South American mangroves occur on protected shores of all of the maritime countries except Chile, Argentina, and Uruguay. Along the Atlantic coast mangroves form a nearly continuous belt from northern countries to Laguna, Santa Catarina State, in southern Brazil (28°30′S), and the latitudinal limits are determined by the frequency, duration, and intensity of cold winter temperatures, rainfall and/or frost (Lacerda and Schaeffer-Novelli, 1992). Along the Pacific coast, the southern mangrove limit is the Tumbes River estuary, in Piura, northern Peru (5°32′S). The restricted distribution at the Pacific coast occurs due to climatic constraints generated by oceanographic conditions along the Peruvian and Chilean coasts, where the Andes Cordilleras and the tropical air currents diminishes rainfall, and the upwelling of cold waters of Peru (Humboldt) Current suppresses convective activity. These result in extremely arid climates, high soil salinity and almost absent freshwater input, limiting mangrove occurrence (Lacerda and Schaeffer-Novelli, 1992). The western limit of South American mangroves is the Galapagos Islands, off the Ecuadorian coast (Latitude 0° and longitude 91°00′W) (Lacerda *et al.*, 1993), and the eastern limit is Fernando de Noronha Islands, off the Brazilian coast (State of Pernambuco, 3°34′S; 32°24W) (Hertz, 1991). At the north of the South Atlantic coast, in Colombia, Venezuela, Guyana, Surinam, and French Guyana, mangrove occurrence is closely associated with protected areas and large rivers.

Peru has two mangrove forests. The larger one, Piura River has 58.5 km^2. The other one is located at Tumbes River estuary (5°32′S), and has only 3 km^2, and is the southern distribution limit of mangroves along Pacific coast. These forests are under a subtropical climate, with annual rainfall ranging from 66 to 300 mm, and temperature ranging from 18°C to 32°C. Peruvian mangroves are under high natural environmental pressure due to low rainfall that results in high salinity

(Echevarria, 1993). Occasionally the "El Nino" phenomenon, which occurs during summer, causes rapid increases in rainfall. During these events, intense rains induce large geomorphological changes in the coast, which strongly affect the mangrove forests. Human pressure, mainly deforestation for shrimp culture, also occurs, although mangroves are legally protected (Echevarria, 1993).

Mangrove forests in Ecuador occupy 161,770 ha, and more than 70% of these are located in the Gulf of Guayaquil (3°S, 80°W), in Guayas Province. This is the largest estuarine ecosystem on the Pacific coast of South America (Twilley *et al.*, 2001), and its fauna is described in South American mudflats. The dominant species is *Rhizophora harrisonii* followed by *R. mangle, A. germinans, L. racemosa*, and *Conocarpus erectus* (Twilley *et al.*, 2001). The structure of mangrove forest in this river-dominated estuary indicates optimum growth conditions with tree heights from 25 to 40 m, although some forests have trees up to 7 m (Twilley *et al.*, 1997), probably due to differences in soil phosphorus concentration and other variations on edaphic conditions. Rainfall is seasonal, with more than 95% of the precipitation occurring from December to May, causing seasonal river discharge ranging from $200\,m^3\,s^{-1}$ during dry season to $1{,}400\,m^3\,s^{-1}$ during wet season. Seasonality does not occur to soil salinity, neither to total litterfall of the forests, but occurs to the leaf component of litter fall (Twilley *et al.*, 1997). Mangrove forests with structural differences (mainly tree height) show different rates of litterfall, ranging from 6.5 to 10.6 ton ha^{-1} $year^{-1}$ (Twilley *et al.*, 1997). Owing to the construction of shrimp ponds and urban expansion along the shore of Estero Salado, mangrove areas of the Gulf of Guayaquil and the Guayas River estuary decreased from 159,247 ha in 1969 to 122,566 ha in 1995. Furthermore, defoliation of *Rhizophora, Avicennia*, and *Laguncularia* by larvae of *Oiketicus kirbyi* has contributed to loss of mangroves, though impacts vary interannually (Twilley *et al.*, 2001).

Colombia has 358,000 ha of mangrove, 90% of these along the Pacific coast and 10% along the Caribbean coast. The most important estuaries are Buenaventura bay (3°54′N; 77°W), in the Pacific coast of Colombia, and the delta of the Magdalena River (Colombia's largest river), that includes the large lagoon complex of Ciénaga Grande de Santa Marta (11°N; 75°45′W), in the central Caribbean coast of Colombia. Climatic differences between the Pacific and Atlantic coasts of Colombia, due to the effects of the Inter-Tropical Convergence Zone, have resulted in Pacific humid tropical forests and Caribbean dry tropical forests. These differences strongly influence mangrove forests structure and productivity, and Pacific mangroves show higher complexity and biomass, whereas Caribbean mangroves are smaller, with reduced crown and smaller biomass (Alvarez-Leon, 1993). Climate and fauna for these areas are described in South American mudflats. Mangroves are the most conspicuous vegetation of Ciénaga Grande de Santa Marta (central Caribbean coast), comprising 50,000 ha. The dominant species is the black mangrove *A. germinans*, followed by the red mangrove *R. mangle*, the white mangrove *L. racemosa*, and buttonwood mangrove *C. erecta*. The lagoon is dotted with small islets of *R. mangle*, and on the alluvial plain a 700 m wide belt of *Avicennia* and *Laguncularia* fringes the shores of the lagoon (Polania *et al.*, 2001). The average height of well-developed stands is 15 m, but 25 m tall trees and also dwarf stands are common (Alvarez-Leon, 1993). The maximum diameter at breast height (dbh) is 30 cm in *R. mangle*, 40 cm in *A. germinans* and 13 cm in *L. racemosa*. About eight species of algae are associated with mangrove prop roots, but they have not been quantified yet.

Mangrove habitats in Buenaventura Bay (Pacific coast) are comprised of *R. mangle, R. racemosa, A. germinans, L. racemosa, C. erecta*, and the associates *Pellicera rhizophorae* and *Mora oleifera*, these two occupying consolidated substrate (Cantera and Blanco, 2001). The mangrove habitats can be classified into three different physiographic types, according to Cintron and Schaeffer-Novelli (1983). Riverine mangroves are well developed (<35 m height, <20 cm dbh) along tidal creeks and estuarine zones of the bay. Bar mangroves are intermediate (<15 m height, <6 cm dbh), growing behind sand ridges near the mouth of the bay. Fringe mangroves growing in platforms resulting from bioerosion of sedimentary cliffs usually develop slowly, or are dwarf, but exceptionally they can exhibit development similar to riverine mangroves (6–9 m height, 4–11 cm dbh) (Cantera and Blanco, 2001). Several red and green algae (*Bostrychia, Catenella, Caloglossa, Bloodleopsis, Cladophora*, etc), as well as benthic diatoms and blue-green algae grow on prop roots, pneumatophores or form beds (Peña, 1998). The litter production ranges from 9.6 ton ha^{-1} $year^{-1}$ in bar mangroves to 11.4 ton ha^{-1} $year^{-1}$ in riverine mangroves, but is much lower in disturbed riverine mangroves, with 7.5 ton ha^{-1} $year^{-1}$ (Cantera and Blanco, 2001), and macroalgae contribute about 26% to total annual mangrove production (Peña, 1998).

Mangrove forests of Venezuela cover 250,000 ha, and major mangrove areas are the Orinoco River delta, the estuaries of the rivers San Juan, Limon, and San Carlos, and the lagoons la Restinga, Tacarigua, Cocinetas, and Sinamaica, and the Gulf of Cuare-Morrocoy Bay. Except for Orinoco River mangrove forests, which are typically fluvial and can attain over 40 m in tree height, all other mangrove forests of Venezuela are located in arid and semiarid regions (Conde, 2001). Annual rainfall in the Orinoco River watershed can be lower than 1,000 mm in northern lowlands and as high as 8,000 mm in southern high relief areas. In the delta, rainfall is markedly seasonal with two dry and two wet periods. The dominant vegetation in the delta is mangrove, which comprises 73% of Venezuela's mangrove forests. The dominant species are *R. mangle, A. germinans*, and *L. racemosa*, though *R. harrisonii* and *R. racemosa* have also been reported. Mangrove forests tend to form a 100 m wide belt along the margins of channels, with some individuals growing up to 20 m height and dbh about 25 cm. Mangroves are replaced landward by tall stands of herbaceous *Montrichardia*, followed by halophobic species (Conde, 2001).

The most part of mangrove forests in Trinidad and Tobago occur in Trinidad, which has about 7,000 ha of well-developed forests, used as timber resource and for tourism. These forests are important places for coastal birds. *R. mangle* is the most abundant tree species, and *R. harrisonii, R. racemosa* are apparently restricted to Trinidad. *A. germinans, A. schaueriana*, and *C. erectus* are also common (Bacon, 1993).

Brazil has 7,400 km of coastline and mangroves occur in a patchy fashion on 92% of this entire coastline. They reach from Oiapoque, Amapá (4°30′N) to Laguna, Santa Catarina (28°30′S) (Schaeffer-Novelli *et al.*, 1990), and mangrove area estimates range from 2,500,000 ha (Saenger *et al.*, 1983) to a more realistic 1,376,255 ha (Kjerfve and Lacerda, 1993). Brazilian tidal ranges decrease southward, from strongly macrotidal, with ranges greater than 4 m (8 m in some places) in the north, mesotidal (2 m) in most parts of the coast, and microtidal (0.2 m) in the south (Schaeffer-Novelli, 1993). Because of the large latitudinal gradient, mangrove forests structure are much more variable in Brazil than in other South America countries. Brazilian mangrove species are *R. harrisonii, R. racemosa, R. mangle, A. germinans, A. schaueriana, L. racemosa,* and *C. erectus. Hibiscus* and *Acrostichum* are very common plants associated with mangrove forests. The smooth grass *Spartina alterniflora* is usual along the entire coast, fringing mangrove and zones of accretion (Schaeffer-Novelli, 1993).

At the northern coast (4°30′N to 3°S) the climate is wet, with rainfall ranging from 2,000 to 3,250 mm $year^{-1}$. Mangroves develop very well north and south of the Amazon delta, reaching 20 m in height. Black mangrove *Avicennia* dominates mangrove forests, and *Rhizophora* stands are more frequent on estuaries under a more direct marine influence. *Laguncularia* is also common, especially in low salinity or backing *Rhizophora* fringes. In the Amazon delta region (1°40′N to 0°36′S) mangroves development and coverage are poor because of the overwhelming influence of the freshwater Amazon discharge, and are mixed with freshwater swamps (Schaeffer-Novelli *et al.*, 1990). Eighty-five percent of Brazilian mangroves occur along the 1,800 km length of this part of the coast, extending more than 40 km inland following the course of estuaries and rivers in the states of Pará and Maranhão. The Maranhão State has the most extensive (500,000 ha) and structurally complex mangrove forests (Kjerfve and Lacerda, 1993). Mangrove trees may reach 45 m height, some with dbh exceeding 0.8 m and above ground forest biomass about 280 ton ha^{-1}. The extension and complexity of these mangrove systems reflect hydrological and topographical characteristics of the coast.

The northeastern coast (3–13°S) has a dry climate, with a long and pronounced dry season. Annual rainfall (1,100–1,500 mm $year^{-1}$) is usually lower than potential evapotranspiration, and seasonal droughts and hypersalinity are usual. This coast is exposed to high-energy waves, characterized by sandy beaches and dunes, with reefs offshore. Mangroves develop poorly due to lack of freshwater runoff and prolonged droughts (Schaeffer-Novelli *et al.*, 1990), and have been restricted to protected areas in association with estuaries and coastal lagoons.

At eastern and southeastern coasts (13–23°S) a mountain chain (Serra do Mar) approaches the coast, restricting the width of the coastal plain. Shallow coastal lagoons are common behind narrow sandy spits. Rainfall (1,200 mm $year^{-1}$) is similar or higher than evapotranspiration, and there is no marked dry season. Where the Serra do Mar is very close to the coast, higher rainfall may occur. In areas protected from high energy, mangrove forests are large and well developed (Schaeffer-Novelli *et al.*, 1990), and trees can reach 6–15 m in height, mean dbh from 0.08 to 0.12 m and above ground forest biomass about 65 ton ha^{-1} (Kjerfve and Lacerda, 1993).

In the southern distribution of mangroves (24–28°30′S), rainfall largely varies in small spatial scale, ranging from 1,100 to 2,000 mm $year^{-1}$, being usually higher than evapotranspiration. Despite the water surplus, mangroves are not as well developed as in northern places, especially due to lower temperatures. *Avicennia* trees are taller than *Laguncularia* or *Rhizophora* in this region, reaching 10–15 m in height (Schaeffer-Novelli *et al*., 1990). The mean of mangrove forests height vary from 2 to 7 m, with dbh from 4 to 12 cm and above ground forest biomass from 9 to 100 ton ha^{-1}, depending on position of the forest and flooding frequency (Tognella-De-Rosa, 2000; Cunha, 2001). South from 28°30′S cold winter temperatures inhibit mangrove occurrence, and salt marsh vegetation, as *Spartina, Scirpus, Juncus*, and other herbaceous plants colonize protected areas and tidal flats.

In all places in Brazil where detailed studies were made (as in Rio de Janeiro, São Paulo, Paraná, and Santa Catarina), there were not always clear zonation patterns for species. However, strong gradients for forests structure (mainly height and dbh) always occur from fringe to inner mangrove forests, reflecting the environmental gradients of flooding frequencies and certainly the geochemistry of the substrate (Schaeffer-Novelli *et al*., 1990). Latitudinal and local gradients of mangrove forests structure strongly influence the patterns of forests productivity. Well-developed forests usually present higher biomass accumulation and higher litter fall than forests with shorter trees. In local scale, however, there is not always correlation between forest structure and litter fall, and it seems to be more related to differences in allocation patterns of production, and accumulation of biomass, which can vary due to edaphic differences (Cunha, 2001 and references therein). Productive processes are generally related to temperature, rainfall, and nutrients availability, but seasonal patterns of litter fall largely vary, and are not always directly related to productivity of the trees. Litter fall measurements are available mainly for southeastern and southern mangrove forests and vary from 3 to 10 ton ha^{-1} $year^{-1}$ (Kjerfve and Lacerda, 1993 and references therein). Seaweed production was quantified only in Santa Catarina and varies from 0.3 to 1.8 ton ha^{-1} $year^{-1}$, where litter fall varies from 2.3 to 3.8 ton ha^{-1} $year^{-1}$ (Cunha, 2001). In northern places, where temperature and water transparency are higher, seaweeds production certainly presents an important contribution to mangrove systems. Trophic interactions in mangrove systems are explained on South American mudflats.

Mangroves play an important role in South American economy, providing many goods and services for the human population (Tognella-De-Rosa, 2000). These include: coastline protection and stabilization, nursery for many economically important shellfish and crabs, and source of timber, firewood, charcoal, chemicals, medicine, and waterways for transport. In the north of South America, a great part of the shrimp fisheries is based on species, which depend on mangroves for completing their development. Timber, firewood, and charcoal seem to be the major uses of mangroves in South America, and mangrove bark is still a source of tannin in most countries (Kjervfe and Lacerda, 1993; Tognella-De-Rosa, 2000).

Despite their ecological and economical importance, South American mangroves are threatened by diverse natural and anthropogenic disturbances. Dredging and filling of channels, industrial and urban pollution have also resulted in large losses of mangrove areas. Low sheltered embayments often containing extensive mangroves are used for establishment of large industrial complexes, resorts, and extensive mariculture projects (Kjerfve and Lacerda, 1993; Schaeffer-Novelli, 1993).

Deforestation in mangrove areas has increased in the last years for all countries, mostly for conversion into salt ponds and mariculture, mainly for shrimp ponds. Land reclamation for building condominiums and marinas and illegal occupation are responsible for the most part of the deforestation, mainly in Brazil (Kjerfve and Lacerda, 1993). These contribute to the degradation of mangrove areas through physical fragmentation of landscape and the impoverishment or irreversible loss of genetic resources. Despite this alarming situation, mangrove forests are protected in almost all South American countries, and there is an increase in the preoccupation of public opinion in conservation matters. Simultaneously there is an increase in the quantity and quality of research in all South American countries in the recent years, especially for sustainable use and conservation of coastal ecosystems, including mangroves. Earlier studies had focused mainly on structural aspects of mangrove forests, but in the last 10 years many research groups around South America have been studying productive and litter dynamics, herbivory and competition, population and community dynamics, valuation of mangroves (economic ecology) biogeochemical and hydrological processes, and restoration and recreation of mangroves. Most of these works are just beginning, but the results already found have helped to plan the use and conservation of these amazing ecosystems.

Simone Rabelo da Cunha and Mônica Maria Pereira Tognella-De-Rosa

Mudflat habitats in South America

When shores become more protected from wave action, they become finer grained and accumulate more organic matter, thus, they become muddier. Mud particles accumulate where currents are low and most of the tidal flats of the world are associated with estuaries and similar embayments. Despite mudflats being characteristic of sheltered habitats, they are far from being static entities, since they represent areas of changing balance between erosion and deposition (Little, 2000). The coastal slope and the tidal range determine the areal extension of the tidal flats (see *Muddy Coasts*). In regularly flooded coasts, the tidal cycles determine the frequency and length of low tide exposure. In irregularly flooded areas, this exposition reflects the environmental unpredictability, mainly, due to the wind, rainfall, and evaporation effects. Waves, tides, and currents transport and sort the sediment particles, and also, determine their distribution, stability, and composition. Together with local climate and geomorphology, these factors constitute the environmental matrix of tidal flats, affecting the composition, abundance, and the distribution patterns of the organisms (Reise, 1985).

The intertidal flat is a rigorous environment for plants and animals, as they are intermittently exposed to the heat of the sun and to the drying action of air and wind. The variety and numbers of organisms gradually increases toward the lowest intertidal zone, which is exposed only during the lowest tides. Here, you will find not only typical intertidal species but also some essentially subtidal ones, able to survive out of water for short periods of time (Little, 2000). For mangrove flora, see "Mangrove Ecosystems of South America," in this entry.

The Gulf of Guayaquil (3°S, 80°W) of the coastal province of Guayas, Ecuador, is the largest (12,000 km^{-2}) estuarine ecosystem on the Pacific coast of South America. Surface water temperatures vary between 21.5°C and 25°C during the dry season and increase by 3°C during the wet season. Salinity decreases from 34 in outer regions to 30 (20 during the wet season) inside the gulf. Tides are 1.8 m near the upper boundary of the Gulf and increase to 3–5 m in the Guayas River estuary near the city of Guayaquil (Twilley *et al*., 2001). The oysters *Crassostrea columbiensis* and *Crassostrea iridiscens*, the mangrove crab *Ucides cordatus*, the pelecypods *Mytella guayanenis, Mytella strigata* live in the intertidal of mangrove habitats, which are dominated by *R. harrisonii*. Mangrove fall rates vary from 6.47 to 10.64 ton ha^{-1} $year^{-1}$. A model of leaf litter dynamics suggests that geophysical energy (tides, river, discharge) controls the fate of mangrove leaf litter, though highest litter turnover rates are associated with the activity of the mangrove crab *Ucides occidentalis* (Twilley *et al*., 1997). High tide predators like the blue crab *Callinectes sapidus* and the shrimps *Penaeus stylirostris, Penaeus vanamei*, that occur near mangrove areas (Twilley *et al*., 2001), develop a severe predation on infauna in mudflats.

The Buenaventura Bay at the central Pacific coast of Colombia, due to the effects of the Inter-Tropical Convergence Zone and intense precipitation, is one of the most humid places in the world, with a mean annual air temperature of 25.9°C, and 228–298 days of precipitation per year. At high slack water, salinity ranges from 18 to 27 at the mouth of Buenaventura Bay to 4.8 at the Dagua River in the inner bay. Complex estuarine conditions and diverse habitats (sandy beaches, rocky shores, mangrove swamps, and mudflats) that maintain rich biological communities, characterize Buenaventura Bay as a diverse and productive ecosystem (Cantera and Blanco, 2001). Extensive mudflats occur around creeks in the inner bay with a rich macrofauna (157 spp.), dominated by deposit-feeders, most of which occupy the aerobic upper subsurface layers of sediments, while some bivalves and polychaetes burrow into deeper layers. The high temperatures and desiccation determine a poor diversity on upper littoral, with few dominants that remain buried most of time. Species richness (32) increases in the mid-intertidal and the lower intertidal zone (up to 67 species) displays high diversity and evenness and is inhabited by gastropods (*Natica, Nassarius, Anachis, Cerithium*), bivalves (*Tagelus, Anadara, Chione*) polychaetes (Amphinomidae, Capitellidae, Glyceridae, Nereidae), crabs (*Panoeus, Callinectes*), and gobiid fishes (Cantera and Blanco, 2001).

The lagoon complex of Ciénaga Grande de Santa Marta, located on the central Caribbean coast of Colombia, is part of the eastern delta of the Magdalena River (Colombia's largest river). The delta and the lagoon complex (1,321 km^{-2}) comprise the Ciénaga Grande (450 km^{-2}), the Ciénaga de Pajarales (120 km^{-2}), several smaller lagoons, creeks, and channels (150 km^{-2}), and mangrove swamps. The lagoon complex can be considered a euhaline–mixohaline system, with mean annual temperature of about 30 °C. Temporal and spatial salinity gradients are common, resulting from variable runoff, seawater intrusion, rainfall, and evaporation. During the dry season (249 mm rainfall), salinity varies between 30 and 40. During wet season periods (1,268 mm), salinity varies between 15 and 20 (short wet season) and close to zero on the long wet season. The Ciénaga Grande complex is a high productive system, where sequential pulses of phytoplankton (990 g cm^{-2} $year^{-1}$) and seasonal export of mangrove detritus (mangrove litter of 15.7 tons ha^{-1} $year^{-1}$), contributes to the carbon budget and sustains high secondary production in the lagoon (Polania *et al*., 2001). Among the invertebrate fauna, mollusks are represented by approximately 98 species (66 genera and 48 families), of which 61 are of marine origin. Six species occur in mangrove sediments, *Melampus coffeus* being the most abundant among the three gastropods. The fiddler crabs *Uca rapax* and *Uca vocator*, the most abundant crabs in areas of mangrove sediments, can construct their burrows on tidal flat area and ingest detritus and macroinvertebrates there. The crabs *Eurypanopeus dissimilis, Pachygrapsus gracilis*, and *Petrolisthes armatus*, species of amphipods and the polychaete *Nereis virens* are abundant on muddy areas (Polania *et al*., 2001). This polychaete is recognized as an important infaunal predator, which can control the nonpredatory infauna densities inside mudflat sediments (Reise, 1985). Fiddler crabs (*Uca* spp.), land crabs (*Cardissoma guanhumi, Ucides cordatus*), and grapsid crabs (mainly the genus *Sesarma*) are often fairly general feeders, depending mainly on scavenging the deposits and a certain amount of predation. The family grapsidae shows a distinct propensity to herbivore, that may include the scraping of epiphytic algae from the surface of mangrove roots, trunks and branches, and also eating the leaves and the reproductive products of mangrove trees. Others important predators in the Ciénaga Grande are the swimming crabs *Callinectes* spp., which invade the intertidal mangroves or mudflats from the subtidal areas, during flooding periods.

Another Caribbean habitat is the Maracaibo system, which acts as an assemblage of interactive brackish water bodies (>220 km^{-2}), comprised of the Gulf of Venezuela, Tablazo Bay, and the Maracaibo Strait, which connect Lake Maracaibo in the interior of the basin to the Caribbean Sea. Water temperature follows a seasonal pattern, with a minimum mean temperature of 29°C at 1-m depth in February and a maximum of 32.5°C in September. The resuspension of bottom sediments is the principal source of nutrients in the gulf Tablazo Bay, and the strait. Elevated phosphorus levels in the lake are largely due to terrestrial runoff and the nitrogen is a limiting factor under most conditions in the lake (Rodríguez, 2001). Dense mangroves (*R. mangle*) occur on muddy intertidal, and in subtidal waters the widgeon grass *Ruppia maritima* dominates. In muddy intertidal bottoms there are the pulmonate gastropod *Melampus coffeus* and high densities of fiddler crabs (*Uca cumulanta* with 330 burrows m^{-2} and *U. rapax* with 113 burrows m^{-2}) and the swamp ghost crab *U. cordatus* (10 burrows m^{-2}). The ubiquitous clam *Polymesoda solida* and the blue crab *C. sapidus* are abundant components in the submersed meadows. The sublittoral community of the Maracaibo system is not well known, however, the fact that 165 species of mollusks have been recorded suggests a diverse subtidal fauna (Rodríguez, 2001). Dominant components are the mytilid pelecypod *Mytella maracaiboensis* (up to 158 g dry $weight^{-1}$ m^{-2}), the tubiculous amphipod *Corophium rioplatense*, and polychaetes, like *Heteromastus filiformis* (980 ind. m^{-2}), *Sigambra* sp. (1,380 ind. m^{-2}), *Streblospio* sp. (4,000 ind. m^{-2}), *Capitella capitata* (160 ind. m^{-2}), and *Nereis succinea* (360 ind. m^{-2}). The composition and distribution of species clearly follows a salinity gradient (Rodríguez, 2001).

In northeastern Brazil, the Itamaracá estuary (824 km^{-2}) shows characteristics of a tropical hot and humid ecosystem. Both salinity (27) and water temperature (26.8°C) are lower in the rainy season (February to August) than the salinity (34.1) and temperature (30.1°C) in dry season (September to January). Mangrove forests (28 km^{-2}), dominated by *R. mangle* and *L. racemosa*, occupy the lowlands along the Santa Cruz Channel and the lower part of tributaries. On mudflat habitats the detritus is the main diet item of macroconsumers, such as fiddler crabs *Uca* spp., the shrimps *Penaeus schimiti* and *Penaeus subtilis*, and the mollusks *Neritina virginea, Heleobia australis*, and *Tagellus plebeius* (Medeiros *et al*., 2001).

In the southern part of the coastal plain of São Paulo State, Brazil (25°S, 48°W), the lagoon region and estuary of Cananéia extends for approximately 110 km. Tropical air masses prevail from the end of spring (September) and the end of summer (February) and cold fronts occur in April and May. The salinity is highly variable (0–34), and the input of freshwater and the introduction of sediments into the system, during the last 150 years, have modified physiographic and hydrologic characteristics, which influence biological structure and ecological functions of the lagoon region (Tundisi and Tundisi, 2001).

Among the invertebrate fauna (73 spp.), polychaete, crustacea, and mollusca dominate in number of species, while deposit feeding polychaetes characteristic of mudflat areas like *Loandalia americana, Laonice japonica, Clymene* sp., and *Clymenella* sp., are the most common species. The seasonal changes in macrobenthic abundance and diversity are attributed to changes in salinity, redox potential, sediment granulometry, and organic matter concentration (Tundisi and Tundisi, 2001).

Paranaguá Bay (612 km^{-2}) a subtropical estuarine system on the coast of Paraná State in southeastern Brazil (25°30′S, 48°25′W), is comprised of two main water bodies, the Paranaguá and Antonina bays (260 km^{-2}) and the Laranjeiras and Pinheiros Bays (200 km^{-2}). Mean salinity and water temperature in summer and in winter are 12–29°C and 23–30°C and 20–34°C and 18–25°C, respectively (Lana *et al*., 2001). Mangroves colonize most intertidal areas around the bay (*R. mangle, A. schaueriana, L. racemosa, C. erectus*). *S. alterniflora* marshes colonize tidal flats or creeks as monospecific, discontinuous narrow (up to 50 m wide) belts in front of the mangroves (Lana *et al*., 1991).

While salinity and environmental energy gradients appear to control large-scale distribution patterns in the bay (Lana, 1986), plant architecture and food availability seem to be the main source of small-scale macrofaunal variability (Lana *et al*., 1991). The opportunistic gastropod *Heleobia australis* is dominant on the mudflats in the inner part of Paranaguá Bay. Two assemblages are characteristics of the low-energy areas in the central part of the bay: (1) one dominated by the polychaete *Clymenella brasiliensis* and the gastropod *Turbonilla* sp., in low-energy environments; (2) the other, dominated by the polychaetes *Owenia fusifirme* and *Magelona* spp., in moderate energy environments. Another sector of the bay, with silty-clay sediments on the lower intertidal flats, showed low diversity macrobenthic invertebrates, probably due to drastic fluctuations of salinity in 4–5 h periods. In this kind of environment, the dominants are the polychaetes *Laeonereis acuta* and *Heteromastus similis* (Lana, 1986).

The Patos Lagoon is a huge choked lagoon with a surface of 10,227 km^{-2}. It stretches in a NE–SW direction from 30°S to 32°12′S, where in the south part there are 971 km^{-2} of estuarine area (approximately 10% of the lagoon). The estuarine region exchanges water with the Atlantic Ocean through a 20 km long and 0.5–3 km wide inlet (Asmus, 1997).

As a consequence of reduced tidal influence (mean of 0.47 m) in the inlet and in the estuarine area, the salinity distribution lacks tidal variability but does correlate with wind forcing and variations in freshwater input on scales of hours to weeks (Garcia, 1997). The high frequency and low predictability of the salinity variations characterize the estuarine region of Patos Lagoon as an area chemically highly unstable (Niencheski and Baumgarten, 1997).

The macrobenthic community in the estuary is composed of approximately 40 spp., most of which are r-strategists with pronounced seasonal and interannual variations in abundance. The long and narrow entrance channel with unstable bottoms, the reduced tidal oscillations, the unpredictable wind and precipitation patterns, that cause a general absence of conservative gradients of salinity, may account for the low diversity of the macrobenthic fauna in the estuarine area (Bemvenuti, 1997a; Bemvenuti and Netto, 1998).

The larger part of the estuarine shallow shoals is dominated by intertidal and shallow mudflats (<1.5 m), either with or without the occurrence of the widgeon grass *Ruppia maritima* beds, but with epibenthic microalgal growth and occasional aggregations of macroalgae (mainly *Enteromorpha* spp.). The motile epibenthic organisms of mudflats are decapods like the blue crab *C. sapidus*, the shrimp *Farfantepenaeus paulensis*, the grapsid crab *Cyrtograpsus angulatus*, and the mud crab *Rhithropanopeus harrissii*. During summer juveniles of decapods and fishes exert a severe predation pressure on the macrobenthic community on estuarine mudflats (Bemvenuti, 1997a).

The epifauna of mudflats is mainly represented by the opportunist gastropod *H. australis* (Hidrobiidae), which densities may exceed 40,000 ind m^{-2} and achieves highest biomass of 246 g m^{-2}, though pronounced spatial and temporal changes in density are common. The densities of amphipods, isopods, and tanaidaceans, which are typical of lower reaches of intertidal flats, increase as a result of macroalgal aggregations, which supply habitat, food, and shelter against predators (Bemvenuti, 1997a).

The infaunal deposit feeder polychaete *L. acuta* reaches densities of 5,127 ind m^{-2} and a biomass of 28.26 g m^{-2} on intertidal and shallow mud habitats of Patos Lagoon estuary. The polychaetes *Nephtys fluviatilis* and *H. similis* have higher densities in mudflats but lower densities in the subtidal bottoms. Adults of both, *H. similis* and *L. acuta* attain refuge against predators by burrowing deeply (approximately 20 cm) in mud bottom habitats (Bemvenuti, 1997b). The deeply burrowing pelecypod *T. plebeius* form patches in mudflats and the deeper tube dwelling tanaid *Kalliapseudes schubartii*, in spite of a severe predation by fishes and decapods, attains densities up to 10,000 ind m^{-2}. This tanaid is a typical r-strategist, with intense reproductive activity in summer months, embryos marsupial protection, and intense recruitment, which maintains elevated densities in mudflats. In shallow habitats the pelecypod *Erodona mactroides* suffer high mortality during the first year and despite high densities (3,722 ind m^{-2}), the mean biomass rarely exceeds 105 g m^{-2} (Bemvenuti, 1997a,b).

Macrobenthic invertebrates display diverse feeding habits but detritus appears to be an obligate food item for most species in mudflats. Infaunal deposit feeders like *L. acuta* and the epifaunal *H. australis* occupy the first level of consumers. In general, the decapods are typically omnivorous and opportunistic feeders, which exploit different trophic levels as food items become available. The predation of infaunal polychaete *N. fluviatilis* on *H. similis* represents an important intermediate link between the non-predatory infauna and epifaunal predators (Bemvenuti, 1997c). The environmental stress of oligohaline estuarine systems are especially enhanced in the Patos Lagoon estuary and may have contributed a soft bottom community with wide trophic niches and abbreviated food chains (Bemvenuti, 1997c).

The Quequén Grande River (approximately 38°S and 59°W) that drains a basin of around 7,800 km^{-2}, has its estuarine area located between the cities of Necochea and Quequén, Buenos Aires Province, Argentina. Salinity shows remarkable fluctuations within the estuary (6–26), mainly to tidal cycle but also due to freshwater inflow (López Gapaetor *et al*., 2001).

The infaunal macrobenthic community of intertidal flats of Quequén Grande River showed a very low species number, being mainly composed of four annelid species: the nereid *L. acuta*, the spionid *Boccardiella ligerica*, the tubificid *Ilyodrilus* cf. *frantzi*, and a species of *Capitella* (Lopéz Gapa *et al*., 2001). The low biodiversity seems to be a characteristic feature of the brackish water environments of the Buenos Aires Province, since there are just three infaunal polychaetes in Quequén Grande estuary (Lopéz Gapa *et al*., 2001), four in Samborombon Bay–Rio de la Plata (Ieno and Bastida, 1998), and five in Mar Chiquita coastal lagoon (Olivier *et al*., 1972).

Bahía Blanca is a mesotidal coastal plain estuary in southwest of the Buenos Aires Province, Argentina. The estuarine area extends over about 2,300 km^{-2}, with extensive tidal flats (1,150 km^{-2}). The mean water temperature is 13°C, while salinity shows drastically differences (17) between the mouth and the head of the estuary (Perillo *et al*., 2001). In the mudflats the polychaetes *L. acuta* and *Eteone* sp. occupy the lower and middle mesolittoral. The mollusks *H. australis* and *T. plebeius* inhabit the middle and upper mesolittoral. Dense populations of *Chasmagnathus granulata* represent the third association in the upper intertidal of salt marshes and mudflats (Elias, 1985). The grapsid crab *C. granulata* diet in marshes is dominated by pieces of marsh grass, while in the mudflats polychaetes, diatoms, ostracods, and nematodes predominate (Iribarne *et al*., 1997).

The diverse and rich mudflats in the coastal habitats of South America are fascinating areas for ecological works, but in general, these areas are still not very well known. An evident lack of knowledge exists on the spatial–temporal patterns of the populations and communities, and of estimates of the secondary production of the macrofauna. Besides, it is also necessary to accomplish studies on the main processes that govern the mudflats. The biological interactions and the related physical variables must also be tested through field experiments. It is also strongly advisable that more attention be paid to the processes of low predictability, such as those related to the success of the establishment and the recruitment of invertebrates with pelagic larvae. It is also urgent that the development of long-term studies, which are powerful tools that allow distinction among the antropic effects of the natural effects, reach the variables and the resources of the ecosystems.

Carlos Emilio Bemvenuti

Seagrass beds in South America

Submerged macrophytes in general, and sea grass beds in particular, are recognized as ecologically important features of the coastal zone (Larkum *et al*., 1989). Seagrasses actively construct and maintain extensive tidal flat structures in South America. Seagrasses provide food for herbivores, a habitat for other organisms, stabilize sediments, reduce or modify water movement and erosion, and present themselves as a substratum for colonization. In all these ways seagrasses add to the biodiversity and productivity of soft sediment environments and protect coastal areas from erosion.

The seagrasses of South America are not well known. Although South America's seagrasses continue to be the subject of some taxonomic debate, at least 10 seagrass species have been reported for the continent. Remarkably, seagrasses are almost absent from the Pacific coast of South America, the only seagrasses on the western continental coast being a couple of small populations of *Heterozostera tasmanica* in northern Chile at Coquimbo (Phillips, 1992). Intriguingly, this species is otherwise known only from Australia and it has been suggested that these are remnants of formerly widely distributed Chilean populations (Phillips, 1992). No seagrasses are known for Peru or Ecuador.

In the Caribbean, on the coasts and islands of Venezuela and Colombia, seagrasses can form very extensive meadows. *Thalassia testudinum*, turtle grass, is probably the most abundant seagrass, although it has not been reported further south. Plants are erect, with shoots up to 1 m, and grow in intertwined turf, forming extensive meadows on shallow sand or mud substrates from the lower intertidal to 20 m (Littler and Littler, 2000). *Syringodium filiforme* (manatee grass) has a similar distribution, the southernmost known populations occurring in Venezuela. This species differs from *Thalassia* in having cylindrical, narrow leaves, which form canopies up to 45 cm high. It grows in sand and mud down to 20 m (Littler and Littler, 2000).

Shoal grass, *Halodule wrightii*, which is common throughout the Caribbean and Brazil, has small supple, grass-like leaves. It is found growing on sand and mud from the intertidal down to 5 m (Littler and Littler, 2000). It has a tropical–subtropical distribution and is found in Colombia and Venezuela and in Brazil from Ceará to Paraná States (Phillips, 1992). The closely related *Halodule emarginata* is endemic to Brazil, occurring from Bahia to São Paulo States (Oliveira *et al*., 1983). Two other species of *Halodule, Halodule lilianeae* and *Halodule brasiliensis*, have been reported as endemic to Brazil but the separation of these three endemic species, based on leaf tip characteristics, has been questioned and some authors consider them forms of *H. wrightii* (Creed, 2000).

Three *Halophila* (sea vine) species, *Halophila baillonii, Halophila engelmannii*, and *Halophila decipiens* grow in finer sands and sediments. *H. decipiens* is found in deepwater (to 30 m) in the southern Caribbean and has a tropical–subtropical distribution in the southwest Atlantic, stretching from the Brazilian State of Ceará to Rio de Janeiro (Oliveira *et al*., 1983). *H. decipiens* can be found very shallow where turbid conditions exist because of run-off or pollution such as at Guanabara Bay, Rio de Janeiro, Brazil. *H. engelmannii* is a species restricted to the Caribbean, which has been reported at two locations in Venezuela and is only found down to 5 m depth (Littler and Littler, 2000). *H. baillonii*, which grows deeper, is found throughout the Caribbean but has also been reported twice (in 1888 and in the 1980s, though not since) at Itamaracá Island in the northeast of Brazil (Oliveira *et al*., 1983).

Ruppia maritima, widgeon grass, is found sporadically from Venezuela down to Argentina, where it forms the southernmost populations of seagrasses in the world, at the Magellan Straits (Short *et al*., 2001). Such records reflect the species' wide latitudinal distribution and tolerance to variable environmental conditions, as it can be found growing in coastal lagoons and estuaries with salinities from 0 to 39. At the Patos Estuarine Lagoon in southern Brazil, a large (about 120 km^2) area of *R. maritima* dominates the benthos and local primary productivity (Seeliger *et al*., 1997).

An unattached leaf of what was reported as *Zostera* (Setchell and Gardner, 1935) has been found at Montevideo, Uruguay. Phillips (1992) commented that the leaf tip resembled that of *H. tasmanica* but that it was unlikely that it came from so far away as Chile. Seagrasses have not been reported for Guyana or Surinam, where information is very limited, although there is indirect evidence of seagrass beds in French Guyana. It is possible that *T. testudinum, H. wrightii, S. filiforme*, and *Halophila* spp. will be reported in the future, when surveys are carried out.

In South America, seagrasses are most abundant in the Venezuelan Caribbean region, in Colombia and sporadically at specific locations along the coast of Brazil. *Thalassia*, and to a lesser extent *Syringodium*, can be dominant, but in the Caribbean it is common to find *Thalassia* in mixed species stands with *Syringodium* or *Halodule*. *Halophila* species can also be found in monospecific or mixed species stands (Short *et al*., 2001). In Venezuela, *T. testudinum* is widely distributed on the western, central, and eastern Venezuelan coast as well as around the islands (Vera, 1992). In Sucre State, northeastern Venezuela, *Thalassia* occupies 70% of the Cariaco Gulf, an area of about 290 km^2.

In classic models of Caribbean seagrass succession, *Halodule* (and sometimes *Syringodium*) are considered to be pioneers species (Gallegos *et al*., 1994). *Halodule* is better able to occupy mobile sediments and facilitates the subsequent growth of *Thalassia* and *Syringodium*. In Brazil, where the competitors *Syringodium* and *Thalassia* are absent, *H. wrightii* is the seagrass that most frequently occurs in shallow waters where it can form extensive monospecific meadows, such as at Itamaracá Island, Pernambuco State (Magalhães and Eskinazi-Leça, 2000).

Of the deeper seagrasses, *H. decipiens* may be of great ecological importance because it may form extensive meadows most of which remain to be discovered. For example, at the Abrolhos Bank, southern Bahia State, Brazil, the suspicion that *Halophila* may be very abundant was recently confirmed in a Rapid Assessment Program (RAP) carried out in the region. Of 45 sites visited, *Halophila* was found at 18 at 5–22 m depth (Figueiredo, personal communication). As these sites were distributed over an area of about 6,000 km^2, the potential importance of *H. decipiens* in the region, especially in terms of primary productivity, could be enormous.

South American seagrasses are often found spatially close by or closely trophically linked to other marine and coastal ecosystems and habitats and this juxtaposition results in higher diversity (Creed, 2000). *Halodule, Syringodium*, and *Thalassia* are associated with shallow habitats without much freshwater input, such as reefs, algal beds, coastal lagoons, rocky shores, sand beaches, and unvegetated soft-bottom areas and nearby mangroves without too much salinity fluctuation. *Halophila* is associated with deeper reefs, algal and marl beds, and deeper soft-bottom vegetated areas. *R. maritima* can be found in lower (coastal lagoon, estuary, fish pond, mangrove, salt marsh, and soft-bottom unvegetated) and higher salinity (coastal lagoon, salt pond, soft-bottom unvegetated) habitats. Numerous physical, chemical, and biological interactions take place between these habitats.

Seagrass beds in South America are known to be important habitat for a wide variety of plants and animals and an enormous diversity of organisms is associated with the South American seagrasses. Groups that contribute most to the richness of seagrass systems in the Caribbean are polychaetes, fishes, amphipods, decapods, foraminifers, gastropods, and bivalve mollusks, macroalgae, and diatoms. Oligochaetes, nematodes, coelenterates, echinoderms, bryozoans, and sponges are other ecologically important groups. About 540 taxa (to genus or species level) of organisms are known to be associated with the Brazilian seagrasses (Creed, 2000). Over 100 macrofaunal and 46 epiphyte floral taxa have been identified in or on *Halodule* at Itamaracá Island, Brazil (Alves, 2000). In Venezuela, at the Caiaco Gulf, 112 mollusk species have been identified in *Ihalassia* beds and 127 species of macroinvertebrates are associated with *Thalassia* beds at Mochimba Bay (Vera, 1992). 372 fish species have been reported associated with seagrasses at Bahia de Chengue, Colombia (UNESCO, 1998). Corals are also found in seagrass meadows throughout the Caribbean and Southwest Atlantic. For example, the corals *Meandrina brasiliensis* and *Siderastrea stellata*, the latter being endemic to Brazil, grow unattached in *H. wrightii* beds and are sold as souvenirs locally (Creed, 2000). At Bahia de Chengue, on the Caribbean coast of Colombia, corals of the genera *Manicina, Siderastrea, Millepora, Diaporia, Porites*, and *Cladocora* grow within the *Thalassia* beds (UNESCO, 1998).

Leaves of seagrasses are a substratum for epiphytic algae and invertebrates. Macroalgae in seagrass beds typically consist of members of the orders Dasycladales and Caulerpales, calcified chlorophytes (*Acetabularia, Halimeda, Penicillus, Udotea*) and rhodophytes such as *Acanthophora* and *Hypnea*. Calcareous chlorophytes which grow in the sediment in seagrass beds are major contributors to the sedimentary cycles of tropical South American shallow-water environments. Other macroalgae grow unattached within the bed as “drift” algae.

Seagrasses are extremely palatable to herbivorous fish, such as parrotfish and surgeonfish, and urchins. Seagrasses are not thought to be chemically defended, and their palatability is such that pieces of *Thalassia* have often been used in *in situ* bioassays to determine relative herbivore pressure on reefs. Such studies have elucidated the strong trophic link between coral reefs and seagrass beds in South America, which is best exemplified by grazing “halos.” Herbivorous fish that graze seagrass beds abutting them create such halos. Because of predators, the herbivores do not distance themselves greatly from the reef; hence the halo. Sea urchins such as *Lytechinus variegatus* and *Tripneustes ventricosus* are also major herbivores of seagrass blades, consuming *Thalassia* and *Halodule*. Echinoids have a double role in the trophodynamics of the seagrasses. Not only are they major grazers on sea grass but also their feces are a food source for detritivores.

Because of the diversity of species assemblages, seagrass beds have been recognized as among the most productive fisheries areas in the Caribbean and southwestern Atlantic. Most of the living resources are associated directly (as food, habitat, or foraging areas) or indirectly (through export of primary production, larvae and juveniles to other habitats) with seagrass areas. Soft-bottom demersal fisheries exploit scianeids, mullets, sharks, penaeid shrimp, conch, loliginid squid, and octopods over seagrass beds and rough-bottom demersal and coral reef fisheries exploit snappers, groupers, grunts, and lobsters which are also found in seagrass habitat. Inshore pelagic fish may also hunt over the seagrass meadows. Other resources which are seagrass associates are turtles, crabs, oysters, sea urchins, sponges, stony corals, and seaweeds.

While the seagrasses of South America contribute to coastal protection, local productivity, and thus fisheries, there is hardly any information available about the value of seagrasses to the local economy. Economically important fish species such as the bluewing searobin (*Prionotus punctatus*), whitemouth croaker (*Micropogonias furnieri*), and mullet (*Mugil platanus*) are found and fished in Brazilian sea grass beds (Creed, 2000). Local fisheries exploit commercially important crustaceans such as blue crabs (*C. sapidus*), stone crab (*Menippe nodifrons*), lobster (*Panulirus argus* and *Panulirus laevicauda*), and shrimp (*Penaeus brasiliensis* and *Penaeus paulensis*), all of which are associated with seagrass beds. Other shellfish which are commercially collected from seagrass beds are clams (*Anomalocardia brasiliana, Tagelus plebeius, Tivela mactroides*), volutes *Voluta ebraea*, rockshells (*Thais haemastoma*), oysters (*Ostrea puelchana*), and cockles (*Trachycardium muricatum*) (Creed, 2000). In Chile, the Chilean scallop (*Argopecten purpuratus*) preferentially settles in *H. tasmanica* beds (Aguilar and Stotz, 2000).

Two threatened species, which feed directly on seagrasses from the Caribbean to Brazil, are the green turtle *Chelonia mydas* (Creed, 2000) and the West Indian manatee *Trichechus manatus* (Magalhães and Eskinazi-Leça, 2000). Both have benefited from specific conservation action sponsored privately and by the Brazilian Environmental Agency IBAMA (green turtles by the Projeto TAMAR and manatees by the Projeto Peixe-Boi Marinho). The black-necked swan *Cygnus melancoryphus* and the red-gartered coot *Fucila armillata* also feed directly on *R. maritima* in southern Brazil and Argentina but are not endangered (Seeliger *et al.*, 1997). Recently, the semi-aquatic capybara (*Hydrochaerus hydrochaeris*), which is the world’s largest rodent, was observed feeding on *R. maritima* near Rio de Janeiro.

As seagrass beds occupy shallow, nearshore depositional environments, they are highly susceptible to damage by human activity. Pollution from land-based sources varies from country to country. Activities related to human settlements, agriculture and industry have been identified as major contributors to the pollutant loads reaching coastal and marine waters. The greatest threats are sewage, hydrocarbons, sediments, nutrients, pesticides, litter and marine debris, and toxic wastes. River loads are enhanced by erosion of watersheds caused by deforestation, urbanization, and agricultural activities. On the continent, the impact of moderate cultural eutrophication on seagrass ecosystem results in greater epiphyte levels and lower shoot density, leaf area and biomass of the seagrass. Sewage pollution has been reported throughout the continent.

Direct reports of impacts on seagrasses on the continent are few. However, pollution by heavy metals from sporadic mining and metalworking activities, by polychlorinated biphenyl congeners and organochlorine compounds and by nutrients from agricultural runoff and sewage discharge have all been reported. Effects of physical damage by anchors and trampling on seagrass and associated macroalgae have also been identified. Loss of water area, because of sediments produced after erosion due to deforestation, infilling for construction and dredging activities have also reduced the area occupied by South America’s seagrasses. *R. maritima* has suffered from reduced freshwater inputs because of rice irrigation, population growth and lock construction (Seeliger *et al.*, 1997). It has been estimated that 100% of Chilean and Argentine, and 40% of Brazilian seagrasses are “highly threatened” (Creed, 2002). Thirty-six percent of Brazil’s seagrasses are “moderately threatened” and 24% are in “low threat” areas.

There are five research groups currently studying seagrasses in South America (Colombia: Instituto de Investigaciones Marinas y Costeras (INVEMAR), Santa Marta; Venezuela: Instituto de Tecnología y Ciencias Marinas, Universidad Simón Bolívar, Caracas; Brazil: Laboratório de Ecologia Marinha, Universidade do Estado do Rio de Janeiro; Universidade Federal Rural de Pernambuco, Recife; Fundação Universidade Federal do Rio Grande—FURG, Rio Grande). Researchers are studying basic biology and ecology of the sea grasses in their region and participate in important regional or global programs. For example, in Venezuela, seagrasses are being monitored by the Coastal Ecosystem Productivity Network in the Caribbean (CARCOMP) Program at the Parque Nacional Morrocoy, which has been the subject of numerous studies, and at Punta de Mangle on the Isla de Margarida. There is also a CARICOMP site in Colombia at Bahía de Chengue within the Parque Natural Tayrona. These sites are used for comparisons of productivity throughout the Caribbean region (UNESCO, 1998). In Brazil three seagrass beds were recently included in the Global Sea grass Monitoring Network—SeagrassNet. At the Patos Lagoon, Rio Grande do Sul State, Brazil, a site where *Ruppia* beds are widespread and which has been studied for the past 25 years, is included in the Brazilian Long-term Ecological Research Program (PELD). In one way or another, all these programs aim to provide a perspective on long-term change in seagrass growth and productivity at regional or global scales.

Joel C. Creed

Marine mammals of South America

The coastal environments of South America are inhabited by a great diversity of marine mammals, from the orders Sirenia (manatees), Carnivora (otters and pinnipeds), and Cetacea (whales, dolphins, and porpoises). Sirenians and cetaceans have a fully aquatic existence, hardly ever coming ashore intentionally, while otters and pinnipeds leave the water from time to time, specially during the reproductive season. In order to better describe the species that occur along the coast of South America, each order will be dealt separately.

Order Sirenia—manatees

This order is divided in two families, Dugongidae and Trichechidae, and only the latter is represented in South America, by two species: *Trichechus inunguis*, the Amazonian manatee, and *Trichechus manatus*, the West Indian manatee. The Amazonian manatee is restricted to freshwater on the Amazon basin and will not be discussed here. The West Indian manatee inhabit coasts, estuaries, and major rivers from Rhode Island, United States, to Alagoas, Brazil (Reeves *et al*., 2002). However, the distribution is not continuous, with gaps along this range. Despite the manatees' ability to move thousands of kilometers along continental margins, strong population separations between most locations were observed on the phylogenetic structure of *T. manatus* (Garcia-Rodriguez *et al*., 1998). This is very important for its conservation, since that although the species has a relatively wide distribution, there is low genetic exchange between locations. Therefore, they should be managed separately. In Colombia this species is considered endangered, with hunting apparently increasing but incidental capture with nets still representing the species' major direct threat (Montoya-Ospina *et al*., 2001). On the Venezuelan coast, a remnant manatee population exists in Lake Maracaibo, but none was found to occur along the more than 1,500 km of Caribbean coastline (O'Shea *et al*., 1988). It is considered as critically endangered on the coast of Brazil, being subject to intentional and accidental mortalities and degradation of its habitat. Total populational size on the Brazilian coast is estimated to be approximately 500 animals (IBAMA, 2001).

Sirenians are the only herbivorous aquatic mammals, feeding on a large variety of coastal and freshwater vegetation, including several species of seagrasses, floating freshwater plants (*Hydrilla* and water hyacinths), and even the leaves and shoots of emergent mangroves (Berta and Sumich, 1999). In Brazil, it was found that shoalgrass, *H. wrightii*, is an important item of the manatee diet, being consumed together with many species of algae from the divisions Chlorophyte (*Caulerpa cupressoides, Caulerpa prolifera, Caulerpa racemosa, Caulerpa sertularioides, Halimeda opuntia*, and *Penicillus capitatus*) and Phaeophyte (*Dictiopteris delicata, Dictyota* sp., *Lobophora variegata*, and *Sargassum* sp.) (Cardoso and Picanço, 1998). Since each manatee may consume from 29.5 to 50 kg of plants per day (Würsig *et al*., 2000), they are probably important in the ecology of seagrass beds.

Order Carnivora

Different from their terrestrial counterparts, aquatic carnivores are well adapted for foraging in water, being excellent swimmers and divers. Along the coasts of South America they are represented by one species from the Mustelidae (marine otter, *Lutra felina*), two of the Phocidae (southern elephant seal, *Mirounga leonina*, and leopard seal, *Hydrurga leptonyx*) and five of the Otariidae family (Juan Fernandez fur seal, *Arctocephalus philippii*; South American fur seal, *Arctocephalus australis*; Galápagos fur seal, *Arctocephalus galapagoensis*; Galápagos sea lion, *Zalophus californianus*; and South American sea lion, *Otaria flavescens*).

The Marine Otter is the only species of the genus *Lutra* that lives exclusively in marine environments. It ranges from the coasts of central Peru south to Cape Horn and along the Atlantic coast of Tierra del Fuego (Reeves *et al*., 2002). Very little is known about this small otter, due to its secretive nature. It is believed that they feed mainly on shellfish, nearshore marine fish, and freshwater prawns.

The seven species of pinnipeds mentioned above are the ones most commonly found on the South American coasts. Vagrants of other species have been reported, but are not regularly observed. The Juan Fernandez and Galápagos fur seals, the Galápagos Sea Lion and the Leopard Seal have breeding colonies in islands around South America, while the other three species have breeding sites on the coast and are more commonly found in the nearshore environment. The breeding systems of these species are polygynous, with males competing among them for territories in the otariids or for dominance in a hierarchical system in the elephant seal. All species feed on fish (demersal or pelagic), cephalopods (octopuses and squid), and more occasionally crustaceans.

Order Cetacea

This order is divided in two suborders, Mysticeti (baleen whales) and Odontoceti (dolphins, porpoises, and sperm whales). Cetaceans occupy marine and freshwater environments in tropical, temperate, and polar regions. Of the 78 accepted species of cetaceans 50 are found on waters around South America (Jefferson *et al*., 1993). They range from coastal specimens that do not go into waters deeper than 30 m, such as the Franciscana, *Pontoporia blainvillei*, to truly oceanic, deepwater species that only occasionally come closer to shore as the Sperm Whale, *Physeter macrocephalus*. Only seven species of cetaceans are endemic to South America: the Amazon River Dolphin, *Inia geoffrensis*; Commerson's Dolphin, *Cephalorhynchus commersonii*; the Chilean Dolphin, *Cephalorhynchus eutropia*; Tucuxi, *Sotalia fluviatilis*; the Estuarine Dolphin, *Sotalia guianensis;* Peale's Dolphin, *Lagenorhynchus australis*; and Burmeister's Porpoise, *Phocoena spinipinnis*.

They occupy different trophic levels, with whales being trophically more basal, consuming zooplankton, and most odontocetes being top predators consuming fish, cephalopods and even other marine mammals, as in the case of Killer Whales, *Orcinus orca*. Considering their large size and abundance, they probably play an important role in the structuring of marine communities. Even allowing for the unpredictability of strandings, cetacean carcasses are an important food source for terrestrial and benthic scavengers (Katona and Whitehead, 1988).

The occurrence of baleen whales on the coast of South America is restricted to the second semester of the year, during the austral winter. Humpback and Southern Right Whales (*Megaptera novaeangliae* and *Eubalaena australis*, respectively) use coastal areas and islands as breeding grounds, but do not feed while there. Thus their impact on local ecosystems is relatively low, apart from being a food source for other top predators (e.g., sharks) or scavengers when dead. However, seagulls have been observed feeding on skin from the back of Right Whales when they are on the breeding grounds (Rowntree *et al*., 1998; Groch, 2001). On the other hand, odontocetes are present all year round and have important roles in the structuring of aquatic food chains, consuming a great variety of organisms. As a rule they are opportunistic, consuming the resource that is most available, including pelagic and demersal fish, cephalopods (octopuses and squids). However, some species are highly specialized, as the Sperm and Beaked Whales (families Physeteridae and Ziphiidae), which feed almost exclusively on squids.

SOUTH AMERICA, COASTAL GEOMORPHOLOGY

Investigation into the coastal geomorphology of Latin America does not have a lengthy history, but there are some indications that Latins and others are turning their attention to this important area (Psuty, 1970; Tavares Corrêa, 1996; Bittencourt *et al*., 1999; Klein *et al*., 2002). Large portions of the coastal zone remain unstudied in detail, and frequently only general descriptions exist (Putnam *et al*., 1960; Dolan *et al*., 1972; Bird and Schwartz, 1985). Questions about regional correlations of depositional and erosional features must await basic research into topical problems. However, the following interpretation of the coastal geomorphology of South America is presented as a base upon which to build many future layers of information.

Colombia

From Venezuela to the east to the border with Panama to the west, the Caribbean coast of Colombia is approximately 1,030 km in length. The Guajira Peninsula is the northernmost arm of the Andean mountain system, and the extreme northeastern tip is fronted by an active coral reef. Some evidence has been presented (Anderson, 1927) that there are raised coral platforms and fossil mollusks representing tectonic displacement of the land terminus. Sandy beaches without accompanying coral line the northwestern margin of the peninsula southward to Cape San Juan de Guia, where crystalline cliffs occur with pocket beaches.

South of Santa Clara the coastal zone is dominated by the delta of the Magdalena River. There is a broad arcuate delta in this area with several active distributaries. Great quantities of sediment are transported to the ocean to be reworked. Mangrove-covered mudflats are characteristic of this area, as is beach ridge and chenier topography. The fluctuating activity of the distributaries is responsible for episodes of accretion and erosion of the shore. Beach ridges and cheniers (*q.v.*) on the delta show the old coastal alignments, and their truncated forms provide evidence of reorientation of the coastline in past times. Near the Colombian–Panamanian border the Atrato delta provides the source of the sediments that form the shore features, but there is little change. Mangrove forest, distributary channels, and sand ridges along the distal margins continue to characterize the coast.

The 1,300km-long Pacific coast of Colombia begins as a high-cliffed coast at the Panamanian border. A portion of the flank of the Andes comes to the sea to create steep, vegetation-cloaked precipices plunging directly into the water. West (1956) described the region from south of Cape Corrientes to the border with Ecuador as having short drainage systems leading from the steep mountainous ridges, a shore consisting of fluvially derived sediments, and, with the exception of three places where the coast is cliffed, narrow sandy beaches lying between the ocean and dense mangrove forests. Large mudflats occurred in front of the beaches and in front of the fluvial plain at the foot of the mountains. In 1995, Martinez *et al.* reported for the first time in the periodical literature that most of the Cape Corrientes to Tumaco shore consisted of a series of barrier islands. Subsequently, Martinez *et al.* (2000) and Morton *et al.* (2000) described barrier washover events resulting from a relative sea-level rise. They attributed the relative rise in sea level variously to long-term subsidence, short-term seismic subsidence, and El Niño events.

Ecuador

The coast of Ecuador, including the shores of the Puna, Jambeli, and Galapagos islands, is about 2,500 km in length (Ayón and Jara, 1985). The northern coast is drenched with rainfall, and supports a dense vegetation down to the shore. However, at the southern margin of the country, the coast is stark and almost devoid of all vegetation. At both extremes, the coast consists of high cliffs fronted by a sandy fringing beach or pocket beaches. The high cliff extends consistently from near the border with Colombia southward to near Santa Elena. Near the latter location the coast takes a right-angle bend and trends southeastward. Along this portion of the coast, Sheppard (1930) described a series of marine terraces rising step-like to an elevation of 60 m. He interpreted these features as evidence of tectonic displacement. Ayón and Jara (1985) reported continental uplifting in this region as high as 200 m, evidenced by Pleistocene beachrock benches (locally called *tablazos*).

The Gulf of Guayaquil is an estuarine system whose shore is fringed by dense stands of mangrove on mudflats (Twilley *et al*., 2000). Near the distal margins of the estuary, beach-ridge systems make up several of the exposed points. However, the southern margin of the estuary remains a cliffed coast. Southwestward toward Tumbes in Peru, a high-cliffed coast dominates with either a sandy fringe or pocket beaches.

Cliffs, shore platforms, and pocket beaches border the volcanic Galapagos Islands (Ayón and Jara, 1985). Eroded craters have resulted in steeply plunging cliffs, and shore platforms are cut into former lava flows. Uplift of some of the islands by about 100 m is shown by exposed sedimentary rocks and submarine lavas.

Peru

The hyperaridity of coastal Peru is responsible in large part for the specific geomorphologic features found there. The lack of precipitation presently limits the contribution of fluvially transported sediments to the littoral zone, and thus limits the development of beaches. During the Holocene, as the sea level was rising and melt-waters were coursing through the river valleys leading to the Pacific Ocean, there were great quantities of sediment discharged to be reworked by the waves and currents. Large sediment volumes were sent into the small estuaries at the river mouths and onto the narrow continental shelf. However, only a few rivers continuously reach the sea at present, and the situation has changed from that of several thousand years ago. The rise in sea level has continuously encroached upon the small estuarine locations, and scattered tectonic displacement has produced further alterations of the coastal features.

Peru is characterized by the presence of a 2,300km-long cliffed coast interspersed with pocket beaches and beaches fronting river mouths. The pocket beaches tend to be located where more easily eroded rock formations of sandstone, shale, or marl are exposed at the shoreline. The rocky promontories are usually composed of crystalline rock units. In a few places the cliffed coasts are cut into colluvial deposits that have moved down spacious interfluves during the Quaternary. At locations where the cliffs are in colluvial gravels and cobbles, a narrow fringing beach usually exists.

South of Pisco there is little or no coastal plain, and the coast usually consists of towering cliffs or small crescent-shaped embayments with narrow beaches. From Pisco north to Chiclayo there are a number of rivers that reach the sea and contribute to the development of localized coastal plains. According to Parsons and Psuty (1975), the mouths of the major river valleys have had a similar geomorphic history and a similar assemblage of landforms. Archaeologic evidence suggests that the fluvial plains found in these river mouths obtained their present characteristics about 1,000–1,500 yr BP. At that time the embayments were filled, and the leading margin of the fluvial plain included a classic beach/dune profile. The profile has been migrating inland since that period over a narrow backmarsh that has formed between the beach and the fluvial plain. Coastal sand dunes reach impressive size: 6 m high at the shore fringing the Sechura Desert and 20 m high at Negritos (Bird and Ramos, 1985). At the southern margins of the valleys, there is frequently a dynamic beach area where sand is being moved inland by the prevailing winds out of the southwest. The coastal dune ridge is frequently enlarged in this area and transformed into longitudinal dunes extending inland. In some instances, barcan dunes break off the sand sheet and migrate independently across the terrace surfaces.

Coastal displacement is evidenced in many locations of coastal Peru by raised shore platforms and raised beaches. Bird and Ramos (1985) reported Quaternary marine terraces (tablazos), incised by transverse valleys (quebradas), south of Zorritos. Other investigators have identified as many as 10 coastal terraces at elevations of up to 250 m at the mouth of the Ica River (Broggi, 1946) and up to 75 m in the Sechura Desert area. However, there is some question whether the displacement is part of regional uplift or local movement. Several detailed inquiries (Craig and Psuty, 1968; Parsons and Psuty, 1975) have shown that the movement is local because the platforms do not extend great distances. Further, flanking terraces in the valleys are Pleistocene depositional features. Most of the major river valleys contain no evidence of post-stillstand uplift (Psuty, 1978). In northern Peru, Richards and Broecker (1963) collected marine shells from several terraces that implied emergence of the platforms. A low terrace at 4.5 m had shells collected on its surface dated at 3,000 yr BP, whereas a high terrace of 75 m had shells assayed beyond 30,000 yr BP.

Chile

The coast of Chile trends parallel to the uplifted longitudinal coast ranges for about 4,400 km, or a total length of 35,000 km when all of the inlets and islands are considered (Araya-Vergara, 1985). The northern two-thirds of coastal Chile has characteristics similar to those of Peru. The Andean coastal range comes down to the sea, and the cliffed coast is interrupted by small pocket beaches or alluvial embayments where infrequent streams lead down to the shore. Numerous terraces appear along the cliffed headlands fronting the foothills. According to Börgel (1967), there are a series of steps reaching to 200 m, thought to be terraces of abrasion, north and south of Valparaiso. Paskoff (Fuenzalida *et al.*, 1965) believes that the highest terraces found in northern Chile at 250–400 m are probably Pliocene, whereas those below 250 m are likely to be Pleistocene. Numerous investigators (Fuenzalida *et al.*, 1965) have identified the considerable number and variety of terraces found in coastal Chile. It is unlikely that the terraces can be considered wholly as products of eustatic sea-level changes, as was suggested in the early investigations. Rather, the lack of uniformity in number, elevation, and kind points to localized tectonic events. However, one terrace at the 85/100 m level does appear to persist throughout much of northern and central coastal Chile. It is considered to have extensive deposits of marine gravel on its surface and also marine mollusks. It is possible that this surface represents an episode of regional displacement.

Rainfall increases southward in Chile, but there are no major coastal alluvial plains developing. The coast range comes to the sea and provides for only modest embayments. Pocket beaches prevail south from Valparaiso to Chiloé. However, the shores near the mouth of the Bio-Bio River and south of the Mataquito River are well developed, with sizeable active dunes penetrating inland. In this region of the Aruaco Province, Tavares Correa (1996) has investigated the potential of coastal dune management and "According to the aeolic potential, the dune environment of the three sectors were classified as for Conservation (South Sector), Stabilization (North Sector) or a combination of them (Central Sector). At the same time, these sectors were divided in small units which were assigned for activities like afforestation, stabilization, conservation, agriculture and grazing." There is also estuarine development at Valdivia, where a small fluvial plain has accumulated at the mouth of a river and a narrow belt of coastal features bounds its shoreward margin. Principal Component Analysis of sand from 16 beaches in the vicinity of Valdivia by Pino and Jaramillo (1992) identified two main groups, fully reflective sites with coarser particles and steeper profiles as compared with dissipative sites with intermediate characteristics. Jaramillo *et al.* (2002) subsequently studied the reflective–dissipative effect upon sandy beach microfauna on both sides of a concrete seawall in the same region.

South of the latitude of Puerto Montt the coastal configuration is dramatically changed. The coastal range becomes broken. The island of Chiloé retains many of the characteristics of the northern coast, but to the south the coast is altered by the processes of glaciation. A fjord coast is present south of 43°S latitude, with many channels extending entirely across the crestal portion of the coastal range into the interior passage. Many of the pocket beaches are cobble-strewn and exist only in sheltered areas. In this region of tidal marshes associated with environments of glacial retreat, earthquake-induced subsidence, and braided river channel migration, Reed (1989) investigated variations in marsh topography and morphology, and found "distinct morphological differences between the marshes developed on glacial outwash and river deposits, and those formed after a major subsidence event."

Weischet (1959) reports that southern Chile has several terrace levels, but they are not continuous through the region. They may be dissected remnants of a larger surface or products of local tectonic activity. However, the degree of glaciation is so thorough in this area that it is the characteristics of glaciation that must be considered rather than those of coastal processes. Patagonia is a region of straits, fjords, drumlins and roches moutonées, with glaciers that reach the sea (Araya-Vergara, 1985). In an 18th century readvance the bay at Lagun de San Rafaél was overrun by glaciers.

Argentina

Argentina is characterized primarily by a 5,700km-long cliffed coast with a narrow beach zone before it. The cliffs vary from only a few meters to the spectacular elevations of greater than 500 m south of Comodoro Rivadavia. Occasional areas of sedimentary accumulations do exist either as beaches fronting the cliffs or as substantial areas of beach ridges and coastal dunes.

The Río de la Plata estuary, 15,000 square km in extent, dominates the northern portion of the Argentinian coast (Schnack, 1985). From the mouth of the river to Cabo San Antonio, the shore is a tidal mudflat. Wave energies are low, and the fine-grained sediments derived from the fluvial system are not reworked into a beach form. However, Urien (1972) has interpreted beach ridge and chenier forms that were created in the period of 7,000–3,000 yr BP along the southern shore of the estuary. These features were part of the sand wedge that was being pushed up the continental shelf as the sea level was rising, and they developed prior to the silting of the estuary. Urien suggests that tectonic displacement of these forms has raised them to elevations of 9 m, where they and a marine terrace form the margin of Samborombón Bay. From Mar del Plata to Bahía Blanca, the coast consists of a low-cliffed shore with a narrow beach before it. Occasionally there are large dune fields leading from the beach. This portion of Argentina is an extension of the Pampas coming to the coast. South of Bahía Blanca the Negro and Colorado rivers transport considerable quantities of sand to the shore, and the beaches are extremely broad. The alluviation is not complete, however, for there are rocky islands and points located between these two river mouths. The Colorado delta is extensive, and there is evidence of coastal aggradation in the form of beach ridges and distributary elongation. Though the Negro delta is not nearly so extensive, it manages to fill its estuary. For further studies of sediment transport along the coast of Argentina see Isla (1997), Mar Chiquita; Kokot (1997), Punta Médanos; and Cuadrado and Perillo (1997), Bahía Blanca.

With the exception of well-developed beaches and associ-ated landforms at the Gulf of San Marcos and the Gulf of San Jorge, the southern half of Argentina is a cliffed coast. Investigators have identified a number of terraces that have been used to describe tectonic or eustatic displacement. Terraces ranging to 140 m have been noted in Patagonia. A 9 m terrace at Comodoro Rivadavia has been dated at 3,000 yr BP (Richard and Broecker, 1963), and has been used to suggest local tectonic movement. Dating beach gravels and beach ridges along the Patagonia coast, Rutter *et al.* (1990) found the penultimate or older glaciation shore at 24 and 41 m above mean sea level, the "intermediate" age shore at between 20 and 28 m, and "young" Holocene beach ridges at 8–12 m. Urien (1970) has indicated that a 9 m terrace also exists in Tierra del Fuego along parts of the Río de La Plata estuary and bordering the Paraná delta. However, he cautioned against attempting any broad correlations. More recent radiocarbon dating with corres- ponding altimetry over present sea level, at 15 locations along 3,500 m of the Argentina coast, by Codignotto *et al.* (1992) indicated relative uplift rates between 0.12 and 1.63 m/1,000 yr during the Holocene. A 20th century sea-level rise of from 1.6 to 3.5 mm/yr along much of the same sector has been reported by Lanfredi *et al.* (1998).

From Santa Cruz to the eastern tip of Tierra del Fuego the cliffs are cut into glacial morainic material. Occasional outcrops of bedrock are noted, as are pocket beaches (Etchichury and Remiro, 1967). At Punta Dungeness there is an excellent series of beach ridges created where currents converge at the point. The more protected western margin shows considerable accretionary history, whereas the exposed southeastern flank gives evidence of truncation of the ridges and extensive dune fields extending inland. Schnack (1985) has described the coast of Islas Malvinas as being indented and cliffy, with some raised Quaternary shore terraces.

Uruguay

The 600-km-long coast of Uruguay is extremely diverse for such a relatively short sector. The northern area consists of an extension of the barrier island system of southern Brazil. The sandy beach continues into Uruguay but narrows and becomes discontinuous, so that it becomes a series of sandy embayments set into Uruguay's crystalline Eastern Highlands Shield (Jackson, 1985). These embayments are not products of marine processes but, rather, the prior irregular topography of the shield encroached upon by a rising sea. In several places, the embayments contain small lagoons behind a sand barrier. This feature is the product of incomplete filling of small estuaries along the margin of the shield (Chebataroff, 1960).

From near Maldonado westward, the coast is the margin of the Río de la Plata estuary. For nearly this entire length there is a cliffed coast with a sand beach lying at its base. Delaney (1963, 1966) suggested that there are terraces cut into this cliff. And it was proposed by Urien (1970) that the beach sand fronting the cliffs is the product of local erosion of the bluffs rather than fluvial transport. The exposure of this portion of Uruguay to the southeast would tend to allow greater wave energies to reach this shore and favor the necessary erosion and sorting responsible for sandy beaches, while much of the rest of the estuary is a shallow muddy tidal flat. Occasionally mudflats dominate along the cliffed coast. The Río de la Plata is formed by the confluence of the Paraná and Uruguay rivers, which flow between Uruguay and Argentina, and owing to the shallow depth across this region, navigation can only be accomplished by dredging channels for large ships (Vieira and Lanfredi, 1996).

Brazil

The great size of Brazil allows for considerable diversity of coastal exposure and geomorphologic development. There are three principal portions of the 9,200km-long coast. The first is the area influenced by the Amazon River and its sediments; the second is the narrow coastal margin fringing the huge Brazilian Shield, creating an escarpment nearly adjacent to the ocean; the third is the southern area, where considerable quantities of sediments have accumulated to provide a barrier island formation.

The mouth of the Amazon River is a great estuary stretching for nearly 1,600 km (1,000 miles). Large quantities of sand and especially silt and clay are discharged by the river and accumulate along the shore margins. From the border with Surinam eastward to the Gulf of San Marcos, the fine-grained sediments blanket the shore and are cloaked with mangrove. The Gulf of San Marcos is another, much smaller, estuary that similarly contributes large quantities of fine-grained sediment.

East of the Gulf of San Marcos the shore begins to be characterized by sandy beaches lying before low hills. The sand beaches are interspersed with mangrove stands that dominate where local deltaic buildout occurs in association with short drainage systems leading off the eastern margin of the Brazilian Shield. Beginning in Rio Grande do Norte and continuing southward to the coastal margin of Alagoas state, the beach zone is severely attenuated. The dry climate and the short drainage systems limit the transport of sediment to the ocean margin. Further, this portion of Brazil is bordered by a fairly extensive coral reef. Where beach sediments have accumulated, there are also likely to be well-developed dune forms migrating inland over terrace surfaces.

South of Recife the coast is cliffed. The combination of cliffed coast and the presence of coral reef extends for 480 km (about 300 miles). Near Recife a small promontory has been investigated for evidence of a high sea level. Van Andel and Laborel (1964) have dated a fossil biogenous limestone that is encrusting granite a few meters above modern sea level as having been active 1,200–3,600 yr BP. The authors interpreted these dates to hypothesize that sea level was higher in that time period.

The sandy beach backed by an escarpment begins near the Alagoas–Sergipe border and continues south to Rio Grande do Sul. The beach often broadens in large curvilinear embayments, and there may be local mangrove stands, beach ridges, and deltaic buildout. However, the escarpment dominates the horizon, and the coastal geomorphic features occupy a small niche on the continental margin. Bittencourt *et al.* (1999) have proposed large-scale tectonic flexure as controlling geomorphic characteristics in this region. In the state of Paraná there is an extensive area of beach ridge development associated with the Maciel river. These ridges appear to resemble cheniers in that they are bounded by clayey deposits rather than forming a broad sandy surface. The beach ridges attain elevations of 10 m in their interior location, and gradually decrease to elevations of 2–3 m near the shore. Bigarella (1965) believed this was further evidence for a fluctuating and generally falling sea level. Where the state of São Paulo borders that of Paraná, Tessler and de Mahiques (1993) have shown that coastal sedimentary features, such as spits and sandbanks, are clearly indicative of longshore sediment transport directions.

Along the coast of Santa Catarina state there are a number of headland bay beach systems bounded by headlands or rock outcrops, where the shore assumes a curvature form. Klein *et al.* (2002) have investigated short-term beach rotation processes at three such sites. They found that erosion–deposition events varied with incident wave direction. And while there was no loss of sediment from a sector, original realignment was attained with a return to the prior wave direction.

The coastal margin of the state of Rio Grande do Sul is distinct from the rest of Brazil—it consists of a classic barrier island–lagoon sequence. Delaney (1963, 1966) described the geologic origin of the barrier island sequence as occupying a unique position in a geologic depositional basin with sediments being transported into it from several directions. Toldo Jr. *et al.* (2000) have suggested an average depositional rate of 0.75 mm/yr during the Holocene in the Lagoa dos Patos estuary. Certainly the positive sediment budget that existed in this area with the changing sea level caused the particular assemblage of broad sandy beach extending along the coast for 640 km and incorporating 120km-wide (Cruz *et al.*, 1985) beach ridge systems and large coastal dunes reaching 25 m in elevation. The northern margin of this Holocene coastal plain comes against a terrace surface with elevations of 15 m. It is probably of Pleistocene age, but whether its origin is wave-cut is unknown.

French Guiana, Surinam, Guyana

The coast of what was once referred to as the European Guianas is somewhat similar for its entire length of over 1,100 km. Basically, the shore is the product of massive quantities of fine-grained sediments discharged by the Amazon River that proceed to drift westward. Some small quantities of sand are contributed by the Amazon and by the smaller streams leading from the Guiana Shield to the shore.

The beach and inland coastal geomorphology of the Guianas is characterized by the active development of cheniers. These ridged features are coarse-grained deposits of sand and shell accumulating on a mud or clay foundation. Intermittent development of these coarser accumulations creates a series of sandy ridges bordered on either side by fine-grained sediments. At times the shore is a broad mudflat rather than a sandy beach. Several investigators (Zonnenfeld, 1954; Vann, 1959; Wells and Coleman, 1978) have described the massive clay waves that migrate along this coast and extend far out into the ocean. Turenne (1985) has described westerly migration of these waves or mudbanks as being at a rate of 1.3 km per year.

There is a type of pattern to the chenier or sand ridge development along this coast. A kind of apex forms near the west bank of the river mouth from which a series of ridges extends. The number and extent of the ridges decrease westward to the point where the coarser sediments are no longer found. Some of the river mouths, such as those of the Marowijne and the Suriname, show evidence of west bank progradation for several kilometers by means of mudflat development interspersed with sandy ridges. The ridge trends also provide evidence that the progradation sequence has not been continuous, because numerous ridges are truncated and new fulcrums have developed from which a fan-shaped series of ridges has spread.

Much of the mudflat area is colonized by mangrove. These trees line the shores in places as well as occupy the troughs between the ridges. Wave action appears to be attenuated by the extremely turbid waters, and thus the coastal clays are only infrequently disturbed. However, during the infrequent higher wave energies, there is considerable movement of the clay waves (see above). Large units of clay are displaced, and the sand and shell are sorted to accumulate as a beach on top of the clay base. These beaches continue to develop to form the cheniers.

Coastal lengths of these sectors are, respectively, French Guiana, 370 km (Turenne, 1985); Surinam, 350 km (Psuty, 1985); Guyana, 434 km (Schwartz, 1985).

Venezuela

Venezuela derives its name from late 15th century explorers finding lake dwellings on piles in mangrove swamps, and thus calling the area “Small Venice” (Ellenberg, 1985). Coastal Venezuela, 3,000 km in length, tends to be dominated by the northern terminus of the Andean mountain system. The distal portion of the Andes splits into two north-trending prongs and between them creates the depression occupied by Lake Maracaibo and the Gulf of Venezuela region. The eastern prong makes a sharp bend due east and establishes the northern margin of the country for most of its length. Modifications of the mountainous coastal topography are caused by deltaic development and by breaks in the Andean ridges.

The eastern coast of Venezuela is completely the product of the Orinoco River and its deltaic forms. A fairly large arcuate delta occupies the position from the Gulf of Paria south to the border of Guyana (van Andel, 1967). The southern third of the delta tends to be a series of coalescing distributaries that retain their fluvial forms as they discharge into the Atlantic. However, the northern two-thirds of the delta is lined with cheniers forming a well-developed shore. Mangrove forests occur at the frontal lobes of the southern margin of the delta and at the northern margin. However, in the area of chenier development, the mangrove is in the protected troughs between the ridges rather than at the exposed coast. Warne *et al.* (2002) have traced the evolution of the delta from a late Pleistocene sea-level lowstand to its present stand in the mid-Holocene.

They have also reported that the Volcán Dam, built on the Cãno Manamo to prevent flooding, expand agriculture, and enhance navigation, has had a negative effect on farming due to the presence of pyrite in the soil.

The Paria Peninsula is bounded on its southern side by sand beaches and fairly broad mudflats. The sand beaches are found in association with small streams that drain the high peninsula and contribute their coarser sediments. The eastern half of the south side of the peninsula is a steep rocky cliffed coast, as is the entire northern portion of this Andean extension. There are some pocket beaches, but not until the Gulf of Barcelona is a well-developed beach found. The shore consists of a broad curvilinear beach that has characteristics of barrier island development because several lagoons are formed behind it.

Westward beyond the Barcelona embayment, a cliffed coast appears once again with a number of pocket beaches. A well-developed sandy beach is located at the Triste Gulf; and there is a low, narrow isthmus connecting the Paraguaná Peninsula with the mainland, the result of recent uplift (Ellenberg, 1985). Along the Gulf of Venezuela most of the shore is sheltered from marine processes, and thus the features are of fluvial origin and the shores are marshy or lined with mangrove. However, that portion of the gulf exposed to swell waves from the northeast does have prominent coastal forms. The exposure to the northeast is also the dominant fetch direction for the tombolo to Paraguaná and the Triste Gulf beaches as well.

Tanner (1970) has shown that the western shore of the Gulf of Venezuela has a barrier island formation with a series of beach ridges prograding seaward over a distance of 7 km. The ridges are (low, (only about 1 m local relief) and there have been several interruptions in the accumulation sequence. These erosional breaks in beach ridge development are marked by longitudinal and parabolic dunes at the erosional shoreline whose form extends inland over older beach ridges. A number of beach ridge sectors along the Venezuelan coast are backed by sabkha salt lagooons (Ellenberg, 1985).

SPITS

General features of sand spits

Longshore currents lose their sediment transporting capacity at the down-current side of the break in coastline orientation, where the wave energy abruptly drops off, causing the currents to weaken (Horikawa *et al.*, 1988). Sediment accumulates at this location, forming elongate spits, which grow in the direction of the predominant longshore drift. The spits are classified according to their plane shape configuration as simple spits (with relatively linear features), recurved spits (with a distal end hooked landwards), and complex spits (with plural hooks). Figure S53 shows an example of the actual plane shape of a complex spit. Material supplied from the upcoast is transported alongshore to the distal portion, resulting in the extension of the spit. The configuration of the spit terminus depends mainly on (1) the longshore sediment transport rate; (2) wave diffraction and refraction processes; and (3) the interaction between dominant waves and waves arriving from different directions (Zenkovich, 1967). The episodic growth of hooks characterizes the development of a complex spit, as illustrated in Figure S54. A double spit, which is a set of spits extending toward each other from two adjacent locations, frequently develops on a coast where the sediment is

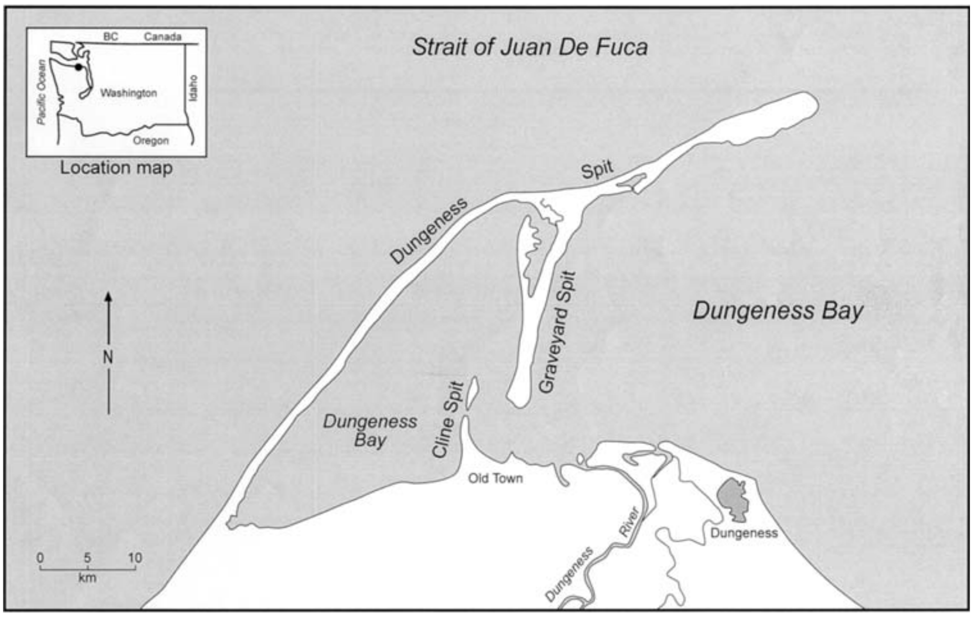

Figure S53 Dungeness Spit, a complex spit on the west coast of the USA (from Schwartz *et al.*, 1984, with permission of the *Journal of Coastal Research*).

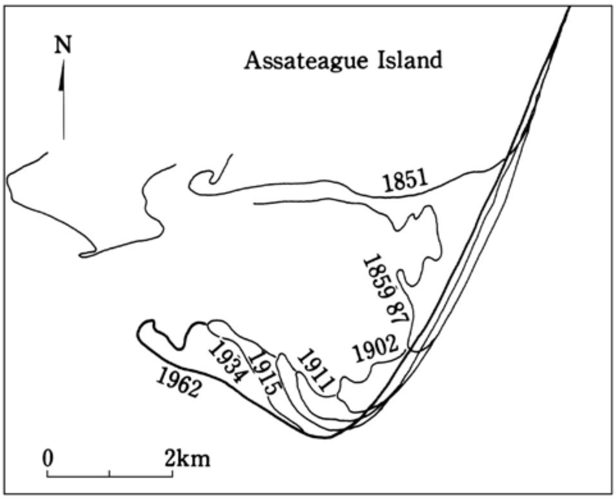

Figure S54 Growth of complex spit, located at southern Assateague Island, Virginia, USA (after Finkelstein, 1983).

transported alongshore in one direction at one time interval of long duration, and in the opposite direction at another time interval.

Longshore growth of spits results in the formation of barriers, with lagoons at their landward side. In addition to longshore spit elongation, barriers can be formed in close association with the postglacial sea-level rise: (1) a straight offshore bar emerged with sea-level rise and migrated landward to form a barrier; or (2) a preexisting subaerial sand mound in the vicinity of the shore moved landward keeping pace with sea-level rise to develop a barrier. Separation of a barrier by estuaries or tidal inlets leads to the formation of a barrier island. The origin of an actual barrier island is complex reflecting local wave climate, sediment supply, and relative rise of sea level (Schwartz, 1973).

Experiment of formation of sand spit and modeling

Sand spits can be reproduced by the movable bed experiment (Uda and Yamamoto, 1991). The initial contours of semicircular shape are made by using sand of median diameter of 0.28 mm in a wave tank, and the bed slope is one-fifth as shown in Figure S55. The initial shoreline is given by a semicircle of $r = 1.5$ m. Given incident wave height of 3 cm and wave period of 0.8 s, subsequent beach changes due to waves were measured. Figure S56 illustrates the shoreline changes under the 2.5-h wave action. The shoreline upcoast of No. 10 retreats, while it progrades downcoast of No. 10. The retreat rate of the shoreline in the eroded zone is faster in earlier stages, and its rate decreases with time. Sand transported by longshore drift accumulates near No. 13 and No. 14 located in the wave shadow zone to form a sand spit. The growth rate of the spit is also faster in earlier stages, and it gradually decreases with time.

Figure S57 shows the bottom contours measured after the wave action of 3 h The interval of the contour lines between 10 and 0 cm on land is very narrow at No. 1 through No. 7, whereas the interval between -2 and -8 cm is wide. This means that the scarp was formed on the foreshore, whereas a gentle slope is formed on the sea bottom due to the erosion. At No. 11 through No.15, the interval of the contour above 2 cm is similar to those at the initial state, but the contour intervals between 2 and 0 cm are widened and those between -2 cm and -16 cm are narrowed, indicating the formation of a flat plane on the foreshore and a steep slope below the sea surface.

The typical beach profiles representing the erosion and accretion zones, and the one in a neutral zone without erosion and accumulation of sand, are compared as shown in Figure S58. Along No. 2, located in the eroded zone, the shoreline significantly retreats with the formation of a scarp. The foreshore slope is constant, and the scarp is formed above the foreshore. During the erosion process, the slope of this scarp and the fore-shore slope remain constant, implying that the steep slope on land deforms as if it moves in parallel. Furthermore, the closure depth is 8 cm and a gentle slope is formed between the closure depth and the depth of 2.5 cm. Along No.13 in the accretion zone, most topographic change is observed below the sea surface. Sand accumulates within the wave run-up zone forming a flat beach surface. During the progradation of the shoreline, the foreshore slope remains constant. The bottom slope remains almost constant in the zone deeper than -2 cm, and the steep slope deforms as if it moves in parallel. In the eroded zone, no topographic deformation takes place below the critical depth for sand movement.

In summary, the initial topography does not change in the upper part of the scarp. In the accretion zone, the initial topography does not change at levels higher than the maximum wave run-up height. Similarly there is no topographic change in the zone deeper than the critical depth

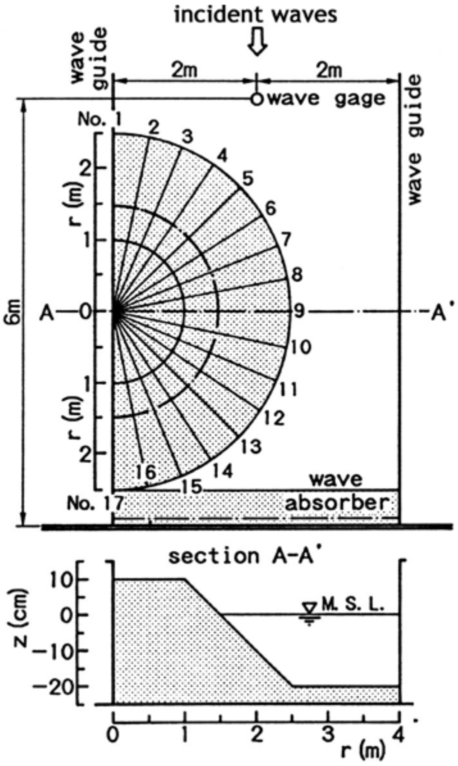

Figure S55 Model beach and alignment of measuring lines (from Uda and Yamamoto, 1991, with permission of the American Society of Civil Engineers).

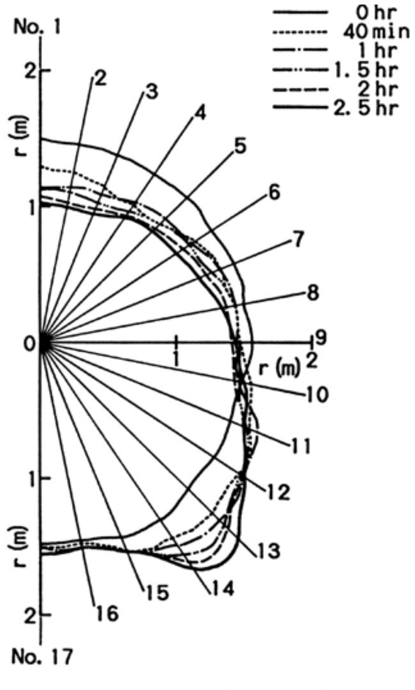

Figure S56 Change in shoreline configuration (from Uda and Yamamoto, 1991, with permission of the American Society of Civil Engineers).

where sediment is deposited. These profile changes can be modeled, as schematically shown in Figure S59.

Numerical simulation of formation of sand spit

Ashuton *et al.* (2001) show that coastline instability takes place when the incident angle of the deepwater waves relative to the shoreline exceeds 45°, and a sand spit can be automatically formed from an infinitesimal disturbance of the shoreline. In their method, the shoreline is divided into the infinitesimal meshes in the x- and y-axes, and unidirectional sediment movement forming a sand spit is reproduced by using this coordinate system. However, longshore sand transport is not provided by the deterministic method from the wave field. Watanabe *et al.* (2002) show that successive development of a sand spit can be numerically predicted using a one-line model with orthogonal curvilinear coordinate system fixed on the ever-changing shoreline. In their model, the breaker height and breaker angle are determined first on this coordinate system and longshore sand transport rate is obtained from these values, resulting in the shoreline calculation based on the continuity of sand. A new sea bottom shape is inversely assessed from the new shoreline configuration at some steps, assuming the profile changes in eroded and accreted areas, as shown in Figure S59, and a new wave field is calculated using this sea bottom data. Furthermore, smoothing of the shoreline configuration and redistribution of grid points are carried out to ensure the stability of the calculation. Figure S60(a) is the sand spit formation around an artificial sandy island measured in Alaska (Gadd, 1979a,b). A rectangular island of 137 m length and 99 m width was created in the very shallow sea of the depth of 0.91 m. Comparison of the shoreline is made between December 1976 and September 1978. Sand was transported from the northeast corner of the island due to the predominant waves from the northeast, and sand deposited to form two sand spits in the wave shadow zone at the southeast and northwest corners.

Figure S60(b) shows the calculation results assuming the incident wave height of 0.3 m and the wave period of 3 s. The wave field is predicted based on the wave orthogonal theory assuming irregular waves. In the calculation of the shoreline change using a finite difference method, time step of $\Delta t = 5.0 * 10^{-2}$ h is selected and the shoreline change was calculated up to 30,000 steps. Renewal of the depth data and resulting wave field was carried out at 300 steps (15 h). Furthermore, the closure depth, wave run-up height, tan β_E and tan β_A as shown in Figure S59 are set to be 40 cm, 20 cm, 0.1 and 0.3, respectively. The initial shoreline of a rectangular shape deformed with the successive recession of the shoreline at the northeast corner of the island. Eroded sand was transported by longshore drift forming two sand spits at the northwest and southeast corner of the island. Observed results are well reproduced by the numerical simulation. Figure S60(c) shows the seabed topography after change. A mild seabed was formed in the eroded zone, whereas in

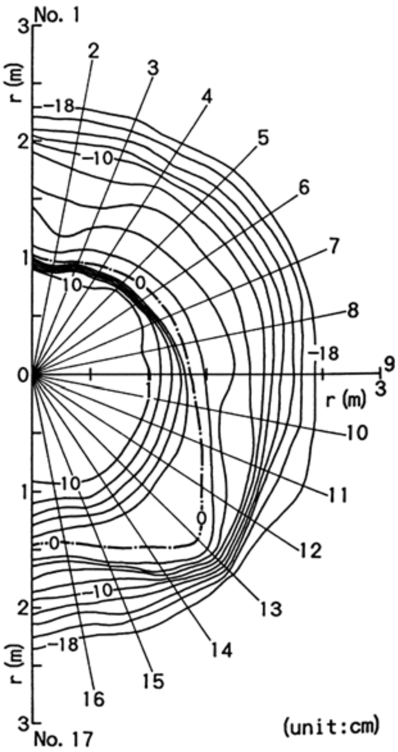

Figure S57 Beach topography after the formation of sand spit (from Uda and Yamamoto, 1991, with permission of the American Society of Civil Engineers).

the accretion area, a flat foreshore was formed due to the berm formation as well as the steep slope due to the falling of sand into deep sea. Thus, in the prediction of the development of the sand spit, coupling of changes in waves and sea bottom is important.

STORM SURGE

A storm surge is the increase in ocean water level near the coast generated by a passing storm, above that resulting from astronomical tides. The atmosphere acts on the sea in two distinctly different ways. A reduction in the atmospheric pressure reduces the vertical force acting on a column of water beneath the sea surface, causing the sea water to rise, and *vice versa*. A decrease in atmospheric pressure of 1 mb will produce an increase in sea level of around 1 cm. This change is called the *inverse barometer* effect. The inverse barometer effect is seldom exactly observed in nature, because of the complex ways in which shallower waters of the continental shelves interact with passing atmospheric pressure systems.

Another major meteorological process contributing to the surge is the drag or stress on the sea surface due to the wind, measured as the horizontal force per unit area. Wind stress depends upon the wind speed and air density. The wind strength as well as direction relative to the coastline are important factors in elevating the sea surface. Wind blowing toward the coast causes a much greater rise in sea surface than wind blowing parallel to the shore. The effect of the wind on sea level increases inversely with water depth. Thus, the surge is amplified when wind blows over wide regions of shallow water, such as the North Sea or the northern end of the Bay of Bengal, off the coast of Bangladesh. The superposition of wave run-up on a high surge increases the storm hazard.

Two distinct types of meteorological disturbances produce major surges leading to coastal flooding and beach erosion (Dolan and Davis, 1994). These include tropical and extratropical cyclones. Tropical cyclones (known as *hurricanes* in the Atlantic basin, *typhoons* in the western Pacific, and *cyclones* in the Indian sub-continent) are intense low-pressure systems that strengthen over the ocean at low latitudes, where sea surface temperatures are at least 27°C (Landsea *et al.*, 1999). Tropical cyclones are usually small in extent but very powerful. The storm surge produced by a hurricane is a dome of water raised by the low barometric pressure, coupled with the strong wind shear (maximum sustained wind speeds of at least 119 km/h; surges 1–2 m), particularly on the right side of the low-pressure system. The hurricane's strength is greatest in the upper right-hand quadrant, as the high-velocity winds flowing counterclockwise around the eye (in the Northern Hemisphere) reinforce the lower-velocity steering winds which direct the forward motion of the cyclone (Coch, 1994).

Extratropical cyclones typically have lower wind speeds than hurricanes. Yet they often inflict considerable damage along the coasts because they cover a much wider area (> 1,000 km for extratropical cyclones versus 100–150 km for hurricanes) and are longer in duration, often persisting over several tidal cycles at a particular location (Dolan and Davis, 1994). South of Cape Hatteras, along the East Coast of the United States, tropical storms occur more frequently than extratropical storms, whereas further north, extratropical cyclones become dominant (Zhang *et al.*, 2000).

In addition to weather systems, surges are influenced by the configuration of the coastline and bathymetry. Surges are amplified by a wide continental shelf and where the coastline makes a right-angle bend, as, for example, at the apex of the New York Bight (Coch, 1994) or along the coast of Bangladesh (Murty and Flather, 1994). Interaction between surges and tides due to local topography may considerably change surge amplitude and phase.

The surge is amplified significantly when it coincides with astronomical tides (Wood, 1986). Above-average tides occur at new or full moon (spring tides), and at the solstices and equinoxes. These fortnightly or seasonal high tides are reinforced when they coincide with perigee (the closest approach of the moon to the earth in its orbit), or perihelion (the closest approach of the earth to sun). Tides, especially at high latitudes, are further enhanced during the 18.6-yr lunar nodal cycle, when the angle between the plane of the moon's orbit and the ecliptic is minimum (see *Tides*).

Many major extratropical storms have struck the eastern North American coastline at times close to perigean spring tides (Wood, 1986). One of the worst in almost 100 years was the "Ash Wednesday Storm" of March 6–7, 1962 which affected the entire Atlantic coast from South Carolina to Portland, Maine. This storm owed much of its destructiveness to its duration over five tidal cycles. Another major perigean spring storm was the "Saxby Tide" or "Saxby Gale" of October 4–5, 1869, which caused enormous damage along the Bay of Fundy, Canada (Desplanque and Mossman, 1999). Tides were nearly 2 m above the previous record. More recently, the entire New York metropolitan transportation system was paralyzed by flooding caused by a powerful nor'easter on December 11–12, 1992. With tides already above normal due to full moon, the water level at the Battery tide gauge peaked at 8.5 ft above National Geodetic Vertical Datum (7.8 ft above mean sea level; US ACOE/FEMA/ NWS, 1995).

Historical observations

Historical storm activity has been monitored using meteorological data and tidal records. Dolan and Davis (1994) have calculated wave heights from wind field data for each important storm along the East Coast, United States between 1942–92. They developed an extratropical storm classification scheme, similar to the Saffir–Simpson scale used for hurricanes, based on significant wave heights, duration, and storm "power," which they define as the square of significant wave height times duration. While this approach provides an index of storm damage potential, it does not specifically measure surge levels associated with these storms.

Another approach is based on measurement of hourly water levels recorded by a tide gauge. Since the water height includes surge, astronomical tide, and long-term sea level trends, the latter two components must be subtracted. Twentieth-century patterns of storm activity along the East Coast, United States have been reconstructed from hourly tide gauge data with records longer than 50 years, after removal of astronomical tide and sea-level factors (Zhang *et al.*, 2000). Storm indices based on surge number, duration, and "integrated intensity" (area under surge curve greater than 2 standard deviations) showed considerable interdecadal variations, but no consistent long-term trend during the 20th century.

The likelihood of future storm surge events can be calculated from daily or monthly surge maxima measured at individual tide-gauge stations, after appropriate correction for tides and secular sea-level trends (Ebersole, 1982). Statistical analyses of such data can then be used to prepare return period curves which show the probability of occurrence of a given surge (or flood) height (Figure S61). The total flood level (surge + tide + sea-level rise) is a more meaningful elevation for assessing impacts to coastal settlements and installations. The 100-year flood level is a commonly employed reference level (FEMA, 1997). It represents the flood height that has a 1% probability of occurrence in any given year.

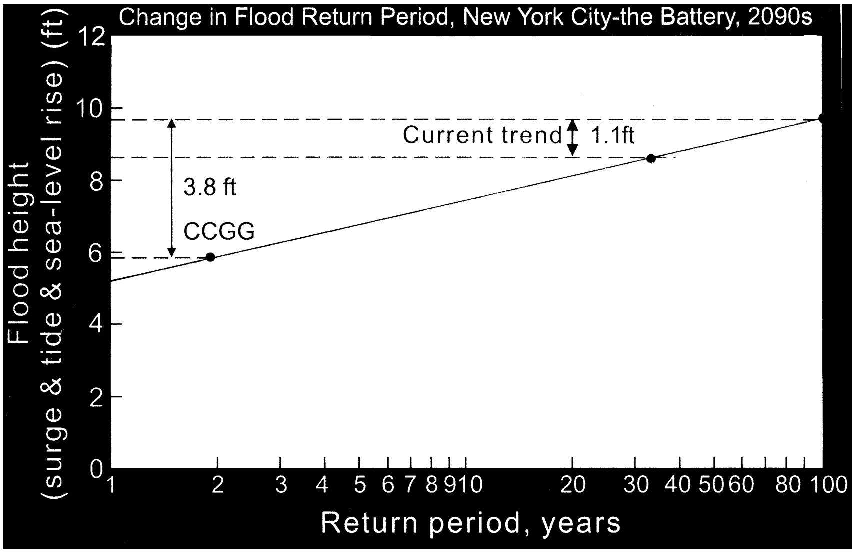

Figure S61 Flood return curve for New York City (based on data from S. Couch, US Army Corps of Engineers, New York District). The present 100-year flood level is 9.7 ft (upper dashed line). Extrapolating current rates of sea-level rise, the 100-year flood height is reduced to 8.6 ft (2.6 m) by the 2090s, with a return period of 33 years. A climate model (Canadian Climate Centre Model, greenhouse gases only, CCGG) projects a sea-level rise of 3.8 ft (1.15 m), with a return period of ~3 years (based on data in Gornitz *et al.*, 2002).

Modeling surges

The empirical data needed to derive return period curves are not available at all locations. Therefore, the storm-induced surge is often estimated by mathematical models, such as the WES Implicit Flooding Model (WIFM), tidal hydrodynamic model, frequently used by the US Army Corps of Engineers (Butler, 1978; Butler and Sheng, 1982). WIFM solves vertically integrated dynamic, shallow-water wave equations of fluid motion, incorporating information on bathymetry, topography, wave, and meteorological data in order to simulate coastal flooding. An important feature of this model is its ability to stretch the numerical grid, which allows a denser grid resolution in areas of particular interest.

The US National Weather Service has developed a numerical- dynamic surge model, SLOSH, for real-time forecasting of hurricane surges on continental shelves, open coastlines, and estuaries (Jelesnianski *et al.*, 1992). The model is activated by inputs of simple meteorological parameters (minimum central pressure, radius, storm track, and speed along track). The storm model balances surface forces including surface friction. Short period wave "run-up" is omitted; other longer-term wind–wave effects are generalized. SLOSH surge predictions are regularly applied to hurricanes affecting the US East and Gulf Coasts.

Another type of surge model treats the land–water interface as a moving boundary with inland grid cells becoming flooded as the water-level rises due to the storm surge or tide, and draining as the water recedes (Hubbert and McInnes, 1997). This model can readily be applied to projections of future sea-level rise.

Effect of sea-level rise on coastal flooding

Anticipated climate change is expected to accelerate rates of global mean sea-level rise by factors of 2–5, by the end of this century (IPCC, 2001). The rise in sea level will come from thermal expansion of the upper ocean layers, melting of mountain glaciers, with a larger uncertainty surrounding possible contributions from melting of the polar ice sheets.

The rise in mean sea level will be superimposed on storm surges from storms and astronomical tides. Locally, sea-level rise could be higher than the global mean change, due to land subsidence. Although the increase in flood height due to sea-level rise may only comprise a relatively small percent of the total elevation (assuming that the storm strikes at high tide), yet even a minor increase in sea level could significantly shorten the flood return period (Figure S61). For example, in New York City, the present-day 100-year flood height is slightly under 3 m. If sea level were to continue rising at current rates (~2.7 mm/yr), by the end of the century a flood of only 2.6 m would be equivalent to today's 100-year event. This flood has a return period of 33 years. In the most extreme scenario of sea-level rise (over a meter above present levels), the return period could be reduced to as little as 3–4 years (Gornitz, 2002). This could lead to much more frequent episodes of coastal flooding in low-lying areas (see also *Natural Hazards*).

Coastal surge hazards

Areas of the world most vulnerable to surges from tropical cyclones include the low-lying coasts of southeast Asia adjacent to major river deltas, the southeastern United States, and the northeastern coast of Australia. The convergence of several conditions places Bangladesh especially at risk to storm surges. The coast is nearly at sea level, the continental shelf is shallow especially in the eastern part of Bangladesh, the tidal range is high, and storms tracks have a tendency to recurve near the apex of the Bay of Bengal (Murty and Flather, 1994). A severe cyclone in November, 1970 produced surges of over 9 m, killing several hundred thousand people (Pugh, 1987). Another cyclone killed 11,000 people in May, 1985.

In the United States, the low-lying Gulf states, Florida, and the Carolinas are at high risk to hurricanes, although the Northeast is not immune. A hurricane that struck Galveston, Texas, on September 8–9, 1900 raised water nearly 5 m and killed almost 6,000 people (NOAA, National Weather Service). In September, 1938, another hurricane swept across Long Island and southern New England, pushing water levels 4.5–6 m above normal, and killed around 700 people (Ludlum, 1988). Other major damaging hurricanes include Hugo (South Carolina, 1989, category 4 on the Saffir–Simpson scale), Andrew (Florida, Louisiana, 1992, cat. 4), Camille (Mississippi, Louisiana, 1969, category 5), and an unnamed hurricane that struck the Florida Keys in 1935 (category 5).

Extratropical cyclones can also result in severe coastal flooding. Regions prone to surges from extratropical cyclones include the east coast of North America north of Cape Hatteras, the coasts surrounding the North Sea, and the Adriatic Sea. The Ash Wednesday Storm of March 1962, affecting much of the US east coast was mentioned above. Other recent major "nor'easters" include the December 11–12, 1992 storm, the March 13–14, 1993 storm, and the "Halloween Storm" of October 31 to November 1, 1991 (also known as "The Perfect Storm"—subject of a best-selling novel and film).

In northern Europe, the North Sea is exposed to Atlantic extratropical storms which move across shallow shelf waters. Furthermore, the gradual subsidence of the southern North Sea area makes low-lying regions of southeast England and the Netherlands increasingly vulnerable to flooding from surges. In January 31 to February 1, 1953, a major storm broke through the dike defenses of the Netherlands, flooding a large portion of the country (Pugh, 1987).

STRANDFLAT

The strandflat is a rim of gently sloping bedrock plain in front of higher land or coastal mountains (Klemsdal, 1982, 1985). The plain has a very irregular terrain with small differences of height. Most of the bedrock plain is covered with a thin mantle of loose material; only locally does the loose material have forms of its own. The gently sloping, undulating, flat produces, when meeting the sea, an uneven coastline with numerous bays, coves, inlets, islands, islets and skerries, all characteristics features of the skerry zone. The gradient of the supramarine zone varies between 5 and 25 m per km. The topography of the supramarine and skerry zones continues into the sea. At a depth between 30 and 60 m a break in the slope occurs and steeper slopes lead down to the paleic, old forms of the bankflats constituting part of the continental shelf. Inland, the strandflat terminates at heights between 30 and 80 m, where in most places a steep slope leads up to higher land, though in some places the transition is more gentle. The coastline of the mainland and the islands of the strandflat is rather long. The shore-zone is mainly either a gently sloping ice-smoothed rocky shore, without any post-glacial alteration, or a stony beach composed of reworked till. Only locally have post-glacial littoral processes produced pocket beaches of sand or clay (Klemsdal, 1982, 1985).

The term strandflat became a geomorphological term in 1894 when Reusch introduced it into the literature. Reusch put forth, from observation of strandflat localities along the Norwegian coast, a description of the strandflat and a discussion of its origin. Marine abrasion and frost weathering were said to be the main processes responsible for the development of the strandflat. Regarding the development of the strandflat, Nansen (1922) proposed frost weathering and sea ice frozen onto the shore, combined with waves breaking up the sea ice. Local glaciation, especially cirque glaciers, and also currents of inland ice, moving and spreading out in the coastal areas, were added to the picture by Holtedahl in 1929.

Today, the origin of the strandflat is closely associated with the general development of the landforms of the Scandinavian landmass. The land was exposed to denudation through the Mesozoic and the first part of the Tertiary. In a warm climate with dry and wet periods, denudation produced a land surface, the paleic surface (Gjessing, 1967), with well-rounded, mature landforms, close to a plain in the peripheral parts of the landmass, a propitious starting point for the development of the strandflat.

