margin of continents and move with the plate, for example, the east coasts of the Americas; and (3) marginal sea coasts that develop along the shores of seas enclosed by continents and island arcs, for example, coasts bordering the Mediterranean Sea and the South and East China Seas.

It is apparent that the morphologic counterparts of collision, trailing-edge, and marginal sea coasts become, respectively, narrow-shelf mountainous coasts, wide-shelf plains coasts, and wide-shelf hilly coasts. However, some marginal sea coasts such as those bordering the Red Sea, Gulf of California, Sea of Japan, and the Sea of Okhotsk are narrow-shelf hilly to mountainous coasts. A more complete coastal classification includes the latitudinal effects of climate and other coastal forming processes such as ice-push and scour and reef-building organisms. The examples of the latter two coastal types described here are (4) arctic form

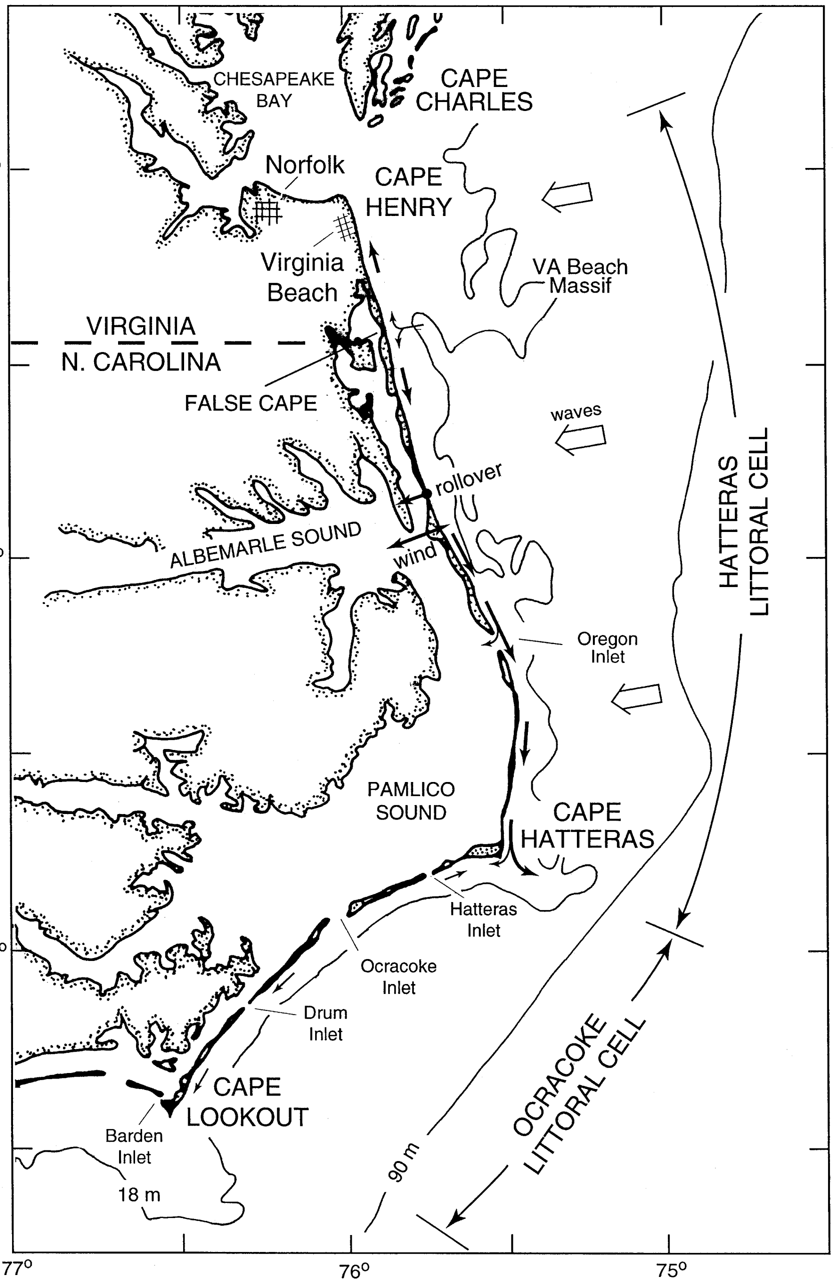

Figure L4 Hatteras and Ocracoke Littoral Cells along the Outer Banks of North Carolina (after Inman and Dolan, 1989).