In the Tertiary the Scandinavian landmass was elevated and tilted, giving a steeper slope towards the west and northwest, bringing the paleic surface to different heights above sea level. Inland along the coast it varies from sea level to 500–700 m above sea level. Along the coast the elevation of the paleic surface may have been negligible.

Probably coincident with the uplift, the climate became temperate and more humid. Fluvial processes produced initial forms along a fluvial pattern in the paleic surface, most distinct in the west and northwest. Along the coast marine abrasion and denudation, favored by the old paleic surface, may have started the development of a peneplain, which can be easily fitted into the development of the strandflat.

Cirque glaciers, descending from higher coastal mountains onto the level surface along the coast, were important in the widening and splitting up of the strandflat. Valley glaciers and ice flows of the inland ice spreading out in the coastal areas (Holtedahl, 1929; Dahl, 1947), may also have taken part in the development. In interglacial times and at the beginning of the glacial periods frost weathering and marine abrasion were momentous, and together with mass movement and littoral transport, most active in the evolution of the strandflat.

Although its origin is still not settled, it is said that it is polygenetic (Holtedahl, 1959, 1960; Klemsdal, 1982, 1985); starting with the denudational processes of the paleic surface and stressing the frost weathering and marine abrasion, even though glacial and fluvial activity also have played a part in the development of the strandflat.

The distribution of the strandflat is closely connected with areas where Quaternary glaciations took place and where a harsh climate in Holocene favored frost weathering.

In Norway, the strandflat is found along the coast from the Stavanger area in the southwest to the western Finnmark in the northeast (Klemsdal, 1982, 1985). In eastern Finnmark, the strandflat is only a narrow strip of land, some broader but still narrow submarine parts, and no skerry zone. The maximum width is approximately 40 km, but as a mean the strandflat is 16 km wide. The supramarine part of the strandflat is normally between 5 and 10 km in width, but can reach 15 km. In other places, the strandflat is a few hundreds meters wide.

Furthermore, the strandflat is found in the archipelago of Svalbard, on Novaya Zemlya; on the peninsula of Taimyr; the archipelago on the west coast of Scotland; on Iceland; along the southwestern coast of Greenland; and in the arctic areas of Canada and Alaska. In the Southern Hemisphere, the strandflat is observed along parts of the Antarctic Peninsula and neighboring islands. The mentioned localities of the strandflat are all in a harsh climate where frost weathering takes place and where Quaternary glaciations occurred or influenced the processes.

SUBMARINE GROUNDWATER DISCHARGE

Background and definitions of terms

Groundwater comprises about 95% of all the freshwater on earth (Winter *et al*., 1998). Of this groundwater, an unknown amount discharges to lakes, rivers, estuaries, bays, and oceans on an annual basis. Groundwater discharged to the marine environment (estuaries, bays, and the ocean) is known as submarine groundwater discharge (SGD), a term originally proposed by Johannes (1980). SGD occurs offshore as seepage (groundwater discharges from both unconfined and confined aquifers) (Simmons, 1989; Simmons and Reay, 1992), as recirculated seawater mixed with freshwater (Buddemeier, 1996), and in springs (Kohout, 1966). Additionally, SGD can occur in geo-thermal heat flows or vents (Kohout *et al*., 1979; Schwerdtfeger, 1981; Nossin *et al*., 1987), upwelling in reefs (Simmons and Love, 1987; Tribble *et al*., 1992) and oceanic islands (Rougerie and Wauthy, 1993).

The chemical makeup of SGD varies spatially and temporally depending upon the composition of the aquifer material, residence time of the freshwater within the aquifer, onshore hydraulic heads, the amount of recirculation of seawater and groundwater in the nearshore, and the magnitude of the tidal fluctuations. The primary chemical characteristics (or *finger print*) of the water are functions of the original geochemical composition of the groundwater and the residence time in the aquifer and minerals contacted along the flowpath.

The geologic principle of *uniformitarianism* states that geologic processes today (including SGD) are similar to the processes of millions of years ago (Wicander and Monroe, 1993). Therefore, SGD processes occurring today in beaches, estuaries, and inlets are thought to be the same as past processes, since the formation of the continental plates, changed only by the conditions that drive them. This is generally true for all types of seepage, except for seepage that is influenced by anthropogenic factors such as drainage canals and aquifer pumpage. SGD is not a recently discovered phenomenon. The earliest account of springs in the ocean was presented by Kohout (1966) in which he indicated that Pausanius, who lived in the second century AD, noticed that off the coast of western Italy ... "there is water boiling in the sea and it has created an artificial island."

Importance of SGD in the coastal environments

The significance of SGD has become more widely appreciated in the last two decades, especially in efforts to improve understanding of marine geologic and geochemical processes, nearshore and offshore water quality anomalies, nutrient loading, and ecological impacts (Kohout, 1966; Johannes, 1980; Simmons, 1992; Zekster and Loaiciga, 1993; Buddemeier, 1996). Recent research, even by lay scientific journals, has been stressing the importance of SGD (Svitil, 1996). Anthropogenic nutrient input from stormwater runoff to the oceans and estuaries was previously believed to have been a major cause of eutrophication of coastal waters (Zekster and Laiciga, 1993; Lapointe and Matzie, 1996; US Environmental Protection Agency, 1998). Although groundwater was traditionally overlooked or underestimated in previous investigations, it has been demonstrated that groundwater input can be a major source of nutrient input to the oceans. Recent research has identified nutrient enrichment as one of the major processes responsible for the degradation of coastal waters. This enrichment, which causes problems ranging from anoxia to harmful algae blooms, is directly related to the transport of nutrient-enriched groundwater into coastal waters through SGD as demonstrated by Lapointe *et al*. (1990); Shinn *et al*. (1994); Harbor Branch Oceanographic Institute (1995). Groundwater and recharge areas are often contaminated by agricultural, urban fertilizers, animal waste, shallow injection wells, septic tanks, cesspools, and other nutrient sources. The result leads to increased concentrations of nitrogen (N) and phosphorus (P) in SGD (Simmons and Love, 1987; Lapointe and O'Connell, 1989; Shinn *et al*., 1994, 1997; Finkl *et al*., 1995; Finkl and Krupa, 2000; Finkl and Krupa, 2003) with disastrous long-term effects.

Governmental agencies and private organizations need SGD information to deal with water degradation issues, develop accurate numerical models, create tidal mixing models, make circulation and temperature predictions, and to establish correct boundary conditions for numerical groundwater and oceanic model simulations (Buddemeier, 1996). Accurate determination of SGD is essential because flow volumes are used to calculate mass balances and in the determination of nutrient fluxes to the coastal waters. However, experience has shown that quantifying SGD input is difficult because of uncertainties in groundwater flux measurements.

Occurrence of SGD

The rate and direction of seepage is influenced by hydraulic heads within the aquifer and by the underlying lithology, watershed topography, and seasonal weather patterns (Freeze and Cherry, 1979). Seepage is known to occur from the nearshore (Cable *et al*., 1997a,b) up to about 100 km offshore (Manheim, 1967). The process of SGD is more complex than seepage to terrestrial water bodies because of the influence of bathymetry, micro-topology, tidal cycles, winds, currents, recirculation at or near the freshwater/saltwater interface, and the chemical, biochemical, geological, and ecological processes occurring at the freshwater/saltwater interface (Huettel and Gust, 1992; Buddemeier, 1996; Huettel *et al*., 1996, 1998; Robinson, 1996; Shinn *et al*., 1997; Uchiyama *et al*., 2000).

Seepage occurs as baseflow (flow from saturated groundwater storage) and interflow (flow from subsurface storm flow) to the surface water (Davis and DeWiest, 1966; Freeze and Cherry, 1979). The baseflow component of seepage can be further divided into two primary velocity components. The first baseflow velocity component provides the normal daily discharge to the estuary/ocean and the second velocity component is controlled by daily tidal cycles. Interflow is the temporary saturated flow within the unsaturated portion of the aquifer. This flow generally begins some time after a rainstorm or seasonal climatic change (winter to spring) and occurs until hydraulic gradients within the aquifer have leveled or have dropped to background levels.

Indentifying and measuring SGD

Nearshore submarine groundwater discharge can be seen by visual observations and measured by pore water devices, seepage meters and results of isotope analysis (Simmons and Love, 1987; Harbor Branch Oceanographic Institute, 1995; Nuttle and Harvey, 1995; Moore, 1996; Cable *et al*., 1997a,b). Offshore SGD can also be identified by side-scan sonar, near bottom echo sounders, seismic profiling, geophysical logging, conductivity, depth, and temperature (CDT) profiling, and deep-sea drilling (Manheim, 1967; Zektser and Meskheteli, 1988; Land *et al*., 1995; Merchant *et al*., 1996; Guglielmi and Prieur, 1997).

Measurement of seepage was initially developed for onshore applications, but adaptation of equipment and practices to the marine environment has recently made offshore applications commonplace. Using this relatively new and sophisticated technology, SGD rates and water quality parameters can be determined in the field. A comprehensive SGD study along coastal regions generally requires a variety of methods to best determine seepage rates. For example, monitor wells and piezometers can be used to determine horizontal and vertical gradients while water quality, radiochemistry, and seepage meter data are used to estimate the quantity and direction of seepage.

Coastal piezometers and groundwater wells

To determine the tidal effects from the horizontal and vertical movement of the groundwater/seawater boundary, Urish and Ozbilgin (1989) recommend the placement of one control well onshore, near the surf area. Onshore monitor wells and piezometers in shallow water can be installed using standard well technology, including casing advancement methods and jetting. Methods for installing monitor wells or piezometers underwater are adapted from land-based techniques, but are far more complicated and time-consuming (Lee and Cherry, 1978; Shinn *et al*., 1994). Wells used to measure vertical gradients require short-screen intervals or open-ended pipes (Freeze and Cherry, 1979; US Army Corp of Engineers, 1993). Screen lengths can be as short as 0.15 m, but are generally 0.6 m. The screens should be sufficiently separated both horizontally and vertically, to calculate differences in hydraulic heads between the monitored groundwater zones and surface water (Harvey *et al*., 2000, 2002).

Continuous logging of water level data from the piezometers, monitor wells, and surface water should be corrected to equivalent freshwater heads, if they are completed on the same flow path, to allow comparison of data (Senger and Fogg, 1990; Reich, 1996; Rasmussen, 1998). Tidal filtering of water level data should be done to obtain average vertical and horizontal gradients. To calculate the equivalent freshwater head, it is necessary to measure the transient salinities and/or total dissolved solids (TDS) concurrently with the water level measurements. All wells, piezometers, and the ground surface at each site should be surveyed vertically (elevation) and horizontally (longitude and latitude or state planar coordinates) to ensure accurate gradient calculations and site maps preparation.

Seepage meters

Since the 1930s, scientists have used a variety of chambers and seepage meters to study the benthic boundary layers associated with canal linings, rivers, and lakes (Gale and Thompson, 1975; Sonzogni *et al*., 1977; Carr and Winter, 1980). One commonly used seepage meter is the modified drum apparatus devised by Lee (1977). This meter, commonly called a "Lee meter" or a conventional seepage meter, has been used in numerous marine studies (Lewis, 1987; Cable *et al*., 1997a,b; Shinn *et al*., 2002). The Lee meter is constructed from a standard metal drum (208 L) cut into thirds. The middle section is discarded and the two end sections are each prepared by using the existing hole on one end and drilling a similar hole on the other end. A connector is fitted to each hole; these are used to attach seepage bags after the meters are placed. The meters are installed into the ground with the open end downward, seepage bags are attached to the connectors and monitored.

Conventional seepage meters operate very simply: a change in water volume in the bag over time represents a seepage flux across the sediment interface. The quantity of water in the bag is compared with the initial volume in order to determine gain or loss of water. When the bag gains water, groundwater is discharging to surface water. Conversely, when the bag loses water, the surface water is recharging the groundwater. The change in quantity of water is averaged, per unit area, and usually converted to units such as milliliters per square meter per hour or centimeters per day.

Seepage can also be measured with automated seepage meters. These devices utilize electronic flowmeters located on the tops of seepage meters or ultrasonic flow meter sensors located on the top of a funnel apparatus (Reay and Walthall, 1992; National Aeronautics and Space Administration, 1992; Taniguchi and Fukvo, 1993; Paulsen *et al*., 1997; Krupa *et al*., 1998; O'Rouke *et al*., 1999). Automated seepage meters can best deal with tidal cycles when continuous recorders are used. This allows the investigator to capture seepage rates over longer periods of time which includes storm events and normal tidal fluctuations, investigation duration (months versus days) and finally increases the statistical significance of the flux readings. Manual seepage meters capture data only over the time the bags have been installed on the meters.

Seepage meters are typically positioned within the first 100 m of the coast, according to Bokuniewicz and Zeitia (1980). Recent studies in Panacea, Florida and Perth, Australia, show that seepage typically decreases with distance from shore. However, multiple seepage meters are required at various locations in order to improve statistical significance and to evaluate spatial variability within a designated seepage location. The typical configuration of a Lee meter in the offshore environment is shown in Figure S62. Sediment changes, onshore topography, bathymetry, distance from shore, and ecological indicators such as sea grasses, corals, or algal mats should be considered when placing seepage meters. Figure S63 shows a typical nearshore seepage meter scenario with shallow and deep piezometer and conventional seepage meter.

Water budget—mass balance approach

The mass balance approach to estimation of SGD summarizes all inflows and outflows in a study area. Cherkauer (1998) states "the principle of conservation of the mass requires that the total quantity of groundwater entering the surface water must equal the net recharge within the watershed contributing flow." This approach assumes the system is in steady-state and there is no net change in the groundwater levels. Thus, the net infiltration (rainfall minus transpiration, evaporation, and anthropogenic uses) to the aquifer is equal to the SGD. Several investigators have completed large-scale regional water budgets (Buddemeier, 1996; Church, 1996), while others have attempted continental water budgets for Australia (Zektser *et al*., 1983).

As with all models, the mass balance approach makes some assumptions about the system being modeled. These approaches and approximations overlook coastal system dynamics and may provide inaccurate results.

Chemical mass balance method

Natural tracers are also used to estimate SGD. Some common natural tracers include radioactive isotopes, silica, and chloride. Geochemical data can provide a long-term integrated picture of hydraulic processes in the aquifer and the groundwater/surface water exchange (Harvey *et al*., 2000, 2002). If a particular solute occurs in groundwater and is not in other sources (or is in reduced concentrations) and the solute concentration in each source is known, the information can be used to infer the magnitude of SGD (Church, 1996; Moore, 1996, 1997; Burnett *et al*., 2003). The magnitude of groundwater contributions has largely been ignored until recent isotope (^{236}Ra) work conducted in the South Atlantic Bight by Moore (1996). Moore indicates that groundwater contribution to the nearshore was approximately 40% of the riverine inputs during his study period.

Using seepage meters to measure SGD

When using seepage meters to make direct SGD flux measurements, the seepage meters, piezometers, and monitor wells should be installed two to three days prior to sampling to allow the sediments to rebound and the system to return to equilibrium. SGD measurements made before equilibration may result in erroneous seepage rates (Belanger and Walker, 1990). The installation of traditional and automated seepage meters on the seafloor or lake/river bottom is a simple task. The installers usually stand on the seepage meter, gently rocking back and forth until the meter is pushed about 15–20 cm into the sediment surface. This can be difficult when the seepage meter is more than 3 ft (1 m) below the surface of the water. Placement of the meter is important; the threaded hole is usually placed on the upslope side of the sediment to allow the movement of water, air bubbles, and gases from the seepage meter to the bag.

Gas collection in the seepage meter can become a problem because gasses are produced by the decomposition of organic material within the seepage meters. Gas production creates additional challenges with automated seepage measuring devices. Several investigators using electronic flowmeters to measure SGD found that air bubbles sometimes render the device useless until a change in the tidal direction or wave action forces the bubbles to move (Krupa *et al*., 1998).

The sampling frequency of the traditional meters is variable and best determined by trial and error at each site. Broken seepage collection bags indicate higher seepage rates and require more frequent sampling. The sampling frequency may be as short as 0.5 h to as long as 12 h.

The seepage data must be adjusted to obtain accurate SGD calculations. Studies show that seepage meters require the use of a frictional coefficient to correct for the frictional losses in the meters and collection bags. (Shaw and Prepas, 1989; Belanger and Montgomery, 1992).

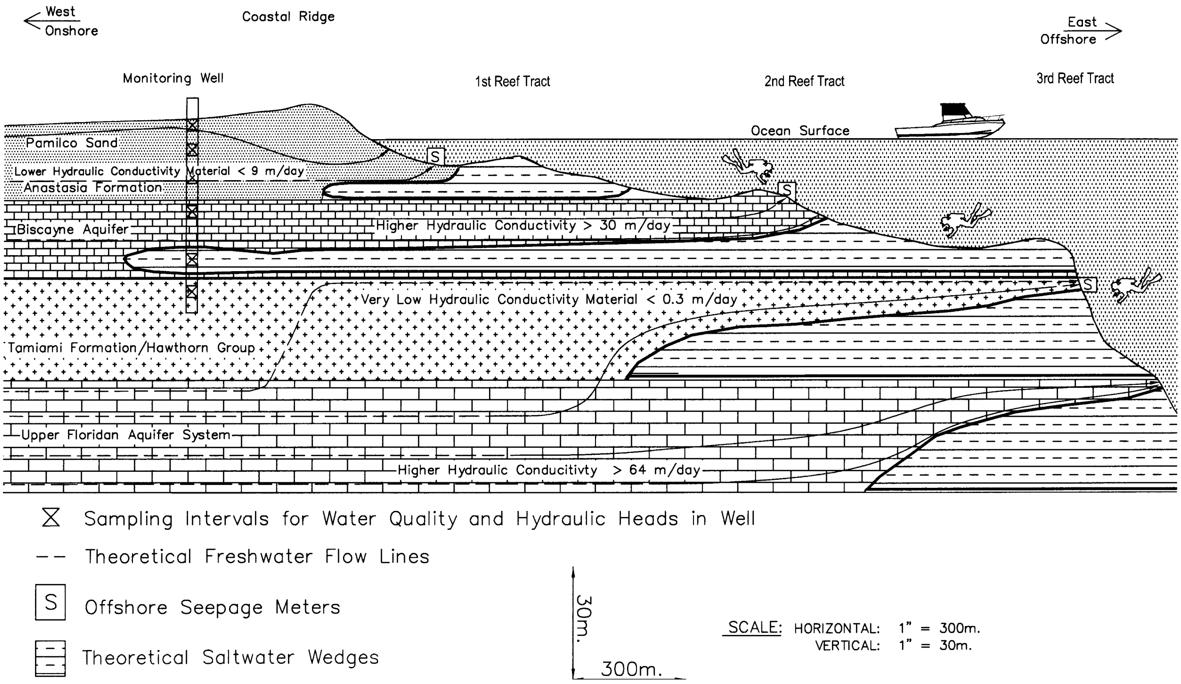

Figure S62 Generalized submarine groundwater discharge locations, lithostratigraphic, and theoretical flow line cross-section of the aquifer for Palm Beach County, Florida.

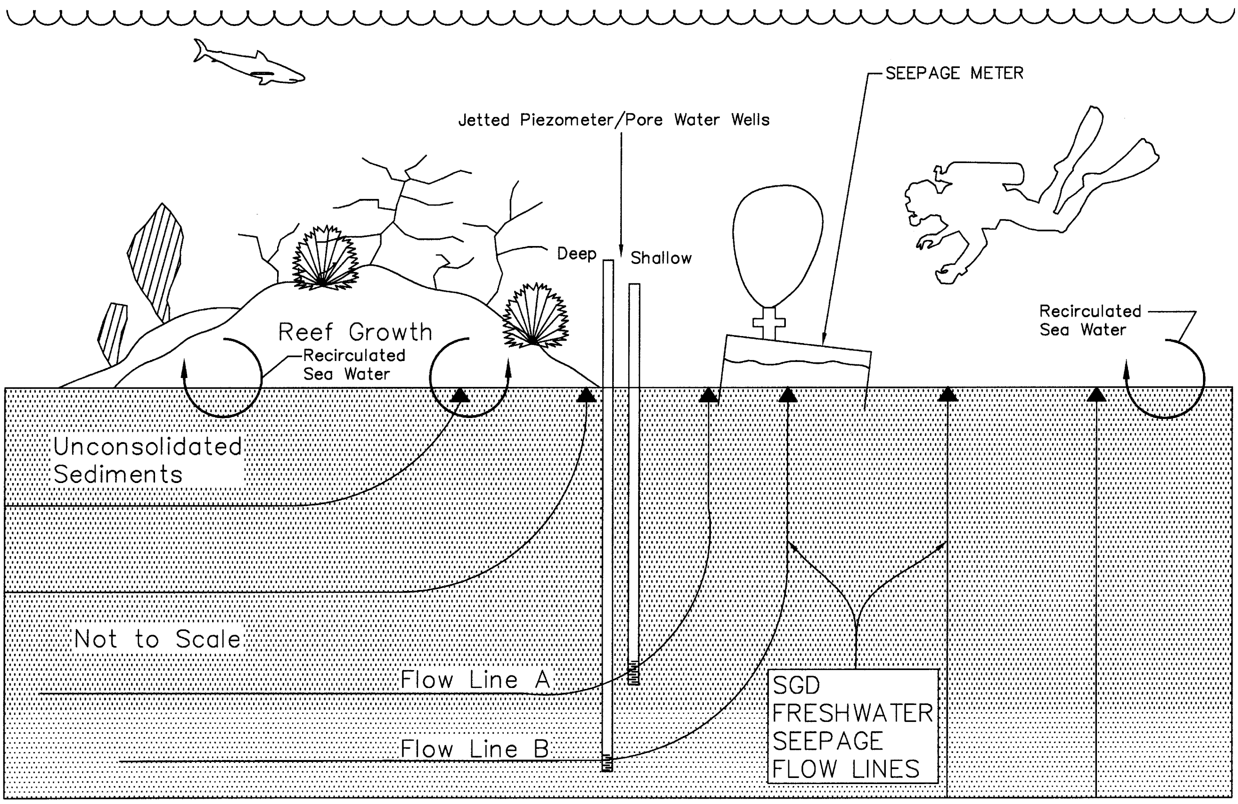

Figure S63 Typical nearshore seepage investigation set-up with theoretical freshwater flow lines, recirculated flow lines and deep and shallow monitoring piezometers.

Recent tank test results by Belanger indicate that different meter designs require different correction factors, and each meter requires different correction factors for discharge and recharge situations. The seepage rate is multiplied by the coefficient to calculate the actual SGD rate.

Factors affecting SGD results

Several factors besides the actual groundwater discharge rates affect SGD measurements and calculations. Gaps in data collection may cause errors. Many of the SGD measurement methods collect data for limited time periods and may miss the enhanced groundwater discharge during storm events. The size of the study area is also a concern because studies have found that SGD varies spatially and temporally. These spatial and temporal differences can be challenging when measurements are required over large areas.

Care must be taken in estimating the groundwater flux. It is important to avoid including oceanic and fluvial fluxes more than once. Riverine groundwater discharge must be calculated between the lowest gauging station and the mouth of the river and biogeochemical processes must also be considered.

Sediment lithology of coastal aquifers will vary based on depositional environments. In the field, any combination of confined and unconfined aquifer scenarios exists. Davis and DeWiest (1966), Strack (1975), Bear (1979), and Todd (1980) include solutions for analytical solution of groundwater flow from the aquifer to the coast for various aquifer combinations including unconfined, confined, stressed (pumping and drainage), and natural flow conditions.

SGD is highly complex and is rarely treated in terms of fully three-dimensional (3D) density dependent miscible fluid flow in a porous medium (Reilly, 1993). Instead, the system conceptualization is usually highly simplified to facilitate physical limitations and project budgets. The accuracy of analysis is dependent on the assumptions in the following three categories: (1) the mixing process, (2) the characteristics of the aquifer under study, and (3) the desired scale and detail of the resulting analysis (Reilly, 1993). These issues are discussed in depth, along with a brief discussion on the mathematical basis of different solution methods in Reilly (1993).

Relating local measurements to regional fluxes can be an arduous task and can result in misleading conclusions. The calculations used to transform water-level measurements in wells, seepage meter rates, and radioisotope data into a flux for an area can be complicated and time-consuming. Seasonal and tidal factors need to be understood and applied to *in situ* seepage results. Often, values obtained through analytical or numerical simulation were not verified in the field. Experience has shown that values determined by models may vary significantly from the estimates based on field measurements (Belanger and Walker, 1990).

Traditional mathematical models do not consider the cyclic or transient discharges from the groundwater component. Many analyses, such as the Darcy solution, assume steady-state conditions (Davis and DeWiest, 1966; Freeze and Cherry, 1979) and overlook the transient vertical position of the land/ocean interface (Urish and Ozbilgin, 1989).

Methodology can also affect seepage results. In traditional seepage meters, empty seepage bags appear to exert a slight suction that pulls water from the meter as the bags slowly unfold. Prefilling the bags reduces the anomalous short-term inflow and allows both discharge and recharge to be measured. Open water wave action and currents are reported to cause induced seepage rates (Libelo and MacIntyre, 1994; Shinn *et al*., 2002). Harvey *et al*. (2002) collectively terms these methodology effects as apparent seepage rates.

A recent septic tank study near a tidally controlled estuary in Tequesta, Florida (US), demonstrates the tidal effect. *In situ* heat-pulse flowmeters in onshore monitor wells were used to measure horizontal velocities during high, low, and slack portions of the tidal cycles. The results showed groundwater velocities varying at low tide from 0.39 m/day to as high as 1.33 m/day in different layers of an unconfined aquifer (Harbor Branch Oceanographic Institute, 1995). Robinson (1996) and others report seepage rates as high as six to eight times higher on an ebb tide. A wide range of *in situ* velocities can occur under varying tidal conditions and with differing aquifer heterogeneities. Therefore, groundwater velocity ranges should be evaluated at each study location.

Additional factors that need to be considered in the collection of SGD from seepage meters are summarized below:

- Mechanical and physical factors affecting seepage meter performance (Libelo and MacIntyre, 1994; Harvey *et al*., 2000; Shinn *et al*., 2002)
- Meter-to-bag connectors and types of bags used (Lee, 1977; Shaw and Prepas, 1990; Belanger and Montgomery, 1992)
- Pre-filled volume in the bag (Lee, 1977; Shaw and Prepas, 1989; Belanger and Montgomery, 1992)
- Method of bag deployment and retrieval (Lee, 1977; Belanger and Montgomery, 1992; Harvey *et al*., 2000)
- Gas produced from decomposition within the sediment (Harvey *et al*., 2000).

Determination of seepage rates

Traditional methods of calculating SGD use one groundwater velocity value derived from hydraulic gradients and hydraulic conductivity estimates. Applying one velocity component to a particular solution can be misleading, as can the approach of using a simplified model to describe a complex system. If measured groundwater velocities and/or gradients are available, this information should be used. Total discharge for the aquifer (equation 1) summarizes the products of the two velocities (tidal, baseflow/interflow) and their respective cross-sectional areas (Figure S64). V_{tide} is defined as the discharge from the seepage face both during low tide and high tide. V_{baseflow} is the groundwater that is discharging regardless of the tide.

Empirical solution methods

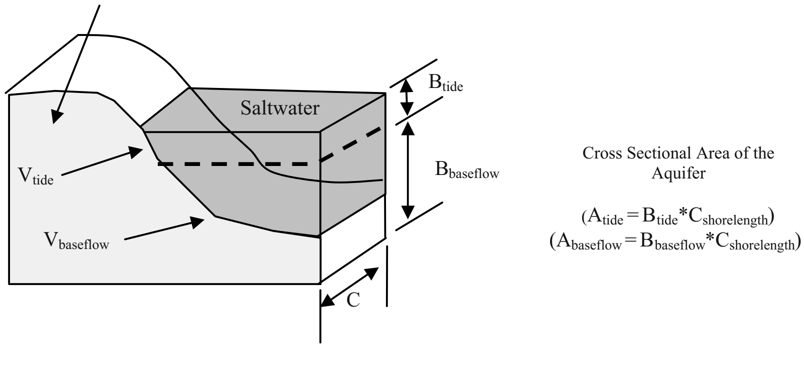
Traditionally, seepage has primarily been estimated by applying Darcy's equation. This approach estimates discharge based on the hydraulic gradient between two points. The discharge is reported in units of length^3/time (L^3/T). Darcy (1856) defined the specific discharge shown below:

$$q = \left(\frac{Q}{A}\right), \qquad \text{(Eq. 1)}$$

where q is the specific discharge (length/time); Q is the is the total discharge or recharge per unit width (length^3/time); A is the cross-sectional area of the horizontal flow (length^2).

By knowing the head loss across the medium and the distance over which it occurred the Darcy equation can be expressed in a differential form:

$$q = -K\frac{dh}{dl}. \qquad \text{(Eq. 2)}$$



$$Q_{\mathrm{total}} = (V_{\mathrm{tide}} * A_{\mathrm{tide}}) + (V_{\mathrm{baseflow}} * A_{\mathrm{baseflow}}) \qquad \text{[Eq. 1]}$$

Figure S64 Generalized cross-sectional groundwater velocities model for tidally-controlled aquifer.

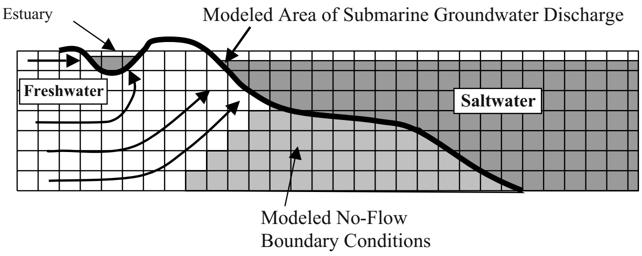


Figure S65 Typical finite difference grid used in modeling coastal boundary conditions in non-density dependent model.

Setting equations 1 and 2 equal to each other, and solving for Q (equation 3) yields the total discharge from the aquifer to the surface water body:

$$Q = -KA\frac{dh}{dl}, \quad \text{(Eq. 3)}$$

where, Q is the total discharge (length^3/time); A is the cross- sectional area of the horizontal flow (length^2); K is the horizontal hydraulic conductivity (length/time); dh/dl is the hori-zontal hydraulic gradient (unitless).

Seepage calculations using Darcy's Law are limited because the solution assumes steady-state conditions and does not consider transient conditions, such as tidal action, rainfall, or onshore surface water levels.

To estimate the SGD for a portion of a coastline, the total discharge of freshwater per length of coast would multiplied by the length of coastline of interest.

$$Q_{\text{shore}} = -KA\frac{(h_1 - h_2)}{(l_1 - l_2)}L, \quad \text{(Eq. 4)}$$

where, K is the horizontal hydraulic conductivity (length/time); L is the length of coastline (length); h_1 is the hydraulic head at point 1 (canal or aquifer water level); h_2 is the head at point 2 (generally the ocean); l_1 is the horizontal spatial location of point 1; l_2 is the horizontal spatial location of point 2.

If the SGD is occurring within a region of the aquifer that is sufficiently close to the shore and if the density of the groundwater varies, the density must be considered. The above equation can be modified to consider the fluid characteristics (Freeze and Cherry, 1979).

$$Q_{\text{shore}} = -\left(\frac{k\rho g}{\mu}\right)A\frac{(\text{h}_1 - \text{h}_2)}{(\text{l}_1 - \text{l}_2)}L, \quad \text{(Eq. 5)}$$

where, k is the permeability (L/T^2); ρ is the density of the fluid (W/L^3); g is the gravitational constant (L/T^2); ρ is the dynamic viscosity (M/LT).

Estimation of actual flow velocities in the aquifer requires that the porosity be considered. Equation 3 is divided by porosity to yield the solute velocity of the flow system (Freeze and Cherry, 1979) as represented in equation 6:

$$V = \frac{q}{n} = \left(\frac{K}{n}\right)\left(\frac{dh}{dl}\right) \quad \text{(Eq. 6)}$$

where V is the average linear groundwater velocity (length/ time); Q should be small "of is the specific discharge (length/time)"; n is the porosity.

This approach, which assumes one seepage rate for a length of coast, is valid when the flow is laminar and the groundwater is not experiencing significant diffusion. When seepage rates differ significantly along the shore it is appropriate to determine the discharge rates for each coastal segment (Cherkauer, 1998).

Numerical solutions

The problems discussed earlier in applying Darcy's equation to SGD also exist in the application of numerical calculations for both non-density and density dependent models. The primary considerations with numerical simulations are as follows:

1. Accuracy of the representation of the aquifer sediment layering, density of the fluids, and the vertical and horizontal hydraulic conductivity.
2. There is limited availability of coastal discharge data around the world. Many numerical modelers/simulators do not check the coastal discharge rates during the simulation process; it is considered an afterthought for the model simulations. The true discharge and spatial locations may or may not be correct. Recent seismic work in support of a modeling effort (Merchant *et al.*, 1996) off the North Carolina coast showed that paleofluvial channels and large-scale collapses constrain the possible discharge locations offshore discharge points.
3. Many numerical models are not designed to simulate density dependent flows, so modelers substitute simulated no-flow boundary conditions for the density difference in a stairstep fashion within the model domain (Figure S65) or use equivalent freshwater heads. Other models account for density but require data that is frequently unavailable and so may still predict an incorrect flux across the boundary condition. As with other numerical simulations, the validity of the application is a function of the modeler's experience.

Additional modeling considerations

Locating the groundwater/oceanic water interface is critical because the morphology, flow patterns (seepage), and solute transport vary significantly with location site (i.e., barrier islands, atolls). Urish and Ozbilgin (1989) state that vertical position of the interface can vary as much as 1.5 m vertically and 61 m horizontally, and is a function of sediment permeability, effective diffusivity, wave amplitude, and wave period (Rasmussen, 1998). Background data collection is essential to understanding the existing porewater salinity profiles at each location.

Additional long-term considerations are rising sea levels and resulting increases in groundwater levels. Nuttle and Portnoy (1992) indicate that relative sea level is rising at 30 cm per 100 years along the east coast of the United States. As a result, groundwater levels are being raised on a regional scale in low-lying areas. With the groundwater level closer to ground surface, decreased aquifer storage will increase runoff and reduce the amount of available recharge to the aquifer, subsequently decreasing SGD to coastal areas.

Empirical solutions versus numerical solutions

A comparison of solution methods for SGD. The South Florida Water Management District (SFWMD) has collected detailed measurements of surface water discharges and associated chemical surface water concentrations over a 9-year period for Palm Beach County, Florida (Finkl and Krupa, 2001). Detailed groundwater levels and groundwater chemical concentrations in this area have been collected by the United States Geological Survey and SFWMD over 10 years. The SFWMD used a regional model, known as the South Florida Water Management Model (SFWMM), to simulate the entire southern peninsula of Florida (SFWMD, 1993a,b). Shine *et al.* (1989) utilized a countywide numerical groundwater model (based on MODFLOW) to also estimate groundwater discharges to the Palm Beach County coast. Groundwater levels and surface water data were used in the models for calibration and verification.

Using these models, SGD values were calculated for the groundwater discharged from Palm Beach County to the offshore environment. For comparison, calculations based on Darcy's law were completed for the same length of coastline.

As seen in the above table, large variations in SGD estimation can occur in calculated and numerical model solutions (Table S11). The SFWMM had the lowest groundwater discharge value; this is likely because the model grid size (2 miles × 2 miles) does not allow the SGD process to be seen and measured. Two of the three solutions yielded SGD that equaled or exceeded the surface water inflows to the ocean. Corresponding groundwater and surface water concentrations for phosphorous and nitrogen were then calculated using the SGD fluxes to yield nutrient loading to the nearshore. It has been estimated that, on a worldwide basis, the total contributions of freshwater and nutrients to the ocean by SGD are roughly equivalent to the total contributions from riverine (in this case canal) discharges (Johannes and Hearn, 1985). Based on the estimated results and statements mentioned above, SGD is nearly equal to the surface water discharges in Palm Beach County, Florida.

Summary

Governmental agencies and private organizations need SGD information to better address water degradation issues and to create numerical models. Accurate determination of SGD is essential in calculating mass balances and in the determination of nutrient fluxes to the coastal waters. Experience has shown that quantifying this input is difficult because of uncertainties in the direct measurement of groundwater flux and in the simulation of groundwater fluxes.

Accurate knowledge of SGD is important because it can be an unseen hazard and can be used to assess environmental problems in coastal environments. The contribution of SGD to the coastal hydrologic regime is occasionally recognized in association with crescendo events and

Table S11 Comparison of three solutions of submarine groundwater discharge compared to actual surface water discharges and nutrient fluxes to offshore Palm Beach County, Florida

Discharge type	Water (million-meters^3/year)	Phosphorous flux (P) (metric tons)	Nitrogen Flux (N) (metric tons)
Surface Water Discharge			
Surface water (actual flow)	1,661	196[a]	2,471[a]
Groundwater Discharge			
Darcian flow solution[b]	2,211	414	5,727
USGS MODFLOW Application[c]	1,659	196	2,469
SFWMM SW/GW model[d]	50	6	75

concurrent marine algal blooms that degrade water quality, bottom habitats, and coral reef ecology (Finkl and Krupa, 2003). However, the more common situation is that SGD laden with nutrients from agro-urban activities on adjacent coastal plains causes environmental degradation so gradually that the cause and effect can escape public attention.

SUBMERGED COASTS

A submerged coast is defined as a coast resulting from the relative submergence of a landmass either through eustatic sea-level rise and/or crustal subsidence against subaerially produced forms and structures. The term carries no implication as to whether it is the land or the sea that has moved. In siliciclastics-dominated shelves, economic mineral deposits associated with submerged coasts include sand and gravel deposits, and, placer deposits such as diamonds, gold, cassiterite, and heavy mineral sands.

Recognition and dating

Submerged coasts are indicated by the occurrence of drowned subaerial features (Table S12). Because of the subaerial exposure of continental shelves during the last low sea-level stand, a paleosol with a lower moisture content and a higher density may exist beneath the Holocene marine deposits. Among the earliest drowned subaerial features recognized are the submerged forests off the English coast (Lyell, 1850). On continental shelves of the world, about 70% of the total area was identified by Emery (1968) to be covered by relic sediments including previously deposited subaerial, lacustrine, and paludal sediments. For sea-level changes during the past 20,000 years, marine zonation, erosional indicators, depositional indicators, archaeological remains, and historical data provide evidence for submergence (Pirazzoli, 1996).

For dating submerged coasts, the radiocarbon method and the U/Th method are widely used. The former was first applied to stable crustal regions for the reconstruction of late Quaternary sea-level history (Godwin *et al*., 1958). In Barbados, the drilling and dating of coral reefs containing *Acropora palmata* indicated that sea level was at -121 ± 5 m around 17,000 yr BP (^{14}C) (Fairbanks, 1989). Subsequent dating of the deepest *A. palmata* using the U/Th method gave an age of ca. 19,000 yr BP corresponding to a sea level of -118 m (Bard *et al*., 1990a). Far away from plate boundaries in Tahiti, a large sea-level jump was identified shortly before 13,800 yr BP with the U/Th method while radiocarbon ages on the same samples were significantly younger (Bard *et al*., 1996). Dating of inner shelf sequences off Hong Kong (Yim *et al*., 1990; Yim, 1999) also indicated a young age bias of pre-Holocene radiocarbon dates exceeding about 8,200 yr BP (^{14}C) while some of the shells with finite radiocarbon dates may instead be of last interglacial age. Pre-Holocene materials on the shelf are likely to yield unreliable radiocarbon dates compared with Holocene counterparts because of possible pedogenic alteration during low sea-level stand(s). For a comparison of radiocarbon and U/Th dates see Bard *et al.* (1990b). Because there is a maximum difference of about 3,500 years for a date of ca. 20,000 yr BP (^{14}C), the last glacial maximum (LGM) dated to 18,000 yr BP (^{14}C) may have occurred 21,500 sidereal years ago.

Sea-level minimum during the last glacial maximum

The global average depth of the shelf break at -130 m below present mean sea level (Shepard, 1973) provides a median value of sea-level lowering resulting from continental ice growth. Since this value is based on the compilation of hydrographic charts, it is probably free from bias (Bloom, 1983). Additional support for the sea-level minimum at -130 m is the change of about 10 m in global sea level through a 0.1‰ change in the oxygen-isotopic record (Shackleton and Opdyke, 1973) and the closeness to the median value sea-level position during the LGM identified on many shelves.

The radiocarbon dating of oolitic and biogenic carbonates associated with drowned beach barriers is a means of identifying the sea-level minimum during the LGM. On the Bengal Shelf, five samples of these materials from depths ranging from 125 to 133 m below the present sea level yielded dates ranging from 16,500 to 24,900 yr BP (^{14}C) (Wiedicke *et al*., 1999).

Examples of submerged coasts

In North America, subaerial features of LGM to late glacial maximum age drowned by the Holocene transgression were reviewed by Bloom (1983). Terrestrial materials and landforms including mastadon and mammoth fossils, Indian artifacts, moraines, river channels, etc. were reported.

Clear-cut cases of coastal subsidence resulting from earthquakes have been documented. One such example is from near Haikou on Hainan Island in southern China where ruins of ancient villages, including a cemetery with engraved tombstones of 1604, were identified up to 10 m below present sea level (Y. Chen in Anonymous, 1983). A coastal area exceeding 10 km by 1 km was affected by subsidence during a Ming Dynasty earthquake recorded in historical documents. The earthquake was estimated to be of magnitude scale 8 and occurred on July 13, 1605.

A long history of submerged coasts has been found on "stable" shelves. Off Hong Kong, the study of offshore borehole sequences revealed a succession of paleo-desiccated crusts formed by the subaerial exposure of marine deposits during Quaternary low sea-level stands dating back to oxygen-isotope stages 2, 6, 8, and 10 (Yim and Tovey, 1995). This sequence is in agreement with the five interglacial–glacial cycles identified in the Vostok ice core in Antarctica (Petit *et al*., 1999) confirming that the sea-level changes found were eustatically controlled. Figure S66 shows an example of an early Holocene submerged coast dated at ca. 8,000 yr BP (^{14}C) when sea level was at ca. -18 m below present mean sea level.

Micropaleontological studies of continental-shelf cores are useful in confirming submerged coasts when they penetrate the formerly exposed soil surface. A pollen sequence identified on the east Queensland shelf shows a transition from terrestrial vegetation (grasses and woodland), to salt marsh and mangroves (Grindrod *et al*., 1999). This sequence is the reverse of mangrove successions recorded for regressive coasts and is compatible with a drowning coast. Similarly, a diatom sequence in a shelf core off Hong Kong with evidence for five marine transgressions showed a record of diatom preservation consistent with aging and pedogenesis during glacial period(s) (Yim and Li, 2000). The tests of diatoms were progressively destroyed through groundwater dissolution during the low sea-level stands with the lowest abundance found in deposits of oxygen-isotope stage 11, followed by stage 9 and stage 7. Deposits of stage 5 were similar in diatom abundance to stage 1 probably because of the "young" age.

Underwater mapping of rocky coasts using SCUBA is a possible way of identifying submerged coasts of late Quaternary age. Off Marseille submerged coasts were shown by the Grotte Cosquer archaeological

Figure S66 An early Holocene submerged coast when sea level was at ca. −18 m below present mean sea level. The exposure was available through seabed excavation for the foundation of the West Dam, High Island Reservoir, Hong Kong SAR. The Holocene marine deposits (darker) rest unconformably on a fining-upward sequence of Pleistocene alluvial deposits (paler). Wood and shells from near the base of the Holocene marine deposits yielded dates of ca. 8,000 yr BP (^{14}C) (Photograph courtesy of R.J. Frost).

site at a depth of about 60 m below present sea level and a paleo-coast at a depth of about 90 m below present sea level dated at 13,800 yr BP (^{14}C) (Collina-Girard, 1996). Underwater mapping off Corsica and the West Indies have revealed discontinuities at common depths of −11, −17, −25, −35, −45, −55 and −100 m below present mean sea level attributed to late Quaternary submerged coasts. However, it is possible that some of the submerged coasts are polycyclic in origin and dating is needed for their age verification.

Future work

Future work should address why late Quaternary sea-level curves do not record a sea-level fluctuation around 11,000 yr BP (^{14}C) attributable to the Younger Dryas. Is this caused by inadequate radiocarbon calibration? In order to obtain answers, samples from appropriate depths on the shelf are needed for dating.

The International Geological Correlation Programme project no. 396 "Continental shelves in the Quaternary" a five-year project initiated in 1996, has filled some of the gaps in knowledge on submerged coasts. Drill rigs have been developed to obtain core samples from shelves. Cable-route surveys undertaken on shelves are providing a wealth of information including cores for the study of submerged coasts since the LGM. An international effort similar to the Ocean Drilling Program operating on continental shelves would help to promote the study of Quaternary submerged coasts.

SUBMERGING COASTS

A coast is submerging when the relative sea level rises above it. Submergence may be caused by sea-level rise, by land subsidence, or by the two.

Between about 20 and 6 kyr ago, when the melting of the Northern Hemisphere continental ice caps was completed, land-ice melting caused the global sea level to rise some 120 m, at an average rate of 8 mm/yr, but with peaks reaching 40–50 mm/yr during certain periods (Bard *et al*., 1996). This rise caused the rapid submergence of huge continental shelf areas. Since about 6 kyr ago, the global sea level has remained almost stable in a high, interglacial position. Global sea-level rise for the last century is estimated to be of decimetric order. For the next century, climatic models that take into account increasing greenhouse effects, have predicted scenarios of sea-level rise between 0.09 and 0.88 m, with a central value of 0.48 m (IPCC, 2001).

Land subsidence may result from several (neo)tectonic processes. Its rate can be much variable in space and time. Since the peak of the last glacial times (i.e., during the last 20 kyr), in deep-sea areas hydro-isostatic displacements have been of the order of 40 m (about one-third of the relative sea-level rise, that is, an average rate of 2 mm/yr). This made the ocean to floor subside. When approaching coastal areas, subsidence rates lessened, depending on the water shallowness and the coastal topography. During the last 6 kyr such isostatic subsidence decreased exponentially. Near delta formations, however, sediment compaction and sedimento-isostasy have often been more significant, with rates of subsidence on the order of one to a few millimeters per year reaching the maximum values near the delta depocenters. During the last centuries, and especially in the 20th century, human-induced land subsidence was caused in many coastal areas by acceleration of compaction due to drainage, oil and gas extraction, or groundwater exploitation. Though the total amount of human-induced subsidence rarely exceeds a few meters, it was often obtained within a limited time range, generally a few decades, thus reaching during these periods dangerously high sinking rates.

As a result of the above processes, most of the world coastal regions have been submerging rapidly between about 20 and 6 kyr ago, due to the rapid postglacial eustatic rise. During the Holocene, most deltaic sequences began to accumulate between 8.5 and 5.5 kyr ago, with a modal age of about 7.5–7.0 kyr (Stanley and Warne, 1994). It is, therefore, only after that time, that is, after the end of the postglacial transgression, that land sinking may have started to be active in delta areas. Similar sinking, for recent sediment compaction, must have occurred, though at slower rates, also in most estuarine and lagoonal areas, and even in coastal plains. However, as long as the fluvial sediment input or the longshore drift could compensate for the land sinking, submergence phenomena could not start. It is especially during the last century that human action has been most active, not only in accelerating land sinking rates, but also in dredging from river beds or constructing breakwaters that cut off a longshore sediment supply.

Shallow coastal areas may also be submerged by marine erosion, in particular at the time of strong storm surges. In seismically active areas, coastal submergence may occur at the time of major earthquakes (Figure S67). One of the most impressive last century events of this kind was probably the great earthquake of March 27, 1964 in Alaska (magnitude $\geq$ 8.4, with an epicenter in the Prince William Sound area) when vertical crustal movements affected a region of at least 200,000 km^2, with a wide coastal zone of subsidence reaching a maximum of 2.2 m (Plafker, 1965). In the Rann of Kutch, on the border between

Figure S67 What is visible is not a fringing coral reef at sea level, but the result of a seismic subsidence that occurred in 1981 during an earthquake at Mavrolimni, in the Gulf of Corinth, Greece. Before the earthquake, Mavrolimni (literally Black Lake) was a lagoon, up to 10 m deep, connected to the sea by an opening to the north. It was delimited seawards by a sand-and-gravel barrier, a few meters wide, which was used as a mole for fishing boats. In 1981, the area subsided about 0.8 m and the top of the barrier was brought down just to sea level (Stiros and Pirazzoli, 1998) (Photo D554, August 1992).

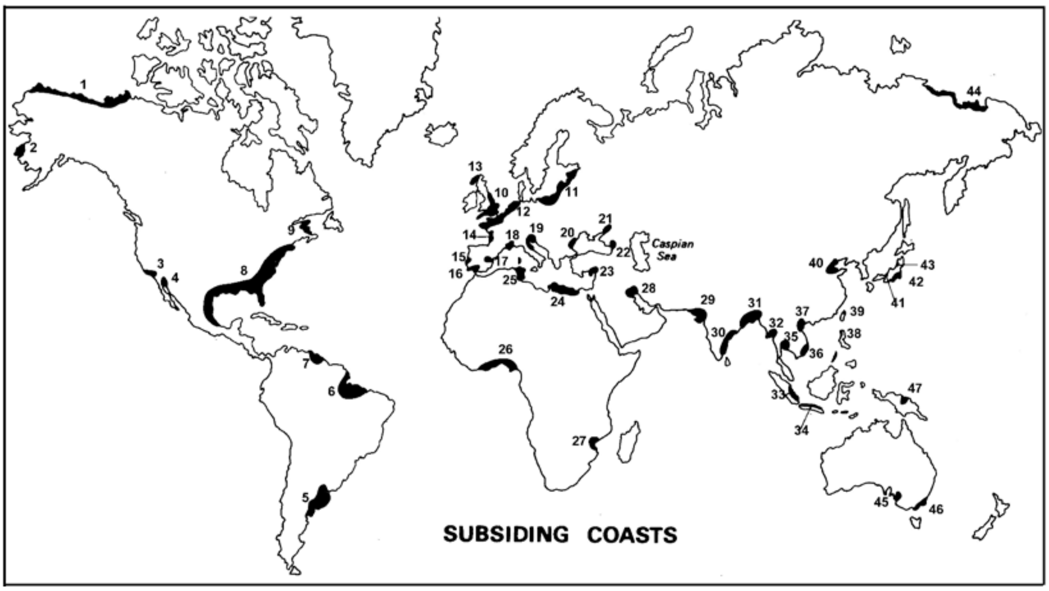

Figure S68 Sectors of the world's coastline that have been subsiding in recent decades, as shown by evidence of tectonic depression, increasing marine flooding, geomorphological and ecological indicators, geodetic surveys, and groups of tide gauges recording a rise of mean sea level greater than 2 mm/yr (assumed to be the present rate of global sea-level rise) over the past three decades. A distinction is made between submerging coasts (where sea level has risen relative to the land) and subsiding coasts (where there has been land subsidence). On the coasts of the Caspian sea level has risen by more than 2 m since 1977 as a result of an increase in water volume, possibly accompanied by some associated subsidence of the bordering land (from Bird, 1993, © Geostudies, reproduced with permission of John Wiley & Sons Limited).
Key to the map: 1, Mackenzie delta and northern Alaska; 2, Yukon delta, Alaska; 3, Long Beach area, southern California; 4, Colorado River delta, head of Gulf of California; 5, Gulf of La Plata, Argentina; 6, Amazon delta; 7, Orinoco delta; 8, Gulf and Atlantic coast, Mexico and United States; 9, Maritime Provinces, Canada; 10, southern and eastern England; 11, the southern Baltic from Estonia to Poland; 12, North Germany, the Netherlands, Belgium and northern France; 13, Hebrides, Scotland; 14, Loire estuary and the Vendée, western France; 15, Lisbon region, Portugal; 16, Guadalquavir delta, Spain; 17, Ebro delta, Spain; 18, Rhône delta, France; 19, northern Adriatic from Rimini to Venice and Grado; 20, Danube delta, Rumania; 21, Eastern Sea of Azov; 22, Poti Swamp, southeastern Black Sea coast; 23, Southeast Turkey; 24, Nile delta to Libya; 25, Northeast Tunisia; 26, Nigerian coast, especially the Niger delta; 27, Zambezi delta; 28, Tigris-Euphrates delta; 29, Rann of Kutch; 30, Southeastern India; 31, Ganges–Brahamputra delta; 32, Irrawaddy delta; 33, Eastern Sumatra; 34, Northern Java deltaic coast; 35, Bangkok coastal region; 36, Mekong delta; 37, Red River delta, northern Vietnam; 38, Manila, Phillippines; 39, northern Taiwan; 40, Hwang-ho delta; 41, Maizuru, Japan; 42, Head of Tokyo Bay; 43, Niigata, Japan; 44, East Siberian coastal lowlands; 45, Port Adelaide region; 46, Corner Inlet region; 47, Sepik delta.

Pakistan and India, the 1819 earthquake resulted in a very wide area subsiding beneath the sea (Bird, 1993).

In volcanic areas, vertical movements can be very fast and lead to local submergence phenomena. This is the case for many calderas, produced by explosion, collapse, or even erosion. Relatively slower movements, probably produced by thermo-isostatic processes, may continue for long periods, that is, for centuries or even millennia in the case of dormant volcanoes, of even for million years for extinct volcanoes capped by oceanic atolls.

If the greenhouse-induced warming predicted by climatic models will be confirmed, a significant relative sea-level rise can be expected during the next centuries. According to IPCC (2001), if greenhouse gas concentrations were stabilized (even at present levels) sea level would nonetheless continue to rise for hundreds of years. It can therefore be expected that submerging coasts, presently confined mainly to sectors where the land has been subsiding (Figure S68), will become more extensive.

SURF MODELING

The purpose of surf modeling is to realistically predict and quantify surf characteristics such as breaker heights, breaker types, breaker periods, and surf zone widths. Many surf models also provide other useful surf zone information such as wave setup and wave-generated longshore currents. Increasing computer capabilities and their availability, as well as research advances, have enabled determination of surf characteristics to evolve from use of relatively simple calculations, nomographs, or tabular methods, that are largely based on empirical relationships, to use of numerical computer models. These models solve mathematical equations that are based on the physics of surf zone hydrodynamics (see *Surf Zone Processes*). But, only relatively recently have computer surf models been developed and applied. In the surf zone, wave breaking, turbulence, nonlinear processes, and other complex phenomena combine to make modeling challenging. Here, the most important aspects of surf modeling for research and practical applications are described.

Modeled parameters

Owing to their potential adverse effects, breaker heights and breaker types are of most interest. A breaker's height is the distance between its trough (lowest point) and crest (highest point). Higher waves break further offshore where depths are deeper so that breaker heights vary across a surf zone. Because incident waves (see *Waves*) have varying heights with time, breaker heights also vary with time. The intervals between individual breakers, breaker periods, are the same as the periods of the incident waves and, thus, are more easily predicted than breaker heights and types.

Breakers are categorized as spilling, plunging, or surging (e.g., Wiegel, 1964; Dean and Dalrymple, 1984; Fredsøe and Deigaard, 1992; Smith, 2000). A breaker type, collapsing, is sometimes defined as an intermediate category between plunging and surging. A spilling breaker is characterized by an unstable crest that cascades down the shoreward face of the wave as a turbulent layer. For typical waves and bottom slopes of most beaches, spilling breakers occur most often. A plunging breaker is characterized by an unstable crest that curls over the shoreward face of the wave and plunges into the water below. Plunging breakers are of most concern for surf zone activities due to the forces of their crashing motion. A collapsing breaker is one for which the crest remains unbroken while the lower part of the shoreward face of the wave steepens and falls to produce a turbulent region. A surging breaker has a crest that remains essentially unbroken as it moves up a beach. For typical waves and bottom slopes of most beaches, surging breakers seldom occur. Most surf models lump collapsing breakers with surging breakers.

Because it represents the distance across possibly hazardous surf, the width of the surf zone is a key parameter. At any time, there is a distribution of wave breaking locations associated with the distribution of incident wave heights (see *Waves*). Higher waves break further offshore than lower waves. A practical definition is that surf zone width is the distance from the shoreline to where a trained conscientious observer sees the limit of depth-induced breaking over a reasonable time period, such as 10 min. This definition is preferable to defining the surf zone as the distance between the beach and the outermost breaker since the location of the outermost breaker varies with time. An analysis of over 600 video images of the surf zone shows that this practical definition results in surf zone widths that are most highly correlated to a location where 10% of the waves are breaking (Earle, 1999). Surf zone widths generally vary inversely with water levels that are caused, at most locations, mainly by astronomical tides (see *Tides*). For beaches without offshore bars, higher water levels cause waves to break on the steeper nearshore part of the beach resulting in more narrow surf zone widths. For beaches with offshore bars, higher water levels may allow waves to pass over the bar, or bars, without breaking while lower water levels may contribute to depth-induced wave breaking near the bar, or bars. An example of a 10 min average video image for Duck, North Carolina, shows wave breaking over an offshore bar and closer to the beach (Figure S69). For this example, the surf zone width along the indicated traverse was 44 m.

Longshore currents that move essentially parallel to the beach, also called littoral currents, are generated by waves breaking at angles relative to the beach. These currents are important for sediment transport and beach erosion applications as well as operations in the surf zone.

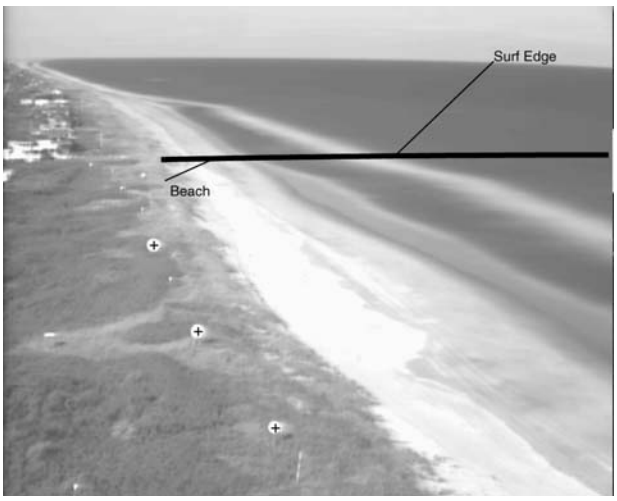

Figure S69 Ten minute average video image showing a surf zone with wave breaking over an offshore bar and at the shoreline. Surf zone width, 44 m, from the shoreline (labeled Beach) at the time of this image past the main outer region of wave breaking (labeled Surf Edge) was determined from this image along the indicated traverse.

Rip currents are hazardous intermittent currents that cannot be predicted reliably by present surf models. Rip currents are strong currents that are confined to a narrow jet that flows seaward from the surf zone in a direction perpendicular to the beach. Several methods by which rip currents are generated have been proposed, but successful modeling requires further research advances.

Other parameters may also be modeled, in some cases as part of the calculations to predict the parameters of main interest. However, most other parameters are generally considered more important for research than for practical applications. A possible exception is wave setup which is relatively simple to estimate and which somewhat affects the total water depth that largely determines breaker heights. Wave setup is a wave-induced increase in mean water level near a beach. Other parameters include wave runup, swash, water motions at periods longer than incident wave periods (e.g., infragravity waves), and cross-shore currents including undertow.

Estimation methods

Without using numerical models, estimates of where waves break and breaker heights can be obtained using simple procedures. The relationship that a wave breaks when its height (crest to trough) exceeds 0.78 multiplied by water depth has long been used in engineering practice as a good first estimate. In the ocean, many component waves, each with different wave heights, periods, and directions, combine to produce a wave spectrum. The root-mean-square wave height that is computed from a spectrum of waves is approximately given by 0.42 multiplied by water depth in a surf zone, where essentially all waves are breaking (e.g., Smith, 2000). These types of breaking criteria have often been combined with equations for wave shoaling and wave refraction (see *Waves* and *Wave Refraction Diagram*), assuming locally parallel depth contours, to develop engineering methods that yield useful estimates of breaker heights (e.g., Wiegel, 1964; Dean and Dalrymple, 1984; Smith, 2000).

Several surf "similarity" parameters that typically depend on breaker height, local bottom slope, and wave period are used to categorize breakers as spilling, plunging, or surging (e.g., Guza and Inman, 1975; Wright and Short, 1983; Smith, 2000). The various formulations provide reasonably similar results. Use of these parameters shows that spilling breakers are most common and that surging breakers are relatively rare.

Mainly for coastal engineering applications, estimation methods have also been developed for other types of surf zone information such as wave setup, runup, and longshore currents (e.g., Wiegel, 1964; Dean and Dalrymple, 1984; Fredsøe and Deigaard, 1992; Coastal and Hydraulics Laboratory, 1996, 1980–2000; Smith, 2000).

Numerical modeling

To characterize surf realistically, however, numerical models are needed. A recent research approach is numerically solving the hydrodynamic equations of fluid flow that govern shallow water waves in the time domain throughout a nearshore region. Boussinesq type models are probably the most common models of this type. Fredsøe and Deigaard (1992) and Svendsen and Putrevu (1996) provide overviews. Equations for variable nearshore bathymetry can be solved for water elevations and currents. Some models solve the fully nonlinear equations of motion that are usually expressed using a velocity potential. Time domain models are mathematically complex and computationally intensive. But, they can consider both cross-shore and longshore depth variations. These models have the potential to better predict wave-induced currents, including rip currents, than simpler one-dimensional models. Because there are several unresolved research issues, such as considering wave breaking, time domain models are not used yet for applied surf modeling.

Where a wave breaks is controlled largely by local depths in the immediate vicinity of breaking. Thus, one-dimensional surf models that consider local depth variations from outside of the surf zone to the shoreline are quite successful in determining breaker characteristics even though longshore depth variations are not considered. One-dimensional models are based typically on the energy transport equation given by

$$\frac{\partial(E_w C_g \cos\theta)}{\partial x} = -\langle \boldsymbol{\varepsilon}_b \rangle$$

where E_w is total wave energy, C_g is wave group velocity, θ is wave direction relative to a normal to the beach, x is a distance from outside the surf zone to the land–water interface, and $\langle \varepsilon_b \rangle$ is the average rate of dissipation of wave energy per unit area of sea surface due to wave breaking. Dissipation due to bottom friction is small compared to that caused by wave breaking. E_w is given by

$$E_w = \frac{1}{8}\rho g H_{rms}^2,$$

where ρ is water density, g is the acceleration due to gravity, and H_{rms} is root-mean-square wave height.

Using various methods for calculating the dissipation rate, the energy transport equation is solved by numerical methods beginning outside the surf zone and progressing to the shoreline. This approach models energy and associated wave statistics rather than time varying characteristics of individual waves. A model that has been modified for several applications (e.g., Earle, 1999) was developed by Thornton and Guza (1983). Because most breakers are spilling breakers that resemble bores, equations for the energy dissipation from bores (e.g., Le Mehaute, 1962) are often employed. Other equations for wave height decreases caused by wave breaking can be used and provide generally similar results (e.g., Dally, 1990). Either wave-by-wave calculations (e.g., Dally, 1990, 1992) or probability calculations (e.g., Thornton and Guza, 1983) can be used to estimate the average dissipation. For wave-by-wave methods, wave heights are usually selected so that they represent a Rayleigh distribution (Longuet-Higgins, 1952) outside of the surf zone, but joint wave height and period probability distributions (e.g., Longuet-Higgins, 1983) may also be used. For probability methods that follow Thornton and Guza (1983), the average dissipation is obtained by integrating, over all wave heights, a bore dissipation function multiplied by the probability that a wave of a given height is or has broken.

Because it involves relatively few calculations and wave breaking probabilities can be used to estimate probabilities of different breaker types, a probability approach is attractive. Surf "similarity" parameters allow categorizing breakers as spilling, plunging, or surging. Given beach slope and wave period, values of breaker heights that delimit surging from plunging waves and plunging from spilling waves can be obtained. Using these limits, a wave breaking probability distribution (e.g., Thornton and Guza, 1983) can be integrated to provide breaker type probabilities that may vary across the surf zone.

This surf modeling description and the provided equations are reasonably general. Various formulations for breaker dissipation, wave breaking probability distributions, and breaker types have been used. Given an incident directional wave spectrum, $E(f, \theta)$, where f is wave frequency and θ is wave direction, the numerical approach involves calculating E_w, root- mean-square wave height, appropriate wave frequencies such as the frequency of maximum energy and the average frequency, and a suitable single wave direction that are contained in the complete equations. Wave direction is usually calculated so that concentration of wave energy in this direction provides the correct longshore momentum flux for later longshore current calculations. The energy transport equation is then solved numerically from outside the surf zone to the shoreline. Numerical integrations are also used for some calculations such as the average wave energy dissipation rate and wave breaking percentages. Fredsøe and Deigaard (1992) and Svendsen and Putrevu (1996) further describe several modeling approaches.

While modeling of only breaker characteristics may be performed in this manner, information about wave-generated longshore currents is often desired. Depth-averaged longshore currents are usually obtained using radiation stress theory (e.g., Longuet-Higgins, 1970a,b) or related equations. Doing this involves solving the longshore momentum equation given by

$$\tau_y^h + \frac{\partial}{\partial x}\left(\mu h \frac{\partial v}{\partial x}\right) - <\tau_y^b> + <\tau_y^w> = 0,$$

where V is the depth averaged longshore current, the first term is the longshore driving stress exerted by the waves, the second term represents horizontal mixing across the surf zone, the third term is the average longshore stress due to bottom friction (also a function of v), and the last term is the average wind- generated longshore stress. Including wind effects in this simple manner adds little to the computations. The parameter, μ, is a horizontal eddy viscosity and h is local water depth. The driving related to wave breaking is given by

$$\tau_y^h = <\boldsymbol{\varepsilon}_b> \frac{\sin\,\theta}{c},$$

where c is wave phase speed.

Dissipation due to wave breaking is a key input for longshore current calculations. Thus, most surf models that calculate breaker information also calculate longshore currents. Breaker and dissipation calculations are first completed across the surf zone. The longshore momentum equation is then solved numerically for depth-averaged longshore currents. Formulation of the bottom stress involves the longshore current, the wave orbital velocities, and a bottom drag coefficient. Formulation of the wind stress involves the wind speed, wind direction relative to the beach, and a sea surface drag coefficient.

Water depths (bathymetry) along a traverse extending from seaward of the surf zone to the shoreline are critical to accurate surf modeling. Solving both the energy transport equation and the longshore momentum equation for one-dimensional models involves the local water depth, h, at each computational step along the traverse. In the energy transport equation, the wave group velocity and the average rate of dissipation of wave energy depend on water depth. In the longshore momentum equation, the longshore driving stress exerted by the waves and the horizontal mixing term depend on water depth. The bottom friction term also includes depth effects because it is a function of depth dependent wave orbital velocities. Because of the small spatial scales of cross-shore depth variations in surf zones, computational steps (calculation intervals) are typically on the order of 1 m. For two-dimensional or three-dimensional time domain models, there are similar depth requirements.

Lack of recent and accurate depth information at a beach of interest is often a limitation. Recent depth data are desirable because nearshore depths may change rapidly and substantially as a result of wave, current, and tide action. Accurate depth data are needed because wave breaking is strongly related to the water depth.

Equilibrium beach profiles (Dean, 1977) that have been used widely in coastal processes and engineering studies provide a method to estimate nearshore depths when actual data are not available. An equilibrium beach profile is given by

$$h(x) = A\, x^{2/3},$$

where h is water depth, x is distance from the mean sea level position of the shoreline, and A is a scale parameter that depends on sediment size. Equilibrium beach profiles were derived from an analysis of over 500 measured beach profiles and consider that beaches with more coarse sediments are steeper than beaches with finer sediments. An infinite slope theoretically exists at the shoreline, but surf models halt their calculations in extremely shallow water before this behavior causes problems. Also, equilibrium beach profiles do not consider the presence of offshore bars indicating the value of actual depth data when it is available.

Breaker heights and types, as well as surf zone widths, can be modeled fairly well by one-dimensional surf models, but longshore currents are often somewhat in error mainly for beaches with shallow offshore bars. At such beaches, modeled longshore current maxima are generally near the bar, but measured maxima are usually further shoreward. Paradoxically, approximately correct energy dissipation, that provides reasonable breaker characteristics and that drives longshore currents, provides relatively poorer longshore currents. Various improvements have been investigated including linear and nonlinear bottom stress equations, turbulent energy production by breakers, longshore pressure gradients caused by wave setup, and wave rollers representing spilling breakers. Turbulent energy and roller approaches delay driving of currents shoreward of breaker locations. Incorporating variable bottom friction to consider varying sediment sizes across the surf zone and to compensate for missing vertical turbulent effects shows promise. An example output of the US Navy's operational one-dimensional surf model with this modification depicts both breaker height and longshore current variations across the surf zone (Figure S70).

Because wave breaking is locally depth controlled and one-dimensional models provide suitable wave energy dissipation rates, research is investigating the use of one-dimensional surf models at multiple longshore locations to calculate the dissipation that subsequently drives two-dimensional current models. These more mathematically complicated models then consider longshore variations in both forcing, such as wave setup, and bathymetry (e.g., Putrevu *et al.*, 1995; Svendsen *et al.*, 1998). As earlier noted, time domain solutions of the hydrodynamic equations for wave motion are also being developed.

Modeling applications

Unlike earlier estimation methods, surf models can provide many types of information across the surf zone. One-dimensional models also can be run at different nearby locations to examine longshore surf variability caused by either incident wave variability or bathymetry changes. Thus, new applications are developing in addition to uses for basic information such as breaker heights. Coastal engineering appli-cations can employ more detailed information such as consideration of different

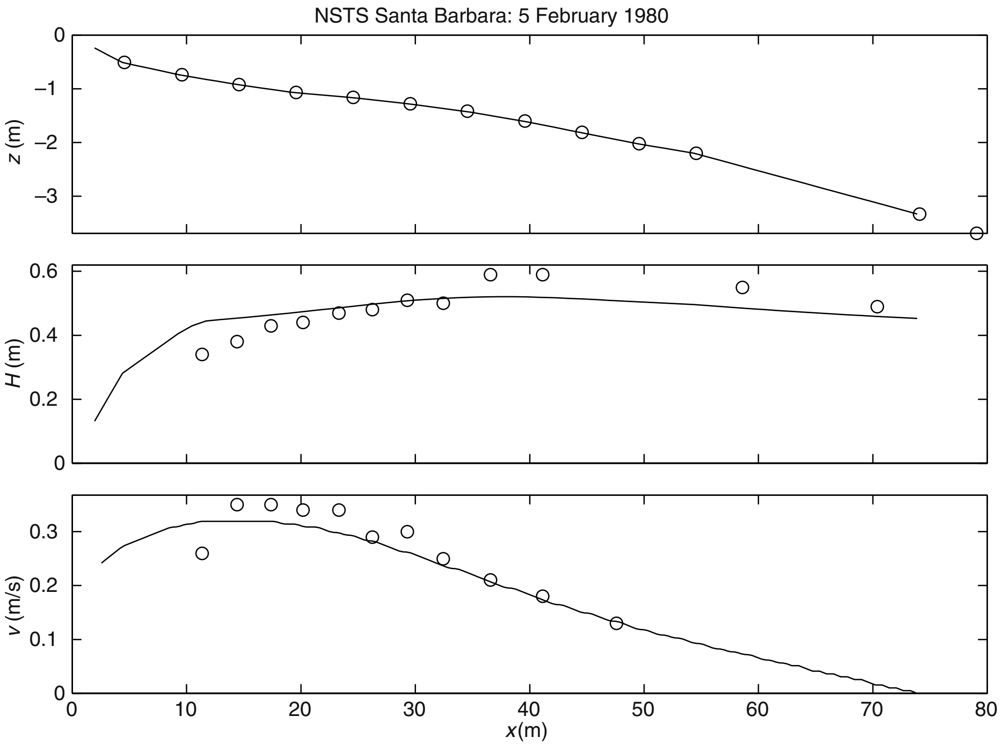

Figure S70 Example of a one-dimensional surf model output showing depth (top panel), root-mean-square breaker height (middle panel), and depth-averaged longshore current (bottom panel) across the surf zone. Measured data are marked by circles.

breaker types. Design of systems that operate in the surf zone, and planning of many types of activities, can be better accomplished with quantitative modeled information.

Information about surf is needed for coastal processes studies, such as beach erosion and sediment transport, and engineering analyses, such as design of coastal structures. The potentially adverse effects of surf on activities in the surf zone and the availability of surf models has resulted in increased use of these models to forecast surf conditions. The US Army Corps of Engineers developed a one-dimensional surf model for engineering applications (Larson and Kraus, 1991). The US Navy routinely operates a one-dimensional surf model to make surf forecasts for amphibious operations (Earle, 1999). Because various military systems require surf information for their designs, this model has also been used to develop surf statistics based on statistics of incident waves (see *Wave Climate* and *Wave Environments*) at locations of interest (Earle, 1999). Surf models have also been driven with real-time measured wave data to provide surf estimates without placing instruments in the hazardous surf zone (Nichols and Tungett, 1998) and have been linked with other models that provide incident wave conditions (Allard *et al.*, 1999).

Summary

A variety of surf models, primarily one-dimensional models, have been developed and applied. Accuracies of particular models are not reviewed here, but such information can be obtained from the references. Models that have been applied or operated routinely are sufficiently accurate for their intended applications. Research using time domain models shows that these models have significant promise particularly for improved calculations of currents. Most importantly, surf modeling provides quantitative surf information that considers the highly location specific nature of surf.

SURF ZONE PROCESSES

The surf zone can be defined as that relatively narrow strip of a body of water that borders the land, and which contains waves that are breaking due to the shallow water depth. However, because the tide level, incident waves, and local wind speed, and direction continually change, the width and character of the surf zone vary incessantly. Therefore, in a discussion of surf zone processes, the region of interest is actually the "nearshore" zone, herein defined as that region that is directly or indirectly affected by depth-induced wave breaking. Finally, a subregion called the "swash" zone is commonly delineated at the boundary between land and water, as that area which is alternately wetted and dried by wave uprush and backrush. These zones are indicated in Figure S71.

The depth-induced breaking of waves drives a progression of intertwined processes that ultimately leads to changes in the morphology of the beach itself, caused by erosion and accretion of sediment. These processes include the creation of the breaking wave roller, maintenance of residual turbulence in the water column, the creation of setup in the mean water level, generation of currents (cross-shore, longshore, and rip currents) and low-frequency motions, entrainment and suspension of sediment, and finally the transport of sediment.

Wave transformation in the nearshore

The phenomena that are most important to wave transformation in the nearshore are (1) refraction, (2) shoaling, and (3) decay due to depth-limited breaking. Refraction (analogous to the refraction of light) is the bending of the waves by variations in bathymetry, and generally tends to align the crests of the waves with the bathymetric contours. Therefore along a straight, smooth coastline, waves that approach from an oblique angle in deepwater may be almost shore-parallel by the onset of breaking in shallow water, as depicted in Figure S71. In this situation, refraction also serves to suppress the wave height. Along an irregular coastline, however, refraction will tend to focus wave energy on headlands and more subtle protruding bathymetric features, thereby locally increasing the wave height. In order to conserve the total amount of wave energy in the system, the wave height is correspondingly reduced in the embayments adjacent to the protruding feature.

As waves refract from deep to shallow water, the process of shoaling is also at work. In rudimentary explanation, as the waves move into shallow water they slow down, but consequently in order to maintain the total amount of energy flux, the wave energy (proportional to the square of the height) must increase. In the situation of a straight, smooth coastline, it is clear that the amplification of wave height due to shoaling typically exceeds the suppression due to refraction, as an increase in wave height prior to breaking is obvious to an observer on the beach.

When the water depth becomes too shallow to sustain the height of the growing wave, the wave becomes unstable and breaking ensues, as characterized in Figure S72. This point of incipient breaking is commonly estimated to be when the wave height reaches roughly 80% of the water depth. Incipient breaking is also dependent upon the wave period and the local bottom slope, for which many empirically derived formulas have been offered (e.g., see Weggel, 1972). In addition, the wind affects incipient breaking with a following wind causing waves to spill sooner, thereby widening the surf zone. An offshore wind delays breaking, thereby compressing the surf zone, and causes waves to plunge (Douglass, 1990).

As the water depth continues to decrease, breaking becomes fully developed and the wave height continues to decrease. The rate of decay of wave height depends predominantly on the bed slope. For slopes around 1/30, the incipient condition of 80% of the water depth continues

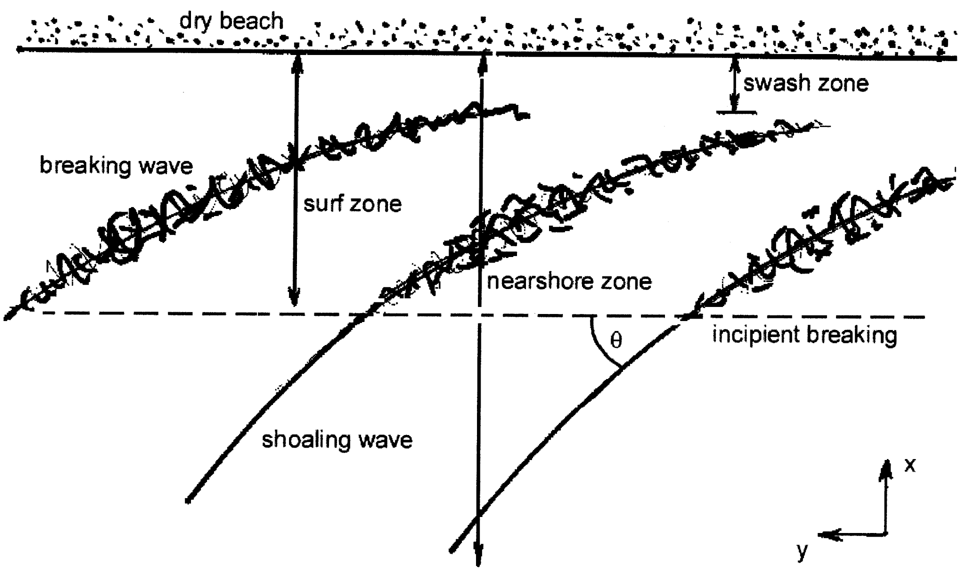

Figure S71 Definition sketch of the nearshore zone, showing overhead view of wave refraction, shoaling, and breaking.

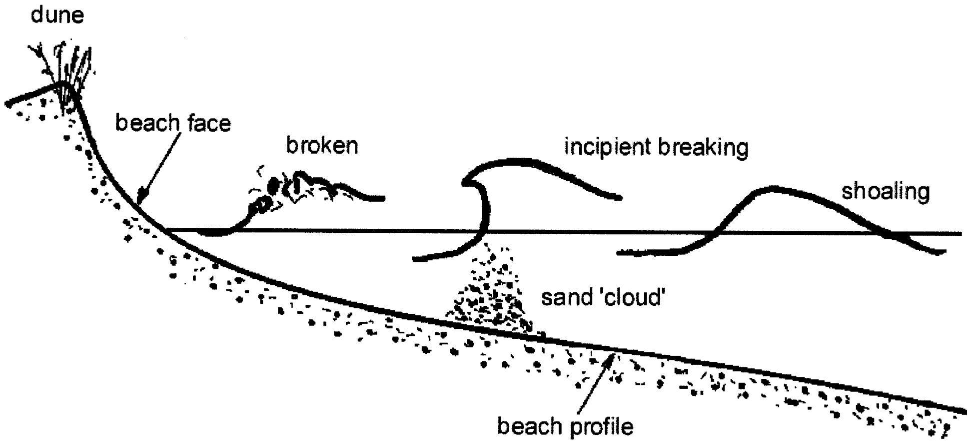

Figure S72 Cross-section of the nearshore zone, depicting wave transformation.

to hold true. For milder slopes, however, this value gradually decreases to as little as 35%, whereas for steep beaches the wave height might maintain a value equal to the local depth. More sophisticated models that describe breaking decay are available (e.g., Battjes and Stive, 1985; Dally *et al.*, 1985).

Because the beach face is typically steep (Figure S72), as the waves approach the mean water-level shoreline they collapse to form the characteristic strong up rush and downrush of the swash zone. This is the case especially during high tide. At low tide, however, the water level may intersect the beach at a much flatter segment of the profile, causing the waves to continue their decay as gently spilling breakers. In this situation, the swash zone may be extremely small, or may not exist at all.

The breaking wave roller

In watching the surf zone the most obvious feature is the "rollers," which characterize wave breaking. At breaking's onset, a portion of the energy that was previously transported in the organized wave motion is converted into a region of highly turbulent, aerated water that moves at roughly the wave celerity, as shown in Figure S73. Energy is dissipated in the form of heat in a shear layer that exists between the roller and the underlying organized flow, as well as inside the roller itself. In addition to its role in the energy budget of the surf zone, the roller is also a significant contributor to the mass and momentum balances (Svendsen, 1984).

Due to its highly turbulent, aerated nature, very few direct measurements of fluid motion in the roller have been obtained (see Mocke *et al.*, 2000), and so detailed knowledge is lacking. However, quantitative models for macro-properties of the roller exist, basically providing the evolution of the size of the roller as it crosses the surf zone (Dally and Brown, 1995).

Residual turbulence

As the roller passes by a particular spot in the surf zone, it leaves behind a layer of residual turbulence that expands downwards through the underlying water column as shown in Figure S73. This turbulence has important links to other surf zone processes, namely the suspension of sediment and the mixing of surf zone currents. The additional "stirring" by the residual turbulence establishes the vertical structure of surf zone currents, with stronger turbulence resulting in currents that are more uniform over depth. Residual turbulence contributes both directly and indirectly to lateral mixing of the currents as well, and is also responsible for maintaining concentrations of suspended sediment in the upper water column that far exceed those under non-breaking conditions.

The behavior of the residual turbulence left in the water column by the passing rollers has been found to mimic that of a free wake created by unidirectional flow past an obstacle. By applying principles from the basic theory for turbulent wakes, the temporal and spatial structure of the residual turbulence has been modeled to some degree (e.g., Sakai *et al.*, 1982; George *et al.*, 1994). The wave-period-averaged turbulence intensity and the vertical mixing in the wake have been quantified in terms of macro-properties of the roller itself (Dally, 2000).

Radiation stress

Although the water particle motion associated with ocean waves is oscillatory, if the momentum flux associated with each wave is mathematically integrated over the water column and then time-averaged over a wave period, one finds that the waves exert a mean residual stress on the water column. This stress, called the "Radiation Stress" (Longuet-Higgins and Stewart, 1964), is actually a stress tensor with three components. In a Cartesian coordinate system with x and y directions in the horizontal plane and z directed vertically upwards (as in Figures S71 and S73), two components, S_{xx} and S_{yy}, act like normal pressure in the x and y directions, respectively, whereas the third, S_{xy}, acts like a tangential shear stress. In the shallow water of the nearshore, they are each functions of the wave height (H) and local wave direction (θ), and are approximated by

$$S_{xx} \cong \frac{\gamma H^2}{8}\left(\frac{1}{2} + \cos^2\theta\right), \qquad \text{(Eq. 1a)}$$

$$S_{yy} \cong \frac{\gamma H^2}{8}\left(\frac{1}{2} + \sin^2\theta\right), \qquad \text{(Eq. 1b)}$$

$$S_{xy} \cong \frac{\gamma H^2}{8}\cos\theta\sin\theta, \qquad \text{(Eq. 1c)}$$

where γ is the density of water. Spatial gradients in these stress components slightly deform the mean water level in the nearshore, as well as drive surf zone currents.

Set-down and set-up

With a coordinate system oriented such that the x-axis is directed onshore, cross-shore gradients in S_{xx} due to shoaling of waves (i.e., an increasing wave height) actually depress the mean water level seaward of the surf zone. This "set-down" begins as waves enter transitional water and begin to feel the bottom, and gradually draws down the mean water level until reaching the point of incipient breaking. At this point the maximum set-down is observed to be roughly 2–4% of the height of the breaking wave (see Bowen *et al.*, 1968).

As breaking ensues and the roller develops, the mean water level first flattens for a short distance because there is a momentary balance between the decrease in S_{xx} and the increase in momentum flux in the roller as it grows in size. However, farther into the surf zone as both the wave and roller shrink, a "set-up" in the mean water level is created (see Figure S73), which reaches a maximum value at the shoreline. Although dependent on the bottom slope and the wave period, this maximum setup is roughly 12–18% of the breaker height. With a large swash zone, however, the maximum setup is difficult to define and measure, due to the intermittent presence of water.

The local wave-induced set-up is superimposed upon any large-scale deviation in mean water level forced by the winds. For example, offshore-directed winds apply a surface shear stress that tends to suppress the water level in the nearshore, whereas onshore-directed winds will push water up against the shore and hold it there, effectively elevating the mean water level as a "storm surge."

Cross-shore currents

Althought the water motion associated with a non-breaking wave is nearly balanced between forward and backward displacement, there exists a residual flux of water in the direction of wave propagation, which occurs mostly in the wave crest. In breaking waves, this flux is augmented by additional onshore flux of water in the aerated roller. Due to the presence of the shoreline, and with longshore-uniform conditions, this mean landward discharge in the upper part of the water column, must be locally compensated by a mean, offshore-directed "return-flow" in the lower water column, depicted in Figure S73. The return-flow current is often called "undertow," but is not to be confused with the rip current discussed below. Although the strength of the return-flow is only roughly 10% of the wave celerity, it is this weak, yet persistent current that is primarily responsible for the net offshore transport of sediment that occurs during storms (Dally and Dean, 1984; Dally and Brown, 1995).

The shear stress applied to the water surface by the wind also contributes forcing that affects the strength and structure of cross-shore current in the surf zone. An onshore-directed stress pushes additional surface water toward the beach which, again because of the presence of the shoreline boundary, must be balanced by an increased return-flow current in the lower water column. Consequently the onshore wind that often accompanies a storm further augments the wave-driven offshore current. With an offshore-directed wind the opposite occurs. That is (neglecting the wave-induced current for the moment), surface water pushed offshore by the wind stress is supplied by water drawn onshore in the lower water column.

Longshore currents

The mean flux of water along the beach is called the "longshore" current, and is also forced by both waves and local winds. For obliquely incident waves, the cross-shore gradient in S_{xy} (equation 1c) due to breaking creates a residual shearing thrust that is directed down the beach as depicted in Figure S74. In the outer surf zone this thrust is locally offset by an opposite-directed shear associated with the creation of the roller. However, as the roller subsequently starts to shrink, its thrust switches direction, and both thrusts now act in harmony to drive water down the beach (Osiecki and Dally, 1996). Consequently, the location where the longshore current is greatest is usually somewhat landward of the break point. The mean longshore thrust of the waves is balanced by the shear stress that the sand bed exerts on the water.

Seaward of breaking, there is no wave-induced forcing of the longshore current because the increase in S_{xy} associated with wave shoaling is exactly compensated by the decrease due to wave refraction. However, lateral mixing processes driven by both turbulence and residual convective acceleration enable the current inside the surf zone to drag the outside water along with it, creating a tail on the longshore current that diminishes in the offshore direction (Svendsen and Putrevu, 1994). Outside the breaker line, this lateral mixing stress is balanced by the mean bed stress of the current.

Depending upon its speed and direction, the wind can also be a significant contributor to forcing of the longshore current. In fact, it is often the primary driver during the initial stage of development of a storm. The alongshore component of the wind stress vector, acting on the water surface, can either act in harmony with the wave-driven forcing, or oppose it. Although a rare event, strong opposing winds can even arrest the wave-driven longshore current.

At the base of the beach face, the behavior of the longshore current is controlled by the character of the swash zone. For very flat profiles with little swash, the current speed approaches zero as depicted in Figure S74. For large swash zones though, the mean longshore current observed at the toe of the swash can be significant.

Rip currents and nearshore circulation

In situations where either the incident wave field or the under-lying bathymetry is not uniform along the beach, complicated circulation patterns can be established. These include the infamous "rip current" that is so dangerous to bathers. Not to be confused with the mild cross-shore current (undertow) described above, rip currents are very strong, yet locally confined, offshore-directed flows that can reach speeds more than 1.0 m/s, making them nearly impossible to swim against. One likely generation mechanism for a rip current is the presence of a low spot in a longshore bar, through which the majority of water carried landward over the bar by the waves along the adjacent beaches is returned. As shown in Figure S75, the rip current is fed by the mild, mean onshore transport of water that occurs in the wave crest and roller as discussed above, which accumulates to form longshore-directed feeder currents that search out the narrow, low section in the bathymetry to form the seaward-directed rip. Set-up is reduced in the rip channel but elevated on either side, which serves to drive the circulation cell. If the bathymetry is rhythmic in the longshore direction, rip currents can form at regularly spaced intervals, and can be present as long as the special bathymetry persists—sometimes even for several days (see Noda, 1972).

Another possible origin of regularly spaced rip currents is the interaction of waves approaching a beach from different directions (Dalrymple, 1975). The waves tend to enhance each other at regular intervals along the beach (antinodal zones), with zones of suppression in between (nodal zones). Where the waves reinforce, the setup is greater than where they negate. This results in structure in the mean water surface that drives water from the antinodes towards the nodes, which is again turned out to sea in the form of a rip.

Additional complex nearshore circulation patterns are often generated adjacent to coastal structures such as groins, jetties, piers, and breakwaters. Basically, the structure perturbs what might otherwise be a longshore-uniform wave climate, creating a region of reduced setup in its wave shadow, to which water is driven from remote regions of higher setup. The shadow can be the obvious result of wave blocking by the structure, as well as more subtle energy losses incurred due to "rubbing" of the waves against the structure.

Low-frequency motions

Often the incident waves arrive at the beach in distinct groups, especially if they were generated by a distant storm and local wind conditions are calm. This groupiness manifests itself as a low-frequency modulation of the wave height, where the wave height grows over several successive waves and then decreases over several more. Each group can last up to several minutes, sometimes with a notable period of calm in-between groups. The setup phenomenon described above responds directly to this rhythmic unsteadiness in wave height, and the gradually varying mean

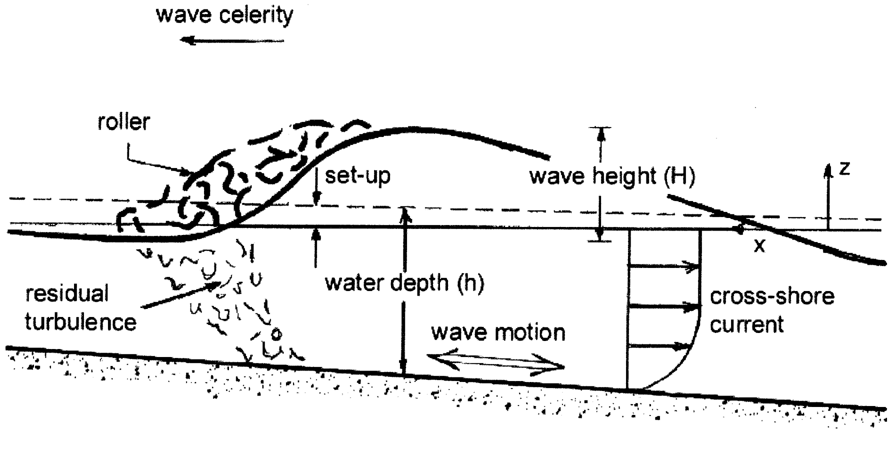

Figure S73 Hydrodynamic features of the surf zone (after Dally, 2000).

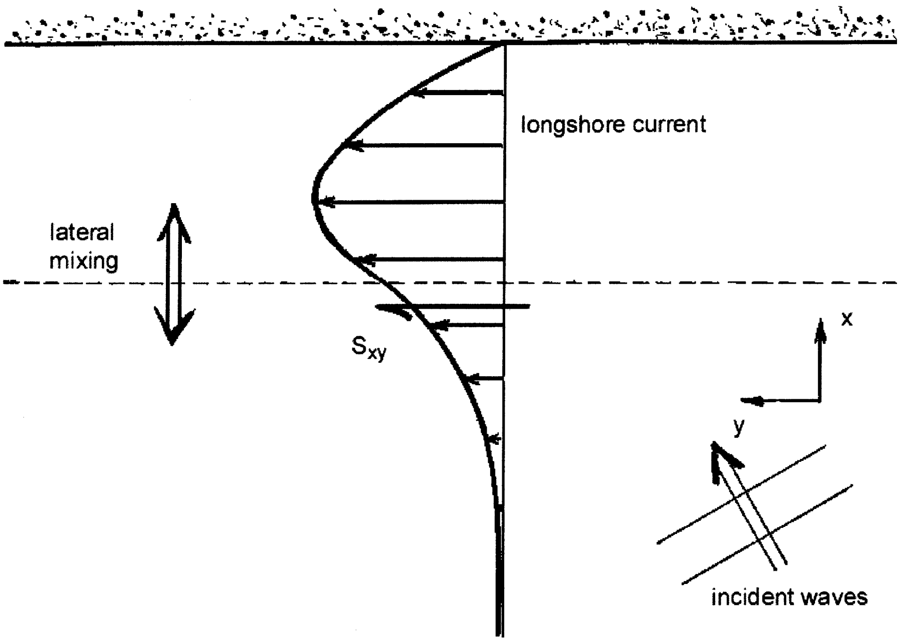

Figure S74 The longshore current, driven by the S_{xy} component of Radiation Stress for obliquely incident waves. Lateral mixing creates the "tail" of the current.

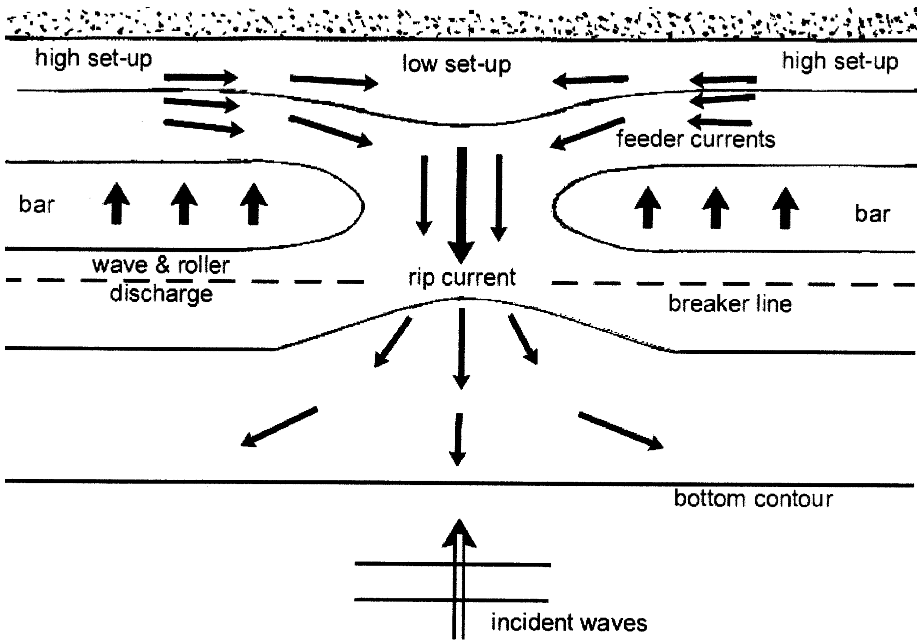

Figure S75 Rip currents generated at a low spot in the crest of a longshore bar.

water level that results is referred to as "surf beat." Surf beat can become particularly pronounced if the bottom slope is slight and the waves are large (i.e., a wide surf zone).

Because surf beat is a low-frequency motion ($f < 0.01$ Hz), some of this energy can be trapped against the coastline by refraction processes or can be amplified, particularly by reflection from headlands and shore-perpendicular structures. These long-period, "edge" waves actually propagate along the beach and, although measurable, are usually undetected by the naked eye (e.g., see Guza and Davis, 1974).

Groupiness in the waves also causes the mean forcing in the nearhore to vary in time, and consequently the cross-shore and longshore currents are unsteady. One additional low-frequency motion sometimes found in the surf zone is the "shear wave," which is actually a periodic instability generated by strong longshore currents. This phenomenon is detectable only with a current meter, as it does not directly influence the mean water-level elevation (Oltman-Shay *et al.*, 1989).

Sand entrainment and suspension

Although researchers continue to struggle with the extremely complicated problem of quantitatively modeling sediment entrainment and suspension in the surf zone, much is known qualitatively. In general terms, sediment is first entrained by the near-bed fluid motion, and then carried up into the water column by small-scale turbulence or larger-scale vortices. The most germane parameters are the size and gradation of the sediment (typically sand), its settling velocity in still water, and the strength and character of the water motion, which is usually quantified in terms of wave height and period, and current strength. Small sand grains with slow settling velocities are easily entrained and suspended in large quantities, whereas large, heavy particles understandably hug the bed. Larger waves suspend more sediment due to their stronger oscillatory velocities, whereas short-period waves support suspension by maintaining higher mean turbulence levels.

Outside the surf zone, the entraining water motion is comprised of oscillatory wave motion, mean currents, and low-frequency motions. Once entrained, sediment is mixed/ suspended higher into the water column by the turbulence generated at the bed as the waves and currents interact with bedforms such as ripples and mega-ripples.

Inside the surf zone, entrainment is enhanced by stronger wave motion, particularly the more pronounced flow that occurs under the crest of nonlinear, breaking waves. Suspension into the upper water column is greatly augmented by the residual turbulence left by the roller. Finally, the extreme flow conditions and large vortices generated by plunging breakers result in dramatic entrainment and suspension events.

At any particular location in the nearshore, the vast majority of entrainment and suspension occurs as the wave crest passes, creating a "cloud" of sediment (depicted in Figure S72). Outside the surf zone this cloud may be quite small, both in size and in concentration, especially if the entrainment is associated with sand ripples that are present on the bed. Near the break point, large, long-period waves can create what is known as "sheet-flow" conditions, in which the bed is scraped flat and, although there is strong entrainment, there is limited suspension due to a lack of turbulence. In both of these situations, the cloud of sand settles back to the bed before the next wave crest arrives. However, in the surf zone, and particularly for plunging breakers, the sediment cloud may take several wave periods to settle back to the bed, and may in fact be resuspended by a subsequent wave. It is for this reason that sediment concentrations inside the surf zone are generally several times greater than those outside (e.g., see Kana, 1979; Nielsen, 1992).

Farther into the surf zone, because the wave energy decreases due to breaking and the oscillatory motion abates, ripples will once again appear if the surf zone currents are weak. If the currents are strong, "mega-ripples" may be created, resembling those found in rivers. Finally, in the swash zone where wave collapse and runup occurs, sheet flow conditions return and the bed is smooth. In this region, sand entrainment and suspension is characterized as a slurry, rather than as a cloud.

Due to the randomness of the incoming waves, the creation of the sediment clouds is an intermittent process. In fact even in laboratory wave channels where so-called "regular" waves can be created, the details of the entrainment and suspension events vary from wave to wave because the underlying hydrodynamic processes are highly nonlinear. Consequently, time-series concentration measurements (typically made using either sonic or infrared instruments) are often averaged over many wave periods so that the basic structure can be identified.

To illuminate the concepts introduced above, Figure S76 presents idealizations of time-averaged measurements of suspended sand concentration observed in the outer surf zone in a large wave channel for regular, plunging breakers (see Barkaszi and Dally, 1992). Note that both the shape of the vertical profile and the overall magnitude of concentration change considerably as one moves from outside the break point (location "a"), to the plunge point (location "c") and into the surf zone (location "d"). However, as is typically the case the mean concentration decreases with elevation above the bed, as intuition would dictate.

Sediment transport and beach evolution

In the discussion of sand transport in the surf zone, and ultimately the changes in the beach that result from spatial gradients in transport, the water column can be split into two layers: (1) a "near-bed" layer, in which both the oscillatory wave motion and the mean current contribute to the displacement of sediment particles, and (2) a "fully suspended" layer where, effectively, only the mean current contributes to the net displacement (Dally and Dean, 1984). The thickness of the near-bed layer, d_f, is simply the distance that a sand grain falls in one wave period, given by $d_f = T \bullet \omega$, where T is the wave period and ω is the fall velocity in still-water. Of course on a natural beach, the incident waves have differing periods and the sand grains are not uniform in fall velocity, so the boundary between the near-bed and fully suspended regimes is not distinct. Also, when the water depth is less than the value of d_f, the nearbed regime extends over the entire water column, as is the case in the swash zone, for example.

The utility in defining the two regimes is that in the fully suspended layer, the average sediment transport rate is well approximated simply by multiplying the suspended sand concentration by the local current velocity. However, in the nearbed layer, because the sediment is in suspension for less than one wave period, the wave-induced oscillatory velocity does contribute to the net displacement, on average (Dean, 1973). Neglecting the mean current for the moment, and with suspension triggered as the wave crest passes, the sand in the lower half of the near-bed layer will experience a net shoreward displacement, whereas that in the upper half experiences a net seaward displacement, as shown in Figure S77. Because generally the concentration in a sand cloud decreases with elevation above the bed, it is apparent that in the nearbed layer the total net transport of sand is directed onshore. Reintroducing the mean current modifies this scenario of course, depending on its strength and direction.

Cross-shore transport and beach profile evolution

With this two-layer framework, the details of the sand transport processes that cause beach erosion and accretion can be described. At

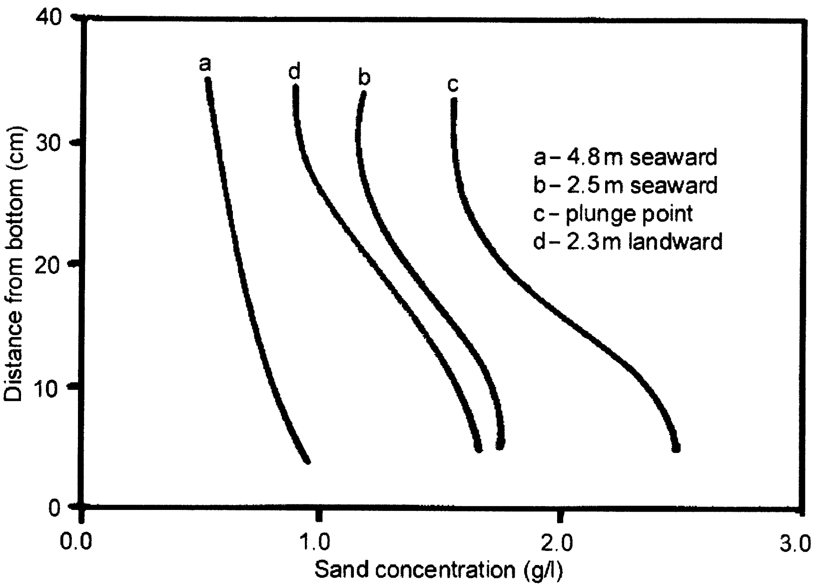

Figure S76 Idealized profiles of mean concentration of sand suspended by plunging breakers. Concentrations at the plunge point can be several times greater than elsewhere.

times when waves directly approach the beach ($\theta = 0$), the mean current in the surf zone and nearshore is comprised of only the offshore-directed undertow. Consequently, mean sediment transport in the fully suspended layer is directed solely offshore. If relatively little sand is being suspended above the nearbed layer, however, the total net mean transport will be onshore, and the beach face will accrete as it receives sand moved from the nearshore. When a storm develops, however, (1) the wave period shortens, thereby reducing the thickness of the nearbed layer, and (2) the residual turbulence levels increase, thereby carrying greater quantities of sediment into the fully suspended layer. Both of these characteristics enhance the offshore-directed transport to the point where it dominates the diminishing onshore transport, and the beach and inner surf zone consequently erode. The material is deposited in a longshore bar that develops near the point of incipient breaking where the entrainment processes weaken. When calmer conditions return and the mild onshore/nearbed transport once again dominates, this bar will gradually migrate onshore and supply sand to the swash zone, thereby rebuilding the beach face. This well-known sequence of beach erosion and recovery is illustrated in Figure S78.

From the discussion above it follows that if wave and water level conditions could be held constant, the beach would evolve until a state of "dynamic equilibrium" was attained, in which the onshore transport in the lower portion of the nearbed layer was balanced by the offshore transport in the upper portion and the fully suspended layer—a balance that must be maintained everywhere across the beach profile. Such a state is easily attained in a laboratory wave channel, but seldom approached in nature.

Longshore transport and coastline change

If waves approach the surf zone obliquely, both the longshore component of the oscillatory wave motion and the longshore current serve to carry sand along the beach. The flux of sand in the longshore direction in the fully suspended layer is again well approximated by the product of the mean concentration and the longshore current speed. In the nearbed layer, although sand initially suspended in the top of the layer may experience net upcoast displacement due to the oscillatory motion, the mean flux for the entire layer is downcoast, and is further enhanced by the longshore current. In the swash zone the uprush can occur at a strongly oblique angle, whereas the downrush typically does not. Consequently, the net longshore transport in the swash can be significant, and in fact is often the predominant zone of longshore transport in the nearshore (see Bodge and Dean, 1987).

If there is no longshore variation in the flux of sediment along the beach, then the beach profile and coastline remain stable. However, if the longshore transport is blocked by a natural immobile feature (e.g., a headland or reef/rock outcrop) or by a man-made structure (e.g., a groin or jetty), sand will accumulate on the updrift side and erode from

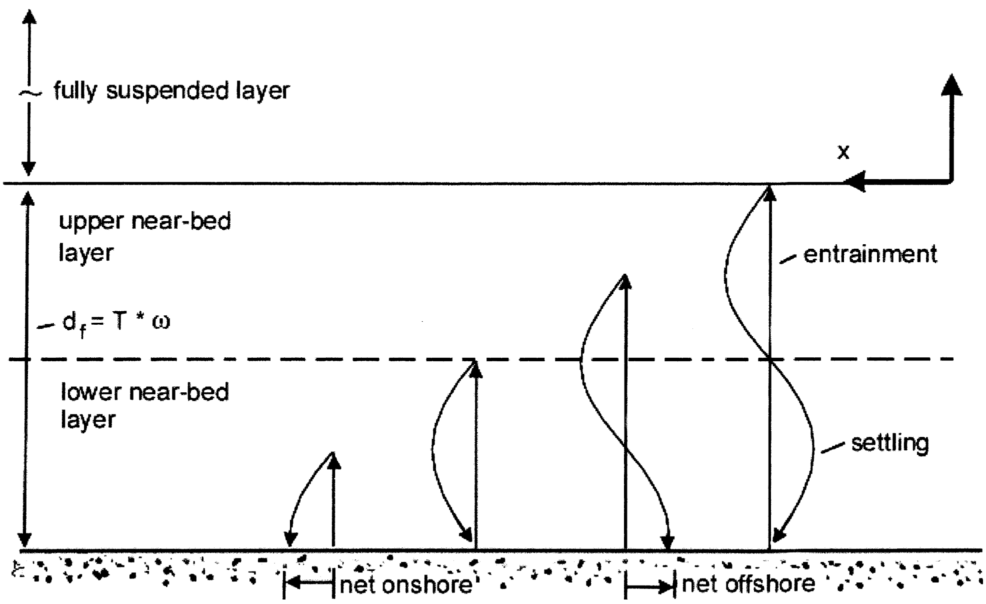

Figure S77 Sediment transport regions in the nearshore. Sand suspended in the near-bed layer returns to the bottom within one wave period, whereas that in the fully suspended layer does not (after Dean, 1973; Dally and Dean, 1984).

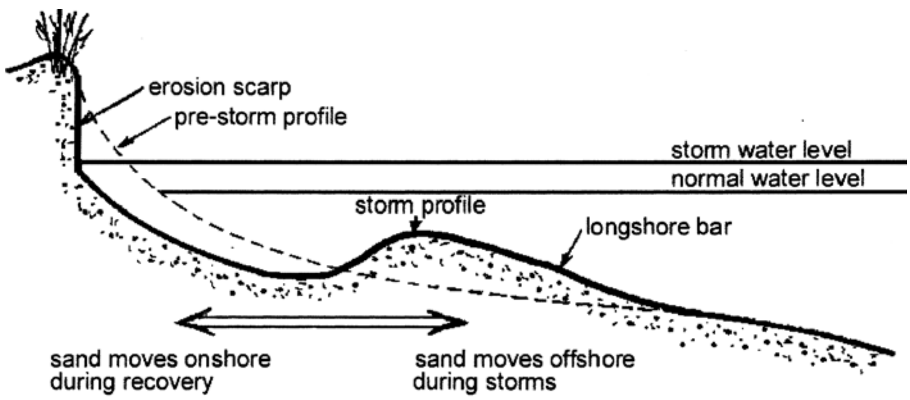

Figure S78 The cycle of storm-induced beach erosion (which creates a longshore bar), and subsequent recovery (which pushes the bar material back onshore).

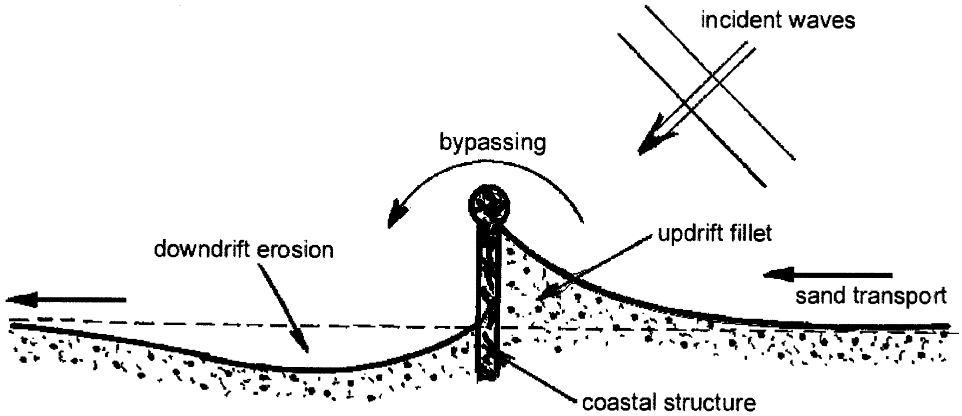

Figure S79 Shoreline change due to interruption of longshore transport of sand by a structure. The updrift fillet grows and the downdrift pocket erodes until the fillet is saturated and bypassing begins.

the downdrift, as shown in Figure S79. Also, on a seemingly unperturbed beach, longshore variations in offshore bathymetry cause variations in the nearshore wave climate, and consequently nonuniformity in the transport along the beach. This can result in erosion "hot spots," as well as otherwise mysterious zones of accretion. Finally, longshore variations in sand characteristics can lead to longshore gradients in transport and ultimately to the creation of a meandering coastline.

Additional suggested readings on this subject may be found in Battjes (1975), Dean and Dalrymple (1984), Fredsoe and Deigaard (1992), Komar (1998), Nadaoka and Kondoh (1982), and Whitford and Thornton (1996).