of cryogenic coasts; and (5) coral reef form of biogenic coasts. The kinds of source, transport path, and sink commonly associated with littoral cells along various types of coast are summarized in Table L2.

Collision coasts

Collision coasts form at the active margins of the earth's moving plates and are best represented by the mountainous west coasts of the Americas. These coasts are erosional and characterized by narrow shelves and beaches backed by wave-cut sea cliffs. Along these coasts with their precipitous shelves and submarine canyons, as in California, the principal sources of sediment for each littoral cell are the rivers that periodically supplied large quantities of sandy material to the coast. The sand is transported along the coast by waves and currents primarily within the surf zone like a *river of sand*, until intercepted by a submarine canyon. The canyon diverts and channels the flow of sand into the adjacent submarine basins and depressions (Figure L3(A)).

However, in southern California most coastal rivers have dams that trap and retain their sand supply. Studies show that in this area the yield of sediment from small streams and coastal blufflands has become a significant replacement for river sediment. Normal wave action contains sand against the coast and, when sediment sources are available, results in accretion of the shorezone. However, cluster storms associated with El Niño–Southern Oscillation events as occurred in 1982/83 produced beach disequilibrium by downwelling currents that carried sand onto the shelf (Inman and Masters, 1991). The downwelled sediment is lost to the shorezone when deposited on a steep shelf such as that off Oceanside, California, or it may be returned gradually from a more gently sloping shelf to the shorezone by wave action. The critical value of slope for onshore transport of sand by wave action varies with sand size, depth, and wave climate, but for depths of about 15–20 m it is approximately 1.5% (1.0 degree).

Trailing-edge coasts

Trailing-edge coasts occur along the passive plate margins of continents and include the coasts of India and the east coasts of the Americas. The mid-Atlantic coast of the United States, with its wide shelf bordered by