SURFING

The origins of surfing are believed to date back to the ancient Polynesians, well before Captain James Cook became the first westerner to document surfboard riding, ca. 1777 (see Lueras, 1984). Simply hand-carved planks of wood, the first surfboards were large (up to 5 m in length), heavy, and difficult to control. Subsequent evolution during the 1920s to 1950s included hollowing the board, as well as shaping from balsa. In the early 1960s, the advent of synthetic foam and fiber-glass ushered in the modern era of surfing, and forever changed the nature of the sport by making surfboards shorter, lighter, faster, and more maneuverable. The modern surfboard is typically made of high-tech, composite materials with high strength-to-weight ratios. A custom-made board starts as a "blank," consisting of a foam core with one or more wooden stringers running its length to provide strength. After cutting to rough dimensions, the blank is shaped by hand, and the finished core is then covered with fiber-glass, using either polyester or epoxy resin. One or more fins, known as "skegs," are incorporated near the tail of the board to provide control and to enhance stability. Although a limited amount of laboratory and computer-simulation modeling of surfboards has been attempted (e.g., see Hornung and Killen, 1976), the evolution of board shape and design has been mostly by trial-and-error. Generally, long boards are used in gently spilling breakers, and shorter boards used in steep-faced, plunging waves.

"Stand-up" surfing is the most prevalent type of surfing, although body-boarding, where the surfer lies prone on a much shorter board and uses flippers to aid in wave catching, has gained significant popularity. Knee-boarding is a more rare form. Finally, in body-surfing no board is needed at all, with the surfer's own body used as a planing surface. This is arguably the "purest" form of surfing, practiced even by sea lions and bottlenose dolphins in the wild.

Catching a wave

In catching a wave, the surfer first takes up a position near the seaward edge of the surf zone, that is, at the break point of the largest incoming waves. As a suitable wave approaches, the surfer pivots to face towards shore and begins to paddle in order to gain forward momentum. With the face of the wave steepening, the surfer is lifted and the board tips forward, consequently accelerating in the direction of wave motion. The surfer then jumps to a semi-crouched position and slides down the wave face, thereby momentarily matching the speed of the wave. After "dropping in," the surfer executes a "bottom turn" in order to establish a path more tangential to the wave. From that moment on the surfer tries to maintain a position somewhere in the area immediately in front of the critical breaking region (the "pocket"), and so the ride is essentially a delicate reconciliation between the speed of the point of incipient breaking (the "break rate"), and the speed of the surfer (the "board speed"). If the break rate becomes greater than the maximum board speed that can be sustained by the surfer, the break point overtakes the surfer and the wave "closes out." If the break rate is less than the maximum sustainable board speed, the surfer has time to "carve," that is, maneuver up-and-down the face of the wave, as well as attempt other acrobatics. Maximum sustainable board speeds have been documented in excess of 18 m/s (40 mph) (Dally, 2001a).

Analysis of natural surfing breaks

What makes a particular site good for surfing? One of the first comprehensive studies of basic surfing mechanics, as well as the analysis of specific surfing breaks, was conducted by Walker (1974) for several famous breaks in Hawaii. Bathymetric surveys were performed, and estimates of surfer speed and "peel angle" (viewed from overhead, the angle between the wave crest and the path of the break point) were collected. The reason for these enduring, high-quality breaks was found to be the interplay of certain wave conditions—for example swell waves of sufficient height arriving from a specific direction—with the underlying reef bathymetry via the processes of wave refraction and shoaling. Recent surveys of other well-known surfing breaks around the Pacific Ocean confirms this, and detailed wave modeling demonstrates the importance of the interaction of bathymetric features of different scales in creating exceptional surfing breaks (Mead and Black, 2001a,b). In addition to bathymetric features, the interaction of waves and coastal navigation structures such as jetties has also created some well-known surfing breaks (Dally, 1990) such as at Sebastian Inlet, Florida (Figure S80). Finally, stochastic modeling has been utilized in attempts to quantify the "surfability" of a site, that is, the proportion of time in which good surfing waves are available (Dally, 1990, 2001b).

Engineering of man-made surfing breaks

For beaches that do not have the benefit of naturally induced, high-quality surfing breaks, the long-contemplated idea of enhancing waves for surfing using man-made structures has only recently been undertaken both in Australia (Pattiaratchi, 1997; Black *et al.*, 2001) and the

Figure S80 Surfer enjoying "First Peak" at Sebastian Inlet, Florida, which is a perennial break created by wave reflection from the northern jetty (photo by Gibber, courtesy of Eastern Surf Magazine).

United States. These artificial surfing breaks are submerged, mound-like structures, designed to both focus wave energy, thereby increasing the breaker height, as well as reduce the break rate by adopting an orientation that is strongly oblique to the crests of the incoming waves. Such reefs have been constructed out of concrete rubble units, as well as sand-filled geosynthetic bags.

SYNTHETIC APERTURE RADAR SYSTEMS

A synthetic aperture radar (SAR) is a remote sensing imaging system whose primary output product is a two-dimensional mapping of the radar brightness of a scene. Radar brightness is an expression of the scene's reflectivity in response to oblique illumination by microwave electromagnetic emissions. By definition, a SAR must be mounted on a moving platform, such as an aircraft or a satellite, and its illumination is directed to the side (and downward) to the surface. Its images are formed by scanning the area in two dimensions: range and azimuth. Range scanning is essentially at the speed of light, as radar pulses are transmitted and their reflections (backscatter) are received and recorded. Azimuth scanning is accomplished by the forward motion of the radar. SAR imaging "works" because the speed of light is very much greater than the along-track velocity of the radar. As the radar progresses along its flight path, the reflected signals from each transmission are collected and stored in memory. The heart of the system is the processor, which derives output image products from the stored data. The name "synthetic aperture" reflects the fact that signal processing algorithms replicate the signal collecting functions of a real aperture antenna array, thus "synthesizing" the effects of a physical antenna from a virtual data array.

One can visualize the key stages in the system through an optical comparison—a simple camera. A SAR's data memory is analogous to a record of the light field from a scene that may impinge on the front surface of a camera's lens, and the processor imitates (at least mathematically) the actions of the lens as it focuses the field and directs the refracted rays to the camera's film. As in a camera exposing black-and-white film, larger reflectivity (greater radar brightness) is expressed as lighter tones of gray tending toward white in a radar image. Lower reflectivity (less radar brightness) is expressed as tones of darker gray tending toward black. Colors may be artificially imposed on radar images to portray added dimensions, such as differences in reflectivity between two or more images, or differences in reflectivity as a function of wavelength or polarization.

A brief history

The original SAR idea is due to Carl Wiley in 1951. It was first reduced to practice by the University of Illinois, and by the Willow Run Laboratories of the University of Michigan. Several airborne systems were developed in the 1960s, although the technique was largely classified at the time. The first satellite SAR was embarked on Seasat (1978). Important earth-observing satellite SARs since then include Japan's J-ERS, the European Space Agency's ERS-1 and ERS-2, and Canada's RADARSAT (1995), which was still operational in June 2004.

Signal processing has been the pacing development in the history of SAR. Early SAR processors were analog optical contraptions, excited by lasers, and depended on relatively conventional photographic film for both the memory medium and the output image format. The first digital processors were developed for Seasat. In the fall of 1978, typically it would take more than 40 h to process one 50 km by 50 km scene, approximately one quarter of the nominal 100 km square Seasat SAR frame. Today, primary SAR image processing has progressed to the point that it is nearly transparent to most users of the data.

Basic concepts and parameters

Resolution is the minimum separation between two small and similar side-by-side reflectors such that they appear discretely in the image to be two, rather than merged into one. The distinguishing SAR performance attribute is the *azimuth resolution* realized through the synthetic aperture technique. The primary advantage of the SAR approach is that the radar-processor combination using data collected by a relatively small antenna can replicate the resolution that could otherwise be delivered only by an impossibly large antenna. For example, the Seasat SAR in its finest (or highest) resolution mode had about 6 m azimuth resolution. If a real aperture imaging radar were to have flown in place of Seasat, its antenna would had to have been about 16 km long (!) to achieve the same results. Azimuth resolution is proportional to range and inversely proportional to antenna length for a real aperture radar, but it is approximately equal to one half of the antenna length for a SAR. Seasat's SAR antenna was only 10 m long, not 16 km. Quite a difference, but not atypical of satellite systems that operate at 1,000 km range or so.

As microwave systems, most SARs employ relatively long wavelengths in contrast to optical or infrared systems. The wavelengths used by earth-observing satellite SARs include L-band (23-cm), S-band (10-cm), C-band (6-cm), and X-band (3-cm). RADARSAT is at C-band. At these wavelengths, roughness is the primary geophysical characteristic of the illuminated surface that determines the power of the backscattered signal, the radar brightness portrayed in SAR imagery. Surface roughness must be judged relative to the radar's wavelength, conditioned by the incident angle of the illumination at the surface, and other less important attributes. A surface appears rough to the radar as the topographic relief becomes comparable to the illuminating wavelength. A given surface always appears to become smoother as the angle of incidence is increased.

SAR backscatter may be enhanced considerably by favorable multi-reflection geometries. For example, stands of mangroves usually appear as bright areas, because the radar illumination bounces off both the water's surface and tree trunks, sending a relatively strong reflection back to the radar. The resulting image contrast is strongest for mangroves in calm (smooth) water.

Synthetic aperture formation requires that the data over the effective azimuth processing field must be phase-coherent. This leads to significant advantages for interferometric measurements, for example, which have demonstrated the ability to measure systematic surface displacements on the order of centimeters.

There is an inherent and not always pleasant consequence to phase coherence. For reflections from many distributed reflectors such as the ocean's surface, the random phases of the individual scattering facets cause mutual interference, leading to brightness modulation of the imaged field. This is known as speckle, whose variance is proportional to the mean radar brightness of the neighboring image area. Speckle may be reduced by averaging, which implies a signal-processing tradeoff with image resolution. "Looks" describes the number of statistically independent sub-images used to form the averaged image. The number of looks, divided by the product of the resolution parameters (in range and azimuth), is a fundamental SAR parameter, which is proportional to the Nyquist information capacity of the system. Usually, SAR range resolution is equal to the inverse range bandwidth (scaled to ground range), and azimuth resolution is approximated by half of the azimuth aperture length multiplied by the number of statistically independent looks. For example, the Seasat SAR used four looks in the processor, thus compromising its azimuth resolution to about 25 m, while reducing the speckle noise variance to a reasonable level (for many applications). The standard mode of RADARSAT, and the conventional modes of ERS image products all have comparable image quality, at least as rated by this norm. A significant increase in this parameter would imply a significant increase in SAR system cost.

All radar observations of scene reflectivity are in competition with additive radar noise. The additive noise is described by an equivalent reflectivity number, known as the noise equivalent reflectivity. Unlike speckle, the effect of additive noise is suppressed for higher relative levels of radar brightness, which can be due to either increased reflectivity or larger effective radar power.

Swath width, the span of the imaged area measured on the surface orthogonally to the satellite path, is the last of the top-level SAR image parameters. Swath widths typically are about 100 km for nominal 25-m 4-look image products. Higher resolution modes induce smaller swaths (e.g., 40 km). The extra-wide (~500-km) swaths available from RADARSAT's ScanSAR mode are of particular interest to the oceanographic community, and can be interpreted to depict the detailed structure of nearshore wind fields. The trade-off implied by a ScanSAR image product is coarser resolution, which for a well-designed system can be offset somewhat by more looks, thus preserving image quality in spite of increased swath.

The SAR seen sea

For a distributed scene such as the sea, radar brightness is an expression of radar reflectivity, which in general is a function of instrumentation and of geophysical parameters. The instrumentation factors include polarization and wavelength of the radar illumination, and the incident angle at which the scene is observed. Geophysical parameters include surface roughness and conductivity, and environmental factors such as water temperature, air–sea temperature difference, wind speed, and surfactants, all of which have an impact on the ocean's roughness at microwave scales. The radar reflectivity of the ocean tends to decrease with increasing incident angle, as shown in Figure S81.

Polarization of an emitted electromagnetic field is determined by the geometry of the antenna. The observed reflectivity depends on the polarization state of the receive antenna as well as of the transmitted field, where vertical (V) or horizontal (H) linear polarizations are the most commonly used for SAR. Most systems use the same antenna for both transmission and reception, leading to like-polarized reflectivity estimates. Ocean reflectivity is usually larger for VV polarization than for HH polarization.

For a wide range of illumination incidence, Bragg scattering is the dominant source of radar backscatter from the ocean. Bragg scattering is due to a systematic phase fit between the illuminating half-wavelength projected onto the sea surface, and a matching periodic ocean roughness component. For the wavelengths and incident angles of typical ocean remote sensing radars, Bragg waves range from long capillaries (~2 cm) to short gravity waves (~50 cm). "Roughness" in the microwave ocean remote sensing context implies a sensible population of these special Bragg surface wave components. These waves, which have relatively short lifetimes, are locally generated, and are modulated and advected by longer and more energetic seas. It follows that the larger wave structure of the ocean is observable by microwave systems primarily through patterns expressed in the shorter Bragg waves. This is known as the two-scale model of microwave ocean scattering.

Roughness at Bragg wavelengths is set up primarily by local wind stress. For a given incident angle and radar wavelength, there is a first order power law dependence between radar reflectivity and wind speed, as suggested in Figure S82. The slope of the quasi-linear part of the response is a function of wavelength, among other parameters. Within this quasi-linear region, a SAR's radar brightness can be inverted to estimate wind speed, realizing in effect a high-resolution scatterometer.

Within limits, the power law is robust. The upper limit is approached as the radar reflectivity tends to saturate with increasing wind speed. The saturation wind speed is above 25 m/s for the radar parameters of RADARSAT at its steeper incident angles, for example.

The lower limit is more abrupt, and may be of considerable interest in coastal oceanographic applications. Bragg wave formation, and hence sensible radar brightness, occurs only for wind speeds above the lower cutoff threshold, which typically is about 2.5 m/s. Both the onset of Bragg waves and the level of reflectivity are functions of environmental conditions. If the system additive noise is sufficiently low such that the reflectivity threshold is visible, then relatively small changes in local environmental conditions may lead to large contrasts in radar brightness. For example, a change in relative air–sea temperature of only one degree or so can invert the boundary layer stability, which can be manifested as a relatively large change in radar reflectivity. These contrasts are often observed in oceanic SAR imagery, and have proven to be invaluable in tracking oil spills, for example. In general, the challenge is to deduce the appropriate geophysical cause from radar brightness patterns seen in the image data.

In oceanographic applications, the scene of interest is in motion, which can have noticeable consequences on oceanic SAR image characteristics. Gravity waves are characterized by the orbital velocities of their elemental surface constituents. These motions are transformed by a SAR into azimuth shifts of the corresponding image features. As a result, an image of azimuthal waves is distorted, an effect known as "velocity bunching." Directional wave spectra can be deduced from

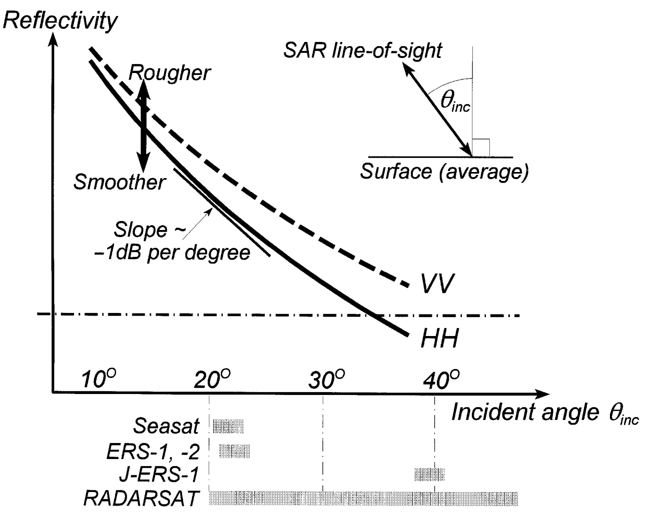

Figure S81 Radar reflectivity (backscattered power) tends to decrease with increasing incident angle, and is larger for rougher surfaces. The span of incident angles of several satellite SAR systems is indicated below the horizontal axis.

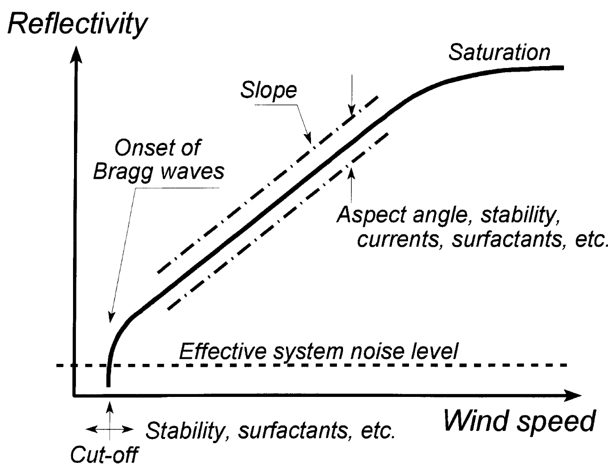

Figure S82 Between the lower and upper limits, the ocean's reflectivity (relative power) increases in proportion to local wind speed. The slope and level of the proportionality depend on radar and environmental parameters. The lower limit is relatively abrupt; backscatter arises only above the minimum wind speed sufficient to excite Bragg waves matched to the radar. The upper saturation limit is more gradual.

oceanic SAR imagery, although extra effort is required to compensate for the degraded azimuthal wave components. The "wave modes" of ERS-2 and Envisat SAR have been designed with these characteristics in mind.

Summary

Image data from satellite-based SAR systems are in increasing demand. Applications span directional wave spectral estimation, ship detection and tracking, oil spill monitoring, fisheries monitoring, coastal wind analysis, coastal erosion, and storm tracking. The major limitation at this time is lack of timely data, due primarily to a shortage of operational systems. This limitation should be at least partially rectified in coming years.

T

TAFONE

Originally used to describe unusual weathering features found in Corsica, tafone (or tafoni, plural) has become established as the generic name for a type of cavernous weathering characterized by the existence of hollows or cavities that range in size from a few centimeters to a meter or more in diameter. Depth is variable, the cavities commonly being nearly hemispherical. The shape and orientation are strongly influenced by the rock fabric, causing the hollows to be elongated in the direction of foliation of bedding planes. Coalescence of the cavities produces mushroomlike shapes, natural arches, and other unusual sculptured forms. Eventually the outcrop surface may be destroyed by this process of expansion. When numerous small cavities occur, the resulting spongelike texture is termed honeycomb weathering. Both honeycomb weathering and tafone may occur independently, but often the two forms coexist and seem to originate from a similar process. Tafone occurs commonly in granitic rocks and in sandstone, but has also been observed in many other rocks. The rate of development may be rapid, cavities having formed in stone seawalls built less than a century ago.

Tafoni are abundant in the polar regions of Victoria Land, Antarctica, but they also occur in deserts of Australia, Africa, central Asia, and South America as well as in such humid regions as Hong Kong and the island of Aruba, West Indies. In North America, tafoni occurs in such diverse areas as the deserts of New Mexico, Utah, Arizona, and the coast of Washington state (Figure T1), and at mid-continent locations in Wisconsin and Illinois (Bryan, 1928; Blackwelder, 1929; Mustoe, 1982).

Tafoni are commonly found in outcrops having a hardened surface layer caused by precipitation of iron hydroxides or other compounds derived during weathering of the interior rock. The cementing action of these oxides produces a resistant rind. Any form of erosion that attacks the outcrop in a localized fashion will produce cavities, since penetration of the protective layer leads to rapid destruction of the weaker interior rock. Differential attack of the surface might result from variations in lithology, the presence of fissures or zones of high porosity that allow water to penetrate, or localized attack by organisms such as lichens. Because the formation of the protective ring requires moisture, this explanation is consistent with the observation that tafone seldom occurs in extremely dry environments, being more common along the margins of deserts than in the arid central regions. In many locations, tafoni occur mainly as coastal features presumably owing to the existence of a favorable microclimate, since even in extremely arid regions sea winds may cause the coastline to be relatively humid. The existence of a protective rind is most favored by an environment where some moisture is present but where periods of dryness allow evaporation to occur at the rock surface.

Tafoni typically form as a result of salt weathering, where evaporation of saline water triggers physical and chemical attack of the rock surface (Evans, 1970; Young, 1987; Rodriguez-Navarro and Doehne, 1999). In general, the distribution of tafone throughout the world correlates well with environments where salt crystallization occurs. In arid zones, salt weathering is concentrated where moisture is retained along the base of cliffs and undersides of boulders, where shadow weathering (tafone) may often be found. Along the coast, cavities are presumed to form by salt crystallization as wave-splash evaporates. Because salt weathering may attack in a relatively selective fashion, being controlled by variations in moisture or exposure to salt spray, tafoni might be formed even on outcrops where a hardened surface layer is absent, though the development of cavities would be enhanced when such a rind is present. Early explanations of tafoni invoking erosion by wind

action, temperature fluctuation, or frost wedging have largely been abandoned owing to lack of substantiating evidence.

TECTONICS AND NEOTECTONICS

Introduction

Rock deformation caused by the structure of the earth (e.g., folds, faults, joints, cleavage) is often the only kind of tectonic deformation considered by geological manuals, giving the impression that areas devoid of such type of deformation are "tectonically stable." However, according to the American Geological Institute (1960), "tectonic" is defined as "designating the rock structure and external forms resulting from the deformation of the earth crust." This definition implies that all processes which modify the external form of the crust, also when they result from forces external to the earth, have to be considered tectonic. This is the case, for example, for unidirectional vertical movements produced by earth surface processes of weathering and erosion (sedimento-isostasy), and also for rise and fall of the solid earth surface, especially in coastal areas, caused by external factors such as climate change (glacio-isostasy, hydro-isostasy) or eventually, at a smaller timescale, by the attraction of the sun and the moon (earth tides).

The term "neotectonics," ignored by most geological dictionaries or glossaries, was introduced by geodesists, geophysicists, and quaternarists during the last decades and defined in 1978 by the Board of the Neotectonic Commission of the International Association for Quaternary Research (INQUA) as "any active earth movement or deformation of the geodetic reference level, their mechanisms, their geological background (how old it ever may be), their implication for various practical purposes and their future extrapolation." This definition shows care not to isolate crustal movements from their geodynamic inheritance. Therefore, neotectonics has a wider scope than "active tectonics" (Wallace, 1986), which is defined as "tectonic movements that are expected to occur within a future time span of concern to society" and no real boundary back in time. It includes all timescales of movements, from instantaneous (seismic), 10–10^2 yr (geodetic), 10^2–10^4 yr (Holocene studies), 10^4–10^6 yr (Pleistocene studies), up to about 10^7 yr, if it is necessary to enable us to understand the origins of recorded movements (Mörner, 1980). The difference between former tectonics and neotectonics is therefore not far from that existing between an extinct fossil and a still living organism. Among the distinctive attributes of neotectonic studies listed by Stewart and Hancock (1994) are: (1) A wide range of methodologies and a variety of experts are commonly involved in a comprehensive study of the neotectonic history of a region, whereas paleotectonic structures are often investigated by structural geologists working on their own. (2) The neotectonician has the ability to compare inferences drawn from field observations with geophysical and geodetic data about rates and mechanisms of present-day processes. (3) Neotectonic displacement histories can be established with greater precision than paleotectonic ones, because Quaternary dating techniques allow relatively short time intervals to be detected. However, the approach by Stewart and Hancock (1994) mainly refers to active fault ruptures which are indeed privileged indicators of neotectonic displacements, but remains limited to boundaries of deformed crustal blocks, which may also remain obscured, without reaching the earth surface, or become obliterated by recent erosion or sedimentation processes.

In the following, various possible processes of tectonic/ neotectonic deformation in coastal areas are briefly reviewed, with special attention to vertical displacements which may be related to sea level. Significant examples of tectonic displacements are provided and rates of vertical movements are assessed. Some developments are partly inspired from ideas already discussed by Pirazzoli (1995).

Present-day and fossil coasts

The coastal outline has undergone major changes during the earth history. Some 300 Myr ago, when all continents are believed to have formed a single, huge landmass, Pangea, marine coasts could only exist along the perimeter of such a landmass. This supercontinent started to split apart about 200 Myr ago, first into two parts, Laurasia at the north and Gondwana near the South Pole, separated by a sea, Tethys. Subsequently Laurasia split out into North America, Europe, and North Asia, whereas Gondwana fragmentated into South America, Africa, Arabia, Madagascar, India, Australia, New Zealand, and Antarctica. Lastly, a slow drift has brought the various continents or continental fragments to their present state.

The reconstruction of the positions of the continents during the splitting or at the time of their coming together, during their migration, as well as the mechanisms of plate tectonics, make possible a comprehensive view of present-day and fossil coastal areas, with some marks of the latter now perched also near the top of mountain chains.

When the separation of two continents had been caused by the opening of a rift, continental margins are usually characterized by a low seismicity and a weak orogeny; in these structurally passive continental margins, which are devoid of an oceanic trench, the continental and the oceanic crust, which belong to the same plate, are joined. Such margins are frequent around the Atlantic Ocean and characterized by a well-developed continental shelf and a relative structural-tectonic stability (though they may be affected by important vertical deformation of isostatic origin).

On the other hand, where subduction processes occur, tectonics of continental margins are structurally active and show high seismicity and relief. Such margins, typical of Pacific coasts, correspond to areas where an oceanic plate is underthrusting beneath a continental plate. The continental shelf if present is very narrow, or even absent. Coastal California corresponds to a variant, with a sliding motion between the Pacific oceanic plate and the continental North-American plate along the San Andreas Fault.

In accretion zones, two continental plates are colliding. These active continental margins with strong seismicity and orogeny are generally located inside continents, far away from present-day coasts. However, at the first stages of collision, wide marine and coastal areas can be affected. This is the case in the present time of the Mediterranean region. Lastly, the coasts of epicontinental seas (bordering oceanic depths) form a special case, because the greater part of these shallow seas extending above continental shelves usually disappear during low sea-level periods and are therefore affected by significant hydro-isostatic vertical deformation.

Processes

Thermo-isostatic and volcano-isostatic tectonics

It is now generally accepted that plate tectonics modify, slowly but continuously, the shape of the oceanic basins. The rock of oceanic plates is formed by lava extrusions along oceanic ridges. After its formation, the oceanic crust moves slowly away and crosses the ocean, to be later destroyed in a subduction trench. When the crust spreads away from the ridges, it cools and thickens, thereby increasing in density. As a result the seafloor subsides isostatically, gradually submerging oceanic islands as they are carried laterally. Over several million years, thermo-isostatic subsidence will be on the order of kilometers. This can be verified easily in any world atlas, where the ocean depth is shown to increase gradually from 2,000–3,000 m above submarine ridges to 5,000–6,000 m or more above oceanic trenches. In tropical waters, the rate of thermo-isostatic subsidence is increased by the load of coral reefs, which have to grow vertically to maintain their sea-level position. The normal vertical evolution of an oceanic island in intraplate areas, when eustatic fluctuations of sea level are disregarded, would therefore be a gradual submergence, accompanied by relatively rapid erosion of exposed rocks by subaerial weathering and wave action. The existence of such general oceanic subsidence was first observed by Darwin, who used it to explain the different types of coral reefs by evolution from fringing reefs, to barrier reefs, and to atolls. Darwin did not know what the cause of subsidence was, but his theory was correct. We know today that oceanic intraplate subsidence is due to thermo-isostasy.

If an intraplate oceanic island is not subsiding, it is anomalous and requires explanation. Two main kinds of anomalies have been recognized: thermal rejuvenation and volcano-isostasy.

When the oceanic crust approaches a hot spot, which normally corresponds to an asthenospheric bump above a more or less fixed mantle melting anomaly, the normal cooling process is reversed, so that the crust is heated, becomes less dense and thinner, and thus rises (thermal rejuvenation process). Moving away from the hot spot area, cooling and subsidence predominate again.

Near hot spots, lava eruptions often occur. Their load produces on the lithosphere an isostatic depression under the volcanic mass and a peripheral raised rim at some distance (volcano-isostasy). According to empirical observations made around oceanic islands, the radius of the depressed area is generally less than 150 km from the load barycenter, whereas the peripheral rim develops at a distance of between some 150 and 300 or 330 km. When the translation movement of an oceanic plate over a hot spot has produced a line of islands, and two or more thermal rejuvenation spots form an alignment in the direction of plate movement, interaction between isostatically depressed areas and uplifted rims of nearby islands is possible and may produce complicated sequences of vertical deformation, with repeated phases of uplift and sinking.

Example of Quaternary thermo-isostatic uplift: Rurutu Island (South Pacific). Rurutu (22°30′S–151°20′W) is a basaltic island of the Austral–Cook island chain, approximately halfway between the hot spot near the active undersea Mac Donald volcano and the northernmost atoll of the Cook Islands (Palmerston). The volcanic basement of Rurutu has been dated 10.5 ± 2 Ma, whereas the age of the surrounding seafloor lies in the range of 40–90 Ma. The age of the volcanic basement of Rurutu is therefore consistent with the migration rate (10–11 cm/yr) of the Austral–Cook lithosphere with respect to the hot spot reference frame and the distance of about 1,350 km from Mac Donald. There is, however, a second hot spot along the Austral–Cook island chain, which generated some Cook Islands (Mauke, Atiu, Aitutaki) during the last 10 Myr. This second hot spot or plume is located near the present position of Rurutu (Dickinson, 1998). During the Quaternary, Rurutu entered the uplifting side of the hot spot swell. No new lava extrusion seems to have occurred, but gradual uplift took place, so that today the volcanic basement of Rurutu is surrounded by raised limestone tabular blocks, dated less than 1.85 Ma, reaching about 100 m in altitude. The limestone blocks finish in high vertical cliffs facing the ocean. Variations in the water table associated with Quaternary sea-level changes superimposed on gradual uplift have provoked karstic dissolution in the limestone at several levels (Figure T2). Dated remnants of the Last Interglacial coastline are now at +8–10 m in elevation; marks of Holocene sea stands have been identified at +1.7, +1.2, and +0.6 m (Pirazzoli and Salvat, 1992). The available evidence indicates that thermo-isostatic deformation has uplifted Rurutu Island at the average rate of 0.05–0.10 mm/yr since the early Pleistocene and at about 0.17 mm/yr in the Holocene.

Example of historical rapid thermo-isostatic deformation: "Temple of Serapis," Pozzuoli (Italy). This site demonstrates repeated rapid up and down displacements in the Phlegraean Fields caldera, near Naples. Burrows of *Lithophaga* mollusca in the three columns still left standing of the "Temple" (a Roman market probably built in the 2nd century BC near the Pozzuoli Harbor), clearly show that the ruins had subsided under sea level and then been gradually uplifted (Figure T3). Geomorphological, archaeological, historical, and radiometric data suggest a complex relative sea-level history. After the "Temple" was constructed, a subsidence of about 12 m took place. Elevated marine fossils indicate two submersion peaks, between the 5th and the 7th century AD, then again in the 13th to 14th century AD (Morhange *et al.*, 1999). An uplift of about 7 m followed, culminating in the Monte Nuovo volcanic eruption in AD 1538, and further subsidence. More recently, tide-gauge data from the Pozzuoli Harbor show two brief periods (1970–73 and 1982–84) of rapid uplift reaching a total of 3.2 m

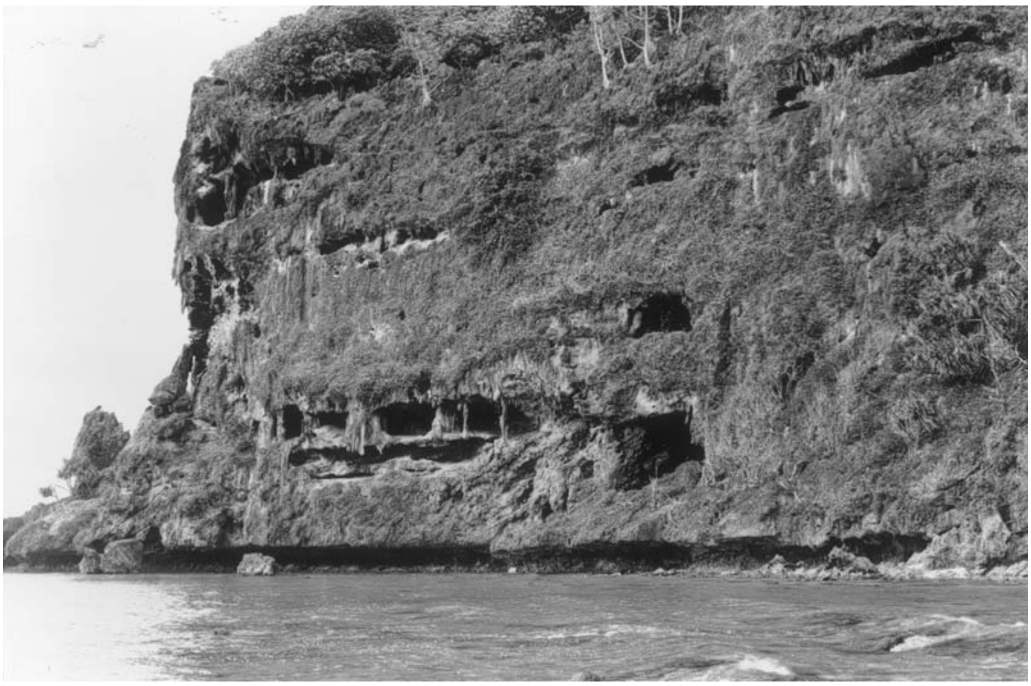

Figure T2 The outer limestone cliff of Rurutu (Austral Islands, South Pacific) appears cut by networks of caves at several levels, remnants of karstic drainage corresponding to higher relative sea-level positions. The lowest line of caves, with the floor at +8–10 m, contains marine material which has been dated from the Last Interglacial. The cliff is also undercut by a slightly elevated deep notch dating from the Late Holocene (Photo 5743, April 1980).

Figure T3 The "Temple of Serapis" in Pozzuoli (Italy). Note the dark band on the columns produced by molluscan borings (the upper limit of which is slightly less than 6 m above the paving of the "Temple," which is partly flooded by a few centimeters of water) (Photo D388, October 1991). The same floor appears more submerged in photos taken in 1982–83 (Vita-Finzi, 1986, p. 10).

between 1968 and 1984, followed by slight renewed subsidence, still going on. Such vertical movements are understood as being of thermo-isostatic origin, with uplift corresponding to rock expansion under the action of heat beneath the caldera, and subsidence to contraction on cooling.

Vertical tectonic deformation near plate boundaries

When oceanic crust approaches the end of its travel, near a trench or a continental margin, the arrival of its mass in a subduction or a collision zone produces high seismicity and vertical tectonic movements become more complex.

In a subduction zone, the underthrusting side, which will be destroyed by plunging into the earth mantle, has a relatively simple tectonic behavior, differing notably from that of the overthrusting side. Before being submerged, the oceanic plate is generally subjected to arching phenomena, in order to make possible the change from a horizontal translation to a plunging beneath the overriding plate. This arching implies a wave-like flexuring of the lithosphere, with first a gradual uplift, as in the case of an oceanic island approaching a hot spot, than a gradual subsidence at accelerating rates. Case studies of such arching phenomena have been reported from Christmas Island, 200 km southwest of the Sunda Trench, from the Daito (Borodino) Islands, 150 km east of the Ryukyu Trench, and from the Loyalty Islands, at varying distances west of the New Hebrides Trench.

On the overthrusting side, various local or regional structural geodynamic factors may be superimposed. Here uplift is frequent and may be caused by: (1) piling up above the oceanic plate, on the inner side of the trench, of sediments too light to be subducted, which will raise the overthrusting edge isostatically; (2) elastic rebound phenomena linked to subduction faulting; (3) tilting of lithosphere blocks or other structural tectonic processes; and (4) volcanic activities. Subsidence in structural basins may also be significant.

Where subduction processes are prevented by the occurrence of a transform fault or by continental lithosphere on both sides of a plate boundary, collision or transform processes will occur with vertical movements which can become highly irregular. The best-known example of a transform fault crossing a coastal area is probably that of the San Andreas Fault, which extends south to north over a distance of about 1,300 km between the Gulf of California and the Mendocino Fracture Zone. South of the Mendocino triple junction, strike slip predominates along a broad and braided system of faults with a roughly northwesterly strike; blocks between faults are warped, folded, uplifted, depressed, and rotated. Farther northwestwards, vertical movements predominate (Crowell, 1986). In several areas along the San Andreas Fault evidence of uplift is missing, however, and aseismic uplift has also been reported from southern California.

The superimposed effects of long-term gradual uplift and of eustatic sea-level fluctuations often produce sequences of stepped marine terraces.

Example of stepped marine terraces in the Santa Cruz area, California. Six marine terraces, in which raised shell beds were first described by Darwin, indent a 60 km stretch of coastal topography. These terraces seem to have been raised by repeated slip earthquakes on the San Andreas Fault, with a return time of three to six centuries, uplifting the terraces at average rates between 0.13 and 0.35 mm/yr (Lajoie, 1986; Valensise and Ward, 1991).

Seismic displacements

In many seismic areas, vertical displacements of land may appear gradual in the long term, but in the short term they can consist of sudden vertical movements, separated by more or less long periods of quiescence or of gradual movement (Figure T4). The sudden movements usually take place at the time of great-magnitude earthquakes, which are often accompanied by surface faulting or folding and ground deformation. Land displacements occurring spasmodically at the time of an earthquake are called *coseismic*. Gradual displacements, often in opposition to the coseismic ones, may occur during the few years or decades preceding (*preseismic*) or following (*postseismic*) the coseismic event. The duration of the time interval between two coseismic events (*interseismic* period) is not perfectly regular and depends on the variability of the local tectonic stress accumulation. It may tend, however, to be repetitive statistically, with a return time which can vary, according to the seismotectonic area considered, from a few centuries to over ten thousand years. In coastal seismic areas, investigation and dating of former shorelines different from the present ones may be used to determine the age, distribution, and succession of vertical displacements. Of special interest for seismic prediction is the identification of the preseismic movements which may indicate the imminence of a great-magnitude earthquake.

Certain coseismic movements can be impressive. In Crete (Greece), a jerk of coseismic uplift raised the southwestern most part of the island as much as 9 m, probably on July 21, AD 365 (Pirazzoli *et al*., 1996); in

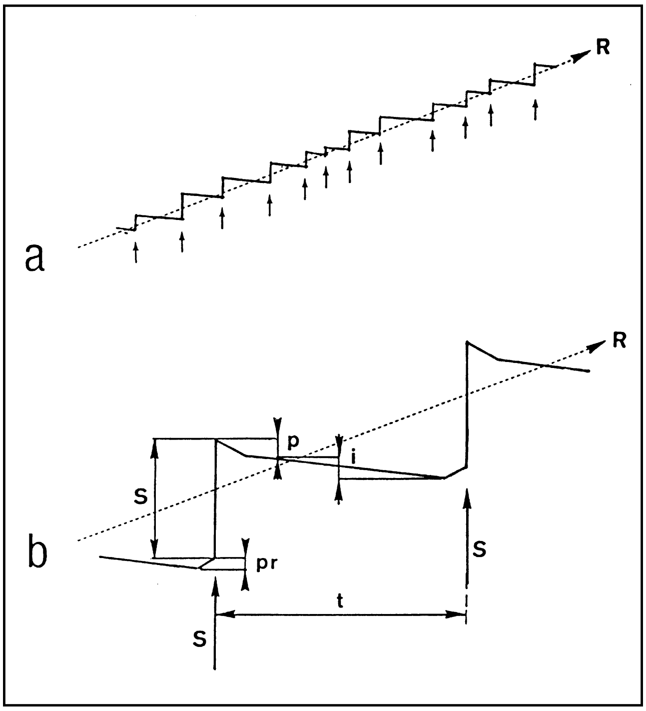

Figure T4 In uplifting seismic regions, the raising trend, though apparently gradual over the long term, may consist in the short term of sudden uplifting movements accompanying great earthquakes, separated by more or less long periods of seismic quiescence and gradual subsidence. pr, preseismic; S, coseismic; p, postseismic; i, interseismic; t, return period.

Alaska, the great earthquake of March 27, 1964 (magnitude ≥8.4) was accompanied by uplift reaching 10 m on land in Montague Island and more than 15 m offshore (Plafker, 1965).

Example of repeated Holocene coseismic deformation: Hatay (Turkey). On the Hatay coasts, clear evidence of uplifted Quaternary coastlines near the Orontes Delta have been recognized up to at least 140 m in elevation. The lower evidence, between 35 and 8 m above present sea level, consists of stepped, elevated, deltaic sedimentary surfaces, suggesting that the Orontes River has built here intermittent delta formations since at least the late mid-Pleistocene. Detailed study of late Holocene marine notches (Figure T5) and bioconstructed rims made of vermetids, oysters, and calcareous algae, have demonstrated that uplift has been episodic rather than gradual (Pirazzoli *et al.*, 1992). Two rapid land movements, probably of seismic origin, have been identified. The first movement, which occurred about 2,500 ± 100 years BP, was the strongest one and caused a local vertical displacement of about 1.7 m. The second movement (an uplift of 0.7–0.8 m) occurred around 1,400 years BP, probably at the time of the great earthquake followed by tsunami waves of May AD 526, which caused devastating damage in Antioch and prevented further use of its harbor Seleucia Pieria. The long-term trend of uplift in this coastal area can be ascribed to episodic reactivation of local fault lines, probably in connection with movements on the East Anatolian Fault system.

Glacio-isostatic and hydro-isostatic neotectonics

Transfers of ice or water masses between ice sheets and the ocean produce load displacements and therefore isostatic phenomena. The load of an ice sheet deforms the earth's crust. The resulting subsidence beneath the ice makes deeper material flow away, and raises an uplifted rim at a certain distance. When the ice sheet melts, an unloading occurs, resulting in uplift beneath the melted ice; the marginal rim will consequently tend to subside and move towards the center of the vanishing load. Part of these glacio- isostatic movements are elastic, and thus contemporaneous with loading and unloading. Due to the viscosity of the earth material, however, part of the movement will continue for several thousand years after the loading or unloading has stopped. Although most of the ice in Canada and Fennoscandia had disappeared between about 8,000 and

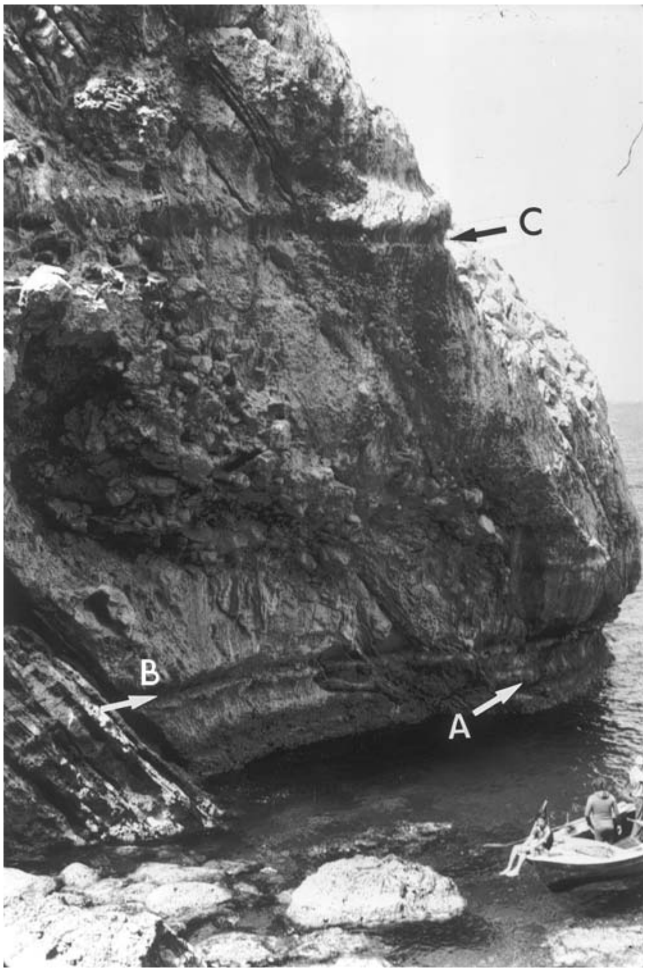

Figure T5 Two continuous notches cut into the limestone cliff at about (A) +0.7 m and (B) +2.0 m, mark the sea-level positions before two coseismic uplift movements which occurred some 1,500 and 2,500 years ago. (C) A similar undated notch at +12.3 m, may correspond to a Late-Pleistocene shoreline. South of the Orontes Delta, near the Turkish–Syrian boundary (Photo A739, May 1988).

6,000 years BP, large vertical movements of uplift and subsidence continue in these areas today.

It was during the second half of the 19th century, when the postglacial coastal record in Fennoscandia became accurate enough to yield a persuasive description of dome-like uplift, that the concept of glacioisostasy could be asserted by De Geer, as had been done at about the same time for Lake Bonneville, in the United States, by Gilbert. During deglaciation, meltwater from ice sheets produces a considerable load on the ocean floor (on the order of 100 t/m^2 for a sea-level rise of 100 m), so that the sea bottom subsides (hydro-isostasy). In the upper part of gently sloping continental shelves, or in shallow seas where the postglacial water depth is less than the global change in sea level, the meltwater load will vary according to the local topography and bathymetry, generally increasing gradually towards the open sea. In this case, the hydro-isostatic constraints will produce a lithospheric flexure with a typical seaward tilting.

Small islands which rise steeply from the deep ocean floor are often considered as potentially good place to measure eustatic changes because, as discussed by Bloom (1971, p. 371) they "will be warped downward by the water load around them, but because the entire deep ocean floor is depressed, the volume of the ocean basin increases and sea level with reference to an island, or to a hypothetical buoy moored in deep water, should not change because of the isostatic deformation." In equatorial and tropical regions remote from the ice sheets, hydroisostatic subsidence may be partly compensated by "equatorial ocean siphoning" (Mitrovica and Peltier, 1991). This mechanism, driven by the subsidence of those portions of the glacial forebulges which exist over oceanic regions, acts to draw water away from most equatorial and tropical regions, in order that the oceans maintain hydrostatic equilibrium, making some emergence possible. For this reason, slight Holocene emergence is frequent in tropical oceanic islands. This is the case, for example, for most Pacific atolls (Figure T6) in spite of their long-term trend towards thermo-isostatic subsidence.

Some geophysical models, based on the mathematical analysis of the deformation of a viscoelastic earth produced by surface loads, have been developed during the last two decades. They have been able to mimic, with an accuracy on the order of a few meters, sea-level changes reported from the field in various areas. These models, which assume a simplified earth structure and a melting history for all the continental ice loads which existed at the time of the last glacial maximum, have demonstrated that the rate, direction, and magnitude of crustal movements must have varied from place to place and, therefore, that no region can be considered as tectonically stable. Though they cannot replace field observation, these models have also been useful in providing a first-order approximation of the deglacial and postglacial sea-level history in areas where no field data are available.

Sediment-isostatic neotectonics

Weathering and gravitational forces cause continuous transfers of sediments in a one-way direction, from the continents to the oceans. This implies isostatic adjustments, with predominant uplift on the continents and subsidence in nearshore basins affected by rapid sedimentation. At the mouth of great rivers, when the rate of fluvial input overtakes the rate of sea-level change, deltaic sequences may tend to accumulate, especially on microtidal coasts. Recent sediment accumulation is affected by compaction, which produces subsidence, but is also expected to form on the lithosphere surface an isostatic depression under the load and a marginal rim slightly rising at some distance. However, remaining in an area where general subsidence predominates, such rims may only appear as an area of lesser sinking. Lateral displacement of major delta branches have often occurred during the late Holocene; they imply, after some time, also a migration if their isostatic peripheral bulge.

The purely isostatic component is generally difficult to estimate, because observed rates of lowering include also sediment compaction, possible faulting, and for the past millennium also anthropogenic influences, such as conversion of wetlands to agricultural fields, river channelization, pumping, and withdrawal of water and diversion of water flow for irrigation. What can be measured is only the total amount of vertical displacement that has occurred during the Holocene delta formation, that is, since the postglacial sea-level rise began to decelerate, generally from about 8,000 to 6,500 years BP (Stanley and Warne, 1994). This vertical displacement varies locally, usually reaching a maximum on the outer delta plain close to the present coast.

Figure T6 Late-Holocene *scleractinian* corals have been left emerged in growth position, at the top of a pinnacle in the lagoon of Takapoto Atoll (Tuamotus), by a slight fall in the relative sealevel of probable hydro-isostatic origin (Pirazzoli and Montaggioni, 1988) (Photo 5478, March 1980).

Structural faulting and folding

Faults (and folds, which can develop ahead of blind faults propagating from depth towards the surface) are generally the main object of study for most structural tectonicians. In coastal areas, however, at least for vertical displacements, the most important neotectonic indicator is sea level. With high-tide shoreline marks, sea level leaves evidence of an altimetric datum all along the coast. An active fault may cross a rocky coast, leaving recognizable displaced high-tide shorelines on both sides (Figure T7). Such an occurrence is precious, because it may enable one to measure very precisely the vertical displacement between the footwall and the hanging wall of the fault, that is, the maximum amount of displacement when we are dealing with a tilted crustal block. In even more favorable cases former high-tide shorelines may be preserved, at least over a certain distance, at various levels on the fault plane; it will then be sufficient to map them along the coast to reconstruct tilting patterns and, if the high-tide shorelines can be dated, vertical displacement rates. Some caution is necessary, however; high coastal cliffs which are abnormally straight or gently curved are commonly suspected of being fault scarps. When uplifted evidence of former high-tide shorelines is missing from the cliff, the footwall of the fault may be underwater, concealed by sediments, or eroded, and this makes estimations of vertical movements hypothetical. But straight high cliffs may also result from differential erosion having removed a weaker seaward rock formation, without any tectonic implication. Many mappable faults may also have been formed by geologically ancient deformations, under tectonic regimes and stress situations long abandoned.

In most cases, active faults do not cut the coastline, but remain at a certain distance from it, on land or offshore; marks of uplift or subsidence indicated by former high-tide shorelines are therefore likely to indicate a lesser vertical displacement than at the fault scarp and a more complete survey is necessary before interpreting the vertical displacement observed.

Example of a paleotectonic coastal scarp: northernmost Chile. Between Arica and Iquique, except locally, an exceptionally high cliff directly drops into the sea, and is still retreating under wave action. In the surroundings of the Cerro Punta Madrid (18°57′S, 70°18′W) it reaches a height of about 1,000 m. This cliff derives from a large system of north–south oriented, *en échelons*, normal faults which formed at the end of the Oligocene epoch and whose scarps retreated under marine erosion during a Middle to Upper Miocene transgression. South of Iquique, the scarp is an abandoned cliff no longer receding under wave action; at its foot lies a shore platform, sometimes wider than 1 km, which has been uplifted to 50 m above present sea level (Paskoff, 1996).

Example of a neotectonic coastal scarp: southwestern Calabria (Italy). Calabria has been affected by strong uplift movements during the Quaternary. At least 12 Pleistocene levels of marine terraces have been identified, reaching as much as 1,350 m in altitude. Near Reggio Calabria, Last Interglacial marine deposits with the guide fossil *Strombus bubonius* at 157 m suggest that the average uplift rate exceeded 1 mm/yr during the last 125 ka. Near Palmi, the steepness of the coastal relief (Figure T8) and the narrowness (only a few hundred meters) of the continental shelf can be ascribed to active faulting, which is leaving abrupt scarps on the gneissic rock formations.

Example of neotectonic coastal folding. Along the southernmost coast of Taiwan (Hengchung Peninsula), the inner edge of the mid-Holocene

Figure T7 The surface of Late Pleistocene raised marine terraces has been displaced by a recent fault near Kupang, West Timor, Indonesia (photo B266, August 1988).

Figure T8 The active fault scarp near Palmi (Calabria, Italy) (photo E722, April 1996).

marine terrace is 10–15 m high, but its elevation gradually increases westwards, deformed by undulation movements. Its altitude ranges from 5 to 36 m along a distance of less than 10 km (Liew and Lin, 1987).

Rates of vertical neotectonic movements

Because of the various potential tectonic processes, rates of vertical movements in coastal areas have varied much in space and time.

Over the long term (10^6–10^5 yr), structural tectonics is indeed the predominant factor, with rates reaching several millimeters per year reported from tectonically very active areas such as near Ventura, California, where Pleistocene marine terraces have been uplifted at average rates exceeding 8 mm/yr (Lajoie, 1986), with even much higher rates reported from the land interior (about 10–15 mm/yr estimated for the crest of the Ventura anticline during the last few hundred thousand years (Wallace, 1986, p. 7)). At Huon Peninsula, Papua New Guinea, uplift of up to 3 mm/yr during the last 124 ka has been demonstrated by Chappell (1974). Evidence of well-preserved Quaternary shorelines is, however, rare in areas of rapid uplift, because strong erosion rates most often effaced most ancient marine marks. At the same timescale, volcano-isostatic factors can be estimated to have been on the order of a few millimeters per year for subsidence and one order of magnitude less for arching uplift; thermo-isostatic vertical displacement rates usually remain limited to the order of a fraction of millimeters per year: average subsidence rates have been estimated at 0.2 mm/yr during the last 60 Myr in the Marshall Islands and 0.12 mm/yr since the Pliocene in Mururoa Atoll (Tuamotus). Glacio- and hydro-isostatic factors cannot be assessed at the timescale of 10^6–10^5 yr.

During the last 20 kyr, the most important vertical displacements have been of glacio-isostatic origin; near the center of the former Fennnoscandian ice sheet, uplift since the last glacial maximum has been estimated at about 800–850 m, that is, at 40–42 mm/yr on average (Mörner, 1979); since the beginning of the Holocene, uplift has been about 284 m, that is, 28 mm/yr on average, decreasing exponentially from over 50 mm/yr at that time to about 9 mm/yr at the present time (Pirazzoli, 1991). Residual present-day uplift is therefore almost 1 m/century. In Canada, with a marine limit close to 300 m in elevation near the eastern part of Hudson Bay (Andrews, 1989) maximum uplift values are probably of the same order as in Fennoscandia.

Hydro-isostatic displacements are also significant over the timescale of 10^4 yr. They can be estimated on the order of about one-third of the sea-level change, that is, some 40 m in deep-sea areas for an eustatic change of 120 m (i.e., 2 mm/yr on average since the last glacial maximum) and less in shallow coastal areas.

At the timescale of 10^4 yr, structurally tectonic displacements can be in some cases on the same order as glacio-isostatic ones: on the east coast of Taiwan, marine evidence suggests an average uplift rate of about 8 mm/yr since 14 kyr ago near Tulan (Pirazzoli *et al.*, 1993) as well as since 4,000–3,000 kyr ago near Hualien (Konishi *et al.*, 1968) (Figure T9). Because the amount of glacio- and hydro-isostatic displacements has been decreasing exponentially with time after complete melting of the

Figure T9 *In situ* coral reefs about 3 kyr old, uplifted up to 25 m above sea level, are visible (arrows) above a cliff at Hualien, east coast of Taiwan (photo B805, January 1990).

ice caps, movements of structurally tectonic origin have become predominant and easily recognizable in several areas during the last few thousand years. Very rapid rates of vertical displacement of thermo-isostatic origin can be reached in volcanic areas during relatively short periods. The most spectacular example is probably Iwo (Sulphur) Island, a volcano situated 1,200 km south of Tokyo, where over 20 steps of marine terraces occupying nearly the whole area of the island (used as military airstrips by the Japanese during the last world war) have been recognized up to 120 m above sea level. The average uplift rate was here of more than 100 mm/yr over the last several centuries, reaching 200 mm/yr in some parts of the island (Kaizuka, 1992). In the case of the Pozzuoli area mentioned above, average vertical displacement rates have reached even faster peaks, such as the uplift rate of up to 800 mm/yr recorded between 1968 and 1984.

Rates of subsidence in delta areas induced by sediment compaction and sedimento-isostasy is often significant over the long term. At the shelf edge of the eastern Mississippi delta, for example, the long-term averaged subsidence rate since the last glacial period has been estimated to at least 1 mm/yr (Stanley *et al.*, 1996). For the four largest modern depocenters in the Mediterranean, long-term mean lowering rates have been reported of 4–5 mm/yr from the Ebro Delta, >7 mm/yr at the mouth of the Grand Rhône Delta, possibly from 1 to 3 mm/yr from the Po Delta, and 4–5 mm/yr from the Nile Delta (Stanley, 1997). The best-known example of land subsidence produced by sediment compaction, accelerated by man-induced drainage during the last centuries, is indeed that of the Netherlands, where the soil level may be as low as 6 m below sea level. More recently, man-induced land subsidence following oil and natural gas extraction or groundwater exploitation has taken place during the last century in many coastal plains of estuarine, delta, or lagoonal areas: the greatest measured land subsidence (a maximum of 4.6 m) is probably that reported from the Tokyo Lowland region, where an area of about 70 km^2, supporting more than half a million inhabitants, is below mean sea level. Significant amounts of land subsidence have been reported also from the Po Delta (3.2 m), Houston-Galveston (3.0 m from 1906 to 1987), Shanghai (2.7 m), Tianjin (2.5 m), the southwestern part of Taiwan (2.4 m), Taipei (1.9 m), and Bangkok (1.6 m). In several big cities built in coastal plains of developing countries (Jakarta, Hanoi, Haiphong, Rangoon), where detailed measurements are lacking, the probable occurrence of land subsidence is revealed by increasing difficulties in drainage which produce more frequent flooding.

Among the many possible causes of coastal change and evolution, tectonics and neotectonics have been indeed major controlling factors, virtually at all timescales. For the present time, however, a new tectonic cause—man-induced land subsidence—is becoming significant in many densely populated or industrial coastal areas, with short-term impacts which may exceed those of all other natural causes occurring in the same area.

THALASSOSTATIC TERRACES

A term derived from Greek roots, the expression "Thalassostatic" obtains its prefix from "thalassic," having to do with the sea, and its suffix "static" referring to its equilibrium state. A fluvial terrace is said to be thalassostatic when it is the product of a former sea level that caused flood-stage sediment load to accumulate as an alluvial surface. Its seaward limit is usually determined by a beachridge or beachridge plain.

The actual term itself was coined by Zeuner (1945), who saw that an estuary created by downcutting during a Pleistocene low sea-level state would become aggraded during a following interglacial phase. Even earlier, Ramsay (1931) pointed out that alluvial terraces of this sort would provide clearer evidence of former eustatic levels than strictly marine terraces that are more liable to erosion or other factors. Clayton (in Fairbridge, 1968, p. 142) mentions the actualistic evidence of modern aggradation behind dams. This filling will extend only a short distancer upstream where the gradient is changed. Zeuner believed that gravel terraces of the lower Thames in England must be solifluction products of glacial-phase stream loading, thus having nothing to do with thalassostatic events.

In the classic work of de Lamothe (1918) on the Somme Valley in northern France, the concept of eustatic control was first presented, but erroneously extended to the entire fluvial terrace system. The Dutch worker, Brouwer (1956) considered the question of thalassostatic terraces in general and showed that only the lowest sectors were appropriately so-named. Earlier, Pleistocene examples would be largely obliterated by erosion.

In the world's major deltas like the Mississippi and the Rhine, a quasi-stable tectonic fulcrum develops, with subsidence on the seaward side, uplift on the landward side. Thus the fluvial terraces are stacked progressively lower and in stratigraphic sequence downstream. On the Mississippi the fulcrum area is above Baton Rouge, on the Rhine about at Nijmegen. However, the exact fulcrum point shifts up- or downstream depending upon the current eustatic level. A problem develops, however, with these large rivers in their propensity to major flood events, their discharge being greatly amplified by the large area and multiple sources of their drainage basins. Such events are likely to overtop levees in the deltaic regions. These so-called "avulsion" breaks are commonly matched by the drying out of other distributary channels, so that a rather complex stratigraphy develops (Törnquist, 1994; Berendsen, 1995). Nevertheless, a strongly cyclical pattern is discernible.

Where an extensive data source has been provided by detailed geophysical transects, as in the Mississippi delta, it can be seen that layers of Holocene transgressive facies are alternating with regressive events when channels deepen and their outlets shift seawards. In contrast, the transgressive intervals are marked by sandy chenier ridges (sand from longshore sources) that form distinctive markers in the otherwise muddy or peaty deltaic facies. Compaction of these water-saturated substrates leads to areas of accelerated subsidence, as shown by very variable tide-gauge evidence, that can be misleading for the delta as a whole, which has a very modest subsidence rate. With each transgression the thalassostatic terrace building shifts upstream, but with the renewed downcutting after avulsion an entirely new delta-lobe is likely to evolve (Lowrie and Hamiter, 1995).

A pioneering attempt to relate thalassostatic eustasy to the rivers of Borneo (Kalimantan) was made by Smit Sibinga (1953). A detailed glacial-age drainage network extends over much of the Sunda Shelf according to the submarine mapping by Molengraaff and referred to as the "Molengraaff River System" by Umbgrove (1947). With each successive eustatic rise thalassostatic terrace deposits must have lined these former waterways. The eustatic curve is not a sine-wave, however, but is a strongly fluctuating one, so that there are extended intervals of pause or reversal, during which there would have been accelerated thalassostatic sedimentation.

Best known and well dated of these interruptions was the Younger Dryas event which lasted approximately 1,000 yr, 11,740–10,740 cal. BP, with abrupt transitions, both at its commencement and terminations. Eustatic sea level at that time fell to about 30 m below present mean sea level. Its coastline is particularly well marked by the presence, in the warmer latitudes and along the more stable coasts, of an abrupt line of reefs or distinctive beach deposits. A wave-resistant beachrock facies is a distinctive marker where carbonate sands permit rapid lithification. In some sectors carbonate sands led to the development of littoral dunes, which also become rapidly lithified to form "eolianites." Today these eolianites form reefs that are well known to fishermen (e.g., "Twelve Fathom Reefs" of Western Australia).

Other sea-level fluctuations were marked in the deep ocean by the "Heinrich events" (at 3–7 kyr intervals) which mark iceberg distribution in the N.W. Atlantic. Heinrich events are marked by climatic extremes, both positive and negative, thus raising the chicken-and-egg problem. Analogous eustatic fluctuations are indicated by the thalassostatic data. Sudden warming of the water around Greenland, such as occurred in AD 1912, accelerates iceberg calving (with disastrous effect on RMS *Titanic*). In this case, however, it was not so much climatic, as tidal, because 1912 marked the largest lunisolar tidal extremes in over 500 years (Wood, 2001).

Thalassostatic terrace building (and its erosion) thus relates to movement of relative sea level (RSL). The bed of a river on reaching the sea is nicely adjusted to velocity and bed-load, which dictate the equilibrium water depth at the river mouth, subject to tidal characteristics and seasonal changes such as storminess and monsoonal shifts.

The equilibrium status may be modified by one or more of several processes: (a) Tectonic, which may be sudden as a result of an earthquake, such as the historic shifts in 1855 and 1931, of Wairapa (Wellington) or Napier in New Zealand or the subsidence of parts of Yokohama in Japan. It may also be secular as a result, for example, of glacioisostatic rebound such as observed today at Stockholm in Sweden (at 5 mm/yr) or at Great Whale River in Quebec (at 8 mm/yr). (b) Eustatic and/or climatic; these are related but partly independent, although not easily distinguished. When a dominant wind system changes, it affects also RSL as observed, for example, in the Hudson Bay, in the Gulf of California and in the eastern Gulf of Mexico, all being partly related to the 11 yr sunspot cycle and the 18.6 yr lunar cycle (Fairbridge, 1992). It is also observed on a 6-month basis in the Red Sea and Arabian Sea and Bay of Bengal, a consequence of the Asiatic monsoon reversal. Longer cycles, of the order of 45, 90, and more years are observed in the arctic and subarctic latitudes, relating in part to the polar anticyclone and the magnetic pole in its periodic shifts from the longitude of Greenland to that of eastern Siberia, and back again.

For whatever reason, a fall in RSL leads to a shallowing of the debouching river mouths. Two possibilities ensue. If the fluvial discharge is linked, as it usually is, to climate fluctuation, a decreased discharge coinciding with a shallowing of the stream beds, then the result will be a "siltation" of local harbors. Around the Mediterranean in Roman times (1st century AD) there was widespread siltation and as a result many Roman docks, harbor facilities, and fish tanks had to be re-engineered. Some harbors, as in Turkey and farther afield in India (entrance of the Narbada River) were abandoned altogether, or the city shifted somewhat downstream (Kayan, 1997).

The opposite condition is associated with a systematic rise in RSL. This occurred, for example, in the post-Carolingian (after Charlemagne) global warming that persisted until about AD 1300. River courses were backed up and deepened. Roman-era dock or defensive facilities were drowned. An example of the latter can be seen at Portchester in the south of England.

TIDAL CREEKS

Is a tidal creek an estuary? Stamp (1966) in his *Glossary of Geographical Terms* quotes the OED definition of creek as, "*a narrow recess or inlet in the coastline of the sea, or the tidal estuary of a river; an armlet of the sea which runs inland in a comparatively narrow channel ...* ." The *Dictionary of Geological Terms* published by the American Geological Institute (1976) defines a creek as, "*a small inlet, narrow bay, or arm of the sea, longer than it is wide, and narrower and extending farther into the land than a cove*."

Figure T10 Tidal creek in mangroves showing the narrow shallow channel and low hydrodynamic energy conditions.

Geomorphically, the essential characteristics of a tidal creek are that they are relatively long and narrow, are shallow, and exhibit tidal water level fluctuations and weak tidal currents. They are relatively small-scale landforms with a low hydrodynamic energy environment without significant wave action or strong current action (Figure T10). Typically along its banks the tidal creek is well vegetated. The friction from the banks and the length of the creek ensure that the tidal wave within the creek is hyposynchronous (reducing tidal range upstream). Such conditions facilitate sediment deposition, so tidal creeks exhibit active deposition and infilling over a time frame of decades. Tidal creeks may drain to the open coast of an enclosed coastal sea or bay, or may be part of a larger estuary or delta system. They also occur at the distal ends of arms of drowned river valley (ria) harbors where tidal creeks drain sectors of mangrove stands and/or salt marsh. In tropical areas, tidal creeks and distributaries create a dense network of small-scale drainage through the mangrove forests, while a similar reticulated plexus of creeks occurs in temperate salt marsh (Guilcher, 1958). Pethick (1984) notes that salt marsh creek systems have a very high ratio of total creek length to drainage area—on the order of 40 km/km^2. Tidal creeks also occur in sinuous meandering forms draining extensive intertidal mudflats. However, tidal creeks do not tend to occur draining to open coast high-energy sandy beaches.

Often the creeks extend as the headwaters of a large estuary into the surrounding drainage basin, and on occasion carry freshwater discharges and episodic floodwaters from surrounding catchments. Thus the tidal creeks are frequently the mixing zones of fresh and saline tidal water, and exhibit an enhanced vertical salinity structure due to the low-energy conditions. Accordingly, they are also favored zones for flocculation processes, so that deposition of muds is typical and ongoing within tidal creeks. Unfortunately, tidal creeks often tend to become a receptacle for human waste and rubbish, and are frequently reclaimed.

TIDAL DATUMS

Introduction

A sea-level datum is a surface constructible statistically from sea-level observations that is used as a reference for measuring and describing vertical positions near the earth's surface. At official intervals, the elevations of sea-level datums are revised to reestablish their relationship to a new mean water level. A multitude of sea-level datums are in use. Each has its own advantages and disadvantages with no universally superior choice. Preferences depend on location, purpose, and past practices. Focus here will be on tidal datums defined at different phases of the tide; for example, high water and low water (Figure T11). Discussion of tidal datums illustrates some of the uses, practices, and limitations common to the broader class of vertical datums.

Scope

Details in the operational definitions of tidal datums evolved as concepts matured, needs for precision increased, field methodologies improved, and new legal issues arose. In this discussion of broad tidal datum issues, operational details may be sacrificed to provide an overall understanding of the basics, at least as understood by a coastal morphologist limited in practice to North America. Specific details continue to evolve with advances in measurement technology and changing society needs. Prescriptions of such details are left to official documents.

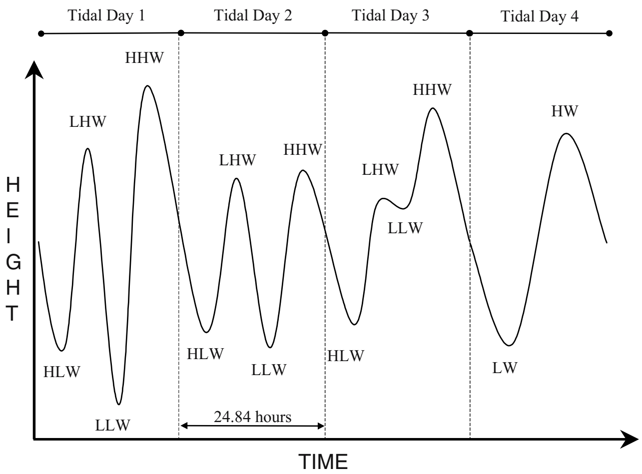

Figure T11 Tide phases labeled on a stylized tide curve. When two high-tide phases can be distinguished in the tide curve during a single tidal day (24.82 h), the higher of the two is called higher high water (HHW) and the other lower high water (LHW). When two low-tide phases are discernable in one day, the higher of the two lows is called higher low water (HLW) and the other lower low water (LLW). When only one high and one low-tide phase appear (e.g., Tidal Day 4), the high phase is called high water (HW) and the low is called low water. The record from sites that usually have only a single high and low per day will periodically transition in and out of multiple-cycles-per-day episodes that can have distinctly different phases like Tidal Day 2 or less distinct phases, more like Tidal Day 3 above.

Historical developments

The astronomical tide causes sea level to vary on daily, monthly, and longer cycles. These deterministic cycles are superimposed on more random water level fluctuations related primarily to weather. Normally, the reference point for repeated measurements should be stable, that is, anchored to the system containing the objects measured. What factors explain widespread adoption of a continually fluctuating water surface as a vertical reference? Early communities developed at sea ports where knowledge of the water depths in navigable channels was vital for the economy and defense. Soil productivity [EBH1] was another fundamental concern related to height above water because of altitudinal climate gradients if not more directly through frequencies of flooding. Referencing elevations to water levels was, therefore, of keen interest to early civilizations. Sea level also provided a common reference elevation applicable widely throughout the world. It could be reestablished with little loss of accuracy near coasts and without the need for long-distance surveys or recover of any destructible marker (e.g., benchmark). Fluctuations of the sea surface (and hence the zero reference) were probably small relative to the precision required to make decisions, especially for civilizations developing around the Mediterranean Sea where the range of tidal fluctuations is small compared with a typical range in the ocean. As coastal property ownership disputes increased, navigation clearances tightened, and tidal fluctuations became recognized (though not yet understood), comparison of elevations with respect to different sets of sea- level observations became more problematic. Later recognition of a broad spectrum of sea-level changes required further adjustments to allow tidal datums to persist as widely used references. Continuing advantages of referencing to sea level, instead of a fixed datum, include: conveniences related to historical precedence, natural differences in human use of property above and below sea level, lateral continuity (at least along coasts), apparent simplicity, lack of geographic bias in definition, and the greater relevance of mean water levels over any truly level surface for most hydrologic and navigation considerations.

Because concerns of navigation and coastal engineering are closely tied to sea level, the reference point in these fields should change with long-term changes in mean sea level. For endeavors in which sea level is irrelevant, a stable nontidal datum may be preferable. For this reason, and to better understand tidal datums themselves, some discussion of nontidal datums is included.

The name of the organization having responsibility for official datum and charting standards within the United States changed with time from the Survey of the Coast, to the Coast Survey, Coast and Geodetic Survey, National Ocean Survey and, now, the National Ocean Service (NOS). The NOS's authoritative references on present and historic coastal boundary determinations are Reed (2000) and Shalowitz (1962, 1964). Kraus and Rosati (1997) summarize procedures for determining shoreline positions for coastal engineering. Prescription for US Army Corps of Engineer surveys of waterways and additional guidance on tidal datums can be found in USACE (2002). All five references can be found on the World Wide Web (www).

Methods of tidal datum determination

Statistically averaging sea-level measurements is the process by which an unsteady surface is fixed to serve as an unambiguous and repeatable datum. There are a number of ways to average sea level, giving rise to a number of different tidal datums. For an unambiguous datum definition, the frequency of the measurements and the time span over which they are to be averaged must be specified. For any tidal datum, the manner of relating the measurements to a clearly defined tidal phase (Figure T11) must also be specified. Breakdown in any one of these fundamental requirements, causes problems as we shall see.

Astronomical cycles and the tidal response

Astronomical tides are the sea's response to gravitational forces of the moon and sun (and to a lesser extent other celestial bodies) that vary over the earth's surface. These forces also vary with time as relative astronomical positions continually change over a wide spectrum of cycles. Procedures to calculate the local elevation of each of six standard tidal datums (upper portion of Table T1) follow similar official algorithms regardless of which of the six is selected. Selection would typically be based on location and purpose, for example, whether it involves resolving legal disputes, promoting navigation, assessing environmental resources, or analyzing geophysical phenomena.

The longest cycle conventionally damped by tidal averaging (the Metonic cycle) has a period of about 18.61 years. The NOS selects a specific 19-year time interval, called the *National Tidal Datum Epoch*, as the official span over which tide measurements are averaged to obtain the current tidal datum elevations throughout North America.

Gauges

The NOS presently maintains about 189 *primary tide gauges* where hourly water levels have been recorded continuously for more than 19 years. *Tidal benchmarks* are physical monuments maintained along the coast and to which tidal datum elevations have been surveyed (see *Geodesy*). Three to five bench marks are tied to NOS tide gauges by precise surveying and monitored to detect possible gauge disturbances.

Elevations are established at a larger set of *secondary gauges* by comparing their shorter tidal records (less than 19 years, but more than one year) with simultaneous measurements from nearby primary stations. Tidal datums can be reestablished by leveling short distances from tidal benchmarks. Numerical modeling of the tide can be used to extend datums longer distances between gauge sites including inland across the continent.

The elevation of water levels (and, therefore, tidal datums) in estuaries and coastal lagoons is typically higher than along adjacent open coasts. This super elevation is primarily due to freshwater flowing into the bay and nonlinear friction in tidal currents. Adjacent to inlets, the transition is smooth, but relatively steep. Therefore, primary gauges are often located away from their immediate vicinity (see *Tide Gauges*).

Table T1 A few North American vertical datums used by coastal engineers and scientists

Acronym	Name and definition	Origin, use or advantages
Tidal datums (based on gauge records)		
MHHW	Mean higher high water Mean of all higher high waters[a, b, c]	
MHW	Mean high water Mean of all high water heights (i.e., HW, HHW, and LWH, see Figure T11)[a, b, c]	Frequently used boundary separating private from state lands. See text. Landward limit for US Corps of Engineers jurisdiction over navigable waters.
MTL	Mean tide level Mean of MHW and MLW datums[a,b,c,d]	More descriptively called half-tide level.
MSL	Mean sea level Mean of hourly water surface heights[c]	Maintained US-wide by the National Geodetic Survey as "the most practicable and stable datum for general engineering," Shalowitz (1962).
MLW	Mean low water Mean of all low water heights (i.e., LW, LLW, and HLWs, see Figure T11)[a, c, d]	Use of the synonymous term, mean low tide, is discouraged by NOS.
MLLW	Mean lower low water Mean of all lower low water heights[a, c, d]	Principal chart datum for all of U.S. since 1981. Used by six states as boundary separating private and state lands.
Orthometric vertical datums (based on topographic surveying)		
NGVD 29	National Geodetic Vertical Datum 1929	Earlier standard geodetic datum. Based on first order survey nets of the United States and Canada fit to MSL at 26 tide gauges.
NAVD 88	North American Vertical Datum 1988	Official vertical datum for all of North America since June 24, 1993. An upgrade of NGVD 1928 based on more measurements over a larger area and independent of any tide gauge measurements.
Three-dimensional datums (based on measurements from space)		
NAD 83	North American Datum 1983	An upgrade using space-based measurements of the previous standard, NAD27.
WGS 84	World Geodetic System 1984	US Defense Mapping Agency equivalent of NOAA's NAD 83.

[a] Each stage of the tide in the time series to be averaged must, by official convention, differ by at least a "0.10 ft" and "2.0 h" from the adjacent measurements in the series. The series usually extend over a specified National Tidal Datum Epoch, but sometimes over a shorter stated duration.

[b] A high water is a maximum in a tide curve reached by a rising tide. The higher of two unequal high waters during the same day (24 h 50 min = the period of the M_1 tidal component) is the higher high water. The other high water is the lower high water.

[c] Definitions from US Department of Commerce Tide and Current Glossary (Hicks, 1989).

[d] A low water is a minimum in the tide curve that is reached by a falling tide. The lower of two unequal low tides during the same day is the lower low water. The other is the higher low water.

Tidal datum elevation algorithms

To calculate the elevations of a particular tidal datum at a primary tide gauge site, select the elevation measurements associated with the chosen tide phase (e.g., high tide) from the set of hourly data that covers the current National Tidal Datum Epoch. Official rules specify which hourly readings are associated with the chosen phase of the astronomical tide, but other factors (primarily weather) contributed to the water level measured at that time. Arguments have been made, especially for regions where the wind is strong, to loosen the required association between astronomical tidal phases and selection of which observations to average. Following the official rules (more details in next major section and in Table T1), a single daily high (or low) water elevation was traditionally selected at stations where the tide is classified as being *diurnal* (displaying a single cycle with one high and low per day, Figure T11, Tidal Day 4); elevations of two high (or low) waters are selected daily at stations classified as *semidiurnal* or *mixed* (displaying two cycles per day, Figure T11, Tidal Days 1, 2, and 3). Sum the selected observations and divide by the number selected. By thus averaging long series of data, the shorter cyclic variations (astronomical tide) and the random (weather-related) variations are damped. Including the full 19th year avoids biasing related to the strong annual cycle. Significant longer term (>19-year) variations arise from astronomical forces, thermal expansion (contraction) of the oceans, crustal movement, glacial melting, etc. These longer-term changes (see *Eustasy* and *Changing Sea Levels*) are compensated for, as needed at irregular intervals, by adopting evermore recent 19-year periods (Epochs) as the National Tidal Datum Epoch. For North America, the current Epoch is 1960–78; previous Epochs include 1941–59 and 1924–42. Agencies responsible for datum definitions elsewhere agree that tidal epochs should span complete 19-year periods, but they do not all use the same 19-year periods.

Spaced-based measurements

After a period of improvement and acceptance, spaced-based measurements derived from the NAVSTAR Global Positioning System (GPS) are now widely used not only as a convenient way to reestablish local datum elevations near benchmarks, but also in defining new coordinate systems (lowest portion of Table T1). Numerical models can introduce tidal datums into these three-dimensional coordinate systems based on idealized reference ellipsoids rather than tidal data. This approach is now quicker and less expensive than collecting tidal measurements or leveling from local tidal datum benchmarks. In the future, direct measurement of sea surface elevations from space may become accurate enough to establish tidal datum elevations essentially continuously along the coast in an iterative blend of observation and tidal dynamic modeling.

Limitations and precautions in applications

Temporal and spatial variations

The difference between successive high and low waters, *tide range*, is neither uniform nor constant. The phases of the moon and the inclination of its orbital plane with respect to the plane of the earth's orbit around the sun (*declination*) are two of the factors contributing to daily variations in tide range on approximately 28-day and 14-day cycles, respectively. In contrast to the elegant theory explaining temporal variations in the astronomical tide, its spatial variations are complex. Tidal dynamics vary with location on the earth, outline of the coast, bathymetry of the seafloor, and such factors as wind, salinity, and river discharge. Each tidal component is characterized by an amplitude and frequency (see *Tides*). The bathymetry and outline of the coast (*basin shape*) modulates sea-level response to the total gravitational force in a manner somewhat analogous to the way the material properties and shape of a poorly tuned musical instrument distorts chords. Some frequencies resonate and are amplified. Others are out of tune with the basin (instrument) and are damped (muffled). Furthermore, frequency-dependent nodes (antinodes) may exist within the basin where responses are maximized (minimized).

Nonuniform height differences between datums

Complexities of tidal propagation cause the mean differences among tidal datums to vary spatially, for example, the difference between MLW and MLLW varies along shore. The mean tide range varies around the world being about 10 m at Anchorage, Alaska; 1 m at San Diego, California; 0.1 m at Galveston, Texas; and less than a centimeter at Chicago, Illinois, on Lake Michigan.

Advent of the www improved the availability and dissemination of the empirically determined elevation differences among tidal datums in the form of tables issued by federal organizations throughout the world (e.g., http://co-ops.nos.noaa.gov/bench. html). Many of these tables also report the highest and lowest observed sea levels. Some sea-level datums (e.g., the British chart datum, Lowest Astronomical Tide) are based on extremes.

Type of tide

The range and timing of the tide goes through cycles as lunar and solar declinations change. They also vary spatially over the earth's surface. The type of tide varies spatially and temporally as well. The type of tide is predominately *semidiurnal* (two similar, semi-sinusoidal cycles per day with little difference between the two lows or the two highs) over most of the US East Coast and *mixed* (two lows and two highs per day that are unequal in elevation) along most of the US West Coast. Along the Gulf of Mexico, the type of tide is not so uniform, but at most locations it is *diurnal* (only one high and one low per day). Figure T11 shows a mixed type during Tidal Day 1 and Tidal Day 3. Tidal Day 2 is semidiurnal and Tidal Day 4 is diurnal. A real tide curve would transition between these types more gradually (see *Tides*).

The most common type of tide throughout the world is semidiurnal. Figure T12 depicts regional variations in type of tide along the north shore of the Gulf of Mexico and a portion of the Atlantic. The basin shapes in Tampa Bay and Charlotte Harbor, on the west coast of Florida, are tuned to diurnal tidal forces. Therefore, the tide type in these estuaries is predominately diurnal even though the open Gulf beaches of west Florida are predominately mixed. *Predominately* means that the type of tide is as designated for more than half of the time at that particular site. Along the Mediterranean Sea, stretches of coast that are predominately semidiurnal alternate with reaches that are predominately mixed. Tides are predominately semidiurnal around most of England, mixed around most of Australia, and diurnal along much of southeast Asia, Japan, and northeast Siberia.

Analysis procedures and datum elevations were established in the Gulf of Mexico prior to a full appreciation of these complex changes in type of tide (Hicks *et al.*, 1988). With the benefit of longer term and spatially denser measurements, it became apparent that some initial datum calculation procedures (as well as inconstancies in terminology) were causing problems. One of the problems was that the MHW and MLW datums had abrupt breaks (*jump discontinuities*) in elevation as one moved alongshore. The global continuity of sea level was a prime feature promoting the widespread adoption of tidal datums. MHW and MLW discontinuities arose because, traditionally, their official definitions included provisions that where the tide was classified as predominately diurnal, only one high (or low) would be included daily in the 19-year series for datum determination. Where the tide was predominately semidiurnal or mixed, both lows and both highs were traditional (and still are) included in these calculations. There are times during the monthly lunar cycle when diurnal forces are small relative to semidiurnal forces. During these times, the tide signal (even at sites where the tide is classified as diurnal) may take on mixed-type characteristics briefly (i.e., exhibit a second daily high and/or low). Likewise at sites that are mixed-type, the second daily high and/or low may become indiscernible for a few days during the month. Tide type is unambiguously classified according to a ratio of amplitude terms for the major tidal constituents. The shape of tide curves vary smoothly along the shore with transition zones between areas with different types of tide. Discontinuities arose

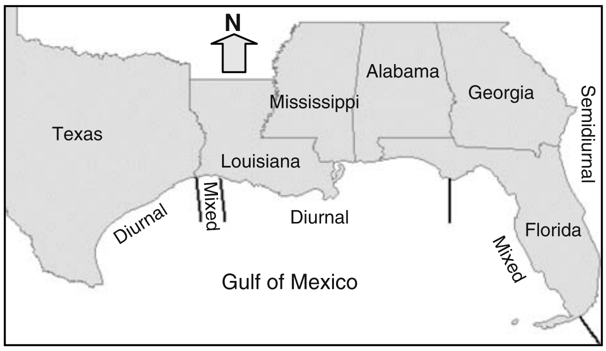

Figure T12 Regional variations in type of tide (modified from Hicks *et al.*, 1988).

from the traditional definitions of MHW and MLW being dependent on tide type. Resulting problems were especially acute in the case of MHW because of its role as a legal state boundary.

Through a series of carefully planned and well-coordinated moves that began as early as the 1970s, the procedures for defining MHW and MLW and the inconsistent naming practices that had crept in at some Gulf sites were changed. Table T1 follows the revised, uniform NOS definitions. Another half dozen modifications were collected into one endeavor that unified analysis, created a single uniform chart datum (MLLW), freed MHW and MLW definitions from dependence on tide type, updated the National Tidal Datum Epoch, moved private–state property boundary seaward along certain reaches, and eliminated all datum discontinuities (Hicks *et al*., 1988). Though announced much earlier, this comprehensive corrective action officially took effect on November 28, 1980. Complete updating of charts and NOS's Coast Pilot actually proceeded incrementally over the following decade. Tide tables predicting tidal heights for East Coast of North and South America switched chart datum from MLW to MLLW starting with the 1989 volume (making it consistent with NOS tables for other regions). This correction (The National Tidal Datum Convention of 1980) thus simplified standards for tidal datums throughout the Americas.

Nontidal datums

The *geopotential elevation* of tidal datums vary spatially (i.e., the potential energy of a unit mass at a given elevation with respect to each datum varies geographically). For long periods, a tidal datum can deviate on the order of a meter from an *equipotential surface* (surface of constant specific potential energy) due to prevailing atmospheric pressure, temperature, wind, currents, and salinity differences (see *Altimeter Surveys, Coastal Tides and Shelf Circulation*). For example, the geopotential elevation of sea level rises (falls) generally northward along the west (east) coast of the United States. For certain applications (e.g., long-distance pumping, ballistics) it is desirable that the elevation of an equipotential surface be spatially invariant. In such cases, a nontidal datum is clearly required (lower portion of Table T1).

The latest geodetic datum (NAVD 88, middle of Table T1) is not parallel to any tidal datum or to the geodetic datum it replaced (NGVD 29). The NGVD 29 was defined so that it approximated the MSL datum. The new NAVD 88 is on the order of a meter above the MSL datum on the West Coast and 0.1–0.5 m below the MSL datum on the East Coast (Figure T13) and is independent of sea level.

Shorelines

Conceptually, the intersection of any tidal datum with the beach rigorously defines a shoreline. The acronym for this shoreline is obtained by appending an "L" to the acronym for the selected tidal datum. In the United States, the mean high water line (MHWL) was adopted by most states as the boundary between private and public land. Six northeastern states allow private ownership down to the mean lower low water line (MLLWL). In Texas, private ownership has, at least in certain cases, been restricted to being above the mean higher high water line (MHHWL). Federal submerged lands, exclusive fishing zones, and national economic zones are related back to the MLLWL by their legal definitions.

In practice, charted shorelines are sometimes inferred from rectified aerial photographs taken at specific phases of the tide. Such mapped shorelines only approximate the rigorously defined tidal-datum shorelines, but are much easier to establish. Unfortunately, imprecise usage often results in them being labeled MHWL or MLWL. Even less-accurate approximations of tidal-datum shorelines are inferred from the wetted bound on the beach, berm line, and toe of the dune as identified in aerial photographs. These charted shorelines may be unlabeled or mislabeled.

Figure T13 Height in centimeters of MSL datum above NAVD88 (redrawn from USACE, 2002).

Statements like "this chart uses the MLLW datum," do not imply that the shoreline is the MLLWL or any other tidal datum, only that printed soundings are referenced to MLLW. The shoreline could be the water's edge at an arbitrary height of the tide, a high water mark, or follow a geomorphic feature like a berm or toe of dune. Caution is advised not to infer too much from shoreline labels without consulting the description of the procedures used in production of that specific chart. Increased use of digital maps may exacerbate problems because chart developers can no longer anticipate the scale to which the user will take measurements from these zoomable products.

The label "HWL" (for high water line as distinct from MHWL) specifically acknowledges that the shoreline has been located less precisely than tidal-datum shorelines. Nevertheless, the HWL does approximate the MHWL, and is therefore considered "of primary importance in distinguishing the upland from the shore on charts" (Shalowitz, 1964). For practical reasons of determination, however, the surveyed HWL is based on observed physical features in the field (such as berm crest). Thus, the HWL stands above the MHWL by an uncertain distance related to wave runup and surveyor judgment.

Concluding guidance

Tidal datums are listed in Table T1 in the order of decreasing elevation from top to bottom. The vertical offset of orthometric and three-dimensional datums (lower portions of Table T1) from tidal datums varies spatially (e.g., Figure T13). Chart depths usually refer to a tidal datum (MLLW is the official chart datum to which depths are referred in the United States). Elevations on maps usually refer to an orthometric or a three-dimensional datum (NAVD 88 or NAD 83 for older maps in the United States). By convention, elevations are positive above datum; depths are positive below datum (i.e., an object 10 m below the water has an elevation of -10 m and a depth of $+10$ m).

In the 1990s, proliferation of personal computer software made it easy to convert between reference systems (see *Geographic Information Systems*). Caution is advised, however, when analyzing measurements made to different references. For example, the effectiveness of coastal erosion mitigation is often assessed by analyzing the difference between variable rates of shoreline change after project completion and a series of measurements made before project initiation. Consider a scrabbled mixture of HWLs and MHWLs. Early shorelines exist only as HWLs. The ratio of HWLs to MHWLs would tend to decrease as aerial surveying and GPS technology became pervasive. The horizontal distance separating a HWL from a MHWL is not recoverable after the HWL survey. Because shoreline positions based on tidal and orthometric datums are more precisely defined than the HWL, MHWL positions may appear more reliable (for analyzing shoreline change rates) than the HWLs that only approximate them. For just the years that have both a HWL and a MHWL, it might seem desirable to delete the less precise of the two measurements, but this would tend to bias the post-construction period and produce the appearance of unwarranted erosion reduction (i.e., deletion the HWLs would tend to displace the shoreline landward more frequently during later years). In most such cases, the more precisely located MHWLs might well be ignored to obtain an unbiased (though imprecise) estimate of changes in the rate of shore retreat.

Adoption of a new National Tidal Datum Epoch is pending. Previous updates have raised datums (reduced the elevations of benchmarks above tidal datums) by amounts that varied with the particular epoch transition, gauge location, and datum selection. For the MHW datum, an increase on the order of 0.25 m would not be unusual from one Epoch to the next. In areas of subsidence (Louisiana, the Netherlands, and portions of Texas, see *Coastal Subsidence*) or crustal uplift (e.g., Alaska, see *Changing Sea Levels*), datums could be raised or lowered on the order of a meter. Comparisons of shoreline positions documented during different Epochs can, therefore, be problematic. Adjustments can be made to estimate the shoreline positions for a common Epoch based on the vertical shift in tidal datum between two Epochs and the slope of the beach at these elevations. The adjusted results would only be as good as the knowledge of the beach slope used to translate the vertical shift into a shoreline displacement, but the results could be useful. Beaches (including the dune, berm, and longshore bars) generally migrate upward with the historic long-term rise of sea level. So, comparing unadjusted shorelines, referred to datums that shifted between epochs, can also be valid from the perspective of quantifying how the volume of beach sand changes in concert with sea-level changes. Whether to accept the inter-Epoch shoreline displacement or adjust the shorelines would depend on the time span, magnitude of sea-level change, and knowledge of slope changes. Analysis from both perspectives can be useful. For example, along a 50 km reach of Lake Michigan, the average shore retreat of 17.9 m (over a specific six years during which the mean lake level rose persistently) was decomposed into 14.5 m (at a fixed datum elevation) due to erosion and recession of the profile and 3.4 m due to submergence under a 0.39 m higher mean lake level (Figure 11, Hands, 1979).

For accuracy, charts and tables should clearly state the method of determining elevations and shorelines, coordinate systems, units of measurement, and any coordinate transform procedures employed. To maintain accuracies on the order of 0.1 m or better, be certain of and document which particular Epoch was used in the tidal datum definition.

TIDAL ENVIRONMENTS

Definitions

A tidal environment is that part of a marine shore which is regularly submerged and exposed in the course of the rise and fall of the tide. Such environments exhibit particular physical and biological characteristics which, among others, play an important role in coastal dynamics, coastal ecology, coastal protection and engineering works, and integrated coastal zone management.

The coastal area affected by the ocean tides is known as the intertidal or eulittoral zone. Being a long-period wave, the tidal water level oscillates about a mean water level, which usually corresponds to the mean sea level. The vertical distance covered by the tide is known as the tidal range, whereas the part above or below the mean tide level is the tidal amplitude, which can hence have a positive or negative sign. In practice, a number of critical tide levels are distinguished on the basis of longer-term averages. Proceeding from high to low water levels, these are: MEHWS, mean equinoxial high water springs (highest astronomical tide); MHWS, mean high water springs; MHWN, mean high water neaps; MWL, mean water level (commonly mean sea level); MLWN, mean low water neaps; MLWS, mean low water springs; and MELWS, mean equinoxial low water springs (lowest astronomical tide). These mean tide levels are well correlated with various morphological and biological characteristics of tidal environments.

Besides the astronomical modulations, instantaneous tidal elevations can, in the short term, be substantially modified by water-level fluctuations induced by wind and/or wave set-up or set-down. The degree of wave and wind exposure can thus have a substantial influence on the nature of a tidal shore. Where such secondary and irregular fluctuations in coastal water levels are so frequent and strong that they completely mask the tidal signal, the coast is considered to be nontidal (e.g., the Baltic Sea).

In summary, tidal shores are highly variable environments which are not only influenced by the astronomically induced periodic rise and fall of the sea level, but also by numerous secondary processes. In combination, these factors define the local physical nature of a tidal environment (e.g., Davies, 1980; Allen and Pye, 1992; Allen, 1997; French, 1997).

Tidal forcing factors

The tides are essentially produced by the interactive forces exerted on the oceans by the sun and the moon. Since the motions of the sun and the earth–moon system are known with great precision, the tide-generating potential can be mathematically resolved into strictly periodic components. These components vary over time as the position of the sun and the moon relative to the position and orientation of the earth changes. The sum of all the tractive forces at any one time defines the total instantaneous potential. Doodson (1922) computed no less than 390 such harmonic components, of which about 100 are long period, 160 diurnal, 115 semidiurnal, and 14 one-third diurnal. Of these, only seven (i.e., four semidiurnal and three diurnal components) are of practical importance (e.g., McLellan, 1975). Indeed, only four of these are used to define the character of the tides around the globe (Figure T14), in which semidiurnal, diurnal, and two mixed tidal types, comprising a predominantly semidiurnal and a predominantly diurnal one, are distinguished (cf. Table T2). Since the tidal type has an important influence on the physical nature of tidal environments, the global distribution of these four types are illustrated in Figure T15.

As the sun, the earth, and the moon move along their elliptical orbits, they continually change their positions relative to each other. As a result, the total potential defining the height of the astronomical tide is modulated as a function of geographic location in the course of a day, a month, a year, and also on longer timescales. The most prominent tidal period is the fortnightly spring–neap cycle (synodic tide). Thus, spring tides coincide with full moon and new moon, whereas neap tides occur at the corresponding half-moon phases. These tidal ranges are further modulated in the course of a lunar month (anomalistic tides), the highest spring tides occurring when the moon is closest to the earth (perigee), the lowest when the moon is furthest away from the earth (apogee), the difference in distance amounting to roughly 13%. The solar component varies in similar manner between perihelion (currently coinciding with the winter solstice) and aphelion (currently coinciding with the summer solstice), the difference in distance between the two amounting to about 4%.

Another important astronomical feature influencing tidal environments on short timescales is the daily inequality of the tide (declinational tide). This feature results from the inclination of the earth's axis relative to the plane of the ecliptic, and hence the tidal bulge. As the earth rotates around its axis, the position of a geographic locality continually changes relative to the tidal bulge, alternating between a maximum and a minimum tidal elevation every 12.42 h, a feature which affects the elevations of both successive high tides and low tides. On this, the declination of the moon is superimposed which, in turn, causes a progressive change in the daily inequality over time. Thus, with the moon over the equator, successive tides are equal in height (equatorial tides), whereas towards the position of maximum declination successive tides become progressively more unequal in height, dividing into a "large tide" and a "half tide" (tropical tides). The solar tide shows a similar inequality, being zero at the equinoxes (spring and autumn) and largest at the solstices (summer and winter).

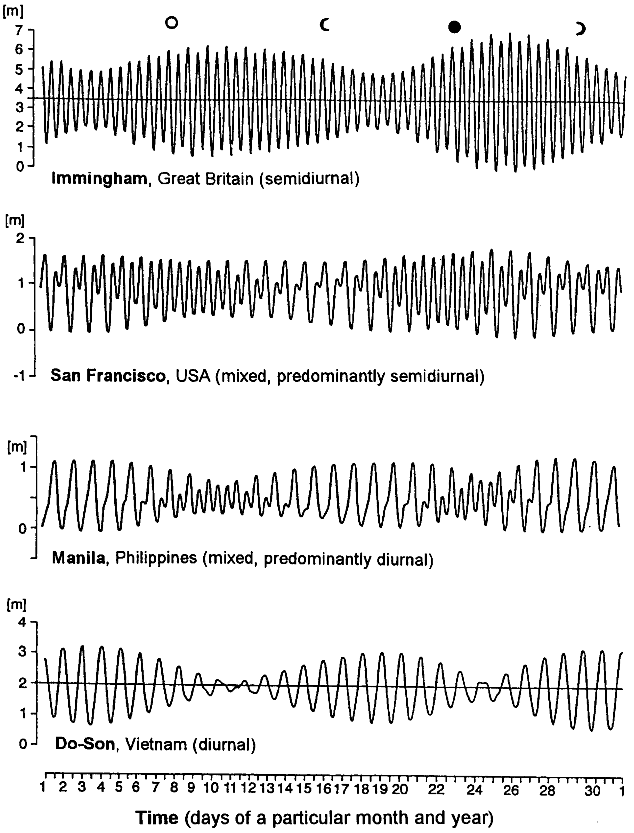

Figure T14 Selected examples of tidal curves from different geographic locations illustrating the main tidal types (adapted from Dietrich *et al.*, 1975). (A) semi-diurnal tides (e.g., Immingham, Great Britain); (B) mixed, predominantly semidiurnal (e.g., San Francisco, USA); (C) mixed, predominantly diurnal (e.g., Manila, Philippines); (D) diurnal (e.g., Do-Son, Vietnam).

The largest astronomical tides, that is, the greatest spring and lowest neap tides, in the course of a year occur at the vernal and autumnal equinoxes when the orbital path of the earth–moon system crosses the plane of the celestial equator (nodal points), that is, when the total potential of the tide-generating forces is largest because of their closest alignment.

In addition to these short-period astronomical cycles, the tide is also modulated by longer period phenomena which need to be considered when analyzing ancient tidal deposits (e.g., Archer *et al.*, 1991; Williams, 1991; Oost *et al.*, 1993; de Boer and Smith, 1994). Among these are the nutational motion or nodal cycle ($\approx$18.6-year cycle) caused by the oscillation of the earth's axis about its mean position, the precessional motion ($\approx$23,000-year cycle) of the earth's axis, the obliquity ($\approx$41,000-year cycle) which defines the angle of inclination of the earth's axis between 22° and 24.8° (currently 23.5°), and the eccentricity ($\approx$100,000-year cycle) controlling the rate of change in the elliptical radius of the earth's orbit around the sun. In addition, it has been shown that the length of the year has decreased from 420 to currently 365 days, while the length of the day has increased from 21 to currently 24 h in the course of the last 500 million years or so (e.g., Williams, 1991).

Besides the geographic variation in tidal type and tidal range resulting from astronomical modulations, the physical nature of a tidal environment is also influenced by numerous secondary factors. Among the more important of these are variations in tidal range with distance from the amphidromic point around which the tidal wave rotates, the Coriolis effect as a function of geographic location, the rate of change in water depth, the coastline configuration (plan shape and slope angle), as well as resonant effects resulting from the shape and depth of a tidal basin. Thus, at the center of an amphidrome the tidal range is considered to be zero, but it progressively increases in height with distance along the axis of the two opposing tidal bulges which rotate around the center offset by 180° or 6 h (tidal phases). The Coriolis force, in turn, forces the tidal wave to rotate clockwise in the Southern Hemisphere and anticlockwise

Table T2 The tidal character (F) as defined on the basis of the ratio between the sum of the lunisolar diurnal (K_1) and principle lunar diurnal (O_1) and the sum of the principle lunar semidiurnal (M_2) and principle solar semidiurnal (S_2) tidal components

$F = K_1 + O_1/M_2 + S_2$	Tidal character
0–0.25	Semidiurnal tides
0.25–1.5	Mixed, predominantly semidiurnal tides
1.5–3.0	Mixed, predominantly diurnal tides
>3.0	Diurnal tides

Source: Dietrich *et al.* (1975).

in the Northern Hemisphere, but this principle can be upset near the Equator. The direction in which the tidal wave propagates along a shore thus depends entirely on the geographic location of the coast. Where tidal waves rotating around neighboring amphidromes meet, the tidal water motion can even be perpendicular to the coast.

In addition, the amplification of the tidal wave and the tidal type are strongly influenced by the configuration of the coastline and the rate of shoaling, the effect of this interaction being illustrated in Figures T15 and T16. With decreasing water depth (h) the length of the tidal wave (λ) progressively decreases proportionally in the form $\lambda \propto h^{0.5}$. When propagating into funnel-shaped estuarine water bodies, the initial increase in tidal range due to convergence of the opposite shores is eventually compensated for by friction along the seabed as a result of which the tidal wave gradually decreases in height. This interplay between friction and convergence is proportionally related in the form $a_0 \propto b^{-0.5} * h^{-0.25}$ where a_0 is the amplitude of the tidal wave (m), b is the width (m), and h is the water depth (m) at a particular location along the estuary. This relationship can take on complicated patterns and in nature three basic modes of tidal wave propagation can be distinguished. Thus, in the case where friction dominates over convergence the tidal range progressively decreases in height up-estuary (hypersynchronic mode). In the opposite case, the tidal range increases in height (hyposynchronic mode), and where friction and convergence are in balance the tidal range remains constant (synchronic mode). Even neighboring estuaries will exhibit quite different modes of tidal wave propagation if they differ in shape and water depth (e.g., Borrego *et al.*, 1995). In many estuarine environments a combination of two or even all three modes can be observed.

In some cases, the entrance channel of an estuary or lagoon is so narrow and shallow that the propagation of the tidal wave is "choked" with the effect that the tidal range is dramatically reduced. This filtering mechanism, expressed by the so-called coefficient of repletion (K), has the numerical form of $K = (T/2a_0\pi) * (A_c/A_b) * [2a_0g/(1 + 2gln^2r^{-4/3})]^{0.5}$ where T is the tidal period, $2a_0$ is the tidal range (a_0 being the tidal amplitude), l is the length of the entrance channel, A_c is the cross-sectional channel area, A_b is the surface area of the water body, r is the hydraulic radius of the channel, g is the gravitational acceleration, and n is the Manning's friction (0.01–0.10 s m$^{-1/3}$). This coefficient of repletion controls reductions in tidal range, phase shifts between ocean and lagoonal tides, non-sinusoidal variations of the lagoonal tides, and flow exchanges between the ocean and the estuarine or lagoonal water bodies (e.g., Kjerfve and Magill, 1989).

A final forcing factor which may affect the behavior of tidal waves in shallow water is resonance, a feature associated with standing waves. Clearly, a standing wave superimposed on a normal tidal wave would dramatically affect the physical nature of a tidal environment. In this context, we distinguish two types. In the case of a half-wave oscillator or seiche, the length of the water body is half the wavelength of the standing wave. The fundamental period (T) of a seiche is defined as $T = 2l/(gh)^{0.5}$ where l is the length of the water body, h is the water depth, and g is the gravitational acceleration. Seiches are particularly common in lakes and marginal seas, where they are forced by wind stress, and hence of less importance in tidal environments. However, quarter-wave oscillators come into operation where the lengths of open-ended elongate gulfs or deep estuaries together with adjacent bays correspond to a quarter of the tidal wavelength ($l = 0.25T * (gh)^{0.5}$). In this case, the period $T = 4l/(gh)^{0.5}$ with notations as above. If this condition is fulfilled, or nearly so, tidal amplification can be quite considerable (e.g., Bay of Fundy, Canada).

Coastal classification by tidal type and range

Besides classifying the world's coastline according to tidal type (Figure T15), coastal tidal environments are also classified on the basis of tidal range, the scheme of Davies (1964, 1980) having been the most

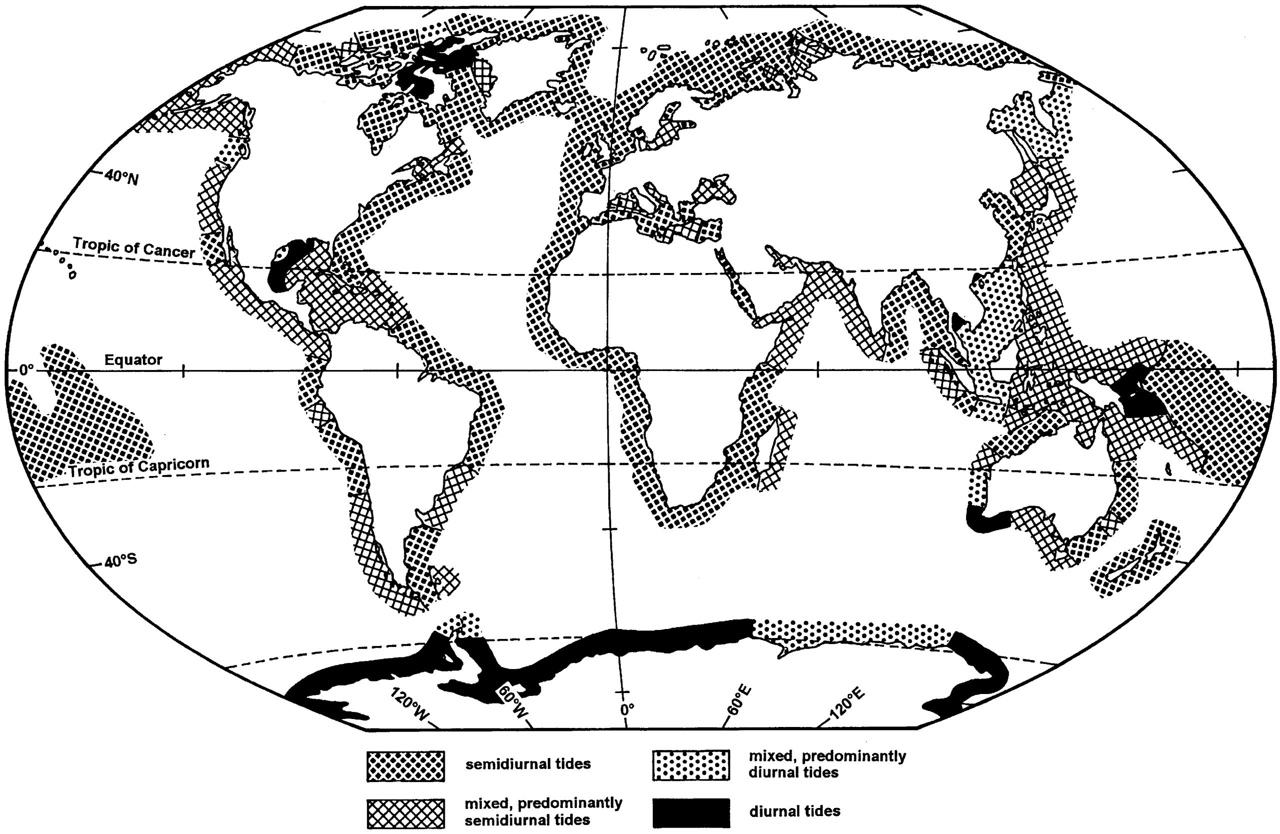

Figure T15 Global distribution of the main tidal types (adapted from Davies, 1980). Note that the transitions between semidiurnal and diurnal tidal types (here represented by so-called mixed tides) are progressive and not abrupt.

Table T3 Contrasting two existing classification schemes of tidal shores on the basis of tidal range

Davies (1964)		Hayes (1979)	
Tidal range (m)	Class name	Tidal range (m)	Class name
<2.0	Microtidal	<1.0	Microtidal
2.0–4.0	Mesotidal	1.0–2.0	Lower mesotidal
>4.0	Macrotidal	2.0–3.5	Upper mesotidal
		3.5–5.5	Lower macrotidal
		>5.5	Upper macrotidal

widely applied to date (Table T3). However, with only three subdivisions, this rather arbitrary approach prevents differentiation where it is most needed, that is, near the lower and upper limits of the potential tidal regime. For example, the Gulf of Mexico coast with an average tidal range of only 0.5 m is very different in character from the west coast of southern Africa where the tidal range averages at 1.6 m, yet both are classified as microtidal. In contrast to this, a more pragmatic classification, comprising five subdivisions (see Table T2), has been proposed by Hayes (1979). This latter scheme takes distinct, process-related geomorphic features into consideration, for example, the upper limit of barrier island occurrence at a tidal range of 3.5 m, which hence marks the transition between upper mesotidal and lower macrotidal regimes in this classification. To contrast the two classification schemes, the global pattern of coastal subdivision using the latter scheme is presented here for the first time (Figure T16).

Rocky versus sandy and muddy tidal environments

The coastlines of the world can be divided into four basic types, namely rocky shores, sandy shores, muddy shores, and bio-shores. In all cases, the character of a particular shore reflects the interaction between the substrate, the local wave climate, the tides, and the biology (e.g., Newell, 1979; Davies, 1980; Raffaeli and Hawkins, 1996). Geographic location, which controls climatic influences and biological species composition (e.g., Chapman, 1974), and the Holocene evolution of a coast (e.g., Bird and Schwartz, 1985) being important additional factors to consider. Rocky shores occupy the smallest overall area because the intertidal zone is commonly narrow as compared with the other shore types. Shore processes have received considerable attention by engineers for constructional purposes (e.g., Horikawa, 1989), whereas biologists have long been intrigued by the distinct faunal and floral zonation patterns along tidal gradients which evidently reflect high degrees of adaptation to the intertidal environment and the overprinting effects of competition between specific organisms (e.g., Lewis, 1972; Raffaeli and Hawkins, 1996). However, the interplay between biological and physical factors in defining zonation patterns is still not well enough understood to allow accurate predictions to be made (e.g., Delafontaine and Flemming, 1989). Different tidal environments are also characterized by different biogeochemical processes due to different climates, substrates, and biological community structures (Alongi, 1998).