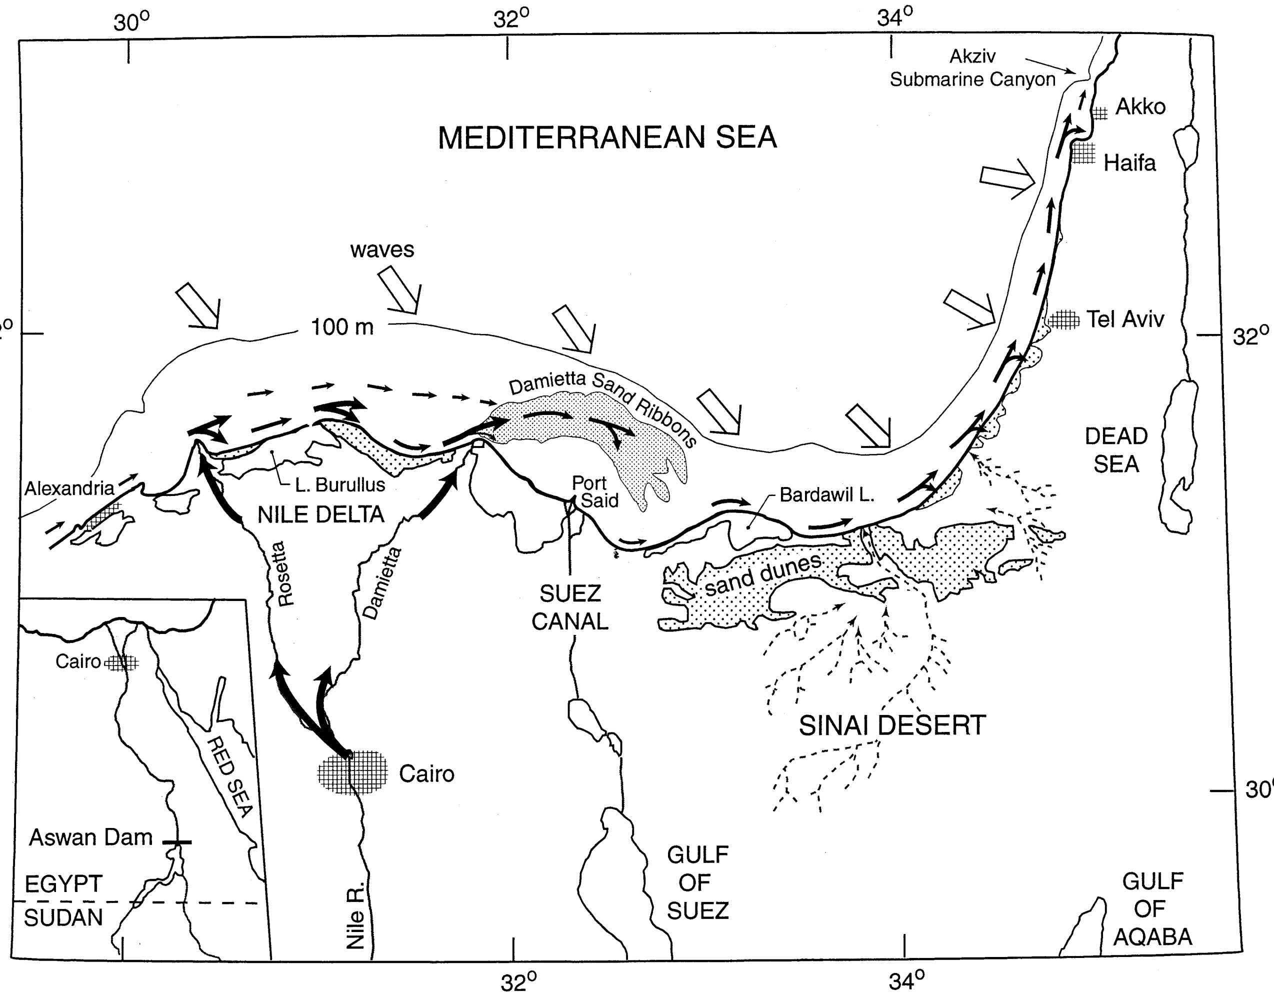

Figure L5 The Nile Littoral Cell extends along the southeastern Mediterranean coast from Alexandria, Egypt to Akziv Submarine Canyon off Akko, Israel. Sediment transport paths shown by solid arrows (after Inman and Jenkins, 1984).

coastal plains, is a typical trailing-edge coast where the littoral cells begin at headlands or inlets and terminate at embayments and capes (Figures L3(B) and L4). This low-lying barrier island coast has large estuaries occupying drowned river valleys. River sand is trapped in the estuaries and does not usually reach the open coast. For these coasts, the sediment source is from beach erosion and shelf sediments deposited at a lower stand of the sea, whereas the sinks are sand deposits that tend to close and fill estuaries and form shoals off headlands. Under the influence of a rise in relative sea level, the barriers are actively migrating landward by a rollover process in which the volume of beach face erosion is balanced by rates of overwash and fill from migrating inlets (e.g., Inman and Dolan, 1989). For these coasts, the combination of longshore transport and rollover processes leads to a distinctively "braided" form for the *river of sand* that moves along the coast.

The Outer Banks of North Carolina, made up of the Hatteras and Ocracoke Littoral Cells, extend for 320 km and are the largest barrier island chain in the world (Figure L4). The Outer Banks are barrier islands separating Pamlico, Albemarle, and Currituck Sounds from the Atlantic Ocean. These barriers are transgressing landward, with average rates of shoreline recession of 1.4 m/yr between False Cape and Cape Hatteras. Oregon Inlet, the only opening in the nearly 200 km between Cape Henry and Cape Hatteras, is migrating south at an average rate of 23 m/yr and landward at a rate of 5 m/yr. The net southerly longshore transport of sand in the vicinity of Oregon Inlet is between one-half million and one million cubic meters per year.