The biological zonation pattern observed along the rocky shores of Great Britain as a function of tidal gradient and the degree of exposure to wave action is illustrated in Figure T17 (adapted from Lewis, 1972; Raffaeli and Hawkins, 1996). This basic scheme can be applied to most rocky shores of the world, the only difference being the species composition and distribution, a good example from subtropical Bermuda being shown in Thomas (1985). Important to note here is that the tidal gradient in Figure T17 is relative, expanding or contracting proportional to the tidal range.

In contrast to rocky shores, into which bio-shores can also be included, sandy and muddy tidal shores can attain shore normal extensions of many kilometers (e.g., Davis, 1994; Flemming and Hertweck, 1994). French (1997) distinguishes no less than seven intertidal coastal types based mainly on morphology and facies successions. The final transition between land and sea along sheltered coasts is characterized by sharp boundaries separating different floral zones, the typical pattern observed along the barrier island shore of the southern North Sea being illustrated in Figure T18 (adapted from Streif, 1990).

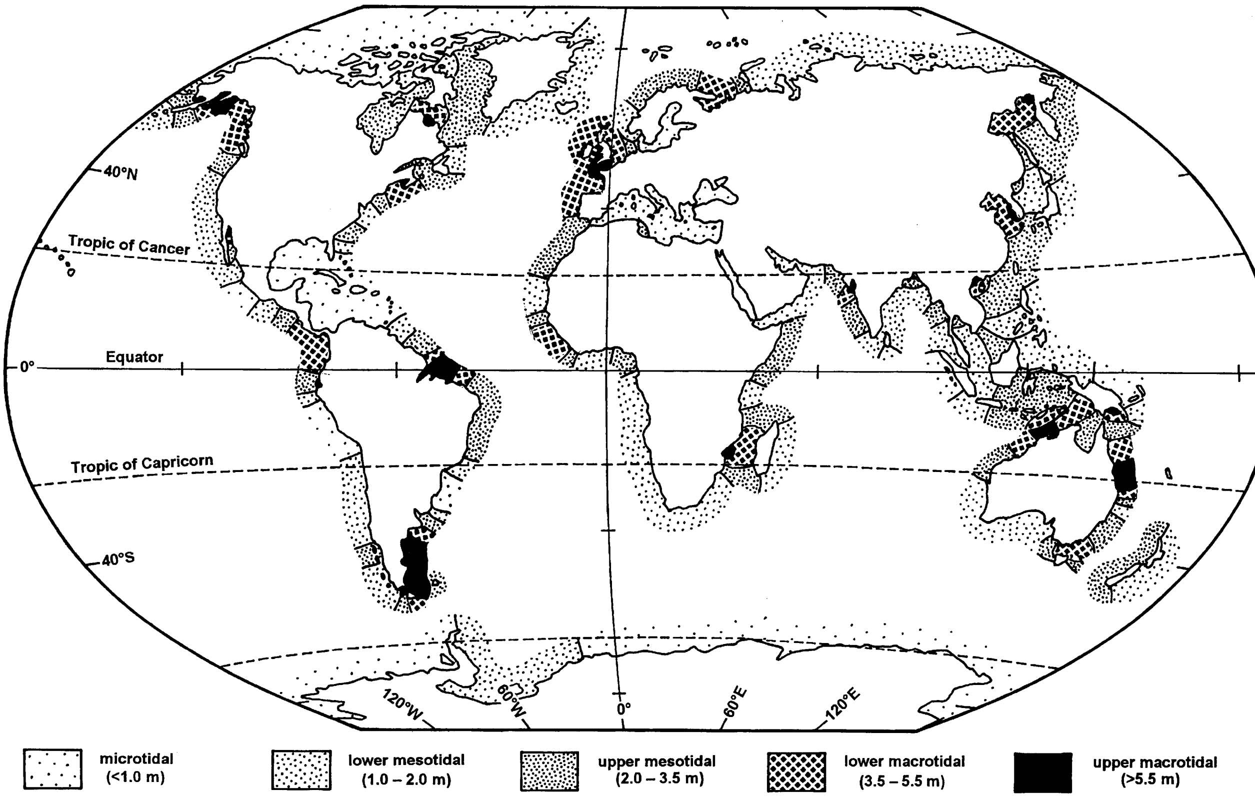

Figure T16 Global distribution of tidal shores based on tidal range according to the classification scheme of Hayes (1979).

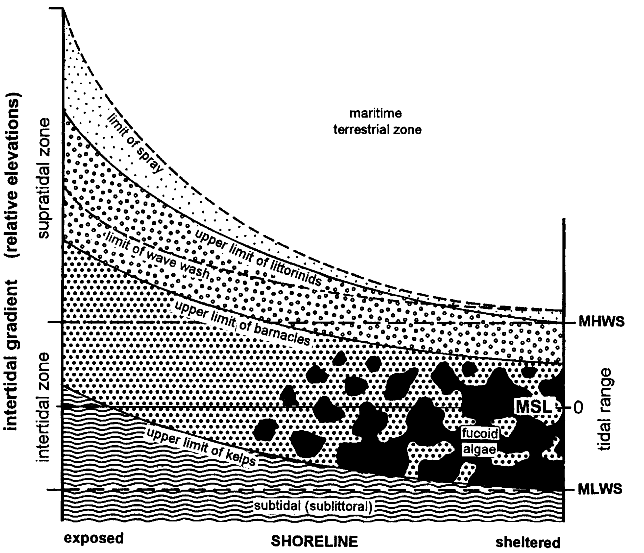

Figure T17 Zonation patterns along rocky tidal shores as a function of exposure to wave action (adapted from Lewis, 1972; Raffaeli and Hawkins, 1996). Note that the scaling is relative to any particular observed tidal gradient.

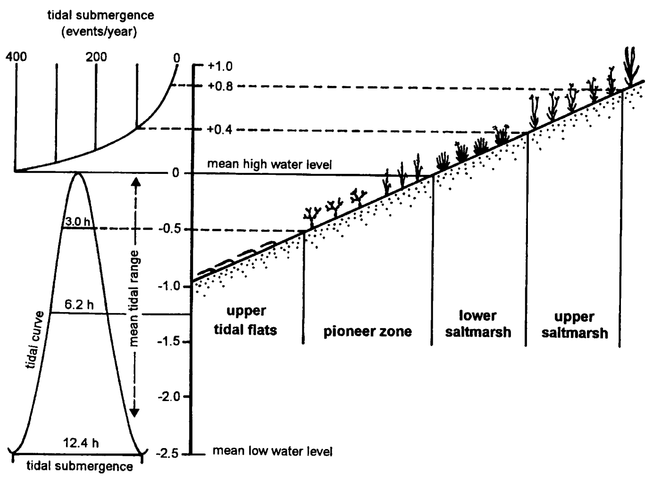

Figure T18 Floral zonation pattern observed at the transition between upper intertidal flats and the terrestrial environment of the Wadden Sea (southern North Sea) as a function of tidal elevation and the frequency of tidal submergence in the course of a year (adapted from Streif, 1990).

In this example the zones are separated by the frequency of tidal submergence in the course of the year which is controlled by the elevation along the tidal gradient. In principle, this basic pattern should be applicable the world over, individual transition levels being dependent on local floral associations, the tidal range, the seasonal wave climate, and the difference in elevation between mean high tide levels at spring and neap tide (e.g., Chapman, 1974; Lugo and Snedaker, 1974). A systematic investigation of the factors controlling the upper and lower limits of occurrence of *Spartina anglica* relative to mean sea level along the coast of the United Kingdom has generated quantitative relationships between the spring tidal range, the fetch available for wave generation and propagation, the area of the tidal basin, and in the case of the upper limit also the geographic location (Gray, 1992). Thus, the lower limit (L_l) is defined as $L_l = -0.805 + 0.366R_s + 0.053F + 0.135 * \log_e A_b$, where R_s is the spring tidal range (m), F is the fetch in the direction of the transect (km), and A_b is the area of the tidal basin (km^2). The upper limit, by contrast, is defined as $L_u = 4.74 + 0.483R_s + 0.068F - 0.199L°$, where $L°$ is the degree North Latitude expressed as a decimal. The correlation coefficients of $r = 0.97$ for L_l and $r = 0.95$ for L_u demonstrate the predictive potential of this approach.

A comprehensive overview of physical and biological processes active along sandy tidal shores is provided in McLachlan and Erasmus (1983).

Outlook

Many features of tidal environments are still poorly understood. Among these are the quasi-periodic, decadal to subdecadal fluctuations in the elevation of mean high tide and mean low tide levels. Being a worldwide phenomenon, one might assume that they result from variations in the astronomical factors defining the tidal potential. A clear correlation, however, is still lacking. As far as sandy tidal environments are concerned, accurate sediment budgets and transport pathways have remained elusive problems whose solution becomes more pressing in view of the predicted acceleration in sea-level rise. The distinction between strictly local features and others of global relevance requires more attention. A number of other unresolved issues have been addressed in the text.

TIDAL INLETS

Introduction

Tidal inlets are found along barrier coastlines throughout the world. They provide a pathway for ships and small boats to travel between the open ocean to sheltered waters. Along many coasts, including much of the East and Gulf Coasts of the United States, the only safe harborages, including some major ports, are found behind barrier islands. The importance of inlets in providing navigation routes to these harbors is demonstrated by the large number of improvements that are performed at the entrance to inlets such as the construction of jetties and breakwaters, dredging of channels, and the operation of sand bypassing facilities.

Diversity in the morphology, hydraulic signature, and sediment transport patterns of tidal inlets attests to the complexity of their processes. The variability in oceanographic, meteorologic, and geologic parameters, such as tidal range, wave energy, sediment supply, storm magnitude, and frequency, freshwater influx, and geologic controls, and the interactions of these factors, are responsible for this wide range in tidal inlet settings.

What is a tidal inlet

A tidal inlet is defined as an opening in the shore through which water penetrates the land thereby proving a connection between the ocean and bays, lagoons, and marsh and tidal creek systems. Tidal currents maintain the main channel of a tidal inlet.

The second half of this definition distinguishes tidal inlets from large, open embayments or passageways along rocky coasts. Tidal currents at inlets are responsible for the continual removal of sediment dumped into the main channel by wave action. Thus, according to this definition, tidal inlets occur along sandy or sand and gravel barrier coastlines, although one side may abut a bedrock headland. Some tidal inlets coincide with the mouths of rivers (estuaries) but in these cases inlet dimensions and sediment transport trends are still governed, to a large extent, by the volume of water exchanged at the inlet mouth and the reversing tidal currents, respectively.

At most inlets over the long term, the volume of water entering the inlet during the flooding tide equals the volume of water leaving the inlet during the ebbing cycle. This volume is referred to as the tidal prism. The tidal prism is a function of the open water area and tidal range in the backbarrier as well as frictional factors, which govern the ease of flow through the inlet.

Inlet morphology

A tidal inlet is specifically the area between two barriers or between the barrier and the adjacent bedrock or glacial headland. Commonly, the recurved ridges of spits, consisting of sand that was transported toward the backbarrier by refracted waves and flood-tidal currents form the sides of the inlet. The deepest part of an inlet, the inlet throat, is located normally where spit accretion of one or both of the bordering barriers constricts the inlet channel to a minimum width and minimum cross- sectional area. Here, tidal currents normally reach their maximum velocity. Commonly, the strength of the currents at the throat causes sand to be removed from the channel floor leaving behind a lag deposit consisting of gravel or shells or in some locations exposed bedrock or indurated sediments.

Tidal deltas

Closely associated with tidal inlets are sand shoals and tidal channels located on the landward and seaward sides of the inlets. Flood-tidal currents deposit sand landward of the inlet forming flood-tidal deltas and ebb-tidal currents deposit sand on the seaward side forming an ebb-tidal delta.

Flood-tidal delta. Their presence or absence, size, and development are related to a region's tidal range, wave energy, sediment supply, and backbarrier setting. Tidal inlets that are backed by a system of tidal channels and salt marsh (mixed-energy coast) usually contain a single horseshoe-shaped flood-tidal delta (i.e., Essex River Inlet, Massachusetts; Figure T19). Contrastingly, inlets that are backed by large shallow bays may contain multiple flood-tidal deltas. Along some microtidal coasts, such as in Rhode Island, flood deltas form at the end of narrow inlet channels cut through the barrier. Changes in the locus of deposition at these deltas produce a multi-lobate morphology resembling a lobate river delta (Boothrdyd *et al.*, 1985). Flood delta size commonly increases as the amount of open water area in the backbarrier increases. In some regions, flood deltas have become colonized and altered by marsh growth, and are no longer recognizable as former flood-tidal deltas. At other sites, portions of flood-tidal deltas are dredged to provide navigable waterways and thus are highly modified.

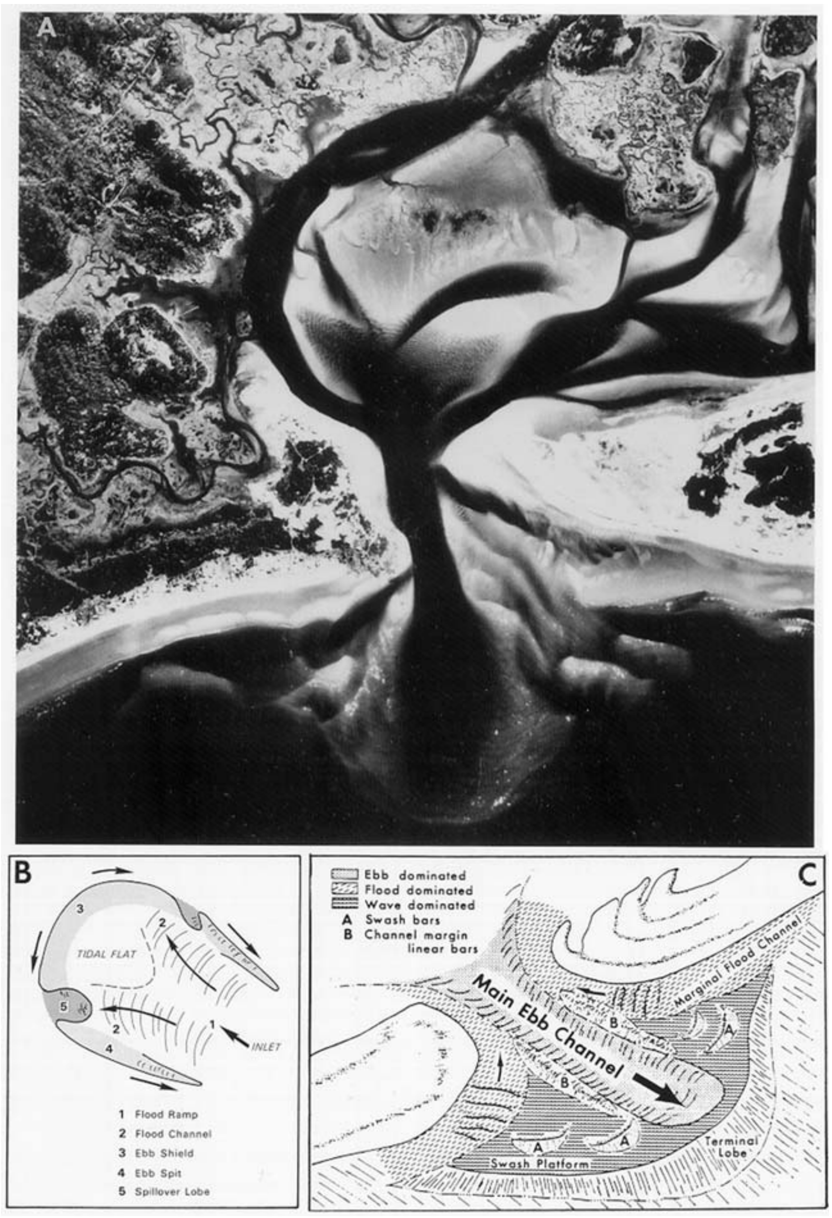

Figure T19 (A) Vertical aerial photograph of Essex River Inlet, Massachusetts with well-developed flood- and ebb-tidal deltas. (B) Flood-tidal delta model (after Hayes, 1975). (C) Ebb-tidal delta model (after Hayes, 1975).

Flood-tidal deltas are best revealed in areas with moderate to large tidal ranges (1.5–3.0 m) because in these regions they are well exposed at low tide. As tidal range decreases, flood deltas become largely subtidal shoals. Most flood-tidal deltas have similar morphologies consisting of the following components (Hayes, 1975, 1979).

1. *Flood ramp*. This is a landward shallowing channel that slopes upward toward the intertidal portion of the delta. Strong flood-tidal currents and landward sand transport in the form of landward-oriented sandwaves dominate the ramp.
2. *Flood channels*. The flood ramp splits into two shallow flood channels. Like the flood ramp, these channels are dominated by flood-tidal currents and flood-oriented sand waves. Sand is delivered through these channels onto the flood delta.
3. *Ebb shield*. It defines the highest and landwardmost part of the flood delta and may be partly covered by marsh vegetation. It shields the rest of the delta from the effects of the ebb-tidal currents.
4. *Ebb spits*. These spits extend from the ebb shield toward the inlet. They form from sand that is eroded from the ebb shield and transported back toward the inlet by ebb-tidal currents.
5. *Spillover lobes*. These are lobes of sand that form where the ebb currents have breached through the ebb spits or ebb shield depositing sand in the interior of the delta.

Through time, some flood-tidal deltas accrete vertically and/or grow in size. This is evidenced by an increase in areal extent of marsh grasses, which require a certain elevation above mean low water to exist. At migrating inlets new flood-tidal deltas are formed as the inlet moves along the coast and encounters new open water areas in the backbarrier. At most stable inlets, however, sand comprising the flood delta is simply recirculated. The transport of sand on flood deltas is controlled by the elevation of the tide and the strength and direction of the tidal currents. During the rising tide, flood currents reach their strongest velocities near high tide when the entire flood-tidal delta is covered by water. Hence, there is a net transport of sand up the flood ramp, through the flood channels and onto the ebb shield. Some of the sand is moved across the ebb shield and into the surrounding tidal channel. During the falling tide, the strongest ebb currents occur near mid to low water. At this time, the ebb shield is out of the water and diverts the currents around the delta. The ebb currents erode sand from the landward face of the ebb shield and transport it along the ebb spits and eventually into the inlet channel where once again it will be moved onto the flood ramp thus completing the sand gyre.

Ebb-tidal delta. This is an accumulation of sand that has been deposited by the ebb-tidal currents and which has been subsequently modified by waves and tidal currents. Ebb deltas exhibit a variety of forms dependent on the relative magnitude of wave and tidal energy of the region as well as geological controls. Along mixed energy coasts, most ebb-tidal deltas contain the same general features including:

1. *Main ebb channel*. This is a seaward shallowing channel that is scoured into the ebb-tidal delta sands. It is dominated by ebb-tidal currents.
2. *Terminal lobe*. Sediment transported out the main ebb channel is deposited in a lobe of sand forming the terminal lobe. The deposit slopes relatively steeply on its seaward side. The outline of the terminal lobe is well defined by breaking waves during storms or periods of large wave swell at low tide.
3. *Swash platform*. This is a broad shallow sand platform located on both sides of the main ebb channel, defining the general extent of the ebb delta.
4. *Channel margin linear bars*. These are bars that border the main ebb channel and sit atop the swash platform. These bars tend to confine the ebb flow and are partially exposed at low tide.
5. *Swash bars*. Waves breaking over the terminal lobe and across the swash platform form arcuate-shaped swash bars that migrate onshore. The bars are usually 50–150 m long, 50 m wide, and 1–2 m in height.
6. *Marginal-flood channels*. These are shallow channels 0–2 m deep at mean low water located between the channel margin linear bars and the onshore beaches. The channels are dominated by flood-tidal currents.

Ebb-tidal delta morphology

The general shape of an ebb-tidal delta and the distribution of its sand bodies tell us about the relative magnitude of different sand transport processes operating at a tidal inlet. Ebb-tidal deltas that are elongate with a main ebb channel and channel margin linear bars that extend far offshore are tide-dominated inlets. Wave-generated sand transport plays a secondary role in modifying delta shape at these inlets. Because most sand movement is in onshore–offshore direction, the ebb-tidal overlaps a relatively small length of inlet shore. This has important implications concerning the extent to which the inlet shore undergoes erosional and depositional changes.

Wave-dominated inlets tend to be small relative to tide-dominated inlets. Their ebb-tidal deltas are driven onshore, close to the inlet mouth by the dominant wave processes. Commonly, the terminal lobe and/or swash bars form a small arc outlying the periphery of the delta. In many cases, the ebb-tidal delta of these inlets is entirely subtidal. In other instances, sand bodies clog the entrance to the inlet leading to the formation of several major and minor tidal channels.

At mixed energy tidal inlets the shape of the delta is the result of tidal and wave processes. These deltas have a well-formed main ebb channel, which is a product of ebb-tidal currents, their swash platform and sand bodies substantially overlap the inlet shore many times the width of the inlet throat due to wave processes and flood-tidal currents.

Ebb-tidal deltas may also be highly asymmetric such that the main ebb channel and its associated sand bodies are positioned primarily along one of the inlet shores. This configuration normally occurs when the major backbarrier channel approaches the inlet at an oblique angle or when preferential accumulation of sand on the updrift side of the ebb delta causes a deflection of the main ebb channel along the downdrift barrier shore.

Tidal inlet formation

The formation of a tidal inlet requires the presence of an embayment and the development of barriers. In coastal plain settings, the embayment or backbarrier was often created through the construction of the barriers themselves, like much of the East Coast of the United States or the Friesian Island coast along the North Sea. In other instances, the embayment was formed due to rising sea level inundating an irregular shore during the late Holocene. The embayed or indented shore may have been a rocky coast such as that of northern New England and California or it may have been an irregular unconsolidated sediment coast such as that of Cape Cod in Massachusetts or parts of the Oregon coast. The flooding of former river valleys has also produced embayments associated with tidal inlet development.

Breaching of a barrier

Rising sea level, exhausted sediment supplies, and human influences have led to thin barriers that are vulnerable to breaching. The breaching process normally occurs during storms after waves have destroyed the foredune ridge and storm waves have overwashed the barrier depositing sand aprons (washovers) along the backside of the barrier. Even though this process may produce a shallow overwash channel, seldom are barriers cut from their seaward side. In most instances, the breaching of a barrier is the result of the storm surge heightening waters in the backbarrier bay. When the level of the ocean tide falls, the elevated bay waters flow across the barrier toward the ocean gradually incising the barrier and cutting a channel. If subsequent tidal exchange between the ocean and bay is able to maintain the channel, a tidal inlet is established. The breaching process is enhanced when offshore winds accompany the falling tide and if an overwash channel is present to facilitate drainage across the barrier (Fisher, 1962). Many tidal inlets that are formed by this process are ephemeral and may exist for less than a year, especially if stable inlets are located nearby. Barriers most susceptible to breaching are long and thin and wave-dominated.

Spit building across a bay

The development of a tidal inlet by spit construction across an embayment usually occurs early in the evolution of a coast. The sediment to form these spits may have come from erosion of the nearby headlands, discharge from rivers, or from the landward movement of sand from inner shelf deposits. Most barriers along the coast of the United States and elsewhere in the world are 3,000–5,000 years old coinciding with a deceleration of rising sea level. It was then that spits began enclosing portions of the irregular rocky coast of New England, the West Coast, parts of Australia, and many other regions of the world. As a spit builds across a bay, the opening to the bay gradually decreases in width and in cross-sectional area. It may also deepen. Coincident with the decrease in size of the opening is a corresponding increase in tidal flow. The tidal prism of the bay remains approximately constant, so as the opening gets smaller, the current velocities must increase. A tidal inlet is formed as the spit reaches a stable configuration.

Drowned river valleys

Tidal inlets have formed at the entrance to drowned river valleys due to the growth of spits and the development of barrier islands which have served to narrow the mouths of the estuaries. It has been shown through stratigraphic studies, particularly along the East Coast of the United States, that in addition to drowned river valleys, many tidal inlets are positioned in paleo river valleys in which there is no river leading to this site today (Halsey, 1979). These are old river courses that were active during the Pleistocene when sea level was lower and they were migrating across the exposed continental shelf. Tidal inlet become situated in these valleys because tidal currents easily remove the sediment filling the valleys.

Tidal inlet migration

Some tidal inlets have been stable since their formation, whereas others have migrated long distances along the shore. In New England and along other glaciated coasts, stable inlets are commonly anchored next to bedrock outcrops or resistant glacial deposits. Along the California coast most tidal inlets have formed by spit construction across an embayment with the inlet becoming stabilized adjacent to a bedrock headland. In coastal plain settings, stable inlets are commonly positioned in former river valleys. One factor that appears to separate migrating inlets from stable is the depth to which the inlet throat has eroded. Deeper inlets are often situated in consolidated sediments that resist erosion. The channels of shallow migrating inlets are eroded into sand.

Although the vast majority of tidal inlets migrate in the direction of dominant longshore transport, there are some inlets that migrate updrift (Aubrey and Speer, 1984). In these cases, the drainage of backbarrier tidal creeks control flow through the inlet. When a major backbarrier tidal channel approaches the inlet at an oblique angle, the ebb-tidal currents coming from this channel are directed toward the margin of the inlet throat. If this is the updrift side of the main channel, then the inlet will migrate in that direction. This is similar to a river where strong currents are focused along the outside of a meander bend causing erosion and channel migration. Inlets that migrate updrift are usually small to moderately sized and occur along coasts with small to moderate net sand longshore transport rates.

Tidal inlet relationships

Tidal inlets throughout the world exhibit several consistent relationships that have allowed coastal engineers and marine geologists to formulate predictive models: (1) Inlet throat cross-sectional area is closely related to tidal prism, and (2) Ebb-tidal delta volume is a function of tidal prism.

Inlet throat area–tidal prism relationship

The size of a tidal inlet is tied closely to the volume of water going through it (Figure T20(A); O'Brien, 1931, 1969). Although inlet size is primarily a function of tidal prism, to a lesser degree inlet cross-sectional area is also affected by the delivery of sand to the inlet channel. For example, at jettied inlets tidal currents can more effectively scour sand from the inlet channel and therefore they maintain a larger throat cross section than would be predicted by the O'Brien Relationship.

Similarly, for a given tidal prism, Gulf Coast inlets have larger throat cross sections than Pacific Coast inlets. This is explained by the fact that wave energy is greater along the West Coast and therefore the delivery of sand to these inlets is higher than at Gulf Coast inlets. Jarrett (1976) has improved the tidal prism-inlet cross-sectional area regression equation for US inlets, separating, into three classes the low-energy Gulf Coast inlets, moderate-energy East Coast inlets, and higher-energy West Coast inlets. Even better correlations are achieved when structured inlets are distinguished from natural inlet.

Variability. It is important to understand that the dimensions of the inlet channel are not static but rather the inlet channel enlarges and contracts slightly over relatively short-time periods (<1 year) in response to changes in tidal prism, variations in wave energy, effects of storms, and other factors. For instance, the inlet tidal prism can vary by more than 30% from neap to spring tides due to increasing tidal ranges. Consequently, the size of the inlet varies as a function of tidal phases. Along the southern Atlantic Coast of the United States water temperatures may fluctuate seasonally by 35–40°F. This and other factors cause the surface coastal waters to expand, raising mean sea level by 30 cm or more. In the summer and early fall, when mean sea level reaches its highest seasonal elevation, spring tides may flood backbarrier surfaces that normally are above tidal inundation. This produces larger tidal prisms, stronger tidal currents, increased channel scour, and larger inlet cross-sectional areas. At some Virginia inlets this condition increases the inlet throat by 5–15% (Byrne *et al.*, 1975). Longer-term (>1 year) changes in the cross section of inlets are related to inlet migration, sedimentation in the backbarrier, morphological changes of the ebb-tidal delta, and human influences.

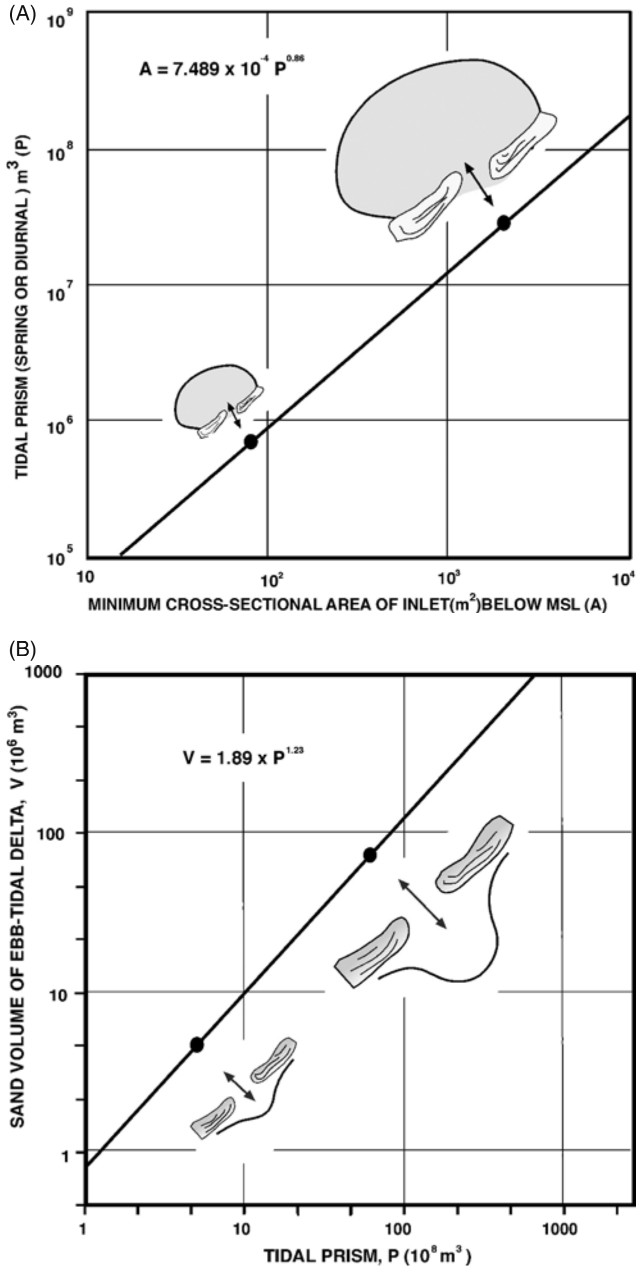

Figure T20 (A) Graph depicting relationship between tidal prism and inlet throat cross-sectional area (data after O'Brien, 1969). (B) Graph showing correspondence between tidal prism and volume of the ebb-tidal delta (data after Walton and Adams, 1976).

Ebb-tidal delta volume–tidal prism relationship

In the mid-1970s, Walton and Adams (1976) showed that the volume of sand contained in the ebb-tidal delta is closely related to the tidal prism (Figure T20(B)). Walton and Adams also showed that the relationship was improved slightly when wave energy was taken into account in a manner similar to Jarrett's divisions. Waves are responsible for transporting sand back onshore thereby reducing the volume of the ebb-tidal delta. Therefore, for a given tidal prism, ebb-tidal deltas along the West Coast contain less sand than do equal sized inlets along the Gulf or East Coast.

Variability. The Walton and Adams Relationship works well for inlets all over the world. However, field studies have shown that the volume of sand comprising ebb-tidal deltas changes through time due to the effects of storms, changes in tidal prism, or processes of inlet sediment bypassing (FitzGerald *et al.*, 1984). When sand is moved past a tidal inlet, it is commonly achieved by large bar complexes migrating from the ebb delta and attaching to the landward inlet shoreline. These large bars may contain more than 300,000 m^3 of sand and represent more than 10% of sediment volume of the ebb-tidal delta (FitzGerald, 1988; Gaudiano and Kana, 2000).

Sand transport patterns

The movement of sand at a tidal inlet is complex due to reversing tidal currents, effects of storms, and interaction with the longshore transport system. The inlet contains short- and long-term reservoirs of sand varying from the relatively small sandwaves flooring the inlet channel that migrate meters each tidal cycle to the large flood-tidal delta shoals where some sand is recirculated but the entire deposit may remain stable for hundreds or even thousands of years. Sand dispersal at tidal inlets is complicated because in addition to the onshore–offshore movement of sand produced by tidal and wave-generated currents, there is constant delivery of sand to the inlet and transport of sand away from the inlet produced by the longshore transport system. In the discussion below the patterns of sand movement at inlets are described including how sand is moved past a tidal inlet.

General sand dispersal trends

The ebb-tidal delta has segregated areas of landward versus seaward sediment transport that are controlled primarily by the way water enters and discharges from the inlet as well as the effects of wave-generated currents. During the ebbing cycle the tidal flow leaving the backbarrier is constricted at the inlet throat causing the currents to accelerate in a seaward direction. Once out of the confines of the inlet, the ebb flow expands laterally and the velocity slows. Sediment in the main ebb channel is transported in a net seaward direction and eventually deposited on the terminal lobe due to this decrease in current velocity. One response to this seaward movement of sand is the formation of ebb-oriented sandwaves having heights of 1–2 m.

In the beginning of the flood cycle, the ocean tide rises while water in the main ebb channel continues to flow seaward as a result of momentum. Due to this phenomenon, water initially enters the inlet through the marginal flood channels, which are the pathways of least resistance. The flood channels are dominated by landward sediment transport and are floored by flood-oriented bedforms. On both sides of the main ebb channel, the swash platform is most affected by landward flow produced by the flood-tidal currents and breaking waves. As waves shoal and break, they generate landward flow, which augments the flood-tidal currents but retards the ebb-tidal currents. The interaction of these forces acts to transport sediment in net landward direction across the swash platform. In summary, at many inlets there is a general trend of seaward sand transport in the main ebb channel, which is countered by landward sand transport in the marginal flood channels and across the swash platform.

Inlet sediment bypassing

Along most open coasts, particularly in coastal plain settings, angular wave approach causes a net movement of sediment, which along much of the East Coast of the United States varies from 100 to 200,000 m^3/yr. The manner whereby sand moves past tidal inlets and is transferred to the downdrift shore is called inlet sediment bypassing. The primary mechanisms of sand bypassing natural inlets include: (l) Stable inlet processes, (2) Ebb-tidal delta breaching, and (3) Inlet migration and spit breaching. One of the end products in all the different mechanisms is the landward migration and attachment of large bar complexes to the inlet shore. Discussion of this topic can be found in FitzGerald (1982) and FitzGerald *et al.* (2000).

Stable inlet processes. This mechanism of sediment bypassing occurs at inlets that do not migrate and whose main ebb channels remain approximately in the same position. Sand enters the inlet by: (1) wave action along the beach, (2) flood-tidal and wave-generated currents through the marginal flood channel, and (3) waves breaking across the channel margin linear bars. Most of the sand that is dumped into the main channel is transported seaward by the dominant ebb-tidal currents and deposited on the terminal lobe.

At lower tidal elevations waves breaking on the terminal lobe transport sand along the periphery of the delta toward the landward beaches in much the same way as sand is moved in the surf and breaker zones along beaches. At higher tidal elevations waves breaking over the terminal lobe create swash bars on both sides of the main ebb channel. The swash bars (50–150 m long, 50 m wide) migrate onshore due to the dominance of landward flow across the swash platform. Eventually, they attach to channel margin linear bars forming large bar complexes. Bar complexes tend to parallel the beach and may be more than a kilometer in length. They are fronted by a slipface (25–33 degrees), which may be up to 3 m in height.

The stacking and coalescence of swash bars to form a bar complex is the result of the bars slowing their onshore migration as they move up the nearshore ramp. As the bars gain a greater intertidal exposure, the wave bores, which cause their migration onshore, act over an increasingly shorter period of the tidal cycle. Thus, their rate of movement onshore decreases. Eventually the entire bar complex migrates onshore and welds to the upper beach. When a bar complex attaches to the downdrift inlet shore, some of this newly accreted sand is then gradually transported by wave action to the downdrift beaches, thus completing the inlet sediment bypassing process. It should be noted that some sand bypasses the inlet independent of the bar complex. In addition, some of the sand comprising the bar reenters the inlet via the marginal flood channel and along the inlet shoreline.

Ebb-tidal delta breaching. This means of sediment bypassing occurs at inlets with a stable throat position, but whose main ebb channels migrate through their ebb-tidal deltas like the wag of a dog's tail. Sand enters the inlet in the same manner as described above for *Stable inlet processes*. However, at these inlets the delivery of sediment by longshore transport produces a preferential accumulation of sand on the updrift side of the ebb-tidal delta. The deposition of this sand causes a deflection of the main ebb channel until it nearly parallels the downdrift inlet shore. This circuitous configuration of the main channel results in inefficient tidal flow through the inlet, ultimately leading to a breaching of a new channel through the ebb-tidal delta. The process normally occurs during spring tides or periods of storm surge when the tidal prism is very large. In this state the ebb discharge piles up water at the entrance to the inlet where the channel bends toward the downdrift inlet shoreline. This causes some of the tidal waters to exit through the marginal flood channel or flow across low regions on the channel margin linear bar. Gradually over several weeks or convulsively during a single large storm, this process cuts a new channel through the ebb delta thereby providing a more direct pathway for tidal exchange through the inlet. As more and more of the tidal prism is diverted through the new main ebb channel, tidal discharge through the former channel decreases causing it to fill with sand.

The sand that was once on the updrift side of the ebb-tidal delta and which is now on the downdrift side of the new main channel is moved onshore by wave-generated and flood-tidal currents. Initially, some of this sand aids in filling the former channel while the rest forms a large bar complex that eventually migrates onshore and attaches to the downdrift inlet shore. The ebb-tidal breaching process results in a large packet of sand bypassing the inlet. Similar to the stable inlets discussed above, some sand bypasses these inlets in a less dramatic fashion, grain by grain on a continual basis.

It is noteworthy that at some tidal inlets the entire main ebb channel is involved in the ebb-tidal delta breaching process, whereas at others just the outer portion of main ebb channel is deflected. In both cases, the end product of the breaching process is a channel realignment that more efficiently conveys water through the inlet, as well as sand being bypassed in the form of a bar.

Inlet migration and spit breaching. A final method of inlet sediment bypassing occurs at migrating inlets. In this situation, an abundant sand supply and a dominant longshore transport direction cause spit building at the end of the barrier. To accommodate spit construction, the inlet migrates by eroding the downdrift barrier shore. Along many coasts as the inlet is displaced further along the downdrift shore, the inlet channel to the backbarrier lengthens retarding the exchange of water between the ocean and backbarrier. This condition leads to large water level differences between the ocean and bay, making the barrier highly susceptible to breaching, particularly during storms. Ultimately, when the barrier spit is breached and a new inlet is formed in a hydraulically more favorable position, the tidal prism is diverted to the new inlet and the old inlet closes. When this happens, the sand comprising the ebb-tidal delta of the former inlet is transported onshore by wave action commonly taking the form of a landward migrating bar complex. It should be noted that when the inlet shifts to a new position along the updrift shore a large quantity of sand, has effectively bypassed the inlet. The frequency of this inlet sediment bypassing process is dependent on inlet size, rate of migration, storm history, and backbarrier dynamics.

Bar complexes. Depending on the size of the inlet, the rate of sand delivery to the inlet, the effects of storms, and other factors, the entire process of bar formation, its landward migration, and its attachment to the downdrift shore may take from 6 to 10 years. The volume of sand bypassed can range from 100,000 to over 1,000,000 m^3. The bulge in the shore that is formed by the attachment of a bar complex is gradually eroded and smoothed as sand is dispersed to the downdrift shore and transported back toward the inlet.

In some instances, a landward migrating bar complex forms a salt water pond as the tips of the arcuate bar weld to the beach stabilizing its onshore movement. Although the general shape of the bar and pond may be modified by overwash and dune building activity, the overall shore morphology is frequently preserved. Lenticular-shaped coastal ponds or marshy swales become diagnostic of bar migration processes and are common features at many inlets.

Tidal inlet effects on adjacent shorelines

In addition to the direct consequences of spit, accretion and inlet migration are the effects of volume changes in the size of ebb-tidal deltas, sand losses to the backbarrier, processes of inlet sediment bypassing, and wave sheltering of the ebb-tidal delta shoals (FitzGerald, 1988).

Number and size of tidal inlets

The degree to which barrier shore are influenced by tidal inlet processes is dependent on their size and number. As the O'Brien Relationship demonstrates, the size or cross-sectional area of an inlet is governed by its tidal prism. This concept can be expanded to include an entire barrier chain in which the size and number of inlets along a chain are primarily dependent on the amount of open water area behind the barrier and the tidal range of the region. In turn, these parameters are a function of other geological and physical oceanographic factors. Wave-dominated, microtidal coasts tend to have long barrier islands and few tidal inlets and mixed energy coasts have short stubby barriers and numerous tidal inlets (Hayes, 1975, 1979). Presumably, the mesotidal conditions produce larger tidal prisms than along microtidal coasts, which necessitate more holes in the barrier chain to let the water into and out of the backbarrier. Many coastlines follow this general trend but there are many exceptions due to the influence of sediment supply, large versus small bay areas, and other geological controls (Davis and Hayes, 1984).

Tidal inlets as sediment sinks

Tidal inlets not only trap sand temporarily on their ebb-tidal deltas, but they also are responsible for the longer-term loss of sediment moved into the backbarrier. At inlets dominated by flood-tidal currents, sand is continuously transported landward enlarging flood-tidal deltas and building bars in tidal creeks. Sand can also be transported into the backbarrier of ebb-dominated tidal inlets during severe storms. During these periods increased wave energy produces greater sand transport to the inlet channel. At the same time the accompanying storm surge increases the water surface slope at the inlet resulting in stronger than normal flood tidal currents. The strength of the flood currents coupled with the high rate of sand delivery to the inlet results in landward sediment transport into the backbarrier. Along the Malpeque barrier system in the Gulf of St. Lawrence, New Brunswick it has been determined that during a 33 year period 90% of the sand transferred to the backbarrier took place at tidal inlets and at former inlet locations along the barrier (Armon, 1979).

Sediment may also be lost at migrating inlets when sand is deposited as channel fill. If the channel scours below the base of the barrier sands, then the beach sand, which fills this channel, will not be replaced entirely by the deposits excavated on the eroding portion of the channel. Because up to 40% of the length of barriers is underlain by tidal inlet fill deposits ranging in thickness from 2 to 10 m (Moslow and Heron, 1978; Moslow and Tye, 1985) this volume represents a large, long-term loss of sand from the coastal sediment budget. Another major process producing sand loss at migrating inlets is associated with the construction of recurved spits that build into the backbarrier. For example, along the East Friesian Islands recurved spit development has caused the lengthening of barriers along this chain by 3–11 km since 1650. During this stage of barrier evolution the large size of the tidal inlets permitted ocean waves to transport large quantities of sand around the end of the barrier forming recurves that extend far into the backbarrier. Due to the size of the recurves and the length of barrier extension, this process has been one of the chief natural mechanisms of bay infilling (FitzGerald and Penland, 1987).

Changes in ebb-tidal delta volume

Ebb-tidal deltas represent huge reservoirs of sand that may be comparable in volume to that of the adjacent barrier islands along mixed-energy coasts (i.e., northern East and West Friesian Islands, Massachusetts, southern New Jersey, Virginia, South Carolina, and Georgia). For instance, the ebb-tidal delta volume of Stono and North Edisto Inlets in South Carolina is 197×10^6 m^3 and the intervening Seabrook-Kiawah Island barrier complex contains 252×10^6 m^3 of sand (Hayes *et al.*, 1976). In this case, the deltas comprise 44% of the sand in the combined inlet-barrier system. The magnitude of sand contained in ebb-tidal deltas suggests that small changes in their volume dramatically affect the sand supply to the landward shorelines.

A transfer of sand from the barrier to the ebb-tidal delta takes place when a new tidal inlet is opened, such as the formation of Ocean City Inlet when Assateague Island, Maryland was breached during the 1933 Hurricane. Initially, the inlet was only 3 m deep and 60 m across but quickly widened to 335 m when it was stabilized with jetties in 1935. Since the inlet formed more than 14 million cubic meters of sand have been deposited on the ebb-tidal delta. Trapping the southerly longshore movement of sand by the north jetty and growth of the ebb-tidal delta have led to serious erosion along the downdrift beaches. The northern end of Assateague Island has been retreating at an average rate of 11 m per year. The rate of erosion lessened when the ebb tidal delta reached an equilibrium volume and the inlet began to bypass sand (Stauble and Cialone, 1996).

In contrast to the cases discussed above, the historical decrease in the inlet tidal prisms along the East Friesian Islands has had a beneficial effect on this barrier coast. From 1650 to 1960 the reclamation of tidal flats and marshlands bordering the German mainland as well as natural processes, such as the building and landward extension of recurved spits, decreased the size of the backbarrier by 80%. In turn, the reduction in bay area decreased the inlet tidal prisms, which led to smaller sized inlets, longer barrier islands, and smaller ebb-tidal deltas. Wave action transported ebb-tidal delta sands onshore as tidal discharge decreased. This process increased the supply of sand to the beaches and aided in lengthening of the barriers (FitzGerald *et al.*, 1984).

Wave sheltering

The shallow character of ebb-tidal deltas provides a natural breakwater for the landward shore. This is especially true during lower tidal elevations when most of the wave energy is dissipated along the terminal lobe. During higher tidal stages intertidal and subtidal bars cause waves to break offshore expending much of their energy before reaching the beaches onshore. The sheltering effect is most pronounced along mixed-energy coast where tidal inlets have well-developed ebb-tidal deltas.

The influence of ebb shoals is particularly well illustrated by the history of Morris Island, South Carolina that forms the southern border of Charleston Harbor. Before human modification, the entrance channel to the harbor paralleled Morris Island and was fronted by an extensive shoal system. In the late 1800s jetties were constructed at the harbor entrance to straighten, deepen, and stabilize the main channel. During the period prior to jetty construction (1849–80) Morris Island had been eroding at an average rate of 3.5 m/yr. After the jetties were in place the shoals eroded and gradually diminished in size, so did the protection they afforded Morris Island, especially during storms. From 1900 to 1973 Morris Island receded 500 m at its northeast end increasing to 1,100 m at its southeast end, a rate three times what it had been prior to jetty construction (FitzGerald, 1988).

Effects of inlet pediment bypassing

Tidal inlets interrupt the wave-induced longshore transport of sediment along the coast, affecting both the supply of sand to the downdrift beaches and the position and mechanisms whereby sand is transferred to the downdrift shores. The effects of these processes are exhibited well along the Copper River Delta barriers in the Gulf of Alaska. From east to west along the barrier chain the width of the tidal inlets increases as does the size of the ebb-tidal deltas (Hayes, 1979). In this case, the width of the inlet can be used as a proxy for the inlet's cross-sectional area. These trends reflect an increase in tidal prism along the chain, which is caused by an increase in bay area from east to west while tidal range remains constant. Also quite noticeable along this coast is the greater downdrift offset of the inlet shore in a westerly direction. This morphology is coincident with an increase in the degree of overlap of the ebb-tidal delta along the downdrift inlet shoreline. The offset of the inlet shore and bulbous shape of the barriers are produced by sand being trapped at the eastern, updrift end of the barrier. The amount of shore progradation (build out) is a function of inlet size and extent of its ebb-tidal delta. What we learn from the sedimentation processes along the Copper River Delta barriers is that tidal inlets can impart a very important signature on the form of the barriers (FitzGerald, 1996).

Drumstick barrier model. In an investigation of barrier islands shores in mixed energy settings throughout the world, Hayes (1979) noted that many barriers exhibit a drumstick barrier island shape. In this model, the meaty portion of the drumstick barrier is attributed to waves bending around the ebb-tidal delta producing a reversal in the longshore transport direction. This process reduces the rate at which sediment bypasses the inlet, resulting in a broad zone of sand accumulation along the updrift end of the barrier. The downdrift, or thin part of the drumstick, is formed through spit accretion. Later studies demonstrated that landward-migrating bar complexes from the ebb-tidal delta determine barrier island morphology and overall shore erosional–depositional trends, particularly in mixed energy settings.

Studies of the Friesian Islands demonstrate that inlet processes exert a strong influence on the dispersal of sand and in doing so dictate barrier form (FitzGerald *et al.*, 1984). In addition to drumsticks, the East Friesian Islands exhibit many other shapes. Inlet sediment bypassing along this barrier chain occurs, in part, through the landward migration of large swash bars (>1 km in length) that deliver up to 300,000 m^3 of sand when they weld to the beach. In fact, it is the position where the bar complexes attach to the shore that determines the form of the barrier along this coast. If the ebb-tidal delta greatly overlaps the downdrift barrier, then the bar complexes may build up the barrier shore some distance from the tidal inlet, forming *humpbacked barriers*. If the downdrift barrier is short and the ebb-tidal delta fronts a large portion of the downdrift barrier, then bar complexes weld to the downdrift end of the barrier forming *downdrift bulbous barriers*.

Human influences

Dramatic changes to inlet beaches can also result from human influences including the obvious consequences of jetty construction that reconfigures an inlet shore. By preventing or greatly reducing an inlet's ability to bypass sand, the updrift beach progrades while the downdrift beach, whose sand supply has been diminished or completely cut off, erodes. There can also be more subtle human impacts that can equally affect inlet shores, especially those associated with changes in inlet tidal prism, sediment supply, and the longshore transport system. Nowhere are these types of impacts better demonstrated than along the central Gulf Coast of Florida where development has resulted in the construction of causeways, extensive backbarrier filling and dredging projects, and the building of numerous engineering structures along the coast. A detailed study of this region by Barnard and Davis (1999) has revealed that since the late-1980s 17 inlets have closed along this coast and at least five closures can be traced to human influences caused primarily by changes in inlet tidal prism. For example, access to several barriers has been achieved through the construction of causeways that extend from the mainland across the shallow bays. Along most of their lengths the causeways are dike-like structures that partition the bays, thereby changing bay areas and inlet tidal prisms. In some instances, tidal prisms were reduced to a critical value causing inlet closure. At these sites, the tidal currents were unable to remove the sand dumped into the inlet channel by wave action. Similarly, when the Intracoastal Waterway was constructed along the central Gulf Coast of Florida in the early 1960s, the dredged waterway served to connect adjacent backbarrier bays thereby changing the volume of water that was exchanged through the connecting inlets. The Intracoastal Waterway lessened the flow going through some inlets while at the same time increased the tidal discharge of others. This resulted in the closure of some inlets and the enlargement of others (Barnard and Davis, 1999).

TIDAL FLATS

Introduction and definition

Tidal flats are low-gradient tidally inundated coastal surfaces. Jackson (1997) defines them as extensive, nearly horizontal, marshy or barren tracts of land alternately covered and uncovered by the tide, and consisting of unconsolidated sediment. Tidal flats may be muddy, sandy, gravelly, or covered in shell pavements, and compositionally they may be underlain by siliciclastic or carbonate sediments. Depending on climate, tidal level, substrate and salinity, tidal flats may be covered biologically in parts by salt marsh, mangroves, sea grass, algal mats, microbial mats, biofilms, as well as mussel beds, oyster beds and reefs, and worm-tube beds and reefs, and inhabited by a burrowing benthos of molluscs, polychaetes, and crustacea.

Tidal flats have been of great interest to sedimentologists and stratigraphers as coastal systems that are readily accessible to sampling and study, and rich in processes and products resulting from oceanographic, sedimentologic, geohydrologic, hydrochemical, and biotic interactions (Ginsburg, 1975; Klein, 1976; Alexander *et al*., 1998; Black *et al*., 1998). They contrast with other steeper gradient wave-dominated sedimentary coasts, such as sandy beaches, composed dominantly of sand, and with a relatively limited biota, because with their generally lower energy conditions, and less scope for physical reworking, tidal flats develop a profusion of natural history coastal features. For instance, there are the sedimentologic products of interactions between waves and tides (e.g., cross-laminated sand, ripple-laminated sand, lenticular bedding, flazer bedding, laminated mud, ripple-laminated silt in clay), the products of interactions between sediments and biota (e.g., various burrow forms zoned tidally across the shore, various types of root-structuring, skeletal remains related to tidal levels), the geomorphic products of tides (e.g., tidal runoff on low gradient slopes to form meandering tidal creeks), and the products of hydrochemical interactions with sediments (e.g., dissolution of carbonate by acidic pore water; cemented crusts and their breccia and intraclast derivatives; carbonate nodules; gypsum precipitates; and products of redox reactions such as biologically mediated precipitation of iron sulfide). For stratigraphers and students of sedimentary rocks, identifying tidal flats in the geologic record is often an important step in the reconstruction of paleoenvironments, the location of facies associated with coastlines, and the recognition of such markers in stratigraphic sequences in basin analyses. Tidal flat signatures derived from studies of modern environments provide important analogs in such analyses.

Coastal settings of tidal flats

Tidal flats around the globe occur in a variety of regional geomorphic settings (Table T4 and Figure T21). Since they are surfaces exposed and inundated by tides, they may simply be part of larger coastal systems, that is, the shores of deltas, estuaries, lagoons, gulfs, bays, straits, rias, sounds, and cuspate forelands. Alternatively, they may be the sole coastal form developed along an open coast or broad embayment, or may comprise wholly tidal lagoons leeward of barriers. The best-developed tidal flats occur along estuarine coasts, protected embayments, or barred lagoons, where the shore slopes are gentle due to sediment accretion, and tides are large. Along many coasts, tidal flats are part of prograded shores (Kendall and Skipwith, 1968; Thompson, 1968; Hagan and Logan, 1975; Reineck and Singh, 1980); but in some instances, they may comprise modern sediment veneers on wave or tidally cut unconformities on rock or Pleistocene sediment, or earlier Holocene sediments (Semeniuk, 1981).

Tides and tidal levels

The tidal ranges that expose tidal flats vary globally from less than 1 m to ca. 15 m amplitude, and are diurnal (one tide daily), semidiurnal (two tides daily), or mixed (two tides daily, but with inequality between tide maxima and tide minima across the day). Over a lunar cycle, tides vary from a lower amplitude neap range (during quarter and three-quarter moon phases) to a higher amplitude spring range (during new and full moon phases). Higher than normal tides occur during equinoctial periods, and in response to the Lunar Nodal Periodicity. As a result, and depending on shore slope, tidal flat width may vary from being a narrow coastal strip, to being broad and expansive coastal forms.

Part of the coast emergent during low tide and submerged during high tide is the *intertidal* zone. That part of the coast permanently submerged below the low-water line is the *subtidal* zone. That occurring above the zone of high-tide inundation is the *supratidal* zone. Some authors consider the "supratidal zone" as the zone above the mean high-water line but sometimes under the water during extremely high tides, or even spring tides, but it is preferable to refer to all gently inclined surfaces and terrain *above* the highest tides as supratidal, and to treat all surfaces flooded by both neap, spring, and equinoctial spring tides as intertidal, and to separate these various tidal zones and levels.

Tidal ranges have been classed by Davies (1980) into three groups: *microtidal* <2 m, *mesotidal* 2–4 m, and *macrotidal* >4 m. While this classification has been generally accepted, large tidal ranges >8 m, might be further classed as *extreme macrotidal*. Generally, tides are microtidal along open oceanic coasts, and tend towards macrotidal where tides are semidiurnal. Tidal range amplification also may occur due to bay geometry and coastal constriction. For example, the Bay of Fundy, in Nova Scotia, because of its basin geometry, amplifies the tide from ca. 5.4 m at entrance to the bay to 15 m at its head.

Zones across the tidal flats are best exhibited in macrotidal settings, where there are marked distinctions in slope, sediments, and biology between the interval of spring tidal and neap tidal range. On microtidal flats, these various differences related to tidal levels are less pronounced.

Various levels within a tidal flat, often delineated by biological and/or sediment zones, can be distinguished as follows:

- low tidal flats—exposed by the mean and extreme low spring tides, generally underlain by sand, and vegetation free,
- middle tidal flats—the flats and low gradient slopes centered around mean sea level, exposed and inundated by neap tides; the upper parts of these flats may be vegetated by samphire in temperate latitude areas, and by mangrove in tropical latitudes,
- high tidal flats—inundated by the mean and extreme high spring tides, generally underlain by mud, and vegetated by salt marsh or mangrove, or in more arid settings, vegetation free and salt encrusted (salt flat).

Typical cross sections through some microtidal to extreme macrotidal flats are shown in Figure T22.

Tidal flats and their particle sizes and sediment composition

Tidal flats may be underlain by mud, sand, rock gravel, and shell pavements, or mixtures of these. Often, where all particle sizes are present, there is a zonation of sediment types across the flats, or an interlayering at a specific tidal level, but in many instances, one sediment type may dominate across the entire tidal flat. This partitioning of sediments across the tidal flat lends itself to a classification of tidal flats, or zones within tidal flats, according to particle size. For example, those composed wholly of mud may be termed muddy tidal flats, and those composed wholly of sand are sandy tidal flats. Tidal level zones within the tidal flat may be classed according to substrate, for example, sandy low tidal flats, muddy high tidal flats. A range of possible tidal flat types based on substrate, with field examples, is presented in Table T5.

In regard to sediment composition, two major groups are recognized: *siliciclastic tidal flats*, composed of terrigenous sediments such as quartz sand, quartz silt, and phyllosilicate clay, and *carbonate tidal flats*, composed of carbonate silt and clay, various sand-sized carbonate grains, and products of cementation (e.g., crusts, breccias, intraclasts). These major groups reflect two extremes in settings: an abundant supply of terrigenous sediment to the tidal coast, such as in deltas or estuaries versus a low supply relative to the rate of carbonate sediment production (as along terrigenous sediment starved coasts). From a historical perspective, the majority of earlier investigations of tidal flats were centered on siliciclastic systems, and much information emerged from studies in the North Sea (Reineck, 1972; Evans, 1975). Later,

Table T4 Some well-known tidal flats, and some extreme macrotidal flats, ordered in tidal range

Tidal flat location	Tidal range (m)	Composition	Tidal flat setting
Bay of Fundy (Nova Scotia)	15.0 m Extreme Macrotidal	Siliciclastic	Broad tidal flats of gravel, sand and mud, with local salt marsh, peripheral to an estuarine gulf in a humid temperate climate (Knight and Dalrymple, 1975)
Bay of Mont St Michel (NW France)	15.0 m Extreme Macrotidal	Siliciclastic	Broad tidal flats of sand and mud, with salt marsh, within complex of funnel-shaped estuary in humid temperate climate (Larsonneur, 1975)
King Sound (NW Australia)	11.0 m Extreme Macrotidal	Siliciclastic	Broad tidal flats of sand and mud, with some cheniers, and erosional tidal channels, with mangrove; peripheral to a seasonal estuarine gulf in a semi-arid tropical climate (Semeniuk, 1981)
Roebuck Bay (NW Australia)	10.5 m Extreme Macrotidal	Carbonate	Broad tidal flats along semi-sheltered embayment, dominated by mud; erosional tidal channels, with mangrove; in a semi-arid subtropical climate (Semeniuk, 1993)
Gulf of California (USA)	6–8 to 10 m Macrotidal to extreme macrotidal	Siliciclastic	Broad tidal flats, dominated by mud, with intermittent beach ridges, with salt marsh; part of the Colorado River Delta within a gulf in a semiarid subtropical climate (Thompson, 1968)
The Wash (England)	7.0 m Macrotidal	Siliciclastic	Broad tidal flats of sand and mud, with salt marsh; along the shore of a large embayment in humid temperate climate (Evans, 1975)
Delta of the Klang and Langat Rivers (Malaysia)	4.5 m Macrotidal	Siliciclastic	Compound delta, with insular/peninsular development of tidal flats, traversed by tidal creeks with mangrove; in a humid tropical climate (Coleman *et al*., 1970)
The Jade and the Dutch Wadden Sea (North Sea)	2.6–4.1 m Mesotidal	Siliciclastic	Broad tidal flats of sand and mud, with salt marsh, leeward of barriers in humid temperate climate (Reineck, 1975)
Niger Delta (Western Africa)	1.0–2.8 m Microtidal	Siliciclastic	Extensive mangrove vegetated tidal flats of mud and sand, developed behind a beach barrier in a delta system in a humid tropical climate (Allen, 1970)
Gascoyne Delta (Western Australia)	2 m Microtidal	Siliciclastic	Local narrow tidal flats of sand and mud, with mangrove, fringing lagoons within a delta in an arid subtropical climate (Johnson, 1982)
Trucial Coast (western Persian Gulf)	2 m Microtidal	Carbonate	Broad tidal flats of carbonate muds and gypsum, with algal mats, salt marsh and mangroves, shoreward of prograding carbonate complex fringing a large gulf in an arid tropical climate (Purser, 1973)
Chesapeake Bay (eastern USA)	1.5–2.1 m Microtidal	Siliciclastic	Narrow to broad tidal flats, with salt marsh, within inlets and along the shore of an estuary in a humid temperate climate
Delmarva Peninsula to Sapelo Island (eastern USA)	<1 m Microtidal	Siliciclastic	Broad protected tidal flats, with salt marsh, leeward of barriers in a humid subtropical climate (Howard *et al*., 1972; Harrison, 1975)
Shark Bay (Western Australia)	0.5 m Microtidal	Carbonate	Local tidal flats of sand or pelleted mud, with salt marsh and algal mat, shoreward of prograding sea grass banks and hypersaline platforms in large elongate embayments in an arid subtropical climate (Hagan and Logan, 1975)
Andros Island (Bahamas)	0.5 m Microtidal	Carbonate	Broad tidal flats of pelleted mud, with mangrove, salt marsh and algal mat, developed capping the Bahama Bank Carbonate Complex in a humid subtropical climate (Shinn *et al*., 1969)

as interest in carbonate rocks grew during the 1960s, linked to their petroleum reservoir potential, a range of studies were undertaken in carbonate tidal flats (Shinn *et al*., 1969; Purser, 1973; Hagan and Logan, 1975; Shinn, 1983).

Generally, regardless of whether the tidal flats are dominantly siliciclastic or carbonate, their sediments commonly contain both siliciclastic *and* carbonate particles. In dominantly siliciclastic settings, there may be minor to moderate carbonate components of shell gravel, shell grit, skeletal sand (e.g., shell fragments, foraminifera), skeletal silt-sized material, and carbonate clay transported to or generated on the flats. Similarly, in dominantly carbonate environments there may be siliciclastic sand, mud, or gravel from oceanic, aeolian, or local erosional sources. The range and origin of mud, sand, and gravel-sized particles comprising tidal flat sediments are noted in Table T6.

Some of the best known siliciclastic tidal flats are along the North Sea coast, for example, the Jade and the Dutch Wadden Sea, The Wash in southeastern England, the Gulf of California, the Bay of Fundy, the compound high-tidal delta of the Klang and Langat Rivers, King Sound in northwestern Australia, Bay of Mont St. Michel in France (Klein, 1963; Thompson, 1968; Allen, 1970; Coleman *et al*., 1970; Reineck, 1972; Evans, 1975; Larsonneur, 1975; Semeniuk, 1981). With most of these examples, there is a grain size variation across the flats from sand in low tidal zones to mud in high tidal zones, with specific biogenic contributions in particular tidal zones, depending on climate setting and biogeography, and sediment types and sedimentary structures are dominantly the result of physical and biologic processes. With increase upslope in pore water salinity, particularly in semiarid and arid climates, the upper parts of siliciclastic tidal flats may develop carbonate nodules or gypsum crystals, or be salt encrusted.

Carbonate tidal flats generally occur in mid- to low latitude warm climates. The best known are Andros Island of the Bahama Banks (Shinn *et al*., 1969), the Trucial Coast along the Persian Gulf Coast (Kendall and Skipwith, 1968; Purser, 1973), and Shark Bay in northwestern Australia (Hagan and Logan, 1975). In these examples, there is little or no terrigenous influx from terrestrial sources to dilute the carbonate accumulation contributed by local biogenic and abiotic sources, and hence the sediments are carbonate-rich. There are a range of diagnostic sediments and structures formed on carbonate tidal flats as result of tidal deposition, biogenic contribution and alteration, and primary and secondary effects of cementation. Cementation of sediments, and formation of their (secondary) structural and sedimentary derivatives is an important and common feature on upper parts of carbonate tidal flats. Under conditions of hypersalinity on the higher zones of such tidal flats, precipitation of carbonate-minerals often is prevalent, and in contrast to siliciclastic tidal flats, since there is an abundance of carbonate grains to act as nuclei for interstitial cements, there is a plethora of diagenetic and sedimentary products such as cemented layers and crust development, progressing to surface mounding, formation of compressional polygons and teepees, and then leading to fragmentation, brecciation, and formation of intraclasts. Carbonate tidal flats set in the

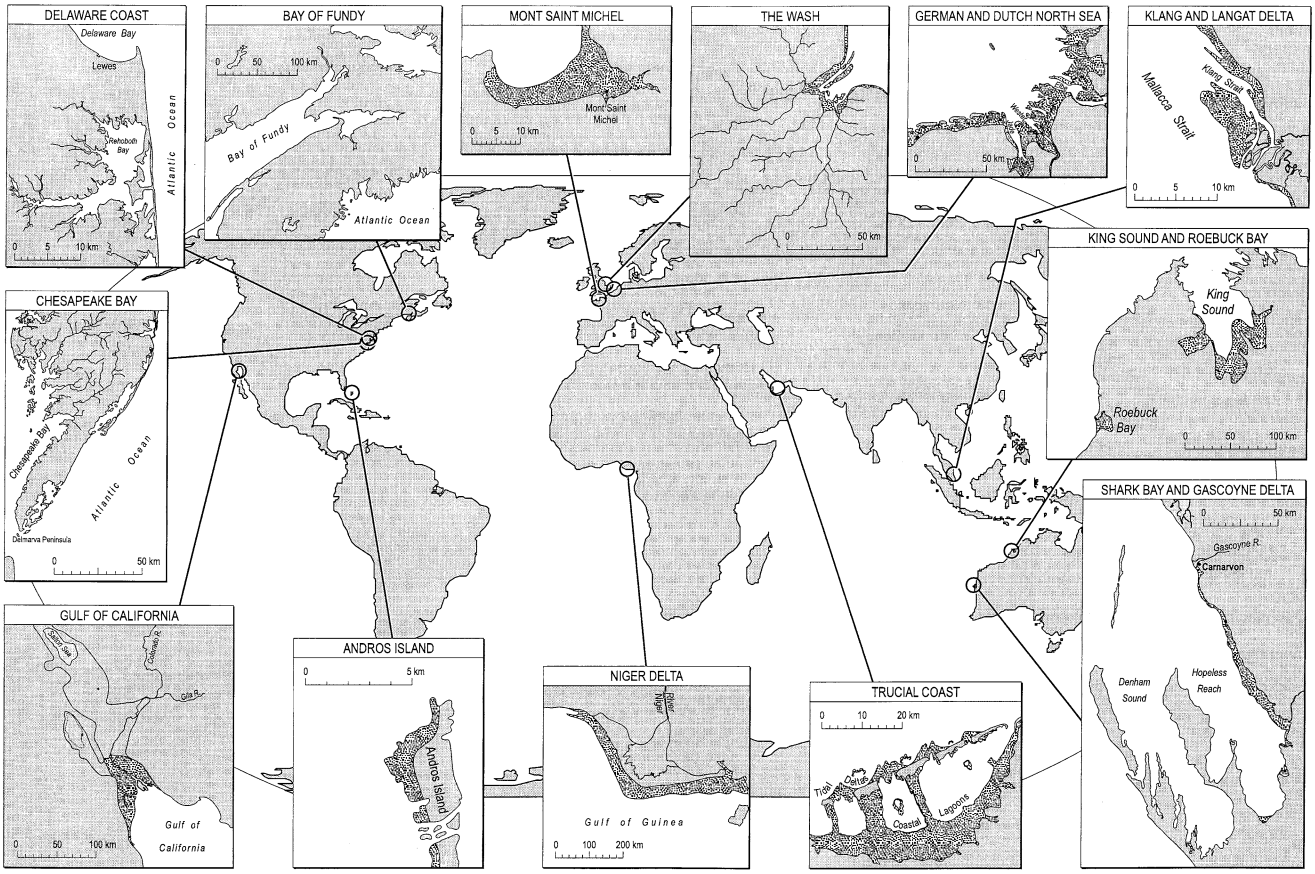

Figure T21 Location, settings, and sizes of various tidal flats around the globe. Table T4 provides more detailed information and references.

more arid climates also develop evaporitic mineral suites such as beds of gypsum nodules, gypsum platey crystals, gypsum mud, halite crusts.

Geomorphic features of tidal flats

While the surface of a tidal flat at the macroscale generally is flat to gently inclined, there may be a range of mesoscale to microscale features therein (Table T7, Figure T23). At the macroscale, the tidal flat may exhibit varying degrees of slope (Figure T22), reflecting the effects of position within either the low and high spring tidal zones, or the neap tidal zone. For example, the low tidal zone may be nearly flat or very gently inclined, the middle tidal flat may be more moderately inclined, and the high tidal flat again may be nearly flat or very gently inclined.

At mesoscale, the geomorphic features of tidal flats may include local cliffs, cheniers, sand waves, shell mounds, skeletal reefs, and gullies, channels and creeks (also called tidal creeks). Cliffs, commonly cut into mud, often separate vegetated and vegetation-free tidal flat zones, but some cliffs are formed due to either the effect of wave energy concentrated at a specific tidal level, or the undercutting of mud through erosion of the underlying sand. Tidal creeks may be ramifying or meandering, with point bars and steep banks. At smaller scales, the surface of tidal flats may be planar and smooth, or hummocky to slightly irregular, or may exhibit linear scours, surface mounding and teepees, desiccation polygons, or mud cracks, produced physically, chemically, or biogenically.

Hydrology

The groundwater hydrology of tidal flats is important for several reasons. Interstitial pore water salinity gradients and moisture gradients, for instance, influence macrophytes (such as mangroves and samphires), microbial mats, and invertebrate biota in relation to their occurrence and zonation. Interstitial pore water salinity and moisture gradients also influence precipitation of evaporitic minerals. Microscale shallow groundwater hydrologic recharges and discharges influence development of sedimentary structures (e.g., seepage zones out of sand mounds to initiate sand erosion, or to initiate hydrochemical exchanges and cementation; formation of bubble sand). The hydrologic functioning of tidal flats additionally can drive geochemical processes that diagenetically modify sediments (e.g., formation of iron sulfide precipitation to form gray sediments, or the oxidation of buried iron sulfide impregnated vegetation to form goethite pseudomorphs).

Tidal flat groundwater levels fluctuate on a diurnal to semidiurnal basis, following the tides, with a dampened effect from mid-tidal levels to upslope. All tidal flat groundwater rises during flood tide, and of course is inundated on high tide. Recharge and discharge, and lateral groundwater flow through tidal flat sediments may be facilitated by specific lithologic layers, or stratigraphic intervals, and at the small scale by burrow and root structures.

Groundwater salinity across tidal flats is commonly zoned, generally with near marine water salinities at about mean sea level, unless the marine waters fronting the tidal flats are hypersaline (e.g., Shark Bay, Australia), grading to hypersaline and extremely hypersaline upslope, and in wet climates becoming fresh where tidal flats interact with terrestrial freshwater. The main source waters for groundwater of tidal flats are marine water, rain, and (through seepage and land overflow) land-derived freshwater. Evaporation, macrophyte transpiration, and increasing infrequency of tidal inundation upslope combine to develop a gradient of increasing salinity across tidal flats. This gradient results in zonation of biota, exemplified by zonation of mangroves, and in zonation of evaporitic minerals and pore water precipitates. Where marine waters are oceanic (ca. 35,000 ppm salinity) and evaporation is extreme, high tidal groundwater may reach 100,000–200,000 ppm salinity, that is, carbonate mineral and gypsum precipitating, but where source waters are already hypersaline, tidal flat groundwater reaches up to ca. 300,000 ppm salinity, resulting in precipitation of halite.

Key processes on tidal flats

Tidal flats are located at the triple junction between land, sea, and atmosphere. In this context, as low-gradient shores, they exhibit a myriad of

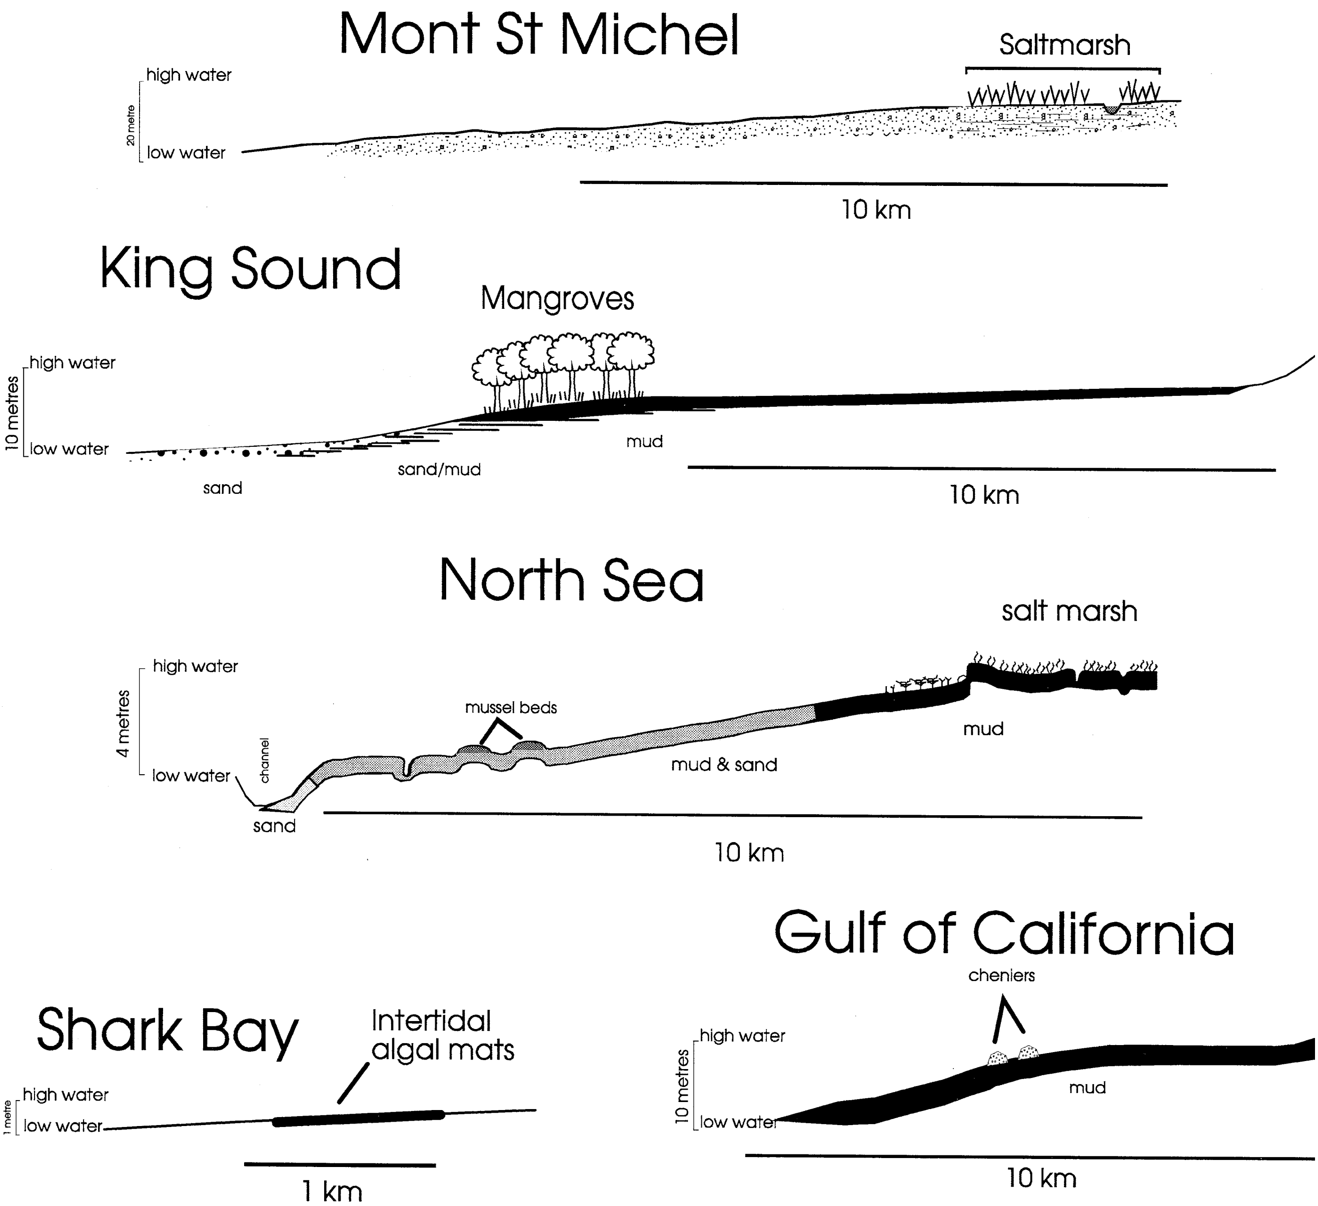

Figure T22 Profiles across various macrotidal to microtidal siliciclastic and carbonate tidal flats (see Table T4) showing nature of the slopes, sediments, vegetation, or morphology.

Table T5 Tidal flat types, according to substrate

Substrate type underlying tidal flat	Terminology	Examples
Whole tidal flats		
Mix of particle sizes across the whole tidal flat, or differentiation not intended	Tidal flat	North Sea, The Wash, Bay of Mont St. Michel, King Sound
Tidal flats wholly underlain mainly by		
mud	Muddy tidal flat	Gulf of California
sand	Sandy tidal flat	
gravel	Gravelly tidal flat	Parts of the Bay of Fundy
shelly pavement across tidal flat	Tidal shell pavement	
Specific zones on tidal flats		
High tidal flats wholly underlain mainly by mud	Muddy high-tidal flat	King Sound
Mid-tidal flats wholly underlain mainly by mud	Muddy mid-tidal flat	King Sound
Mid-tidal flats underlain mainly by mud and sand	Mixed mid-tidal flat	North Sea
Low tidal flats wholly underlain mainly by sand	Sandy low-tidal flat	North Sea; Bay of Mont St. Michel
Shelly pavement on specific zone of tidal flat, e.g., low tidal	Low-tidal shell pavement	Parts of Shark Bay
Crust pavement on specific zone of tidal flat, e.g., high tidal	High-tidal crust pavement	Dampier Archipelago
Breccia pavement on specific zone of tidal flat, e.g., high tidal	High-tidal breccia pavement	Parts of Shark Bay

Table T6 Types of sedimentary particles on tidal flats, and their origin

Sediment particle	Origin (information from various tidal flats)
Clay (<4 μm particle size)	
Phyllosilicate clay (kaolinite, illite, montmorillonite)	Fluvially delivered to the coastal system Reworked Pleistocene coastal deposits Reworking of glacial deposits Aeolian
Calcitic and aragonitic clay	Reworked, comminuted skeletons Precipitated from seawater Disintegrated calcareous algae
Goethite	Fluvially delivered to the coastal system Aeolian
Quartz clay	Aeolian
Amorphous silica	Diatom (*in situ* or transported)
Silt (4–63 μm particle size)	
Quartz, felspar, various silicate minerals	Fluvially delivered to the coastal system Reworked Pleistocene coastal deposits Reworking of glacial deposits Aeolian
Skeletal silt	Reworked and *in situ* comminuted shelly exoskeletons
Amorphous silica	Diatom (in situ or transported)
Sand (63–2,000 μm particle size)	
Quartz, felspar, various silicate minerals, rock fragments	Fluvially delivered to the coastal system Reworked Pleistocene coastal deposits Reworking of glacial deposits Aeolian
Skeletal sand	Comminuted to whole reworked and *in situ* exoskeletons, e.g., shell fragments, foraminifera
Carbonate sand (ooids, pellets)	Generated nearshore and reworked onto tidal flat, and for pellets, carbonate grain destruction by boring algae
Carbonate intraclast sand	Reworking of cemented carbonate crusts
Gravel (>2,000 μm particle size)	
Quartz pebbles, rock fragments	Fluvially delivered to the coastal system Reworked Pleistocene coastal deposits Reworking of glacial deposits
Mud pebbles and cobbles	Eroded tidal mud
Armored mud balls	Mud pebbles and cobbles with adhering gravel and shell
Skeletal gravel	Comminuted to whole, reworked and in situ shell
Carbonate intraclast gravel	Reworking of cemented carbonate crusts

Table T7 Geomorphic features of the tidal flats

Geomorphic, or surface feature	Origin
Microscale surface features (<meter sized)	
Smooth planar surface	Deposition on and erosion of the surface
Linear scours (mm to cm deep)	Tidal erosion
Slightly irregular	Tidal erosion of the surface, and/or bioexcavations by small biota and fish
Hummocky surface	Tidal erosion of the surface, and/or bioexcavations by stingrays, fish, and large burrowing benthos
Mud cracks	Desiccation
Surface moundings grading to teepees and brecciation	Mineral precipitation in surface sediments and resultant surface crust expansion
Mounded surface	Mineral precipitation in surface sediments
Mesoscale surface features (>meter-sized, up to tens of meters long)	
Meandering gullies, channels, creeks, meandering or ramifying	Tidal erosion, with local deposition on point bars
Crust lined, and locally brecciated meandering channels	Tidal erosion, with local deposition on point bars, with mineral precipitation in surface sediments and resultant surface crust expansion
Sand waves	Large bodies of sand developed in low tidal zones
Spits	Shoestring sand and sandy gravel body across tidal flat from local headland, formed by tidal currents and wave action
Cheniers	Isolated shoestring sand and sandy gravel body on tidal flat, variably formed by tidal currents, wave action, and storms/cyclones
Salting cliff	Small cliff, 30–100 cm high, cut in to salt marsh, marking junction between high-tidal salt marsh and vegetation-free mid-tidal to low-tidal flat
Mid-tidal cliff	Small cliff, up to 100 cm high, marking junction between mangrove front at ca. MSL and vegetation-free mid-tidal to low-tidal flat

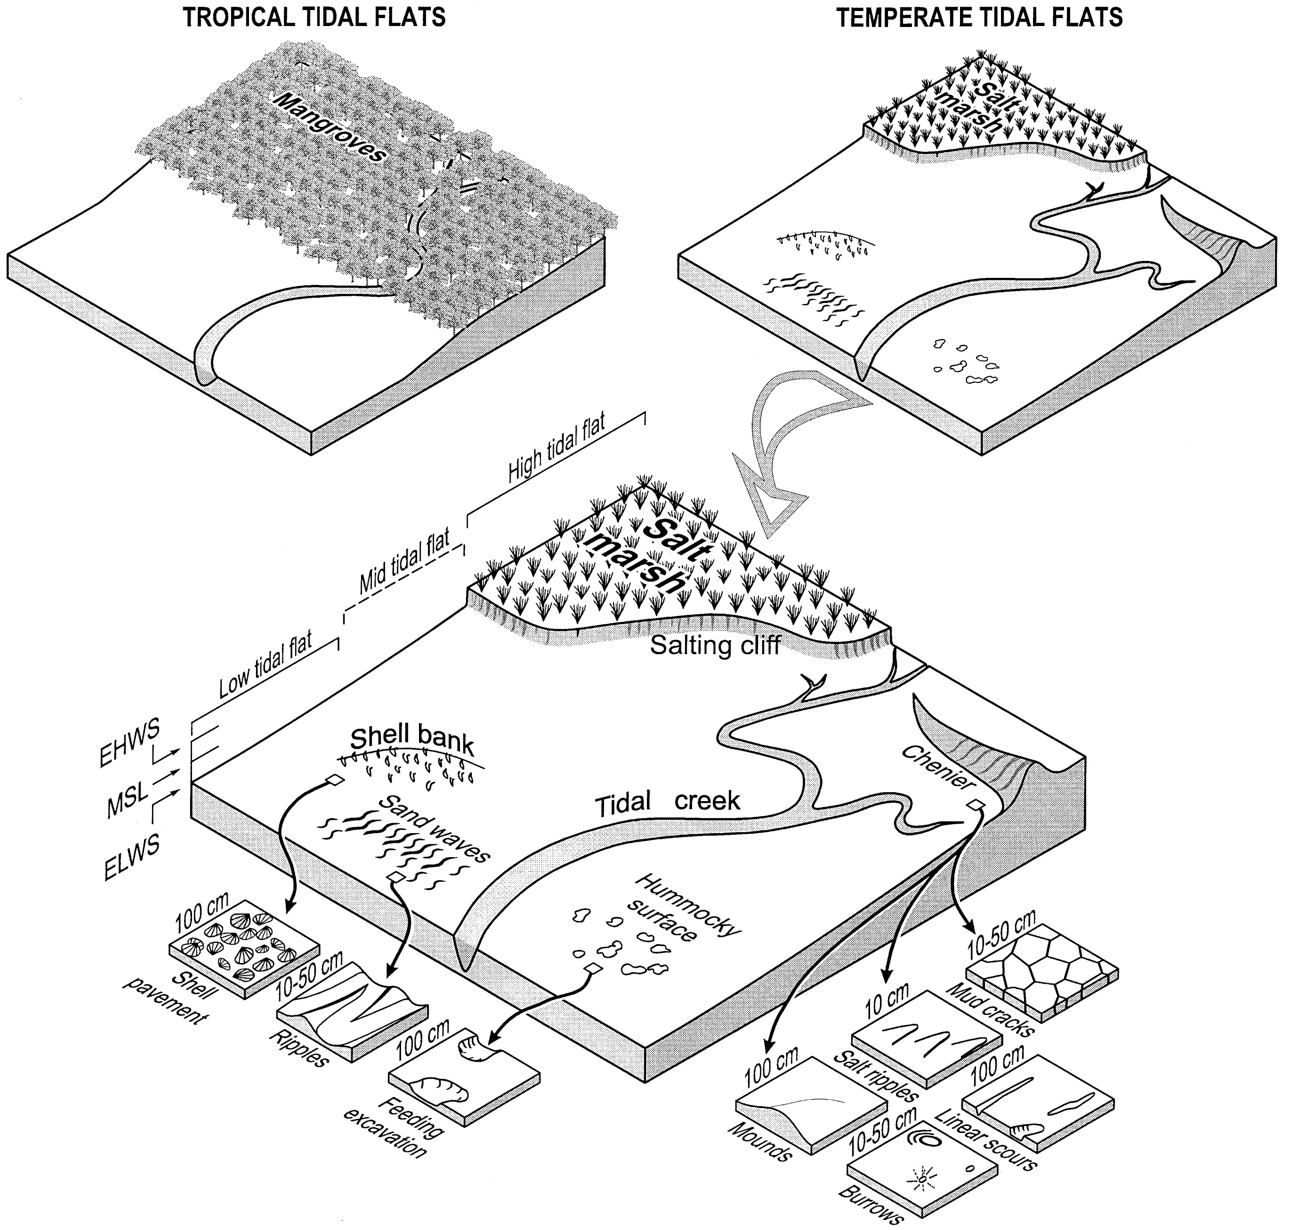

Figure T23 Generalized geomorphology of tidal flats. Macroscale geomorphology of tropical climate tidal flats with mangroves, and temperate climate tidal flats with salt marsh. More detail shown of mesoscale and microscale features of a temperate climate tidal flat.

products resulting from interactive, interrelated and overlapping exogenous and endogenous agents and processes, which include oceanographic, meteorologic, atmospheric, fluvial, hydrologic and hydrochemical, and biological processes (Table T8). These processes commonly are distributed along physicochemical gradients (e.g., tidal, wave, chemical) and operate on a range of basic sediment types such as mud, sand, and shell gravel to develop a complex of geomorphic, sedimentologic, and diagenetic products which are commonly zoned across the tidal flats and are often specific to a coastal setting, sediment setting, climate, and biogeography.

Oceanographic processes involve erosion, transport, and deposition associated with tidal currents, wave action, storms, and cyclones. Meteorologic/atmospheric processes involve evaporation, wind erosion, transport and deposition, rain, ice crystallization, and water temperature fluctuations. Fluvial processes include the delivery of sediment and freshwater to the shore, especially in estuaries and deltas. Hydrologic and hydrochemical processes involve the rising and falling of the water table under the tidal flat, the solution and precipitation of carbonate minerals, evaporite minerals and iron minerals, and redox reactions. Biological processes include: at the largest scale, the accumulation of beds of biogenic material (shell beds, biostromal reefs, and plant material), the modification of tidal current by macrophytes (e.g., mangroves) to induce sedimentation, and the trapping and binding of sediment by vegetation and algal mats; at intermediate scales, the burrow structuring and root-structuring of sediment; and at the smallest scales, the boring of shells, the pelletization of grains by endolithic algae, and the biomediation of the precipitation of minerals such as iron sulfides.

The dynamics of tidal currents is a major factor in the transport and deposition of sediment on tidal flats. Tidal currents transport mud in suspension, and sand by traction. The rise and fall of the tide, with periods of slack water, result in a systematic increasing, decreasing, zero flow, and then reversal of tidal currents. Transport of sand is effected during the main part of the flooding and ebbing tidal cycle when tidal currents are progressing to and regressing from their maximum velocities, with various bedforms developed as the currents systematically increase and then decrease across the tidal cycle resulting in the development of ripples, then megaripples, and then ripples. Deposition of mud is effected during periods of low current velocity and slack water (the times of near-zero to zero current velocities). Mud deposition is accentuated further by fluctuations in water temperature, since cold water and warm water have different viscosity which results in varying mud particle settling velocities (Krogel and Flemming, 1998).

Table T8 Key processes

Some selected processes	Examples of products on the tidal flat
Oceanographic	
Flood and ebb-tidal currents, and slack water	Deposition of mud from suspension, and sand transport by traction; silt ripples, sand ripples, sand waves and megaripples; laminated mud, lenticular bedding, and flazer bedding; scour, and cut-and -fill; tidal creek formation; erosion of mud beds along creek banks and clifflines to form mud ball conglomerate; rolling of mud balls on sandy/gravelly floors to form armored mud balls
Waves	Winnowed sand sheets and shell gravel; rippling; erosion of clifflines cut into mud
Meteorologic/atmospheric	
Wind (erosion, transport, deposition)	Sand transport and fall-out deposition onto tidal flats; formation of adhesion ripples
Evaporation minerals	Mud desiccation and cracking; increasing pore water salinity of groundwater; precipitation of minerals
Rain, ice crystallization	Rain imprints; ice crystal imprints; cryogenic disruption
Water temperature variation	Mud deposition from suspension; mortality of benthos
Groundwater hydrologic/hydrochemical	
Rising and falling of tide	Wetting and drying to form desiccated sediment; development of bubble sand
Solution/precipitation of carbonate minerals	Shell voids, other vughs; cemented crusts, teepees
Evaporite mineral precipitation	Beds of nodular to platey crystalline gypsum; precipitation of gypsum disrupting primary structures
Iron mineral precipitation	Staining of sediment to dark gray with iron sulfide; staining of sediments to orange-brown with iron oxides
Biological	
Accumulation of shell beds and biostromal reefs	Shelly sediments and coquinas, and skeletal biostromes
Plant detritus accumulation	Organic rich sediments, peat
Sediment trapping and binding by vegetation and algal mats	Root-structured sediment; algal-laminated sediment
Feeding/foraging by nekton	Pocked, excavated and hummocky surfaces
Burrowing by benthos	Burrow-structured to fully bioturbated sediment

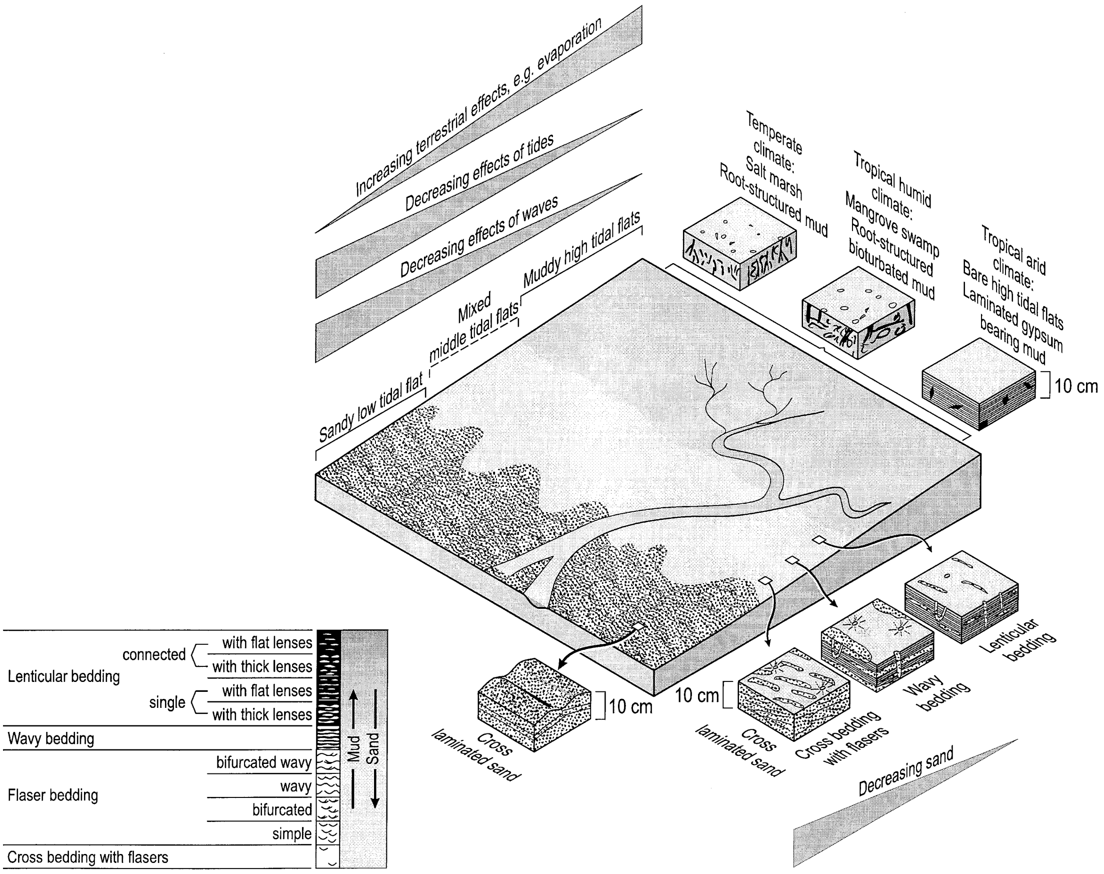

Figure T24 Generalized sedimentology of a typical tidal flat, relating sediment types to oceanographic and terrestrial processes, and inset detail of some sediment types in relation to facies setting and position on tidal flat. Also shown is the systematic variation in bedding types as the sand to mud ratio changes (modified after Reineck and Singh, 1980).

The basic tidal flat sediment types are strongly related to their position on the tidal flat slope as a result of the interplay of tidal action and waves (Figure T24). If there is sand and mud on the tidal flat, tidal and wave processes result in a partitioning of particle sizes: generally, sand dominates the low tidal flats, mixed sand and mud occur on mid-tidal flats, and mud on the high tidal flats. If biogenic activity is not intense enough to bioturbate sediments, the sand and mud on mid-tidal flats are separated in layers and laminae to develop flazer bedding, lenticular bedding, wavy bedding, or interlaminated sand and mud. With more intense burrowing, mid-tidal flats are thoroughly mixed muddy sand with bioturbation structures.

Accumulation of mud in the upper parts of tidal slopes is a general product of tidal processes. There are three main reasons for this. First, with scour lag and settling lag, mud is progressively transported up the tidal slope to accumulate ultimately at the level of the highest tide (Postma, 1961). Scour lag and settling lag processes are particularly accentuated if the tidal flood and ebb are asymmetric. Second, mid- to lower tidal slope environments, more constantly under water, are subject to more continuous and intense wave and tidal current reworking, and hence any mud settled there is prone to remobilization. In contrast, high tidal areas generally are inundated by tides on slackening water, with low to nil current, and any wave trains arriving here are dampened by translation across the tidal flat floor. Hence, there is less scope for reworking. Third, high tidal zones in many regions are vegetated by mangrove or salt marsh, which function in current baffling, and sediment trapping and binding.

The interplay of tidal currents with mud and sand results in an interesting and geologically important range of bedforms and sedimentary structures. Sand transported during flood and ebb tide develops ripple bedforms with internal cross-lamination. Mud deposited during slack water blankets these ripples, or preferentially settles in inter-ripple troughs. Tidal currents, during the ensuing flood or ebb tide, rework the mud layers to diminish their thickness, leave inter-ripple lenses of mud, and remobilize sand forming ripples to bury the mud layers and to form more ripple cross-lamination. Ongoing deposition and burial of these bedforms results in mud-dominated bedding with scattered sand lenses (lenticular bedding), to subequal mud and sand (wavy bedding), to sand-dominated bedding with thin inter-ripple mud lenses (flazer bedding). Thus depending on the proportion of mud to sand, which is a function of the location of the sediment type on the tidal flat, or the inherent proportion of mud to sand regionally, the sedimentary structures produced by the processes described above range from mud-dominated lenticular bedding to flazer bedding (Figure T24).

Sedimentology, sedimentary structures, and stratigraphic sequences

Sediment bedforms, surface features, and near-surface features on tidal flats are produced by oceanographic, other physical, biotic, and hydrochemical processes. Wave action and tides and winnowing result in ripples, megaripples, sand waves, plane sand beds, linear scours, plane mud beds, and gravel pavements. A range of other physical processes result in mud cracks, air escape holes, bubble structures. Biological activity results in burrow-pocked surfaces, animal tracks, crab burrow workings, vesicular structures, crab balls, accumulation of shell banks and shell gravel. Chemical and physical processes combine to develop sheets of gypsum mush and nodules, platey gypsum pavements, carbonate crusts, and breccia pavements.

Sedimentary structures deriving from burial of the sediment bedforms, and the surface and near-surface features include cross-bedding and cross-lamination, herring bone cross-lamination, sand ripple cross-lamination, silt ripple cross-lamination, lenticular bedding, flazer bedding, laminated mud, sand dykes, mud dykes, bubble sand, vesicular mud, root-structuring, vertical burrows to labyrinthoid burrow networks, shell laminae and beds, shell reefs, silt and sand balls, bioturbation and swirl structures, breccias, nodular gypsum beds, platey gypsum beds, and teepee structures.

Key sediments, diagnostic of their formative processes, occur in different parts of the tidal flat. For example, mangrove-vegetated muddy tidal flats develop root-structured and bioturbated (shelly) mud, and crustacean-dominated mixed tidal flats develop burrow structured interbedded sand and mud varying to bioturbated muddy sand. Some examples of sediments and the processes involved in their development from siliciclastic tidal flats are noted in Table T9.

Table T9 Examples of sediments in their setting, and processes in their development

Environment	Main processes	Resulting sediment(s)
Siliciclastic sediment settings		
Mangrove or salt marsh vegetated high-tidal mudflat	Mud accumulation; root-structuring, bioburbation; shell contribution; groundwater alteration	Gray bioturbated root-structured (shelly) mud
Algal mat covered high-tidal mudflat	Mud accumulation; binding; trapping; redox reactions; cracking	Laminated mud; desiccated laminated mud
Bare high-tidal mudflat	Mud accumulation; surface shear; cracking of mud; reworking of desiccation polygons; gypsum precipitation	Laminated mud; desiccated mud; mud chip breccia; gypseous mud
Burrow-pocked midtidal mudflat	Mud accumulation; surface shear; benthic fauna burrowing	Burrow-structured laminated mud; bioturbated mud
Mollusc inhabited mid-tidal mudflat	Mud accumulation; surface shear; accumulation of shell winnowing to concentrate shells	Laminated shelly mud; shell gravel bed
Mid-tidal mudflat with sand ripples	Mud accumulation; surface shear; traction transport of sand	Flaser bedding
Megarippled low- to mid-tidal sand flat	Traction transport of sand; air trapped by rise and fall of tide	Cross-laminated sand; bubble sand
Mid-tidal burrow-pocked sand flat	Traction transport of sand; benthic fauna burrowing	Burrow-structured cross-laminated sand; bioturbated sand
Carbonate sediment settings		
High-tidal breccia pavement	Mud accumulation; carbonate cementation; root-structuring; groundwater alteration	Limestone breccia sheet
High-tidal algal mat covered mudflat	Mud accumulation; binding; trapping; redox reactions; cracking	Laminated mud; desiccated laminated lime mud
High-tidal bare mudflat	Mud accumulation; surface shear; cracking of mud; reworking of cracks; gypsum precipitation	Laminated lime mud; desiccated lime mud; mud chip breccia; gypseous lime mud laminated gypsum; gypsum nodule bed
Mid-tidal burrow-pocked mudflat	Mud accumulation; surface shear; benthic fauna burrowing	Burrow-structured laminated mud; bioturbated mud

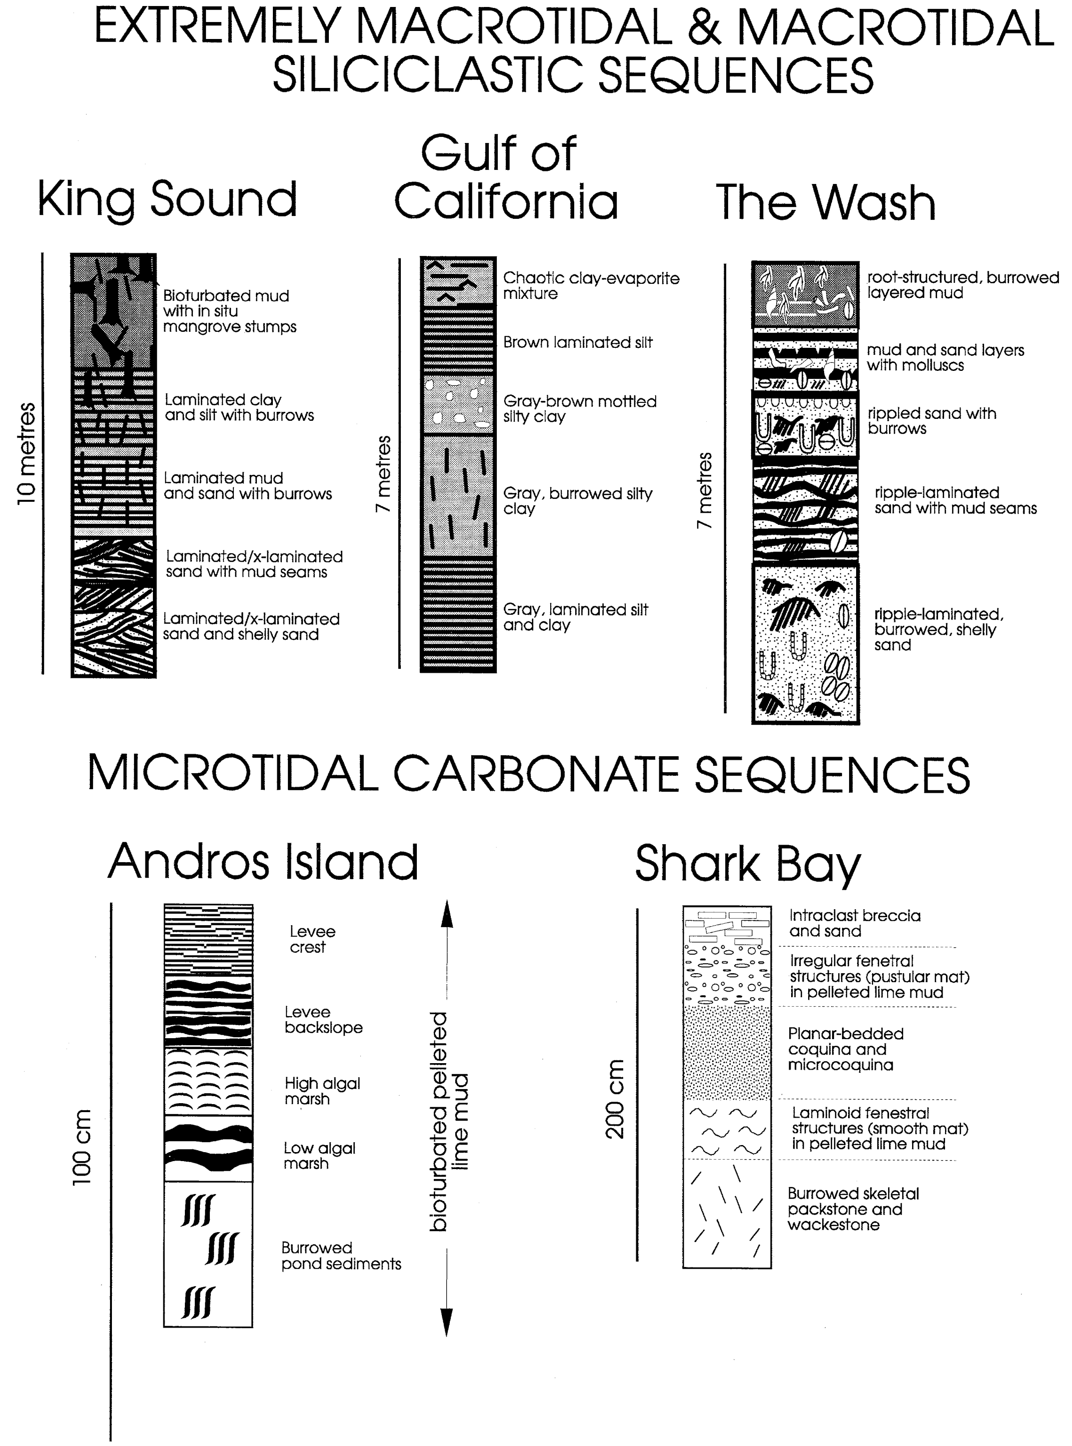

Figure T25 Stratigraphic sequences from various tidal flats (see Table T4). For the macrotidal siliciclastic settings there is comparison for three sequences: a tropical semiarid mangrove-vegetated tidal flat, shoaling from sand to mud, with burrows, root-structures, and *in situ* mangrove stumps; a subtropical semiarid vegetation-free tidal flat dominated by mud, with local burrows, and evaporitic mineral structures; and a temperate humid salt marsh vegetated tidal flat, shoaling from sand to mud, with burrows, root-structures, and shell. The microtidal carbonate sequences compare the structures of a subtropical humid tidal flat with that of a subtropical arid tidal flat.

With progradation, siliciclastic tidal flats develop characteristic stratigraphic sequences. A range of stratigraphic sequences are shown in Figure T25, from various macrotidal to microtidal settings, from flats that are mud dominated, to sand to mud sequences, from temperate to tropical climates. Some examples of sediments from carbonate tidal flats, and the processes involved in their development, are noted in Table T9. With progradation, carbonate sediment tidal flats also develop characteristic stratigraphic sequences, some of which are shown in Figure T25.

Table T10 Key biota of the tidal flats

Biota	Occurrence and function
Mangroves	Tropical tidal flats; massive primary production in the mid-upper tidal zone; detritus sustains biota in adjoining tidal zones (Tomlinson, 1986)
Samphires (salt marsh)	Temperate to tropical tidal flats; primary production in the mid-upper tidal zone; detritus sustains biota in adjoining tidal zones (Chapman, 1977; Beeftink *et al.*, 1985)
Spartina (salt marsh)	Temperate tidal flats; primary production in the mid-upper tidal zone; detritus sustains biota in adjoining tidal zones (Chapman, 1977)
Algal mats and stromatolites	Tropical tidal flats; primary production in the mid-upper tidal zone (Kendall and Skipwith, 1968; Ginsburg and Hardie, 1975)
Molluscs, polychaetes, crustacea	These invertebrates present generally on all tidal flats, although species diversity may decrease towards the temperate regions; molluscs, polychaetes, and crustacea are primary and secondary consumers, and sustain higher level trophic feeders (Dankers *et al.*, 1983; Knox, 1986)
Fish and avifauna	On tidal flats; fish and avifauna generally are primary and secondary consumers, and sustain higher level trophic feeders, and in many instances are the highest trophic level in the region (Knox, 1986; Sylva, 1975; Owen and Black, 1990)

Some key biota of tidal flats

The well-known biota of tidal flats include mangroves, salt marsh, algal mats and stromatolites, polychaetes, molluscs, crustacea, resident fishes and invading nektonic fishes, and avifauna (Table T10). Biogeography and climate, substrate and hydrochemistry are major factors that determine what biota inhabit tidal flats. Species abundance and zonation at site-specific level is determined by physicochemical and biological conditions. For example, with macrophytes, at a global scale, mangroves dominate mid- to upper tidal flats in tropical climates and are replaced by salt marsh in temperate climates. With increased salinity, the upper tidal interval may be inhabited by algal mats and stromatolites. Diversity of flora and fauna is linked to climate setting, with high species richness and abundance in tropical areas, and relatively lower species richness in temperate areas.

Primary production within specific parts of the tidal flat, for example, from mangroves and salt marsh, often drives the ecosystems of tidal flats. With mangroves and salt marshes, these macrophytes fix nutrients and carbon on the mid- to upper tidal flats, supporting the local resident fauna, and the export of detritus sustains benthic biota of polychaetes, molluscs, and crustacea elsewhere on the mid- to low-tidal flats. The biologically rich tidal flat environments also support nekton and avifauna. Fish and other nekton invade the tidal zone for feeding on the high tide, and the avifauna invade the tidal flats at low tide.

Tidal flats typically are biologically zoned. For any benthic group, such as polychaetes, molluscs, or crustacea, there is species zonation across the flats related to frequency of inundation, substrate, pore water salinity, inter-species competition and predation pressure, among other factors. Macrophytes (mangrove and salt marsh) also exhibit zonation, as related to groundwater salinity, substrates, and elevation of habitat above mean sea level. Many of the benthos are burrowing forms, and the macrophytes have diagnostic root structures, and hence sedimentologically, zonation of the biota results in facies and tidal level specific signatures across tidal flats: sand-constructed *Arenicola* burrows, for instance, are diagnostic of low-tidal sand flats, vertical to u-shaped to labyrinthoid crustacean burrows in a root-structure-free mud are diagnostic of mid- to low tidal flats, coarse root-structured substrates and associated faunal burrows are diagnostic of mangrove vegetated high tidal flats, while fine root-structured substrates are diagnostic of salt marsh vegetated high tidal flats. Some diagnostic biogenic structures, and biofacies related to tidal assemblages, are often signatures for specific tidal levels and lithofacies within a given region.

Definitions and distribution

Although tidal-flat deposits have been studied extensively over several decades, most studies were focused on embayment and estuary tidal flats, where wave energy is typically low. In contrast, studies of open-coast tidal flats, which differ significantly from the embayment and estuary tidal flats, are scarce. This entry describes the characteristics of open-coast tidal flat in comparison with the well-documented embayment and estuary tidal flats.

A tidal flat is generally defined as an extensive, nearly horizontal, marshy or barren tract of land that is alternately covered and uncovered by the tide, and consisting of unconsolidated sediment, mostly mud and sand (Bates and Jackson, 1980). The tidal flat is also often referred to as an intertidal zone, although in some general discussions, it may include subtidal and supratidal zones. In the following discussion, the term tidal flat strictly refers to the intertidal zone, lying between low-spring tide and high-spring tide levels, as defined in the Glossary of Geology (Bates and Jackson, 1980). A tidal flat generally shows a zonation related to the duration of submergence, which is reflected in apparent differences in sedimentary characteristics. Therefore, based on characteristics of the sedimentary structures and the general trend of lamina thickness, a tidal flat is often divided into upper, middle, and lower intertidal zones (Reineck and Singh, 1980). Although the transitions between the zones are gradual and somewhat subjective, the division provides convenience in describing sedimentary characteristics.

Tidal currents are generally considered to be the dominant driving force for sediment movement on tidal flats, whereas wave-driven sediment motion is often regarded to be minimal and is often neglected. Over 70% of locations classified as tidal flat occur in wave-sheltered areas, such as bays, estuaries, lagoons, and behind spits or barriers, while the remainder occur along open coasts, the majority of which are characterized by low wave conditions (Eisma, 1998). Although high wave energy is often considered to be unfavorable for the development of gentle tidal flats (Boggs, 1995), they can nonetheless develop rather extensively along open coasts given a large tidal range and tremendous sediment supply. Examples of this type of open-coast tidal flats are found in the vicinity of the large river mouths along the Chinese coast (Figure T26; Chen, 1998; Shi and Chen, 1996).

In comparison with extensively studied wave-sheltered tidal flats, open-coast tidal flats are characterized by: (1) facing an open ocean or sea; and (2) flooding and ebbing tidal currents are not confined and/or regulated by tidal channels. In other words, large tidal channels are generally absent along open-coast tidal flats, especially those along the Chinese coasts.

Hydrodynamics and sediment dynamics

Most of the published studies on modern tidal flat deposition have concentrated on wave-sheltered areas in Europe and North America (e.g., Klein, 1976; Boersma and Terwindt, 1981; Dalrymple *et al.*, 1991; Allen and Duffy, 1998; Eisma, 1998). Not surprisingly, therefore, sedimentary characteristics associated with tidal currents, especially those flowing through tidal channels, have been studied extensively, with little attention being paid to sediment motions driven by waves. Generally speaking,

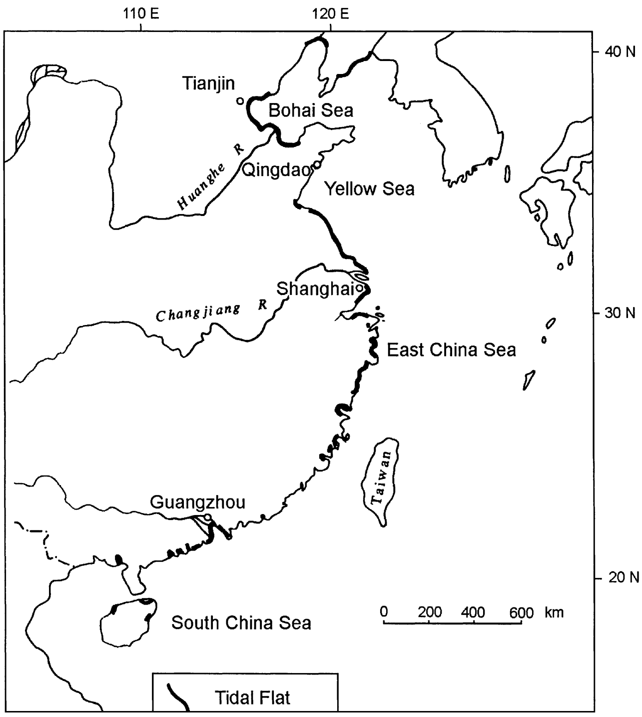

Figure T26 Distribution of open-coast tidal flats in China.

open-coast tidal flats are rather poorly studied and documented, and as a result, the characteristics of hydrodynamics and sediment dynamics presented subsequently are largely based on the studies along the Chinese coasts.

Along open-coast tidal flats, tidal channels are generally absent and, therefore, do not significantly regulate flood and ebb currents. Sedimentary features, such as mega-ripples and dunes, associated with bedform migration in the tidal channels are rare to non-existent. Wave energy is significantly dissipated over the extensive and gentle muddy flats during normal weather. However, during storms, due to the lack of wave shelter, open-coast tidal flats are vulnerable to the impact of storm waves, which may induce substantial reworking and redeposition of normal weather tidal deposits. The tidal flats, especially the middle and upper intertidal zones, are much sandier during the storm seasons than during the calm-weather seasons.

Sediment dynamics along open-coast tidal flats carry strong regional characteristics. The sediment dynamics along the Chinese open-coast tidal flats are significantly influenced by the tremendous sediment supplies from the adjacent large rivers, for example, the Changjiang river (Figure T26). Most open tidal flats along the Chinese coast are accretional owing to the abundant fine (silt and clay) riverine sediment supply. Coastal erosion is typically caused by starvation of sediment supply due to switching of river mouths, artificial flood controls, or drainage withdrawal. Mean sediment grain size along the Chinese open-coast tidal flat ranges from 4 to 8 ϕ (0.063–0.004 mm). The fine nature of the sediment also contributes to the absence of the mega-ripples in addition to the general lack of tidal channels. The width of the tidal flats ranges from 3 to 4 km with a maximum of approximately 8 km. The average slope of the tidal flat is typically 1 : 1,000 with a maximum of 1 : 200 and a minimum of 1 : 5,000.

Characteristics of sedimentary structures

The sequence of sedimentary structure variation from upper to lower intertidal zones as described by Reineck and Singh (1980) was also observed on open-coast tidal flats. The upper intertidal zone is characterized by relatively finer sediment with thicker muddy laminae. Lenticular bedding is common in the upper intertidal zone. The lower intertidal zone is characteristic of coarser sediment and thicker sandy laminae. Flaser bedding is common in the lower intertidal zone. Wavy bedding is common in the middle intertidal zone.

It is generally accepted that four laminae may theoretically be deposited during one tidal cycle (Allen, 1985). Two sandy laminae may be formed during flood and ebb phases, and two muddy laminae deposited during high and low tide slack water. It was also found that thicker sand laminae correspond to relatively higher-energy events during spring tides, while thinner sand laminae correspond to relatively low-energy events during neap tides (Boersma and Terwindt, 1981; Allen, 1985). Time-series analysis of laminae thickness has been applied to quantify the paleo-tide periodicities and paleo-sedimentation rates in both modern and ancient tidal deposits (Yang and Nio, 1985; Kvale *et al*., 1989; Tessier and Gigot, 1989; Kuecher *et al*., 1990; Kvale and Archer, 1990; Tessier, 1993; Miller and Eriksson, 1997), and an approximate 14-day periodicity related to neap–spring cycles has been identified in most of these studies. In the above studies, deposition and erosion induced by waves have largely been neglected. Along open-coast tidal flats, four laminae were rarely observed to have been deposited during one tidal cycle due to their poor preservation potential. Over a continuous daily observation of eight months, the preservation of all four laminae after one tidal cycle was only recorded twice (Li *et al*., 1965).

Two different grouping patterns of sandy and muddy laminae were distinguished on open-coast tidal flat deposits (Figure T27). Groups with generally thicker sandy laminae than adjacent groups, are termed sand-dominated layers (1), while groups with generally thinner sandy laminae than adjacent groups, are referred to as mud-dominated layers (2). Although determination of the exact boundaries between sand- and mud-dominated layers was somewhat subjective, the overall differences between adjacent sand- and mud-dominated layers were apparent (Figure T27). The thickness and number of sandy and muddy laminae in each sand- or mud-dominated layer were not necessarily identical. Detailed description of sand- and mud-dominated layers can be found in Li *et al*. (2000).

Daily, monthly, and yearly sedimentation monitoring along a Chinese open-coast tidal flat near the Changjiang river mouth indicated that the mud-dominated layers described above correspond to calm-weather deposition, while the sand-dominated layers are related to high-energy storm events. These findings are contrary to the neap–spring-cycle interpretation of lamina-thickness variations. The above interpretation of event-related lamina-thickness variation incorporated the much more significant influence of waves, especially storm waves, to the open-coast tidal flat deposits. High-energy storm events along the east-central Chinese coasts are mainly driven by the typhoon passages typically during the months of August to November, and to a lesser extend the passages of winter cold fronts.

Sedimentation rate and preservation potential

The correspondence of thick–thin variations of tidal laminae with the neap–spring tidal cycles has provided a promising tool to study the paleo-tide periodicities and the paleo-sedimentation rate (Tessier and Gigot, 1989; Miller and Eriksson, 1997). Time-series analysis of the tidal bundle thickness variation has been applied successfully in tidal channel deposits (Yang and Nio, 1985). However, direct application of this neap–spring analysis is not valid along open-coast tidal flats due to the non-negligible and largely random impact of wave-induced erosion and sedimentation. Sedimentation rate and preservation potential vary from region to region, and are strongly influenced by sediment supplies and regional hydrodynamics. In the following, a case study from east-central China is discussed as an example.

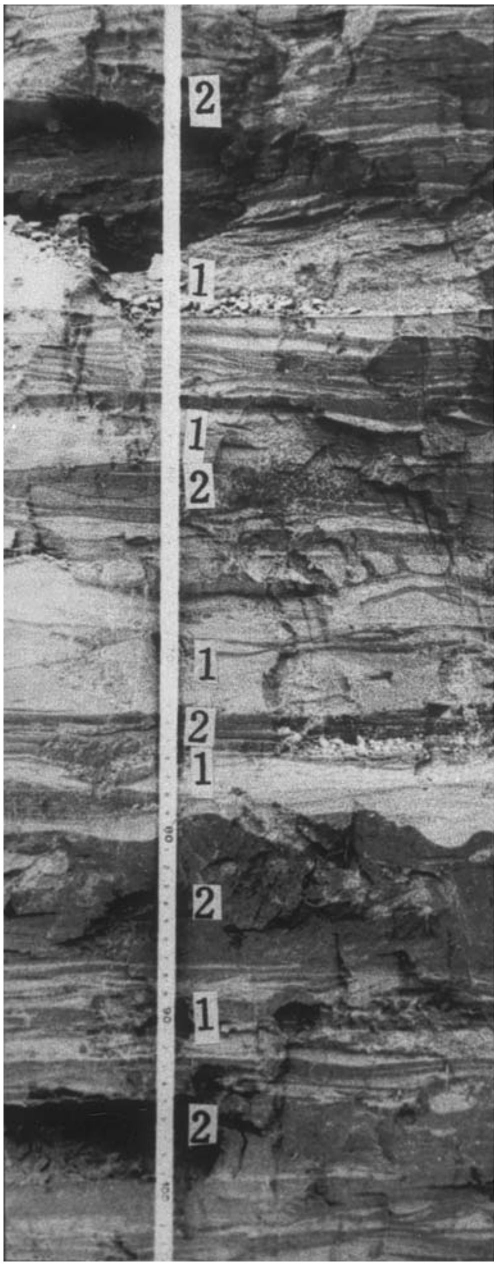

Figure T27 Different grouping patterns of tidal bedding. 1 Denotes a sand-dominated layer, and 2 denotes a mud-dominated layer.

Realizing that 100% preservation potential may be far from realistic on an open-coast tidal flat, Li *et al.* (2000) conducted an intensive, time-series *in situ* monitoring of the sedimentation rate and preservation potential. Their methodology included two aspects to understand and quantify the deposition and preservation of tidal bedding. The first aspect emphasized *in situ* observations on the modern tidal flat. Selected points were visited daily during low tide to examine deposition and erosion of the previous two tidal cycles. This daily observation had been conducted for 17 days over a neap–spring tidal cycle. Seasonal sedimentation and erosion observations across an intertidal profile were conducted over a four-month period extending from calm-weather season to storm season. The second aspect of the study focused on examination of the vertical characteristics of tidal laminae and bedding, in terms of the lamina numbers and lamina-thickness variations. Knowledge gained from the *in situ* observations was applied to interpret the vertical distribution of tidal bedding and the preservation potential of individual sandy and muddy laminae in cores and trenches.

Short-term observation was conducted using two thin plastic plates (40 cm long, 40 cm wide, and 2 mm thick). The plates were placed in the transition area between middle and upper intertidal zones. The thin plates were placed flush with the average sediment surface, and their surfaces were sanded to increase the roughness. Plate 1 was left in place for a period of 17 days and one observation was made at the end of the experiment. The objective for monitoring plate 1 was to obtain short-term information without daily disturbance. Deposits on plate 2 were measured daily, or every two days in cases of poor weather conditions. The objective of the plate 2 experiment was to quantify daily sedimentation rate and the number of laminae formed.

The daily monitoring spanned one neap–spring tidal cycle. No apparent trend of lamina-thickness variation was observed from the daily plate experiments. The daily sedimentation rates were rather uniform ranging 17–22 mm/day, except two abnormal values of 12 and 45 mm/day, both measured during spring tides. The calculated 17-day deposition was 378 mm with 50 sandy and muddy laminae, while 12 laminae with a total thickness of 75 mm were measured on the 17-day plate. Thus, the uninterrupted 17-day sedimentation was 20% of the cumulative daily deposition in terms of thickness (75 mm versus 378 mm), or 24% in terms of total number of laminae (12 versus 50). Furthermore, comparison between the results from the 17-day monitoring (12 laminae) and the theoretical estimate (4 laminae per tidal cycle for 33 tidal cycles over 17 days) of 132 laminae indicates that only approximately 9% of the laminae were preserved, even during a short period of one neap–spring tidal cycle. Continuous daily observation of tidal lamina number and thickness, conducted over three neap–spring cycles in 1999, yielded similar preservation potential.

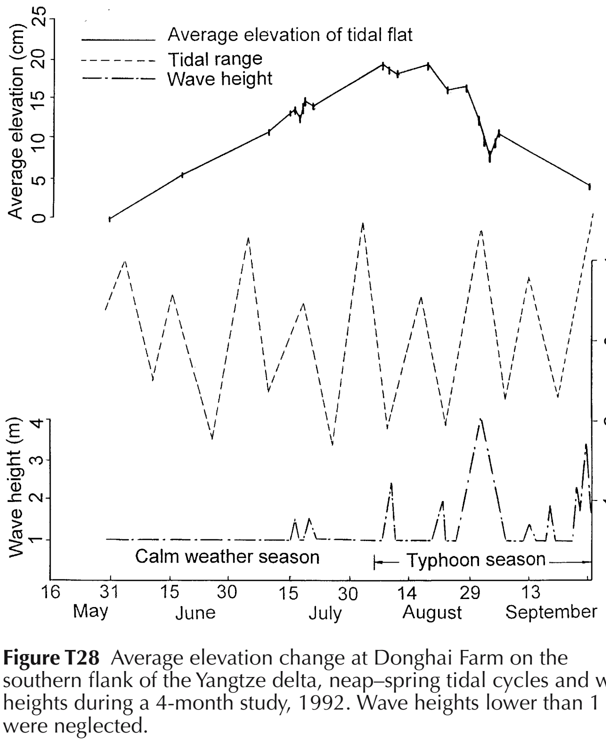

Figure T28 Average elevation change at Donghai Farm on the southern flank of the Yangtze delta, neap–spring tidal cycles and wave heights during a 4-month study, 1992. Wave heights lower than 1 m were neglected.

Seasonal monitoring spanned four months with two months at the end of a calm-weather season and two months at the beginning of the following storm season. Sedimentation and/or erosion were measured at 35 locations relative to a series of graduated rods. A total of 22 measurements were conducted during the four-month period. Overall, the intertidal zone was accreting during the studied calm-weather season (Figure T28), as indicated by the increasing of the average elevation at all the rods. During the studied storm season, net erosion (elevation decrease) was measured and the flat was covered by a sandy lamina that was much thicker than those deposited during the calm-weather season. Sharp elevation decrease was usually measured directly after the storms, apparently indicating the erosion caused by storm waves. For the convenience of discussion, the calm- and storm-weather season was divided somewhat subjectively by the first significant typhoon impact in the study area. The frequent observations throughout the four-month period indicated that the tidal flat was generally muddier in the calm-weather season than during the stormy season. The changes of average elevation were related not to the neap–spring tidal cycles, but closely to high wave events (Figure T28). Deposition of a relatively thicker sandy lamina was directly related to the high-energy wave events induced by the passage of a typhoon, instead of during spring-tide conditions.

Long-term sedimentation rate and preservation potential were determined through counting the number of laminae and mud- and sand-dominated layers in core sections that were deposited over 100 years. Details are described in Li *et al.* (2000). The centennial sedimentation rate was found to be on the order of 4 cm per year. It is worth emphasizing that the high sedimentation rate is closely related to the tremendous sediment supply from the adjacent river. Such a high sedimentation rate should not be expected at locations without overwhelming sediment supply. Over the 100-year period, the preservation potential of individual lamina, including both calm-weather and storm deposits, was found to be on the order of 0.2%, which was 45 times smaller than the 9% estimated for a short-term of a neap–spring cycle. It is expected that the preservation potential decreases as temporal interval increases. The 100-year preservation potential of storm-induced sand-dominated layers was estimated to be of the order of 10%, 50 times higher than the overall potential of 0.2%.

Summary

Waves, especially high storm waves, have a significant influence on sedimentation and preservation of intertidal deposits along the open-coast tidal flats. The thickness variation of sandy laminae on an open-coast tidal flat is related not to neap–spring tidal cycles, but directly to storm activities. The mud-dominated layers containing thinner sandy laminae were deposited during calm-weather conditions, while the sand-dominated layers containing relatively thicker sandy laminae were deposited during storm seasons. In other words, the thick–thin variation of sandy laminae may reflect a much longer cycle of calm-weather and storm seasons, instead of the fortnightly neap–spring tidal cycles as suggested from studies on wave-sheltered tidal flats.

One hundred percent preservation of both the number and thickness of individual laminae in tidal flat deposits, which has often been assumed in the interpretation of time-series analysis of laminae-thickness variation, was found to be unrealistic along the studied open-coast tidal flat. Preservation potential decreases as timescale increases. During one neap–spring tidal cycle under calm-weather conditions, the preservation potential of individual lamina was approximately 9%. However, over a period of 100 years, the preservation rate of individual lamina decreased to about 0.2%. The preservation rate of storm-induced, sand-dominated layers during the 100-year period was found to be on the order of 10%, much higher than the 0.2% of the individual sandy and muddy lamina. Storm deposits have a much higher potential for being preserved due to the higher energy level at which they were deposited.

TIDAL POWER

Tidal energy

Tidal energy is derived from the earth's inherent force, the earth's rotation within the disturbing field of moon and sun. In relatively shallow seas friction dissipates almost all the energy. Though tides can be predicted very accurately, they are not in phase with moon and sun movements, the tide waves being distorted as landmasses, narrow passages and shallow depth areas impede and/or influence their progression. (Charlier, 1982). The tidal current is the rotary current accompanying the turning tide crest in an open ocean. It becomes a reversing current, nearshore, moving in and out as flood and ebb currents. Both of these can be harnessed to produce mechanical and/or electrical power (Charlier and Justus, 1993).

Major disadvantages of tidal power electricity generation is that tides are linked to the lunar rather than to the solar cycle, and vary in range throughout the year due to their periodic components. These negative aspects can be partially overcome by ingenious engineering and retiming of use of potential energy accumulated at low-demand periods. Such retiming had even been suggested several decades ago using retaining basins, compressed-air, or hydrogen—even electrolytically produced—usable as fuel when tide and peak-power demand are not synchronic (Gilbert, 1982). Storing has been proposed in exhausted deposits, abandoned mines, and artificial cavities.

Of the 3,000 million kilowatts equivalent dissipated by tidal energy, one billion (10^9) develop in shallow seas. But only a fraction of this "power" can be captured. The geographical site must be suitable from engineering and economics viewpoints and the "usable head" has to be high (5 m or more). The latter requirement has drastically changed with the development of low, and ultra-low, head turbines, greatly increasing the number of potential sites; thus the 200 million kW theoretically harnessable 20 years ago has sizably increased. The economic geographical factor has also been altered as a result of improvement in transmission possibilities; indeed, national grid systems and high voltage transmission lines have minimized the problem of distance between generating plant and consumer (e.g., in Canada) and the problem of protection (insulation) against extreme temperature amplitudes was resolved more than a decade ago by the Soviets. Finally, where the emphasis has been placed on huge, even gigantic (e.g., Chausey Islands, France) projects, small plants are often favored currently, an advantage for developing countries or isolated areas (Suriname, Half Moon Cove [Maine, USA], China).

The plant

The tide mill (gm) and the tidal power plant are similar. The latter has an electric generator. The plant's major components are a dam which houses the powerhouse, a retaining basin, and a link to the electricity grid. Construction of a barrage or dam is necessary; earthen dams have been used in construction of Chinese plants. The dam consists additionally of dikes connecting with the natural embayment and a sluiceway. A passage way for fishes is now provided. A reasonable tidal range is required, although quite small ones will suffice today. Estuaries and gulfs in shallow areas are privileged sites. A closed basin is thus created which fills and empties daily, sometimes more than once, depending on the local tidal regime. Equipped with sluices and turbines placed in the barrage, the system retains the water entering at flood tide and releases it at ebb tide.

Generally turbines produce electricity as the water flows out of the retention basin (or "pool") but reversible blade (the so-called *bulb*) turbines, originally invented by Harza and later developed by French engineers (Hollenstein and Soland, 1982), can produce electricity both as the water enters and when it exits the basin. Practice—based upon 30 years of operation of the Rance River, France, plant—has, however, shown that entering water generation is perhaps not always economically profitable. By judiciously selecting tide gates opening and closing times, power generation can be synchronized with peak-demand periods, even if these do not coincide with tide peaks. The hydraulic head can be increased by reversing power units, temporarily turning the turbine-generator into a pump-motor; the bulb turbine precisely regulates flow in both directions and acts as turbine and pump. Pumping, however, consumes electricity.

A so-called "site value coefficient" for plants (k) was calculated by Robert Gibrat based on dam length and natural energy (k = L/NE), however, these are not the only "factors" involved in site selection; considered should be tidal range, potential pool size, ratio of basin aperture section to basin surface, length of dam, basin characteristics (such as geometric shape and surface, opening, widening shape), geological structure, lithology and petrology, foundation soil quality, gradient of resistance layer, probability of silting, rate of sedimentation, climate, market distance, competitiveness of conventional and/or alternative (e.g., nuclear, aeolean) power sources. Some economists maintain that today tidal power is competitive and may even be less expensive than fossil fuel and nuclear generation. Calculations made by Voyer and Penel (1957) have been revised (Charlier, 1998). All the factors are seldom, if ever, simultaneously favorable, which, with the high capital investment for large plants, probably accounts for the small number of plants constructed (Charlier and Justus, 1993).

Types of plants

Plants are single- or multiple-basins systems, a tide-powered air storage scheme, tide-powered hydrostatic pump scheme or Gorlov setup. Single-basin plants function either as a one-way operation (ebb generation only), two-way operation (generation at both ebb and flood flow), two-way operation with pump-turbines generation (excess used to pump water in storage reservoir[s]), or high-tide pumped storage (non-tide-connected power production). Multiple-basin schemes are either double-pool (station placed in-between basin, filling one basin at flood, emptying the other at ebb), both basins pumping (pumping high pool up and low pool down, pumping at off-peak), pool-to-pool dam pumping, pool-to-pool dam pumping combined with pump-turbines, tide-boosted pumped storage (basins may be of different sizes and in different places), or variations of the latter.

The tide-powered air storage scheme differs in that it uses the tidal energy to drive air turbo-compressors and stores the compressed air. In the tide-powered hydrostatic pump a propeller turbine is linked to a pump and the tidal energy is converted in a flow of high-pressure oil which turns a Pelton wheel coupled to an alternator. The Gorlov proposal involves a thin plastic barrier hermetically anchored to bottom and bay sides supported by a bay-spanning cable. The tidal energy would be converted into power by an air motor piston at ebb with direct generation or compressed air storage (Gorlov, 1982). Finally, one technology would anchor in line a series of floating turbine and generator units along the flow of the tidal current (Charlier and Justus, 1993). This approach, less onerous probably than a "traditional" tidal power plant, would perhaps be attractive for small local or regional schemes.

Reversible blade (bulb) turbines have been placed in the Rance River (France) and the Kislogubskaia (Russian Federation) single-basin plants. The Russian plant was built in modules, which considerably reduced construction costs and avoided construction of expensive cofferdams. The turbines can be used as low-head pumps.

Operating plants

If the literature on tidal power plants is extensive (cf. Charlier, 1982, 1998, 2003; Charlier and Justus, 1993), it is not easy to always determine where plants were built (Figure T29). Little is known of a plant built in the mid-1920s in Suriname (then Dutch Guyana) or in Boston Bay (end of 19th century, and dismantled because of harbor extension). Information on China's post-World War II "more than one hundred" plants is scant and even in the country itself is poor, though a few papers have been recently published (Ch'iu Hou-Ts'ung, 1958). Occasionally construction of plants is announced, as in Korea or India (cf. Sharma, 1982; Song, 1987), but proves premature. Three major plants have been built and are operating: the Rance River (France), the Kislogubskaia (Russia), and the Annapolis-Royal (Nova Scotia, Canada) plants. The first one is large and dates from 1956, the second, a pilot plant, is much smaller and was heralded as a forerunner of more ambitious ones to come, and the third one is an experimental and pilot installation.

The Rance River Plant

Twenty-four bulb groups of 10,000 kW were placed in horizontal hydraulic ducts entirely surrounded by water at the Rance plant. The cost of the cofferdams represented a third of the building cost, an expense which can now be dispensed with as was in the Russian plant and to some extent in the Canadian plant. The cost of the project ran about US$100 million (in 1966-$).

Started in 1993 and completed in 1966, the 53 m wide and about 390 m long plant protrudes 15 m above water, with foundations 10 m below sea level, accommodates a four-lane roadway (eliminating a ferry) and has substantially contributed to the economic development of the former lethargic region besides furnishing 544 MW h of usable power. The mean net annual energy production exceeds slightly 500 GW h and the mean capacity throughout the year is 65 MW. It has six modes of operation. The operation policy has aimed at optimizing the value of the energy generated, reaching maximum profit, instead of eyeing to generate the maximum amount of energy. Generation by overemptying the basin (by pumping) has been done only rarely during the last decade.

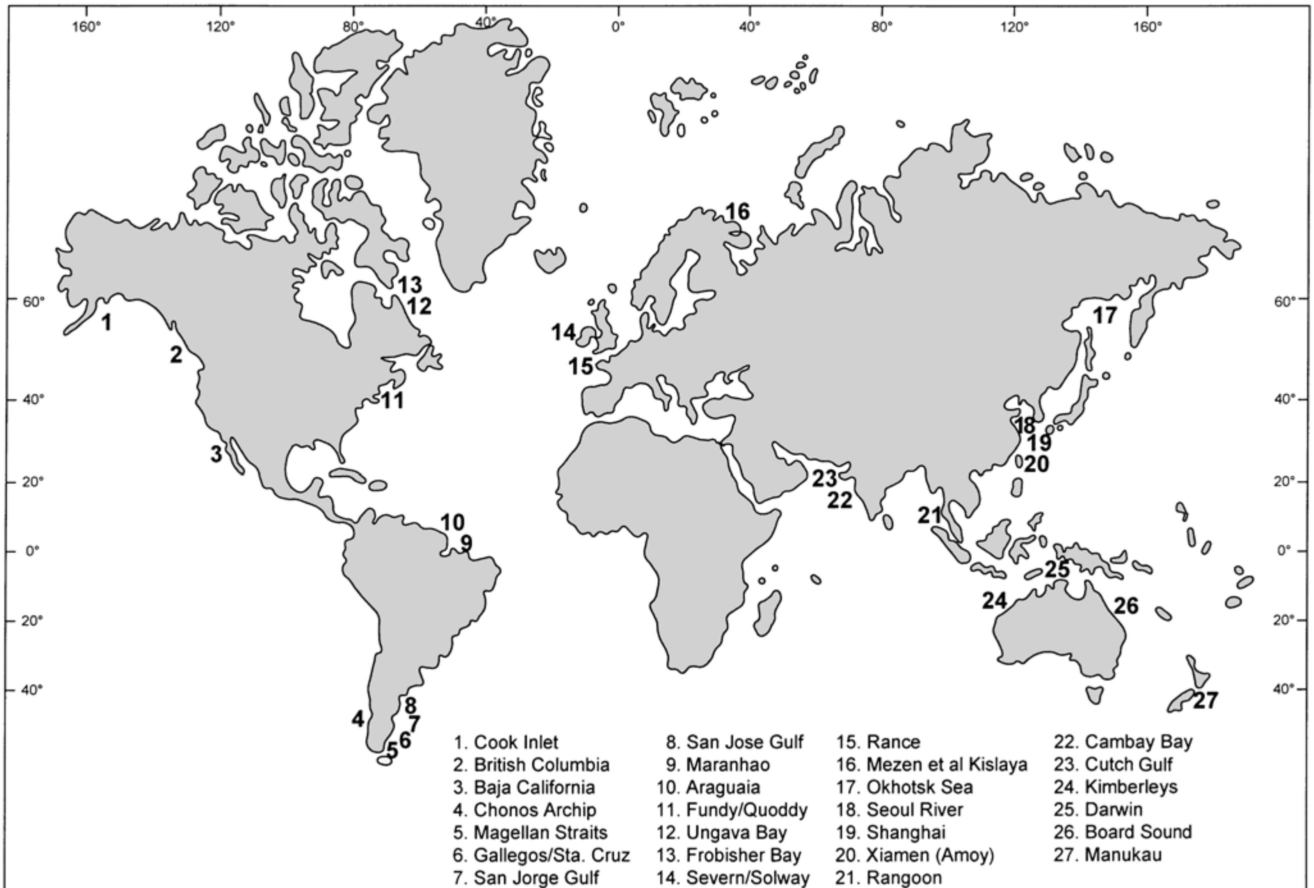

Figure T29 Location of major tidal power plants (after Charlier, 1993, with permission from Elsevier Science).

Environmental aspects at the Rance Plant. Environmental impact, at the French Rance River Plant, has been extremely mild causing only the disappearance of one species of fish. No major biological modifications have occurred. New species have appeared. Sandbanks have disappeared, high speed currents have appeared near sluices and also near the powerhouse where sudden surges have been observed. Tidal ranges have been reduced from 13.5 m to 12.8 m and minima increased. The fishing industry has not been affected contrarily to fears, and tourism has increased.

The Russian plant

The Kislaya Bay plant is located near Mezen on the Arctic. The small Russian Arctic coastal bays hold a 3.2 billion kW potential. Completed in 1968, the 18 m long, 36 m wide, 15 m high, with a 15.2 m head, plant was built by towing preconstructed concrete caissons to the site and then sinking them into place. A narrow passage connects bay and sea; no long dikes were necessary as the powerhouse itself closes the basin. Transmission lines existed close to the site. The power set capacity is 400 kW. The reversible hydraulic turbine is coupled with a synchronous generator, with the help of a multiplicator.

Russians are still considering a variety of schemes and stress that by harnessing tides in the Sea of Okhotsk bays, some 174 billion kW h could be produced.

The Canadian plant

An experimental plant was constructed in the early 1980s at Annapolis-Royal (Nova Scotia) in the Bay of Fundy whose "electricity potential" is huge; studies on Fundy tidal power go back to at least 1944. It is here that the first tide mill was built in North America (1607) using tidal and river water. A low-head STRAFLO turbine has been installed in the new plant whose generator and turbine form a coupled unit without driving shaft, particularly compact, and thus cutting powerhouse costs (Douma and Stewart, 1982). The costs amounted to CA$46 million (approximately US$44 at the time). Situated on Hog's Island in the middle of an intake canal on the lower reaches of the Annapolis River where tidal ranges reach 7 m, it took advantage of an existing dam protecting farm land. The Chinese, similarly, have commonly used existing (often earthen) dams to install tidal plants.

The turbine is a single effect one and generates electricity only during discharge of water from the retaining pool. In the event that the pool level would be below sea level, the turbine's water passage would sluice seawater into the basin during each tidal cycle. A cofferdam of local material was used to construct, in the dry, the powerhouse. Turbine and generator are located in the center of the turbine pit. The dam is 225 m long, 60 m wide at low water level, and 18 m wide at the crest. A fish pathway is provided. Fifty million kilowatts are generated.

Environmental impact. The Canadian project was designed to assess both the operational characteristics and the reliability of the Straflo turbine, and, of course, the possibility of implementing major tidal power utilization in eastern Canada. The impact study showed that interactions can be mitigated and that physical, biological, and human impact would be minimal and residual impacts small, while economic outfall would be considerable both for the short- and long-terms.

The Chinese plants

Information is difficult to secure, even in China. Claims of a large number of plants—as many as 105—and their successful operations have been repeatedly made, and so have plans to undertake new construction (Ch'iu, 1958). There are also records of the "temporary" abandon of some plants due to siltation.

Chinese engineers acknowledged a problem with siltation whose extent proves difficult to assess, but it has been said that some tidal power plants were put out of commission because of sediments accumulation. A comparative study on devising siltproof systems was carried out using data from the Baishakou tidal power plant and envisioned environmental protection to control sedimentation in the tallwater channel and reservoir (Xhikui Zu, 1992); at about the same time other studies explored the optimum patterns for double-effect single-basin plants (Shuyu Want *et al*., 1991) and calculated (modelization) of the optimum tidal energy at any location (Lee Kwang Soo *et al*., 1994). Zhikui Zhu presented in 1992 an analysis of data pertaining to the Baishakou tidal power station. It describes measures apparently taken to control sedimentation in the tallway channel and the reservoir area. Comprehensive management is outlined, including mechanical sandproofing methods and environmental protection.

The interest of Chinese researchers in tidal power plants has not waned, nor has it been somnolent as in Europe and the United States, due undoubtedly to the abundance and generally low cost of fossil fuel. An exploratory study and modelization were recently conducted (Zhuang Ji, 1991).

A review article on Chinese activity in tidal power utilization covering the 1950–90 period was published in the somewhat unfamiliar [to westerners] *Collection of Oceanographic Works*. The information rather contradicts other releases which talk about a hundred small tidal power plants. Guixiang Li (1991) mentions eight small power stations and discusses their tangible economic and social benefits. He further discloses that "many more" small and medium size, even one or two large, plants "will be built by the year 2000" along the coasts of China's mainland and the coastal islands. The publication is rather difficult to obtain, except perhaps through the good offices of the University of Karlsruhe (Germany).

Other geographical locations

No accurate information is available about the two-basin plant that functioned in Boston harbor at the turn of the preceding century until it was dismantled to make room for the port's extension, nor of the Van Bemmelen plant in Suriname. The tidal current plant in Iceland seems to have left no traces either. Plans were afoot in the 1990s to build a tidal power plant in [South] Korea (e.g., Garolim Bay) but came to a halt for political reasons (recognition of North Korea by France whose Sogreah was to build the facility) (Song, 1987). Other sites which have been considered, and for which periodically plans re-surface are the Kimberleys in Australia, San Jorge Gulf in Argentina (Aisiks and Zyngierman, 1984), and the Severn River in Great Britain (Severn Barrage Committee, 1986). There are of course numerous other suitable sites worldwide (Charlier and Justus, 1993), and studies were conducted for some of them, for instance for India (Sharma, 1982).

Tidal stream's rapid currents have been recently examined as sources of power, for example, in the Orkney and Shetland islands (Bryden *et al*., 1993–1995), perhaps using Darrieus turbines (Khio *et al*., 1996), and conversion of kinetic to electrical energy with a barrage in New York's East River (Birman, 1994). In Maine and South Carolina experiments proved that using tidal stream power with speeds up to 1.5 knots cuts the cost of seeding rafts with a wooden scoop on the bow that directs the following water to an enclosed compartment containing upwelling units and is less expensive that using other sources of power (Hadley, 1994; Rhode *et al*., 1994).

TIDAL PRISM

The tidal prism is the amount of water that flows into and out of an estuary or bay with the flood and ebb of the tide, excluding any contribution from freshwater inflows. For this reason, it is often reported as the volume of the incoming tide, and the contribution of river inflow calculated from the difference of the ebb and flood volumes. The tidal prism can be determined from hydrographic charts, where the volume in the estuary between low water and high water is calculated from sounding data. The tidal prism can also be determined by measuring the amount of water flowing into an estuary using a technique known as a tidal gauging. This is normally undertaken at a narrow section in an estuary of regular shape, and at a time when river inputs are low. Measurements of current velocity and water depth are made continuously at various points throughout the section using current meters suspended from a boat or bridge, along with measurements of water (tide) level in the section over the tide. The tidal prism is computed as the product change in cross-section area and mean velocity in section, integrated over half the tidal cycle. Today a vessel mounted ADCP (acoustic doppler current profiler) which returns depth, tidal change, and current at many points in the water column as the vessel travels back-and-forth across the section greatly simplifies and improves the accuracy of a tidal gaugings.

The tidal prism is an important metric for an estuary. It is an indicator of the hydrodynamic processes operating in an estuary. In shallow estuaries where the tidal prism forms a large proportion of the water in the estuary at high tide, tidal processes dominate and flushing is good. In deep estuaries with relatively small tidal prisms density-driven flows and river inputs play a greater role in the hydrodynamics. In estuaries where there are semidiurnal tides and a large difference in spring and neap tidal ranges, the amount of water flowing into the estuary (the tidal prism) on a spring tide may be double that on a neap tide and tidal currents and sand transport increase along with this. Empirical relationships developed between tidal prism and various estuary parameters help with the conceptual understanding of processes and provide a simple tool for easy calculations of stable channel design (e.g., Bruun, 1990).

The tidal prism is related to inlet dimensions, the amount of sand stored in tidal deltas, and has been used to describe inlet stability. The empirical relationship between the gorge cross-sectional area and tidal prism of a tidal inlet has been described in numerous studies (O'Brien, 1931; Jarrett, 1976; Hume and Herdendorf, 1992) by:

$$A = c\Omega^n,$$

where A is the gorge cross-sectional area (m^2), Ω is the tidal prism (m^3) and c and n are constants. Inlet gorges that are stable conform to the relationship and there is considered to be a balance between the inlet geometry and tidal flow through the gorge. Those lying off the line are out of equilibrium and characterized by either scour or deposition. A similar relationship has been found to exist between the ebb tidal delta sand volume, which increases with increasing tidal prism. In this situation, the volume of the sand body also increases with decreasing wave energy and as the angle that the ebb jet makes with the beach on the adjacent barrier shore increases (Walton and Adams, 1976; Hicks and Hume, 1996). On coasts where there is little wave energy and estuaries have large tidal prisms the delta will be elongated offshore under the influence of the ebb tidal jet. Where estuaries with small tidal prisms occur on coasts with high wave energy the ebb tidal sand body will be more flattened against the shore. A–Ω relationships have been used to quantify the morphological stability of tidal inlets. Bruun and Gerritsen (1960) showed that the size of the tidal gorge is one of the main factors determining the ability of flow to transport sediment through the entrance. Inlet gorges that are morphologically stable (i.e., have the ability to return to their original configuration after a disturbance) conform to the relationship because there is a balance between tidal flow and littoral drift to the gorge, so the inlet stays open. They demonstrated that when the ratio of the tidal prism to total (gross) annual littoral drift delivered to the inlet from the ocean is in excess of 300 the inlet has a high degree of stability. In cases where the ratio is less than 100 there will be a low degree of stability and entrance bars will shallow and navigation difficult. A–Ω relationships like those for tidal inlets on sandy shores also hold for many different estuary types ranging from lagoon to river mouth and even to large coastal embayments, and have been used to characterize and classify inlets (Hume and Herdendorf, 1993).

TIDE-DOMINATED COASTS

As first enunciated by Price (1955), and later elaborated upon by others (e.g., Hayes, 1975), tides play an important role in defining the geomorphology of depositional shores, namely coastal and deltaic plains. On such shores, it is the ratio of tidal energy, usually dictated by tidal range, to wave energy, a function of average wave height, that determine the morphology of the coast, with sediment supply being an important modifier near major river mouths. As a generalization, coasts with small tidal ranges (microtidal ≤2 m (Davies, 1964)) are dominated by wave energy. Such coasts were termed *wave-dominated coasts* by Price (1955). On the other hand, coasts with large tidal ranges (macrotidal ≥4 m) are typically dominated by tidal energy, and were hence termed *tide-dominated coasts* by Price. The effectiveness of wave energy diminishes (i.e., waves cannot break in a concentrated area for a long period of time), and tidal current energy increases as the vertical tidal range increases. Exceptions to this generalization occur where waves are so small that even small tides generate adequate energy to shape the coast. An example of a *tide-dominated coast* with a relatively small tidal range occurs at the head of the embayed coastline of northwest Florida (Hayes, 1979). Coasts with intermediate wave energy and tidal ranges (typically mesotidal = 2–4 m) were termed *mixed-energy coasts* by Hayes (1979).

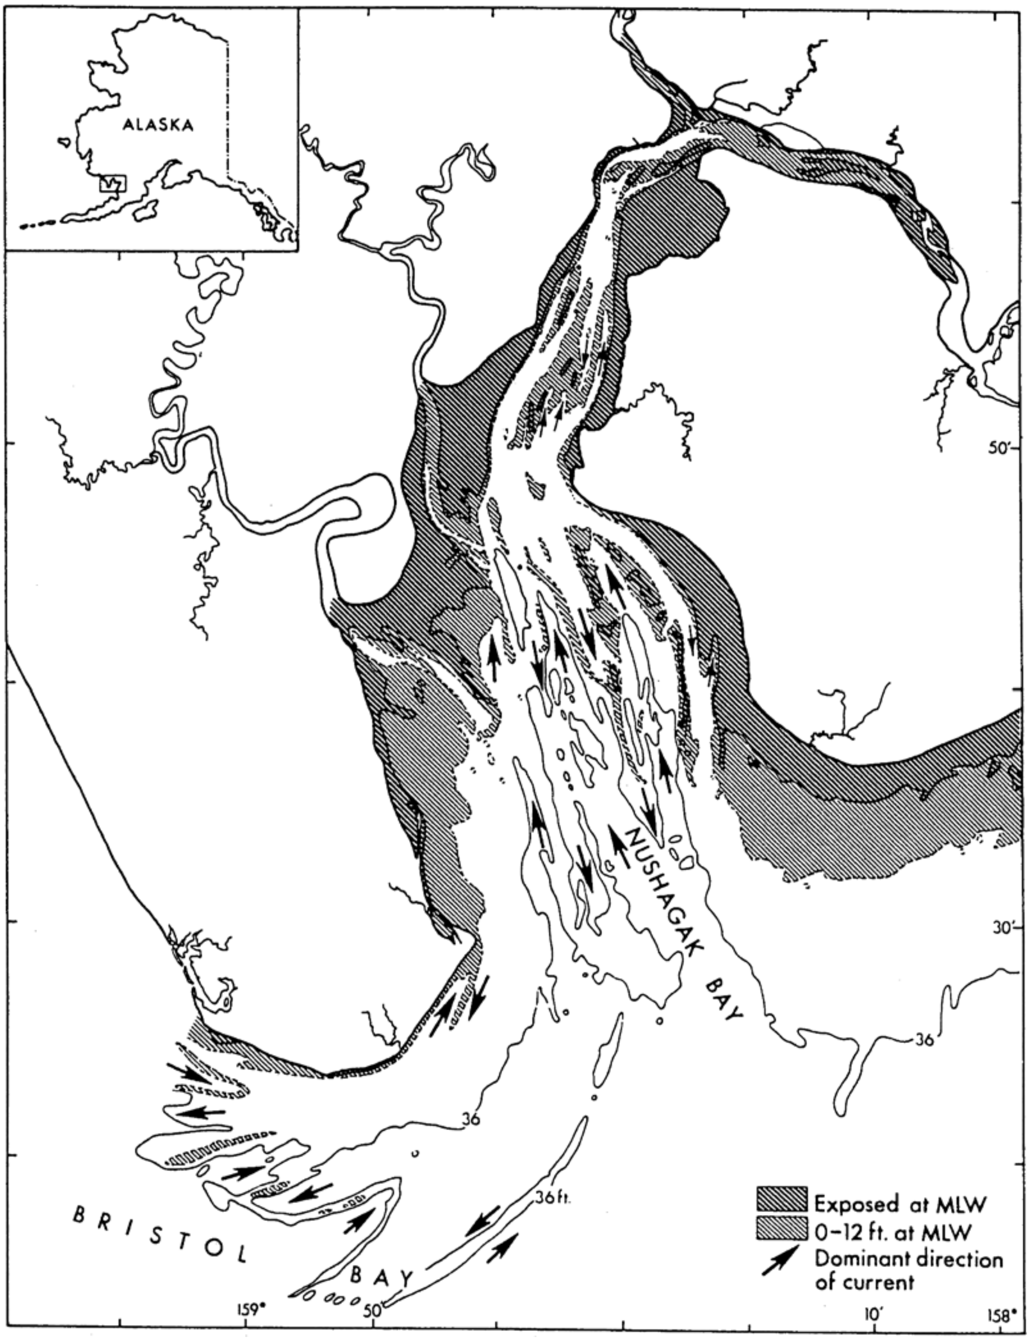

Figure T30 Nushagak Bay, Alaska, a tide-dominated embayment (tidal range = 5.5 m). Note lineation of shoals parallel with tidal currents.

Tide-dominated, non-deltaic coasts

The bathymetry of a typical tide-dominated, non-deltaic shore, Nushagak Bay, Alaska, is illustrated in Figure T30. The coastal morphology of major river mouths on tide-dominated coasts are most commonly open-mouthed estuaries, as shown in Figure T30. Between major rivers on these types of coasts, the shore is occupied by extensive salt marshes and tidal flats. Barrier islands are completely missing, because wave action is not focused enough at a single topographic level to build a barrier island and tidal currents are strong enough to disperse the sand to offshore regions. Examples of this type of coast occur in northwest Australia (Coleman and Wright, 1975), western Korea (Kim *et al.*, 1999), the Bay of Bengal, northern end of the Gulf of California (Thompson, 1968), the Wash, England (Evans, 1979), and many other depositional coasts with tidal ranges greater than 4 m. Generally speaking, the sediment distribution patterns on coasts of this type are exactly opposite to those on wave-dominated coasts, inasmuch as finest sediments occur on mudflats and in wetlands of the upper intertidal zone and coarsest sediments occur lower in the intertidal zone and offshore where tidal currents are strongest.

Studies by Evans (1975) documented the characteristics of the sediments of the tidal flats of the Wash, an indention in the coastline of the east coast of England, which has a tidal range of 7.0 m. The seaward portions of the flats are made up of complex sand bodies covered by sand waves, whereas the upper part is fringed by a salt marsh composed of fine-grained sediments. Studies of the tidal flats of the Bay of Fundy, by Knight and Dalrymple (1975), Dalrymple *et al.* (1990), Yeo and Risk (1981), and numerous others, describe the sedimentology, sediment transport dynamics, and potential stratigraphy of this intertidal zone, which has the largest tidal range in the world.

Figure T31 gives a hypothetical prograding stratigraphic sequence for the intertidal zone of a tide-dominated coast based on the references cited above and other sources.

Tide-dominated deltas

On tide-dominated coasts where the rivers have enough sediment load to have filled the antecedent lowstand valley and build a bulge in the shore (within the time frame of the present highstand), the resulting river deltas are typically referred to as *tide-dominated deltas* (Fisher *et al.*, 1969; Galloway, 1975). However, the distinction between such deltas and estuaries is somewhat obscure. Tide-dominated deltas usually are composed of a series of funnel-shaped water bodies (estuaries?) at multiple river mouths with a series of shore perpendicular sand ridges that extend offshore of the river mouths. Broad tidal flats and marsh or mangrove wetlands occur along the shore of the embayments. A generalized model of a tide-dominated delta is given in Figure T32.

The tide-dominated Ord River Delta, described by Coleman and Wright (1979), is located on the coast of northwest Australia were the tidal range varies between 3.8 and 6.6 m. Tidal currents are oriented primarily in an onshore and offshore direction within an embayment which composes the major mouth of the Ord River. Linear sand ridges, which range in relief from 10 to 22 m and average 2 km in length, occur in the most seaward portion of the embayment. These sand ridges are formed and shaped primarily by tidal currents, which dominate over wave energy effects. A composite prograding stratigraphic column for this delta shows a fining upward sequence resulting from the progradation of muddy upper intertidal flats and marsh sediments over the sand bodies of the lower intertidal and shallow subtidal regions.

Tide-dominated estuaries

The concept of tide and wave dominance has also been applied to estuaries by Dalrymple *et al.* (1992). However, they state that estuaries are unlike many other coastal systems, because they are "geologically ephemeral." If the rate of sediment supply is sufficient to eventually fill the lowstand valley within which the estuary is located, the filled valley then becomes a delta. The estuaries they term wave-dominated are composed of a sand body complex (barrier/tidal inlet) at the entrance, a muddy central basin, and a bayhead delta system. *Tide-dominated estuaries*, on the other hand, contains elongate sand bars and sandy tidal flats at the entrance and complex tidal channel/ wetland habitats further inland.

TIDE GAUGES

Historical origin

Tide gauges have a relative long history. At some places, systematic sea level observations have been performed and recorded since the late 17th or early 18th century. This is the case in Amsterdam, for instance, since 1682, in Liverpool since 1768, or in Stockholm since 1774.

The first devices were simply graduated rods, usually called tide poles, placed at locations where the instantaneous water level height of the sea could be read off at any time by an observer. Most of such measurements were undertaken in or at the entrance of harbors. They were restricted to observations of high and low water levels, as well as the time of their occurrences (Cartwright, 1999).

Automatic recording devices appeared only in the 1830s, although basic instructions were already detailed and published in an Italian journal in 1675. An extract was transcribed in the "Journal des Sçavans" of April 22, 1675 (Observatoire de Paris, 1675). These were mechanical gauges, equipped with float, wires, counterweights, clock, pen, paper chart recorder, and stilling well. They provided the first complete tidal curves which could be examined in detail and digitized for further analysis.

Tide or sea-level gauges?

Whatever technique is employed, the basic quantity provided by tide gauges is an instantaneous height difference between the level of the sea surface and the level of a fixed point on the adjacent land. The vertical reference point is a nearby benchmark which can be observed by traditional surveying techniques. Thence, tide gauges not only record ocean tides but also a large variety of sea-level signals that can be caused by variations in atmospheric pressure, density, currents, continental ice melt... as well as vertical motions of the land upon which the measurement instrument is located, due to tectonic changes, isostatic adjustments, volcanism inflation, sediment consolidation, pier subsidence, etc. Records of such devices are indicative of what are called relative sea-level changes (Pugh, 1987). The recorded processes have characteristic timescales from several minutes to centuries.

Therefore, tide gauge data is valuable information to a wide range of activities over a variety of timescales, for scientific research as well as for many practical applications. For instance, data have uses: for navigation and ship traffic (guidance, tidal timetables...), for coastal engineering design (dike building, dredging works...), for statistics of extreme levels over long periods, for studies of upwelling and fisheries, for hydrographic surveys (sound charts, chart datum...), for storm-surge predictions and alert, for analysis of the risk of flooding and coastal protection, for input or validation of ocean circulation models, for long-term trend of sea-level variations, for global change research and monitoring and, of course, for tidal analysis, prediction and validation of tidal models. In spite of the numerous applications, the historical and conventional term of tide gauge still prevails for such devices, although sea-level gauge would be more adequate.

Technical evolution

The most common type of gauge in use around the world still consists of the float and stilling well system which was devised more than a century ago. In this system, the height measurement of a floating gauge is taken by measuring, on a reduced scale, the length of the wire holding a counter-balanced float. The float sits on the surface of the water inside a well. The vertical movement of the float is transmitted and reduced in scale through a more or less sophisticated system of wires, pulleys, and counterweights to a pen. A continuous record of water height against time is obtained in this way as a drawn curve on paper, the paper being in motion at a fixed speed in a normal direction to the pen displacement. The stilling well is a vertical tube long enough to cover any possible range of tide. It prevents the float from drifting in the presence of currents or winds. The well is designed to provide a mechanical filtering of short-period oscillations due to waves by restricting the flow of water into and out of the well.

Traditional mechanical float devices are progressively replaced by new technologies. Modern type gauges are mainly based either on the measurement of the subsurface pressure or on the measurement of the time of flight of a pulse, acoustic or radar.

The principle of a pressure system is the measurement of the hydrostatic pressure of the water column above a fixed point below the lowest expected tide level. The conversion of that hydrostatic pressure into a sea-level equivalent height is performed according to the law: $\boldsymbol{h} = (\boldsymbol{p} - \boldsymbol{p}_a)/(\rho g)$ by measuring or assuming values of water density ρ, air pressure $\boldsymbol{p}_a$, and local acceleration due to gravity g. Pressure sensors usually exploit strain gauge or ceramic technology. Water pressure translates then into changes in resistance or capacitance in the pressure element. The resulting signal is normally a specific frequency which is converted into physical units of pressure.

The acoustic or radar systems determine the vertical distance from a transducer, located above the sea surface, to the water by measuring the elapsed time of a pulse that is emitted, reflected, and returned back to the sensor. The distance to the water is then derived from the velocity of the type of wave considered (sound or radar).

Whereas technical description may be provided by manufacturers, IOC manuals (1985, 1993, 1997) are a helpful source of information. Valuable detailed information can be found there on each type of gauge, their respective advantages, drawbacks, performances, and limitations, as well as advice on operational methods and environmental conditions of use.

A critical part of the tide gauge system is probably the benchmark on land as it provides the fundamental zero point or datum to which the values of sea level are referred. This benchmark is extremely important as it serves to build useful long-term sea-level time series, even if parts of the time series were obtained from different gauges and different benchmarks (as long as they were geodetically connected). Tide gauge benchmarks are ultimately the source of the long-term coherence and stability of the measurements. It is therefore common sense to preserve the datum by installing and connecting a set of 5–10 benchmarks within a few hundred meters of the tide gauge. Usually, one of them is arbitrarily called the tide gauge benchmark, the "most" stable, the "most" secure or the closest, although all of them are representive of the datum. Even though the station is equipped with the most modern equipment, long-term instrumental drift and local stability surveying should be performed at least annually.

In the era of modern communication technologies, data in electronic form is essential as it can be retrieved immediately from a gauge to a data center by automated modem dial-up or satellite transmissions. Data can then easily be made accessible worldwide via the Internet. Paper chart recorders are no longer acceptable. They require slow labor-intensive digitization and are cost-effective. Moreover, they contain many sources of inaccuracy and are inadequate for certain applications.

Scientific applications

Many scientific applications other than the natural tidal research and modeling benefit from tide gauge records. For instance, tide gauge data are used to establish vertical reference systems on land and on sea in order to define the height and depth datums. The belief, about a century ago, that the average level of the sea was constant over long periods of time led to define the concept of geoid and, subsequently, to establish the origin of the leveling networks on "mean sea level." Typically, countries chose one tide gauge station to compute this quantity over an arbitrary time period: in France, for example, the datum was determined at Marseilles from continuous tide gauge records performed during the period 1885–97; in Britain, the Ordnance Datum was determined at Newlyn from records extending from May 1915 to April 1921. However, mean sea level varies from place to place and at one specific place over time. Today, mean sea level at Marseilles is about 11 cm above the local 1885–97 datum, whereas it is about 0.2 m above the Ordnance Datum at Newlyn. Thus, the datums no longer represent the "real" average of the sea level at these sites.

Tide gauge data are also used to establish the datums to which the depths are referred on nautical charts and above which tide predictions are provided for practical purposes. Since 1996, the International Hydrographic Organization has recommended that Lowest Astronomical Tide be adopted as the International Chart Datum. This datum is defined as the lowest tide level which can be predicted in average meteorological conditions and in any combination of astronomical conditions.

Owing to the rhythmic nature of the tide, the components of its oscillations can be represented by a series of sinusoidal curves, mainly depending on the relative positions of the moon and the sun. In each place, the major tide components are determined empirically from hourly records during at least 29 days (a moon cycle), by the use of harmonic analysis. Because astronomical orbits are known, tides can be predicted at any time. Random deviations from the predicted tide can be due to changes in air pressure or wind (sea surges), currents, changes in water density, discharge (especially at a river mouth) and can be analyzed after filtering the astronomical tide. The occurrence of short-lived oscillations in random deviations, following a sea surge, may correspond to seiches. Finally, if periodic, short-lived and random components are removed by filtering processes, and if the series investigated are long enough, long-term trends will appear.

Tide gauges have been carefully studied for indications of recent global sea-level rise. They include land movement and sea-level movement and depend, therefore, on local or regional tectonics as well as global climate change effects (eustasy). By analyzing the difference in trend between the records in two stations, local and regional components can be easily revealed, though their interpretation may be not univocal. In order to keep the statistical accuracy of a trend estimation below ± 0.5 mm/yr, almost continuous records of at least 40 to 60 years long are usually necessary. At the present time, less than 300 stations in the world can provide such long records. Their geographical distribution is unfortunately very uneven, most of the stations being located in the Northern Hemisphere, with a great majority on both sides of the North Atlantic and few or no data in very wide coastal areas. Since the late 1980s, international projects like GLOSS have made deserving efforts to improve the existing tide-gauge network, but the duration of the new records is still too short to assess long-term trends. In spite of such globally unrepresentative distribution, of the difficulty in separating the various components of relative sea-level change, and of the fact that long-term trends show a great spatial variability, several authors have attempted an estimation of the recent global (average) sea-level rise from tide-gauge records, with various approaches (Emery and Aubrey, 1991; Pirazzoli, 1996). The results obtained are quite variable: a "global" sea-level rise between 0.5 and 3.0 mm/yr is inferred by various authors, with several estimates around 1 mm/yr; higher rates are obtained when tide-gauge trends are "corrected" using isostatic models; however, other authors infer that an accurate global sea-level trend is indeterminable of the basis of tide-gauge data alone. This precludes for the moment a more precise quantification of the recent global rise in sea level only with tide gauges.

Perspectives: synergy with space techniques

Recent advances in space geodesy and gravity measurements allow consideration of monitoring of land movements in a global geocentric reference frame rather than in a local one. Repeated or continuous precise positioning of tide gauge benchmarks by geodetic techniques like GPS or DORIS, over periods of a decade or so, will enable vertical crustal movement to be determined and, subsequently, provide a possible discrimination between eustatic sea-level rise and land subsidence within tide gauge records (IOC, 1997; Neilan *et al*., 1998). Moreover, tide gauge data will then be expressed in the same global geodetic reference frame as satellite altimeter observations and can therefore be directly compared and combined with the altimetric sea levels, providing at last a more reliable and accurate estimate of sea-level variations.

Probably the most significant improvement in sea-level research comes from satellite radar altimetry. However, altimetry cannot provide detailed local high-frequency sea-level information due to the specific sampling pattern. Tide gauges continue to possess important attributes for certain applications, like continuity with historic measurements, high accuracy, continuous sampling, and ability to record at the coast at a relatively low cost.

TIDE MILL

Tide Mills (*moulins à marée, molinos de mar, Gezeitenmoehlen, getijdenmolens*) dotted the coasts and estuaries for several centuries until more efficient, but not less costly, alternatives all but wiped them off the map. A few are making a comeback. Some were still functioning during World War II in England and Wales, but most were derelict or their buildings transformed and used for other purposes (Wailes, 1941). History records show that tide mills once functioned on the rivers Thames (London Bridge), Tiber (in besieged Rome), and Danube (Charlier and Menanteau, 1998). A mill stood at the entrance of Dover Harbor in (1000) according to the *Domesday Book*.

Tide Mills consisted of a dam with sluices, a retaining basin, and a float or a water wheel and transformed the energy of running water into mechanical power to run flour-mills, saw-mills, even breweries, and as late as 1880 to pump sewage. They apparently were also put to work in the *polder-works*.

Tide Mills require sites with tidal amplitude—and thus a tidal current—though even a tidal creek may do. They are the forerunners of today's tidal power plant in the same manner as the windmill is the precursor of the contemporary air turbines. The tide mill is in fact a conventional water mill using the tidal current as its source of power, occasionally both ebb and flood tide, but most used only the ebb current as the retaining basin filled at flood time, emptied at ebb time. A few mills used a proportion of freshwater from the stream in addition to seawater.

The most common idea was the "float method" by which the incoming water raised a floating mass which, as it fell down to original position, provided "work;" another approach included a shaft-mounted rotating paddle wheel activated by ebb and flood, with power transmitted by the shaft; finally somewhat more sophisticated types would let air contained in a metal or concrete conduit be compressed by the incoming tide, thus furnishing compressed air power, an idea which has resurfaced today in proposed schemes (Gorlov, 1982). The fourth system, even more elaborate, dams part of the sea (bay, gulf) and this pool fills up at incoming tide; the water when released at low tide passes through turbines to flow back to sea or to another basin. The latter scheme appeared in the 19th century and with its wheel rotating at as much as 150 rpm, had a much higher yield.

Tidal mills were quite numerous in England, Wales, The Netherlands, Brittany, and Spain. The Europeans brought them to the United States, seemingly on both coasts (Creek, 1952) and Canada. There are some claims that they were not uncommon along the South China Sea coast. Besides the touristic value of restored mills, as near Southampton (Ewing Mill), Plougastel (Brittany), and in Massachusetts (Chatham Spice Mill), tide mills are making a timid come back, in an improved version, to provide power in remote areas.

TIDES

Introduction

Tides are the periodic motion of the waters of the sea caused by the changing gravitational effects of the moon and the sun as they change position relative to the rotating earth. The tides in the oceans are actually very long waves hundred or thousands of miles long. Although produced by astronomical forces, their behavior in the oceans and connected bays (and the size of resulting water level oscillations) is determined by hydrodynamics (i.e., the physics of the water movement).

The vertical rise and fall of the water surface is usually referred to as the *tide*, while the accompanying horizontal movement is referred to as the *tidal current*, with the tidal flow into a bay called the *flood* and the flow out of a bay called the *ebb*. For most areas of the earth the rise and fall, and flood and ebb, occur twice a day (referred to as a *semidiurnal* tide), but in some areas there may only be one *high water* and one *low water* per day (referred to as a *diurnal* tide). In many areas, there are two high waters and two low waters per day, but one high water and/or one low water is a different height than the other (referred to as a *mixed* tide).

The tide is only one phenomenon that produces variations in water level and currents. Such variations can also be caused by changes in the wind, atmospheric pressure, river discharge, and water density (due to changes in salinity and temperature), but they are not periodic like the astronomical tide and are not nearly as predictable, being associated with weather. Nontidal water level changes caused by changes in the wind and barometric pressure are usually referred to as *storm surges* (*q.v.*). The term *sea level* is generally used for longer-period, slower changes in water level. *Mean sea level* is the average of water level measurements over some time period (such as a day, a month, or a year), which averages out shorter-term oscillations like the tide.

Water level is the height of the water surface above some reference level, called a *datum*. A datum for a particular waterway is generally defined as an average height of a particular stage of the tide. For example, *chart datum* on a nautical chart in the United States is defined as the mean lower low water (MLLW) at each location. (*Lower low water* is the lower of the two low waters that occur each day, and MLLW is the average of all the lower low waters over some time period, usually at least a year). Depth soundings on a nautical chart are the depths below the chart datum, and the predicted tidal heights found in Tide Tables are the heights above the chart datum. Adding the two together gives the total water depth at that moment in time. These tidal datums also provide the legal definition of *marine boundaries*. MLLW, for example, is the dividing line between federal territorial seas and state submerged lands, and mean high water (MHW) is the dividing line between state tidelands and private uplands. Tidal datums at a particular tide gauge are referenced to the land through geodetic leveling to a number of *benchmarks*, which are brass markers driven into solid rock or other permanent structures. Tidal datums can change over decades if the land subsides (or rises due to glacial rebound) or if relative sea-level rises due to other effects.

The tide dominates our thinking about changes in water level, not only because it usually causes the largest changes (except during storms), but also because it is very predictable (especially in comparison to how well we can predict the weather). After analyzing only a month's worth of water level measurements from a tide gauge, we can predict the tide quite accurately (for that location) for years into the future. This high predictability is due to the tide's periodic nature and our very precise knowledge of its astronomical forcing. The earth–moon orbit, the revolution of the earth around the sun, and the rotation of the earth on its axis involve periodic motions with fixed and precisely known time periods. Tidal energy is found at the same frequencies that describe these astronomical motions.

To fully understand and predict the tides one must understand both its astronomical forcing and the hydrodynamics of the oceans and bays. While it is the astronomical forcing of the tide that is the basis for the tide's predictability, it is the hydrodynamics of the tide that is responsible for the size of the *tidal range* (i.e., the height difference from low water to high water), the timing of high and low waters, and the *type of tide* (i.e., semidiurnal, mixed, or diurnal). It is the length, width, and depth of the bay or river (and of any adjoining waterways) that control the hydrodynamics. In shallow waterways, the hydrodynamics also transfers tidal energy to new frequencies, and distorts the shape of the tide curve away from perfect sine curves. These same shallow-water processes also lead to interactions between the tide and nontidal phenomena such as storm surge and river discharge.

The largest tidal ranges occur in shallow coastal waters, in particular, at the ends of certain bays and along coasts with very wide continental shelves. The increase in tidal range and tidal current speeds that one sees in the shallow waters of bays, rivers, and straits can go to dramatic extremes if the circumstances are right. Tidal ranges reach 15 m (50 ft) in Minas Basin in the Bay of Fundy. Tidal ranges greater than 12 m occur at the northern end of Cook Inlet near Anchorage in Alaska, in the Magellan Strait in Chile, in the Gulf of Cambay in India, along the Gulf of St. Malo portion of the French coast bordering the English Channel, in the Severn River in England, and along the open coast of southern Argentina. In a few rivers, a portion of the tide wave propagates up the river as a tumultuous wall of water, called a *tidal bore*. The largest tidal bores are found in the Tsientang River near Hanchow, China, and in the Amazon River, Brazil, where at certain times they can reach 7.5 m in height and travel up the river at a speed of 7 m/s. Smaller bores occur in the Meghna River in India, in the Peticodiac River at the end of the Bay of Fundy, in Turnagain Arm near Anchorage, and in the Severn River in England. Tidal current speeds greater than 7.5 m/s occur in Seymour Narrows, between Vancouver Island and the mainland of British Columbia, Canada. Tidal currents of 5 m/s are found in South Inian Pass in southeast Alaska and in Kanmon Strait, Japan. In some narrow or shallow straits, the tidal currents create dangerous whirlpools or *maelstroms*. Most famous is the whirlpool in the Strait of Messina (between Sicily and the southern tip of the Italian mainland), which Homer depicted in his *Odyssey* as the second of two monsters, Scylla and Charybdis, faced by Ulysses.

The generation of tides

The tides are caused by both the moon and the sun, but the moon though smaller has roughly twice the effect because it is much closer to the earth than the sun. Although the moon appears to orbit around the earth, the earth and moon both actually revolve around a common point, which, because the earth is much more massive than the moon, is inside the earth, but not at the earth's center (see Figure T33). At the

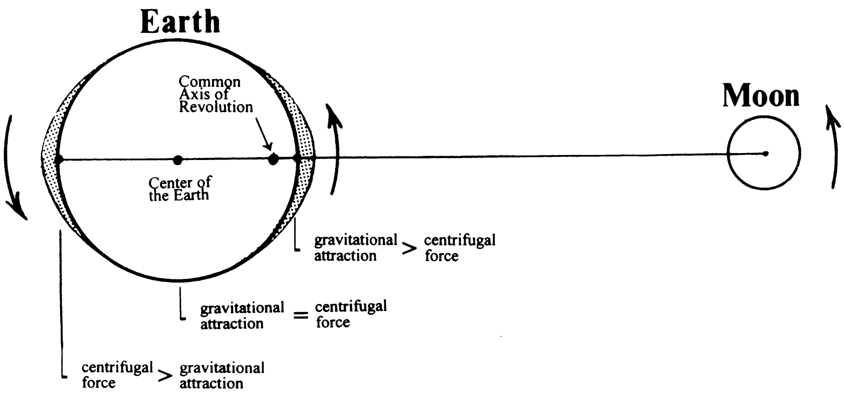

Figure T33 The earth–moon system (viewed from above the North Pole) revolving around a common axis (inside the earth). The earth is shown with a hypothetical ocean covering the whole earth (with no continents) and *two* bulges, resulting from the imbalances of gravitational and centrifugal forces.

center of the earth there is a balance between the gravitational attraction (trying to pull the earth and moon together) and the centrifugal force (trying to push the earth and moon apart). At a location on the earth's surface closest to the moon, the gravitational attraction of the moon is greater than the centrifugal force. On the opposite side of the earth, facing away from the moon, the centrifugal force is greater than the moon's gravitational attraction. Figure T33 shows a hypothetical ocean (covering the whole earth with no continents) with *two* bulges, one facing the moon and one facing away from the moon, that result from the two imbalances of gravitational and centrifugal forces. However, if we look at the side of the earth facing the moon, the force vertically upward from the earth toward the moon is so small compared with the earth's gravitational force that it could not cause the bulges. If we move away from the equator to another point on the earth that is not directly under the moon, we see that the attractive force is still pointing toward the moon, but is no longer perfectly vertical relative to the earth (see Figure T34). At this point, the force toward the moon can be separated in a vertical component of the force and a horizontal component, the latter one being parallel to the earth's surface. This horizontal force, though small, has nothing opposing it, and so it can move the water in the ocean. One can see from Figure T34 that all the horizontal components shown tend to move the water into a bulge centered around the point that is directly under the moon. Similarly, on the other side of the earth another bulge results.

One can easily envision the earth rotating under these bulges in this hypothetical ocean that covers the entire earth. In one complete rotation in one day there will be two high tides (when under a bulge) and two low tides (when halfway between bulges), and thus one entire tidal cycle would be completed in approximately half a day (actually 12.42 h, for reasons to be explained below). However, this is an extreme simplification (called the *equilibrium tide*) used merely to show how the tide generating forces change as the earth rotates. Not only are the continents left out, but this assumes that the oceans respond instantly to the tide-generating force, which they do not.

Now consider the addition of continents and look at one of the oceans, with a bay connected to it. The tide-generating forces are too small to cause a tide directly in a small body of water like a bay. Only in a large ocean are the cumulative effects of the tide-generating forces throughout the ocean large enough to produce a tide. What is actually generated is a very long wave with a small amplitude, on the order of a half a meter or less (see Figure T35). However, when this wave reaches the reduced depths of the continental shelf, there is a partial reflection of the wave, and the part of the wave that continues toward the coast is increased in amplitude. At the coast another reflection further increases the height of this long wave, now reaching at least a meter along most coasts. When the wave moves up into a bay there can be even more amplification depending on the depth, length, and width of the bay, with tidal ranges reaching 5, 10, or even 15 m for bays with the right dimensions.

How large the tide range is depends on how close the natural period of free oscillation of the basin is to the period of the tide-generating force. If the natural period of the basin is same as the period of the tide-generating force, then the energy from the tidal forcing will be input in the same direction as the water is already moving and the resulting tide range will be larger. This is called *resonance*. The natural period of a basin, T_n, is approximately equal to $2L/(gD)^{1/2}$, where L is the length of the basin, D is the depth, and g is the acceleration due to gravity. The Atlantic Ocean is too wide for there to be resonance (its 19-h natural period being much longer than the 12.42-h tidal period). The largest tide ranges in the world are in shallower basins with just the right length and depth combination to have natural periods close to the tidal period.

Astronomical considerations

Because it is a forced oscillating system, the tide will oscillate with the periods determined by the relative motions of the earth, moon, and sun. There are many different periods involved due to the complex nature of the orbit of the moon around the earth and of the orbit of the earth around the sun. However, astronomers have very precisely determined all of these periods. To predict the tide at a specific location for any time in the future one must simply analyze water level data from that location to determine the amplitude and phase associated with each of the important tidal periods.

If the earth–moon orbit and the earth–sun orbit were circular and in the plane of the earth's equator, there would only be two tidal frequencies, and only thus two semidiurnal constituents, M_2 and S_2 (defined below), would be needed to make tidal predictions. However, the orbital motions are more complicated. Distances between the moon and earth and between the earth and sun vary with time (the latter changes over a 20,942-year period and so is of no concern, except perhaps in paleoclimatology). Orbital planes are at angles relative to the earth's equatorial plane and these angles also vary with time. All these motions modulate the tidal forces, so that tidal energy shows up at many more frequencies than at just M_2 and S_2. The changing angles of the orbital planes also means that the moon and sun will not always be directly over the earth's equator, thus making the two tidal bulges (on the opposite sides of the earth) asymmetric with respect to the axis of rotation, which introduces diurnal tidal frequencies. The fundamental periods in the motions of the earth, moon, and sun are shown in Table T11. Table T12 shows how key tidal constituents are derived from these fundamental frequencies. (The *Doodson numbers* used in many tidal papers are a shorthand that indicates which of the six frequencies, ω_L, ω_1 through ω_5 from Table T11, are used to produce a particular constituent.) To make this a little clearer, we will describe the origins of a few of the more important tidal frequencies.

The moon orbits around the earth in the same approximate direction as the rotation of the earth, so that one lunar day (i.e., one complete rotation of the earth *with respect to the moon*) is 24.8412 h long ($1/\omega_L$, see Table T12). There are two tidal high water bulges on the earth, so the period of the largest semidiurnal lunar harmonic constituent, M_2, is half a lunar day, or 12.4206 h.

The earth turns under the sun exactly once every solar day, which leads to the main solar semidiurnal tidal constituent, S_2, with a period of 12.0000 h. Because the sun is so much farther from earth than the moon (and the tidal force is inversely proportional to the cube of the distance), S_2 is much smaller in size than M_2. When the moon and sun are in alignment (at new and full moons) their tidal forces work together to create *spring tides* with larger tidal ranges, while they work against

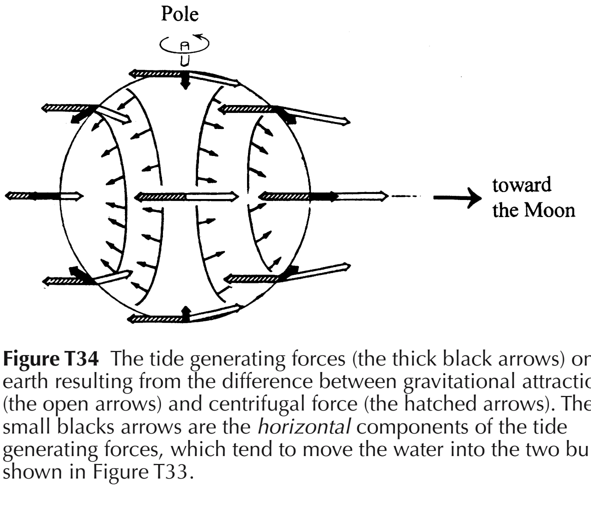

Figure T34 The tide generating forces (the thick black arrows) on the earth resulting from the difference between gravitational attraction (the open arrows) and centrifugal force (the hatched arrows). The small blacks arrows are the *horizontal* components of the tide generating forces, which tend to move the water into the two bulges shown in Figure T33.

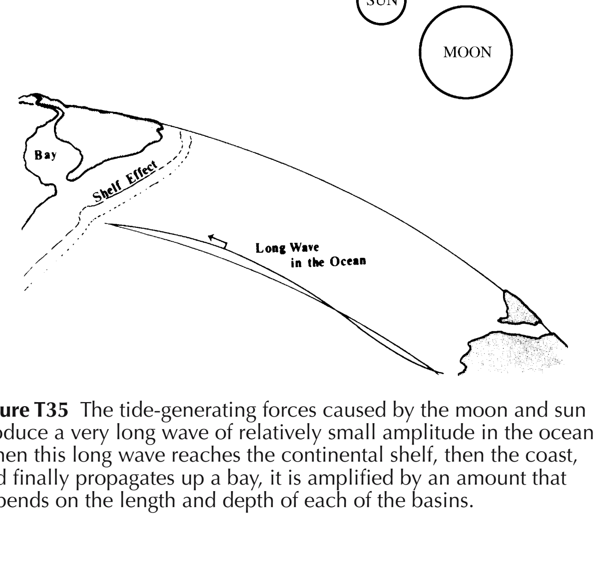

Figure T35 The tide-generating forces caused by the moon and sun produce a very long wave of relatively small amplitude in the ocean. When this long wave reaches the continental shelf, then the coast, and finally propagates up a bay, it is amplified by an amount that depends on the length and depth of each of the basins.

Table T11 Fundamental periods in the motions of the earth, moon, and sun (after Parker *et al.*, 1999)

Description	Period (mean solar units)	Frequency (1/period)
Sidereal day (one rotation wrt vernal equinox)	23.9344 h	Ω
Mean solar day (one rotation wrt to the sun)	24.0000 h	ω_S
Mean lunar day (one rotation wrt to the moon)	24.8412 h	ω_L
Period of lunar declination (tropical month)	27.3216 days	ω_1
Period of solar declination (tropical year)	365.2422 days	ω_2
Period of lunar perigee	8.847 years	ω_3
Period of lunar node	18.613 years	ω_4
Period of perihelion	20,940 years	ω_5

Table T12 Tidal constituents and their origins (after Parker *et al.*, 1999)

Symbol	Description	Period	Speed (°/h)	Derived from	Coefficient C
Semidiurnal tides					
K_2^L	declinational to M_2	11.967 h	30.0821373	$2\omega_L + 2\omega_1\ (=2\Omega)$	0.0768
K_2^S	declinational to S_2	11.967 h	30.0821373	$2\omega_S + 2\omega_2\ (=2\Omega)$	0.0365
S_2	principal solar	12.000 h	30.0000000	$2\omega_S$	0.4299
M_2	principal lunar	12.421 h	28.9841042	$2\omega_L$	0.9081
N_2	elliptical to M_2	12.658 h	28.4397295	$2\omega_L - (\omega_1 - \omega_3)$	0.1739
L_2	elliptical to M_2	12.192 h	29.5284789	$2\omega_L + (\omega_1 - \omega_3)$	0.0257
Diurnal tides					
K_1^L	declinational to O_1	23.934 h	15.0410686	$(\omega_L - \omega_1) + 2\omega_1\ (=\Omega)$	0.3623
K_1^S	declinational to P_1	23.934 h	15.0410686	$(\omega_S - \omega_2) + 2\omega_2\ (=\Omega)$	0.1682
P_1	principal solar	24.066 h	14.9589314	$(\omega_S - \omega_2)$	0.1755
O_1	principal lunar	25.819 h	13.9430356	$(\omega_L - \omega_1)$	0.3769
Q_1	elliptical to O_1	26.868 h	13.3986609	$(\omega_L - \omega_1) - (\omega_1 - \omega_3)$	0.0722
Long-period tides					
Mf	declinational to M_0	13.661 days	1.0980331	$2\omega_1$	0.1564
Mm	elliptical to M_0	27.555 days	0.5443747	$(\omega_1 - \omega_3)$	0.0825
Ssa	declinational to S_0	182.621 days	0.0821373	$2\omega_2$	0.0729

The speed is another form of frequency. M_0 and S_0 represent constant lunar and constant solar forces. The coefficient, C, gives a global measure of each constituent's relative portion of the tidal potential (i.e., it ignores a latitudinal variation that is different for each species).

each other at first and third quarters to create *neap tides* with smaller ranges (see Figure T36).

The earth–moon orbit is elliptical, so that the distance between them varies over a 27.5546-day period ($1/[\omega_1 - \omega_3]$, see Table T12), from perigee (the moon closest to the earth, and so a stronger tidal force) to apogee (the moon farthest from the earth, and so a weaker tidal force) and back to perigee. This modulates the lunar tidal force. This modulation of M_2 shows up in a spectra (of water level or current data) as a line to the left of the line for M_2, this lower frequency line representing a second lunar harmonic constituent, N_2, whose period is 12.6583 h. The stronger *perigean* tidal force will occur when M_2 and N_2 come into phase (leading to larger tidal ranges), while the weaker *apogean* tidal force will occur when M_2 and N_2 are exactly out of phase (leading to smaller tidal ranges). We can use Figure T36 to illustrate this, if, in that figure, we replace S_2 with N_2, spring tide with perigean tide, and neap tide with apogean tide. The difference is that with the M_2 plus S_2 case there really are two distinct effects being added, but in the case of the changing distance between the moon and earth, this directly varies the amplitude of the tide; and N_2 is merely a convenient way (in combination with M_2) to represent this variation of amplitude. There are several times a year when lunar perigee is reasonably close in time to new or full moon to produce the largest tidal ranges of the year, called *perigean spring tides*.

The plane of the moon's orbit around the earth is at an angle to the plane through the earth's equator. Thus, as the earth rotates under the moon, there will be times of the month when the moon is north of the equator (Northern Declination), over the equator (Equatorial Declination), and south of the equator (Southern Declination). When the moon is north or south of the equator, one of the tidal bulges is more north of the equator and one is more south, so that at a particular location on the earth there will either be only one high water per day (a diurnal tide), or, if there are two, they will be of different heights (the difference being the *diurnal inequality*) (see Figure T37). The diurnal lunar tidal forces resulting from lunar declination are represented by two tidal constituents, O_1 and K_1, with periods of 25.8193 and 23.9345 h, since they must cancel each other out every 13.66 days ($1/2\omega_1$, see Table T12), at the times when the moon is over the equator. (The maximum angle between the plane of the moon's orbit and the earth's equator varies from 18.3° to 28.5° over a 18.6-year period; see below for further discussion of this *nodal* cycle.) The sum of the O_1 and K_1 frequencies is equal to the M_2 frequency, so that the time of the diurnal high water does not change with respect to the times of the two semidiurnal high waters.

The plane of the earth's orbit around the sun (called the *ecliptic*) is also at an angle to the plane through the earth's equator. Around December 21st the sun is furthest south of the equator (December solstice) and around June 21st it is furthest north of the equator (June solstice), the angle between the ecliptic and the equator reaching 23.5° in each case. December solstice marks the beginning of winter in the Northern Hemisphere and the beginning of summer in the Southern Hemisphere, and *vice versa* for June solstice. Around March 21st the sun is over the equator (vernal equinox) and again around September 21st (autumnal equinox). This movement of the sun north and south of the equator also leads to diurnal tidal constituents, in this case P_1 with a period of 24.0658 h ($1/(\omega_S - \omega_2)$, see Table T12), and another K_1. Thus, the K_1 used for tidal prediction has both lunar and solar parts. P_1 and the solar part of K_1 cancel each other out every 182 days, at vernal and autumnal equinoxes.

As mentioned above, the angle between the plane through the moon's orbit and the plane through the equator varies over a 18.6-year period ($1/\omega_4$, see Table T12). This is referred to a *lunar nodal regression* because the intersection of the moon's orbital plane with the ecliptic, called the ascending lunar node, regresses backwards along the ecliptic over this 18.6-year period. Lunar distance also varies with time because the longitude of the lunar perigee rotates with an 8.85-year period ($1/\omega_3$, see Table T12). The spectral splitting due to these long-period effects can also be represented by harmonic constituents, called "satellite" constituents, but harmonic analyses using them must use data series that

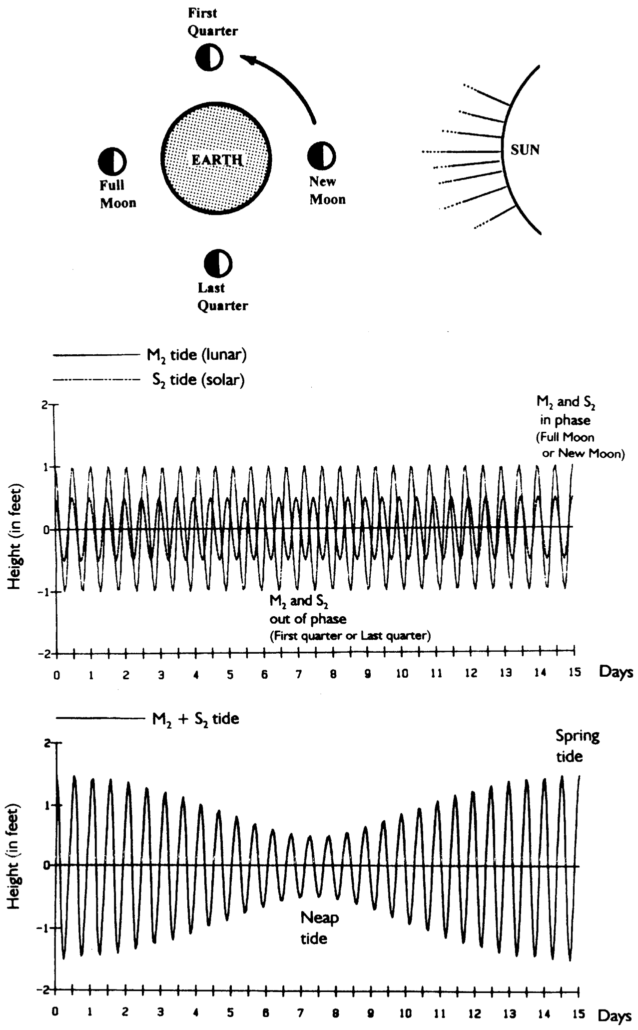

Figure T36 The combined effect of the moon and sun varies throughout the month. When the moon and sun are working with each other (at full moon and new moon) one sees the largest tidal ranges (*spring tides*). At First Quarter and Last Quarter the moon and sun work against each other resulting in smaller tidal ranges (*neap tides*).

are 18.6 years long. Traditionally the nodal effects have been handled in a form that directly represents the modulation of each lunar tidal constituent. The amplitude of each modulation is called the *node factor, f*, and the phase is called the *equilibrium argument, u. f* and *u* are regarded as constants for the period of analysis (or prediction) and are obtained from astronomically calculated tables (e.g. Tables 14 and 15 in Schureman, 1958). The largest variation in f over a 18.6-year period is found in O_1, which varies $\pm 18\%$, and in K_1, which varies $\pm 11\%$. The variation of f for M_2 is $\pm 4\%$, but since M_2 is much larger than O_1 and K_1 in many locations, it may only be the 4% variation with which one is usually concerned. There is no direct nodal effect on solar constituents such as S_2 or P_1.

Tidal analysis and prediction

Knowing only the periods of these and other smaller tidal constituents, one can analyze a data series of water level observations from a particular location. The result of such a *harmonic analysis* is an *amplitude* and *phase* for each of these tidal constituents, which represent how large each effect is *at that particular location*, and when in time the peak of each effect will take place (such as relative to when the moon passes over (transits) that location). The hydrodynamics affect both the amplitude and phase (timing) of each tidal constituent, but we really do not need to know the details of how it happened, only that it did happen. Hydrodynamics in shallow-water areas will also produce additional tidal constituents not seen in deeper water (discussed in the next section) that

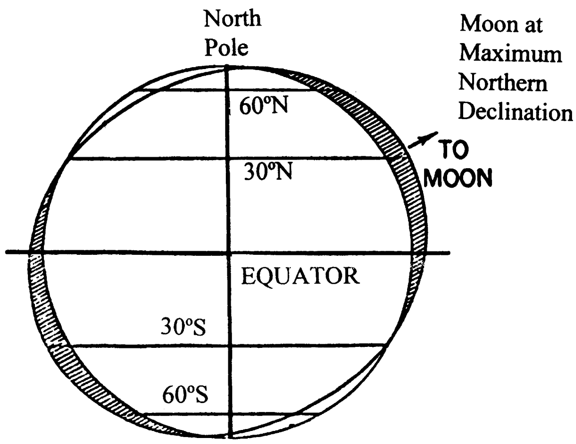

Figure T37 When the moon is at maximum declination north or south of the equator the tidal bulge also shifts north or south. When this happens certain locations on the earth would rotate under only one high water "bulge," that is, there will be a diurnal component of the tidal forces. Hydrodynamics will determine which oceans and bays have significant diurnal tides.

can also be easily handled by the harmonic method. As long as the hydrodynamics stay the same (i.e., the depth of the basin stays the same), the tide predictions from these calculated harmonic constants will be accurate. For small bays, shoaling or dredging can change the hydrodynamics and thus change the tide range and times of high and low waters.

Harmonic analysis is still the most common method used for the analysis and prediction of tides and tidal currents. It has not changed much from the theory first developed by Lord Kelvin in 1867 and later refined by George Darwin, except that the Fourier analysis solution technique (e.g., Schureman, 1958) has generally been replaced by a least-squares solution technique (e.g., Foreman and Henry, 1989) that minimizes the squared differences between measurements and computed tidal predictions. Doodson (1921) carried out a complete harmonic development of the tide-generating potential, determining over 400 tidal constituents (most very small), which has been the standard reference work for tidal analysis and prediction. This was recalculated and updated 50 years later by Cartwright and Tayler (1971).

Harmonic analysis is used to produce the predictions at the reference stations in all nationally published Tide and Tidal Current Tables. Nonharmonic analysis, which is simply one of several methods of comparing the tide or tidal current at two locations, is used to calculate the time differences, height differences, velocity ratios, etc. for the thousands of secondary stations in these tables that are referred to the reference stations. Several refinements to the harmonic methods have been developed in recent decades, as well as the nonharmonic/cross-spectral approach of the response method developed by Munk and Cartwright (1966). Whatever the method used, some principles will always apply. For example, the analysis of longer data time series will lead to more accurate predictions because more tidal frequencies can be resolved in a longer series.

Using the harmonic method the tide is represented by the sum of various tidal constituents, each representing one of these frequencies. The height of the tide at any time is typically represented by a formula such as (Schureman, 1958):

$$h = H_0 + \sum f H \cos[at + (V_0 + u) - \kappa],$$

where

h	=	height of tide at any time t
H_0	=	mean height of water level above the datum used for prediction
H	=	mean amplitude of any constituent A
f	=	node factor
a	=	speed of constituent A (i.e., its frequency)
t	=	time, reckoned from some initial epoch (such as the beginning of the year of predictions)

$(V_0 + u) =$ value of equilibrium argument of constituent A at $t = 0$.
κ = epoch (phase) of constituent A.

The *"speed" of a constituent* is merely its frequency, but it has been traditionally given in terms of degrees per solar hour, where 360° is one complete cycle. Thus, M_2, which has a period of 12.42 h and a frequency of 1.932 cycles per day, has a speed of 28.984104°/h.

For tidal current predictions the same equation is used twice, once for each of two orthogonal components (e.g., major and minor axes of flow), which when combined will give the speed and direction of the flow. The major and minor component for each tidal constituent can be combined to produce a *tidal constituent ellipse*, which shows what the constituent flow would be for each instant in a constituent cycle.

The more tidal constituents that can be calculated the more accurate the tidal prediction will be. The number of constituents that can be calculated depends on the length of the data series. The length of a data series needed to resolve two tidal constituents is inversely proportional to the difference in the frequencies. Table T13 lists the 37 typically most important tidal constituents, listed in order of length of time needed to resolve that constituent from a nearby larger constituent. One sees natural groupings near 15 days, 29 days, 6 months, and one year.

If one has only 15 days of data, for example, then a harmonic analysis will provide values for the major constituents M_2, S_2, K_1, and O_1, plus a few higher harmonics and a couple of less important constituents. However, these calculated values will also include energy from the constituents that could not be separated out in only 15 days. For example, the M_2 will include energy from N_2 (which could have been resolved from M_2 if there had been 29 days of data). This N_2 contribution could make the M_2 value calculated from 15 days of data larger than it should be, or smaller than it should be, depending on when the data were measured. Likewise, K_1 will include the effects of P_1 (which could have been resolved from K_1 if there were 6 months of data). If we harmonically analyzed successive 15-day periods, we would see the amplitude of K_1 slowly vary over a 6-month period because of the influence of P_1. The key to an accurate tidal prediction is determining amplitudes and phases for the most tidal constituents that can be calculated with a given length data time series.

To carry out a tide prediction in the era before the above equation could be programmed on a computer (as it is done routinely today), large machines were built with gears and pulleys connected by a wire to a pen. Each tidal constituent had a different size rotating gear and a pin and yoke system connected to a pulley (see Figure T38). The pin and yoke system turned the rotating motion of the gear into a vertical up and down motion of the pulley, which moved the wire over it and thus moved the pen up and down on a roll of moving paper. The wire ran over a number of pulleys so all the constituent effects could be added together. The first tide predicting machine was a wooden model built for Kelvin in 1872, but later models were huge brass machines with dozens of finely made gears and pulleys. The first one built in the United States was by William Ferrel in 1885. Prior to the use of harmonic analysis there were other less sophisticated methods based on recognized relationships between the tides and the movements of the moon and sun. For example, for a particular place, high tide might occur a certain number of hours after the moon was directly overhead, and the highest (spring) tide might occur a certain number of days after full moon or after new moon. In many of the early maritime nations, tide prediction schemes were treasured family secrets passed on to the next generation. The two earliest tide tables discovered were for the tidal bore in the Tsientang River in China in 1056 and for London Bridge in England in the early 1200s.

Table T13 Thirty-seven tidal constituents that can be calculated from a one-year series, listed in order of length of data time series needed to resolve each constituent from a nearby larger constituent, and size

Constant	Speed (°/h)	Origin	Days needed to separate	From	Amplitude at Trenton, NJ (feet)

Amplitudes from a 1981 analysis of water level data (from Trenton, NJ, on the Delaware River) are provided as an example (after Parker *et al.*, 1999).
[a] Values are determined predominantly by long-term meteorological effects and thus vary from year to year.

Hydrodynamic considerations in coastal waters

When the very long tide wave generated in the ocean reaches the shallower water of the continental shelf and the even shallower water of the bays and rivers, it is slowed up, amplified, modulated, and distorted by a number of hydrodynamic mechanisms. The long wave enters and propagates up a river as a *progressive wave*, that is, the crest of the wave (high water) moves progressively up the river, as does the trough of the wave (low water) (see Figure T39). In such a progressive tide wave the flood current (the tidal current flowing up the river) is fastest at approximately the same time as high water, and the ebb current (the tidal current flowing down the river) is fastest at approximately the same time as low water. Slack water (the time of no current) occurs approximately halfway between the times of high water and low water.

If there is nothing in a river to impede or stop the tide wave (like a dam or rapids or a sudden decrease in width), it will continue to travel up the river until bottom friction wears it down. However, if the width of the river decreases as the tide wave moves upriver, then the tidal range will be increased, because the same energy is being forced through a smaller opening. If the depth of the river decreases there is a similar but less dramatic amplifying effect generally outweighed by the increased frictional energy loss.

The greatest amplification of a tide wave usually occurs in a bay (or in a river with a dam). In this case, the tide wave is reflected at the head of the bay and travels back down the waterway toward the ocean. This *reflected* wave is not observable by someone on the shore because it is superimposed on the next incoming tide wave that is propagating up the bay, and it is the combination of the two waves that one observes. The resulting combined wave is called a *standing wave*, because the high and low waters do *not* progress up the bay or river. The water simply moves up and down everywhere at the same time (see Figure T40), with the greatest tidal range at the head of the bay. With a standing wave, the tidal range decreases as one moves from the head of the bay toward the ocean entrance, and, if the bay is long enough, reaches a minimum at one location (called a *node*) and then starts increasing again. This node occurs at one-fourth of a tidal wavelength from the head of the bay (see Figure T40). (In a progressive wave high water comes half a wavelength before low water, so if a high water travels a distance equal to one-fourth of a tidal wavelength up the bay to the head, where it is reflected, and then travels one-fourth of a wavelength back down the bay, it will have gone half a wavelength and so coincide with low water of the next incoming wave, and the two will cancel each other out at that location, producing a very small tidal range.) For a standing wave high waters occur at the same time everywhere on one side of the node, which is the same time as low waters occur on the other side of the node. The strongest tidal currents occur when water level is near mean tide level, approximately halfway between the times of high water and low water. At the times of high water and low water there is no flow (slack water). The water flows into the bay, stopping the inward flow at high water, reverses direction, flows out of the bay until low water, at which time it reverses again and starts flowing into the bay again.

When length of a bay is exactly one-fourth of a tidal wavelength, then resonance occurs, which creates the largest tides possible. When the water in the bay is forced to move up and down by the tide at the entrance, it will freely oscillate (slosh up and down) with a natural period that depends directly on its length and inversely on the square root of its depth. If the basin has the right combination of length and depth so that the natural period is the same as the tidal period, then the oscillation inside the bay will be synchronized with the oscillation at the entrance due to the ocean tide. In other words, the next ocean tide will be raising the water level in the bay at the same time that it would already be rising due to its natural oscillation (stimulated by the previous ocean tide wave), so that both are working together, thus making the tidal range inside higher.

Most bays actually fall in between the extremes of pure progressive wave and pure standing wave described above, because bottom friction reduces the amplitude of the tide wave as it travels. Thus, the reflected wave will always be smaller than the incoming wave, especially near the bay entrance, and the combination of the two frictionally damped progressive waves will not be a pure standing wave. There will be no point of zero tidal range, but only an area of minimum tidal range. There will be some progression of high waters and low waters up the bay, and maximum flood or ebb currents will not occur exactly half way between high water and low water. A basin one-fourth of a wavelength long will still produce the largest possible tidal range at the head of the bay, but friction keeps that tidal range much smaller than it would be without friction.

In some bays, the very high tidal range at the head of the bay is due to a combination of both a narrowing width and a near resonant situation (due to the right length and depth). The highest tidal ranges may involve several amplifications, the bay being perhaps connected to a gulf with perhaps a wide continental shelf beyond that, with amplifications of the tide wave occurring in each basin. This is the case with the Bay of Fundy tides, the tide wave being already amplified by the Gulf of Maine and the continental shelf prior to entering the Bay of Fundy.

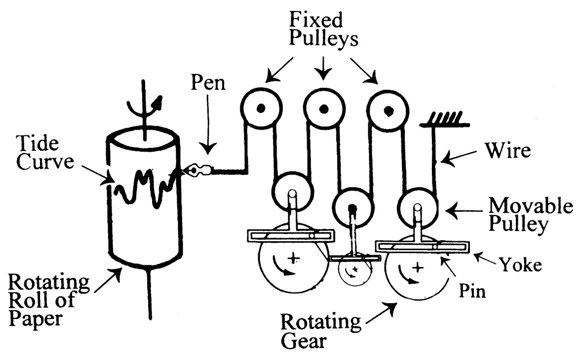

Figure T38 A schematic of an early tide prediction machine. Each gear and pulley combination represented one tidal constituent. The wire running over every pulley summed the motions and moved a pen on a moving roll of paper to draw a tide curve.

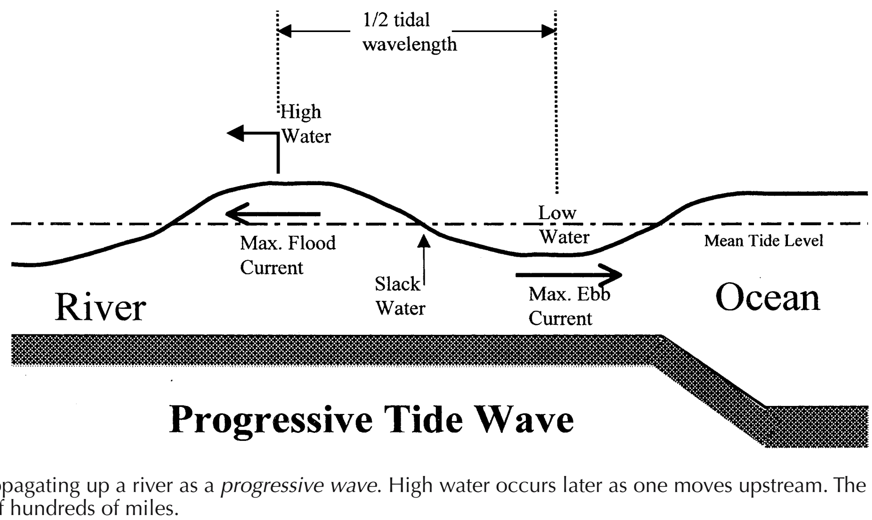

Figure T39 The tide propagating up a river as a *progressive wave*. High water occurs later as one moves upstream. The tidal wavelength is typically on the order of hundreds of miles.

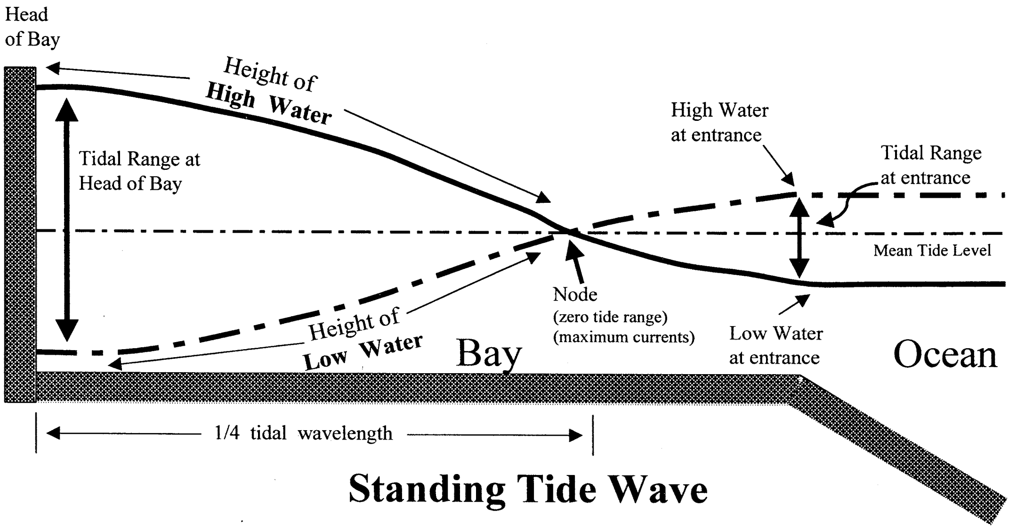

Figure T40 The tide in a bay as a *standing wave* (the water level is shown for two extremes, high water and low water). High water occurs at approximately the same time everywhere on one side of the node (the point of zero tidal range). This is an idealized case assuming there is no bottom friction effect. With friction the tidal range at the node is not zero and the times of high water do progress slightly up the bay.

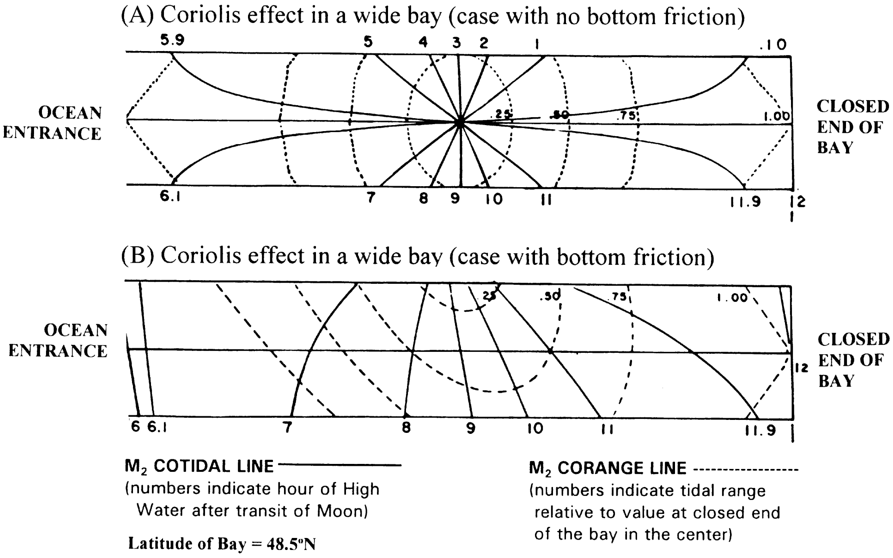

Figure T41 The effect of Coriolis force on M_2 tidal range (corange lines) and the times of high water (cotidal lines) for an idealized rectangular bay. The top figure assumes no bottom friction effects, and a single point of zero tidal range in the middle of the bay results. The bottom figure, which includes friction, is more realistic, and there is no point with zero tidal range.

If a bay is wide enough one also sees larger tidal ranges on the right side of the bay (looking up the bay) due to the Coriolis effect. Figure T41(A) shows lines of locations with the same time of high water (cotidal lines) and lines of constant tidal range in an idealized rectangular basin for the case where the effect of bottom friction is ignored. A single point of zero tidal range occurs in the center of the bay. A more realistic case, including the damping effect of bottom friction, is shown in Figure T41(B), with the point of no tidal range disappearing onto land. (The effect of Coriolis can also be seen in Figure T42, where the shape of the M_2/K_1 lines near Victoria are caused by the point of zero M_2 tidal range having moved to the left on land.)

Huge tidal ranges are not restricted to bays. If the continental shelf is the right combination of depth and width, a near resonant situation can also result. This is the reason for the 12 m tidal ranges along the coast of southern Argentina. The continental shelf there is over 1,000 km (600 miles) wide, and includes the Falkland Islands near the edge of the shelf (where the tidal range only reaches 2 m. The distance from the Argentinean coast to the edge of the shelf is fairly close to one-fourth of a tidal wavelength for that depth of water. Essentially, that wide shelf has a natural period of oscillation that is fairly close to the tidal period.

The largest tidal currents in bays tend to be near the entrances. Maximum tidal current speeds are zero at the head of the bay (since there is no place for the water to flow). As one moves down the bay toward the ocean the maximum flood and ebb tidal current speeds increase, with the greatest speeds occurring at the entrance, or, if the bay is long enough, at the area of smallest tidal range (the nodal area). However, if the width of the bay decreases at any point, the current speeds will be increased in that narrow region (since the same volume of water is being forced to flow through a smaller cross section, it must flow faster). This can be especially dramatic if there is a sudden decrease in width and depth. The largest tidal currents are found in narrow straits in which the tides at either end have different ranges or times of

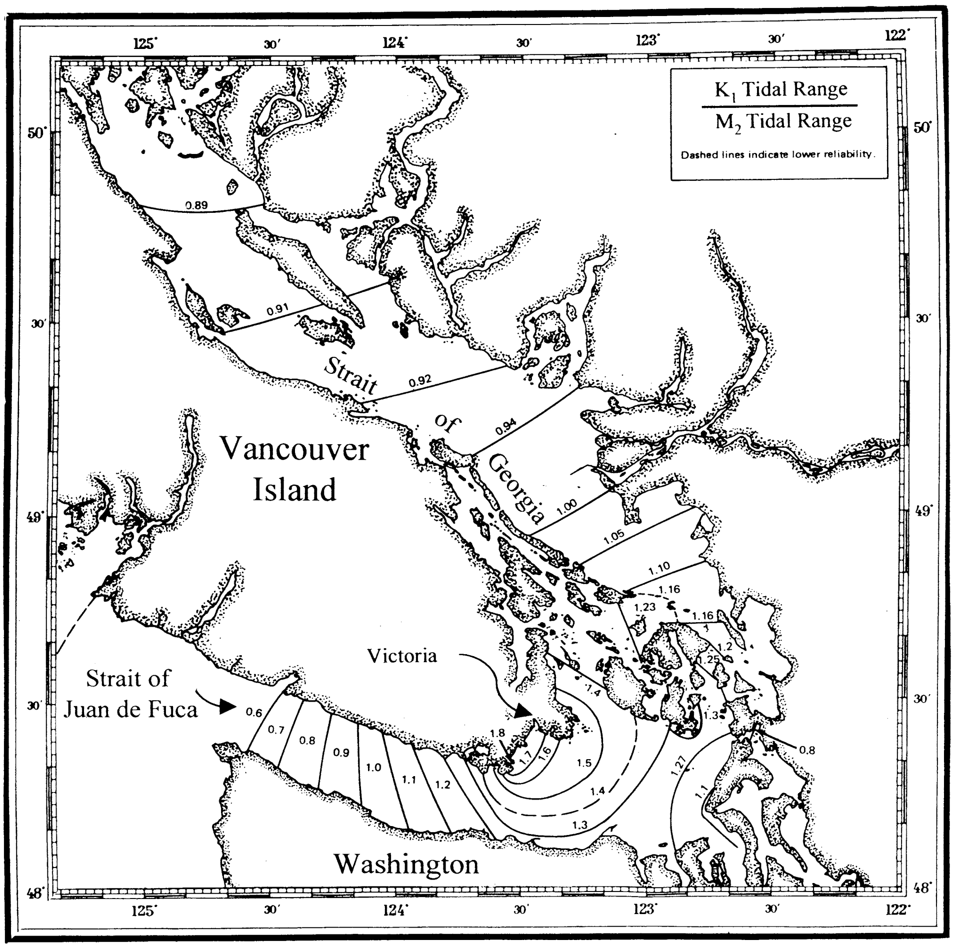

Figure T42 The ratio of the largest diurnal component of the tide (K_1) to the largest semidiurnal component of the tide (M_2) along the length of the Strait of Georgia-Strait of Juan de Fuca. The highest ratio of diurnal range to semidiurnal range occurs near Victoria, British Columbia, because that is the area of the semidiurnal node (minimum M_2 tidal range), which is one-fourth of a semidiurnal tidal wavelength from the northern end of the Strait of Georgia (see text).

high water. Where a strait suddenly becomes very narrow or where it bends, eddies and whirlpools can be formed as the result of the sheltering effect of the land and the inertia of the coastal flow.

The dimensions of a basin can also determine the size of the diurnal tidal signal compared with the usually dominant semidiurnal tidal signal. A particular bay could have a natural period of oscillation that is closer to the diurnal tidal period (approximately 24.84 h) than to the semidiurnal period, thus amplifying the diurnal forcing at the entrance to the bay more than the semidiurnal signal. Depending on the size of the diurnal signal at the entrance the result could be a mixed tide or a diurnal tide. At such locations (such as parts of the Gulf of Mexico) the tide will be diurnal near times of maximum lunar declination, but will be semidiurnal near times when the moon is over the equator.