Averaged over the 160 km from False Cape to Cape Hatteras, sea-level rise accounts for 21% of the measured shoreline recession of 1.4 m/yr. Analysis of the budget of sediment indicates that the remaining erosion of 1.1 m/yr is apportioned among overwash processes (31%), longshore transport out of the cell (17%), windblown sand transport (14%), inlet deposits (8%), and removal by dredging at Oregon Inlet (9%). This analysis indicates that the barrier system moves as a whole so that the sediment balance is relative to the moving shoreline. Application of a continuity model to the budget suggests that, in places such as the linear shoals off False Cape, the barrier system is supplied with sand from the shelf (Inman and Dolan, 1989).

Marginal sea coasts

Marginal sea coasts front on smaller water bodies and are characterized by more limited fetch and reduced wave energy. Accordingly, river deltas are more prominent and are often important sources of sediment within the littoral cell. Elsewhere, barrier island rollover processes are similar to those for trailing-edge coasts. Examples of marginal sea coasts include the shores of the Gulf of Mexico with the prominent Mississippi River delta, the seas bordering southeast Asia and China with the Mekong, Huang (Yellow), and Luan river deltas, and the Mediterranean Sea coasts with the Ebro, Po, and Nile river deltas.

Although the Mediterranean area is associated with plate collision, the sea is marginal with restricted wave fetch and prominent river deltas. The Nile Littoral Cell extends 700 km from Alexandria on the Nile Delta to Akziv Submarine Canyon near Akko, Israel, one of the world's longest littoral cells (Figure L5). Before construction of the High Aswan Dam, the Nile Delta shore was in a fluctuating equilibrium between sediment supplied by the river and the transport along the coast. Now the sediment source is erosion from the delta, particularly the Rosetta promontory, in excess of 10 million m^3/yr. The material is carried eastward in part by wave action, but predominantly by currents of the east Mediterranean gyre that