The wavelength, L, of a tide wave in a bay depends on the depth of the water, D, and on the tidal period, T, according to $L = T(gD)^{1/2}$ (if we ignore frictional effects). The shallower the bay the shorter the wavelength. The longer the tidal period the longer the wavelength. A diurnal tidal component has a wavelength twice as long as a semidiurnal tidal component since its period is twice as long. When a waterway is shallow enough and long enough so that more than one-fourth of a semidiurnal wavelength fits in the waterway, there will be a nodal area with a very small semidiurnal tidal range. This will be an area where the diurnal tide could dominate, since the diurnal tide would still be large at the semidiurnal nodal area (its the diurnal node being twice as far from the head of the bay). Thus near the head of the waterway the tide could be semidiurnal, but near the semidiurnal nodal area the tide could be mixed or even diurnal. This is the case near Victoria, British Columbia, at the southeastern end of Vancouver Island (see Figure T42). At that location along the Strait of Georgia-Strait of Juan de Fuca waterway, the semidiurnal tidal component decreases to a minimum, but the diurnal component does not, and so the tide becomes diurnal (while at the northern end of the Strait of Georgia the tide is semidiurnal).

Whether due to a basin size conducive to amplifying the diurnal signal or due to the existence of a semidiurnal nodal area (leaving the diurnal signal as the dominant one), there are numerous areas around the world with strong diurnal tides—places like Norton Sound in Alaska near the Bering Strait, and various (but not all) locations in the Philippines, New Guinea, and the islands of Indonesia. In southern China, at Beihai, and at Do Son, Vietnam, the diurnal signal is very dominant, with tidal ranges that reach 5 m and 3 m, respectively (near times of maximum southern declination of the moon); the tide remains diurnal even near times when the moon is over the equator.

The primary effect of shallow water on the tide that we have discussed so far is that it shortens the tidal wavelength down to the same order of magnitude as the lengths of bays and river basins, thus bringing the dynamic situation closer to resonance and increasing the tidal ranges. (Or, one can also look at it from the point of view of the shallower depths increasing the natural periods of these bays and rivers (which are very small basins compared to the ocean) to be closer to the tidal period.) However, very shallow water can have other effects on the tide, for example, distorting the shape of the tide wave, that is, making it very asymmetric, so that its rise and fall (and its flood and ebb) are no longer equal (see the second curve in Figure T43). The tide can then no longer be described by a simple sine wave (the first curve in Figure T43). In some cases such distortion leads to double high waters or double low waters (see third curve in Figure T43). The extreme case of distortion is a tidal bore (the fourth curve in Figure T43).

Shallow water distorts the tide through several mechanisms. The speed, C, at which a long tide wave travels depends on the depth of the water, D, according to the formula $C = (gD)^{1/2}$. When depth of the

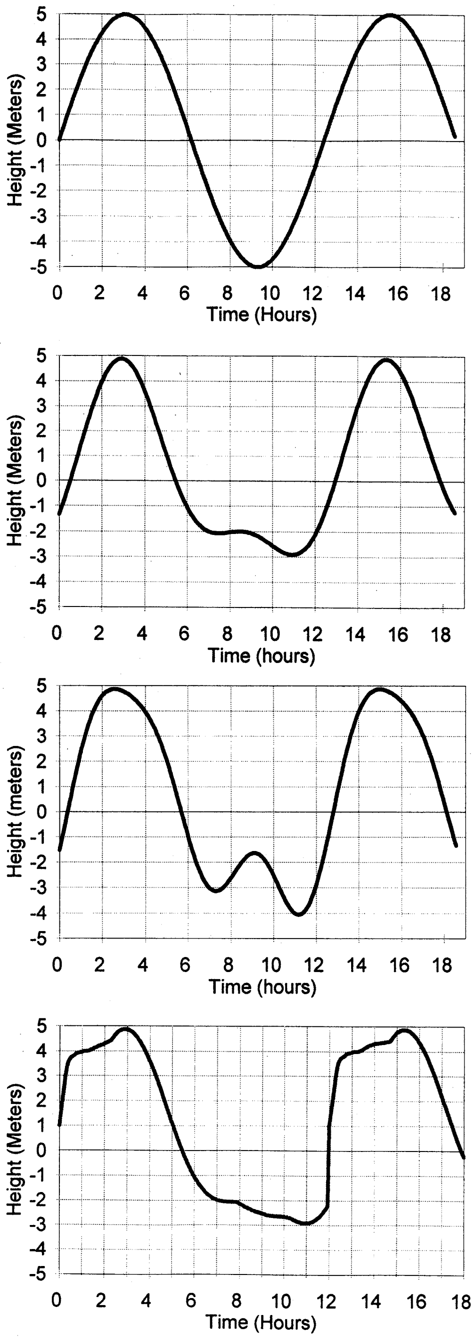

Figure T43 Typical tide curves (i.e., tidal height plotted with respect to time), over one-and-half tidal cycles for an area with no shallow-water effects (top panel) and for three areas with different degrees of distortion caused by the shallow water. In the third panel a double low water occurs. The fourth panel shows the almost instantaneous rise in water level due to the passage of a tidal bore.

water is much greater than the tidal range, the speed of the crest of a tide wave and the speed of the trough are virtually the same, since the tide wave itself has only a very small effect on the total water depth. But in the shallow water where the depth is not much greater than the tidal range, the total water depth under the crest is significantly larger than the total water depth under the trough. In this case, the crest of the wave (high water) travels faster than the trough of the wave (low water). If the tide wave travels far enough the crest begins to catch up with the trough ahead of it (which is falling behind the crest ahead of it). The shape of the tide wave then begins to look like the second curve in Figure T43, with a more rapid rise to high water and a slower fall to low water. In terms of harmonic constituents, this distortion transfers energy from M_2 into a constituent called M_4, with half the period.

Another shallow-water distorting mechanism is caused by bottom friction, which can have both asymmetric and symmetric effects. The asymmetric effect (similar to that just discussed and represented in Figure T43) results because friction has a greater effect in shallow water than in deepwater (there being less water to have to slow down), and so it slows down the trough more than the crest, contributing to the distortion of the tide wave and the generation of M_4. A symmetric effect results because energy loss due to friction is proportional to the square of the current speed. This means that there will be much more energy loss during times of maximum flood and maximum ebb than near slacks. This results in the generation of another higher harmonic, M_6, with a period of one-third that of M_2. This effect, combined with the asymmetric effect, can lead to double high or low waters (see third curve in Figure T43). Higher harmonic tidal constituents like M_4 and M_6 are referred to as *overtides*.

The above symmetric frictional effect also causes the interaction of two tidal constituents, for example, M_2 and N_2. M_2 and N_2 go in and out of phase over a 27.6-day cycle (perigee to apogee to perigee). In this case, the greatest energy loss occurs when M_2 and N_2 are in phase and producing the strongest tidal currents, and the lowest energy loss occurs 13.8 days later with M_2 and N_2 are out of phase and producing the weakest tidal currents. The increased energy loss when M_2 and N_2 are in phase is greater than the decreased energy loss when they are out of phase, and the result is that each constituent will be smaller than if it existed without the other present. There is a 27.6-day modulation of this energy loss from M_2 and N_2, which produces two new *compound* tidal constituents called $2MN_2$ and $2NM_2$. (Similarly, the above asymmetric mechanisms also cause interactions between constituents, producing higher frequency constituents such as MN_4 from M_2 and N_2.)

Friction, of course, dissipates energy from the entire wave and slowly wears the entire wave down. However, if, as the wave propagates up the river, the river's width is decreasing significantly, this can keep the amplitude of the wave high in spite of the friction. Thus, the tide wave can continue to travel up a narrowing river, getting more and more distorted in shape. A further distortion can be caused by the river flow interacting with the tide (see below). In the extreme case, the distortion from all these effects can lead to the creation of a tidal bore (see fourth curve in Figure T43).

In a river there will also be the river current itself (resulting from fresh water flowing downhill) added onto the tidal current, the result being a faster and longer lasting ebb current and a slower shorter flood current phase. Far up a river where the river flow is faster than the strongest tidal current, the flow of water will always be downstream, but the speed of flow will oscillate, flowing the fastest downstream at the time of maximum ebb for the tidal current and flowing the slowest downstream at the time of maximum flood for the tidal current. This is a simple addition to the tide, but the river flow also interacts with the tide and distorts it through interaction caused by bottom friction. As just mentioned, energy loss due to friction is proportional to the square of the total current speed. When the river current, flowing in the same direction as the ebb current, creates a larger combined ebb current, there is a greatly increased energy loss. Likewise, when the river current flowing opposite to the flood current reduces the total speed, the energy loss is greatly reduced. This not only has an asymmetric effect that distorts the tide (causing a faster rise to high water, delaying the time of low water, and contributing to M_4), but it also further wears down the entire wave because the increased energy loss during ebb is larger than the decreased energy loss during flood.

Another type of shallow-water effect causes interactions between tide and storm surge (generated by the wind) that have periods longer than tidal periods. In this case, when the water level is raised by an onshore wind, that increases the water depth and changes the tidal dynamics, usually increasing the tidal range. When an offshore wind lowers the water level, decreasing the water depth, the result is usually a decreased tidal range. Knowing that river discharge and storm surge can modify the tide, it is important when harmonically analyzing water level data to make sure that these data were not taken only during such meteorological events. These shallow-water effects that distort and modulate the tide and cause interactions with storm surge and river discharge are called *nonlinear* effects because the mechanisms that produce these effects are represented by several *nonlinear* terms in the equations of motions used to model the tidal hydrodynamics.

We have shown how tidal prediction can be accomplished quite accurately by harmonic analysis of a water level data time series knowing only the astronomical frequencies involved, and ignoring hydrodynamics. Accurate inclusion of the additional tidal constituents produced by nonlinear shallow-water effects into the harmonic prediction method does involve some knowledge of hydrodynamics (especially when deciding the formula for each constituent's node factor). However, recently tidal prediction has begun to involve the use of sophisticated hydrodynamic numerical models, which have two important advantages over statistical techniques. First, such models can provide tide and tidal current predictions at locations where there are no water level data, thus providing predictions at hundreds or thousands of locations in an area, as opposed to the few locations where statistical methods can provide them (limited by needing data to analyze). Second, such models handle very nicely the nonlinear interaction between the tide and nontidal phenomena like storm surge and river discharge.

TIME SERIES MODELING

Fundamental concepts of coastal time series

There has been a considerable expansion in the coastal database in the past two decades. Discrete and continuous data are collected from the coast and its interacting hydrodynamic, biological, morphological, sedimentological, and other associated subsystems in order to make better decisions on coastal management and sustainable development. While the quality and length of the collected coastal data vary greatly, many datasets fall within the domain of time series analysis. Any time series can be considered as a time (or space) ordered sequence of realizations (or observations) of a variable of interest. The set of observations generated sequentially in time could be either continuous or discrete. In statistical terms, a time series is a realization or sample function from a certain stochastic or random process. The time series to be analyzed can be considered as a particular realization, produced by the underlying probability mechanism of the system (i.e., coastal) under consideration. The observed values of a stochastic process are generally considered as a realization of the stochastic process. Time series analysis can consider a class of stochastic processes, called stationary processes, which assume that the process is in a particular state of statistical equilibrium (Box *et al*., 1994). In the analysis of stationary stochastic processes it is worthwhile to note that "stationary processes generally arise from any 'stable' system which has achieved a 'steady-state' mode of operation" (Priestley, 1981, p. 14), whereas a nonstationary series is regarded as having properties which change with time.

Since in time series analysis, inferences can be made from a realization to the generating process, it is necessary to consider the statistical properties of the time series. Essentially, the properties of a time series can be obtained from a single realization over a time interval or based on several realizations at a particular time. The properties based on a time interval of a single realization are referred to as time-averaged properties. The properties from several realizations at a given time are considered as the ensemble properties. "Since different sections of a time series resemble each other only in their average properties, it is necessary to describe these series by probability laws or models" (Jenkins and Watts, 1969, p. 2).

Coastal time series modeling

Since stochastic processes deal with systems which develop in accordance with probabilistic laws, stochastic models can be used to gain insights on the spatial and temporal behavior of the coastal system (Lakhan, 1982; Lakhan and Trenhaile, 1989). Time series modeling of the many natural phenomena occurring in the coastal environment, which appear to behave in random or probabilistic ways, is essential for understanding not only the operating processes, but also for many coastal applications. Many examples of the use and applications of probabilistic and time series models in coastal studies have been provided by Guedes Soares (2000). Even the modeling of one sea-state parameter has many applications in coastal and offshore engineering. For example, modeling a time series of significant wave height at a location is a useful complement to long-term probabilistic models that describe the wave climate in different areas (Cunha and Guedes Soares, 1999).

The complex nature of the coastal system makes it necessary to develop models which can explain both the deterministic and random features of the time series for any coastal process (Lakhan, 1989). For example, sea-states can be visualized as random and unpredictable. However, there is some constancy of a sea-state for a short duration of several minutes to fractions of minutes, and therefore it is possible to assume stationarity for such short wave records. Conversely, a wave record of long duration will not exhibit stationarity because the significant wave height and other statistics are known to vary with respect to time (Goda, 2000). To characterize and predict the probabilistic nature of the sea surface a time series model can be developed to represent the sea surface elevation as a nonstationary stochastic process, with the sea-state considered to be a Gaussian, statistically stationary stochastic process in short time periods. In modeling stationary or nonstationary time series, coastal and allied researchers have utilized either the frequency domain or the time domain approach.

Approaches to time series analysis

Given the fact that there are various terminology, theoretical and practical aspects of time series analysis, this short review will introduce only the fundamental concepts for coastal and allied researchers. Hannan *et al*. (1985) pointed out that since its inception the theory and practice of the analysis of time series has followed two lines. One of these proceeds from the Fourier transformation of the data and the other from a parametric representation of the temporal relationships. The two approaches to time series analysis, commonly referred to as the frequency domain approach (or spectral analysis approach) and the time domain approach, have been discussed in several books (e.g., Anderson, 1975; Otnes and Enochson, 1976; Gottman, 1981; Kendall and Ord, 1990; Wei, 1990; Bendat and Piersol, 1993; Harvey, 1993; Hamilton, 1994; Brockwell and Davis, 1996; Pollock, 1999; Shumway and Stoffer, 2000). In brief, the frequency domain approach uses spectral functions to study the nonparametric decomposition of a time series into its different frequency components. The time domain approach concentrates on the use of parametric models to model some future value of a time series as a parametric function of the current and past values.

While the frequency and time domain approaches can be used to provide different insights into the nature of the actual time series it should, however, be pointed out that both approaches are mathematically equivalent. According to Gottman (1981), the two approaches are linked by the famous theorem called the Wiener-Khintchine Theorem which provides a shuttle between the frequency and time domains. The Wiener-Khintchine Theorem shows that there is a one-to-one relationship between the autocovariance function of a stationary process and its spectral density function (Pollock, 1999). Knowing the correlation structure in the time domain corresponds to knowing the form of the spectrum in the frequency domain. Essentially, the autocorrelation function and the spectrum function form a Fourier transform pair (Kendall and Ord, 1990).

Although the two approaches are complementary rather than competitive (Harvey, 1993), there are situations when one approach is more appropriate to use than the other. According to Shumway and Stoffer (2000) the two approaches may produce similar answers for long series, but the comparative performance over short samples is better done in the time domain. Given this observation, brief remarks and selected coastal applications for both approaches will, therefore, be provided. Emphasis will then be placed on modeling in the time domain because there are well-established techniques for model selection, identification, and estimation.

The frequency domain approach

Extensive discussions on the frequency domain, or spectral approach, to time series analysis can be found in several books (e.g., Jenkins and Watts, 1969; Rayner, 1971; Kanasewich, 1973; Koopmans, 1974; Brillinger, 1975; Bloomfield, 1976; Priestley, 1981; Brillinger and Krishnaiah, 1983; Brigham, 1988; Brockwell and Davis, 1996; Fuller, 1996; Ramanathan, 1998; Pollock, 1999). According to Jenkins and Watts (1969, p.16), "spectral analysis brings together two very important theoretical approaches, the statistical analysis of time series and the methods of Fourier analysis." Since, in the frequency domain approach, Fourier transforms play a very important role (Brillinger and Krishnaiah, 1983), some brief remarks will be made on Fourier's methods which form the basis of all spectral analysis (Rayner, 1971).

Time series spectral analysis can be traced to Jean Baptiste Joseph de Fourier (1768–1830) who made the claim in 1807 that an arbitrary function defined on a finite interval could be represented as a infinite summation of cosine and sine functions (see Lasser, 1996). Many mathematicians have worked on the development of the techniques of Fourier analysis, and contemporary books (e.g., Körner, 1988; Lasser, 1996; Ramanathan, 1998; Howell, 2001) have presented various aspects of the mathematics of Fourier analysis. Without discussing the details of Fourier techniques it is worthwhile to note that one notable early investigation which focused on analyzing time series in the frequency domain was Schuster (1898) who employed the technique of periodogram analysis. The early underlying model expressed the series as a weighted sum of perfectly regular periodic components upon which a random component was superimposed. While much of the theory of spectral analysis of random processes focused on stationary processes, in recent years, "a new form of spectral analysis has been developed which, while not accommodating all nonstationary processes, does however enable us to treat a fairly large class of such processes in a unified theory which includes stationary processes as a special case" (Priestley, 1981, p. 17).

The Fourier analysis of stochastic processes can provide a representation of an infinite sequence in terms of an infinity of trigonometric functions whose frequencies range continuously. The underlying stochastic process can be represented by the Fourier integral. This can be attained by describing the stochastic processes which generate the weighting functions. There are two weighting processes, associated respectively with the sine and cosine functions; and the function that defines their common variance is the so-called spectral distribution function whose derivative is the spectral density function or the "spectrum" (Pollock, 1999). For practical purposes, the spectral density function can be referred to as the power spectrum. "Since the power spectrum is the Fourier cosine transform of the autocovariance function, knowledge of the autocovariance function is mathematically equivalent to knowledge of the spectrum, and vice-versa" (Box *et al.*, 1994, p. 39). The power spectrum provides significantly more information about the time series than simply the total power. The estimated spectrum can be used to obtain insights about the mechanism that generated the data (Koopmans, 1974).

The power spectrum plays a very important role in the analysis of coastal time series. By considering the probability distribution of the sea surface as nearly Gaussian, a good approximate description is provided by the covariance function, the Fourier transform of which is referred to as the wave spectrum. In coastal studies, the wave spectrum has physical meaning because it can be demonstrated to be the density function specifying the distribution of energy over wave components with different wave number vectors and frequencies. Its integral over all wave components is proportional to the total wave energy per unit area (see Komen *et al.*, 1994). It should be noted that the components of the spectrum are the squares of the wave amplitude at each frequency, which are related to wave energy. Since the covariance function can be related directly to the energy spectrum or the wave spectrum, the covariance function is computed, and then its Fourier transform is calculated to obtain the power spectrum (Dean and Dalrymple, 1984).

With the implementation of the Fast Fourier Transform (FFT) algorithm of Cooley and Tukey (1965), many researchers have followed the contributions of some significant early studies (e.g., Pierson and Marks, 1952; Munk *et al.*, 1959; Hassleman *et al.*, 1963) and utilized spectral concepts for either the analysis or the modeling and prediction of ocean waves. Simplified discussions on the use of spectral techniques for the analysis and modeling of the spectrum of ocean waves have been provided by Dean and Dalrymple (1984), Tucker (1991), and Goda (2000). Timely reviews on the importance and applications of spectral concepts to the description and modeling of water waves have been presented by several authors, among them Cardone (1974), Cardone and Ross (1979), Komen *et al.* (1994), and Cardone and Resio (1998). Recent advances in the development of spectral wave modeling for various application purposes have been presented by several researchers (e.g., Holthuijsen *et al.*, 1993; Rivero *et al.*, 1998; Booij *et al.*, 1999; Ris *et al.*, 1999; Monbaliu *et al.*, 2000; Schneggenburger *et al.*, 2000).

In the frequency domain perspective, some researchers (e.g., Guedes Soares and Ferreira, 1995; Lakhan, 1998) have modeled parameters such as significant wave height. A Fourier representation described the periodic components of time series of significant wave height values from different coastal locations. In addition, Hegge and Masselink (1996) also demonstrated the usefulness of spectral techniques to model data from topographic profiles. The results of the spectral analysis represented the amount of variance of the time series as a function of frequency. With spectral modeling, coastal researchers are obtaining greater insights on the physical characteristics of the generating mechanisms of coastal time series.

The time domain approach

The time domain approach, which focuses on the contribution of parametric models for single series or models for two or more causally related series, can be traced to the classical theory of correlation. Details on modeling and forecasting in the time domain can be found in several books (e.g., Box and Jenkins, 1970, 1976; Kendall, 1973; Anderson, 1975; Gottman, 1981; Abraham and Ledolter, 1983; Hoff, 1983; Pandit and Wu, 1983; Pankratz, 1983; Vandaele, 1983; Chatfield, 1984; Montgomery *et al.*, 1990; Bowermand and O'Connell, 1993; Harvey, 1993; Box *et al.*, 1994; Hamilton, 1994; Hipel and McLeod, 1994; Armstrong, 2001; Pourahmadi, 2001). The time domain models that originated with Yule (1927) and Slutsky (1937) provided a strong foundation for time series analysis in the time domain. Yule (1927) pioneered the concept of autoregression and his autoregressive model was generalized by Walker (1931) to allow for dependence on more than two previous values. Wold (1938) followed the practice of Yule and Walker and plotted correlation coefficients against their lags. According to Pourahmadi (2001, p. 35), "the term correlogram was coined by Wold (1938, p. 7) as a substitute to the Schuster's periodogram and has been used effectively ever since as a means of identifying model or appropriate probabilistic description of time series data." The early autoregressive (AR) model of Yule (1927) and moving average (MA) models of Walker (1931) and Slutsky (1937) were not widely used because of the lack of appropriate methods for identifying, fitting, and checking these models (Jenkins, 1979). AR and MA types of models were combined into the mixed autoregressive moving average (ARMA) model.

ARMA models have their foundation in the work of Box and Jenkins (1970, 1976) who utilized concepts from mathematical statistics and classical probability theory. Box and Jenkins also extended ARMA models to include certain types of nonstationary series, and proposed an entire family of models, called autoregressive integrated moving average (ARIMA) models, which can be applied to practical problems in several disciplines. Besides ARMA and ARIMA models, Box and Jenkins (1976) presented other models, including transfer function noise (TFN) models and seasonal autoregressive integrated moving average (SARIMA) models. "The ARMA and ARIMA classes can provide very useful descriptions for a wide range of time series data and the Box-Jenkins approach (as it has become known) has been used extensively by time series practitioners in a wide variety of fields" (Priestley, 1997, p. 16). In the field of coastal research, several autoregressive models have been utilized for data on sea-state parameters. For example, Lakhan (1981) and Lakhan and LaValle (1986) modeled the correlation structure of wave heights and wave periods, and then parameterized stochastic models with autocorrelated distributed variates. Spanos (1983) used ARMA processes to simulate individual waves in short-term periods. Scheffner and Borgman (1992) also simulated individual waves but accounted for long-term variability. Several other studies (e.g., Guedes Soares and Ferreira, 1996; Cunha and Guedes Soares, 1999; Guedes Soares and Cunha, 2000) have modeled time series of sea-state parameters with autoregressive models. Besides sea-state parameters, researchers (e.g., Walton, 1999; LaValle *et al.*, 2001) have also modeled shoreline changes with time series techniques. The study by LaValle *et al.* (2001) utilized Box–Jenkins modeling procedures to identify models which best described a time series (1978–94) of beach and shoreline data. By following the Box–Jenkins model construction approach described below, it was found that a spatial model described the variation for beach net sediment flux, and a space–time autoregressive model provided the best fit for data on spatial–temporal variations of shoreline retreat. Here, it must be mentioned that ARMA models can be generalized to include spatial location (Cressie, 1993).

Time domain modeling—the Box–Jenkins approach

The success of the Box–Jenkins modeling approach in coastal and other studies can be attributed to the fact that Box–Jenkins models have several advantages over traditional models because there is a large class of models, there is a systematic approach to model identification, and the validity of models can be verified (Hoff, 1983). While a publication of this kind cannot provide technical details on the construction of Box–Jenkins models, it is, nevertheless, worthwhile to note that no matter what type of stochastic model is to be fitted to a given dataset it is recommended that the identification, estimation, and diagnostic check stages of model construction be followed (Box and Jenkins, 1976). By following Box and Jenkins, univariate models for any coastal time series can be constructed by using the iterative approach presented in Figure T44.

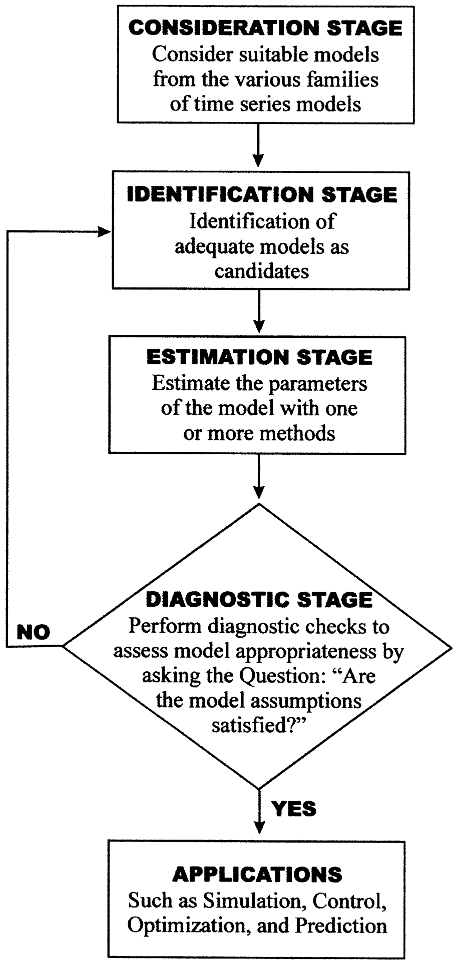

Figure T44 Stages in the iterative approach to model construction (modified from Box *et al.* (1994, p. 17)).

Consideration stage

In the consideration stage, it is necessary to be cognizant of all standard time series models. Consideration must be given to the various families of stochastic models, which can be fitted to the coastal time series. It is of paramount importance to consider those models, which on the basis of theory, practical experience, understanding of the problem, and the published literature, have the potential to fit the observed data.

Identification stage

At the beginning of the identification stage it is best to ascertain the subclasses of models that hold greater promise for adequately modeling the coastal time series. The first step is to obtain a graphical plot of the data because a plot of the time series can demonstrate some of the essential mathematical characteristics of the data. From the plot, it can be determined whether the series contains a trend, outliers, seasonality, nonconstant variances, and other non-normal and nonstationary phenomena. This knowledge allows for possible data transformations. Differencing and variance stabilizing transformations can be used. The normal procedure is to apply variance stabilizing transformations before taking differences because differencing may create some negative values. To stabilize the variance the Box–Cox power transformation can be used. For a series with nonconstant variance a logarithmic transformation can be employed (Wei, 1990). In modeling time series of significant wave height data, Guedes Soares and Ferreira (1996) tried both the Box–Cox transformation and the logarithmic transformation. Following transformation to stationarity it is necessary to compute and examine the sample autocorrelation function (ACF) and the sample partial autocorrelation coefficient (PACF) of the original series to determine the need for further differencing.

After performing the necessary differencing, the ACF and PACF are computed for the properly transformed and differenced series. The autocorrelations and partial autocorrelations of a series are considered principal tools for identifying the correct parameters to include in a Box–Jenkins ARIMA model. Autocorrelations are statistical measures computed from the time series data. An autocorrelation measures how strongly time series values at a specified number of periods apart are correlated to each other over time. The number of periods apart is called the lag. The rule of thumb is that the maximum number of lags should not exceed one-fifth of the number of observations. The partial autocorrelation is similar to autocorrelation, except that when calculating it, the (auto)correlations with all the elements within the lag are partialled out (Box and Jenkins, 1976). In univariate Box–Jenkins modeling, it is normal practice to produce correlograms depicting the autocorrelation coefficients plotted against the lag intervals. According to Harvey (1993), the correlogram is the basic tool of analysis in the time domain. An inspection of the correlogram provides important information as to whether the series exhibits a pattern of serial autocorrelation which can be modeled by a particular stochastic process or whether the series is random. Figure T45 is a correlogram of significant wave height data which shows that the data values are not independent of each other. The series is not random because the autocorrelations should be near zero for randomness. By understanding the association between the ACF and PACF and their corresponding processes, a tentative model can be identified. In the case of Figure T45, with the autocorrelation function decaying exponentially, and knowing that the PACF has a distinct spike at lag 1, it is possible to specify an AR(1) model. It should, however, be stressed that several other models could fit the data. The primary goal is to identify a model with the smallest number of estimated parameters.

Parameter estimation

Subsequent to identifying an adequate model for fitting to a particular series, the next step is to estimate the parameters in the model. Hoff (1983) outlined several objectives in estimating a model, among them obtaining fitted values that are nearly identical to the original series values, obtaining residuals that are not correlated to each other, and using a minimum number of parameters as necessary. A good model incorporates the smallest number of estimated parameters which are needed to fit the patterns in the data. To estimate parameters such as the mean of the series, AR parameters, MA, and other parameters for an identified ARMA model, several estimation procedures can be utilized. Details in estimation theory and estimation procedures can be found in several publications (e.g., Kruskal and Tanur, 1978; Sachs, 1984; Mendel, 1987;

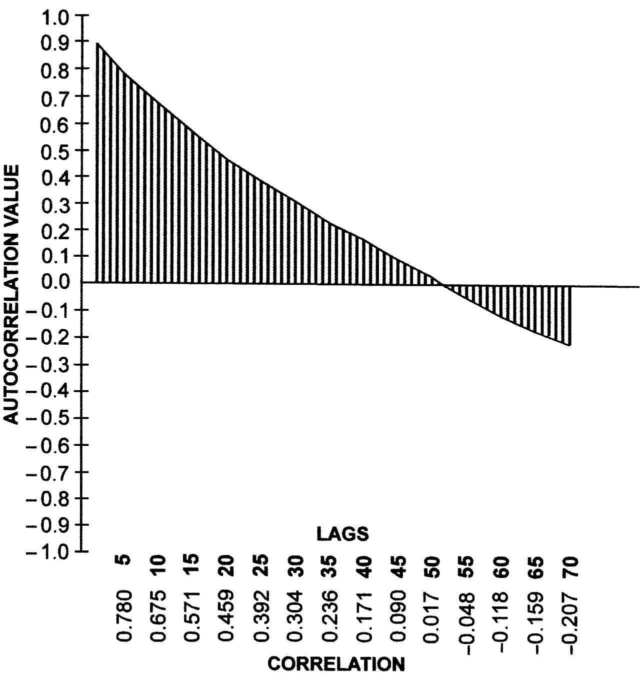

Figure T45 Correlogram of significant wave height (from Lakhan, 1998).

Kotz and Johnson, 1988; Box *et al.*, 1994). For the time series modeling of coastal data, the method of moments, and the maximum likelihood method are widely used approaches to parameter estimation.

Diagnostic checking

Once the parameters of the identified model have been estimated, the next phase is to perform diagnostic checks to determine whether certain assumptions about the model can be verified. Two assumptions to be checked are usually the normality of residuals of the model, and independence. To ascertain whether the residuals are white noise, the residuals from the estimated model are used to calculate the autocorrelation coefficients. Ideally, the residual autocorrelation function for a properly constructed ARIMA model will have autocorrelation coefficients that are all statistically zero. If the residuals are autocorrelated they are not white noise, and this requires formulating another model with residuals that are consistent with the independence assumption (Pankratz, 1983).

The portmanteau lack of fit test is usually applied for testing the independence of a time series. The portmanteau lack of fit test, originally proposed by Box and Pierce (1970), was improved by Ljung and Box (1978). Applications of the portmanteau test for physical time series can be found in several studies (e.g., Hipel and McLeod, 1977; Salas *et al.*, 1980; Hipel and McLeod, 1994). The test statistic is the modified Q statistic which uses all the residual autocorrelations as a set to check the joint null hypothesis. The Q statistic approximately follows a chi-square distribution, with degrees of freedom equal to the total number of lags used minus the number of model parameters and their associated probability values. Recent studies (e.g., LaValle *et al.*, 2000, 2001) have demonstrated that the Q statistic is appropriate for determining the goodness-of-fit of autoregressive models fitted to data on water levels and beach and shoreline changes.

Applications

When a model is accepted it could be used for various applications, among them filtering and control, simulation and optimization, and prediction. A model that fails one or more diagnostic checks is rejected. To construct a good model it becomes necessary to return to the identification stage, and repeat the iterative process of identification, estimation, and diagnostic checking.

Selection of the best model

In coastal time series analysis, it is possible to have several appropriate models that can be used to represent a given dataset. To solve the problem of choosing the best model from the various adequate models, several model determination procedures and model selection criteria have been proposed (e.g., Stone, 1979; Hannan, 1980). Selection criteria are different from the model identification methods discussed above because when there are several adequate models for a given dataset the selection criterion is normally based on summary statistics from residuals computed from a fitted model or on forecast errors calculated from the out-sample forecasts (Wei, 1990).

Some well-known model selection criteria based on residuals are the Akaike Information Criterion (AIC) of Akaike (1974), Parzen Criterion for Autoregressive Transfer (CAT) Functions of Parzen (1977), and the Schwartz's Bayesian Criterion (SBC) of Schwartz (1978). Of the various selection criteria, the AIC is widely used in time series model fitting because it increases the speed, flexibility, accuracy, and simplicity involved in choosing the "best" model. In addition, the AIC is useful for application to many different kinds of time series (Hipel, 1981; Hipel and McLeod, 1994), and facilitates the selection of a parsimonious model that, at the same time, provides a good statistical fit to the data being modeled.

TOPIC CATEGORIES—See APPENDIX 6

TORS

The word "tor," Celtic in origin, is used generally in the British Isles to denote a rather tall rock column (Cunningham, 1968; Jackson, 1997). Linton (1955) was the first to propose it as a scientific term in describing the tors at Dartmoor, Devonshire, England, now considered the type area for the feature (Palmer and Neilson, 1962). Early hypotheses for the origin of tors invoked deep weathering along joint planes in granite, with subsequent removal of the loose material leaving exposed columns. Alternate possibilities outlined by Cunningham (1968) include differential erosion during scarp recession and relict subaerial prominences formed in the Tertiary. Since tors have been found worldwide, often in granite but also in other igneous, sedimentary, and metamorphic rocks, it is appropriate to consider Palmer and Neilson's (1962) pronouncement that "It is not possible to offer a definition that will encompass the many landforms to which the name "tor" has been given." With such wide distribution and varied lithology it is arguable that the most scenic among all of these are coastal tors, as can be seen in the Seychelles and Virgin Islands.

Seychelles

The Seychelles, along with Madagascar, were displaced in a northeasterly direction away from the African landmass during the early formation, in the Jurassic, of the Indian Ocean (Brathwaite, 1984). As such, 42 of the 116 islands comprising the Seychelles Archipelago are the world's only mid-ocean islands composed of granitic rocks (Cílek, 1978). Grey and pink amphibolitic granite, of late Precambrian age, is spectacularly displayed on the northern island of La Digue and at Mahe as discussed by Wagle and Hashimi (1990).

La Digue Island has long been known for its world-class resorts featuring tropical flora, white-sand beaches, swimming in crystal clear waters, snorkeling among coral reefs and magnificent scenic views. Anse source d'argent beach, located on the island, is the site of several tors, chief among them that is pictured in Figure T46. The size of the pink tor can be judged when compared with the heads of the three swimmers seen in the mid-foreground. Graphic too is the weathered "fluting" described as typical of tors by Linton (1955) in his pioneering work, and by Brathwaite (1984) for a tor on Mahe.

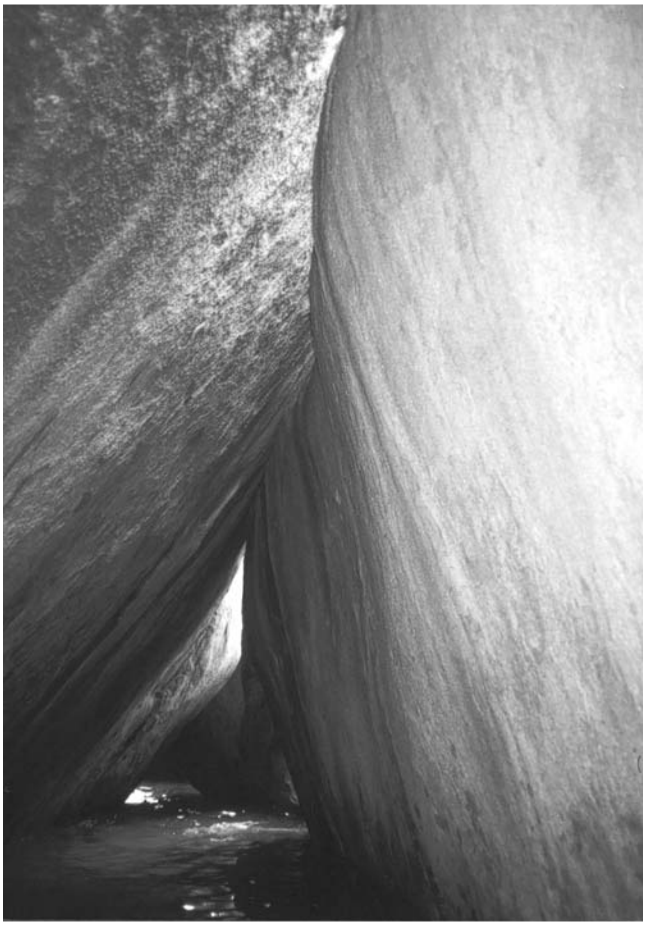

Figure T47 Grotto at the base of the tors at The Baths, Virgin Gorda, British Virgin Islands (Photo, M. Schwartz).

Virgin Islands

The Virgin Islands, located in the northeastern Caribbean along the leading edge of the Caribbean plate, are composed of Mesozoic and lower Tertiary deformed island-arc terrane. Much of the northeastern British Virgin Islands region is underlain by the Virgin Gorda granitic pluton or batholith, which was intruded into the surrounding country rock in mid- to later Eocene time (Mattson *et al*., 1990). Weathered exposures in tonalitic rocks at the southern end of the island of Virgin Gorda reveal huge boulders now located upon the beaches (Weaver, 1962) in a park system managed by the B.V.I. National Parks Trust.

The origin of these boulders has been described by Ratté (1986) in the classic Linton (1955) style for tors of deep weathering along joints followed by removal of the rotted material. A favorite with tourists, the site is called "The Baths," not because of the underlying batholith as a geologist would imagine, but for the salt water pools in the grotto at the base of the tors (Figure T47). Here one may walk, and crawl, along a trail between boulders that range up to 4 m in height.

TOURISM AND COASTAL DEVELOPMENT

Coastal tourism is a process involving tourists and the people and places they visit. It is more specifically defined as tourism brought to bear on the coastal environment and its natural and cultural resources. Most coastal zone tourism takes place along the shore and in the water immediately adjacent to the shoreline. Coastal tourism activities occur outdoors and indoors as recreation, sport and play, and as leisure and business (Miller and Ditton, 1986). As with other human endeavors in the coastal zone associated with development, tourism is viewed positively by some for the opportunities it creates. Others condemn coastal tourism for its unacceptable consequences.

Coastal tourism destinations fall all along an urban–rural continuum (see *Demography of Coastal Populations, q.v.*). At one end of the scale are major cities and ports (Hong Kong, Venice, New York, Rio de Janeiro, and Sydney come to mind) known for their cultural, historical, and economic significance. At the other end of the continuum are the relatively isolated and pristine coastlines found around the world that are valued for their natural beauty, flora, and fauna. Of course, many coastal tourism destinations offer rich mixtures of cultural, historical, social, environmental, and other values to visitors.

Coastal tourism technologies of travel include both those which carry tourists from their homeland (e.g., airplanes, ships, cars, buses, and trains) and which are regarded by travelers as mere means to the end of arriving at destinations, and those which transport tourists at coastal destinations but which become part of the touristic experience (e.g., cruise ships, personal watercraft, sailboats, dive boats, motorcycles, bicycles, and forms of animal transportation). Again, some transportation technologies can, depending on the circumstance, be important for being both convenient and for being interesting or pleasing.

In a manner of speaking, all tourism is a matter of supply and demand. With this perspective, coastal tourism is a business for those who make a living by developing accommodations and attractions, and by providing touristic and recreational products and services. Competing marketing programs of a multifaceted industry alert tourists and would-be travelers to coastal tourism amenities. Today, tourists travel to the coastal zone for parts of a day, for weekends, for short vacations, and for prolonged stays. Depending on the circumstances, they may travel alone, with family, or in groups. Some coastal tourism is organized for a special purpose such as ecotourism, adventure tourism, scientific tourism, and dive tourism. Coastal tourism accommodations range from small residences and camping sites rented out as opportunities arise, to single bed-and-breakfast and hotel rooms, to luxury suites in resort enclaves.

Many coastal tourism activities count as a business for those in the tourism industry and as an experience for tourists. Scuba diving, for example, provides an excellent example of how advances in technology have provided foundations for business and have facilitated touristic access to the marine environment. Other coastal activities that have a business aspect (involving, for example, guides and instructors, or special equipment) include recreational and sport fishing, boating, sailing and parasailing, and whale and bird watching. Then too, there are many forms of coastal tourism—swimming and body surfing, snorkeling, beachcombing, hiking and rock climbing, sketching and painting, photographing, sightseeing—that are "free," or for which costs to providers are recovered indirectly through taxes, or are incorporated in standard hotel or accommodation billing practices. In recent years, windsurfing, body-boarding, wake-boarding, kite-surfing in addition to surfing (*q.v.*), have reached new levels of popularity in the coastal zone.

At the same time that coastal tourism fosters economic relationships between industry producers and tourist consumers, the process has shown itself to be an enormously potent force in transforming the natural environment and the lives of people who are neither part of the business of tourism nor a member of the community of tourists.

Coastal tourism is inherently controversial. The coastal zone is a scarce resource prized not only by those who engage in and profit by tourism, but also by those with personal residences near the sea, and those who find employment in fishing, aquaculture (*q.v.*), maritime shipping, nuclear energy, and national defense, among other industries. Congestion and competition in the coastal zone frames the characterization and the resolution of tourism issues. Coastal tourism problems and opportunities are therefore properly debated as "multiple-use" or "multiple-value" conflicts.

Origins of tourism

Although the early Greeks and Romans were known to enjoy the seashore for leisure purposes, coastal tourism has its roots in the Grand Tour traditions beginning with the Renaissance. As an educational institution, the Grand Tour offered young men first-hand exposure to European courts, customs, and prominent cities and ports. Not surprisingly, the Grand Tourists and their "bear-leader" tutors mixed education with pleasure. By the start of the 18th century, these tourists had begun to develop an aesthetic vocabulary that allowed them to more fully appreciate not only the "beautiful" in nature, but the "picturesque" and the "sublime" as well. Especially popular with the Grand Tourists were seascape paintings by Claude Lorrain (1600–82), Salvator Rosa (1615–73), and Gaspard Poussin (1615–75), depicting storms, shipwrecks, harbors, rocky coastlines, and ruins.

The mid-18th century European "discovery" of the seashore for spa and medicinal purposes in England gave rise to early forms of coastal tourism. In the first half of the 19th century, coastal resorts saw a faster rate of population increase than manufacturing towns and by the mid-19th century the medicinal beach was replaced by the pleasure beach. In 1841, the London to Brighton railway was opened, and in the same year Thomas Cook began a legendary career by promoting his first group excursion (Manning-Sanders, 1951; Hern, 1967; Corbin, 1994). Since that time, beaches, atolls, islands, and harbors around the world have supported coastal tourism (see *Beach use and Behaviors, g.v.*).

Magnitude of coastal tourism

Although there are no standardized practices for reporting tourism statistics within the coastal zone, it is not difficult to see how tourism has a major coastal aspect. More than 70% of the earth is covered by water, and only several dozen out of well over 200 nations in the world lack coastlines (Miller and Auyong, 1991a).

International trends

World Tourism Organization statistics confirm that tourism is the world's largest industry as measured by the number of people involved and by economic impacts. From 1945 to 2000, international arrivals increased from 25 million to a record 699 million (WTO, 1996 and 2001). Between 1970 and 1990, tourism grew by nearly 300% (United Nations Environment Programme, 1992).

By the year 2020, it is estimated that international tourist arrivals will reach over 1.56 billion. Statistical estimations for total tourist arrivals by region show that in 2020 the top three receiving regions will be Europe (717 million tourists), east Asia and the Pacific (397 million tourists), and the Americas (282 million tourists), followed by Africa, the Middle East, and south Asia (WTO, 2001).

The World Travel and Tourism Council (WTTC, 1995) reports that between 1980 and 1989, economic expenditures on international travel (excluding transportation) doubled to $209 billion, rising one-third faster than the world gross national product. Additionally, travel and tourism generated an estimated $3.4 trillion in gross output in 1995—creating employment for 211 million people, and producing nearly 11% of the world gross domestic product. This growth reflects investments of $694 billion in new facilities and equipment, and contributions of more than $637 billion to global tax revenues (WTTC, 1995).

In 2000, tourism generated total international receipts of US$ 476 billion (WTO, 2001). Of the world's top 15 tourism destination countries in 2000, 12 were countries having coastlines (WTO, 2001). In 2000, the cruise ship industry expected to host over 6.5 million passengers which would represent a 1,200% increase in number of passengers since 1966 (Godsman, 2000).

Sun, beautiful beaches, and warm ocean waters have become standard vacation requirements for many tourists. Of those visiting the Caribbean 49% do so for the beaches, while 28% are primarily interested in sightseeing, and 17% in water sports (Waters, 2001). The Pacific region (which includes Australia) has enjoyed a healthy annual growth rate of nearly 4% since the mid-1990s, though arrivals represent only 1.4% of the world's inbound travelers. Of the Pacific territories, French Polynesia is the most dependent on travel with 78% of the nation's GDP coming from tourism. Tourism in the African region has been growing at a faster rate than for many other parts of the world (Waters, 2001).

US trends

The Travel Industry Association of America (TIA, 2001) reports that tourism is the nation's largest services export industry, the third largest retail industry, and one of America's largest employers. TIA (2001; see also WTTC, 1995) has tabulated that travel and tourism in the United States alone has an impact exceeding $541 billion a year in expenditures which includes spending by US resident and international travelers within the United States on travel-related expenses (i.e., transportation, lodging, meals, entertainment, and recreation, as well as international, fares on US flag air carriers). This generates more than 17.5 million jobs, and fuels the largest trade surplus of any industry, totaling nearly $25 billion in 1999. Between 1986 and 1996, international visitation to the United States grew by 78% and expenditures by foreign visitors grew by 223%. It is estimated that more than 90% of foreign-tourist spending occurs in coastal states (US Travel and Tourism Administration, 1994).

US coastlines are popular sites for tourism and recreational activities. Coastal beaches, wetlands, fisheries, aesthetic landscapes, and the human-designed facilities and attractions in the touristic hinterland combine in an endless list of inviting opportunities for visitors, local residents, and entrepreneurs. The major recreational elements of coastal tourism are visiting beaches, swimming, snorkeling and scuba diving, boating, fishing, surfing, and wildlife watching.

It is important to note that coastal tourism and recreation activities often overlap and are not always confined to the marine and coastal environment. For example, diving, fishing, and whale watching are often done while boating, surfing, swimming, and bird watching are usually done while visiting beaches and coastlines; and not all recreational boats are used exclusively in marine and coastal waters.

In the United States, beaches are the leading foreign and domestic tourist destinations (Houston, 1996). In 1995, coastal states made up 11 of the top 15 destinations for overseas travelers visiting the United States (Waters, 1997). A 1999 survey that measured travelers' satisfaction with their visits revealed that Hawaii, Alaska, California, and Florida—all coastal states—were the top four "most liked" destinations in the United States (Volgenau, 2000).

Tourism and recreation are highly significant economic activities in the US coastal zone. By one estimate, approximately 180 million people visit the coast for recreational purposes, and 85% of tourist-related revenues are generated by coastal states (Houston, 1996). Overall, beach tourism and recreation have been estimated to contribute $170 billion annually to the US economy (Houston, 1995). Coastal states receive 85% of all tourist-related revenues in the United States (Houston, 1995). Coastal districts (defined in terms of state congressional districts) received more than $185 billion in tourism expenditures in 1997 (TIA, 1998). In addition, it has been estimated that US beaches and marine waters support 28.3 million jobs (Environmental Protection Agency, 1995).

Comprehensive and time-series statistics measuring employment, and the economic and social value of coastal tourism and recreation in the United States are not available. Quantitative and reliable data measuring involvement in specific coastal recreation and tourism activities in the United States are limited (and often proprietary). Nonetheless, many small and unconnected studies have been conducted on specific tourism topics and destinations in the coastal zone.

Several boating and fishing statistics provide some idea of the economic and social importance of coastal tourism. In 1998, according to the US Coast Guard, registered boats numbered 12.3 million, with 10 coastal and Great Lakes states (Michigan, California, Florida, Minnesota, Texas, Wisconsin, New York, Ohio, South Carolina, and Illinois) accounting for nearly half of them (National Marine Manufactures Association, 2000). In 1999, 77.8 million people participated in recreational boating and recreational boaters spent nearly $23 million on related products and services (National Marine Manufacturers Association, 2000). Between 1991 and 1996 the number of Americans (age 16 and older) who participated in recreational saltwater fishing increased 5.6% from 8.9 million to 9.4 million (Cordell *et al.*, 1997).

Coastal tourism systems

Coastal tourism systems involve interactions between people and place in destinations that include small communities and villages, self-contained resorts, and cosmopolitan cities. From a sociological perspective, coastal tourism systems have three kinds of actors: (1) *tourism brokers*, (2) *tourism locals*, and (3) *tourists* (Miller and Auyong, 1998a).

A "broker-local-tourist" (BLT) model of a coastal tourism system is displayed in Figure T48 (see, Miller and Auyong, 1991a, 1998b). Tourism brokers consist of persons who in one way or another pay professional attention to tourism. Main subcategories include (1) private sector brokers who are part of the tourism industry, (2) public sector brokers at various levels of government who study, regulate, and plan tourism, and (3) social movement brokers in nongovernmental, nonprofit, and environmental organizations who address tourism issues. Tourism brokers of these and other types do not necessarily agree on the kind of tourism that is "best" for coastal tourism systems. Indeed, broker–broker conflict is as common as cooperation. Tourism locals consist of persons who reside in the general region a coastal tourism destination, but do not derive an income from tourism or engage in its management and regulation. Finally, tourists consist of persons of domestic and international origin who travel for relatively short periods of time for business, recreation, and educational purposes before returning home.

Motivation

From the times polite society planned their Grand Tour itineraries through Europe to Rome and other Italian destinations in the 18th and 19th centuries, all who have participated in or witnessed the growth of tourism have pondered the motivations of those fortunate enough to travel. While there are many psychological, social psychological, and social concepts and frameworks for accounting for tourism, only several are mentioned here.

First and looking to the motives of tourists, Miller and Ditton (1986, p. 11) suggest that the fundamental promise of travel "lies in its promise of *contrast*." In elaboration, these authors show that individual trips and vacations allow opportunities for contrast or personal change along three dimensions. *Recreational tourism* as engaged in by the athlete or escapist has a restorative purpose, and provides for change in the physiological or emotional state of the tourist. *Educational tourism* as pursued by the student has a philosophical purpose and provides a basis for change in the intellectual and artistic understanding of the tourist. *Instrumental tourism* as involving entrepreneurs, reformers, and pilgrims exhibits an economic, political, or religious purpose and leads to change in business, network, or moral opportunities available to the tourist. With this framework, a trip by one tourist to, say, a South Pacific island might be experienced as highly recreational, mildly educational, and not at all instrumental. Those accompanying such a tourist could, of course, experience the trip with different weightings along the three dimensions of touristic contrast.

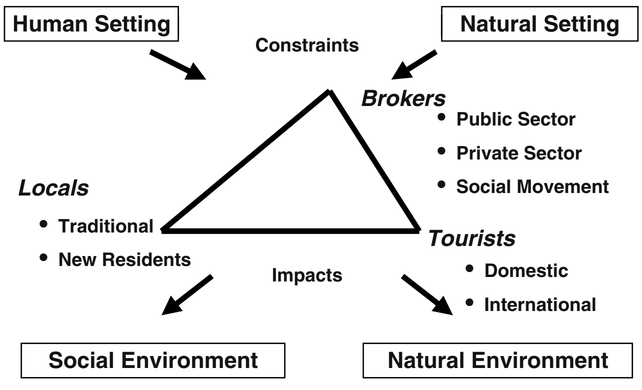

Figure T48 Broker-local-tourist (BLT) model of coastal Tourism (adapted from Miller and Auyong, 1991a, p. 75).

A second way of considering the motivation of tourists emphasizes their intention to experience a psychological state of *challenge* that Csikszentmihalyi (1975, 1990) terms *flow* or *optimal experience*. When in a state of flow—as one might be when surfing, sailing, scuba diving, or even engaging in stimulating conversation—the tourist has found a fine match between his or her abilities and the physical, intellectual, or social challenge at hand. Flow, then, is a state of mind between boredom and anxiety. More fully:

> [f]low denotes the wholistic sensation present when we act with total involvement. It is the kind of feeling after which one nostalgically says: 'That was fun,' or 'That was enjoyable' (Csikszentmihalyi, 1975, p. 43).

According to Csikszentmihalyi (1975) the flow experience is engaged in for its own sake and is marked by (1) a merging of action and awareness, (2) a centering of attention on a limited stimulus field, (3) a feeling variously described as "loss of ego," "self-forgetfulness," "loss of self-consciousness," and even "transcendence of individuality," and "fusion with the world," (4) a feeling of control over one's actions and the environment, (5) coherent, noncontradictory demands for action, and clear unambiguous feedback, and (6) its autotelic [from Greek *auto* = self and *telos* = goal, purpose] nature.

It is often remarked that people who travel together gradually develop a kind of touristic solidarity. By seeing and doing the same things, by sharing emotions and reactions, by facing a common set of logistic obstacles, and even by jointly creating a set of "story lines" with which they might talk about a trip with others, tourists are brought together through the small and multiple secular rituals of travel. In acknowledging this ritual potential, a third perspective on touristic motivation stresses the passionate *commitment* that some tourists exude in performing their favorite coastal touristic activity.

In a series of sociological studies of amateurs, volunteers, and hobbyists in sports, science, and the arts, Stebbins (1992, p. 3) noted intense levels of personal involvement and high levels of technical competence, and coined the term *serious leisure* to describe commitment that was tantamount to professionalism:

> [S]erious leisure can be defined as the systematic pursuit of an amateur, hobbyist, or volunteer activity that is sufficiently substantial and interesting for the participant to find a career there in the acquisition and expression of its special skills and knowledge.

In the realm of coastal tourism, tourists who pursue serious leisure are omnipresent as evidenced by scuba divers, sailors, whale watchers, amateur naturalists and marine conservationists, and the like.

System dynamics

Coastal tourism systems change in size and character over time. To understand and ultimately to predict these changes, and also to plan for desired societal and environmental outcomes, analysis must focus on the behavior of components of the system. In this regard, two processes merit attention.

First, population dynamics of the BLT model should be monitored. It is not unusual for individuals in the system to change statuses. This can occur as, for example, tourists who visit a coastal destination decide to stay and take on a residence, either as a broker of some kind (e.g., as a scuba dive shop entrepreneur or restaurant owner), or as a local (e.g., as a lawyer or teacher). Other transformations in status take place as locals change occupations and become private sector brokers by engaging in a tourism business, or become public sector tourism brokers by finding government employment that concerns tourism. Of course, locals and brokers take on the role of a tourist when they vacation on travel of their own.

Second, power dynamics of the BLT model should be taken into account. Tourism is often examined as a product of the aggregate decisions of individual tourists. The relationship forged between the tourist and the local is accordingly depicted as socioeconomic in nature; tourists and locals interact as "guests" and "hosts" or as consumers and producers. Where power relationships are perceived to exist (e.g., as between First World tourists and Third and Fourth World locals), it is argued that these reveal the colonial and imperialistic leverage tourists have over those whom they visit. From this perspective, tourism systems are controlled and determined—often in unfortunate ways—by the behavior of tourists.

While there certainly are many instances in which tourists have exercised their influence to selfish and inappropriate advantage in coastal tourism settings, a narrow concentration on the power of tourists can result in analysts missing the power of tourism brokers. As Cheong and Miller (2000) have pointed out, tourists are frequently vulnerable to the power and control of brokers and locals. This is the case when, for example, tourists abide by laws and regulations of public sector brokers, and when they follow the advice and instructions of private sector brokers such as tour guides and travel agents.

Tourism development

Coastal tourism development in the coastal zone has become a constant since the end of World War II. Well-known examples are found on the coastlines and islands of Europe, North and South America, Africa, and Asia (Miller and Auyong, 1991b, 1998a; Conlin and Baum, 1995; Lockhart and Drakakis-Smith, 1997). Tourism development necessarily leads to changes in society and the environment of some kind. While conclusions about the "appropriateness," "success," "inappropriateness," or "failure" of coastal tourism development projects vary to a degree with the political and economic orientations, aesthetic standards, and environmental philosophies of analysts and observers, there is no question about the power of tourism development to quickly effect dramatic change.

From a societal point of view, tourism development promises better quality of life. In theory, poverty is alleviated through the creation of new jobs. Personal income and taxes derived from tourism then fosters better health, education, and other social services. In practice, these goals are only sometimes met. In many cases, failures of political institutions have led to unfair distributions of tourism-generated revenues and to problems of environmental justice.

As noted above, the tourism process provides incentives for locals to become tourism brokers. The lives, then, of both locals and new brokers are changed by coastal development. In some instances changes in the community that are derivative of tourism are undeniably positive. In other cases, the effect is negative. In a study of tourism in a Mexican coastal community, McGoodwin (1986) has identified a *tourist impact syndrome* which identifies the possible cultural costs to tourism system locals as including: (1) loss of political and economic autonomy (including loss of real property), (2) loss of folklore and related cultural institutions, (3) social disorganization (including radical changes in value orientations and in norms regarding social relations; heightened desire for material objects; changes in norms regarding work, sexual behavior, and drug use; promotion of illusory life aspirations; and loss of parental control and of respect for elders), and (4) hostility towards tourists (e.g., thievery, hustling, verbal aggression).

From an environmental perspective, tourism development is often seen to promise degradation of ecosystems (see *Human Impacts on Coasts, q.v.*). This, of course, is unavoidable with the building of airports, ports, road systems, hotels, resorts, and other facilities. This said, tourism development can also provide financial support for the protection of the marine environment and endangered species, as for example, in the creation of underwater and marine parks (*q.v.*) and protected areas.

Over the last decades, there has been growing recognition of the social and environmental trade-offs of tourism and also of the unintended consequences and economic externalities of tourism development (e.g., see Mathieson and Wall, 1982; Edwards, 1988; Pearce, 1989; Clark, 1996; Orams, 1999). With this, coastal tourism development is increasingly designed, debated, and evaluated against the ideal of *sustainable development*. Two prominent statements on this important concept follow:

> Economic growth always brings risk of environmental damage, as it puts increased pressure on environmental resources. But policy makers guided by the concept of *sustainable development* will necessarily work to assure that growing economies remain firmly attached to their ecological roots and that these roots are protected and nurtured so that they may support growth over the long term. (World Commission on Environment and Development, 1987, p. 40)
>
> (*Sustainable development* means) improving the capacity to convert a constant level of physical resource use to the increased satisfaction of human needs. (World Conservation Union, the United Nations Environment Programme, and the World Wide Fund for Nature, 1990, p. 10)

Toward the resolution of coastal tourism issues

Coastal tourism has been seen to be responsible for both positive and negative impacts to the natural and social environment (see Figure T48). The impacts of coastal tourism on the social environment involve social, cultural, political, and economic issues. On the positive side, coastal tourism can foster community pride, improved quality of life and new job opportunities; on the negative side, coastal tourism can lead to problems of overcrowding, social displacement, and crime. Impacts on the natural environment are often biological, physical, and ecological in nature. Increased protection and conservation of many areas and species has been a positive result of coastal tourism; nevertheless problems of erosion, pollution, and loss of species diversity occur far too frequently. It should not surprise that many coastal tourism issues simultaneously affect the social and natural environment.

The viability of coastal tourism systems and the natural environment in which they occur is very much dependent on human behavior. The resolution of coastal tourism issues can arise from the work of tourism system brokers and also from the individual decisions of locals and tourists.

Of the multiple ways available to society to control human conduct, three broker-driven mechanisms are prominent in the coastal tourism context. These mechanisms are *tourism management*, *tourism planning*, and *tourism education*.

Tourism management, planning, and education are crucial to the sustainable evolution of a touristic destination. It is therefore imperative that each are administered in such a way as to provide for the social and economic needs of the community, while at the same time ensuring that environmentally sensitive areas and ecologically important habitats are identified and excluded from tourism pressure. It is also recognized that tourism management, planning, and education are necessarily not only for scientific purposes and to conserve the environment for the benefit of residents, but also for the protection of long-term investments in tourism infrastructure, attractions, facilities, services, and marketing programs. It deserves to be noted that coastal tourism management, planning, and education programs are often designed and implemented by the same agencies and organizations. This overlap is often desirable and is found in some instances of larger efforts of government to promote integrated coastal zone management (see *Coastal Zone Management, q.v.*; see, also, Clark, 1996; Cicin-Sain and Knecht, 1998).

The manner in which a country, region, or community chooses to conduct touristic management, planning, and education activities is framed by societal (political, economic, etc.) and environmental (geography, natural resource, etc.) constraints. In the long run, the wisest course of action is to balance environmental, business, management, and social concerns so that tourism development is recognized as a potentially dangerous, but also potentially valuable and responsible course of action.

Coastal tourism management

Very generally, management concerns the actions of an executive decision-making entity in accordance with overarching goals of the larger enterprise in which it is housed. Although resorts, hotels, restaurants, transportation businesses, and many other firms in the coastal tourism sector do make decisions in strategic and professional ways, management, as the term is employed here, points to work engaged in or sponsored by public sector brokers to address problems and opportunities of coastal tourism.

Throughout the world, coastal tourism is managed by regulatory entities in accordance with the structure and procedures of the prevailing political system. In the United States, coastal tourism management is undertaken by federal agencies, and by regional, state, and local authorities at other levels of government. These executive entities rely on the two other branches of government for guidance. Thus, legislatures provide the mandate for tourism management in the design of laws, and the judicial branch of government interprets law as it applies to regulatory actions and the behavior of constituencies and tourists.

In the United States the growing importance of coastal tourism to the Nation was communicated to the general public with publication of *Year of the Ocean: Discussion Papers* in 1998. In a major chapter in this document, "Coastal Recreation and Tourism" is defined as embracing:

> the full range of tourism, leisure, and recreationally oriented activities that take place in the coastal zone and the offshore waters. These include coastal tourism development (hotels, resorts, restaurants, food industry, vacation homes, second homes, *etc.*), and the infrastructure supporting coastal development (retail businesses, marinas, fishing tackle stores, dive shops, fishing piers, recreational

> boating harbors, beaches, recreational fishing facilities, and the like). Also included is ecotourism and recreational activities such as recreational boating, cruises, swimming, recreational fishing, snorkeling, and diving. Coastal tourism and recreation … likewise includes the public and private programs affecting all the aforementioned activities (US Federal Agencies, 1998, p. F-2).

In stressing the need to coordinate federal coastal tourism policies and programs, the chapter discusses governmental management and planning, management of clean water, and healthy coastal ecosystems, management of coastal hazards, and beach restoration programs.

At the federal level, the United States does not have a "Department of Tourism" with regulatory authority. Instead, touristic, recreational, and leisure activities are regulated by a host of executive agencies in accordance with a suite of legal mandates. Prominent in the control of coastal tourism and recreation are the National Park Service, the National Marine Fisheries Service, the Fish and Wildlife Service, and the US Army Corps of Engineers (Table T14). These agencies oversee many programs that conserve and protect natural resources and the environment while also fostering public access to the shore and to the marine environment.

At the state-level and at the local-level of government, coastal tourism is managed through the regulatory efforts of a variety of departments (e.g., departments of fish and wildlife, and park departments) with mandates that resemble those of federal counterparts. It is also common for city governments to cooperate with chambers of commerce in the development of infrastructural and business practice standards.

In practice, then, coastal tourism management is conducted by public sector brokers at all levels of government, by private sector brokers in businesses, and by some NGOs and environmental and social movement brokers. An array of tourism management tools (e.g., licensing regulations, zoning rules, tourist quotas, time and areas restrictions, and carrying capacity and limits of acceptable change regulations) have been used successfully throughout the Pacific, in the Caribbean, in the Atlantic and elsewhere (see Pearce, 1989; Miller and Auyong, 1991b, 1998; Conlin and Baum, 1995; Lockhart and Drakakis-Smith, 1997; Orams, 1999). The concepts of *zoning* and *carrying capacity* deserve further attention due to their particular applicability to the management of tourism in coastal areas.

Two very significant parks utilize zoning as a means of tourism management. The Great Barrier Reef Marine Park in Australia is a multiple-use protected area. With zoning, conflicting uses are physically separated. The range of protection in the park varies from virtually no protection to zones where human activity is conditionally permitted. The adoption of this zoning scheme allows the park authority, in association with interested members of the public and with other agencies, to develop and apply a tourism strategy for the entire Great Barrier Reef Marine Park. Zoning ensures that the Reef will not become overpopulated with tourist and other structures, but also allows for careful development in areas which are suitable for that purpose. The Galapagos Islands National Park in Ecuador also employs zoning strategies. The park is effectively managed with intensive use, extensive use, and scientific use (off limits to all but a few visitors) zones.

Carrying capacity (*q.v.*) regulations illustrate the "precautionary principal" method of natural resource management and are highly regarded by practitioners of tourism management. Coastal tourism managers who seek to determine the appropriate level of use that can be sustained by the natural resources of an area are well aware that carrying capacities and use-intensity limits of tourism destinations are dynamic, and depend greatly on the biological and ecological processes of natural resources.

Coastal area carrying capacity can be evaluated in four ways (Sowman, 1987). Physical carrying capacity is concerned with the maximum number of "use units" (e.g., people, vehicles, boats) which can be physically accommodated in an area. Economic carrying capacity relates to situations where a resource is simultaneously utilized for outdoor recreation and economic activity. Ecological carrying capacity (sometimes referred to also as physical, bio-physical, or environmental carrying capacity) is concerned with the maximum level of recreational use that can be accommodated by an area or an ecosystem before an unacceptable or irreversible decline in ecological values occur. Social carrying capacity (also referred to as perceptual, psychological, or behavioral capacity) is concerned with the visitor's perception of the presence (or absence) of others simultaneously utilizing the resource of an area. This concept is concerned with the effect of crowding on the enjoyment and appreciation of the recreation site or experience.

The *limits of acceptable change* (LAC) framework developed by Stankey *et al*. (1985) enables managers to move beyond calculation of carrying capacity figures to address actions needed for management goals. This approach concentrates on establishing measurable limits to human-induced changes in the natural and social setting of parks and protected areas, and on identifying appropriate management strategies to maintain and/or restore desired conditions (Stankey *et al*., 1985). Knowledge of the natural (physical, biological) setting is combined with knowledge of the human (social, political) setting in order to define appropriate future conditions.

The LAC method employs nine steps as follows: (1) identification of area concerns and issues, (2) definition and description of opportunity classes, (3) selection of indicators of resource and social conditions, (4) inventory of resource and social conditions, (5) specification of standards for resource and social indicators, (6) identification of alternative opportunity class allocations, (7) identification of management actions for each alternative, (8) evaluation and selection of an alternative, and (9) implementation of actions and monitoring of conditions. To date, the LAC system has proved to be a valuable tourism management tool in several wilderness areas in the United States and has direct applications to coastal areas as well.

Table T14 US federal statutes and actions influencing coastal tourism (selected)

- Antiquities Act (1906)
- National Park Service Organic Act (1916)
- Fish and Wildlife Coordination Act (1934)
- The Wilderness Act (1964)
- National Sea Grant College Program Act (1966)
- National Historic Preservation Act (1966)
- Executive Reorganization Plan Number 4 and Executive Order 11564 establishing the National Oceanic and Atmospheric Administration (1970)
- Coastal Zone Management Act (1972)
- National Marine Sanctuaries Act (1972)
- Fishery Conservation and Management Act (1976; renamed Magnuson-Stevens Fishery Conservation and Management Act)
- Archaeological Resources Protection Act (1979)
- Fish and Wildlife Conservation Act (1980)
- Presidential Proclamation 5030 establishing a 200-mile Exclusive Economic Zone (1983)
- The Recreational Boating Safety Act (1986)
- Abandoned Shipwreck Act (1987)
- Executive Order 13158 establishing a national system of Marine Protected Areas (2000)

Coastal tourism planning

Planning, broadly conceived, entails the consideration of a range of actions likely to contribute to the attainment of organizational goals. In some instances, overarching goals are well known in advance and planning professionals concentrate on the means that will ensure these ends. In other situations, the determination of goals requires prolonged deliberation.

Coastal tourism planning is often integrated with other resource analyses in the development of coastal area or region. Planners take into account not only visitation rates and statistics, but also the fact that tourists increasingly insist that destinations be high-quality and pollution-free, as well as inherently interesting. Therefore, it is in both the public and private sector brokers' interest to implement a planning strategy for tourism. The goals and policies of government agencies and businesses are, however, frequently different from one other and may even be in direct conflict. To minimize and even prevent disruptions and loss of time, communication between tourism brokers is crucial. Planning also leads to equitable distributions of coastal tourism benefits.

The success or failure of a tourism project frequently hinges on the conditions of natural amenities in the surrounding environment. This is especially true for tropical environments found, for example, on Pacific and Caribbean islands. Parks and natural resource areas, scenic vistas, archaeological and historic sites, and coral reefs are all touted tourism attractions. Marketing strategies for coastal, marine, and island tourism especially promote destinations for being close to white sand beaches. However, development of permanent structures for tourism near beaches often exacerbates beach erosion, property damage, and requires construction of shore protection structures. If touristic facilities are to be sited near beaches, proper planning is essential for the protection of the coastal zone and private property.

In many numerous coastal and island states located in the Mediterranean, Caribbean, and the Pacific where tourism is a major economic force, major national-level departments of government shape coastal tourism through the design of investment incentives and international joint venture opportunities. In nations such as Mexico and Costa Rica, these activities are linked to the preparation of strategic tourism plans.

In the United States—and with notable exceptions such as those provided by the National Park Service—very little coastal tourism planning takes place in the federal government. At the state-level, it is commonplace for departments of tourism to promote tourism. While many states have experienced great success in attracting tourists with advertising strategies, most state departments of tourism have yet to augment the marketing of tourism with the monitoring and assessment of coastal tourism's effects on the environment and quality of life. At the local-level, many city governments have utilized their planning departments to recommend approaches to issues having to do with public use of the coastline and natural resources, the revitalization of waterfronts, and zoning appropriate to resort and marina development.

Within the private sector, coastal tourism planning is an established professional specialty. Firms of all sizes develop coastal tourism plans tailored by expert consultants to the needs of developer clients. Increasingly, social movement brokers are being seen to engage in professional coastal tourism planning.

Coastal tourism planning falls into two main categories, depending on whether the project in question is driven by a preservation or a development ethic. Preservation goals predominate in the planning of recreational areas, in national park and marine protected area planning, and in planning that is part of natural resource management. The development framework has found application in seaside resort and theme park planning, in condominium time-share planning, and in varieties of coastal city planning. There are many examples worldwide of coastal tourism zones, replete with both preservation and development projects, that extend from major cities. The Costa Brava in Spain, the French Riviera, the Yucatan Peninsula, the East Coast of Australia, and the coastlines of the United States and many Polynesian islands illustrate mixed planning.

Landscape architecture and urban planning are important in shaping coastal tourism. Both fields have public and private applications, and design and planning aspects. Both tailor products and services to preservation and development goals and, accordingly, address biophysical and social and economic objectives.

Landscape architects design parks and gardens, resort and hotel facilities, marinas and waterfronts, plazas and squares, and transportation corridors providing access to coastal touristic destinations. Urban planners design circulation facilities, city districts and spaces, and produce master planning and site design products.

Planning activities and products of landscape architects include resource management plans, environmental analyses, and multidisciplinary feasibility studies, and needs assessment and community structure plans. In overlapping ways, urban planners produce tourism policy plans, functional plans, and environmental assessments.

Because coastal tourism planning efforts are attuned to local conditions, constituencies, and financial constraints, there is no single planning process for guaranteeing success. This said, most professional planning endeavors share a general structure. Grenier *et al.* (1993) suggest a three-phase tourism planning process. With this, a first "Front-end Planning" phase encompasses scoping (entailing a statement of project philosophy, pre-assessments of key issues and themes, and formulation of objectives) and research (involving data collection and analyses supporting cultural, institutional, and environmental profiles; site reconnaissance; eco-determinant mapping; and analyses of constraints and opportunities). A second "Project Planning" phase is focused on refinement of project objectives, design and evaluation of alternative development plan concepts, and selection and approval of the preferred development plan concept. A third and final "Project Management" phase concerns activities of implementation, monitoring and evaluation, and refinement.

In summary, coastal tourism planning has been fostered by public sector brokers at all governmental levels, by consultants among other private sector brokers, and by an impressive range of nongovernmental and environmental organizations in roles these have taken on as social movement tourism brokers. Coastal tourism planning practitioners have developed an array of planning methodologies (e.g., comprehensive land-use planning, integrated coastal zone planning, and strategic and special use planning) and have utilized these throughout the world, in many instances by cooperating with tourism brokers with management expertise (see, Gunn, 1988; Pearce, 1989; Miller and Auyong, 1991a, 1998a; Conlin and Baum, 1995; Lockhart and Drakakis-Smith, 1997; Orams, 1999; Hadley, 2001).

Coastal tourism education

The two mechanisms for the control of human behavior in coastal tourism systems discussed above—management and planning—are similar to one another in that the tourism experts who analyze coastal tourism situations channel their recommendations upward to regulatory and planning authorities. These tourism brokers then implement policies and plans downward, influencing tourism businesses, tourists, and locals.

A third mechanism concerns coastal tourism education and communication. Although education about coastal science and environmental issues is effectively transmitted in classrooms, discussion here focuses on education and outreach in nontraditional settings and how people learn through the experience of being tourists or learn in the course of daily life. Guided tours, museums, brochures, public lectures, newspapers, and signage are but a few of the devices that figure importantly in the educational processes linked to coastal tourism.

In a manner of speaking, tourism education contrasts with management and planning in that the first clients of analysts are not managers and planners in positions of authority, but tourists and locals. Whereas managers achieve goals through policies and regulations and planners depend on plans, coastal tourism educators succeed when people take personal initiative to change their own behavior because they have been taught something. Tourism education, then, is a process in which analyst brokers direct their ideas outward to people involved in tourism. Tourism educators and communicators do not evaluate success or failure at attaining their goals with studies of "enforcement" or "compliance." This is so because successful education motivates individuals by persuasion, not coercion.

By definition and referring to Figure T48, coastal tourism educators are public sector, private sector, and social movement brokers. These brokers design products and strategies to educate people and through this to change human behavior in coastal tourism systems. While educator brokers seek to impart their message to tourists and to locals, they also educate one another as, for example, when a nongovernmental organization (NGO) educates public sector and private sector brokers.

Efforts to resolve problems and opportunities of coastal tourism through education are steadily growing throughout the world. Tourism brokers who are advancing this promising agenda are benefiting from the work of educators who have focused on environmental and sustainability issues. Monroe (1999) has characterized successful environmental education and communication projects as having features that allow for: (1) empowerment of local communities and use of their expertise, (2) attention to scientific, social, economic, political, and cultural topics, (3) identification of a variety of stakeholders and integration of them into the process, (4) advancement of an environmental ethic as well as assistance to residents in developing decision-making skills, (5) development of a gender component, (6) flexibility in project design (including realistic timetables), and (7) project evaluation.

Coastal tourism brokers (e.g., those in government or in NGOs) that provide international aid in developing and poverty-plagued states have also benefited from the cross-cultural advice of Brazilian educator and philosopher, Paulo Freire. Freire has contended that the education process has for too long been regarded as a "delivery service" from the scientific and technological elite of the Western World to those suffering in the Third World. Freire's (1999, p. 61, emphasis added) solution lies in education projects that emphasize collaborations between experts and clients at all stages of the process:

> Through dialogue, the teacher-of-the-students and students-of-the-teacher cease to exist and a new term emerges: teacher-student with student-teachers. The teacher is no longer merely the-one-who-teaches, but one who is himself taught in dialogue with the students, who in turn while being taught also teach. *They become jointly responsible for a process in which all learn*.

Few would disagree with the proposition that coastal tourism education has great potential to enhance the quality of tourism for tourists and locals, and to also protect the environment through responsible human conduct. The importance of education (and of overlapping fields such as communication, journalism, and environmental and science reporting by the media) is recognized by virtually all marine scientists and researchers (see Pearce, 1989; Miller and Auyong, 1991b, 1998; Conlin and Baum, 1995; Lockhart and Drakakis-Smith, 1997; Orams, 1999). Still, many opportunities to integrate coastal tourism education with the mechanisms of management and planning have been missed.

Challenges ahead

Over the last several centuries, the world's coastlines have been substantially transformed to support recreational and touristic pursuits. In some cases, coastal tourism dominates the skyline. In others, tourism is one of many industries. As coastlines become more populated and accessible, it is ever more clear that, however, beneficial coastal tourism is to the tourist, it is neither a panacea that will invigorate any local economy, nor a pollution that will necessarily ruin environments and corrupt cultural traditions and values. Coastal tourism is a process amenable to management, planning, and education. Sustainable coastal tourism obliges humanity to have respect for other life forms and the environment, while it affords opportunities for people to learn, recreate, and reach their potential as individuals through travel.

Because the stakes are high and because mistakes can be virtually irreversible, societal resolution of pressing tourism and coastal development issues requires imagination as well as sustained scientific and policy attention. Work to be done falls in the areas of research, and tourism broker and individual responsibility.

Tourism research

Researchers in government, academe, and in the private and social movement sectors constitute a first group of practitioners whose work induces positive change in coastal tourism systems. Fundamental questions about physical, biological, ecological, social, cultural, economic, demographic, and political processes of coastal tourism are posed and answered in assessments, impact statements, profiles, and other products of natural, biological, and social scientists. With reference to the condition of the environment and society, the possibilities of coastal tourism development raise not only the question "What is?" but also questions about "What is ethical?," "What is fair?," and "What is beautiful?" As a result, analyses by professionals with backgrounds in the humanities and arts have proven to be useful in complementing those of scientists.

The need to formally study tourism is recognized more than ever in academe. Tourism research methods are under continual development in such fields as public affairs, business and marketing, architecture, urban planning and design, political science, sociology, geography, cultural anthropology, marine affairs, and environmental studies (e.g., see Gunn, 1979; Murphy, 1985; Ritchie and Goeldner, 1987; McIntosh and Goeldner, 1990).

Tourism broker responsibilities

A second professional group made up of the different types of coastal tourism brokers will be counted upon heavily in the future to cooperate with one another. This can occur, for example, when investors and developers in the private sector coordinate goals and activities with those of government agencies and NGOs to make sustainable tourism a reality. Another kind of cooperation calls for tourism brokers to work effectively with government, business, and nongovernmental organizations in other economic sectors. Better understandings of tourism-fishery interactions, tourism-aquaculture interactions, and tourism-ocean shipping interactions can lead to an improvement on single-sector governance with partially (or, under ideal conditions, fully) integrated coastal management.

In the aftermath of the terrorism attack on the World Trade Center in 2001, the responsibilities of tourism brokers have been enlarged. Brokers now must function not only as stewards of the coastal environment, businessmen, and representatives of constituencies, but also as protectors of residential and traveling publics.

Uncertainties generated by the terrorism of 2001 will change the ways in which coastal tourism is conducted in the United States and elsewhere. It has long been known that too much tourism can be bad by when it leads to degraded ecosystems and undesirable changes in quality of life. Now it is apparent that too little tourism can put entire coastal economies at risk. Declines in coastal tourism can create serious social problems in the same way declines in fishery resources can threaten livelihoods. Ultimately, coastal tourism and recreation destinations negatively affected by security-related changes in itineraries will become sustainable only to the extent brokers make tourism safe.

Individual responsibilities

The discussion above has concerned the proactive roles researchers and brokers can play in promoting sustainable tourism and coastal development. To this must be added a comment about the personal responsibilities of tourists and locals to contribute toward sustainability in the coastal tourism systems which they visit or in which they live.

To a certain extent, the social role of the ethical tourist can be formulated to resemble that of the good citizen. Good citizens learn from their families and schools to reach their potential in society while knowing how to behave in socially appropriate ways. Using this template, tourists would be expected to behave in ecologically and culturally appropriate ways in the course of their domestic and international travel. Ecotourism and ethnic tourism are two forms of tourism that have emerged to stress this self-conscious orientation. Many tourism brokers in business, in government, and in non-governmental organizations are now promoting the development of "best practices" and "tourism guidelines" to this end.

It is obvious that there are many benefits of coastal travel that accrue to the tourist. These are found in recreational, aesthetic, and educational activities. In exchange, the ethical tourist will strive to behave in a culturally and environmentally responsible manner. As this occurs, locals are given an added incentive to orient their conduct to the same ends. Improvements in the behavior of tourists and locals toward one another and toward the coastal environment will assist tourism providers and managers as they do their part to monitor and control tourism, and improve the tourism experience for all involved.

Concluding remarks

Coastal tourism has demonstrated its considerable power to influence the fundamental configurations of coastlines and the social structures these support. Coastal tourism is sometimes found to be unfortunate in every respect. Coastal tourism can, however, be designed to improve the lives of tourists and those who are part of the tourism industry, conserve natural resources and protect the environment, and not offend locals. For this to occur, coastal tourism brokers—in government, business, and non-governmental organizations—will need to cooperate to insure that tourism is sustainable and safe.

It will also be necessary for tourists and locals to adopt "best practices" that underwrite cross-cultural communication and respect for the environment. In the eyes of many, it is time for all to abide by a coastal system *tourism ethic*. Such an ethic might reasonably incorporate Aldo Leopold's (1949, p. 224–225) famous caution about natural resource use based solely on economic self-interest:

> [a] thing is right when it tends to preserve the integrity, stability, and beauty of the biotic community. It is wrong when it tends otherwise.

Through the implementation of responsible management, planning, and education policies—together with the diffusion of a tourism ethic—tourism and coastal development can be shaped to reflect the best tendencies of humanity.

TOURISM, CRITERIA FOR COASTAL SITES

Historically, seaside resorts date back to Roman times with a string of resorts along the Campanian littoral on the northern shore of the Bay of Naples (Turner and Ash, 1976, p. 24). The modern seaside resorts had their origin in England and their early growth was attributed to the therapeutic value of seawater drinking and bathing. From the mid-19th century, the era of railway saw the rapid growth of more seaside resorts, spreading to western Europe (Romeril, 1984; Walton, 1997). Partly as the result of the railway ending at about right angles to the coast, the European coastal resort has a basic T-shaped morphology, although factors varied. Usually, coastal resort morphology is dependent on site characteristics, tourist elements, and other urban functions (Pearce, 1995, pp. 136–140; Nordstrom, 2000, pp. 10–13).

This entry is concerned with such physical site factors as the "emphasis … on aspects of the physical implications of site selection such as coastal erosion rather than resort form … underlies the potential which this approach has to complement the more traditional resort morphologies" (Pearce, 1995, p. 137). This approach is increasingly significant, as developing countries seek out appropriate beaches and islands for tourism development. On a worldwide scale, coastal tourism (see *Tourism and Coastal Development*) in the traditional Mediterranean area is complemented by the Caribbean area, South Pacific area, and Southeast Asia. Islands, especially *small islands (q.v.)*, are actively sought for tourism development. To the usual three "Ss" (sun, sea, and sand) for coastal tourism, one could add two more "Ss" (sunrise and sunset) if one were on a small island.

Coastal site criteria

Coastal tourism development involves the identification of a suitable site, developing the site by clearing, and providing access, accommodation, recreation facilities, and services for the tourists (Ahmad, 1982). Site criteria for coastal tourism are more than just association with white sand beaches and coral reefs. An analysis of the site criteria includes a wide variety of physical and other factors such as land-use, ownership, etc. The objective is to assess the site opportunities and constraints which have a significant implication for the resort entrance, backdrop, views, beaches and swimming areas, buildable area, vegetation, boating tours, fishing and diving opportunities, etc. In addition, various site planning considerations and development standards, including architectural, landscaping, and engineering design, have to be considered (Inskeep, 1991, pp. 303–335).

Planners and architects usually acknowledge that two powerful forces make coastal tourism distinctive and have a bearing on site criteria. The first is the special amalgam where land meets the sea and the coastal site is a junction of landscape and seascape. The second is the linear character of the coast in which the natural resources for tourism are arranged in a linear fashion (Gunn, 1988, p. 87).

The linearity of the coast presents special challenges for planning and tourism design. Generally, four zones with different characteristics can be identified with the more important criteria and implications for tourism development given in Table T15 (Gunn, 1988, p. 88; Mieczkowski, 1990, pp. 243–246). On the seaward side is the marine zone or neretic zone which is the ecological zone from the continental shelf to the beach. This area contains the marine life, reefs, and sandbars and is suitable for a number of marine-based activities. The beach consisting of the foreshore and backshore is the most important of the four zones. It is used for many activities, especially if it is sufficiently wide and sandy. More specific requirements identified for beach resort development in this zone include beach protection and beach capacities (Baud-Bovy and Lawson, 1998, pp. 71–72). The third zone is the shoreland which includes the dunes and is the area for camping, hiking, and other accommodation, food, shopping, and other service businesses. Its serves as the visual linkage between land and sea. The most landward zone is the vicinage or hinterland which provides the setting for tourist business and vacation homes. It is often the zone of population and supporting services and is enhanced by variations in topography and vegetation. Its nearness and access to the sea is more important than the visual linkage.

An example of the application of the linear zones is the planning of development for southern Thai beaches facing the Andaman Sea (Tourism Authority of Thailand, 1989). Three zones for development with 12 categories of landuse have been identified. The first two zones have specific widths. The beachfront area extends 300 m away from the beach; the interior area is 700 m wide and the hinterland is landward of the interior area.

As the coast is a basic component in coastal tourism, any potential resort site can be assessed by an initial understanding of its coastal geomorphology. As coasts differ widely, each type of site has implications for coastal tourism. For example, the potential of a specific coastal type or landform, such as, coral reef, coastal dune, sand spit, river-mouth barrier, rocky headland, can be known. Also, specific advantages and disadvantages of each landform, coastal type, or ecosystem have their influence on the choice of resort sites and also influence the pattern and development of resorts. Coastal geomorphology also helps to reduce negative impacts, protect valuable habitats and provide valuable information for subsequent alteration to the coastal environment, for example, changes to the drainage and water bodies (Wong, 1999, 2000).

More important and often underestimated, geomorphology also takes note of the seasonal factor which can have a marked impact on the coast. For example, in Southeast Asia and Indian Ocean islands, a strong seasonality prevails in the coastal environment. Beaches undergo accretion/erosion cycles and during the onshore wind season, wave action can reach a higher level or further inland. With reversals in wind, wave action and currents, sand movement varies in the offshore–onshore

Table T15 Major criteria in coastal zones for tourism development

Zone[a]	Factor	Comments
Sub-tidal to offshore (Marine or neretic zone)	• Climate • Waves • Tides • Currents • Water temperature; clarity of water • Biodiversity, e.g., marine life, corals, seaweeds	• Physical conditions determine type, extent and seasonality of many recreational activities, e.g., swimming, water skiing, surfing, sailing, boating, travel to nearby island • Biodiversity presents additional attractions for recreational use, e.g., snorkeling, scuba diving, fishing • Free of pollution
Intertidal-nearshore (Beach)	• Beaches: width, gradient, material size, color • Risks from tidal movements • Potential erosion • Public access • Shore platforms: width, access • Wetlands: extent, access	• Physical properties of beach and coast influence type and extent of recreational activities • Beach capacity as useful management tool • Soft protection measures are preferred if need arises • Environmental guidelines, especially for wetlands
Backshore (Shoreland)	• Area • Views • Geomorphology (cliffs, dunes, wetlands) • Coastal vegetation • Microclimate • Scope for improvement • Access, e.g., roads	• Location of various tourist accommodation and service businesses • Proper setback, conditions for use • Preserve view (visual linkage is important) • Maximize specific advantages of geomorphological features • Dunes normally preserved as defense line and for selective uses • Good views from cliffs, headlands • Phased development; minimize degradation • Improvement, e.g., drainage
Onshore (Hinterland or vicinage)	• Topography • Vegetation • Existing development, e.g., population, supporting services	• Provides setting or backdrop • Separate planning zone • Access to sea is important

[a] Terms in parentheses are used by Gunn, 1988 and Mieczkowski, 1990.

direction and alongshore direction. The seasonal site features include beach morphological changes, a backshore with two berms, nearshore topographic changes, changing stream mouths, flooding, shifts in beach vegetation belts, etc. In particular, the analysis of the seasonal factor provides some idea of the potential hazards in various coastal zones. The seasonality arising from waves, wind, and tides, and the potential erosion and pollution are among the coastal hazards considered in environmental planning for site development (Beer, 1990, pp. 63–64).

Besides geomorphological criteria associated with tourist sites, other criteria in planning and development of resorts also have a strong physical base. These include adequate access, *setbacks* (*q.v.*), and EIA (environment impact assessment) before construction and carrying capacity. Pearce and Kirk (1986) have suggested specific types of carrying capacity that are closely associated with the linear zones of the coast. One recent development has been the application of a single criterion in the form of an ecolabel to assess the suitability of resort beaches. An example is the Blue Flag award for European beach resorts that focuses on *water quality* (*q.v.*), beach management, and safety (see *life saving and beach safety*) (UNEP/WTO/FEEE 1996).

Coastal site classification

Of various types of *classification of coasts* (*q.v.*) (Bird, 2000) none is suitable for determining site criteria for coastal tourism. Classifications with an emphasis on coastal processes can be useful for resort sites focusing on recreation, such as *surfing* (*q.v.*). For example, Bird (1993) identified various types of surf reflecting geomorphological and oceanic factors. Since the mid-1980s, the beach morphodynamics model with its identification and explanation of beach hazards, such as steep beaches and rip currents, is particularly useful for resort beaches in Australia (Short, 1999).

Generally, physical or morphological types of coastal classification are more useful for recreation/tourism planning, development, and management. For recreational purposes in the temperate countries, coastal landforms are classified as sand and shingle beaches, tidal forms (mudflats, salt marshes), estuaries, cliffs, and shore platforms (Pickering, 1996). Defert (1966 in Mieczkowski, 1990, pp. 247–248) provided one of the earliest classifications for coastal resort development, in which four types of coasts were identified:

1. *Oceanic: continuous and linear*: Straight oceanic beaches with tourism facilities following straight sandy coasts.
2. *Oceanic: discontinuous and concentrated*: Bays alternate with promontories and peninsulas with tourism located in the bays.
3. *Mediterranean: continuous and linear*: Wide and gentle beaches prevail as a result of the absence of tides or very small tides.
4. *Mediterranean: discontinuous and concentrated*: This consists of two types (1) wide bays bordered by promontories or capes, and (2) coves with small beaches.

In a situation where the site is clearly restricted or limited to one coastal type, it is possible to have further categorization in terms of criteria other than physical. For example, in the Ko Samui/Surat Thani region located in the Gulf of Thailand, the beaches are further identified for tourism development as follows: (1) conservation beaches, where tourism activities are not allowed; (2) nature-oriented development beaches where activities and services are permitted to a certain extent; and (3) progressive development beaches where activities and services can be developed to meet international standard (Tourism Authority of Thailand, 1985).

For the east coast of Peninsular Malaysia which is exposed to the northeast monsoon, resort sites are identified for tourism development with a strong consideration given to the seasonal factor. Four major types of sites are identified on the mainland coasts (Tourist Development Corporation, 1979).

1. Beach front site. This is backed by relatively flat land, sandy soils, and coconut groves and exposed to the sea.
2. Site oriented to both ocean and river or brackish lagoon. The topography is generally flat or rolling gently with coconuts and other vegetation.
3. Site situated adjacent to a substantial headland promontory with sufficient flat land for development. The beach may be interrupted by large boulders. Hill and weather patterns influence architectural design and site plan.
4. Site on hillside or hilltop with panoramic views located on headlands adjacent to good beaches. Weather and wind can be either greater or sheltered depending on the position of the development area. More constraints are placed on resort design.

Table T16 Types of resort sites on tropical coasts

Coastal type	Form/feature	Resort sites
A. Rock coast	1. Cliff	1. Good view; generally exposed; adequate setback necessary
	2. High headland	2. Good view; stability is crucial; can be sheltered or exposed. Requires compact design solutions
B. Mainland beach Coast	1. Linear	1. Large area available; can be exposed
	2. Crescentic bay	2. Can be at head of bay but has higher wave energy; decreasing wave energy towards the limbs of bay
	3. J-shaped bay (zetaform)	3. Sheltered in upcoast curve; increasing exposure to downcoast straight sector
	4. U-shaped bay	4. Can be at head of bay; often decreasing sand toward the limbs of bay
	5. Cuspate foreland	5. Only on large foreland; need to determine stability of convexity
	6. Spit	6. Only on large stable spits; river can be integrated into design; adequate setback from channel to avoid flooding
	7. River mouth associated with above	7. To be avoided because of rapid changes and seasonal closure of mouths, especially of small streams
C. Barrier coast	With/without dunes	Can be on barrier; but behind active dunes. Maintain seaward line of dunes as buffer zone. Lagoon can be integrated into design
D. Small island	As in A and B, where applicable.	Wider choice on many types of beaches on sheltered side. Limited beaches on exposed side. Access is important, especially during seasonal weather
E. Coral island	1. With/without lagoon	1. Adequate setback required avoid destruction of reefs
	2. Cay	2. Adequate setback required. Strong seasonal changes; no dredging or structures interfering with sand movement
F. Mangrove coast		On piles to minimize impact on ecosystem. Tidal range can be critical factor in accessibility and jetty length
G. Developed coast	1. Original sandy coast	1. Sufficient setback from protection measures. Beach nourishment required
	2. Original low rock coast	2. Selective removal or rock to create bays, artificial beaches. Beach nourishment required. Also raised sandy platform with coastal protection

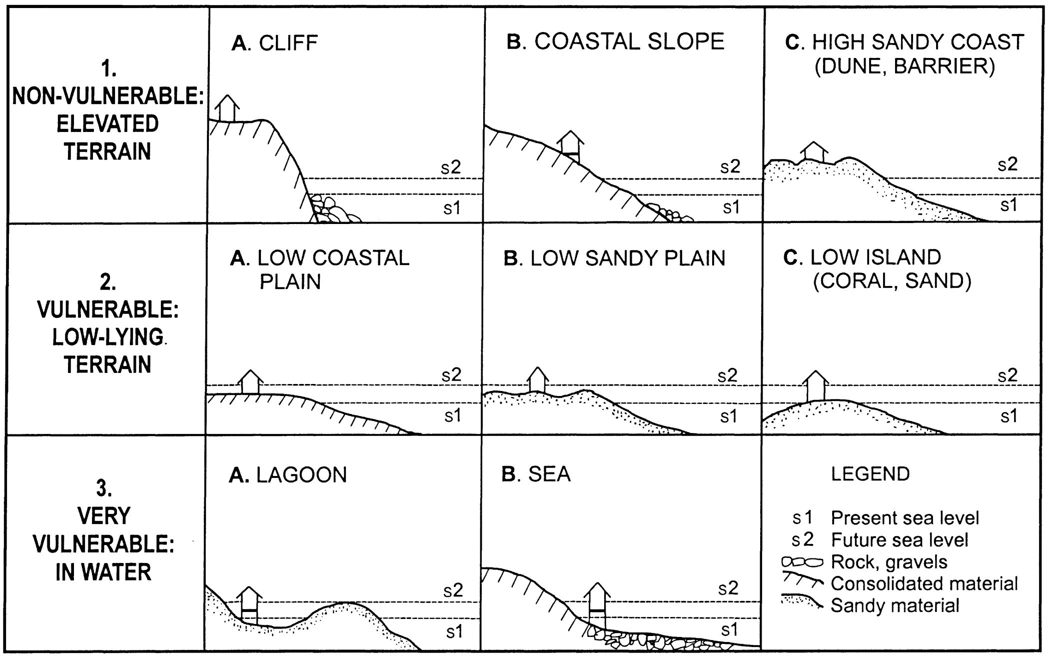

Figure T49 Types of resort sites affected by a sea level rise (redrawn from Teh, 2000).

These four types of sites can also be found on the islands which may provide a change of wind and sun orientation not possible with the mainland coastal site. However, access to islands is an important factor in construction and operation.

Based mainly on field examples from Southeast Asia and Indian Ocean islands a classification of resort sites is proposed for tropical coasts (Table T16). Where possible, the type of coast or coastal form is followed by an identification of specific suitable sites. Mainland *sandy coasts* (*q.v*) are the most important for resort development, with various suitable sites depending on the planform and degree of protection offered by rock headlands. Small islands, especially *coral reef islands* (*q.v*), are also favored for resort sites but they have fragile environments. Mangrove coasts hold a potential although the vegetation is being cleared cut down for other uses. Dunes are limited on tropical coasts and lagoons are actively used for local fishing. Stream mouths can be integrated into the resort site but requires adequate setback from possible flooding. Except for selective headlands, rock coasts (see *rocky coasts*) are underutilized for resorts. High rock coasts offer good views but require careful design and engineering. Low limestone coasts can be altered variously for resort sites, as evident on Mactan Island, where the modification can be limited or minimal (e.g., short seawalls, stone bunds), localized (e.g., groins, breakwaters, artificial islands) or effective (e.g., artificial beaches, selective excavation of rock to form small bays) (Wong, 1999).

With a *sea-level rise* (*q.v.*) in the future, many resorts on low-lying sandy plains or beach-ridge plains will be threatened as the coastline is cut back by the rising sea. For small islands dependent on tourism, the situation can be serious. Perhaps the most badly hit would be the island resorts of the Maldives, where the height of cays are within a couple of meters of the sea level and the entire island resort industry can be wiped out (Domroes, 2001). Mauritius has projected its loss of tourist beaches and in the major tourist area of Flic-en-Flac, an estimated 26,000 m^2 of beaches could be flooded by a meter sea-level rise (Mauritius National Climate Committee, 1998, p. 45). The response to the threat of rising sea level can be adaptive strategies classified as (managed) retreat, accommodation, and protection. Although various hard structural and soft structural options are considered for protection, new methodologies are being sought to estimate coastal vulnerability and resilience to the sea-level rise. For some low islands in the Pacific, coastal types can be used to assess vulnerability if further information is available. For example, while the upper shore can be of sand or shingle or a mixture of both, the lower shore can be a conglomerate platform, ramp outcrop, beachrock, mangroves, or seawall. Such details would be useful for assessing the vulnerability of a resort coast (Mimura and Harasawa, 2000).

Except for some island resorts, the vulnerability of resort sites to a sea-level rise has not been fully appreciated. In Malaysia, Teh (2000) has classified coastal resort sites according to their vulnerability to inundation arising from a sea-level rise. The sites can be (1) non-vulnerable (on a coastal slope or a high beach-ridge plain), (2) vulnerable (on a low coastal plain, low beach-ridge plain, or low island of coral, sand, or mud), and (3) highly vulnerable (in a lagoon or built over the sea). An additional coastal type (cliff) is added to this classification to cover other coastal types in Southeast Asia and the Indian Ocean islands (Figure T49). Compared with the classification of coasts for resort sites, this classification emphasizes the sea level relative to the two-dimensional coastal profile and much of the variety of coastal types and landforms is consequently made redundant. Nevertheless, it is an initial step in providing some idea of the vulnerability of resort sites to a sea-level rise.

Conclusion

Although many factors have to be considered in coastal sites for tourism, geomorphology remains basic as long as the coast is a necessary resource for tourism. Site analysis has to assess various types of coasts and its various zones. As coastal tourism caters to a widening demand, coastal sites for resorts are also being assessed for their suitability for other demands such as golf courses, marinas, oyster culture, and other related types of development. In the future, resort sites are likely to extend beyond the usual sandy coast and rock headland and include more adaptive use of the mangrove coast which has a potential for coastal ecotourism. Coastal sites are also likely to incorporate better technology not only for resort construction and infrastructure but also for coastal protection against erosion and beach management.

TRACERS

Introduction

Tracers are essentially sediment particles that can be easily identified within a large mass of grains having different characteristics. The concept is widely used in sedimentary petrography, where particular mineral assemblages are inherited from the characteristics of the provenance basin. Another approach is to use sediment from the environment to be studied and tag it using an artificial agent (e.g., paint or radioactivity).

Since the early stages of research on sediment transport, it became evident that natural and artificial tracers had a high potential, both for qualitative and quantitative assessments. The first examples of tracing experiments using artificial materials date back to the beginning of the 20th century, with the experiments of Richardson at Chesil Beach (UK) in 1902 and the reports of the Royal Commission on Coast Erosion published in 1907 (in Kidson and Carr, 1971). Although the last 20 years have seen the development of alternative methodologies for measuring sediment transport (see entry on *Instrumentation*), it can be noted that tracers are the only technique that can be applied at a broad range of temporal and spatial scales. Although both the sandy and the coarser fractions have been the object of tracer studies in sedimentary research, sand size material is generally used. A comprehensive review of tracer studies using pebbles can be found in Kidson and Carr (1971), while recent field studies and applications are described in Cooper *et al*. (1996).

Historical and technical development of the tracer technique

Fluorescent tracers

From the 1950s onwards, a group of investigators in the former Soviet Union started to use sands marked with fluorescent paints on a large scale (Zenkovitch, 1960; Zenkovitch and Boldyrev, 1965). The methodology consisted in marking sand grains with a fine film of a colloid (agar-agar) containing fluorescent material. The film was resistant to water, chemical reactions, and mechanical abrasion. The marked sand was then dried and injected on the beach. Thereafter, at regular time intervals (e.g., from minutes to days), samples were collected at fixed distances from the injection point. The research team also experimented using different colors of marked grains, to be injected at different water depths in the nearshore or for different grain sizes to assess differential transport. Almost at the same time, Portuguese investigators were testing the technique using a slightly different approach. Abecassis *et al*. (1962) tried initially to use heavy minerals and grain size trends as indicators of transport, but with scarce results, and therefore decided to employ sand marking either with fluorescent paints or using artificially tagged radioactive sands. The first method did not give good results, since natural luminescence was present in the sands. The methodology employed using fluorescent tracers was similar to that of the Russian team and they injected and collected samples on the foreshore.

In the following years, there was a boom in the use of fluorescent tracers for the study of sediment transport and investigators in the United States started to experiment with this technique. Yasso (1965) studied selective transport of different grain sizes in New Jersey; he used different colors of fluorescent paint, using a mixture of acrylic lacquer and beetle resin. Ingle (1966) undertook a study on beaches in southern California where sand samples were collected along profiles orthogonal to the coastline spacing from the foreshore to the inshore areas. He tested five marking techniques that are described in his book, probably the only published manual on the topic. Boon (1968) undertook one of the few studies that concentrated on carbonate beaches, in this case in the Bahamas, Florida. Three sand populations were considered, with different grain sizes and shapes, and marked using different colors, using fluorescent lacquer. Boon (1970) also applied his expertise on a beach in Virginia, where sand was collected from the local dunes and sieved through a series of meshes to obtain a population with a range of

0.29–0.59 mm. The sand was painted in large plastic bags, where it was mixed with acrylic lacquer, toluene, and beetle-resin.

In the 1970s, the application of tracers to measure longshore drift (see entry on *Longshore Sediment Transport*) became widespread. Empirical measurement of longshore transport to calibrate mathematical predictors for engineering studies was needed. Komar and Inman (1970) carried out several experiments on the western coast of the United States to build a database that eventually lead to their famous transport predictor. Another example of tracer application within the context of a coastal engineering project (see entry on *Engineering Applications of Coastal Geomorphology*) is that of Allen and Nordstrom (1977). In a multidisciplinary study for the assessment of beach form changes within a groin field (see entry on *Shore Protection Structures*) in New Jersey, the authors studied sediment exchange between the foreshore, the surf zone, and the bar. One of the largest experiments ever carried out on beaches is that of Chapman and Smith (1977) on the Gold Coast of Australia. Fifty tons of sand were marked and continuously injected using a dredge for about three weeks. Because the sand had a high degree of natural luminescence, the use of fluorescent paints was ruled out and a blue dye was used. Radioactive tracers were also excluded because of the large quantities involved and the subsequent environmental impact.

The fluorescent marking technique has become of interest to many European researchers in the 1990s, with the development of experiments in France (Corbau *et al*., 1994; Pedreros *et al*., 1996), Belgium (Voulgaris *et al*., 1998), and Portugal (Taborda *et al*., 1994; Ciavola *et al*., 1997a, 1998). These experiments introduced several improvements to the older methodology, in particular regarding the automatic detection of marked sand grains and the study of tracer advection in three dimensions.

Radioactive tracers

Despite the fact that radioactive tracers were at first very popular, they never became widely used, since the marking technique is complex and the method has a considerable environmental impact. Trying to compare results obtained using at the same time fluorescent and radioactive tracers, Abecassis *et al*. (1962) had already experimented with isotopes ^{110}Ag and ^{32}P, obtaining the best results with the latter. Two noteworthy field experiments using radioactive tracers were carried out by Heathershaw and Carr (1977) to assess tidally induced transport in the Severn Estuary (UK). The tracer was produced by neutron irradiation of Scandium (^{46}Sc) into glass. The glass was then sieved to obtain a population with different size classes. The detector consisted of a sodium iodide (NaI) crystal, doped with Thallium (TI) and optically coupled to a photomultiplier tube. This assembly, together with electronic components, was housed in a waterproof brass case. Measurements were made by lowering the counter on the seabed and readings were transmitted to a ship.

Clearly, the radioactive method offers many advantages such as the small quantities required, the possibility of tagging several grain size populations, the fact that the hydraulic properties of the grains are left untouched. However, although weak radioactive isotopes are used, it is most unlikely that nowadays an application for this method could be approved in the context of an environmental impact assessment.

Essential concepts for applying the fluorescent tracer method

Applicability and assumptions

The method must fulfill some basic assumptions: the marked sands should have a hydraulic behavior comparable to the unmarked ones; *advection* of the tracers should be prevalent over *diffusion* and *dispersion*; the transport system must be in equilibrium. Madsen (1987) presents an exhaustive mathematical description of the terms advection, diffusion, and dispersion.

It is no surprise that many investigators have used this method for studying sediment transport. The usage of fluorescent sands is simple, marking can be done easily and rapidly, and there is no impact on human health and the environment. Different colors can be used to tag various grain fractions, to study differential transport, and the sensitivity of the technique is on the order of 1 ppm (Ingle, 1966). The most interesting experiment on differential transport is that described by Komar (1977) on a reflective shoreface (see entry on *Reflective Beaches*) in Baja California, Mexico. A single injection of tracer took place and collection of over 200 samples was undertaken along a grid extending more than 200 m alongshore. The samples were sieved into different size fractions and the number of marked grains within each class was annotated. Later Blackley and Heathershaw (1982) revisited the issue and, in agreement with the previous author, reached the conclusion that different grain size transport was related to the transport mechanism, for example, the relationship between bedload and suspended load at a point on the foreshore. Allen and Nordstrom (1977) even used different colors to examine spatial changes of sediment exchange between the foreshore and the bar, albeit in a qualitative way.

Preparation of the tracers

Regarding this first stage of the method, an essential factor is the quantity of tracer sand to be produced. For large quantities (e.g., 1,000 kg or more), industrial preparation is probably the only feasible method, trying to use sediments with a mean grain size and density comparable to those of the natural environment. In any case, the best balance between handling during tagging and percentage of recovery during the experiment should be met. If sand is collected from the local beach, a composite sample could be obtained by mixing equal subsamples collected on the lower-, mid-, and upper-shoreface. It is important to carry out grain size analyses (see entry on *Beach Sediment Characteristics*) of each sub-environment and of the composite distribution, to compare the effects of mixing. Care should be taken to avoid local sedimentary effects due, for example, to the presence of large-scale bedforms or moribund beach cusps (see entry on *Rhythmic Patterns*).

The sand is then washed with freshwater to remove the salt and dried. Regarding the marking procedure, a number of different types of resins and paints can be used. The main requirement for the paint is to be resistant to chemical and mechanical abrasion caused by seawater. Initially, substances such as seaweed glue, bone-glue, gum, and starch were used but many authors later switched to acrylic paints, which offer better resistance to abrasion. If natural luminescence of the sediment is a problem, the solution of Chapman and Smith (1977), a blue dye dissolved in methylated spirit, can be adopted. Knoth and Nummedal (1977) marked the sand using a mixture of fluorescent paint, resin, and organic solvent. In recent experiments, fluorescent paint soluble in toluene has been widely used (Corbau *et al*., 1994; Ciavola *et al*., 1997a, 1998).

The next step is to dry the sand, minimizing the effects of aggregation. As far as the paint is maintained as thin as possible, aggregation should generally be negligible, especially if the sand is rapidly dried in the open air under sunlight. Even in the case of aggregate formation, if the sand is sieved with appropriate meshes after tagging, the mode of the populations should remain the same.

Injection of the tracer into the transport system

Injection of the sand into the transport system takes place according to the type of study being carried out. As Madsen (1987) concluded, it is possible to adopt three different techniques to analyze tracer advection. The *Time Integrated Method* (TIM) has an Eulerian nature, whereby a known quantity of tracer is released at a point and variations in tracer concentration are monitored throughout time at a location downdrift. The *Continuous Injection Method* (CIM) is similar to the previous one, with the exception that injection of the tracer is continuous at a known rate. The *Spatial Integration Method* (SIM) involves a Lagrangian approach, since it allows monitoring of tracer movement both in space and in time. Other advantages of the SIM over the previous methods is that the velocity of transport is computed referring it to the *centroid* (or center of mass) of the tracer cloud and that it is possible to calculate with confidence a recovery rate.