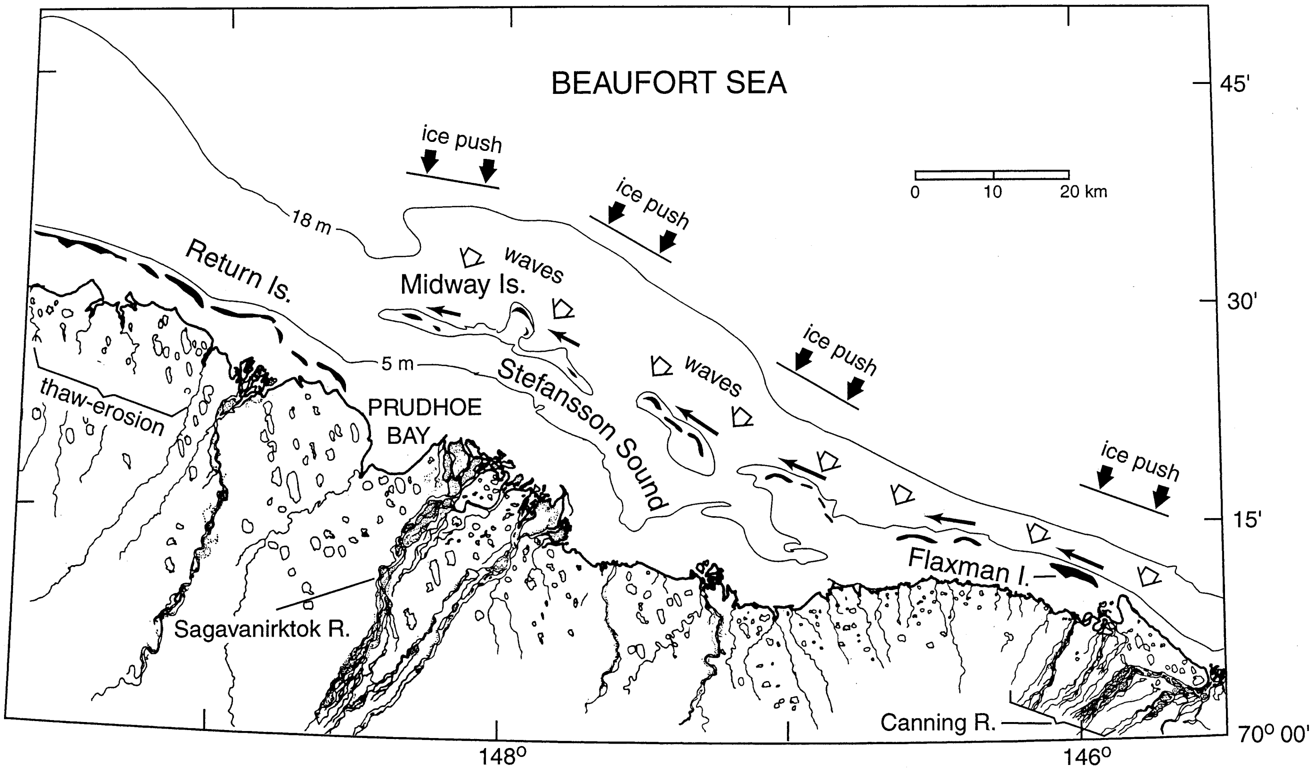

Figure L6 Flaxman Littoral Cell extending 100 km from the mouth of Canning River to the Midway Islands. The barrier chain of islands is enclosed by the 5 m depth counter. Major axis of oriented thaw lakes are normal to the direction of summer winds (after Inman, 1994).

Table L2 Typical source, transport path, and sink for littoral cells of various coastal types

Coastal features	Collision	Trailing-edge	Marginal sea		Arctic form of cryogenic	Coral reef form of biogenic
Morphology	Narrow-shelf mountainous	Wide-shelf plains	Narrow-shelf mountainous	Wide-shelf hilly	Wide-shelf [a] plains	Coral reef
Latitude/climate	Temperate and subtropical	Temperate and subtropical	Temperate and subtropical	Temperate and subtropical	Arctic	Tropical

Littoral cell						
Sediment source	Rivers Cliffs Blufflands	Headlands Cliffs Shelves	Rivers Deltas	Rivers Deltas	Shelf Rivers Thaw-erosion	Reef material
Transport path	Longshore (river of sand)	Longshore and, rollover[d] (braided river of sand)	Longshore	Longshore and rollover[d]	Ice-push Rafting Longshore	Reef surge channels to beach, longshore to awa
Sink	Submarine canyons Embayments Dune migration	Estuaries Shoals Rollover Dune migration	Various including submarine canyons	Embayments Shoals Rollover Dune migration	Shoals Spit-extension	Awa channels to shelf

[a] All high latitude coasts appear to be trailing-edge coasts.
[b] Average incident wave energy-flux per meter of coastline (Inman and Brush, 1973).
[c] Tides may be important along any ocean coasts, but are sometimes amplified in marginal seas.
[d] Rollover processes include overwash and dune migration.

sweep across the shallow delta shelf with speeds up to 1 m/s. Divergence of the current downcoast from Rosetta and Burullus promontories forms accretionary blankets of sand that episodically impinge on the shoreline. The sand blankets move progressively downcoast at rates of 0.5–1 km/yr in the form of accretion/erosion waves. Along the delta front, coastal currents augmented by waves transport over 10 million m^3/yr, and the longshore sand transport by waves near the shore is about 1 million m^3/yr (Inman and Jenkins, 1984; Inman *et al.*, 1992).