In the case of continuous injection on the submerged beach outside the breakers, dumping from a vessel is a possible method, while in the case of working in the breakers this may be unfeasible in terms of safety of the boat. For this reason, researchers using the TIM and CIM methods preferred injecting the tracer from several points along a transect orthogonal to the beach (Yasso, 1965; Ingle, 1966; Boon, 1970). Other experimentalists, mainly using the SIM method, placed the tracer at low tide into a shallow trench dug on the beach face, after washing it with liquid soap to avoid grain floating. There is no standard for the size and depth of the trench: the most important requirement is that all the tracer grains are removed almost instantaneously as soon as the site is covered by water. A delay in removal or burial of the tracer at the trench site could invalidate the basic assumptions of the method.

Sediment sampling

Despite the fact that many authors only worked at surface level (e.g., Ingle, 1966; Corbau *et al*., 1994; Taborda *et al*., 1994) it is preferable to collect shallow cores to assess the three-dimensional (3-D) advection of the tracer (e.g., Boon, 1970; Kraus *et al*., 1982; Ciavola *et al*., 1997a, 1998). PVC cores or other simple coring techniques are suitable for this

Figure T50 The SADAM system of Pinto *et al*. (1994) for *in situ* mapping of surface dispersal of fluorescent grains. It consists of an ATV, a dark camera with UV light, and computer with image processing software.

purpose. Inman *et al*. (1980) collected their samples according to the type of analysis to be performed: the first technique was employing a grab sampler, especially designed to collect only the first two centimeters of the surface layer and was used to carry out a spatially distributed sampling to apply the SIM. The second method was using corers that were collecting samples along a cross-shore profile at constant time intervals, for the TIM method. Duane and James (1980) adopted a similar approach for the CIM technique. Sampling was frequent along four profiles, to obtain a description of changes in concentration with time at each station. Samples were collected using a hand-held sloop, built on broad runners, that was penetrating the sand column no more than 1 cm, to avoid sampling at depths where the sand concentration was already in equilibrium. If sampling takes place on submerged sites, vaseline coated cards like those of Ingle (1966) can be used.

In case it is decided to assess surface distribution, to increase the significance of the results from the cores, it is possible to use automatic detection techniques like the system of Pinto *et al*. (1994), where a computer system in installed on an ATV (All Terrain Vehicle), to perform rapid assessments using image analysis techniques (Figure T50).

Dyed grain detection

Counting of the grains in the samples under a UV lamp can be tedious and involve several days of work. Whenever the number of tracer grains in a sample is high, automatic detection or indirect detection methods can be helpful, once the considerable calibration difficulties are overcome. In the study of Chapman and Smith (1977), where the dye was not fluorescent, counting took place following two different methodologies: photography and subsequent enlargement; affixing the samples to long strips of pressure-sensitive adhesive tape and passing the strips under a binocular microscope at an enlargement of 30–40 times to detect the grains. In both cases, the counting was undertaken using an automatic image analyzer.

At the very beginning of tracer research, Zenkovitch (1960) and Zenkovitch and Boldyrev (1965) examined the samples in the laboratory using a luminoscope. Such a piece of equipment used a UV source that stimulated fluorescence from the grains, similarly to the photometer that Yasso (1966) developed to count the number of marked grains directly on the beach. The spectrofluorimetric of Farinato and Kraus (1981) was instead based on a more original approach: the technique consisted in washing the sand samples with a solvent able to dissolve the resin and the paint covering the grains. The fluorescence of the effluent can then be measured using a spectrophotometer: the measured intensity is proportional to the number of tagged grains, the solution transmission, and the uniformity of the paint cover. The calibration of the intensity coefficient versus the number of marked grains per gram has to be undertaken according to the degree of marking, the grain size distribution, the chemical properties of the solvent and of the resin. For the method to work, all sand grains should be almost equi-dimensional: certainly in the case of a uni-modal, well-sorted sand that can be true, but as sorting becomes worse, the method looses significance. Besides, the technique assumes that the paint cover of the grains is uniform; probably this might be possible if industrially done, but since most authors mark the sands themselves to save money and time, especially when small quantities are involved, variations in color thickness must be expected.

Controversies and gaps in current knowledge

A simple conceptual model of longshore transport describes the system as two layered. The upper layer is where movement of the tracer occurs as advection longshore, while in the lower layer the sand is not activated. In order to calculate the volume of transported sand, it is necessary to calculate the *mixing depth* (see entry on *Depth of Disturbance*), that is considered equivalent to the thickness of the moving layer described above. Within this layer, grains are subjected to vertical and lateral movements caused by direct wave action and by the superimposed longshore current. There are different methods in the literature for determining the thickness of the mixing layer. While in many experiments it was simply determined in the field by digging one or more control holes, filled with marked sand, a different methodology was generally used in parallel with the previous one, considering as mixing depth the interval within the beach cores where 80% of the total mass recovered in each sample was observed (Kraus *et al*., 1982; Kraus, 1985; Ciavola *et al*., 1997b, 1998).

Workers using a detector at surface level may be confronted with the problem of assessing indirectly the burial depth of the tracer. Heathershaw and Carr (1977) estimated it using the *tracer balance method*, assuming that a reduction in the recovery rate of the tracer is

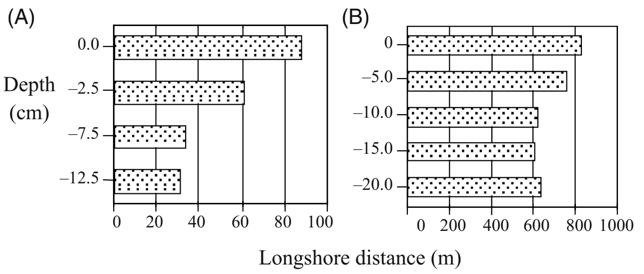

Figure T51 Vertical patterns of advection of tracer clouds from shallow beach cores: data in figure (A) was collected by Ciavola *et al.* (1997a); data in figure (B) was collected by Ciavola *et al.* (1998).

simply due to burial, and that burial can be estimated using a response function typical of the detector used. The method assumes that the tracer is uniformly distributed down to the depth of maximum burial; several field evidences points out that this might not always be true, unless total mixing is achieved, which implies that the tracer had enough time to reach equilibrium conditions. From the diagrams in Figure T51 (data from Ciavola *et al.*, 1997a, 1998), it is possible to notice that the displacement of the center of mass of the tracers, and consequently its velocity, decreases with depth, becoming almost constant in proximity of the maximum depth of activation. When there is an anomalous variation with depth in the speed of displacement, this is probably related to tracer burial. In this case, it might be necessary to reject some of the core samples: simple surface studies could therefore lead to an overestimation of the speed of displacement of the center of the tracer cloud, ultimately causing a miscalculation of the volume of sediment being transported. In experiments where the tracer sampling was extended to several days (e.g., Heathershaw and Carr, 1977; Ciavola *et al.*, 1997a), it was found that as time passed by, total mixing was taking place, with the whole sediment column moving almost at the same speed.

Another limitation of the method is the calculation of a significant *percentage of recovery* of the tracer. Recent experiments (Sherman *et al.*, 1994; Ciavola *et al.*, 1998) used grain size statistics of the tagged sediment to derive approximations for concentrations, based upon assumptions of uniform density and diameter. Estimates of total tracer recovery were made by extrapolating the point concentrations to representative control volumes, by constructing surface polygons and using tracer-depth distributions obtained from recovery depths.

Conclusions

Recently, many investigators throughout the world have been revisiting the tracer technique, especially for field measurements of longshore transport. *Tracer advection* can be measured on a 3-D basis; it is considered essential that investigators adopt such an approach if they want to obtain meaningful observations.

Most field experiments have been confined to small- to medium-scale beach studies, but tracers can be employed successfully to study transport along sandbanks and on continental shelves. In a similar fashion, the timescale of these experiments tends to be short (hours to days), because of the small quantities of tracer injected. In the past, long-term monitoring was undertaken using radioactive tracers, where a small quantity (e.g., less than 1 kg), provides enough material for a monthly exercise; however, possible negative impacts on the natural environment rule out this method. In the case of fluorescent tracers, only the usage of thousands of kilos of sand will ensure a significant recovery rate at the end of a long-term experiment. Large quantities mixed with sand during a beach recharge scheme (see entry on *Beach Nourishment*) could, for example, provide coastal managers with an independent method of assessing *where the sand is going* during monitoring activities, in addition to data for the calibration of longshore drift predictors, to decide whether further intervention is needed.

The main limitations of the method are the time and the effort required for data collection and analysis. Recent applications of automatic analyzer, particularly using image analysis methods, suffered from the cost and availability of high-resolution systems. With the recent boom of digital cameras, the power of image analysis has increased in parallel with a decrease in the costs involved, therefore a rapid development of automatic methods for grain detection and counting is likely to happen in the years to come.

TROTTOIRS

The term “trottoir,” French for pavement, is a very imprecise one in coastal geomorphology, referring to a range of intertidal landforms formed by a variety of processes. At their simplest, they form a bioconstructional overhang perhaps a meter wide attached to steep rocky shores at about mid-tide level. Elsewhere, on less steeply sloping coastlines, erosional platforms tens of meters wide may be covered by a similar variety of calcareous algae, vermitids, and other bioconstructional organisms which, on the outer edge form a distinctive rim where wave agitation encourages more rapid accumulation. These forms are particularly prominent over calcareous substrates and in the tropics, where they cover platforms cut into raised reef limestones, may merge with the algal terraces of high-energy reef margins (Emery, 1962). In deeper water beyond the trottoirs, mushroom-shaped bosses constructed of the same organisms, may rise to the sea surface where their morphology may resemble that of coral micro-atolls.

Processes

Because of the range of morphologies which have been termed trottoirs, there are probably a number of processes involved in their formation. The simpler intertidal overhang or corniche may be entirely the result of bioconstruction. However, the protection of the coating of algae, vermitids, and other organisms give the underlying rock surface in comparison to the zones above and below this mid-tide level, where mechanical, chemical, and bio-erosional processes may be acting, can make the protuberance more prominent and give it a bedrock core. On wider rimmed platforms the paradox is that the bioconstructional layer overlies a platform which is obviously erosional which has led to contradictory hypotheses to explain the landforms’ origin as either constructional or erosional (see e.g., Emery, 1962). Probably, both processes occur, either at different times or even simultaneously as many bioerosional organisms including blue-green algae and sipunculid worms may be associated with or beneath the veneer of rock-building biota.

Organisms involved

The constructive or protective activity of many organisms is involved in the formation of trottoirs. The most ubiquitous are calcareous algae (e.g., *Neogoniolithon notarisii, Lithothamnium* sp., *Lithophyllum tortuosum, Tenarea tortuasa*), vermetid worms (e.g., *Dendropoma petraeum, Vermetus triqueter, Vermetus nigricans, Pomatocerus caeruleus*), Sabellariae (*Sabellaria kaiparaensis, Sabellaria vulgaris, Galeolaria caespitosa, Phragmatopoma iapidosa, Vermilia* sp., and oysters (*Crassostrea amasa, Crassostrea glomerata, Saxostriea* sp.) the exact combination of species depending on climate, exposure, and the environmental factors (Kelletat, 1989, 1995).

Location

Although the overall distribution, limiting factors, and importance in coastal processes are not fully investigated, trottoirs, *sensu lato* are found from northern Scotland to the tropics (Kelletat, 1989). A very wide range of forms has been described from the Mediterranean (e.g., Crete, Kelletat and Zimmerman, 1991). Rimmed platform types, are more common in warmer waters and have been described from the southern Mediterranean, the Caribbean, Micronesia, and Australia (e.g., Kelletat, 1989, 1995).

Rimmed platforms are best developed over limestone substrate and may occur closer to high tide levels than the corniche type of trottoirs, though still permanently wetted by spray even at low tide. Low to moderate tidal ranges therefore appear to be most appropriate for the development of all types of trottoirs. Moderate wave activity also appears favorable. Where too great, the amount of overhang may be limited by mechanical breakage.

Rate of growth

Trottoirs can accumulate rapidly, in tropical waters their growth rates being only a little less than those of coral reefs (Kelletat, 1989). In Crete, trottoirs of algal reefs have grown to a width of 10 m since the coastline was last uplifted 1,530 years ago representing lateral growth rates of more than 6 mm/yr. Marginal extension rates of more than 13 mm/yr and increase in thickness of 0.8 mm/yr have been reported from algal reefs in St. Croix (Adey and Vassar, 1975). Given sufficient stability, sea-level trottoirs have the ability to build significant coastal features.

TSUNAMIS

Introduction

The word “Tsunami” is derived from the Japanese meaning “Harbor Wave.” Tsunamis are often described as tidal waves but this view is incorrect since they have nothing to do with tides. Tsunamis are generated by offshore earthquakes, submarine slides, and occasionally by subaerial landslides that enter water bodies. In each case, large-scale displacement of water takes place as a result of submarine sediment slides or from earthquakes that induce faulting of the seabed. The initial water movement is often characterized by a rapid drawdown and a lowering of the sea surface at the coast as the water moves into the area of seabed displacement. Thereafter, large kinematic waves are propagated outwards from the zone of seabed disturbance. The waves travel across the ocean at very high velocities, often in excess of 450 km/h, and possess very long wavelengths and periods. At the coast, the tsunami flood level (runup) is partly a function of the dimensions of the propagated waves but is greatly influenced by the topography and bathymetry of the coastal zone and as such the waves can reach considerable elevations causing widespread destruction and loss of life.

Historical accounts of tsunamis

The majority of tsunamis occur around the Pacific Ocean but many are also known from other areas. The frequency of Pacific tsunamis is due to the high occurrence of severe earthquakes under or close to the seabed as a result of the subduction of oceanic crust adjacent to continental margins. Such geological processes are a characteristic feature of Japan where there is a long history of devastating earthquakes and tsunamis. Between 1596 and 1938 the Japanese islands were struck by no less than 15 major tsunamis. One of the worst of these took place on June 15, 1896 as a result of a large submarine earthquake on the ocean floor 150 km offshore. Since the epicenter of the earthquake was located beneath the ocean floor, the inhabitants on nearby coasts, although they knew that an earthquake had taken place, were unaware that a major tsunami had been generated. The following account provides a vivid description of what followed. (Myles, 1985).

> This great Sanriku tsunami came on a festival day when the townspeople were enjoying a holiday. Twenty minutes after the first shock, the sea was seen to recede, while a little past eight in the evening, noises like that of a rainstorm were heard. The tsunami was now on them—a wall of water some tens of feet high—and the holiday revellers, before they realised the awful situation, were swept away and drowned … the fishermen, who at the time were some distance out at sea, and had noticed nothing unusual, were on their way home the next morning, amazed to find the sea for miles strewn with house wreckage and floating corpses.

According to the Japanese Government, 10,617 houses were swept away, 2,456 houses were partly demolished, 27,122 persons killed, and 9,247 persons injured. Practically, every coastal town and village in the provinces of Mino and Owari on the Sanriku coast of Japan was destroyed.

One of the most severe earthquakes and tsunamis took place on the January 11, 1693 in eastern Sicily. This disastrous earthquake resulted in the loss of life of ca. 70,000 victims. A tsunami occurred at Catania and also at Augusta. According to reports, there were three withdrawals of the sea and three major waves. Similarly severe earthquakes and tsunamis took place in Calabria on February 5 and 6, 1783. At this time, a tremendous earthquake occurred in this area associated with five very strong quakes. Considerable stretches of the coastline of Calabria were badly affected by a tsunami and the sea was reported to have receded and then inundated the shore with recessions and inundations repeated at least three times at intervals of about 10 min. At Messina harbor, quays and buildings were flooded and in one area the sea withdrew for more than 7 m leaving the sea bottom dry and a lot of fish on the beach. Then suddenly the water came back surpassing the limit previously reached and flooding the coast. Local tsunamis were also produced as a result of a large earthquake-induced rockfall into the sea. The tsunami of February 6 was particularly disastrous because of the very high number of victims where many, frightened by the earthquake shocks, escaped to the beach and were drowned by waves which reached the roofs of harbor buildings. In excess of 1,500 people were drowned and the tsunami flood level was estimated to have been between 6 and 9 m. Tinti and Maramai (1996) observed that in one area the tsunami was associated with deposition of "… some sand on the ground."

A very strong earthquake and tsunami took place in the Messina Straits, Italy, on December 28, 1908. The towns of Messina and Reggio di Calabria were completely destroyed together with many neighboring villages. The area of destruction was about 6,000 km^2 and more than 60,000 people died. The earthquake produced a violent tsunami in the Straits of Messina that caused severe damage and many victims. In all places the first observed movement was the withdrawal of the sea (in some places by about 200 m). Thereafter coastal flooding took place in association with at least three large waves. According to Tinti and Maramai (1996) the tsunami lasted many hours and reached its maximum intensity along parts of the Calabrian coast and on the coast of Sicily. In some localities, the biggest wave was the first while at others it was the second. Tsunami runup was observed to decrease for increasing distances away from the epicenter but in the Messina Straits this was obscured by the effects of wave resonance. At Messina the wave height reached 3 m, numerous boats were damaged, harbor quays were destroyed, walls collapsed, and several boats were transported onshore. In certain areas the maximum level reached by the tsunami was in excess of 10 m above contemporary sea levels, resulting in the destruction of many buildings and considerable drowning (Tinti and Maramai, 1996).

Probably, the most destructive tsunami in Europe during historical times took place on November 1, 1755. An earthquake took place offshore ca. 200 km WSW of Cape St. Vincent, on the Gorringe Bank on the seafloor west of Portugal and attained a magnitude estimated at 8.5 Ms. The epicenter of the earthquake was in an area along the Azores–Gibraltar plate boundary that forms the western part of the lithosphere boundary between the Eurasian and African plates (Moreira, 1985). The eastern section of the Azores–Gibraltar plate boundary (which includes the Gorringe Bank) is a zone of active plate compression and in this area faults tend to have a large source component that results in high-magnitude and deep-seated tsunamigenic earthquakes).

The considerable destruction that took place in Lisbon, in addition to widespread fires, was mostly attributable to three tsunami waves estimated to be between 5 and 13 m high that took the lives of 60,000 people in Portugal alone. There are also numerous reports of tsunami flooding and fatalities on a large-scale along the Algarve coast and on the coastline of Morocco. In England, contemporary observations by Borlase (1755, 1758) describe the arrival of the tsunami in Mounts Bay, Cornwall. Borlase noted

> … the first and second refluxes were not so violent as the 3rd and 4th (tsunami waves) at which time the sea was as rapid as that of a mill-stream descending to an undershot wheel and the rebounds of the sea continued in their full-fury for fully 2 hours … alternatively rising and falling, each retreat and advance nearly of the space of 10 minutes until 5 and a half hours after it began.

Reconstructed tidal changes for this day for the Isles of Scilly show that the time of high tide coincided approximately with the arrival of the first tsunami wave some 5 h after the first shocks were reported on the Portuguese coast. There are no known reports of the progress of the tsunami northeast along the Channel but it is reasoned here that the coastal flooding effects must have been considerable. There is some evidence to indicate that the 1,755 Lisbon tsunami was not solely caused by a seabed fault. Recently, a large turbidite/submarine slide complex has been identified on the seafloor adjacent to the Gorringe Bank and tentatively dated to AD 1755. This discovery raises the possibility that the tsunami was partly generated by an earthquake-triggered fault on the seabed and partly by submarine sediment slumping.

Geological evidence for tsunamis in prehistory

Historical accounts of former tsunamis have particular value since they can provide information on the frequency and magnitude of events for the time period for which historical records are available. For example, in Italy the oldest historical record of a tsunami having taken place is for the AD 79 eruption of Vesuvius. Since numerous tsunamis have taken place along the coastline of Italy since then, historical accounts are a particularly valuable archive that can be used to estimate tsunami (and earthquake) recurrence. In recent years, however, geological investigations have been used to identify former tsunamis that took place in prehistory. This has proved possible owing to the recognition that, in many cases, tsunamis deposit sediment in the coastal zone (Dawson and Shi, 2000). Identification of such sediment layers in coastal sediment sequences has led to a different perspective on the past frequency and magnitude of tsunami events in different coastal regions.

Geological investigations of former tsunamis is a relatively new research area. The recognition that many tsunamis deposit sediment in the coastal zone has only become an accepted idea during the last 5–10 years. Discussion of this concept has been accompanied by a proliferation of academic papers that have described a range of sediments that have been attributed to a series of former tsunamis (Figure T52).

Unlike storm surges, tsunami runup across the coastal zone is frequently associated with the rapid lateral translation of water and suspended sediment. Thus, tsunami deposits can be used to provide an indirect record of former offshore earthquakes and underwater landslides. It is exceptionally difficult, however, if not impossible, to

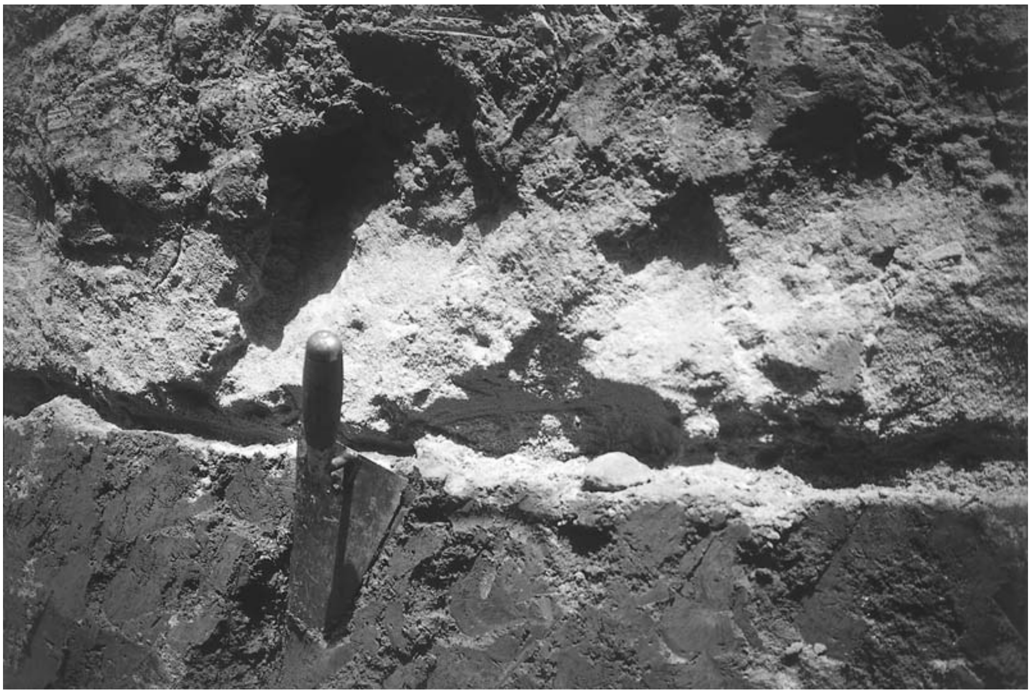

Figure T52 Sheet of sand and overlying boulders, Boco do Rio, Algarve, Portugal deposited by tsunami that accompanied the Great Lisbon earthquake of November 1, AD 1755.

differentiate tsunami deposits attributable to former submarine slides or offshore earthquakes. In particular areas of the world, especially in areas of an active plate motion where an offshore earthquake has taken place, it may be a gross oversimplification to attribute the triggering mechanism solely to earthquake-induced seabed faulting. Frequently, an offshore earthquake may also generate local submarine slides thus leading to complex patterns of tsunami flooding at the coast. In other areas (e.g., Hawaiian Islands, Norwegian Sea) submarine sediment slides may be the dominant mechanism of tsunami generation.

Tsunami deposits are distinctive. They are frequently associated with the deposition of continuous and discontinuous sediment sheets across large areas of the coastal zone. Frequently they consist of deposits of sand containing isolated boulders. On occasion, such boulders exhibit evidence of having been transported inland from the nearshore zone. In addition, microfossil assemblages of diatoms and foraminifera contained within sand sheets may provide information of onshore transport of sediment from deeper water.

Field observations of tsunami flooding usually describe the rapid lateral translation of water across the coastal zone. Frequently, the lateral water motion associated with runup is influenced by local wave resonance. Thus, the tsunami waves as they strike the coast are unlike waves associated with storm surges since not only are they associated with considerably greater wavelengths and wave periods, but they are essentially constructive as they move inland across the coastal zone. The rapid water velocities (provided that there is an adequate supply of sediment in the nearshore zone), are in most cases associated with the transport of a variety of grain size ranging from silt to boulders. Unlike storm surges individual tsunami waves reach a point of zero water velocity prior to backwash flow. At this point, large volumes of sediment may be deposited out of the water column onto the ground surface. Young and Bryant (1992) have made reference to isolated boulders in tsunami deposits in Southeast Australia. In that area, thicknesses of massive sands and silts include occasional isolated boulders, described by Young and Bryant (1992) as “boulder floats”.

One of the most awkward problems in reconstructing chronologies of former tsunamis for different areas of the world is how to be able to distinguish tsunami deposits from sediments deposited as a result of hurricane-induced storm surges. For example, in coastal Alabama, USA, a series of hurricanes during historical time have resulted in the deposition of multiple sand layers in low-lying coastal wetlands. While it is accepted that storm surges result in the deposition of discrete sedimentary units, it is argued that tsunamis in contrast to storm surges, generally result in deposition of sediment sheets, often continuous over relatively wide areas and considerable distances inland. For example, sediment sheets in the Algarve, Portugal, associated with the Lisbon earthquake tsunami of 1,755 occur in excess of 1 km inland. In addition, it may be the case that tsunami deposits contain distinctive microfossil assemblages that can be differentiated from those produced by storm surges (Dawson and Shi, 2000).

Tsunamis and submarine slides

Along the coasts of the northern North Sea, Norwegian Sea, and northeastern Atlantic Ocean, a very prominent sand layer, first thought to have been deposited by a storm surge, has more recently been attributed to a large tsunami ca. 7,100 ^{14}C years ago (Figure T53). This event was generated in the Norwegian Sea as a result of the Second Storegga submarine slide. The widespread deposit is now regarded as a marker horizon against which to compare the age of related deposits and with which to more closely define patterns of land uplift.

The detail with which the tsunami is known is impressive. Several studies have examined the sedimentology of the deposit, including its particle size, microfossil content, and even the time of year it occurred. The diatom ecology of the layer has been examined and over 100 ^{14}C dates on biogenic material both within the layer and from adjacent horizons have been obtained.

Geological investigations of these tsunami deposits on the northern and eastern coastlines of Scotland as well as in uplifted lake basins along the west coast of Norway provide evidence of minimum tsunami runup. In eastern Scotland, the minimum value of runup associated with this tsunami is on the order of 4–6 m above contemporary high water mark. However, this value as stated above, should be treated with caution since tsunami flooding to higher elevations may have taken place yet did not leave a sedimentary record. Harbitz (1992) attempted to develop a numerical model of the Second Storegga submarine slide. He noted that the scale of tsunami runup along the Scottish and Norwegian coastlines very much depended upon the average landslide velocity that was used into the model. For example, he noted that an average slide velocity of 20 m/s resulted in runup values onto adjacent coastlines of between 1 and 2 m. By contrast, a modeled landslide velocity of 50 m/s resulted in runup values of between 5 and 14 m, values significantly in excess of the estimates for adjacent coastlines based on geological data. Harbitz (1992) concluded that a landslide velocity of 30 m/s provided the closest

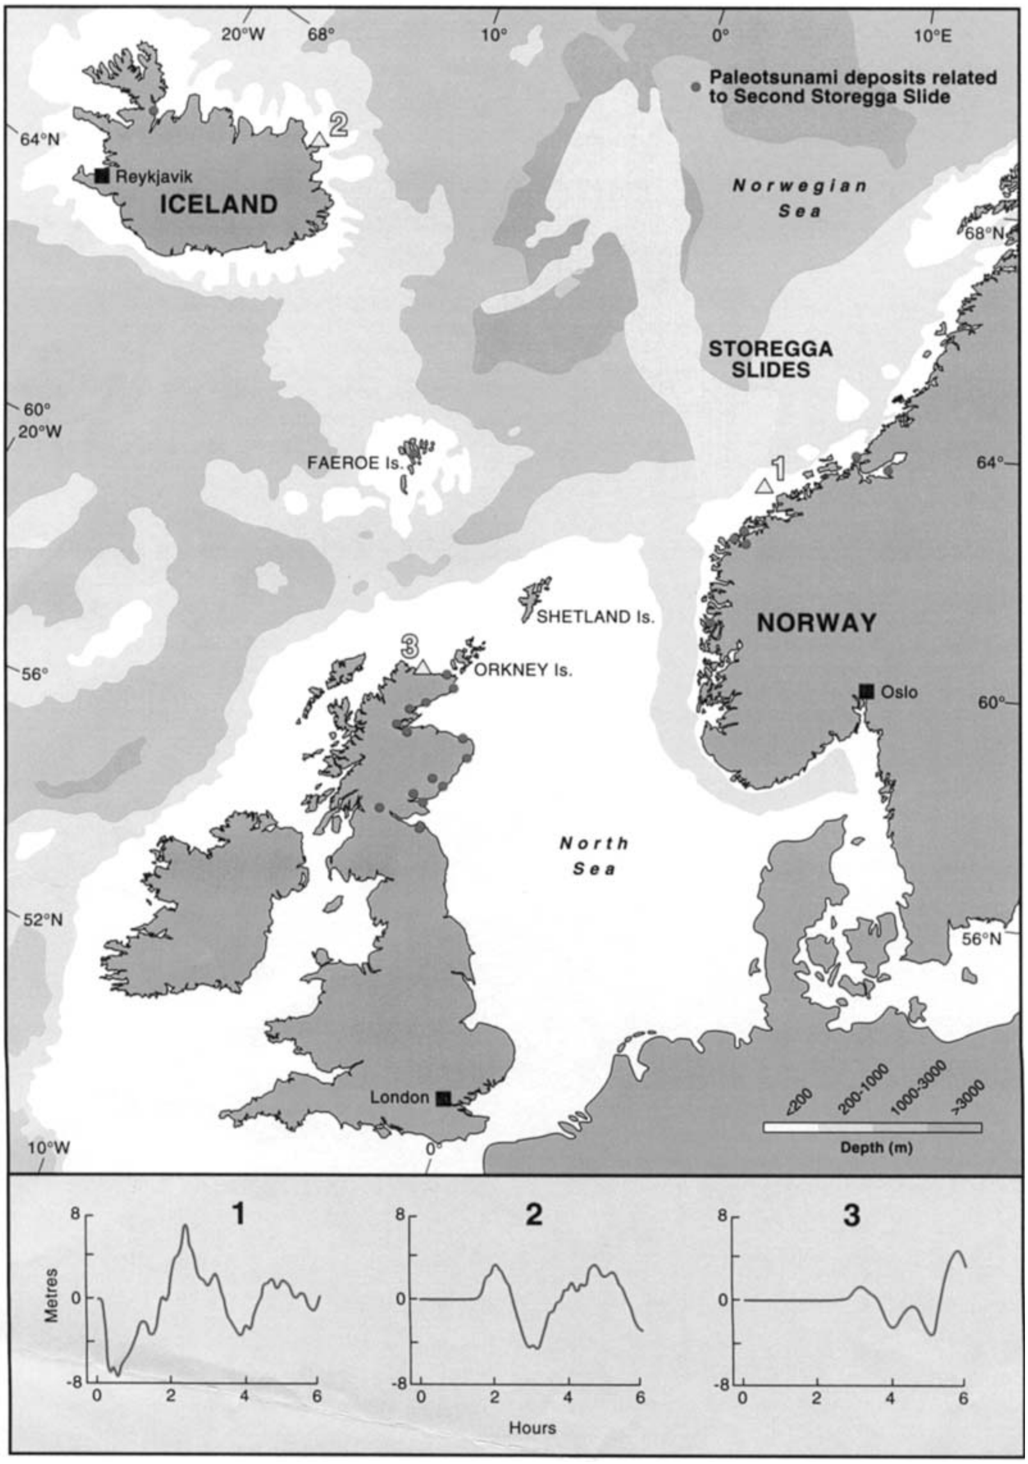

Figure T53 Map of the location of the Second Storegga slide, believed to have generated a tsunami about 7,100 ^{14}C years BP, with sites where the tsunami deposits have been found (see Dawson and Shi, 2000).

approximation to the estimated runup values based on geological data. However, the weakness in this argument is that the geological data only provide minimum estimates of likely flood runup and therefore the related numerical models of the same tsunami will always underestimate the likely average value of the submarine slide velocity.

The occurrence of this tsunami is unusual since it appears to have been generated by one of the worlds largest submarine sediment slides rather than by an earthquake. This serves to demonstrate that severe tsunamis can be generated by submarine slides in aseismic areas where there are considerable thicknesses of unconsolidated sediments on the seafloor.

Giant submarine slides and their potential to generate tsunamis are not restricted to the Norwegian Sea. Recently, Nisbet and Piper (1998) recognized a giant submarine slide occupying the majority of the seafloor of the western Mediterranean. The slide appears to have been generated in deepwater adjacent to western Sardinia and radiometric dates appear to indicate that it took place during the last glaciation of the Northern Hemisphere (probably ca. 20–30,000 years BP). At present, there is no geological evidence that this submarine slide generated a large tsunami. That such a large tsunami took place, however, can hardly be doubted. However, paleoenvironmental reconstruction of this event appeared to indicate that the slide took place at a time when sea level in the western Mediterranean may have been at ca. −100 m below present and hence any geological record of the tsunami having taken place may lie below present sea level. Submarine slides and offshore earthquakes are not mutually exclusive, however, in their capacity to generate tsunami. For example, recent investigations have shown that the islands of Amorgos and Astipalea in the southern Aegean Sea were subject to severe tsunami flooding caused by an offshore earthquake in 1956 that simultaneously generated a major sediment slump and the two processes together acted to generate complex patterns of tsunami flooding.

Tsunami warning systems

As a result of the severe damage and loss of life caused by tsunamis, attempts have been made to develop warning systems designed to alert the public in advance of the arrival of individual tsunamis. Tsunami warning systems did not exist prior to the Aleutian Trench earthquake and tsunami of April 1, 1946. However, the destruction of the Scotch Cape Lighthouse on Uminak Island and the devastation of Hilo, Hawaii by this tsunami eventually led to vociferous calls for the establishment of a tsunami warning system designed to protect life and property.

The network was developed by the US Coast and Geodetic Survey and has its center of operations on the Island of Oahu, Hawaii. The center, known as the Pacific Tsunami Warning Center (PTWC) became operational in 1948 and was linked to over 30 seismographic stations throughout the Pacific Basin. These provide data on Pacific earthquakes whose magnitude and epicenters make them tsunamigenic (capable of producing tsunamis). When such an earthquake has taken place, the PTWC issues a tsunami watch to all receiving stations. The PTWC is also linked to over 50 tide-gauge stations located throughout the Pacific. Any tsunami that has been generated by an earthquake is automatically recorded in the tide-gauges closest to the epicenter. If a tsunami has been detected then the tsunami watch is upgraded to a tsunami warning. At this stage, the estimated times of arrival of the first waves are computed for all stations across the Pacific. Once the PTWC has issued a tsunami warning and has provided information on the times of arrival of the first waves, it is the responsibility of the local police, military, and civil defense agencies to decide on whether or not particular areas should be evacuated.

The accuracy of PTWC tsunami warnings is well-illustrated by the famous Chilean earthquake and tsunami that took place on May 21, 1960. Once the earthquake epicenter had been calculated and a brief study of local tide-gauge data had been completed, it was estimated that the velocity of the tsunami was 710 km/h and that the tsunami would reach the Hawaiian islands 14 h and 56 min after its generation off the Chilean coast. The prediction was that the first wave would strike Hilo at 9.57 p.m.—it arrived 1 min late.

In areas where the coast is located close to the epicenter of a tsunamigenic earthquake, the time that elapses between the generation of the tsunami and its arrival on the coast is often frighteningly short. For example, the first tsunami waves that struck the Chilean coast on May 21, 1960 arrived only 15 min after the main earthquake shock. Similarly, there was only a relatively short time interval between the March 27, 1964 earthquake in Alaska and the arrival of tsunami waves at the coast. In both cases, loss of life was due to the fact that the tsunamis struck coastlines long before any PTWC warning could be given.

As a result of these two great tragedies, it was realized that it was important to establish regional warning systems for Alaska (the Alaskan Regional Warning System—ARWS) and the Hawaiian Islands. In 1967, a regional center was established in Alaska at Palmer, Anchorage. The center makes use of numerous automated seismographic and tide stations and is capable of issuing tsunami watches and warnings within seconds of a particular earthquake. A regional tsunami warning center for the Hawaiian Islands was later established in 1975.

Tsunami hazards and paleoseismicity

In Europe, due to the much lower frequency of tsunamis there are almost no tsunami warning systems in place. The only one that exists has been built by Portuguese authorities who have installed seismometers and wave recorders west of Portugal with the aim of providing advance warning of any future tsunami similar to that which caused such devastation in AD 1755.

In response to the perceived hazard posed by tsunamis to European coastlines, the European Union funded a major research initiative in 1992 concerned with European tsunami risk. The Project “Genesis and Impact of Tsunamis on European Coasts (GITECs)” completed in 1998, had two principal objectives. The first was to study tsunami generation mechanisms in Europe, for example, those caused by earthquakes and by submarine or coastal landslides. The second objective is to evaluate the tsunami hazard in European seas in order to reduce tsunami risk in Europe. As part of this research effort, a unified catalog of historic and prehistoric European tsunamis has been prepared. In addition, it has proved possible to estimate tsunami frequency for selected coastal regions over long (geological) timescales. In this respect, attempts are also being made to assess tsunami hazard and the likely impact of such tsunamis for particular coastal areas. Detailed investigations have also been made to develop numerical model simulations of major European tsunamis. The project has also attempted to compare the development and implementation of two new European tsunami warning systems.

Summary

In addition to the importance of paleotsunami research in terms of coastal hazard assessment, the calculation of long-term tsunami frequency for particular coastal regions provides valuable data on the past frequency of offshore earthquake activity. In certain parts of the world (e.g., Japan), the historic frequency of offshore earthquakes and tsunamis has been so high that preparedness for future earthquakes and tsunamis is of the highest priority. By contrast, it is now known that while earthquakes have induced minor tsunamis that have struck the Portuguese coastline during the last 3,000 years, there has been only one major earthquake and one tsunami during this period that have been highly destructive. In areas where the past occurrence of tsunamis is extremely rare, a difficult problem is presented to politicians and engineers since many complex decisions have to be made in establishing appropriate coastal defenses for catastrophic marine flooding that may only take place once in several thousand years. This problem becomes more acute in areas where nuclear power plants are located close to present sea level. Sadly for most areas of the world, coastal populations have no protection from tsunamis and rely on chance that none will ever take place.

UPLIFT COASTS

From the late 1800s the early geologists and geomorphologists such as W.M. Davis identified coasts of "emergence" (uplift coasts) and "submergence" (drowned coasts) relative to modern sea level. The idea was promulgated further by Johnson (1919) and Cotton (1974). In a more modern sense we now recognize continental margins as "passive" or "active" (subject to ongoing tectonic processes). Uplift coasts are typically associated with the latter.

Three primary mechanisms of coastal uplift may be identified:

(1) Contemporaneous subduction processes at active plate margins are particularly evident around the circumference of the Pacific Ocean. Above the subduction zone the coastline is subjected to numerous tectonic and seismic processes, but particularly uplift and lateral

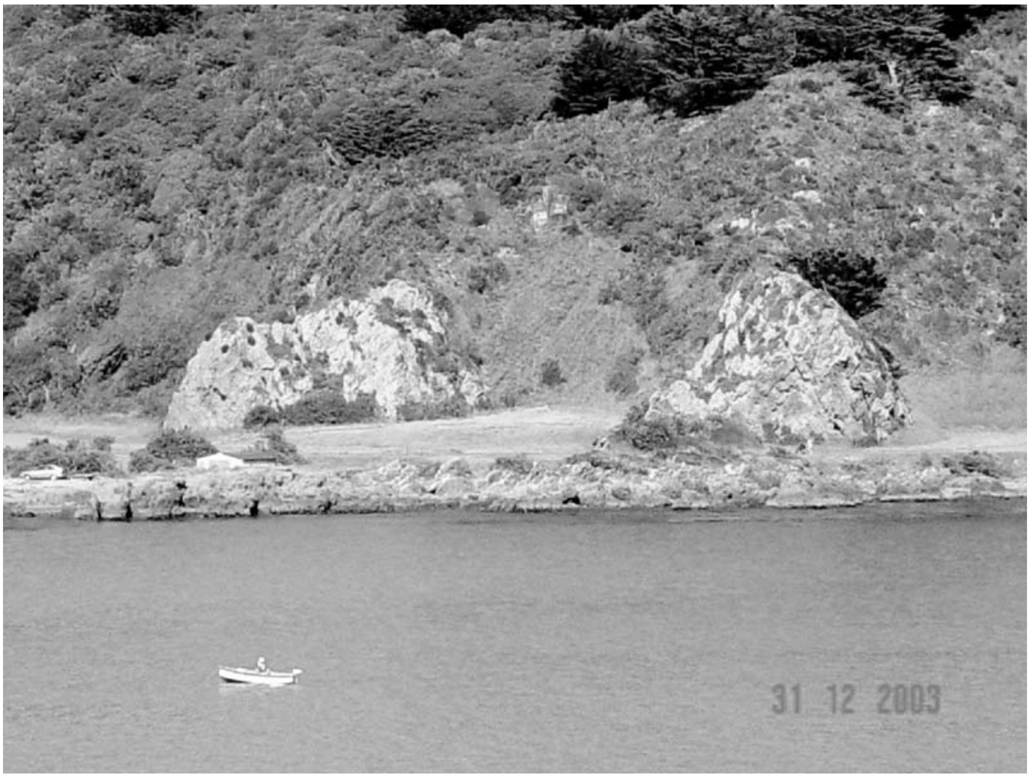

Figure U1 The uplift shoreline at Wellington, New Zealand, which emerged ~2 m after the 1855 earthquake. Note the degraded cliff and uplifted shore platform, now grassed (photo: T. Healy).

Figure U2 The tectonically upthrust emerged coastal plain, which was previously the Ahururi lagoon (remnant in the foreground), as viewed in 1981, some 50 years after the uplift of ~2 m associated with the 1931 earthquake at Napier, New Zealand. Note the abandoned stacks, and degraded cliffs. This is in an active subduction zone, with the hills in the background subject to continuing tectonic uplift (photo: T. Healy).

(wrench) faulting, as for example along the northern California coast. Active plate marginal processes creating uplift coasts also occur at a medium regional scale along the Pacific South American coast, New Zealand, New Guinea, Indonesia, and Japan. A type site for an active subduction coast undergoing uplift is the East Coast province of New Zealand.

(2) Isostatic rebound from the melting of continental ice sheets, whose load depressed the earth's crust, provides a second mechanism for uplift of the coast. Resulting uplift coasts are particularly evident over large coastal regions in the northern hemisphere, in particular Alaska, Canada, and northeastern USA; Russia, Scandinavia, and northern Europe. The latter include uplift coasts of the ancient rock terrains of Scandinavia and the British Isles, as well as the modern Pleistocene glacial tills of the north German plain.

(3) Diastrophism—tectonic movements of the earth's crust, including both epeirogenic (regional uplift without significant deformation) and orogenic (mountain building with deformation)—can produce sectors of uplift coasts. For example, block faulting producing horst and graben structures occur along the South Australian coast (Twidale, 1968), while block faulting influences much of the central coast of China, as well as the coast of Chile and Japan.

Seibold and Berger (1993) illustrate how throughout geological time, a major sedimentary wedge formed around the perimeter of the continents. Upon uplift, it is these sedimentary wedge deposits which undergo erosion from marine action at the coast. Subsequently when they are uplifted beyond the marine influences, subaerial denudation over time erodes out and masks the original specific coastal geomorphic features. However, epeirogenic uplift may also occur on continental margins where there is no sedimentary wedge, so that granitic rocks of continental origin characterize the coastal geomorphology subject to the uplift. On a larger spatial scale, some uplift coasts also present emerged "continental shelves" and continental slopes, and possibly even the "continental rise."

When considering uplift coasts, one needs also to bear in mind the timescale of its formation: (1) Recent emergence of the coastline leaves a distinctive imprint on the terrain from the previously active marine processes. Landforms that result include raised terraces, often in flights as in New Guinea, abandoned strand lines as in Scandinavia, coastal plains and abandoned cliffs, shore platforms, and stacks. Examples of the latter include the uplifted shore platforms from historical earthquakes such as the 1855 Wellington event which raised the shoreline by ~2 m (Figure U1), and the coastal plain at Napier which, prior to the 1931 earthquake which destroyed the City of Napier, was a large shallow lagoon, but is now a coastal plain (Figure U2). (2) As time of emergence progresses, normal subaerial weathering and denudation processes take over, acting on the emerged features. Thus the cliffs become degraded, and stream incision occurs on the raised terraces. Eventually all that is identifiable in the landscape is the break of slope indicating location of a previous shoreline.

V

VEGETATED COASTS

Vegetated coasts are those where rooted vascular plants are a persistent feature of the coastal landscape. This can include dunes, salt marshes, sea-grass beds, gravel barriers, and rocky coastlines. The type of vegetation, as well as its importance in shaping the coastal environment, varies according to climate, sedimentary deposits, and wave and tidal energy regimes. These variables control both the type of vegetation that can survive, and the physical context within which the plants interact with sedimentary and geomorphic processes to shape coastal landscapes. Vegetation not only exists in many coastal settings, it is an important biogeomorphic agent and as such is an integral link between the ecological and landform dynamics of coastal systems. While the presence of vegetation in dunes or on salt marshes has long been recognized as an essential characteristic of those environments, the importance of plant growth forms and their adaptations to stressful physicochemical conditions in shaping coastal landforms has only more recently received attention. For example, Bauer and Sherman (1999, p. 73) describe foredunes as being "geomorphologically conditioned by the germination, colonization, and succession of vegetation assemblages characteristic of coastal environments." Clearly, understanding the dynamics of vegetated coasts requires not only knowledge of the prevailing physical and sedimentological conditions but insights into vegetative form and function.

Vegetation at the coast

Ecological role

Coastal ecosystems are widely recognized as some of the most productive on earth. Carter (1988) summarizes the net productivity of coastal ecosystems and notes that, with the exception of coral reefs, highest levels are associated with vegetated coastal systems including subtidal seaweeds and sea grasses, and intertidal marshes and mangroves. The ecological importance of vegetation to coastal systems was recognized by Teal (1962) who suggested that plant detritus, after undergoing microbial decomposition and enrichment, was the basis of the salt marsh food chain. While more recent work has shown that much of the detritus in mangroves and salt marshes is directly consumed by benthic scavengers, and that benthic microalgae and phytoplankton provide important high-quality food sources for higher trophic levels, the importance of vegetation as structure and refuge for secondary producers and consumers, especially nekton, is widely accepted (see Weinstein and Kreeger (2000) for review of current understanding of tidal marsh ecology).

The high productivity of some vegetated coastal systems can result in a large amount of plant debris in the coastal zone. Where high tides and wave action raft this debris onto beaches, the ecological processes can be similar to those described above for marshes. Alongi (1998) described how detached algae and sea grasses can form stacks up to 2 m high on beaches in western Australia, and that the main utilization pathway for the detritus is via colonizing microbes and surf-zone amphipods.

Adapting to stress

Rapid and regular fluctuations in water level, along with salinities varying from fresh to hypersaline, are among a number of stresses facing coastal vegetation. In some environments these combine with direct attack from waves, human disturbances, and grazing pressure to produce conditions where only specialized plant growth forms can survive. Table V1 illustrates the variety and combination of stresses facing coastal plants. The presence of vegetation in these various coastal environments is testament to their ability to adapt and cope with such harsh conditions. Duke (1992, p. 65) notes of mangroves that the "combination of morphological and physiological adaptations seen in this diverse and unique group of plants have no equal." The prop roots of *Rhizophora* spp. and the pneumatophores of *Avicennia* spp. are two of a number of ways in which different mangrove species deal with one of these stresses—waterlogging and soil anoxia. Another of the more commonly known adaptations of coastal plants is that way in which the common dune grass *Ammophilia arenaria* rolls its leaves under dry conditions to limit the leaf area exposed and reduce water losses. Even lower plants, such as seaweeds, show adaptations such as the way they cope with extreme water losses during low tide and can rapidly rehydrate and resume photosynthesis soon after resubmergence.

The adaptations made by coastal plants to survive in these conditions are frequently structural. Plants that are exposed to excessive flooding and anoxic soils conditions respond by developing air spaces, or aerenchyma, in their root and stem tissue allowing oxygen to diffuse from the aerial parts of the plant to the roots. Common responses to high salt concentrations include barriers to salt uptake within the root system, such as in the mangrove *Avicennia*, and the excretion of unwanted salts through specialized salt glands in the leaves.

Some plants which can tolerate stressful conditions are so specialized that they are readily outcompeted as conditions ameliorate. For example, in laboratory experimental studies, Adams (1963) found that *Spartina alterniflora* tolerates a wide range of salinities. However, in the natural environment it is restricted to the lowest parts of salt marshes where salinity and waterlogging stress are highest. Bertness (1991) showed that at higher elevations in New England salt marshes, *S. alterniflora* is outcompeted by other species such as *Spartina patens*. Importantly, Bertness (1991) concludes that while the lower intertidal limit of growth for individual marsh species is set by their tolerance for physical stresses, the upper intertidal limits are set by plant competition.

Table V1 Examples of the physical stresses on vegetation in various coastal environments

Stress/environment	Rocky shore	Gravel barriers	Sand dunes	Sea grasses	Salt marshes	Mangroves
Salinity	■	■	■	■	■	■
Waterlogging			■		■	■
Water deficits	■	■	■		■	■
Lack of anchorage		■	■			
Lack of nutrients		■	■			
High wave activity	■	■				
High temperature fluctuations	■	■	■			■
Grazing	■		■	■	■	
Human disturbances		■	■	■	■	■

A similar type of situation seems to occur with the beachgrass *Ammophilia*. According to Packham and Willis (1997) it is capable of withstanding sand accretion rates of approximately 1 m/year, but measures of vegetative vigor usually decline with lower burial rates and in more stable parts of coastal dune systems it is commonly replaced by other species. This has been attributed to competitive interactions among plants, but Disraeli (1984) showed that the growth of *Ammophilia* was lower in areas of shallower burial in the absence of competitors. This phenomena has variously been attributed to the lesser ability of older roots to uptake nutrients and the effects of soil-borne pathogens and parasites which are ameliorated by the delivery of new sand.

The net result of these adaptation and interactions is that many vegetated coasts exhibit clear zonation of plant species in response to stress gradients (e.g., in tidal inundation, salinity, or wave energy).

Sensitivity to disturbances

Most coastal environments are subjected to periodic physical disturbance by storm waves, storm surges, or other events that alter, at least in the short term, the stability of the substrate. In addition to such episodic events, vegetated coasts can be sensitive to more regular erosional or depositional events that result in progressive environmental change. For gravel barrier systems, Scott (1963) identified five stability classes each characterized by different plants. Very unstable areas were devoid of vegetation, while gravel beaches stable between spring and fall were characterized by annuals. Increasing stability led to the presence of short- and then long-lived perennial plants and areas which had been stable for longer periods became covered with heath-like vegetation. The response of the vegetative community in this case appears to be to the frequency of physical disturbance. However, the importance of organic matter within gravels both for holding moisture and for preventing seeds from sinking too deeply for establishment and germination (Packham and Willis, 1997) implies that this is not simply a response to surficial disturbance of the plants. With increased gravel stability, the accumulation of organic matter can proceed providing an environment more hospitable to a wider array of plants. Many smaller annual plants in gravel systems rely on rain and dew as a source of moisture, while larger perennials can penetrate deeper and although unlikely to be able to access the water table may be able to reach freshwater lenses held in smaller gravel barriers.

While physical disturbances associated with storm events or floods usually impact coastal systems at the scale of kilometers, coastal plants can be sensitive to natural disturbances at smaller spatial scales. The most common of these in coastal salt marshes are ice and wrack. In northern latitudes, seasonal ice cover and ice rafting of vegetation, debris, and substrate, as well as scouring by ice blocks is an almost annual occurrence. Bertness (1999) characterizes salt marshes in these areas as in a continual state of recovery—both vegetatively and morphologically. The deposition of wrack—mats of dead plant material rafted to high marsh areas by high tides or storms—can lead to the burial of underlying marsh vegetation. In north Norfolk marshes, Pethick (1974) attributed the increased density of shallow marsh pans on high marshes to wrack. Once vegetation dies, soil salinity increases in the bare areas on the high, infrequently flooded marsh. This salinity can prevent the recolonization by marsh plants and the pans become permanent features of the marsh surface. Bertness (1999) describes how when such bare areas can be colonized by more salt tolerant species, these "fugitives" can ameliorate soil conditions facilitating the invasion of the site by the dominant plant species. Thus the persistence of the disturbance "feature" in the coastal system depends upon the harshness of the physical conditions and the availability of plants that can tolerate such conditions.

Vegetation as biogeomorphic agent

The role of plants in coastal biogeomorphology is largely constructive—acting to enhance deposition or protect surfaces from erosive forces. The vascular plants inhabiting soft sediment substrates on the Atlantic Coast of the United States have been termed "bioengineers" by Bertness (1999) because of their ability to stabilize substrates and enhance sedimentation. The role of salt marsh plants in contributing to the vertical growth of coastal marshes, both directly through the accumulation of organic substrate and indirectly by baffling tidal flows and enhancing sediment deposition has been well documented (Reed, 1995). Similar direct and indirect effects of vegetation appear to operate on cobble beaches in New England, where Bertness (1999) describes how, where *S. alterniflora* has colonized areas of the high intertidal, it ameliorates summer heating effects by shading, and stablizes the cobbles which would otherwise be subject to dislodgement and rolling during winter storms. The *Spartina* also "buffers" the effect of waves and provides a calmer environment where other salt-tolerant plants can survive. The recruitment of these plants is also facilitated by the *Spartina* as it traps waterborne seeds.

Perhaps one of the clearest examples of a vegetated coast where the vegetation plays a crucial role in the formation and development of geomorphology is the beach–foredune environment. Hesp (1984) asserts that foredunes develop on the seaward most vegetated sand surface behind active beaches and identifies four types of incipient foredune formation, each distinguished by their relationship to specific vegetative forms or structures. As Hesp also claims that beach ridges are actually relict foredunes, he implies an overriding role for vegetation, in various forms, for the initiation of coastal dune systems, clearly stating (p. 88) that he "believes that biologic processes and pan-aerodynamic interactions assume foremost importance in influencing initial morphologic variation on foredunes." Furthermore, Carter and Wilson (1990) attribute the role of vegetation in the initial stages of foredune development to the development of complex three-dimensional fluid flow over dunes at Magilligan Point, northern Ireland. They note that gaps in vegetation during foredune initiation can result in gullies or "low saddles" that cross the foredune. These features were observed to funnel airflow through the dune, sometimes creating aeolian mounds on the leeward side, and occasionally resulting in blowouts.

Intertidal vegetation interacts with waterflows slightly differently than dune grass with airflows in that the vegetation can be either completely or partially submerged by the waterflow depending upon the tide. For instance, sea grasses have been shown to strongly influence flows over the bed by reducing turbulence within the canopy and the development of a "stratificiation" above the canopy. Living in seawater means sea grasses do not require the structure support as terrestrial vegetation and their growth forms are frequently extremely flexible. This leads to deflection and compression of the plant canopy under strong flows, reducing friction. Differences in sea-grass morphology, from small shallow rooted to larger strap-bladed forms, alter the specific interaction between the plants and the flow but in most cases the presence of the vegetation significantly increases the mean threshold velocity for sediment motion when compared to adjacent bare sands.

The role of vegetative bioengineering in coastal dynamics is sometimes more readily seen when disturbance to the vegetation results in dramatic system change. Bertness (1999) reports a dramatic change from sandy and muddy subtidal substrates to coarse cobble bottoms after a wasting disease destroyed much of the eelgrass beds on the northern Atlantic shores of the United States. In addition to this physical change, the ecological consequences were substantial with a population crash in the bay scallop which relies on eelgrass not only as a food source but to provide structures for young recruits to attach to.

In dune environments, the loss of vegetative cover due to human disturbances such as trampling and all-terrain vehicle (ATV) use are frequently viewed as leading to the degradation of the dune system and prompting a need for management action. However, Thomas (1999) cautions that patchy development of blowouts is a natural feature of most dune systems and that although disturbance of the vegetation can undoubtedly lead to increased turbulence this should not simply trigger efforts at revegetation. Rather a detailed understanding of the vegetation surface conditions must be used to project the implications of the apparent disturbance and plan any remedial action. This call for a more holistic recognition of vegetated coastal environments as biogeomorphic systems recognizes that management actions must appreciate the natural dynamics of the system as well as its form and surficial characteristics.

Future issues for vegetated coasts

The importance of plant growth and survival to the sustainability of both landforms and ecosystems of vegetated coasts means that environmental changes that alter vegetative structure can have important implications. Two factors that threaten vegetated coasts are the massive increases in coastal populations, and the associated development pressures, and future climate changes.

The coastal population of the United States is currently growing faster than the nation's population as a whole, a trend that is projected to continue. By 2010, 75% of the US population is expected to live within 50 miles of the coast. Nicholls and Small (2002) identify 23% of the global population as living in coastal areas and note that most of the near-coastal population does not live in large cities but in smaller towns and in rural areas. The growing coastal population, increasing economic development, and expanding coastal communities exert pressure on vegetated coasts through recreational pressures, direct damage due to filling or development, and lowered water tables. Pinder and Witherick (1990) point to the loss of coastal wetlands associated with growth of ports and urbanization in the second half of the 20th century, and dunes and other intertidal vegetated habitats have been similarly consumed. The societal need for development space at the coast, especially for industries and port facilities that are directly functionally related to the coastal ocean, combined with the diminishing area of land available and the recognition of the ecological, recreational, and esthetic value of vegetated coasts, has led to increasing examination of the potential for creating new land specifically to support development. However, while this approach may relieve development pressure on existing systems, it has consequences for coastal sedimentary and hydrodynamics. Arens *et al*. (2001) examined the potential environmental impacts of offshore island development in the Netherlands and noted effects associated with construction and to the marine ecosystem based on the footprint of the island and the direct loss of habitat. Coastal dunes and higher plants were largely unaffected and Arens *et al*. projected only local alterations in the sediment budgets and wave climates that support the adjacent vegetated coasts.

While vegetated coasts are often characterized by plants adapted to living in stressful conditions, changes in climate may increase stresses beyond their tolerance range resulting in shifts to nonvegetated coastal systems and potentially dramatic geomorphic transitions. Scavia *et al*. (2002) note that projected increases in sea level are unlikely to have near-term catastrophic impacts on coastal wetlands and mangroves, but when combined with other stresses such as alterations to local hydrology or sediment movement patterns associated with development pressures, the long-term consequences may be severe. For vegetated coastal forms to survive they must increase elevation in place (e.g., accrete soil), or migrate inland to keep pace with the rising sea. However, coastal structures and river management alter sediment supplies, and thus limit vertical building, and developed coastlines limit migration. Management approaches for vegetated coasts during climate change must be focused on alleviating the stresses imposed by human alteration of coastal systems, and allowing transitions in form and ecology to cope with the changing sea level, temperature, and precipitation regimes. Vegetated coasts are among our most valued, and highly pressured systems. By their very nature they can survive change and harsh conditions. Our management actions must allow the natural cycles that have sustained them in the past to continue long into the future.

VIBRACORE

Vibracoring is a state-of-the-art sediment sampling methodology for retrieving continuous, undisturbed cores. Also referred to as *vibrocoring*, this mechanical drilling technique is used to collect core samples (referred to as either *vibracores* or *vibrocores*) from unconsolidated, loosely compacted, or semi-lithified materials by driving a tube with a vibrating device. Large, heavy-duty vibracorers can work in water up to 5,000 m deep and can retrieve core samples up to 13 m in length. In coastal shallow-water environments where use of heavy equipment is limited by trafficability and ground support on land and high-energy conditions alongshore, cores are shorter, usually about 6 m in length.

The coastal/marine environment presents specialized conditions that are not encountered on *terra firma* or in deeper oceanic waters. Because many onshore areas are characterized by coastal wetlands with extensive areas of organic soils in marshy or swampy conditions, tidal sand and muds, or lacustrine and lagoonal facies, beach sands, or chenier-type materials, access for conventional drilling equipment and personnel is often limited, if not by biophysical conditions, then at least economically. Financial considerations are often limiting when costs of sediment retrieval are very high on a per-sample basis. Large multinational corporations involved in petroleum exploration can go almost anywhere to penetrate the most inhospitable environments while sparing no expense to obtain conventional long-drill cores. Most coastal/marine research, however, operates on a reduced cost basis that must be efficient and cost-effective. There are also numerous subaqueous environments that are normally hostile to the positioning of conventional drilling equipment and so alternative sediment-sampling methods are sought. Retrieval of shallow-water sediments using conventional cylindrical coring methods (e.g., those that employ gravity or piston cores) is limited by shallow water depth as well as the nature and habit of the materials requiring undisturbed collection. Resistance of the sediment restricts penetration of gravity cores and core-lengths typically obtained are less than 3–5 m, depending upon the firmness of the sediment.

Sediment cores obtained from a vibracore system are invaluable because they permit direct, detailed examination of composition and layering in sequences of subsurface sediment (Lanesky *et al*., 1979; Watson and Krupa, 1984). Examination of material sequences in vibracores provides information regarding the history of depositional environments (e.g., Brooks *et al*., 1995) and the physical processes that were operative during sedimentation. Vibracores and subsamples derived from them find almost limitless applications in scientific geological research, engineering and geotechnical pre- and re-design, and environmental investigations. The versatility of the vibracoring technique is illustrated by its utilization in sampling riverine sediments, lacustrine deposits, organic accumulations in marshes and bogs, as well as nearshore shallow water coring. Although examples of applications are legion, of primary interest to most coastal specialists are results that are relevant to the scientific study of coastal zone morphodynamics, evolutionary sequences, and exploratory searches for beach-quality sand that is suitable for beach renourishment.

The utility of vibracores, as seen in these few examples from a huge literature, has been demonstrated in: (1) subsurface exploratory sampling for geotechnical purposes (e.g., Meisburger, 1990; Larson *et al*., 1997), (2) determination of depositional stratigraphy and geomorphological history in marine, estuarine, fresh water, or wetland environments including marshes, swamps, and peat bogs (e.g., Snowden *et al*., 1977; Amos, 1978; Kraft *et al*., 1979; Stevenson *et al*., 1986; Morang *et al*., 1993; Kirby *et al*., 1994), (3) glacioeustatic sea-level changes (e.g., Gehrels, 1994; Harvey *et al*., 1999), (4) integrating studies of barrier island evolution, bars, lithofacies, and sedimento-stratigraphy (e.g., Davis and Kuhn, 1985; Davis *et al*., 1993; Brooks *et al*., 1995), (5) offshore sand searches to locate beach-quality sands for beach restoration (e.g., Finkl *et al*., 1997; Freedenberg *et al*., 2000), (6) environmental studies of pollution or contamination by hydrocarbons or heavy metals (e.g., Varekamp, 1991), (7) investigations to determine seafloor environments or bottom types (e.g., Barnhardt *et al*., 1998; Knebel and Poppe, 2000), (8) deltaic and sedimentary shelf processes (e.g., Delaune *et al*., 1983; Brooks *et al*., 1995; Levitan *et al*., 2000; Toldo *et al*., 2000), (8) collection of samples for chemical, biological, and physical analyses (e.g., Kadlec and Robbins, 1984; Gehrels, 1994), (9) verification of seismic stratigraphy or seismic stratigraphic sequences (e.g., Shipp *et al*., 1991; Knebel and Poppe, 2000), (10) preliminary investigations for the purpose of determining the presence and positions of paleoshorelines (e.g., Gayes and Bokuniewicz, 1991; Shipp *et al*., 1991), and (7) stratigraphic and mineral surveys (e.g., Barusseau *et al*., 1988; Brooks *et al*., 1995). Use of vibracores to substantiate seismic interpretations (e.g., sidescan sonar, Uniboom seismic reflection—sub-bottom boomer profiles) is a major application that integrates geological and geophysical methodologies to advantage in many studies. Marine or subaerial unconformities, seismic reflectors, stratigraphic units, internal structures of morphodynamic units, sediment textural properties, and even geomorphic features can be identified in vibracores. Although vibracores find use in many diverse applications, the overall setup of coring systems is an important consideration.

Early attempts to obtain (undisturbed) samples in coastal/marine environments

Retrieval of marine sediments is nearly as old as the science of oceanography itself. Initial interest focused on getting an idea of what kinds of sediments were deposited on the seafloor but, then, as technological advancements assisted the desire for more complete information, new methods of bottom sampling were developed. The purposes of sampling marine sediments varied among professionals as the pioneering biologist, petrographer, sedimentologist, and civil engineer had different demands. Reviews of some historical efforts in bottom sampling are summarized, for example, by Trask (1939), Sanders (1960), Rossfelder and Marshall (1967), and Watson and Krupa (1984) who note the pros and cons of numerous platforms, rigs, and devices such as the Strøm coring tube, Twenhofel coring tube, Varney pile-driver sampler, Trask suction sampler, Renn sampler, Piggot coring apparatus, Kudinov vibro-piston core sampler, etc. These early devices suffered from a variety of shortcomings that were eventually overcome by improved sampling methods. Modern methods of coring are not without problems, but they have been reduced to the greatest possible extent to satisfy the purpose of a particular analysis.

Terrestrial deposits in coastal marshes and on coastal plains were initially sampled using hand augers, which are still in use today for special applications (see discussion in Soil Survey Division Staff, 1993). Screw or worm augers do not provide undisturbed samples, but they can bring up materials from several meters depth by adding extra lengths to the shaft. Barrel augers, core augers, bucket augers, on the other hand, have a cylinder or barrel to hold the soil, which is forced into the barrel by cutting lips at the lower end. The upper end of the cylinder is attached to a length of pipe with a crosspiece for turning by hand at the top. Although both ends of the cylinder are open, the soil generally packs so that it stays in place while the auger is removed from the hole. Barrel augers disturb the soil less than screw augers. Soil structure, porosity, consistence, and color can be better observed. Barrel augers work well in loose or sandy soils and in compact soils. They are not well suited for use in wet or clayey soils, though an open-sided barrel is available that works well. They also work poorly in stony and gravelly soils. Barrel augers bore more slowly than screw augers or probes, but they are easy to pull from the hole.

The Dutch auger is a modified barrel auger having two connected straps with lips. The cylinder is about 5–10 cm in diameter. The Dutch mud auger works well in moist or wet soils of moderately fine or fine texture, but poorly in other moist or wet soils and in all dry soil.

Although soil augers are simple in design and somewhat crude in appearance, considerable skill is required to use them effectively and safely. They must be pulled from the soil by using a technique that puts stress on the leg muscles, rather than the back muscles, to avoid serious back injury. Twisting the auger firmly while pulling takes advantage of the inclined plane of the screw to break the soil loose. A pair of pipe wrenches is needed to add and remove lengths of shafts and bits.

Examinations of deep deposits of peat are made with special tubelike samplers. A peat sampler designed by the Macaulay Institute for Soil Research (Aberdeen, Scotland), for example, takes a relatively undisturbed volume that can be used for measurement of bulk density. The Davis peat sampler, consists of 10 or more sections of steel rods, each 60–120 cm in length, and a cylinder of brass or Duralumin, approximately 35 cm long with an inside diameter of about 1.9 cm. The cylinder has a plunger, cone-shaped, at the lower end and a spring catch near the upper end. The sampler is pressed into the peat until the desired depth for taking the sample is needed. Then the spring catch is released, allowing the plunger to be withdrawn from the cylinder. With the plunger withdrawn, forcing it further downward fills the cylinder. The cylinder protects the sample from contamination and preserves its structure when the sample is removed. With this instrument, one can avoid the error of thinking that firm bottom has been hit when actually a buried log is encountered.

Probes consist of a small-bore tube that has a tempered sharp cutting edge slightly smaller in bore but larger in outside diameter than the barrel. Approximately one-third of the tube is cut away above the cutting edges so that the soil can be observed and removed. Probes are about 2.5 cm in diameter and about 20–40 cm in length. The tube is attached to a shaft with a "T" handle at the opposite end. Adding or removing sections can vary shaft length. Probes can be used to examine the soil to a depth of 2 m. Rubber or plastic mallets can be used to drive the tube into the soil; a pair of pipe wrenches is needed to add and remove lengths of shaft.

Probes work well in moist, medium textured soils that are free of gravel, stones, and dense layers. Under these conditions, the soil can be examined faster than with an auger. Probes are very difficult to use in dry, dense, or poorly graded soil, and in soil containing gravel or stones. Probes disturb the soil less than augers, but they retrieve less soil for examination. Probes are light and easily carried, and they pull from the hole more easily than screw augers. Use of a soil probe is the fastest method to collect samples of surface layers for analysis. Probes used with power equipment have wide applications in surveys of surficial sediments. Coastal specialists are increasing turning to mechanical sampling devices as the need increases for longer cores of undisturbed samples. Vibracores meet these needs in many different types of environmental situations, but there are still limitations to collection of coastal/marine sediments. The essentials of vibracoring systems, which supplement hand sampling in terrestrial coastal environments and partially replace other types of marine bottom samplers, are briefly summarized in what follows.

Vibratory coring systems

These relatively simple devices, referred to as vibracorers, consist of three essential components: frame, core barrel, and vibrator (Hoyt and Demarest, 1981). The frame, which allows the corer to stand free on the seafloor, consists of a quadrapod or tripod arrangement with legs attached to a vertical beam that in turn supports and guides the core barrel and vibrator (Figure V1). The core barrel and vibrator slide on the beam for coring and retraction. The core barrel assembly consists of 7.5 or 10 cm diameter (thin walled) aluminum pipe fitted with a cutter head and core catcher (which holds the sediment inside the barrel when it is withdrawn from the sediments), and a plastic tube inner liner that contains the core material (cf. Figure V11). There are many different kinds of innovative assemblies that can include, for example, an electronic penetrometer to record time and depth of penetration of the core pipe into the sediments (Smith, 1992). Deploying and retrieving the corer usually requires a hydraulic crane (Figure V2), A-frame, or similar winch or hoisting equipment with a lifting capacity of at least 10–15 tons (Meisburger, 1990). Shallow protected waters may allow use of small barges, often of simple construction from polystyrene blocks wrapped in heavy-duty industrial plastic and encased in a wooden frame, mounted with a superstructure from which the vibracoring device can be deployed (e.g., Wright *et al.*, 1999). A marine Kiel Vibracorer can, for example, be adapted for deployment from a well in the barge.

Smaller, lightweight, hand-carried units are used to advantage in coastal environments on marshland or in very shallow water. Figure V3, for example, shows a small backpack power unit that is deployed in shallow water to obtain marsh sediments. Once driven into the marsh sediments, the core is retrieved by various methods for pullout but in this case a hand-operated come-along is used to extract the core (Figure V4). After the core is extracted, it can be transported to the laboratory or split in the field as shown here (Figure V5). Because there was easy access to a grassy work area near the sample site, the core barrel was carried to dry land and split using a skill saw. Splitting in the field provides opportunity for immediate inspection of the core and assessment of environmental conditions, as shown in Figure V6. Other advantages accrue from splitting a core in the field because it can be immediately determined whether the core is short due to loss of sediment or compaction, or whether there are other abnormalities such as coarse materials that plug the core causing gaps in sediment retrieval, etc. The sampling program can be modified on the basis of what is observed in the recovered materials. This flexibility in the field is important because deployment and setup are often significant costs in sample retrieval.

Figure V1 A 10-m vibracore (Alpine rig) being raised from the Gulf of Mexico seafloor offshore from Louisiana. The quadrapod stand stabilizes the vibracore frame, which sits on the seabed and allows the pneumatic vibrahead to slide downwards with core penetration. The entire apparatus is lifted aboard the research vessel using a hydraulic crane that reaches over the stern (photo courtesy of Coastal Planning & Engineering, Boca Raton, Florida).

Equipment, design, and function

The main consideration in developing vibracoring systems, often referred to as the “Rule of Deployment,” that most researchers learn by experience is that “the cost of an operation is related to the size of the

Figure V2 Same vibracore assembly unit shown in Figure V1 being laid down on the deck. The long core inside the 10-cm-diameter core barrel will provide valuable undisturbed sediment data from the seabed on the continental shelf off Louisiana. Operations such as this one require experienced crew to handle these large vibracoring units (photo courtesy of Coastal Planning & Engineering, Boca Raton, Florida).

Figure V3 Small, portable vibracore. A backpack power unit operates this pneumatic vibracore; the core barrel is stabilized by hand as the unit penetrates the marsh sediments. The lightweight aluminum A-frame is carried to the site and waits for use in retrieval of the core (photo courtesy of Steve Krupa, South Florida Water Management District, West Palm Beach, Florida).

Figure V4 Retrieval of vibracore using a portable aluminum A-frame. The lightweight A-frame has pads on the feet so the unit does not sink into the sediment when load is applied. One leg of the A-frame has steps so the driller can extract the core barrel with a hand-operated come along. The A-frame must be placed vertically over the core barrel to ensure easy extraction without flexure or bending of the core. The A-frame collapses into a compact unit for transporting (Photo courtesy of Steve Krupa, South Florida Water Management District, West Palm Beach, Florida).

Figure V5 Splitting a vibracore. As shown here, the core barrel is laid in a wooden frame and an electric circular saw uses the frame as a guide to cut the flight lengthwise. The upper half is then rotated away from the frame and placed on the ground for observation and sampling (Photo courtesy of Steve Krupa, South Florida Water Management District, West Palm Beach, Florida).

Figure V6 Split core. After cutting the core barrel lengthwise, the contents are visually inspected for a range of physical parameters such as sediment grain size, color, stratigraphic discontinuities, coarse fragments, etc. Shown here is a fine-grained marsh sediment from the south coast of Long Island, New York (photo courtesy of Steve Krupa, South Florida Water Management District, West Palm Beach, Florida).

vessel which is related to the size of the draw works which is related to whatever hangs at the end of the cable." These concerns are especially important to boggy onshore sites where access is limited and in shallow-water work where vessel size and equipment load is restricted. Realizing the need to minimize the weight of individual parts while maximizing the overall force/weight ratio, it becomes obvious to select equipment that can be handled with limited manpower from all-terrain vehicles, small vessels, and even inflatable barges (e.g., Hoyt and Demarest, 1981). A variety of vibracore units are commercially available. Some are small, lightweight, and portable, whereas others are large heavy units that can only be deployed from large vessels. There are various types of bottom-standing rigid frames that are ordinarily used for stabilizing and guiding vibracores (cf. Figures V1 and V2 for heavy-duty marine examples and Figures V3 and V4 for light-duty terrestrial setups).

The principle behind a vibracore is the development of high-frequency, low-amplitude vibration that is transferred from the vibracore head (vibrahead) down through the attached barrel or core tube (Figure V7).

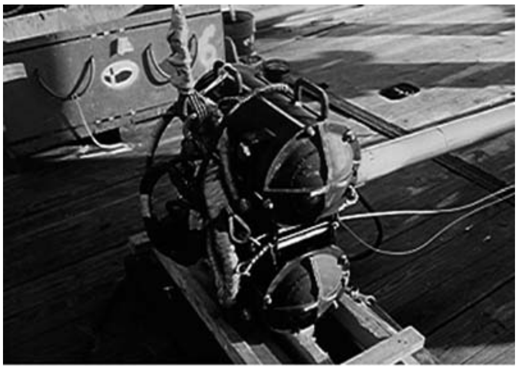

Figure V7 Detail of the parallel mount of electric vibracore heads, showing extension of the core barrel below the vibrahead (photo courtesy of Coastal Planning & Engineering, Boca Raton, Florida).

Figure V8 The 7.5-cm-diameter core barrel is attached to the electric vibrahead assembly prior to being lowered overboard into the Atlantic Ocean as part of an offshore sand search near Miami, Florida. Although the unit is of medium size, the weight of the vibracore assembly requires crane winching from the deck (photo courtesy of Coastal Planning & Engineering, Boca Raton, Florida).

The vibrator generates sufficient vibrations by means of pneumatic/hydraulic/electric motors that are sealed in a submersible housing. Vibrations combined with instrument weight drive the core barrel into the sediment/substrate. The vibrational energy delivered to the core tube (Figure V8; cf. Figures V1 and V2) induces vertical penetration by temporarily displacing sediment particles to overcome frontal resistance and wall friction. The technique is thus most efficient in water-saturated sediments because vibration increases the pore pressure along the wall of the core tube by generating a thin layer of liquefaction. As the vibrating tube penetrates the sediment, it displaces the bedded particles on both sides of the wall. This results in the collection of a largely undisturbed core of sediment within the vibrocore tube. Although useful in water-saturated subaerial environments, such as in marshes, underwater sediments present the optimum medium of application. Starting in the 1950s, vibracoring became increasingly accepted as an efficient and useful method for collecting underwater core samples. The technique was initially slow to gain acceptance because vibrators could not be easily outfitted for underwater use; the problem was soon overcome and a variety of vibrators are now available. Figure V9 shows a typical medium-sized vibracore assembly being lowered over the side of a research vessel.

Figure V9 Diver's view of vibracore being lowered over the side of the research vessel. The dark area in the upper left of the photo is the bottom of the vessel's hull. Cables to power the vibrahead and a lifting cable are visible to the left of the diver near the water surface (photo courtesy of Coastal Planning & Engineering, Boca Raton, Florida).

Among the three basic types of vibrators (i.e., pneumatic, hydraulic, and electric), pneumatic piston vibrators were preferred in early research because they worked underwater and did not involve the undersea use of electrical current. Although still deployed in many surveys, this type of vibracoring setup requires an air compressor and the hoses that sometimes become an impediment in swift or choppy waters. Hydraulic vibrators use fluid flows in a closed circuit in balance with the ambient environment. A hydraulic power plant and an umbilical hose are required, presenting similar drawbacks to pneumatic vibracorers. All things considered, including the force/weight ratio from the power source to the vibrahead, electric vibracorers become an attractive choice, particularly when the power source is already part of the vessel system. Many researchers conclude that electric vibracores are good choices for work in shallow waters viz. those characterized by surf or spray zones. There are two main types of electric vibracorers, electromagnetic vibrators and rotating-eccentric vibrators. The second type is often preferred because the dynamics of the overall spring-like system soil–coretube–vibrohead, the contra-rotating eccentric vibrators mounted in parallel (cf. Figure V7), does not require mechanical linkage or special gear for establishing synchronized motion for delivering oscillatory force along a vertical axis. Many combinations of vibracore assembly are available for a variety of environmental conditions. Lightweight parallel-mount twin vibrators that, for example, run at 8,000 V/m on standard 110 V AC current, can be operated with a 5 kW camping-type generator. Heavier models often run at 2,800–3,400 V/m on 3-phase, 50 or 60 Hz, 220–440 V power sources. There are also vibracorers, operating in the medium-frequency range, based on a single vibrator that delivers an oscillatory force to the vertical axis, also often operating on 3-phase 220–440 V. Other variations of basic setups include a "vibrotorsional" operating mode where the two contra-rotating vibrators are mounted along the same axis instead of being in parallel. This coaxial configuration or arrangement synchronizes spontaneously, as in a parallel mount, while adding a horizontal oscillatory torque of small amplitude to the main vertical oscillation. Above the medium range, there is a domain of vibracoring known as "resonant drive" with frequencies on the order of 200–360 Hz (12,000–22,000 V/m) and amplitudes down to a fraction of a millimeter. In this resonant drive mode, the core tube vibrates like a musical string with stationary nodes and antinodes that help to efficiently overcome wall friction, but these units lack force and amplitude for frontal penetration. There is thus a range of vibracore types that can be deployed to specific use.

Advantages and disadvantages of vibracoring

Classical problems associated with coring in general include, for example, flow of external sediment into the core barrel due to increased or reduced stress below the core nose, wall friction, sediment deflection below the cutter, shear failures, thinning or compression of softer strata, thixotropic liquefaction, and textural rearrangement (e.g., Rossfelder and Marshall, 1967; Smith, 1984; Crusius and Anderson, 1991; Morton and White, 1997). Withdrawal disturbances may take place in response to decrease in hydrostatic pressure below the sample, increase in pressure over the sample, lack of wall friction, and adhesion between the sample and the core wall. The sampler may inadvertently be tipped over and dragged along the bottom because of improper retrieval. Even though modern sampling methods have been overcome, there are still sampling problems associated with state-of-the-art core retrieval using vibracore samplers. Some of these difficulties are briefly outlined as precautionary observations for a system of bottom sediment sampling that is generally reliable (e.g., Blomqvist, 1985).

Vibracorers have the advantages of simple construction and easy mobilization, but they are sometimes unwieldy in congested commercial areas such as harbors, and their cost may be beyond the budget of small consultants or universities (Larson *et al*., 1997). Vibracores are not very effective in either very compact (dense) or very loose sediment; they are not suitable for sediments containing large clasts that can block penetration of the core barrel.

While common vibratory corers are capable of penetrating 6 m or more in unconsolidated sediment, actual performance depends on the nature of the sub-bottom sediment. Under unfavorable circumstances (viz. rough seas, rocky bottom) very little sediment may be recovered. Limited recovery may be primarily due to lack of penetration of the core barrel, blockage of the bit by rock, or loss of sediment during recovery. Core penetration is measured both visually and with an electronic penetrometer. Core recovery is determined by measuring the total length of sediment in the core barrel immediately following retrieval, and the percent recovery calculated as follows (Brooks *et al*., 1999):

$$\%\ \text{Recovery} = (\text{length recovered}/\text{length penetrated}) \times 100$$

In certain instances, penetration refusal is met before full penetration of sediment is achieved (Anders and Hansen, 1990; Morton and White, 1997). In such cases the vibracore is removed, and the short core is extracted and stored. A new core liner is installed and the vibracore is again deployed. The core barrel is hydraulically jetted down to the depth of the refusal and then the regular vibracoring is resumed to the targeted depth. In other cases, refusal means that the vibracore cannot be driven any further into the sediment and the borehole is terminated. Coarse fragments such as diamictite, scree, lag, or carbonate/coral rubble may, for example, be larger than the core barrel or the deposit may be so densely packed, if containing smaller diameter clasts, that vibracoring into these materials becomes problematic. Core barrels sometimes get stuck in the sediment and removal requires patience, strength, and some ingenuity.

Vibratory corers are capable of penetrating up to 12 m of unconsolidated sediment, but actual performance depends on the nature of the sub-bottom material. Under unfavorable conditions, however, less than 1 m may be recovered; no coring device has been developed that eliminates the potential for core shortening. There are, however, practical solutions to problems associated with vibracore sample loss or compaction (Smith, 1992). Core shortening may result from several factors that include, for example, physical compaction, sediment thinning, or sediment bypassing (Morton and White, 1997). Limited recovery occurs in response to lack of penetration where stiff clays, gravel, and hard-packed fine to very fine sand are usually most difficult to penetrate. "Freezing" of material in the core liner, which is an age-old coring problem due to skin friction before full penetration is reached (e.g., Rossfelder and Marshall, 1967), stops new material from entering the sampler while the core barrel continues to penetrate; this process may result in exclusion of underlying sediments so that some strata are bypassed and not recovered in the core barrel. Lubrication of the inner wall of the core barrel can reduce friction and prevent plugging as additional sediments enter the core barrel. Choice of lubricant to reduce friction is recommended as long as the chemical additives do not interfere with chemical analyses planned for the cores (Morton and White, 1997). Compaction and loss of material during recovery can also cause discrepancy between penetration and recovery, but occurs less frequently. It is sometimes not possible to correct for shortening when it is not certain whether the shrinkage was due to dewatering or loss of core out of the bottom (Wright *et al*., 1999). Harvey *et al*. (1999) found, for example, that compaction may range from negligible in clay-rich cores up to 40% for organic-rich mangrove-dominated cores. The coring technique, including setup and deploying the corer, coring and recovery is quite rapid compared with standard soil boring operations. Usually, a 6-m-long core can be obtained in a matter of minutes under ideal conditions.

In some areas where vibracoring is difficult, rough ideas of sediment composition can be obtained by alternative sampling procedures. Wash borings, for example, can sometimes provide estimates of grain size and composition by flushing out sediments using compressed air (Figure V10). Jet probes (*q.v.*) also provide rough estimates of bottom sediment types but, like wash borings, they do not provide undisturbed samples that are recoverable for further offsite analysis.

Figure V10 A "wash boring" that is operated by jetting down a pipe within a pipe at intervals of 1–2 m and "washing" up a sample with a blast of compressed air between the pipes. This exploratory technique was previously used to provide preliminary information on the quality of sand in a potential borrow area before engaging more expensive vibracoring operations. Although surface sand samples can be easily obtained, it is necessary to know what type of material lies at depth. This method of sampling provided an inexpensive way to sample sediment at depth, which would be "washed up" the pipe and trapped in cloth bags that were used to catch the samples. The heavier materials (gravel, etc.) could not be lifted in the pipe, but divers could "hear" gravel and rocks banging against the casing to establish the presence of unusable coarse materials. Fines could not be trapped because the material would pass through the cloth bags used to trap sediment samples; the "cloudiness" of the water, however, provided experienced divers with a rough indication of how much silt plus clay was present in the sediment. The penetration of the pipe was similar to jet probes that are now used in order to test the depth of unconsolidated sediment. Although crude, this method provided useful information for refining sand searches. The limitations of disintegrated wash borings compared to undisturbed vibracores emphasize the value of cores that can be subsampled, analyzed, and archived. Wash borings today find specialized applications by most researchers (photo courtesy of Coastal Planning & Engineering, Boca Raton, Florida).

Core logging and sample analysis

During the field data collection phase in large surveys, a preliminary analysis of the cores and samples from the cores is made on a daily basis to obtain information for making advantageous modifications to the survey plan. In addition, when the specific site surveys of high-potential borrow sources are undertaken immediately following the general survey; the preliminary analysis must suffice for selection of these sites, and needs to be as complete as possible. The scope of preliminary core and sample analyses in the field is limited by: (1) only partial visual and physical access to the cores for preliminary logging and sampling; (2) the type and extent of sample analyses that are possible in the field, which in many respects are not comparable to laboratory analysis; and (3) the field analysis for each core that must be completed in a limited time frame in order to keep pace with the progress of the survey.

After each core is taken, the liner containing the cored materials is removed and replaced by a fresh liner. Liners may be clear acrylic plastic tubes that allow observation through the wall. Heavy scratching by granular material or silt and clay particles may smear the inner wall obscuring the contents. Where the cored material is visible, logging and selection of samples can be made. Some corers use aluminum or opaque plastic tubing as core barrels without liners and use the core barrel themselves as the containers using a fresh core barrel for each core run.

Access to cores is best obtained by splitting the cores lengthwise to expose the cored section (Figures V6 and V11). Prior to sampling or disturbance, the core materials are usually photographed next to a scale. Prior to sampling for laboratory analysis, cores are examined visually to determine pertinent characteristics such as size distribution and composition in terms of relatively broad categories. For this purpose, a hand lens and size comparison charts are useful aids. In addition, samples that appear on visual examination to be possibly suitable as fill material should be further analyzed to obtain data on their size distribution characteristics by more accurate means than visual inspection. This can be done using small-diameter sieves to separate small samples into appropriate size fractions, which are then weighed to determine the percent weight of each size fraction. Minimal equipment needed for this procedure is a drying oven, small-diameter sieves covering the Wentworth sand size ranges at $\frac{1}{2}$ phi intervals, and a small top-loading electronic balance with a precision of at least 0.01 g (Meisburger, 1990).

Figure V11 Split core liners from vibracore that penetrated sandy bottom sediments in an inter-reefal area offshore from Miami, Florida. The vibracores are split longitudinally, one half is retained for archival purposes and the other is logged and analyzed in the laboratory for grain-size parameters, organic content, coarse fragments (e.g., loose shell hash, pieces of coral, chunks of coquina), mineral composition (e.g., silicates versus carbonates), etc. Note: Core barrels are generally cut into sections that are about 2 m in length. Depending on the length of core obtained, there may be a small section left over that would be difficult to split lengthwise. These small leftover sections also tend to be disturbed because they are at the end of the core. The two PVC ends shown here are used to store "bit samples" because the core-cutting bit does not have a liner. Typically, when a core is being recovered, the material in the bit falls out because it is below the core catcher. Sometimes the sample stays in the bit and it is saved as shown in the photo. The two piled samples sitting on paper in the center of the photograph are plugs of rock, cut from the subsurface, that were lodged in the bit (photo courtesy of Coastal Planning & Engineering, Boca Raton, Florida).

Usually, cores are opened in the laboratory, logged, photographed, and portions are then sampled for various purposes. The presence of carbonate shelly debris or shell layers, bioturbation clasts and infills, gravels, (de)oxygenated surfaces, color changes, and other notable features are recorded prior to sample removal (Figures V12 and V13). Notations are also made for the presence of epifauna, abraded foraminifera tests, coproliths, or any other unusual biological feature such as insect carapaces and appendages. Molluscan assemblages (including microfossils) are, for example, often removed from the core prior to subsampling for other types of analyses (e.g., Barusseau *et al.*, 1988; Wright *et al.*, 1999). Standard laboratory sediment analysis may be conducted following the sieving methods proposed by Wentworth (1929), by using a rapid sediment analyzer (sand fraction) (e.g., Schlee, 1966), or a Coulter Counter (silt and clay fractions) (e.g., Shideler, 1976). In addition to standard particle-size analyses, there are numerous other kinds of analysis that can be performed on core materials, depending on their nature and composition. Organic-rich deposits such as peat, for example, can be vibracored taking care to make corrections for compaction (usually −10%) by making stratigraphic comparisons with an uncompacted Eijkelkamp core from the same site (Gehrels, 1994). Detrital plant fragments are often selected for dating by the accelerator mass spectrometer (AMS) ^{14}C method (e.g., Gehrels and Belknap, 1993), in preference to bulk samples that can be contaminated by humic acids and younger roots (Belknap *et al.*, 1989). Methods for foraminifera sampling and sample preparation are similar to those described by Scott and Medioli (1980).

Bottom sampling for coastal sand searchers

Samples of seafloor sediments are required for numerous purposes, the least ambitious of which is to gain a rough idea of sediment types. Different kinds of sampling devices are usually geared for the collection of fine or coarse-grained surficial sediments or continuous cores to specified depths. There are a variety of grab-type samplers of different sizes and design that are used for obtaining surficial samples. Most consist of a set of opposing, articulated, scoop-shaped jaws that are lowered to the bottom in an open position and closed by some mechanism. In this process, a sample is retrieved between the closed jaws. Many grab samplers can be deployed by hand while others require lifting gear. Dredge samplers, which can be dragged a short distance along the bottom to dredge up a sample, are sometimes used in place of grab samplers that are subject to losing finer material during recovery when shells or gravel prevent complete closure of grab samplers. Jet probes (*q.v.*) and wash bores are sometimes used on a reconnaissance basis to gain general information on sediment types. While obtaining surficial samples is helpful, it is of limited value because vertical projection of surface data is highly unreliable. Also, the expense of running tracklines for the sole purpose of sampling surficial sediments is not economically justified by the value of the data obtained (Meisburger, 1990).

Direct sampling of sub-bottom materials is essential for borrow source identification and evaluation. This is usually accomplished by means of a continuous coring apparatus that can obtain cores 7–13 m in length (cf. Figure V1). In the types of sediment usually encountered in borrow site exploration, gravity corers are not suitable for obtaining cores of the requisite length, and some form of powered corers must be used. In most cases, vibrator-driven coring devices have been used for this purpose (Meisburger and Williams, 1981).

Collection of surface samples is not useful for most geological and geotechnical applications because depth parameters are required for various purposes. Although surficial samples (e.g., those obtained from grab samplers or jet probes) may provide rough ideas about recent submarine processes, they do not provide at-depth information about sediment thickness, structure, composition, and stratigraphic information. Jet probes (*q.v.*) provide useful information on a reconnaissance basis because large areas of seafloor can be covered relatively quickly at modest costs. Even though jet probes provide a rough idea of sediment types, specialized information is required to prove out potential borrow areas. Because vibracores provide the kind of detailed information that is required, vibracore surveys are often conducted in tandem with geophysical investigations. Geophysical surveys and geotechnical work is thus able to definitely establish deposit geometry, and the quality and quantity of sand. Vibracores are thus commonly deployed in the final stages of sand search investigations, that is, after evaluation of all available bathymetric, seismic, and jet probe data (e.g., Finkl *et al.*, 1997). Closely spaced (e.g., about 300 m apart) vibracores thus help to minimize uncertainty factors related to sediment quantification and type, thereby maximizing confidence in selection of offshore borrows. Figure V14 shows an east–west, cross-shore seismic reflection profile

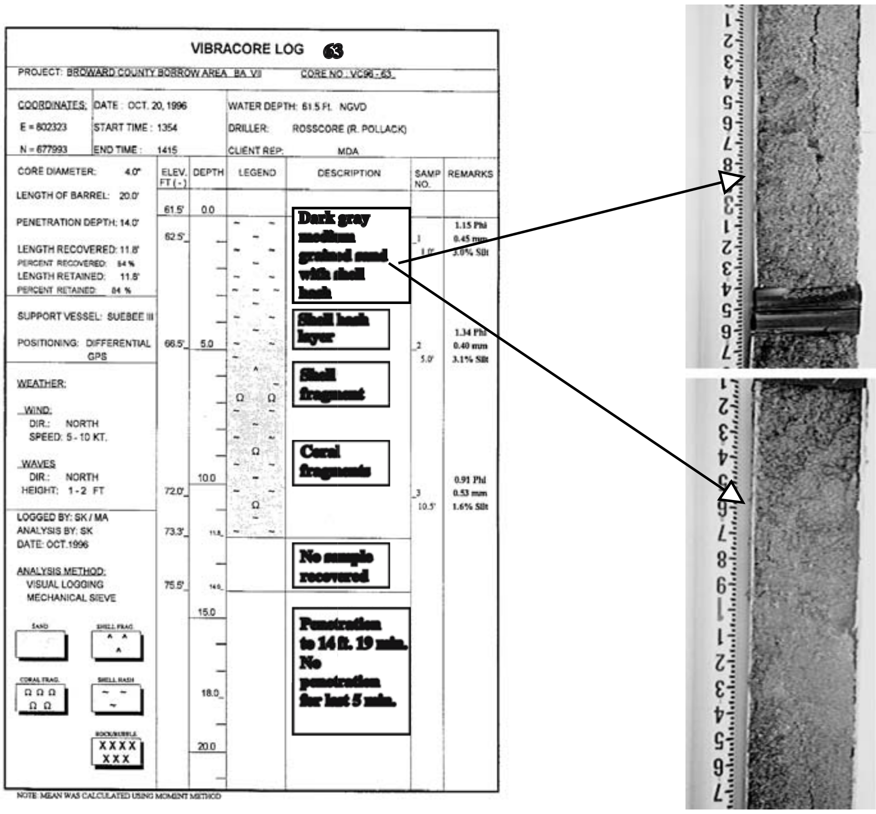

Figure V12 Example of a vibracore log showing uniform sands. This standardized summary format brings together many different kinds of data that are used to help characterize the materials contained in the cores. In addition to photographs of the core section (right side of diagram) with numbers inverted for easy determination of depth, the core log provides visual description, results of mechanical sieve analyses, notable features of the cored materials, penetration rates, and depth at refusal. The arrows point to relatively uniform dark gray, medium-grained sand with sparse inclusions of shell hash (courtesy of Coastal Planning & Engineering, Boca Raton, Florida).

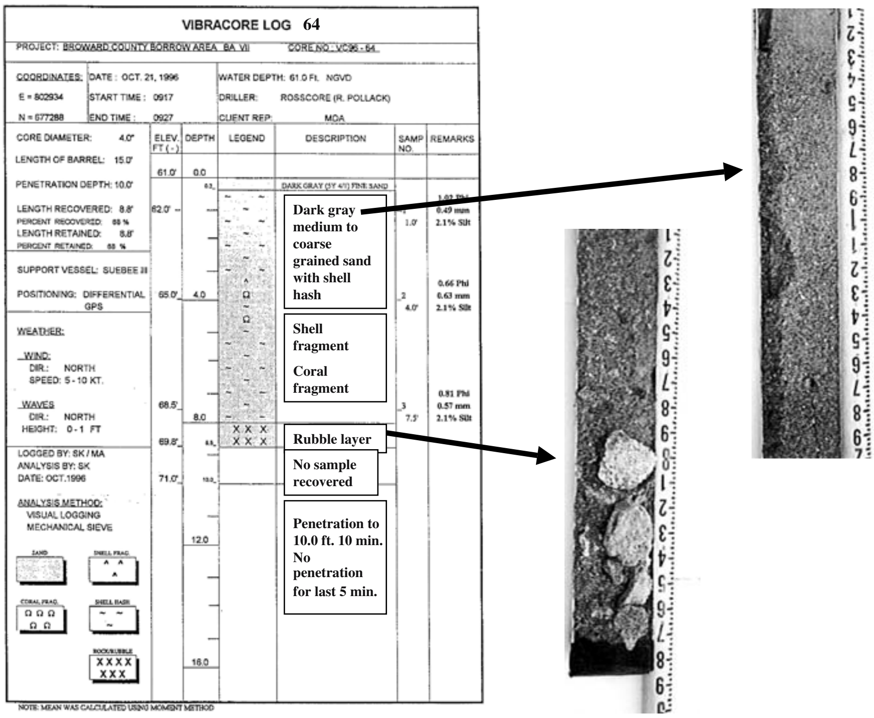

Figure V13 Example of a vibracore log showing a marked discontinuity in a basal rubble layer. Photographs of the split core (right side of diagram) show medium to coarse-grained sand interspersed with shell hash inclusions that terminate in a very coarse carbonate rubble layer. Sediment loss and refusal of the core barrel occur in the rubble layer that cannot be penetrated. The value of composite vibracore logs, as displayed here, is immediately apparent because they red flag potential problems when dredging for beach-quality sands that will be mined offshore and pumped onshore for beach replenishment (courtesy of Coastal Planning & Engineering, Boca Raton, Florida).

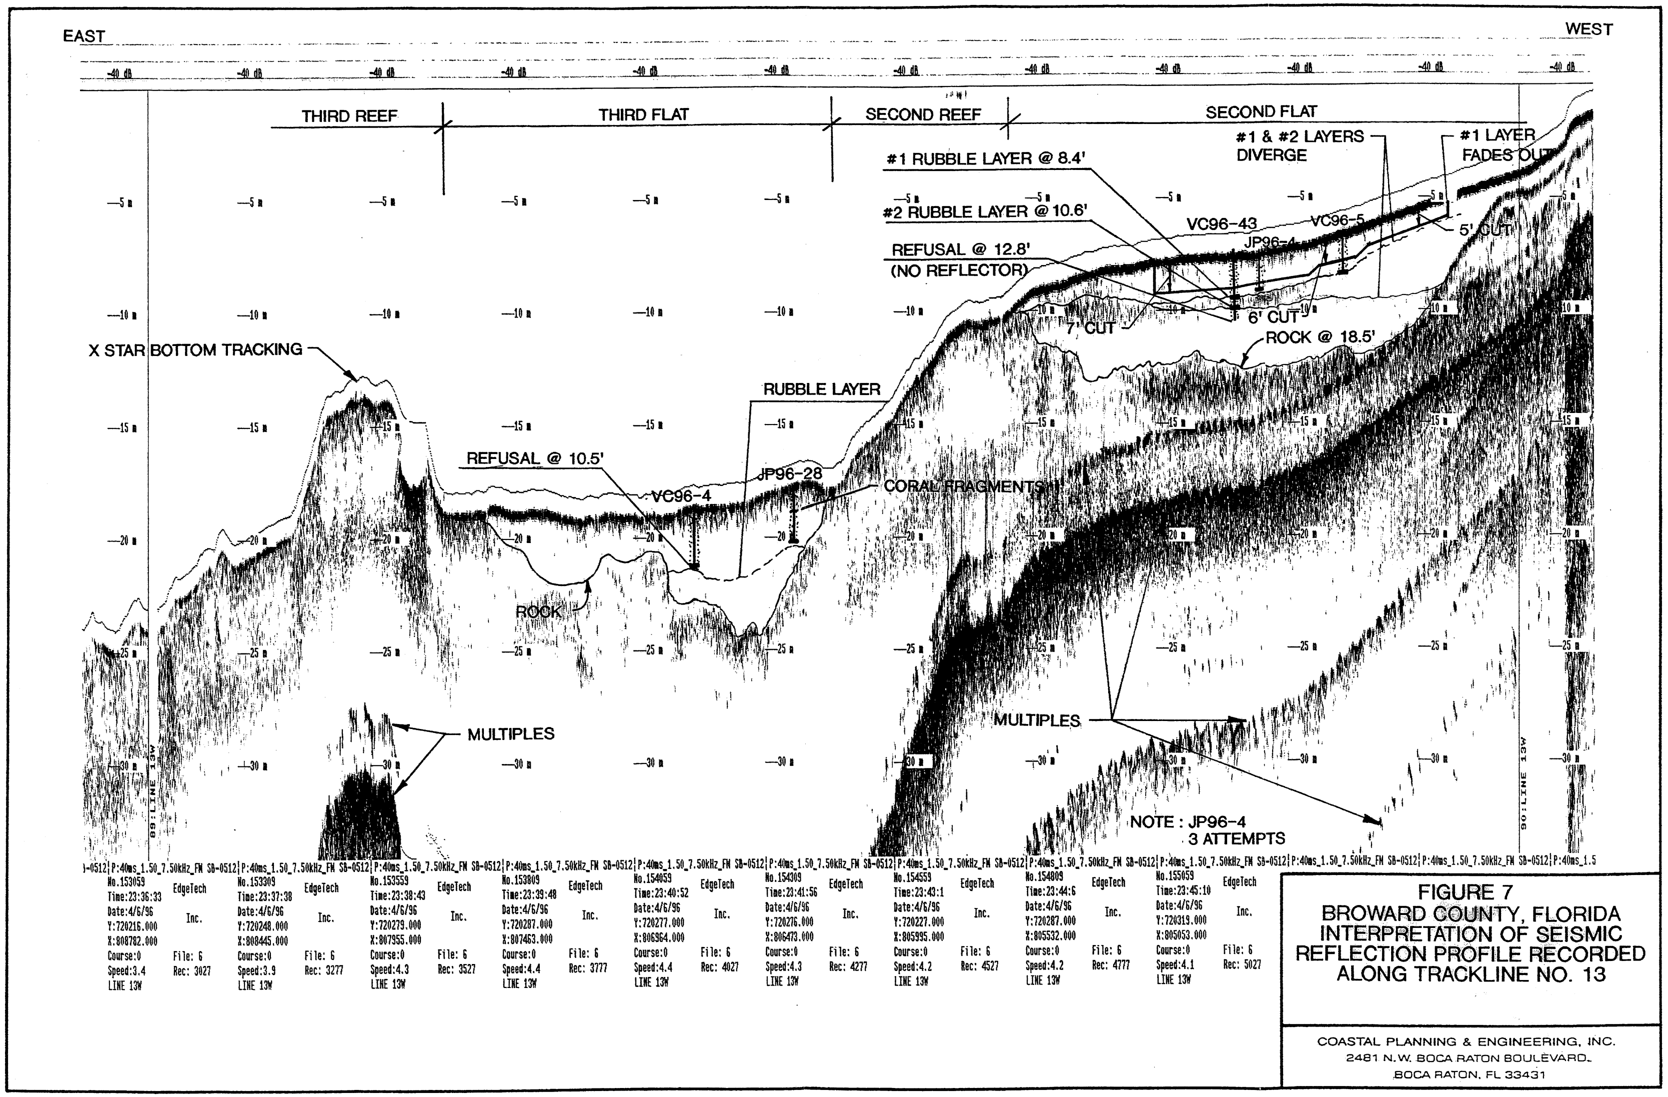

Figure V14 Cross-shore seismic reflection profile and vibracore locations, southeast coast of Florida in Broward County. This north to south view transects the shore-parallel Florida Reef Tract (so that the east or left side of the diagram leads to deeper offshore water). Depressions between parabathic coral reefs fronting the southeast Florida Peninsula contain sedimentary deposits that range from areas of silt plus clay to coarse rubble accumulations, but most areas supply sandy deposits. The second sand flat lies at about 5 m depth whereas the deeper third flat lies under approximately 17 m of water. The vibracores groundtruth the seismic reflection record by verifying the thickness of inter-reefal sandy sediments. Note the presence of carbonate rubble layers at depth in the second and third sand flats (shore is to the west, right side of diagram). Information obtained from the vibracores is essential to complete interpretation of seismic data. The presence of carbonate rubble and coral fragments delimits dredging operations to areas within inter-reefal sand flats that are devoid of materials that are unsuitable for beach renourishment. Offshore sand searches often rely on vibracore data for detailed analysis of sedimentary deposits and interpretation of geophysical surveys (courtesy of Coastal Planning & Engineering, Boca Raton, Florida).

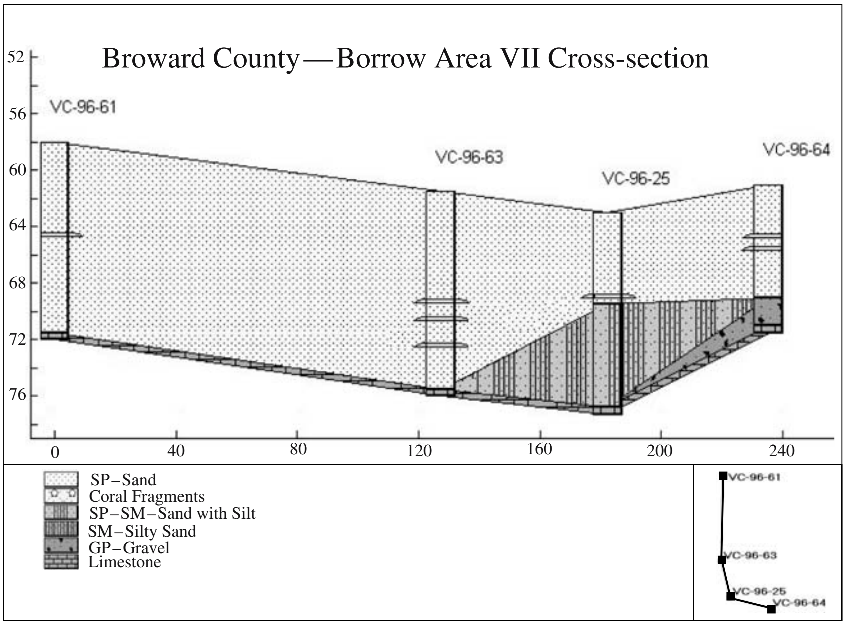

Figure V15 Example of a typical cross-section constructed from vibracore logs for a borrow area offshore southeast Florida in Broward County. The section shows the presence of inter-reefal sands overlying a limestone base (left side of section) and highlights unsuitable fine-grained (silty) materials and coarse gravels (right side of section) as in core VC-96-25. Fine-grained and coarse-grained materials are unsuitable for beach renourishment projects and must be identified prior to dredging so they are not placed on the beach. Because such materials are not compatible with native beach sands, their presence reduces the potential of borrow areas and becomes an important factor in estimating offshore reserves of extractable beach-quality sands (courtesy of Coastal Planning & Engineering, Boca Raton, Florida).

(based on a CHIRP X-Star sonar) on the inner continental shelf of southeast Florida in Broward County. The interreted and annotated sub-bottom profile shows the sedimentary cover that overlies and partially infills inter-reefal troughs, identified as the second and third flats. Even though the seismic survey results can identify rock surfaces of the coral reefs (and buried reef), some carbonate rubble layers are not shown on the trace if they do not present a reflector. Examination of vibracores precisely locates the depth and thickness of coral fragments present in the sandy inter-reefal infills. Summary cross-sections, as shown in the example of Figure V15, although based on seismic and geotechnical data, are confidently constructed using closely spaced vibracore logs. As shown in Figure V15, materials that are unsuitable for beach renourishment (i.e., should not be dredged) are indicated (by a warning red color in the original diagram) as sand with silt, silty sand, gravel, coral fragments, and limestone. Vibracore locations are noted in this fence diagram by a simple coded annotation such as VC-96-61, which indicates a vibracore borehole (VC) that was collected in 1996 (96) as borehole number 61 in a sequence. The strategic role of vibracores as verification or seatruthing of geophysical survey data and as key indicators of actual sedimentary conditions in their own right is patently obvious.

Conclusion

Vibracores are specialized sampling procedures for obtaining continuous, undisturbed cores. Although limited by the maximum length of retrievable core (about 7–10 m for most purposes), vibracores find application in many different kinds of coastal studies where undisturbed samples need to be collected from surficial sediments on land or under water. Vibracores can provide invaluable physical, chemical, and biological information that is otherwise unobtainable. Vibracoring systems range from portable, inexpensive setups to more complicated assemblies that require elaborate service platforms on ships or barges fitted with powerful hoisting equipment. Vibracores are an essential component of multifaceted surveys, such as offshore sand searches that attempt to locate potential borrow areas containing large volumes of beach-quality sands. Although vibracores have a number of limitations that preclude their use under a range of conditions, they are deployed to advantage in many different kinds of scientific and engineering applications. In many respects, vibracores are the unsung heroes of coastal research that depends on acquisition of information posited in the sedimentary record. Collection of unbiased reference information concerning vibracores is somewhat difficult because few papers focus on the vibrocoring methodology *per se*. Vibracoring is a sample collection technique that usually only finds mention in the "methods" section of research reports, often as a backup to broader topics such as geophysical or engineering survey. Nevertheless, information obtained from vibracores should not be minimized, as ancillary when in fact in many cases it is primary, even though it is often collected last.

VORTICITY

Vorticity is the tendency for spin or rotation in a fluid (i.e., vortex flow). As such it is a vector and can be separated into components of spin about the vertical axis and either or both of the horizontal axes. Eddies observed as water moves past obstacles such as bridge pilings is an example of relative vorticity flow about the vertical axis.