The Damietta promontory causes the coastal current from the east Mediterranean gyre to separate from the coast and form a large stationary eddy that extends offshore of the promontory, locally interrupting the sediment transport path. The jet of separated flow drives a migrating field of sand ribbons northeasterly across the delta (Figure L5). The ribbons arc easterly than southeasterly towards the coast between Port Said and Bardawil Lagoon (Murray *et al.*, 1981). The Damietta sand ribbons form the eastern edge of a subcell within the Nile Littoral Cell.

Off Bardawil Lagoon, the longshore sand transport is about 500,000 m^3/yr and gradually decreases to the north with the northerly bend in coastline. This divergence in the littoral drift of sand results in the build up of extensive dune fields along the coasts of the delta, Sinai, and Israel. This sediment loss by wind blown sand constitutes a major "dry" sink for sand in the Nile Littoral Cell.

Arctic coasts

Arctic coasts are those near and above the Arctic Circle (66°34′N Latitude) that border the Arctic Ocean and whose littoral cells have drainage basins in North America, Europe, and Asia. Tectonically, Arctic coasts are of the stable, trailing-edge type, with wide shelves backed by broad coastal plains built from fluvial and cryogenic processes. The coastal plains are permafrost with tundra and thaw lakes. A series of barrier island chains extends along the Beaufort Sea coast of Alaska (Figure L6). For these coasts, cryogenic processes such as ice-push and permafrost thaw compete with river runoff, waves, and currents as important sources, transport paths, and sinks for sediment. Ice-push is a general term for the movement of sediment by the thrust of ice against it. Some common features include ice-push ridges and mounds, ice-gouge, ice pile-up, ride-up rubbling, and bulldozing.

During the nine months of winter, Arctic coasts are frozen solid and coastal processes are entirely cryogenic. Wind stress and ocean currents buckle and fracture the frozen pack ice into extensive, grounded, nearshore, pressure-ridge systems known as stamukhi zones. The stamukhi zone is a shear zone of ice grounded in 10–25 m depth that molds and moves shelf and barrier island sediment. The keels from the individual pressure ridges groove and rake the bottom, plowing sediment toward the outer barrier islands. Ice-gouge relief up to 2 m occurs across the shelf to depths of about 60 m (Barnes *et al.*, 1984).

Winter is terminated by a very active transitional period of a few days to a few weeks during spring breakup when a combination of factors associated with ice movement, waves, and currents, and extensive fluvial runoff all work in concert along the coast. The grounded ridges in the stamukhi zone break up and move, producing ice-push features and vortex scour by currents flowing around the grounded ice, creating an irregular bottom known as ice-wallow topography. Closer to shore, vertical drainage of river floodwater and sediment through cracks in the shorefast ice form large strudel-scour craters in the bottom (Reimnitz and Kempema, 1983).

Finally, a short summer period occurs in which the ice pack withdraws from the Beaufort Sea coast forming a 25–50 km wide coastal waterway. Although the summer season is short, storm waves generated in the band of ice-free water transport relatively large volumes of sand, extending barrier islands and eroding deltas and headlands. The summer processes are classical nearshore phenomena driven by waves and currents as shown by the beaches and barrier island chain beginning with Flaxman Island in the vicinity of Prudhoe Bay (Figure L6). The sediment sources include river deltas, onshore ice-push of sediment, and thaw-erosion of the low-lying permafrost sea cliffs. Thaw-erosion rates of the shoreline are typically 5–10 m/yr in arctic Russia and, over a 30-year period, averaged 7.5 m/yr for a 23-km coastal segment of Alaska's Beaufort Sea coast midway between Point Barrow and Flaxman Barrier Islands (Reimnitz and Kempema, 1987).

The Flaxman Barrier Island chain extends westward from the delta of the Canning River. It appears to be composed of sand and gravel from the river, supplemented by ice-push sediments from the shelf (Figure L6). The prevailing easterly waves move sediment westward from one barrier island to the next. The channels between islands are maintained by setdown and setup currents associated with the Coriolis effect on the wind-driven coastal currents. The lagoons behind the barrier islands appear to have evolved in part from collapse and thaw-erosion of tundra lakes (Wiseman *et al.*, 1973; Naidu *et al.*, 1984).

However, even the summer period is punctuated by occasional "Arctic events," including ice-push phenomena and unusually high and low water levels associated with storm surges and with Coriolis setup and setdown, a phenomenon whose intensity increases with latitude. The active summer season ends with the beginning of fall freeze-up.

Coral reef coasts

Coral reef coasts are a subset of the broader category of biogenous coasts where the source of sediment and/or the sediment retaining mechanism is of biogenous origin as in coral reef, algal reef, oyster reef, and mangrove coasts. Coral reefs occur as fringing reef, barrier reef, and atolls, and they are common features in tropical waters of all oceans at latitudes within the 20°C isotherm.

Although the concept of the littoral cell applies to all types of coral reef coast, the most characteristic are littoral cells along fringing reef coasts bordering high islands, where both terrigenous and biogenous processes become important. Reefs may be continuous along the coast or occur within embayments. In either case, the configuration of the fringing reef platforms themselves incorporates the nearshore circulation cell into a unique littoral cell (Figure L7). The circulation of water and sediment is onshore over the reef and through the surge channels, along the beach toward the awas (return channels), and offshore out the awas. An awa is equivalent to a rip channel on the sandy beaches of other coasts (Inman *et al.*, 1963).

Along coral reef coasts, the corals, foraminifera, and calcareous algae are the sources of sediment. The overall health of the reef community determines the supply of beach material. Critical growth factors are light, ambient temperature, salinity, and nutrients. Turbidity and excessive nutrients are deleterious to the primary producers of carbonate sediments. On a healthy reef, grazing reef fishes bioerode the coral and calcareous algae and contribute sand to the transport pathway onto the beach.

The beach behind the fringing reef acts as a capacitor, storing sediment transported onshore by the reef-moderated wave climate.

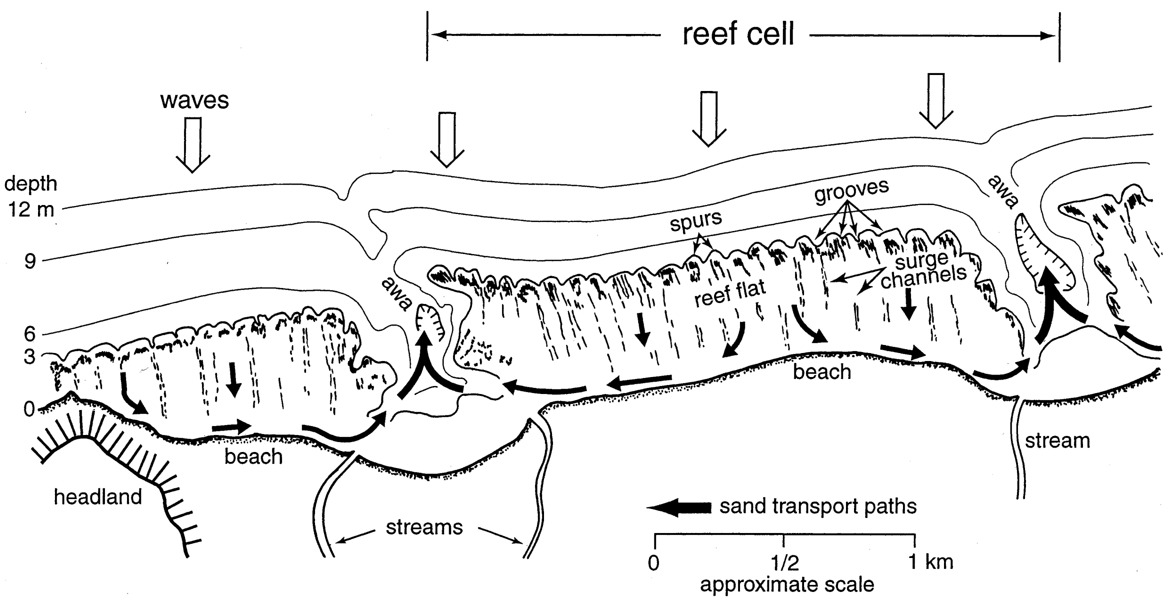

Figure L7 Schematic diagram of littoral cells along a fringing reef coast (after Inman, 1994).

It buffers the shoreline from storm waves, and releases sediment to the awas. In turn, the awas direct runoff and turbidity away from the reef flats and out into deepwater. Where the reef is damaged by excessive terrigenous runoff, waste disposal, or overfishing, the beaches are imperiled.

LITTORAL DRIFT GRADIENT

It is well known both empirically, and theoretically from sediment transport modeling that rates of net littoral drift or longshore sediment transport rates (m^3/yr), vary progressively along a littoral drift coastline—see, for example, figure 9-9 in Komar (1998, p. 386; also pp. 434–435). Disparity in net littoral drift rates along the coastline may arise from several causes, but fundamentally important is variation of the angle of the breaking waves, which drive the alongshore sediment transport. This typically results from change in direction of the wave power resultant relative to the coastline alignment, or from irregularities in nearshore bathymetry influencing the wave shoaling and refraction processes, for example, wave focusing. Other causes include the loss of the littoral drift to a sedimentation "sink" such as a dredged tidal inlet, an offshore submarine canyon, or the action of headlands and cuspate forelands partially blocking and accumulating the littoral drift. The general effect is that progressively alongshore in the net drift direction, some segments of coastline have increasing rates of net littoral drift, and others decreasing rates. This alongshore variation in net littoral drift rates constitutes a *littoral drift gradient*. Van de Graaff and Bjiker (1988) state: "In many cases a gradient in the longshore sediment transport is the main reason of the erosion problems of sandy coasts." An alongshore increase in sediment transport rates in the net drift direction creates a *positive* littoral drift gradient; conversely a decrease in transport rates in the net drift direction results in a *negative* littoral drift gradient.

Littoral drift gradients have significant implications for the beach geomorphology. Consider a given point on a coastline with *positive littoral drift gradient* (increasing rates of net drift alongshore). Because more sediment is being transported away from the sector of beach at that given point than is being replenished from updrift, a net beach sediment budget deficit would be expected. Accordingly, the beach will likely exhibit long-term geomorphic manifestations of an erosive beach, such as a tendency for a dissipative beach state, faceted dune faces, frequent occurrences of lag deposits of surficial laminae of heavy mineral concentration, or cobble–pebble concentrations on the beach surface, slow beach recovery after an episodic erosive event, and a steepening of the beach-nearshore profile. Conversely, for a sector of beach exhibiting a *negative littoral drift gradient* (decreasing rates of net littoral drift alongshore), more material is being supplied from updrift than is being transported away in the net drift direction, and the beach will tend toward a positive sediment budget projecting an accretionary beach state with concomitant geomorphic features of well-developed beach berm, well-formed accreting frontal dune, and, in certain morphodynamic circumstances, a well-formed nearshore bar, and low gradient beach-nearshore profile. On a small scale, a littoral drift gradient is manifest as updrift accumulation against a jetty or groin with leeside down-drift erosion.

In situations of marked littoral drift gradient but little long-term beach morphological change, the effects of the littoral drift gradient may be compensated for by onshore or offshore (diabathic) sediment transport mechanisms. Thus on "lee coasts," onshore sediment drift from the shelf and shoreface, induced by longer period swell waves, assisted by quasi-permanent offshore winds and concomitant bottom return upwelling currents, may mask the erosive effects on the beach induced by a positive (increasing alongshore) net littoral drift gradient. Conversely, for "exposed coasts" facing predominantly onshore winds, the wind forced waves, and downwelling current effects induce an erosive morphodynamic beach state, which may mask the potential beach sediment accretion associated with a negative (decreasing alongshore) net littoral drift gradient.