Figure V16 shows a Cartesian coordinate system with the x-axis pointing eastward, the y-axis pointing northward, the z-axis pointing upward in the opposite direction to the gravity vector $\vec{g}$. The x–y plane is parallel to a level surface, and relative vorticity (ζ) about the z-axis is defined as $\zeta \equiv (\partial v/\partial x) - (\partial u/\partial y)$. In this equation $+v$ is the flow in the northward direction and $+u$ is the flow in the eastward direction, relative to the fluid in which the eddy is imbedded. Components of relative vorticity can be defined about the other two axes, but the most important one in mesoscale oceanography and meteorology is the vertical component ζ.

To interpret ζ, imagine a disk rotating cyclonically (counterclockwise in the northern hemisphere) about a spindle (*q.v.* Figure V16). Along the x-axis, the farther from the center of rotation, the larger will be the positive v-component of velocity. Similarly along the y-axis, the negative u-component increases as distance from the center increases. On such a disk, both $\partial v/\partial x$ and $-\partial u/\partial y$ are positive quantities, thus defining positive relative vorticity as cyclonic circulation.

Since the ocean and the atmosphere are imbedded on a rotating planet, there is another component of vorticity called planetary vorticity. Planetary vorticity is the familiar Coriolis parameter $f = 2\Omega \cdot \sin\phi$, where Ω is the rotation rate of Earth, 7.2921×10^{-5} radians per second [or 360° per sidereal day], and ϕ is latitude. The sum of relative and planetary vorticity, $\zeta_A \equiv \zeta + f$, is known as the absolute vorticity.

Absolute vorticity, or more precisely the timechange of absolute vorticity, $d\zeta_A/dt$, is related to vertical motion in geophysical fluids. Hydrodynamicists have shown that when following along the path of a parcel of fluid, the so-called Lagrangian perspective, that $d\zeta_A/dt = -\zeta_A D_h$. In this equation D_h is the horizontal divergence of flow where $D_h = (\partial u/\partial x) + (\partial v/\partial y)$. This very important expression shows that in the ocean changes of absolute vorticity are related to upwelling and downwelling, because if a surface flow is divergent, water from below must upwell to replace the water that is moving away.

As an example of the relationship between absolute vorticity timechange and vertical motion, consider the Gulf Steam as it meanders eastward in the offing of Cape Hatteras, North Carolina. For simplicity, think of the meanders as horizontal waves and that changes in f are small. As a parcel of fluid moves from the crest of a meander where ζ_A is negative toward the trough where ζ_A is positive, the time-change $d\zeta_A/dt$ is positive and thus D_h is negative. Negative divergence is convergence, and thus there is an area of downwelling water between the meander crest and trough. Similarly, as the parcel moves from the trough to the next meander crest, $d\zeta_A/dt$ is negative and an area of upwelling is observed.

When the ocean is regarded as a barotropic fluid and D_h is integrated from the surface to the bottom where the water is H deep, yet another form of vorticity can be written: $(\zeta + f)/H =$ constant. This ratio is known as potential vorticity, and it is a conservative property of the ocean and the atmosphere. This very important equation shows that geophysical fluids change direction when either its latitude changes or when the water depth H changes.

Two well-known observed examples of conservation of potential vorticity are found in the Atlantic Ocean (Figure V17). First, as water from the southern hemisphere flows across the equator in the Brazil Current, the Coriolis parameter f changes from negative to positive. If H is constant, then ζ must become negative in order to conserve the sum $\zeta + f$. A negative relative vorticity is anticyclonic flow, and thus the water must turn eastward as it passes north of the equator. This is the formation of the Brazil Current Retroflection that eventually leads to the North Equatorial Countercurrent in the Atlantic Ocean.

A second example is found in the Gulf Stream off Charleston, South Carolina. As the Gulf Stream flows northward it encounters a shallow bottom topography feature known as the Charleston Bump. In order to conserve potential vorticity, with f approximately constant, a decreasing H must be balanced by a negative ζ. As with the Retroflection region, negative relative vorticity ζ implies that the Gulf Stream must turn anticyclonically offshore and flow eastward. However, H increases quickly as the current enters the deep water of the continental slope, and ζ changes again, causing the Gulf Stream to meander cyclonically onshore. Thus conservation of potential vorticity initiates meanders in the Gulf Stream that are amplified downstream off Cape Hatteras.

Further reading on this subject may be found in the following bibliography.

VOLCANIC COASTS

Volcanism, the ejection of molten magma from the earth's interior onto the surface, is petrologically classified into three types, namely, basic, intermediate, or acidic, depending upon the proportion of silica in the volcanic ejecta. Basic volcanic rocks contain a high proportion of ferromagnesian minerals (Fe + Mg) relative to silica (SiO_2), and are thus relatively dense, heavy, and dark colored, and tend to be ejected as relatively nonexplosive and fluid lava streams. Acid volcanic ejecta contains a much higher proportion of silica, is accordingly relatively light and light colored, more viscous, and is ejected explosively. Intermediate volcanic ejecta products are also intermediate in composition and explosive properties. These properties determine the rock hardness and influence the susceptibility of the rocks to physical and chemical weathering.

Basalts are the major basic volcanic deposits. These are typically extruded as fluid lava streams, such as at Kiluea, on the main island of Hawaii (Macdonald *et al.*, 1983). The fluidity of basalt lava normally allows it to exude interstitial gases easily so that the eruptions are relatively explosive-free, and the flowing lava streams follow pre-existing valleys, forming lava pools or sheets in low-lying topography. Often the fluid lava solidifies as massive thick sheets on land, and as a result of the slow cooling, the basalt fractures into hexagonally jointed vertical columns. When fluid basalt is extruded into water the surface cooling is much faster, typically resulting in closely jointed "pillow lavas." Basalt extruded from a single vent often forms a concave upward volcanic cone due to minor "fire fountaining" of pyroclastic deposits occurring around the vent, and resulting in scoria cone formation. However, little volcanic ash (tephra) is ejected.

Andesite lavas tend to possess greater viscosity, with which is associated greater explosiveness as the lava is ejected. Andesitic eruptions can form thick sheets but when ejected from a single vent tend to be explosive and accompanied by ejection of large volcanic "bombs" into the atmosphere, along with scoriaceous material, and finer tephra material. When ejected from a single vent, the volcano tends to form a mound around the vent. Frequently, however, much of the volcano form is built up from the intermittent eruption of volcanic lava chunks, bombs, and tuff. If these materials become fluidized with waters, they flow as mudflows or *lahars* down the volcano slopes, ending up as irregular hummocky topography around the lower slopes of the volcano (Cotton, 1944). Frequent lahar activity may form a ring plain of laharic deposits—Mt Taranaki in New Zealand is a classic example.

Acid, or *rhyolitic* volcanism, produces gas-rich and viscous lava (Cotton, 1944), and typically the volcanic ejecta is explosively extruded as viscous rhyolitic or dacitic lava. In extreme cases of Pelean type eruptions, massive burning clouds of molten incandescent pumiceous and fine ash ejecta, exuding gases, are explosively erupted and reach high into the atmosphere. The explosion cloud of incandescent particles eventually collapses, creating *nuées ardentes*, consisting of hot glowing clouds of self-lubricating gas-exuding pumice and ash, which may flow at great speed across the landscape. When this material pools in topographic lows and cools relatively slowly, the fragmented rock clasts liquefy, weld together, and solidify as *ignimbrite* sheets—but typically of less density and hardness than the andesitic and basaltic flows. Acid volcanic eruptions often result in considerable ejection of pumice deposits, which may blanket the landscape and are subsequently easily eroded to provide considerable sediment input from the rivers to the coastal littoral zone.

Apart from these "fundamental" types of volcanic deposits, volcanic breccias, and conglomerates can be deposited into the marine environment. The resulting rocks possess a fine tuffaceous matrix of mixed marine and volcanic origin separating the larger breccia clasts of basalt or andesite.

The various volcanic lithologies subjected to coastal marine processes exhibit a wide variety of rock hardness, composition, jointing pattern, as well as existing in a variety of wave energy, tidal range, and climatic (temperature) regime environmental conditions. As expected, a concomitant variety of coastal volcanic landforms result.

Erosion processes and geomorphology of volcanic rocky coasts

Erosion processes along rocky coasts are primarily physical, subaerial, and biological. Physical processes include the destructive power of breaking waves, and the consequent hydraulic and pneumatic pressures exerted when broken wave bores are forced along joint planes. Abrasion by the sediments carried by the waves can occur at the base of cliffs and on shore platforms surfaces, but for coastal outcropping volcanic rocks, is generally a minor process. Subaerial processes include weathering occurring within the atmosphere. Particularly potent, especially for fine grained tuffaceous volcanic rocks, is the effect of constant wetting and drying in the intertidal and supratidal zones, a process controlled by the level of permanent pore space saturation of the rock, termed "water level weathering" by Wentworth (1938). Above the level of pore water saturation, subaerial weathering and chemical oxidation predominates. Volcanic breccias can illustrate the importance of subaerial weathering and wetting drying process in shore platform evolution. Wetting and drying is particularly effective on the fine-grained tuffaceous matrix, so that in areas of low wave energy a near-horizontal, high-tide level bench-type shore platform evolves (Figure V18). On the other hand, where the breccia outcrops and is subjected to high-energy waves, a higher-level irregular notch forms as a result of a higher level of rock pore space saturation, but no horizontal bench occurs.

Biological weathering is typically not an important geomorphic process for volcanic deposits, although it is for certain other coasts such as limestone.

Figure V18 A high-tide bench-type shore platform with undercut notch cut into a cliff of volcanic breccia. The sub-horizontal platform planed at the high-tide level is due to "water level weathering" (photo: T. Healy).

Because volcanic rocks are often massive, indurated, hard, and with coarse jointing patterns, they are typically resistant to the various erosion processes operating at the coast, especially the subaerial and biological processes. Paradoxically a major function of marine action (i.e., the physical power of the breaking waves) is to erode along joint planes and fissures, leading to destruction of the platforms and cliffs, and removing the weathering debris from the foot of the cliffs, thereby maintaining a steep cliff profile. The weathered products from the marine erosion of the volcanic rocks are typically of boulder and cobble size, which are often transported by the waves to create coarse boulder and gravel beaches nearby (Figure V19).

Where unweathered basalts or andesites outcrop at the coast, these hard, dense rocks, are resistant to weathering by marine processes, especially where they possess a low intensity of jointing, that is, the resulting geomorphology is of terminally steep cliffs, perhaps exhibiting incipiently formed narrow high-level benches and topographically irregular platforms. Caves are frequent where the breaking waves have forced along the vertical joints. A classic case is the well-known "Giants Causeway" in Ireland. For tropical coasts, chemical weathering is much more intense, and basalts may be weathered to clays; in such cases broader shore platforms can evolve.

For rhyolite flows, the more viscous lava tends to form "plastered layer mounds" or domes, and these are also relatively resistant to erosion by the sea. Over Holocene time since sea level has been at its approximate present level, the sea has often eroded jagged irregular cliffs, as at Mayor Island, New Zealand. Ignimbrites are likewise typically massive with few joints, and thus form high cliffs, as along New Zealand's Coromandel coast. Compared to basalt and andesite, the rhyolites and ignimbrites are less dense and susceptible to greater weathering rates. Some ignimbrites with high calcium content may evolve coastal geomorphology similar to tropical limestones (Figure V20) with undercut notches and sub-horizontal, subaerially weathered shore platform surfaces planed to the level of rock pore space saturation.

Erosion of coastal lahar deposits along New Zealand's high-energy Taranaki coast, results in lahar cliffs, irregular shore platforms, often littered with boulders, small embayments with boulder and cobble beaches, and rugged offshore reefs surmounting submarine platforms. Erosion of the lahar deposits also produce large quantities of titanomagnetite "black" ironsand (Figure V21) which further updrift produce high dunes mined as an iron ore deposit at Taharoa.

Figure V19 Erosion of an andesite cone in a high-wave energy environment, resulting in steep cliffs, and a coarse clastic beach of boulders surmounting a subaqueous shore platform (photo: T. Healy).

Other volcanic landforms at the coastline

Often specialized volcanic landforms occur coincidentally in the presently active coastal environment. Thus, large-scale collapsed volcanic vents, or *calderas*, such as Santorini in the Greek archipelago (Figure V22), or Banks Peninsula of New Zealand, have become modified by stream erosion, and flooded by the sea, forming enclosed harbors (Cotton, 1942). Scoriaceous tuff rings and *maars* formed from relatively small-scale phreatic explosions, are relatively easily eroded and the sea can erode through to form a horseshoe-shaped harbor (Searle, 1964).

Active volcanism in the coastal zone can lead to some spectacular visual effects. When lava flows into the sea "pillow lavas" are formed, along with steam and phreatic eruptions, from the rapid cooling of the lava skin in contact with the water, creating closely packed ellipsoidal masses with radial jointing.

Collapsing *nuée ardente* pumice clouds flowing into the sea are a spectacular site and are even believed capable of causing tsunamis from the rapid displacement of the seawater. Likewise a major eruption in the sea can also cause tsunamis (Dudley and Lee, 1988; Seibold, 1995). In most cases a flank of an active volcano is suddenly uplifted or depressed,

Figure V20 Gently sloping shore platform (foreground) with a veneer of sediment, passing to a high-tide level, sub-horizontal bench and notch cut into ignimbrite in a low-wave-energy environment. The high-tide bench and notches are reminiscent of tropical limestone cut features (photo: T. Healy).

thereby generating the tsunami. But for the case of the island of Krakatoa in 1883, the actual violent explosion itself produced waves as high as 40 m crashing ashore in Java and Sumatra, and killing some 36,000 people.

Sediments originating from coastal volcanic rocks

A range of sediments are derived from weathering and erosion of volcanic deposits in the coastal zone.

- Basalts and andesites rarely weather to sand, but rather to cobbles pebbles and boulders. An unusual example of a specific beach material originating from basalt flows is at Kalapana beach, Hawai, which comprises black glass fragments from the nearby active Kilauea volcano lava tongue entering the sea (Macdonald *et al.*, 1983).
- Iron-rich heavy minerals weathered from andesitic and rhyolitic deposits may introduce a specific concentration of beach sediments, occasionally in vast volumes. The black ironsand deposits of titanomagnetite on the west coast beaches and dunes of New Zealand's North Island, result from weathering of the Taranaki andesitic laharic deposits which form the cliffs around Taranaki. But heavy minerals more typically occur as trace rather than bulk minerals; thus they can be used as tracers for the direction of littoral drift and the provenance of the beach sands (Komar, 1998).
- Acid volcanism, typically producing softer deposits of pumiceous tephras and ignimbrites, may produce large suites of minerals for sandy beach deposits. Pumiceous tephra, for example, is easily broken down in the fluvial and marine environments to its constituent minerals such as quartz, feldspars, obsidian (volcanic glass), and heavy minerals (including augite, hypersthene, hornblende, cummingtonite, and titanomagnetite). New Zealand's Bay of Plenty Holocene dune ridge barrier systems provide an excellent example of sand deposits related exclusively to acid volcanic provenance from the nearby Taupo Volcanic Zone.
- Clays weathered from acid volcanic products include allophane, while volcanic glass weathers in very short time to the montmorillonitic type clay, smectite, in shallow marine deposits.
- In areas of coastal dune deposits blanketed by a series of tephras, the sequence of tephras can be used for dating the coastal progradation and evolution. The classic paper illustrating this method is by Pullar and Selby (1971).

WASHOVER EFFECTS

Although there is extensive geomorphological literature on barrier islands (e.g., Schwartz, 1973) and a similar volume of work on overwash processes (e.g., Leatherman, 1981), studies of the barrier islands associated with present and past positions of the Mississippi Delta (Penland *et al.*, 1988), where there is accelerated subsidence and an absence of a sufficient supply of sand, have demonstrated the critical role of sand dunes in the evolutionary sequence (Ritchie and Penland, 1990a; Ritchie, 1993). This model may have wider applications as evidence accumulates for greater coastal submergence as a consequence of a possible global rise in sea level (Bird, 1993).

In addition to the normal processes of coastal dune development associated with beach-dune exchanges, barrier island dunes and sub-eolian sand terraces have three characteristics which relate to the typical evolution of barrier islands; these are: rapid change, the importance of position (i.e., at the center or at the flanks of the island, Ritchie and Penland, 1990b) and the significance of overwash processes. (Other factors such as sand supply and patterns of vegetation are equally important but are not considered further here insofar as they are not unique to barrier island dunes, although according to Goldsmith (1985), "The most important contribution that humans can make toward the preservation of barrier islands is to prevent damage to the dune vegetation.") Similarly, the evolution of transgressive or regressive barrier islands need not be described. Nevertheless, for reasons such as a rapid reduction in sand supply or tectonic subsidence, a relative rise in sea level will, typically, enhance the frequency and therefore the significance of washover processes (Viles and Spencer, 1995).

The model barrier island (Figure W1) will retreat landwards and migrate alongshore depending, primarily, on the strength and direction of coastal currents. Hydraulic processes at tidal inlets also control the shape and rate of change. Larger beaches occur at the ends of the island and are nourished by alongshore transport and from accretionary berms and sand bars which are formed by flood and ebb tidal flows. This pattern of sand movement along the beach toward the flanks of the barriers produce large, sometimes multiple accretionary dunes of several types. In contrast, central areas, unless there is abundant sand supply from the beach or exceptional relict features such as old sand hills or beach ridges (cheniers in Louisiana, Ritchie, 1972), are typically eroding. Thus, in the central part of the barrier dunes are often little more than narrow, low, ephemeral accretions along the coastal edge.

Where overwash processes occur, usually as tongue-shaped penetrations leading to a depositional fan, a surface of bare sand is produced which, on drying, provides a local source for wind transport with the sand being trapped at the line of vegetation along the perimeter of the sand flat. In time this surface will revegetate to become a terrace which may have some additional wind-blown sand accumulations from the beach or from local coastal edge erosion and other redepositional processes. Although it is often a fine distinction, the terminology which has been developed consists of "washover terrace" if low and flat and "dune terrace" if higher and undulating. Dune terraces might also originate as thin spreads of sand which form the backslope of most types of coastal dunes. From numerous surveys of barrier island dune systems, including investigations of the rate of change, a generalized model of dune types has been constructed (Figure W2) for the Louisiana barrier islands.

The rate, frequency, and penetration of overwash events is highly variable and are functions of hurricane, storm, and subtropical frontal passages. The preexisting height of the dune barrier and the width of the beach are the prime defenses against overwash. Thus, the high dunes at the ends of the barrier may be surmounted once every 5 to 10 years whereas the low coastal terraces may be crossed by surges several times every year (Ritchie and Penland, 1990a). Overwash processes transfer sand from the beach and dunes inland thereby contributing to landwards retreat. If these processes are dominated by extreme events such as the passage of a hurricane or a severe storm, consequential topographic orientations can be at different angles to the orientations which are produced by normal eolian processes. At the north end of the Chandeleur Islands, for example, the biggest, dune ridges run inland at 90° to the coastline, being a combination of post overwash residual features and later eolian deposition. It is often possible on the barrier islands of coastal Louisiana to detect relict washover features including lagoon and bay deposits which can be correlated with known hurricane events over the last 20 to 30 years.

Where severe storm events also produce significant elevation of sea levels which are normally accompanied by very strong storm wave effects, barrier island dunes, of all types, may be eliminated completely and the mass of sand which is stored in these features is translated landwards as sheets and spreads some of which cross the entire width of the island and extend as delta-like deposits into the back—barrier lagoon or bay—and as such are lost to the active coastal beach–dune zone. If these back-barrier spreads of sand are laid down during exceptional high water events (and this is normally true), when the water level subsides they will be colonized by vegetation and remain as visible features until the next extreme event. Complete planation of the barrier island can occur at the penultimate stage of the barrier island cycle (Penland *et al.*, 1988) but in younger, more sand-rich barrier islands, the higher sand dunes, normally at the downdrift end of the island survive, albeit severely eroded and often with local washover penetrations through preexisting low and weaker sections. Accordingly, the importance of dune and similar forms to the maintenance and evolution of barrier islands cannot be overemphasized but these dunes (unlike coastal dunes in non-barrier coastlines or in higher latitudes or in areas lacking frequent

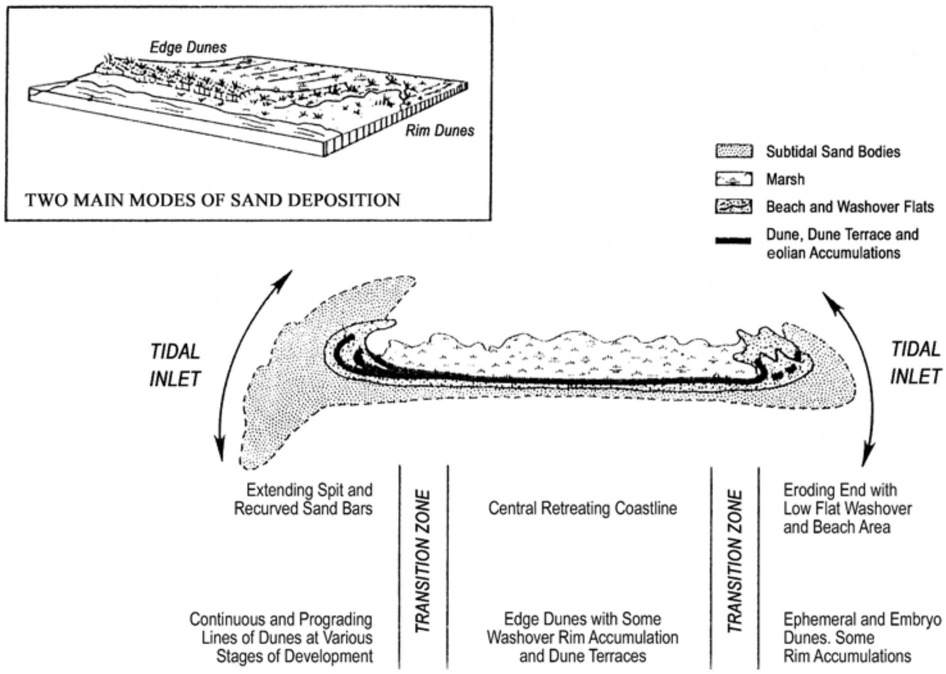

Figure W1 Generalized location of eolian accumulation forms.

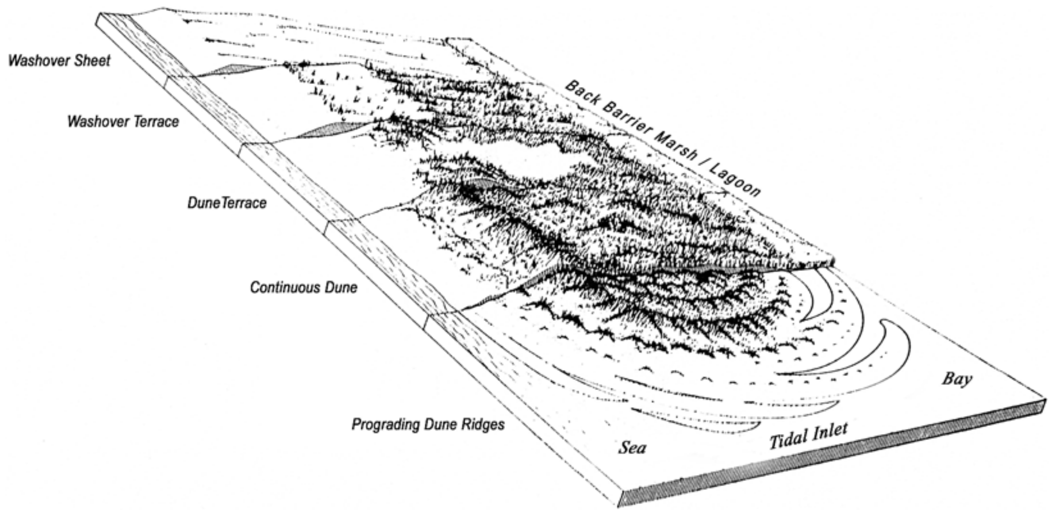

Figure W2 Dune types associated with barrier islands in south Louisiana.

periods of significantly elevated sea levels) change, with great rapidity, not solely as a consequence of eolian processes but also as a consequence of powerful episodic effects of overwash surges. In most locations, however, it is possible to detect cycles of washover activity, with the 7- to 10-year return period of hurricanes of the Louisiana coast being the shortest (Ritchie and Penland, 1990a). It is therefore necessary to conclude that eolian coastal dune processes need to be considered alongside overwash processes in regions of rapid barrier island submergence which, if the predictions of global rises in sea level are correct, might be found, increasingly, in areas other than the margins of large deltaic systems.

Extensive surveys of all the barrier islands of Louisiana were undertaken by the Louisiana Geological Survey and published in four regional volumes, that is, Isles Dernieres, 1989; Plaquemines, 1990; Chandeleur Islands, 1992; Lafourche Barrier System, 1995.

WARFARE—See COASTAL WARFARE

WATER QUALITY

There are around 177 nations open to an ocean, sea, or gulf and around another 30 coastal semi-sovereign states have the legal power to manage their own natural resources and land. Coastal waters are used for a variety of purposes such as food production, hydroelectricity generation, recreational activities, as a transport medium, and as a repository for sewage and industrial waste. For some of these purposes, primarily, food production and recreational activities, the quality of the water is vitally important. The water environment and associated habitats such as coral reefs and beaches may offer significant financial benefit to the associated communities and these opportunities provide the motivating factors for creating a management program.

Water, however clean, is an alien environment to man and thus it can pose hazards to human health even when it is of pristine quality. It is therefore necessary to implement effective management policies in order to minimize and reduce the health consequences of all anthropogenic activities related to water use. In addition to human health implications of poor water quality, poor land use practices, and excessive domestic and agricultural pollution have lead to ecological effects such as the decline of localized coral reef ecosystems (Huber and Jameson, 2000).

Factors affecting the quality of water

Water quality is a multi-faced concept. In addition to microbiological factors, monitoring of coastal waters used for recreational or shellfish harvesting purposes includes the observation of turbidity or transparency, the presence of floating objects, foams on the surface and odor. Apparently clean waters—that is, those that appear clear, may in fact be polluted with high bacterial concentrations or toxic substances.

Coastal waters have traditionally been considered as the ultimate sink for the by-products of human activities. The key sources of pollutants affecting coastal water quality are riverine inputs of domestic, agricultural, and industrial effluents and direct sewage discharges from the local population. Discharges may be regular, through long and short sea outfalls and irregular through storm water and overflow outfalls, and unregulated private discharges. It is the point sources of pollution due to domestic sewage discharges that cause most human health concern. Discharge of sewage to coastal waters exert a variable polluting effect that is dependent on the quantity and composition of the effluent and on the capacity of the receiving waters to accept that effluent. Thus, enclosed, low-volume, slowly flushed water systems will be affected by sewage discharges more quickly than water bodies that are subject to fast change and recharge.

Pollution originating from water-based recreation such as leisure crafts, jet skis, etc. includes sanitation discharges, environmentally toxic effects of antifouling paints and general debris. Estuarine water will be particularly vulnerable to pollution due to the enclosed nature of the system and the subsequent accumulation of pollutants. Controls on sanitation discharges from pleasure craft are dependent on suitable holding tanks and port reception facilities (see entry on *Marine Debris*).

Water quality may also be adversely affected by fuel spillages and discharges from pleasure craft. Oil, petrol, and diesel may be spilt at filling barges and bilge waters may be discharged, adding to pollution of the coastal water. In addition to the fuels themselves, the emissions from the engines may be harmful and the oil and gasoline mix in two-stroke fuels has been implicated in the contamination of fish and shellfish products.

Antifouling paints applied to boats and coastal installations to prevent the subsequent attachment and growth of organisms may have an undesirable effect on water quality, especially where the area is closed or where the vessels or installations are concentrated.

Aesthetic pollution of water quality stems from a variety of sources such as recreational users, leisure boats, fishermen, etc. It has been estimated that 70–80% of marine debris comes from land-based sources (Pond and Rees, 1994) (see entry on *Marine Debris*).

Environmental factors such as rainfall or sunshine may also significantly influence the microbiological quality of water. Heavy rains can cause sewage overflows thus bypassing sewage treatment facilities, increasing surface water runoff and directly influencing microbiological water quality. In contrast, as the intensity of sunlight increases some microorganisms (e.g., *Escherichia coli*) die-off rapidly.

Salinity is another factor that has been shown to affect the die-off of microorganisms. Hanes and Fragala (1967) suggest that enterococci, for example, die-off more rapidly in saline water than in freshwaters.

Eutrophication (the enhancement of the natural processes of biological production, caused by increases in levels of nutrients) has been recognized as a growing concern since the 1950s. The most visible indicator of coastal eutrophication is extensive blooms of phytoplankton and/or benthic macroalgae. In many regions, eutrophication in large water bodies has been characterized by blooms of planktonic species such as *Phaeocystis* (the North Sea; Davidson and Marchant, 1992), *Noctiluca miliaris* (the Black Sea; Mee, 1992), and mucus aggregates (the northern Adriatic Sea; Stachowitsch *et al*., 1990). Some of the algae are toxic and may cause fish kills while others are aesthetically "nuisance" algae, causing spoiling of beaches, offensive odors, and slimy water. Many cause secondary blooms of undesirable fauna, such as the ctenophore *Mnemiopsis leidyi* (the Black Sea; Mee, 1992) which has reached bloom biomass densities of 1 kg m^{-2}.

In Australia, a large number of estuaries, bays, and coastal lakes have begun to experience algal blooms in the last 30 years. In coastal marine environments many toxic species of dinoflagellates, diatoms, nanoflagellates, and cyanobacteria occur, and have led tohuman health impacts after consumption of shellfish and fish. In Tasmania and Victoria, the closure of shellfish beds has resulted from blooms of algae suspected to have been introduced into Australia in ballast water (Hallegraeff and Bolch, 1992).

In 1995–96, nearly 400 manatees (about 20% of the Florida population) died from exposure to red tide, a toxic algae bloom that occurs naturally in the Gulf of Mexico, and to which manatees have been exposed for many years. It is thought that the blooms were more concentrated due to increasing levels of pollution in Florida's coastal waters, and that pollution factors may also reduce the manatees natural level of resistance to disease.

Continuing construction and development in coastal areas, loss of wetland habitat, which filters surface water runoff (which had previously reduced pollution to coastal waters), and the resulting contamination and loss of the coastal grasses which are the manatee's food supply, all contribute to forcing manatees into smaller ranges.

Most of the problems affecting humans associated with toxin-containing aquatic cyanobacteria have involved freshwater planktonic species. Severe illness due to direct dermal contact with cyanobacterial mats has been reported in tropical marine bathing sites.

Management of nutrient loading to coastal environments, and any subsequent problems of eutrophication, is based on the reduction of nutrient-rich effluents from the land or better dispersion of existing discharges. This may be achieved by the control of soil erosion, changes in the use or nature of fertilizers, reuse rather than discharge of nutrient-rich effluents, diversion of discharges into less-sensitive or better-flushed environments, engineering works to improve flushing, and nutrient removal from effluents.

Human health implications of poor water quality

Epidemiology is the scientific study of disease patterns in time and space (Kay and Dufour, 1999). Epidemiological studies have played an important role in providing information to characterize risks associated with swimming in waters of poor quality and of particular relevance, those risks associated with swimming in feces-contaminated recreational waters. Although the water environment is of a highly variable nature, a number of credible studies have been carried out since 1953 (see Kay and Dufour, 1999 for a review), which have shown an association between a variety of symptoms and exposure to fecally polluted recreational waters.

Coastal waters generally contain a mixture of pathogenic and nonpathogenic microbes derived from sewage effluents, the population using the water for recreational purposes, industrial activities, and farming and wildlife, in addition to indigenous microorganisms. If an infective dose of pathogens colonizes a suitable growth site in the body of a bather there is the possibility of disease.

There are a broad variety of illnesses that have been associated with swimming in marine and fresh recreational waters. *E. coli*, Leptospira, Norwalk virus, and adenovirus 3 are some of the microbes that have been linked to swimming-associated disease outbreaks. A number of outbreaks of *Giardia* and Cryptosporidium have been shown to occur in very small, shallow bodies of water that are generally frequented by children. Epidemiological investigations of the outbreaks found that the source was usually the bathers themselves, most likely children (WHO, 1999).

Enteric illness, such as self-limiting gastroenteritis, is the most frequently reported adverse health outcome investigated in recreational users of contaminated bathing waters and it is now accepted that there is an association between gastrointestinal symptoms and indicator-bacteria concentrations in recreational water. Most of the literature suggests a causal relationship between increasing recreational exposure to fecal contamination and frequency of gastroenteritis (WHO, 1999). Higher symptom rates have been reported usually in the lower age groups (Cabelli, 1983; Pike, 1994). Children are particularly at risk from waterborne diseases compared to other age groups due to weak body defenses, susceptibility, and inadequate or no understanding of how to avoid hazards. Children have a natural curiosity and disregard for safety, and thus may play in or drink contaminated water. As their mobility increases they expose themselves to more hazards thus increasing risk of infection.

Escherichia coli is a well-known indicator of fecal pollution. *E. coli* are capable of causing many diseases and is a major cause of gastroenteritis: Enterotoxigenic *E. coli* cause a dehydrating diarrhea in children, enteroinvasive *E. coli* can cause fever and watery mucoid diarrhea in infants; enterohemorrhagic *E. coli* is associated with hemorrhagic colitis, some cases progressing to hemolytic uremic syndrome, particularly in children. Many waterborne outbreaks of *E. coli* are known—some associated with drinking water and others with recreational water.

Other associations, although fewer, have been reported for other health outcomes, such as ear infections and respiratory symptoms. There is less evidence for the link between recreational water use and more serious diseases although it is biologically plausible. Cholera, for example, can be transmitted through water and food. Environmental sources of the causative agent include sewage, sea, and surface waters. Direct person-to-person transmission is uncommon.

Giardiasis is a common disease throughout the world, affecting all age groups, although the highest incidence is in children (Hunter, 1997). Waterborne outbreaks are particularly common and a few outbreaks have been reported from recreational waters.

Meningitis, hepatitis A, typhoid fever, and poliomyelitis could also be acquired through bathing but it is difficult to determine unequivocally.

Limited evidence suggests that local populations bathing in sewage-contaminated water may suffer less illness than visiting populations, probably due to the influence of the immune status (WHO, 1999). It has also been suggested that viruses could be transferred from the water to the air and therefore nonswimmers could be at a certain risk (Feachem *et al*., 1982).

Water quality standards

Coastal water quality standards relate primarily to recreational waters and water used for shellfish production. The implementation of water quality standards have had some successes in promoting cleanups, increasing public awareness, contributing to informed personal choice, and to a public health benefit.

Water quality is primarily measured against standards for microbiological parameters and present regulatory schemes for the microbiological quality of recreational waters are primarily or exclusively based on compliance with fecal indicator counts. A variety of water quality standards exist throughout the world (Table W1). The World Health Organization (WHO) have recently developed Guidelines for Safe Recreational Water Quality Environments (WHO, 1998). To comply with standards of quality authorities must monitor the water a minimum number of times during the defined bathing season. There is considerable concern about the financial cost of monitoring water quality, especially in the light of the precision with which the monitoring effort assesses the risk to the health of water users and the effectiveness with which it supports decision-makers to protect public health.

In addition to microbiological hazards there are a number of other diverse physical and chemical pollutants that should be addressed in monitoring programs where they are known or suspected to be locally significant. It is important that standards, monitoring and implementation enable preventative and remedial actions that will prevent health effects arising from such hazards.

Water quality determination

The wide variety of factors affecting the quality of coastal water (together with the vagaries associated with monitoring) makes it inappropriate to compare the quality between different coastal locations. However, individual studies have highlighted particular problems in various regions. For example, Ozkoc *et al*. (1997) investigated the specific issues affecting the quality of the Black Sea. Land-based pollutants were considered the main pollution source in this case.

Jensen *et al*. (1997) investigated the sources of pollution and other impacts for the Mediterranean Sea, the Gulf of Suez and the Red Sea, and Gulf of Aqaba. The study found that industrial wastewater and domestic sewage from residential and tourist areas were a major problem in the Mediterranean Sea. Oil pollution from refineries, ships, and offshore oil platforms were considered the main pollutants for the Gulf of Suez and sewage, oil pollution, landfilling, dredging, and siltation the main contributors to poor water quality in the Red Sea and the Gulf of Aqaba.

Standard methods exist for the determination of the microbiological parameters that identify the quality of the water according to current legislation and methods (see e.g., ISO, 1992, 1997). Many waterborne pathogens are difficult to detect and/or quantify and instead present regulatory schemes for the microbiological quality of recreational waters are primarily based on percentage compliance with fecal indicator organisms (organisms that are always found in feces and which are easy to detect on simple bacteriological media) to show the potential presence of organisms that cause gastrointestinal disease (Table W1). Fecal streptococci are suggested as the recommended indicator for saltwater and either fecal streptococci or *E. coli* can be used for monitoring freshwaters. Sulfite-reducing clostridia may be suitable as indicator organisms for parasitic protozoa and viruses from sewage-impacted waters (Ferguson *et al*., 1996).

Other indicator organisms for sewage, include the bacteriophages to *Bacteroides fragilis* HSP40, somatic coliphages, F-specific RNA phages, and fecal sterols. The *B. fragilis* phages appear to survive in the same way as human enteric viruses against a variety of environmental conditions, but they may exist in lower numbers than various coliphages and it is thought that only between 1% and 5% of humans excrete these phages and therefore they may be unsuitable indicators in areas of small communities.

Sanitary plastics can act as an immediate indicator of sewage contamination. However, the presence of sanitary plastics may reflect old sewage contamination and may not be a good indicator of human health threats.

No one indicator organism is suitable for representing all the issues associated with fecal contamination of recreational water.

Monitoring only for microbiological parameters does not provide the most accurate and feasible index of health risk. There are a number of acknowledged constraints associated with the current standards and guidelines:

- Management actions are retrospective and can only be instigated after users have been exposed to the hazard.
- The risk to human health is mainly from human excreta, the traditional indicators of which may derive from other sources.
- There is poor inter-laboratory and international comparability of microbiological analytical data.
- Recreational waters are generally classified as safe or unsafe, but there is no gradient of severity.

It is suggested that the measure of a microbiological indicator of fecal contamination be combined with an inspection-based assessment of the susceptibility of an area to direct influence from human fecal contamination. This allows regulators to identify the possible source of the

[h] Period of 60 days.
[i] Satisfactory waters, samples obtained in each of the preceding weeks.
[j] Geometric mean of at least five samples.
[k] Not to be exceeded in at least five samples.

contamination and since sources other than human fecal contamination are generally less of a risk to human health, it is possible to reflect this modified risk. Knowing the possible sources of contamination and their likely influence upon water use provides a fast and robust means to increase the reliability of the overall assessment. This could lead to a classification system based on relative risk as suggested by the WHO and United States Environmental Protection Agency (USEPA) (WHO, 1999).

Environmental health indicators

The WHO has recently developed a set of environmental health indicators to aid policy makers in their roles in public and environmental health policies (WHO, 2000) (see entry on *Environmental Quality*). This included coastal waters used for recreation. To evaluate the relevance of these indicators for widescale implementation a pilot testing has been initiated in several countries in the European region of the WHO.

Conveying information on water quality to the public

The primary reason for monitoring water quality and for informing the public is for the protection of public health. The public is unlikely to want to know the technical details of sample treatment in the laboratory but wish to know only whether the water is safe or not. It is essential that any information relating to water quality is presented to the public in a clear, unambiguous, and easily understood way.

Raising awareness and enhancing the capacity for informed personal choice is an important factor in ensuring the safe use of coastal water environments. It acts directly (by allowing users to choose an area which is known to be safe), and indirectly (the exercise of preference for safer environments will encourage investments in improvements). In order for it to be successful it is essential that the public is generally aware and that the information is available and easily understood.

Currently, a number of schemes exist which convey information to the public. Unfortunately, as yet the public is often provided with information on the previous bathing seasons water quality rather than current results. For example, in the European Community, the EC Directive on the quality of bathing waters requires that Member States submit to the Commission a comprehensive report on their bathing water and the most significant characteristics. The Commission then publishes this information by means of a report just before the beginning of the next bathing season. Real-time information services do exist—generally provided by local authorities for individual beaches.

Other schemes to inform the public of water quality exist; for example, award schemes are common—in Europe the best known is European Blue Flag scheme. Many countries have national equivalents. Human health is not always the prime concern of these schemes. The quality of recreational water is often used in publicity to attract visitors to the area. Award schemes are often used as incentive programs to involve all parties concerned in participating in optimizing beach safety, water quality, and education activities (see entry on *Rating Beaches*).

Pollution abatement and water quality

Water quality is often affected by pollution due to sewage and industrial discharges, combined sewer overflows, and urban runoff. Pollution abatement is therefore a key part of coastal zone management aimed at minimizing both health risks to bathers and ecological impacts. The main action to reduce sewage pollution requires a large investment in sewage treatment and discharge. Pollution abatement measures for sewage may be grouped into three alternatives: wastewater treatment; dispersion through sea outfalls; discharge to non-surface waters (reuse). The traditional measures are often prohibitively expensive and therefore in some cases in view of costs of control, it may be preferable for integrated beach zone management to focus on alternative options such as restricting beach use or warning the public of the potential health risks during and after risk events (see entry on *Coastal Zone Management*).

Summary

Exposure to fecal pollution through contaminated waters leads to detectable health effects and there is clear evidence of a dose-response relationship linking fecal pollution with enteric and non-enteric illnesses. Evidence also indicates that health effects linked to pollution occur at levels of fecal indicator bacteria which are found in recreational waters globally and which may be below the legal standards in many parts of the world. In order to manage coastal water quality, national authorities should take account of a variety of factors, including social and economic factors, some of which are conflicting, in order to ensure safe waters.

WAVE AND TIDE-DOMINATED COASTS

Introduction

Wave and tide-dominated coasts may be defined as coasts whose morphology is shaped by short- to long-term background hydrodynamic conditions generated jointly by waves and tides. Few of the world's coasts are devoid of wave action (Davis and Hayes, 1984), such that waves are generally considered as the dominant agent of coastal change at short (order of hours to weeks) to medium (order of months to years) timescales. The importance of tides in determining coastal processes and morphology has long been overlooked, mainly because of lack of studies that properly evaluate their role, notably in settings deemed as wave-dominated. One probable reason for this is that by far the largest number of process studies on the open coastline has concentrated on beaches in areas of low tidal range where the tidal process signature is extremely weak or negligible. This situation has been changing in recent years, especially with regards to beach studies carried out in areas with large tidal ranges, which increasingly recognize the importance of tidal modulation of the hydrodynamics, sediment transport patterns, and resultant morphology (Short, 1991; Masselink and Short, 1993; Levoy *et al*., 2000). Identification of the joint influence of waves and tides is important in terms of understanding the physical processes involved in coastal change and its implications for coastal management.

From first principles, tidal forces are felt universally on all coasts, although their effect is modulated by position. However, waves are variable in time and space. As a result, waves might mute, modulate, obliterate, amplify, or dominate the tidal signal. Coasts where waves are absent or where waves obliterate the tidal signal are the extremes previously recognized as tidal- or wave-dominated coasts. Inevitably, the rest must be mixed wave and tide-dominated coasts. Between the wave-dominated coast and the tide-dominated coast therefore exists a wide range of mixed wave–tide-dominated coastal types that comprises a considerable proportion, if not the majority of the world's coastline. Any tidal influence in shaping the coastal morphology occurs directly through tidal currents and their asymmetry, through enhancement of tidal currents due to shoreline configurations, as in the case of estuaries and inlets, through tidal interactions with waves, and indirectly through the effects the large vertical and horizontal tidal translations have on wave processes.

Wave and tide-dominated coastal settings and characteristics

Between the wave- and tide-dominated coastal extremes is a broad spectrum of wave and tide-dominated coasts. These range from settings with high wave energy and perceptible tidal energy associated with a low tidal range, to settings with low wave energy and large tidal ranges. While tides show a regular predictable temporal cycle, wave conditions generally exhibit large temporal variability expressed by irregular, but short-term (order of days to weeks), to seasonal variations in energy and period. As a result, the wave and tide-dominated spectrum is not constant in power level and is probably very irregular, characterized by a few key spikes associated with certain coastal types. Examples are the stubby barrier coasts with frequent tidal inlets associated with low- to moderate-energy waves and moderate tidal ranges (Hayes, 1979), and beaches with very large tidal ranges and low- to moderate-wave energy whose shorefaces are characterized by storm wave and tidally molded sand dunes and ridges. Further variability occurs in wave and tide-dominated settings where wind forcing plays an additional important role in modulating the power level.

In the high wave energy–low tidal range part of the wave and tide-dominated spectrum, strong tidal currents are only generated where local bathymetric/topographic factors lead to tidal strengthening and slackening. This situation may occur in both fixed and migrating tidal inlets linked to estuaries or lagoons. A case of wave and tide-dominated coast that is often overlooked is that of alongshore migrating inlet systems associated with barriers (see entries on *Tidal Inlets* and *Barriers*). Such migrating inlet systems, especially active in areas with low tidal ranges favorable to barrier development, are maintained by the tidal flux. The tidal inlets may capture and store significant amounts of sand transported alongshore by wave-induced longshore drift as tidal inlet fill and flood tidal delta deposits. It is noteworthy that the sediment record of barrier coasts comprising inlets may exhibit important longshore sequences of wave-deposited barrier sand that overlies such tidal deposits (Hayes, 1980; Reinson, 1984). Another situation where this may occur is in the vicinity of headlands where sand banks may accumulate as a result of tidal eddies (Pingree, 1978; Ferentinos and Collins, 1980). It must be noted, however, that this headland–tidal current relationship may span the whole spectrum, depending on tidal range and wave-energy conditions. The high wave-energy end of the wave and tide-dominated spectrum may comprise a spatially narrow or limited zone of tidal influence vis-à-vis a spatially wide but temporally fluctuating zone of wave influence.

At the other end of the spectrum are coasts with low net wave energy and strong tidal action. Coasts subject to low wave action are found where fetch or wave energy conservation conditions are such that significant waves are either not generated regularly or are not energetic enough as to have the dominant impact on the coast. The former situation may be found in protected settings such as large bays and epicontinental seas. Wave conservation depends on nearshore morphology which largely determines frictional energy dissipation and energy spread through refraction and diffraction. The highly periodic nature of wave generation or extreme wave attenuation may result in open fine/cohesive clastic-dominated coasts whose process signature and morphology are dominantly shaped by tidal currents. However, for this to happen, these currents need to be sufficiently strong to mobilize or entrain sediments. This end of the wave and tide-dominated spectrum may comprise, in contrast to the high wave-energy end, a spatially narrow but widely temporally fluctuating zone of wave influence vis-à-vis a spatially wide zone of tidal influence whose temporal fluctuations are regular, being hinged on the lunar cycle. Swell wave attenuation may be expected on coasts fronted by wide, shallow continental shelves that are themselves favorable to tidal range amplification (Clarke and Battisti, 1981).

Schematically, the wave–tide relationship may be presented in terms of a spatial band wherein the tidal influence tends to increase in the offshore zone and the wave influence toward the beach. As wave energy increases, waves would tend to mute the tidal signal and even dominate. This relationship would however, vary both spatially and temporally as a function of the temporal fluctuations in wave energy and in tidal power during the lunar cycle.

On modally low wave-energy coasts, especially in protected wave environments, the tidal signal would tend to dominate over a wider area of nearshore zone. This tidal domination would be maintained up to the high-tide shoreline in the periodic absence of waves, or in areas where attenuation of swell wave energy is complete up to the high-tide shoreline, or would diminish toward the mid- to high-tide part of the beach where wave energy still attains the high-tide shoreline. This mixed energy regime may also be expressed by depth variations in protected settings characterized by short-period waves, with wave action being efficient over the shallower coastal and nearshore deposits, and tidal action in the deeper areas.

Wave and tide-dominated coasts may vary from sandy beaches to mudflats and mangrove-colonized tidal flats (see entries on *Tidal Environments, Tidal Flats, Mangroves, Muddy Coasts*, and *Salt Marsh*). Within the moderate to high wave and high tidal energy end of the spectrum, beaches may exhibit characteristics typical of their counterparts in settings with low tidal ranges. However, tidal modulation of their wave hydrodynamics and sediment transport patterns still occurs, together with significant tidal current activity offshore. Examples of this are Cable Beach in Western Australia (Wright *et al*., 1982) and beaches on the Aquitaine coast of France. Low- to moderate-energy beaches in settings with very large tidal ranges (above 8 m at mean spring waters) such as those of Normandy, France (Levoy *et al*., 2000) show even stronger tidal modulation of their morphology and dynamics, essentially through large fluctuations in water level due to the important tidal excursion. Ridge and runnel beaches occupy the modally low to moderate wave energy part of the spectrum in settings with short-period waves and moderate to large tidal ranges.

The topography of the nearshore zone or inner shoreface on wave and tide-dominated coasts may be very regular and akin to that of wave-dominated coasts on open coasts exposed to moderate-to high-energy waves, such as the Aquitaine coast. As tidal action increases, this topography may, where abundant loose sediment is available, be characterized by numerous banks and ridges (see entry on *Offshore Banks and Linear Ridges*) that are typical of a tide-dominated process signature, such as in the eastern English Channel and the Huanghai (Yellow Sea).

Muddy wave and tide-dominated coasts may be considered as being close to the tide-dominated end of the spectrum of coastal types and are generally found in the vicinity of major river mouths with large tidal ranges and that drain catchments with fine-grained sediments such as the Amazon, Huanghe, Yangtze, Ganges–Brahmaputra, and Mekong. They may also be found in tropical areas where several smaller high-discharge rivers form coalescing estuaries along significant stretches of coasts with moderate to large tidal ranges, as on the Guinea coasts of West Africa (Anthony, 1991, 1996). On these coasts, significant swell wave-energy dissipation may occur over muddy inner shorefaces and over alongshore migrating mud banks. The longshore transport of particulate mud and mud banks on these coasts is generally assured by strong tidal currents aided by synoptic wind-forced currents. In all such settings, periodic storm wave activity over the muddy shores may lead to the reworking of disseminated shells, sand, or gravel into distinct ridges called cheniers (see entry on *Cheniers*).

Examples of wave and tide-generated processes and interactions

The fundamental process feature of wave and tide-dominated coasts which differentiates them from pure wave or tide-dominated coasts is the way the waves and the tides interact to give distinct process signatures, sediment transport patterns, and coastal morphologies.

Depending on the position in the wave and tide-dominated spectrum, the inner shoreface on moderate- to high-energy swell wave coasts may show a regular bathymetry related to long-term planing by waves, with tidal and wind-induced currents aiding in the transport of sediment that becomes suspended by the high energy waves. On low- to moderate-wave-energy coasts with strong tidal action, the inner shoreface may exhibit either an irregular, poorly reworked topography comprising inherited drowned features, or may be reworked, when loose sand is abundant, into tidal current ridges. Off high sediment discharge river mouths, the inner shoreface may be draped with mud that may be in equilibrium with waves and tidal and wind-induced currents. On sand-rich shorefaces, the organization of tidal current ridges may be hinged on a long-term balance reflecting the joint action of strong background tidal currents and the imprint of periodic storm waves. The linear current ridges and dunes are generally oriented more or less parallel to the shore in response to the longshore tidal currents. From detailed monitoring of sand dunes off the Belgian coast, Van Lancker (1999) showed a vertical pattern of wave-and-tide reworking. Dune mobility in shallow depths (<5 m), whatever the distance offshore, was due mainly to wave action while deeper water mobility was caused by tides. In these shallow epicontinental seas of the eastern English Channel and southern North Sea, storm waves tend to drive dunes and ridges inshore, a process that sometimes tends to be countered by the longshore tidal currents. This may result in stretching and eventually division of the ridges (Tessier *et al*., 1999). Ridges that do get close inshore may eventually become attached to the beach, leading to significant accretion (Anthony, 2000) and onshore feeding of dunes. On coastal sectors where the morphodynamic balance is such that the ridges do not move inshore, this may eventually deprive beaches and dunes of sand in spite of the abundant nearshore sand stocks.

The nearshore residual tidal current signature may become strengthened or weakened by synoptic winds, thus supporting the differentiation of tidal asymmetry patterns that determine medium- to long (order of tens to hundreds of years)-term sediment transport. These ebb- or flood-dominated flows lead to well-defined sand transport pathways such as those that run along both the French and English coasts in the eastern Channel and Dover Straits (Beck *et al*., 1991; Grochowski *et al*., 1993). As a result of various hydrodynamic conditions, notably orientation of the synoptic wind field and Coriolis deflection of the water mass, tides are larger on the French coast and the tide-dominated sand transport pathway on this coast has been much more active than that on the English side. It has been suggested that this sand-rich pathway has fed the large Holocene dune fields on the French coast via storm reworking of the nearshore sand stocks, and shoreward transport by winds over the wide dissipative beaches (Anthony, 2000).

The relationship between tides and waves has been most readily invoked in explaining the influence of large tidal ranges on beaches (Davies, 1980), and on beach morphodynamics (Wright *et al*., 1982; Carter, 1988; Short, 1991; Masselink and Short, 1993; Masselink and Turner, 1999; Levoy *et al*., 2000). Generally, when sediment supply conditions are favorable, coasts with large tidal ranges adjust, over the long term, to the important vertical tidal excursion by having a significant intertidal volume of sand or gravel that necessitates relatively high wave-energy levels in order for large-scale morphological changes to occur. In northern France, ridge and runnel beaches with mean spring tidal ranges of 5–9 m have intertidal volumes of up to 1,200 m^3/m of coastline, compared to the moderate volumes of beaches in settings with low tidal ranges (generally less than a tenth of this volume). As a result, whatever the background wave-energy level, the rates of sediment transport and beach morphological change are retarded. The greater the tidal range and the lower the modal wave energy, the more retarded are these changes. Daily wave reworking of beach morphology in such cases may become limited to minor changes in bedforms that are themselves strongly hinged on the tidal cycle. In storm wave settings, such as those of northwestern Europe, change becomes significant only during storms. This effect may extend to the shoreface. From hydrodynamic data collected on several megatidal beaches (beaches with tidal ranges exceeding 8 m), Levoy *et al*. (2000) identified significant beach and shoreface tidal modulation of wave heights, with wave heights being lower at low tide than at high tide. The effect is exacerbated over shallow offshore areas where the tidal fluctuation induces corresponding changes in water depth.

The large beach volume and the important horizontal tidal translation also imply a reduction in overall beach gradient. A common feature of the tidal influence on beaches with large tidal ranges is that the various wave zones migrate rapidly across this wide, low-gradient profile during the tide, resulting in significant cross-shore variations in the hydrodynamics and resulting morphology. The wave influence is toned down because the sum of energy spent per unit area over time is much less than on beaches with low tidal ranges. While entrainment thresholds are the same, the volume of sediment transport is thus much less on beaches with large tidal ranges. The beach sediment volume and slope being equal, the larger the tidal range the greater the variations in morphodynamic behavior between the lower beach and the upper beach. On megatidal beaches in northern France, the morphodynamic domains may range from extremely dissipative at low tide on the lower beach to moderately reflective on the upper beach at high tide. At high tide, the extreme lower beach is subject to a combination of shoaling waves and strong longshore tidal currents. On similar megatidal gravel beaches fronted by sand flats in northern France, the upper beach is extremely reflective and is dominated by subharmonic gravity wave motions while the lower beach is highly dissipative and shows infragravity edge wave motions and strong, tidally induced longshore currents. Where wind, sand size, and supply conditions are favorable, wide, low-gradient beaches associated with large tidal ranges may provide significant surfaces for eolian reworking of beach sand into coastal dune fields. These wide beaches are also sometimes characterized by strong groundwater table fluctuations that may actively affect beach face hydrodynamic conditions and stability (Turner, 1993; Masselink and Turner, 1999).

On wave and tide-dominated beaches, waves induce sediment suspension while transport is by strong tidal currents (Davidson *et al*., 1993; Masselink and Pattiaratchi, 2000), although the most active tidal phase appears to differ on different beaches, depending on the effects of friction and on whether the tidal wave is progressive or standing. Tidal flow asymmetry on such beaches may determine preferential sediment transport patterns and directions. On some French sandy beaches in the eastern English Channel, the progressive tidal wave is associated with strong longshore currents at high water that are highly effective in terms of sand transport because they coincide with higher high-tide waves that lead to suspension of fine sand. Such currents are always directed northwards or eastwards, and are therefore very important in terms of the net long-term bedload and suspended sediment (including pollutants) transport in these directions. Low-tide waves and tidal currents on the lower beaches are generally much weaker, probably because the shallower water results in both enhanced wave dissipation and tidal retardation by increased bed friction, while tidal current strength is generally greater seaward in deeper water.

Concluding remarks: management aspects of wave and tide-dominated coasts

One rationale for recognizing distinct wave and tide-dominated coasts is that such coasts may be characterized by specific management aspects that require an understanding of the mixed process regime and sediment transport and accumulation patterns. The commonly wide beaches in settings with large tidal ranges may be utilized for a wide range of activities (notably space-consuming leisure activities such as speed-sailing) that may be mutually exclusive and whose practice may therefore require set regulations and space allotments in highly frequented zones. The distinctive coastal profile of such areas may require the clear recognition in management strategies of the specific cross-shore and longshore dynamics due to both wave action and tidal currents. The classic management notion of coastal sediment cells (e.g., Bray *et al*., 1995), generally based on longshore wave-energy gradients when coasts with low tidal ranges are considered, is not tenable on wave and tide-dominated coasts because of the significant modulation of the energy spectrum by tidal currents. Sediment cell definition criteria need to integrate the tidal dimension in sediment transport when transferred to wave and tide-dominated coasts. Wave and tidal sediment transport may work over wide low-gradient intertidal and subtidal profiles and this dimension needs to be taken into account in the design of coastal structures such as groins. Port breakwaters, for instance, are much more easily bypassed by tidal transport of sediment than on simple wave-dominated coasts, thus requiring constant dredging operations downdrift.

In areas where the nearshore zone is characterized by tidal sand banks and ridges, such as the English Channel and southern North Sea, changes in the volume and positions of these features in time may lead to navigation hazards as well as exposure or destabilization of cables and pipelines. These banks and ridges are also important in dissipating storm waves and are therefore significant in terms of shorefront protection, while being also a potential source of sand for beaches and dunes, as well as of dredged aggregate.

Although it has become clear that tides play a significant role in settings associated with waves, thus warranting the recognition of mixed, wave and tide-dominated coasts, more studies are needed to elucidate the various ways tides interact with, and modulate waves, and overall sediment transport.

WAVE CLIMATE

Ocean waves may be defined as periodic undulations about an interfacial reference level, and as such can move horizontally, vertically, or at angles inclined to the horizontal. In the simplest sense, waves transport energy without transporting mass. Sound waves, electromagnetic waves, and sand waves, amongst others, are also part of the oceanic realm, but are not dealt with herein.

Most human experience is with those ocean waves visually described as vertical undulations about the air–sea interface. These are generally known as *gravity* waves because gravity is the restoring force. Oceanographers also recognize internal waves, Rossby waves, tidal waves, solitons, Kelvin waves, and many other complex periodic motions. Table W2 is a brief summary of the commonly recognized wave types in the marine environment. This article however, will focus on those waves generally known as *sea* and *swell*, because most of the wave energy in the ocean is contained in such gravity waves—of which sea and swell are the major types.

Waves are characterized by wavelength, height, period, and steepness. Wavelength (L) is the horizontal distance from crest to crest or trough to trough. Wave height (H) is the vertical distance from crest to trough, and steepness is the ratio H/L. When steepness exceeds 1/7, waves tend to break as is seen routinely at a beach. Period is the time for two successive crests or troughs to pass a fixed point, the reciprocal of which is frequency. Significant wave height ($H_{1/3}$) is the height of the highest 1/3 of the waves in a large number of waves as estimated by an observer. The human eye seems to pick $H_{1/3}$ as the observed wave height.

The effect of the wind on water is to produce capillary waves (which are seen as ripples), ultragravity waves (which are seen in sunglint), sea (which are the shorter-period gravity waves), and swell (which are the longer-period gravity waves). Tsunami waves and seiches are examples of infragravity waves, storm surges such as caused by tropical storms are generally thought of as long-period waves, and transtidal waves are the realm of Kelvin waves and Rossby waves. The classification boundaries in Table W2 should not be held too rigid as many waves extend across a broad range of periods. The general category of *wind-waves* includes capillary and ultragravity waves, sea, and swell. *Sea* is the result of the direct action of wind on the ocean, and *swell* is caused by a nonlinear transfer of energy from shorter-period waves toward longer-period waves.

Table W3 is an adaptation of the Beaufort Scale using verbiage from the World Meteorological Organization supplemented by the classic "seaman's" description of wind and sea. This scale is the basis of much of the data oceanographers have regarding winds and waves. It is at best qualitative and depends on the experience and training of the observer for its accuracy. Scientists who study wave climates over extended time need to appreciate the limitations of such data for trend analysis and climate change.

A quantitative theory for wind-waves from first principles does not exist. The sea surface is rarely at rest, and thus almost always presents an uneven surface for the wind to act upon. Most likely, gustiness (turbulence) in air moving over still water has sufficient spatial inhomogeneity in speed to cause capillary waves. Once the sea surface is roughened, small pressure differences on the windward and leeward sides of wave crests transfers more energy from the air to the water, and the waves grow.

Stress (τ) between two fluids or between fluid layers is a force per unit area. At the air–sea interface it is classically given by $\tau = \rho_{air} C_D v^2$, where ρ_{air} is the density of air, C_D is the drag coefficient, and v^2 is the square of the wind velocity. Surface friction (F_r), a force per unit volume, is the vertical gradient of stress $F_r = \partial\tau/\partial z$, and is related to the square of the wind speed. Since wind velocity is a vector, stress and friction too are vector quantities. Interestingly, linear wave theory is approached by assuming that wave-motion is frictionless.

Based on numerous observational experiments, oceanographers and ocean engineers have developed parametric relationships between wind speed (i.e., τ), fetch, and duration leading to quantitative values of wave height and wave period. The maximum wave height and period from a given wind speed, blowing over a minimum distance (fetch) and for a minimum time (duration) leads to the concept of a fully developed sea. Table W4, calculated from parameters in the *Shore Protection Manual*

Table W2 Classification of ocean waves

Name	Period	Disturbing force	Restoring force
Capillary waves	<0.1 s	Wind	Surface tension
Ultragravity waves	0.1–1 s	Wind	Gravity
Gravity waves	1–30 s	Wind	Gravity
Infragravity waves	0.5–5 min	Wind	Gravity
Long period waves	0.1–12 h	Storms/earthquakes	Gravity/coriolis
Tidal waves	12–25 h	Gravitation	Gravity/coriolis
Transtidal waves	>1 day	Land–Air–Sea coupling	Gravity/coriolis

Table W3 Beaufort wind scale

Beaufort number	Wind description	Wind speed ($m\ s^{-1}$)	Wave height (m)	Wave description
0	Calm	0–0.2	0	Calm, mirror-like
1	Light air	0.3–1.5	<0.05	Glassy, scale-like
2	Light breeze	1.6–3.3	<0.1	Rippled, no white caps
3	Gentle breeze	3.4–5.4	0.1–0.5	Wavelets, few white caps
4	Moderate breeze	5.5–7.9	0.6–1.2	Slight, numerous white caps
5	Fresh breeze	8.0–10.7	1.2–2.4	Moderate, some spray
6	Strong breeze	10.8–13.8	2.5–4.0	Rough, white caps everywhere
7	Near gale	13.9–17.1	4.1–6.0	Very rough, streaky foam forms
8	Gale	17.2–20.7	4.1–6.0	Very rough, marked foam streaks
9	Strong gale	20.8–24.4	4.1–6.0	Very rough, dense foam streaks
10	Storm	24.5–28.4	6.1–9.1	High, visibility reduced
11	Violent storm	28.5–32.6	9.2–13.7	Very high, foam everywhere
12	Hurricane	>32.7	>13.8	Phenomenal, sea completely white

Table W4 Characteristics of a fully developed sea

Wind speed ($m\ s^{-1}$) at 10 m	Fetch (km)	Duration (h)	Significant wave height (m)	Period (s)
5	60	10	0.6	4
10	235	20	2.5	8
15	530	30	6	12
20	940	41	10	17
25	1,475	51	16	21
30	2,125	61	22	25

of 1984, summarizes typical values of fetch and duration for generation of the maximum deep-water significant wave height ($H_{1/3}$) and the longest period in a fully developed sea.

The higher the wind speed, the longer must be the duration and fetch for the sea to develop fully. Wave height and period in a fully developed sea will not increase if the minimum fetch and duration required is exceeded. If either the minimum fetch or duration required for a fully developed sea is not met, the resulting waves will have smaller heights and shorter periods. A comparison between Tables W3 and W4 shows that the two approaches are not fully compatible, but there is general agreement between the seaman's view of wave height and the ocean engineer's.

Energy (E) in sea and swell is a function of the wave height squared (H^2) and the density of the water (ρ_{water}), and is given by $E = 1/8\rho_{water}gH^2$; wave power $P = E \cdot c_g$ is the product of wave energy and the wave's group velocity (c_g). From linear wave theory, the *group velocity* of a shallow-water wave (a wave whose length L is 20 times or greater than the water depth Z) is $c_g = c = \sqrt{gZ}$ and for a deep-water wave (a wave whose length is less than one-fourth the water depth) is $c_g = 1/2c = 1/2\sqrt{(L \cdot g)/2\pi}$. In these expressions, g is the acceleration of gravity, 9.8 $m\ s^{-2}$, and c is the phase speed or *celerity* of the wave. In the expressions for wave energy (E) and power (P), the units are energy per unit wave area and energy per unit of wave front along a crest or trough, respectively. Longer waves have more energy and power for a given height than shorter waves.

As waves transit from the deep sea into shallow water, their period remains the same, but their height increases. This can be seen by equating the shallow-water wave power in one water depth (Z_1) with that in another water depth (Z_2), and solving for the height (H) changes. The resulting equation,

$$\sqrt{\frac{Z_1}{Z_2}} = \frac{H_2^2}{H_1^2},$$

quantifies the growth in the height of a wave as it enters shallower water. The underlying physical reason for this is conservation of energy and power in shoaling wave systems. Another consequence of wave period remaining constant and energy (per unit area) conservation is the steepening of deep-water waves if they encounter an ocean current flowing in opposition to the direction of the waves. Marine meteorologists often use the term "… and slightly higher in the Gulf Steam." to warn mariners of increased risk due to wave–current interaction.

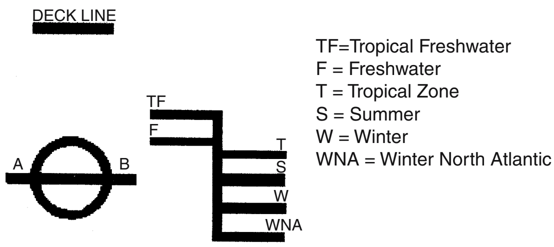

Figure W3 Load line markings for merchant vessels plying the oceans. A vessel loading in tropical freshwater may add cargo until the water is at the TF marking. Then as the ship proceeds out to sea, the greater buoyancy of saltwater over freshwater will cause the ship to ride higher and add additional freeboard or margin of safety.

Risk to shipping and marine operations has been of great concern to sailors, marine transportation companies, and insurance firms for well over 100 years (*q.v.* Table W3). In the late 19th century, Samuel Plimsoll championed the use of load lines to guide mariners in safety. An example of load lines (or Plimsoll marks as they are often called) is given in Figure W3. The A–B designates the American Bureau of Shipping as the issuing agency. The other terms are marks that show how deep a ship may be loaded in different environments. The marking "WNA" designates "Winter North Atlantic" and requires the vessel operator to allow the maximum freeboard (safety margin) for a ship operating in that environment. From well before Plimsoll's time, the Atlantic Ocean in winter was known to have one of the most dangerous wave climates on earth.

Surface winds over the ocean are to first approximation given by the geostrophic equation $\rho_{air}fv_{\sqrt{g}} = \partial p/\partial x$, where the Coriolis parameter $f = 1.459 \cdot 10^{-4} \sin \phi$, p is the sea-level air pressure, ϕ is latitude, and x is the horizontal distance. The term $\partial p/\partial x$ is known as the pressure gradient and is a force per unit volume. Over the area of the WNA, ∂p is the sea level pressure difference typically chosen as that at Iceland minus that at the Azores; ∂x is the horizontal distance between Iceland and the Azores. The deep Icelandic Low minus the Bermuda–Azores High gives rise to the large pressure gradients that cause geostrophic winds to exceed $v_g = 25\ m\ s^{-1}$. Given that these winds often blow most of the winter and across thousands of kilometers of fetch, a glance at Table W4 will convince the reader that $H_{1/3} = 16$ m waves with >20 s periods is why WNA requires the greatest caution for the mariner operating in those seas.

Until the late 20th century, knowledge of conditions at sea such as winds, waves, and currents, were from reports by the vessels plying those waters using the codes shown in Table W3. American navigators credit a US Naval Officer, Matthew Fontaine Maury, with bringing together much of the information that underlies scientific understanding of winds, temperatures, sea, and swell. Those thousands of individual reports, collated and digested, have resulted in numerous atlases and pilot charts depicting average conditions to be expected. Since ships infrequently visit certain areas (such as the southeast Pacific Ocean), or when shipping routes change (such as after the opening of the Panama Canal in 1914), in certain areas the data in these atlases and pilot charts are nonuniform, very sparse, or even nonexistent. Satellite oceanography has changed much of this lack of data homogeneity, both spatially and temporally.

Figure W4 was developed from the satellite altimeters flown during the last decades of the 20th century. The upper panel depicts the average wave heights as measured from the altimeter return-pulse-spreading due to surface roughness. While the WNA is obviously an area of large wave heights, it is the region of the Southern Ocean where Earth's greatest waves are observed. Here, the sea-level atmospheric pressure gradients $\partial p/\partial x$ are large, and the fetch is essentially infinite as there is only one significant land barrier: the Drake Passage between South America and Antarctica.

In low latitudes, Figure W4 shows the lower sea states associated with the gentle Trade Winds. While the mean wave heights in the tropics and subtropics is on average small, these are the same regions whose weather is punctuated by tropical storms, hurricanes, typhoons, and cyclones. Sea states in these extreme storms are very high because the winds are oftentimes stronger than anything listed in Table W4, and also because the circular air flow at the sea surface leads to a long fetch. In addition, such storms create a solitary wave known as the storm surge, which can easily raise sea level at least 5 m—on top of which is the sea and swell!

The lower panel in Figure W4 depicts the variability of sea state about the mean shown in the upper panel. With the large seasonal wind changes in high northern latitudes come the largest changes in wave climate. Again the wisdom of Samuel Plimsoll's "WNA" designation warns the mariner to take due precautions. In the Southern Ocean, the variability is much lower than in the North Pacific Ocean or the North Atlantic Ocean; the enormous ice-mass of Antarctica provides the thermal inertia for fairly constant and large sea-level pressure gradients $\partial p/\partial x$ and hence large geostrophic winds v_g and resulting waves $H_{1/3}$. The northwestern Indian Ocean (lower panel, Figure W4) shows the large variability in sea states from the reversing monsoonal winds of western India, with a smaller effect caused by the Southeast Asian Monsoon seen in the vicinity of the Philippines.

Earth's wave climate is not static. Although the general picture presented herein is stochastically stable, the same satellite data that allows Figure W4 to be compiled, has shown decadal trends in certain areas. Notably, the wave climate of the Norwegian Sea seems to be changing toward higher sea states. This change in wave height is correlated with a deepening of the Icelandic–Azores atmospheric sea-level pressure gradient—a variable known as the North Atlantic Oscillation. Whether this increase in $H_{1/3}$ is long term or cyclical is unknown, but it would be prudent to continue to monitor sea and swell both from spacecraft and oceanographic observatories. Only through the concerted efforts of scientists such as Matthew Fontaine Maury will oceanographers and ocean engineers be able to make statements with certainty about wave climate change.

The coastal science community is embarking on the design of an integrated and sustained ocean observing system. Conceptually, an Integrated Ocean Observing System (IOOS) must include measurements, modeling, and forecasts of numerous variables including wave height, direction, and period. Modern issues in coastal zone management require improved forecasts of natural hazards for Earth's burgeoning coastal populations, and wave energy will be of paramount importance not only for the immediate need in emergency management, but in the design of future infrastructure. The "S" in IOOS will require

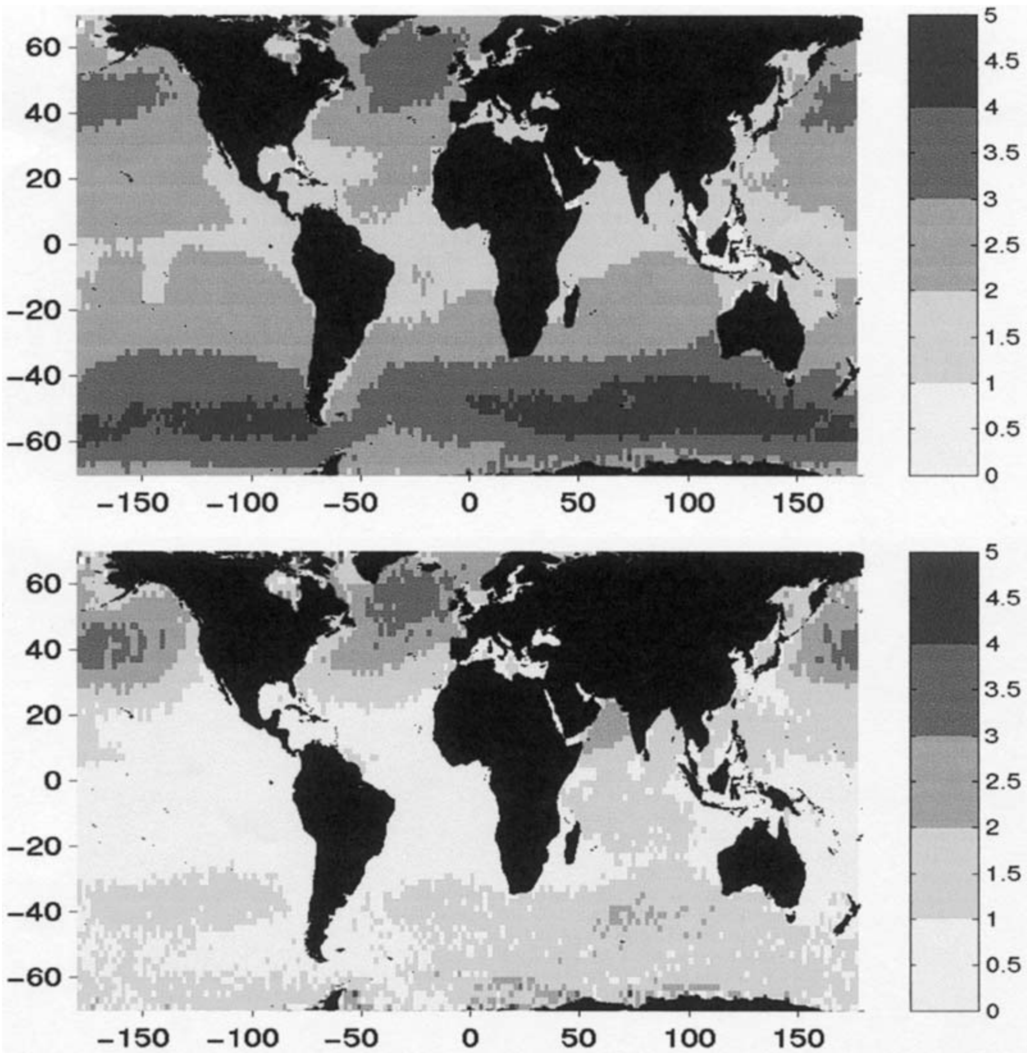

Figure W4 Average wave height (upper panel) and variability about the average (lower panel) in meters. Dr. David Woolf processed these data at the Southampton Oceanography Centre in the United Kingdom from satellite altimeter data for the period 1985–97. Figure used by permission.

effective integration of science, engineering, and management—an intellectual environment where wave climate is a dynamic, not a static, concept. Ocean waves are one component of the earth system, and it will be from a systems-approach that all components will be incorporated into effective decision-making.

WAVE–CURRENT INTERACTION

Flows observed in shallow marine environments are frequently combinations of currents and waves. Currents, with variations on timescales of hours or days, are principally tidal, wind-driven, or related to larger-scale patterns of ocean circulation. Wave-generated oscillatory flows, with periods on the order of seconds to tens of seconds are produced by surface gravity waves, though lower frequency internal waves can also be present. When wave-generated oscillatory motion of the water column extends to the seabed, wave–current interactions lead to increases in bed shear stress and the bottom roughness affecting bottom-boundary-layer currents. These effects are important for understanding ocean circulation and sediment transport in coastal environments.

Currents and wave-driven flows interact with the seabed to produce boundary layers where frictional effects are important. The ubiquitous presence of currents in the ocean results in a turbulent bottom boundary layer with a thickness on the order of meters to a few tens of meters. Waves produce a boundary layer only when wave oscillatory motion extends to the seafloor, a condition that is satisfied when water depth is less than half the wavelength of surface gravity waves. The boundary layer produced by waves in the ocean is most often turbulent, with a thickness of the order of 0.1 m. The disparity in wave- and current-boundary-layer thickness has several important consequences, including wave-generated bed shear stresses that are generally higher than current-generated stresses, the confinement of combined wave–current turbulence to the region of the wave boundary layer, and a large gradient in shear stress and turbulent mixing near the top of the wave boundary layer when wave shear velocities are significantly larger than current shear velocities.

Theory

Analyses of wave–current interactions are commonly carried out on timescales long enough to average over many individual waves and short enough that the currents can be considered quasi-steady. Hourly averaged currents and wave conditions are often used to characterize effects of wave–current interaction. Near the seafloor, the velocity profile associated with the currents is logarithmic under steady, uniform flow conditions

$$u_c(z) = \frac{u_{*c}}{\kappa} \ln \frac{z}{z_{0c}},$$

where u_c is current velocity, u_{*c} is current shear velocity, κ is von Karman's constant (0.41), z is elevation above the seabed and z_{0c} is a roughness parameter. In the absence of waves, z_{0c} is related to the physical roughness of the bed. When waves are present, an apparent roughness associated with the presence of the wave boundary layer dominates the roughness parameter z_{0c}. The applicability of the equation above is limited to near-bed depths greater than the height of the wave boundary layer, δ_w. Wave boundary layer height, assuming turbulent flow, can be estimated as $\delta_w = u_{*w}/\omega$, where u_{*w} is wave shear velocity (discussed below), $\omega = 2\pi/T$, and T is wave period.

The velocity of wave-generated water motion varies throughout the wave period. The wave-generated velocity just above the seabed (at the top of the wave boundary layer), termed the bottom or near-bed wave orbital velocity, u_b, can be related to surface wave conditions and water depth using linear wave theory. For monochromatic waves

$$u_b = u_{bm} \cos \omega t, \quad u_{bm} = \frac{\pi H}{T \sin h(kh)},$$

where u_{bm} is maximum near-bed orbital velocity, t is time, H is wave height, $k = 2\pi/L$, L is wavelength, and h is water depth. When a spectrum of waves is present, as is typical of coastal environments, u_{bm} is most accurately determined by applying the above equation to each frequency band in the full wave spectrum to determine the average or significant maximum near-bed orbital velocity (e.g., Madsen, 1994); significant orbital velocity is analogous to significant wave height.

The time-varying wave orbital velocity at the top of the wave boundary layer results in a time-varying bed shear stress. It is common practice in calculations of wave–current interaction to characterize wave-generated bed shear stress, and associated turbulent mixing within the wave boundary layer, in terms of the maximum value of near-bed wave orbital velocity, u_{bm}. Wave shear velocity, u_{*w}, or bed shear stress, τ_{bw}, can be related to u_{bm} through the equations for an oscillatory boundary layer (e.g., Smith, 1977; Grant and Madsen, 1979) or a wave friction factor, f_w:

$$\tau_{bw} = \frac{\rho}{2} f_w u_{bm}^2,$$

where ρ is fluid density. Wave friction factor is a function of wave orbital amplitude ($a = H/[2\sin h(kh)]$) and bed roughness, k_s. A number of empirical relationships for f_w are available, such as:

$$f_w = 0.04\left(\frac{a}{k_s}\right)^{-1/4} \quad \text{for } \frac{a}{k_s} > 50,$$

(Fredsøe and Deigaard, 1992). Because of the dependence of u_{bm} on water depth, τ_{bw} decreases with increasing depth for a given set of wave conditions.

When waves and currents both contribute to near-bed flow, the velocity profile of the currents within the wave boundary layer can be expressed as

$$u_c(z) = \frac{u_{*c}^2}{\kappa u_{*cw}} ln \frac{z}{z_{0c}}, \quad z < \delta_w,$$

where u_{*cw} is the combined wave–current shear velocity and z_0 is the hydrodynamic roughness related to the physical roughness of the bed. The combined flow shear velocity, u_{*cw}, depends on the shear velocities associated with the current, u_{*c}, and with the waves, u_{*w}. The wave–current shear velocity can be found from the combined-flow bed shear stress as,

$$\tau_{bcw} = [(\tau_{bw} + \tau_{bc} \cos \varphi)^2 + \tau_{bc}^2 \sin \varphi^{1/2}] = \rho u_{*cw}^2$$

where φ is the angle between the direction of wave propagation and the direction of the currents, and τ_{bc}, τ_{bw}, and τ_{bcw} are the current, wave, and combined wave–current bed shear stresses, respectively. In this case, wave boundary layer thickness and turbulent mixing within the wave-boundary-layer scale with u_{*cw} rather than u_{*w}.

Solutions and applications

Solving the equations given above for $u_c(z)$ requires specification of z_0 and matching the profiles for current velocity above and below the wave boundary layer at the top of the wave boundary layer. Often, particularly in shallow water, wave-boundary-layer flow is fully rough, so that z_0 is just proportional to the physical roughness length of the bed, k_s. Wave-formed ripples on the bed typically dominate bottom roughness in shallow, sandy coastal environments, though grain roughness and saltating grains also contribute to bottom roughness, particularly when ripples are very small or absent. Current shear velocity, u_{*c}, which also must be specified when calculating the velocity profile $u_c(z)$, is seldom known in advance. In practice, a measured value of current velocity at some level near the bed is specified, and an iterative calculation is performed to determine the value of u_{*c} that is consistent with the measured velocity given the bottom roughness parameter. The equations for $u_c(z)$ provided here assume a linear eddy viscosity of the form $\nu_e = \kappa u_* z$; within the wave boundary layer $u_* = u_{*cw}$ while above it $u_* = u_{*c}$. This form of eddy viscosity, while yielding a simple analytical solution for $u_c(z)$, is discontinuous at the top of the wave boundary layer. Other formulations for ν_e exist that are continuous across the top of the wave boundary layer (e.g., Wiberg and Smith, 1983), but most of these require a numerical solution for $u_c(z)$. Higher-order closures have also been used.

Solving the equations for current velocity within and above the wave boundary layer yields a characteristic profile exhibiting an inflection near the top of the wave boundary layer (Figure W5). Current velocity within the wave boundary layer is more uniform than is the profile above it owing to the larger shear velocity (u_{*cw}) in the wave boundary layer. The zero-velocity intercept of a semilogarithmic line drawn through the velocity profile above the top of the wave boundary layer gives the apparent roughness felt by the currents above the wave boundary layer (Figure W5). The equations for $u_c(z)$ given above can be rearranged to solve for the apparent roughness, z_{0c}, giving

$$z_{0c} = \delta_w \left(\frac{z_0}{\delta_w}\right)^{\lambda}, \quad \lambda = \frac{u_{*c}}{u_{*cw}}.$$

Resulting values of apparent roughness are often several orders of magnitude larger than the roughness parameter associated with the physical roughness of the seabed.

Field observations of bottom boundary flow motivated the initial formulation of the theory of wave–current interaction, but the first comprehensive wave–current interaction models (Smith, 1977; Grant and Madsen, 1979) were developed before there were adequate data available to test them. Since that time, many field studies of near-bed waves and currents have been carried out in wave-dominated coastal environments around the world. Some laboratory studies have also been performed. These have demonstrated the importance of waves in increasing bed shear stress above values generated by currents alone. Under storm conditions, waves can dominate the combined wave– current bed shear stress across most or all of the continental shelf. Calculated and measured values of current shear velocity have been shown to agree reasonably well in

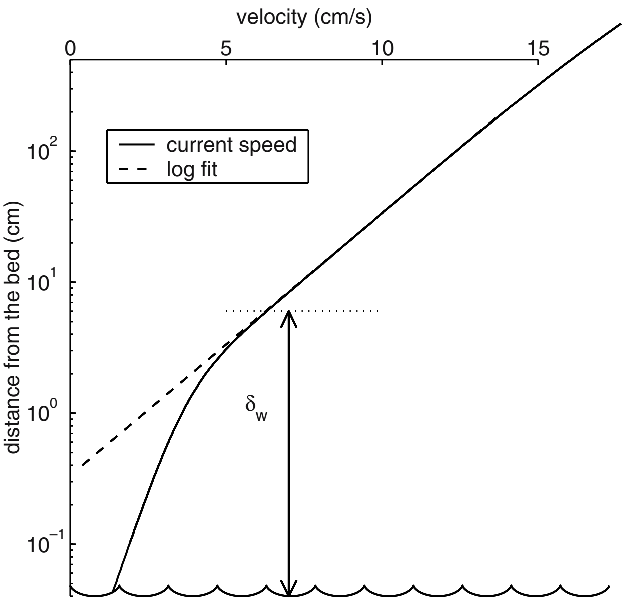

Figure W5 Profile of near-bed current illustrating the effect of wave–current interaction. Profile slope changes near the top of the wave boundary layer (δ_w, indicated by the horizontal dotted line) owing to differences in shear velocity above and below δ_w when waves and currents are both present. The slope of a semi-logarithmic line fit to the profile above δ_w is related to current shear velocity, u_{*c}, and the zero-velocity intercept of the line is the apparent bottom roughness felt by the current, z_{0c}. The profile shown in the figure is cut off above the level, z_0, at which the velocity reaches zero.

a number of studies. However, calculated values depend on bed roughness, a term that is difficult to predict because of its dependence on bedform height and spacing, which vary in ways that are not fully understood. Nonuniform flows and stratified flows also complicate the application of wave–current interaction models to field data.

Increases in bed shear stress, turbulent mixing within the wave boundary layer, and apparent bottom roughness associated with wave–current interaction at the seabed have implications for a variety of processes. For example, observations from a number of continental shelves have concluded that bottom drag coefficients for near-bed currents can be increased by up to an order of magnitude larger when waves are present. This is important for studies of wind-driven coastal ocean circulation. Effects of wave–current interaction on bottom drag have been incorporated into models of ocean circulation applied to the coastal ocean.

Sediment transport in coastal environments is strongly affected by wave–current interactions. Coastal currents in many locations are insufficient to mobilize sediment outside of the nearshore zone. In these regions, it is only when moderate to high wave conditions are present that bed shear stresses are sufficient to mobilize sediment at the seabed.

Even at depths of 50–100 m, mean winter combined wave–current shear velocities can be considerably larger than current shear velocity. The wave boundary layer, because of its high shear velocity, is able to maintain both higher concentrations of sediment and coarser sediment in suspension than can the overlying current boundary layer. When differences between u_{*cw} and u_{*c} are large, gradients in suspended sediment concentrations near the top of the wave boundary layer can cause significant stratification which inhibits turbulent mixing and modifies near-bed flow and sediment transport.

WAVE-DOMINATED COASTS

Price (1955) used the term *wave-dominated coasts* to describe the morphology of depositional shores where consistent, relatively large waves, with their associated strong wave-generated currents, have produced a smoothed shore of sandy sediments. Where such shores are building seaward (prograding), sand beaches associated with long barrier islands and prograding beach ridges are the dominant intertidal habitats. As a generalization, coasts with small tidal ranges (microtidal = <2 m (Davies, 1964)) are dominated by wave energy, thus most wave-dominated coasts are microtidal. On the other hand, coasts with large tidal ranges (macrotidal = >4 m) are typically dominated by tidal energy, and were hence termed *tide-dominated coasts* by Price. Coasts with intermediate wave energy and tidal ranges (typically mesotidal = 2–4 m) were termed *mixed-energy coasts* by Hayes (1979).

Wave-dominated non-deltaic coasts

Between major rivers on wave-dominated coasts, the shore is typically occupied by long, uninterrupted barrier islands. Inasmuch as wave-dominated barrier islands occur most commonly on microtidal coasts, the barrier islands are typically backed by open-water bays and lagoons. The sediment patterns of barrier islands show a simple gradation of grain size from coarse to fine away from shore as a result of decreasing bottom agitation by waves with increasing water depth.

Barrier islands occur primarily on depositional coasts on the trailing edges of continental plates, or on enclosed tideless seas such as the Baltic and the Mediterranean. Barrier islands are the dominant coastal type along the Atlantic and Gulf coasts of the United States, with those on the Gulf Coast of Texas, the Outer Banks of North Carolina, and Northeast Florida being wave-dominated. Tidal inlets are widely spaced on wave-dominated barrier islands (e.g., over 40 km apart in North Carolina). See Davis (1994) for a detailed synthesis of the barrier islands of the United States.

Most barrier islands have formed within the last 4,000–5,000 years during a near stillstand in sea level. Two types of barrier islands may be present—those that consistently migrate landward (retrograding) and those that build seaward (prograding). How an island builds depends upon the ratio of relative sea-level change to sediment supply. Where the sediment supply is inadequate or sea level is rising rapidly, the island retreats landward. Sediment supply for an island can be diminished through several natural mechanisms and by dams and jetties.

Retrograding barrier islands are composed of coalescing washover fans and terraces that are overtopped at high tides, usually several times a year. Stratigraphically, a relatively thin wedge of sand and shell from the washover terrace overlies back-barrier sediments, which are typically composed of muddy sediments deposited in the lagoons behind the islands. Prograding barrier islands are composed of multiple beach ridges. Stratigraphically, they consist of sand 8–10 m thick which has prograded over offshore muds.

Wave-dominated deltas

On wave-dominated coasts, where the rivers have enough sediment load to have filled the antecedent lowstand valley and build a bulge in the shore (within the time frame of the present highstand), the resulting river deltas are typically referred to as *wave-dominated deltas* (Fisher, *et al*., 1969; Galloway, 1975). A generalized model of a wave-dominated delta is given in Figure W6. Note the arcuate shape of the delta, which is comprised mostly of prograded beach ridges. The prograded sand sheet associated with such deltas is typically thick because of the massive shorefaces that are created by the large waves.

The depositional patterns of sand at wave-dominated river mouths is illustrated in Figure W7 (modified after Wright, 1977). On river mouths where waves approach the shore with a parallel orientation (normal wave incidence), the crest of the submerged river-mouth bar is arcuate in shape and projects straight offshore with the intertidal portion of the bar being covered with swash bars that migrate more or less straight onto the shore. With oblique wave incidence, the river mouth, as well as the submerged river-mouth bar, is diverted in a downdrift direction.

The São Francisco delta on the coast of southern Brazil, which bears a close resemblance to the general model given in Figure W6, is a spectacular example of a wave-dominated delta. The average tidal range is 1.9 m, which is on the border between micro- and mesotidal conditions. However, the offshore slope is steep, and waves are exceptionally large for deltaic shores. According to Coleman and Wright (1975, p. 131), more wave energy is expended in 10 h on the São Francisco delta front than in 365 days on the Mississippi delta shore. The result is a smooth-faced delta plain dominated by beach ridges and coastal dunes. The composite stratigraphic column for this delta shows a thick sequence of sandy beach, dune, and upper shoreface sediments in the upper half of the stratigraphic column.

Wave-dominated estuaries

The concept of tide and wave dominance has also been applied to estuaries by Dalrymple *et al*. (1992). However, they state that estuaries are unlike many other coastal systems, because they are "geologically ephemeral." If the rate of sediment supply is sufficient to eventually fill the lowstand valley within which the estuary is located, the filled valley then becomes a delta. The estuaries they term wave-dominated are composed of a sand body complex (barrier/tidal inlet) at the entrance, a muddy central basin, and a bayhead delta system. Their general model for this type of estuary is given in Figure W8.

WAVE ENVIRONMENTS

Introduction

Wave environments are those area of the seas and oceans that have similar wave sources and climatologies. The environments are closely related to wave generating systems, namely the global and regional wind and cyclonic regimes, and second to the shape and orientation of the oceans and their surrounding coastlines.

Waves are the most characteristic surface feature of the globe, with a presence over 71% of the surface. They are also the most transitory feature as they continually form, travel, and ultimately, after a few minutes to days, dissipate their prodigious energy. As ephemeral as waves are, they are ever present, moving across the seas and great oceans, and at the coastline supplying on the order of 2.5×10^9 kW energy each year (Inman and Brush, 1973) to build, maintain, rearrange, and erode the coastal systems. This represents over half the energy in the coastal zone.

The seas, oceans, and water column play a passive role in the formation and movement of waves. While waves do move water, their source of energy and movement comes from external sources. For ocean or gravity waves that source is wind, particularly the great zonal westerly and trade wind systems, including cyclones in all their forms.

Wave sources

Ocean waves are entirely dependent on wind for their formation, and on a global scale can be defined by the location of the zonal wind systems. In the high latitudes are the polar easterlies (>70° latitude), in the mid-latitudes the strong westerlies (30–70°), in the subtropics the most extensive, though moderate wind system, the trade winds (30–70°), while straddling the equator are the quieter doldrums (10°N–10°S). These idealized wind systems and their ocean impacts are however, substantially modified by continents and oceans, seasonal shifts, latitude and in high-latitudes sea ice. In addition, cyclones (tropical, east coast, and mid-latitude) while more limited in extent generate the world's biggest waves. At a regional scale the monsoons and local sea breeze wind systems all generate waves and have important impacts on their regional wave environments. Finally, the Coriolis effect plays a major role in redirecting waves as they travel across the oceans veering wave direction to the right in the Northern Hemisphere and left in the Southern Hemisphere. An overview of wave environments must therefore take all these factors into account.

Wave generation

Waves are generated by the wind blowing over a stretch of water (estuary, lake, sea, or ocean). Wave height and period will both increase with increasing wind velocity and duration, together with length of fetch, the length of ocean over which the wind blows, and uniformity of wind direction. Water must also be deep (>150 m) otherwise the higher waves will shoal and break. The largest waves are therefore produced in those parts of the world's deep oceans where strong, unidirectional winds, blow for long periods (days) over long stretches of ocean (1,000 km). The single most important factor is wind speed, with wave energy increasing exponentially with increasing wind speed.

Most of the worlds wind systems the polar easterlies, trades, and doldrums are low to moderate velocity winds with wind speed rarely exceeding 12.5 m s^{-1}, and while they might blow for long periods, over long section of oceans, particularly the trade winds, they are not capable of producing high waves, with trade wind waves less than 3 m 90% of the year and less than 2 m 50% of the year (Young and Holland, 1996). In addition, the polar eastleries blow over land in Antarctica, and for much of the year, over sea ice in the Arctic.

Wave sources

The world's largest and most influential wave environments is that produced under the westerly wind stream between 30° and 70° latitude, but focused on 50–60°N and S. In addition to the strong flow of westerly winds are the mid-latitude cyclones. At any time between 6 and 15 cyclones are embedded in this westerly stream, encircling the globe at these latitudes. The cyclones form year round over the Southern Ocean and more in the winter season over the North Pacific and North Atlantic oceans. The cyclones and their associated winds exceed 15 m s^{-1} 10% of the year, and 10 m s^{-1} 50% of the year. They generate waves 2–3 m high 90% of the time across the Southern Ocean, and in excess of 5–6 m 10% of the time in both hemispheres (Figure W9; Young and Holland, 1996).

Secondary cyclonic sources are the East Coast Cyclones that form off the east coasts centered around 25–35°N and S. They occur in the United

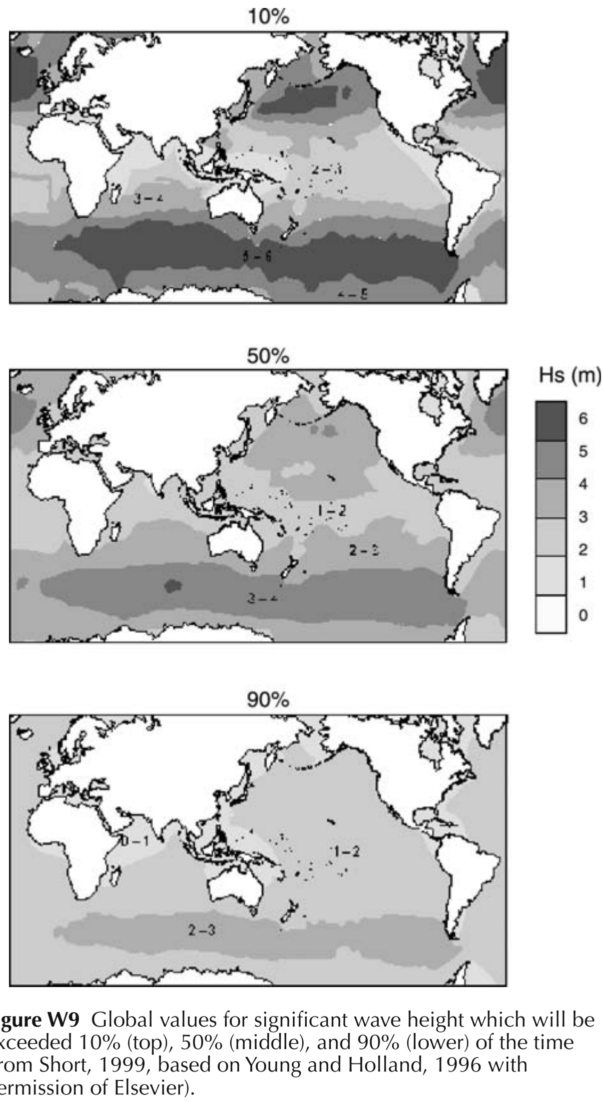

Figure W9 Global values for significant wave height which will be exceeded 10% (top), 50% (middle), and 90% (lower) of the time (from Short, 1999, based on Young and Holland, 1996 with permission of Elsevier).

States (the northeast storms), southeast Australia (east coast cyclones), south Brazil, and South Africa. In Australia they form on average 10 times a year in all months with an early winter maximum and regularly generate waves in excess of 10 m, with waves recorded up to 19 m. Tropical cyclones (hurricanes, typhoons) are generated in summer months between 5° and 15°N and S toward the warmer western side of the tropical oceans. While they can generate both high seas and associated storm surges in affected regions (10–30°N & S), their low and seasonal frequency (several per year in each region), and variable source area and erratic trajectory, means that they do not have a significant impact on longer-term wave climates.

Important regional winds include the reversing monsoons of India and southeast Asia, northern Australia and central Africa, and the local sea breezes that can affect most of the world's coast, though more so in the mid- to lower latitudes.

All the above wind and cyclonic systems vary spatially, shifting with the seasons, and temporally in terms of occurrence and intensity. Some such as polar easterlies and trade winds are relatively uniform in direction and velocity and blow over large areas of oceans. All the cyclonic sources are more variable in their occurrence, trajectory, and wind direction and speed. Both the monsoons and tropical cyclones are seasonally dependent, and like weather and climate all have a high degree of variability, both in terms of location, trajectory, frequency, duration, and intensity.

Davies (1964, 1980) was the first to put some sense into this seemingly wide range of wave sources and types. He developed a morphogenetic classification of the world's wave environments, based on their wind sources, their latitudinal location, and the nature and direction of wave travel.

Global wave environments

Davies identified four major deepwater wave environments the high-energy storm wave of the upper mid-latitudes, the west coast swell, the east coast swell, and finally low-energy protected coasts of both polar and tropical regions (Table W5 and Figure W10).

Storm wave

The most important and most energetic wave environment is the storm wave environment located between 40° and 60°N and S, under the circumpolar west wind belt and its migratory mid-latitude cyclones or sub-polar lows. This is a region where all the ingredients for high waves are found. Winds exceed 15 m s^{-1} 10%, 10 m s^{-1} 50%, and 5 m s^{-1} 90% of the time. While they rotate around, the cyclones at any given latitude tend to dominate from a relatively uniform direction (south through west). In the Northern Hemisphere there is the wide fetch of the North Pacific and North Atlantic oceans, while in the Southern Hemisphere there is the world's only continuous stretch of ocean the circumpolar Southern Ocean, providing in principle unlimited fetch, all across deep oceans with few impediments to wave generation or movement, such as islands or reefs.

Storm wave environments are exposed to persistent strong westerly winds, year round in the Southern Hemisphere, and in the winter season in the Northern Hemisphere. They produce the world's highest waves averaging over 2–3 m 90% of the year and 5–6 m 10% of the year (Young and Holland, 1996), with extreme waves reaching several meters. Periods are 10–14 s, however, being a *sea* environment in the area of generation, waves are high, short, steep, and highly variable in both size, shape, and direction (Table W5). Sailors often use the term confused seas when referring to such conditions, with white caps and "rouge" or "freak" breaking waves characteristic of such environments. Wave direction is predominately to the west, with the Coriolis effect deflecting waves equatorward in both hemispheres.

West coast swell

West coast swell refers to the long persistent swell that reaches the west coast of many of the world's mid- to low-latitude continents, including the west coast of the Americas, Africa, Australia, and New Zealand. The *swell*, unlike the storm seas, refers to waves that have left the area of wave generation, the storm wave environment, or the wind has stopped blowing. When this happens the sea waves quickly reform into lower, longer, faster, more uniform swell waves, uniform in size, shape, and direction of travel. Once transformed into swell they are able to travel across deep oceans for thousands of kilometers with minimal loss of energy (Figure W11). The waves are however, affected by the Coriolis effect, which turns them equator-ward causing the initially westerly waves to arrive from the northwest in the Northern Hemisphere, and southwest in the Southern Hemisphere. The swell is higher in the higher latitudes, slowly decreasing toward the equator. They are characterized by moderate to high (2–3 m 50%), long

Table W5 Characteristics of major world deepwater wave environments (from Short, 1999)

	Latitude/ location	Source—wave type	Seasonality	Deepwater height	Period	Direction
Storm wave	40–60°N & S S & W facing coasts	Mid-latitude cyclones—sea (roaring 40s raging 50s)	Northern Hemisphere—winter Southern Hemisphere—year round	High (2–5 m)	Long (10–14 s)	Westerly to south westerly
West coast swell	40–0°N & S west-facing coasts	Mid-latitude cyclones—swell	Northern Hemisphere—winter Southern Hemisphere—year round	Moderate–high (1.5–3 m)	Long (12–14 s)	Northern Hemisphere—NW Southern Hemisphere—SW
East coast swell	40–0°N & S east-facing coasts	Mid-latitude cyclones—swell	Northern Hemisphere—winter Southern Hemisphere—year round	Moderate (1–2 m)	Moderate–long (8–12 s) coasts	Northern Hemisphere—NE Southern Hemisphere—SE
East coast cyclones	25–35°N & S	East coast cyclones—sea/swell	Year round winter max	High (2–5 m)	Moderate–long (8–12 s)	Northern Hemisphere—E Southern Hemisphere—E
Trade winds	25–0°N & S exposed coasts	Trades—sea	Trades in winter	Moderate trades (0.5–1.5 m)	Trades—6–9 s	Parallel winds
Monsoons Tropical cyclones		Monsoons—sea Tropical cyclones—sea	Monsoons and tropical cyclones in summer	Low monsoons (0.5–1 m) TC—high	monsoons—4–6 s TC—short	NE & SE trades NW & SW monsoons TC—variable
Protected coasts	70–90° N & S pole facing coasts	Polar easterlies (+ sea ice)	Summer open water season	Low (0.5 m max)	Short (3–5 s)	NE
	Tropics 10–0°N & S	Doldrums	Year round	Low (<0.5 m)	short (<5 s)	variable

N, north; S, south; E, east; W, west; NW, northwest; SW, southwest; NE, northeast; SE, southeast; TC, tropical cyclones.

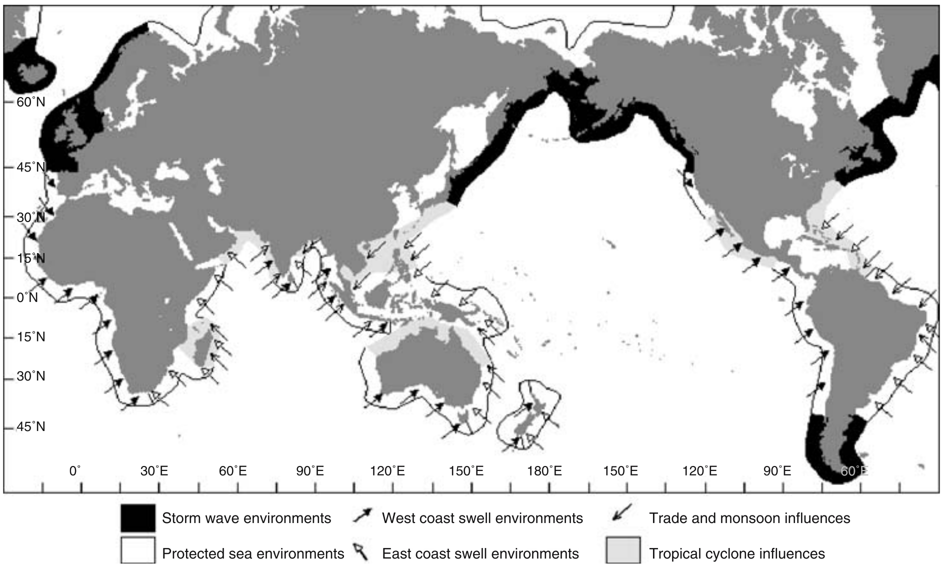

Figure W10 The world's major wave environments (adapted from Davies, 1980, and reprinted by permission of Pearson Education Limited). Note storm wave and west coast swell environments operate year round in Southern Hemisphere and during winter season in Northern Hemisphere.

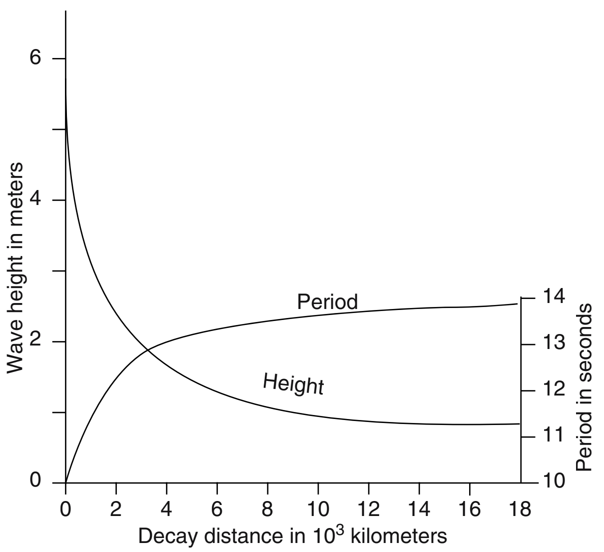

Figure W11 Transformation of sea (left) to swell (from Davies, 1980, and reprinted by permission of Pearson Education Limited).

period, uniform swell, with the period of higher swell associated with major cyclones, and lower swell in between, which in the Southern Hemisphere arrives on average 350 days a year. It is however, distinctly seasonal in the Northern Hemisphere (Table W5) where it delivers the big winter surf to Hawaii and the California coast. The higher winter swell and lower summer swell along the California coast, gave rise to the winter cut-summer fill beach cycle, which while applicable to California, has limited application in other wave environments.

East coast swell

East coast swell refers to swell generated in the storm wave environment, that travel equatorward, but has to undergo more refraction to reach the east coast of the continents below 40°N and S. Because of the initial trajectory and greater refraction required to reach the coast the swell is lower and arrives less frequently. On the southeast coast of Australia it arrives 200 days, as opposed to 350 days on the south coast, and averages 1.5 m down from 2.5 m on the south coast. It still provides a relatively persistent (60%) low to moderate swell. In addition, the mid- to low-latitude east coasts are exposed to additional wave regimes, which produce the world's most complex wave environment (Short and Trenaman, 1992). These include periodic east coast cyclones centerd on 40–25°, persistent trade winds peaking between 20° and 5°, summer tropical cyclones—hurricanes originating between 15 and 5° and summer sea breezes. All these wind regimes produce largely sea waves, ranging from lower frequency but high wave conditions associated with the cyclones, to moderate short waves with the trade winds, to low, short waves with the sea breeze. In addition, all these waves can be generated while swell arrives from the storm wave environment, resulting at times two wave trains arriving from different sources and directions. East coast swell environments also undergo an equatorward transition from predominately easterly swell conditions in the higher latitudes (40°), to increasing influence from first east coast cyclones (40–25°), strong trade winds influence between 20° and 0°, together with periodic tropical cyclones between 30° and 10°.

Protected wave environments

Protected wave environments refer to ocean and sea environments protected from ocean swell. They occur in both the tropics where they are protected by location in the doldrums, distance from major wave sources, and physically by coral reefs, island archipelagos, and smaller seas, as well as polar locations protected by sea ice from the low velocity polar easterlies. Around the Antarctic continent the Coriolis effect sends most of the westerly tending storm waves equatorward, ensuring further protection of the polar continent. All protected locations are devoid of swell, relying on local winds for generation of short, low seas, interspersed with long calms.

Other influences

Sea ice can form over the ocean surface as around Antarctica and across the Arctic Ocean, and seasonally along the shores of high latitude coasts such as Labrador and the Bering Sea. The ice both prevents the formation of waves, and at the shore prevents waves reaching the shore.

Islands and reefs

Islands and reefs wherever they occur in the mid-ocean or fringing the coastline will cause wave attenuation and refraction, leading to a reduction in wave height and changes in wave direction.

Breaker wave environment

All the above refers to deepwater sea and ocean wave environments. As waves move from deep to shallow water surrounding the continents and coastlines they undergo a predictable transformation from deep to shallow water waves. In doing so they may undergo wave attenuation as they shoal across the continental shelf and nearshore zone, wave refraction over variable submarine topography, and ultimately wave breaking. The height of the breaker wave is therefore not only a function of the deepwater wave environment, which will determine the maximum possible wave height,

Ocean Wave Generation, Transformation and Breaking

Wave type	Breaking	Shoaling	Swell	Sea
Environment	Shallow water–surf zone	Inner continental shelf	Deep water >>100m	Deep water>>100m Long fetch= sea/ocean surface Wind velocity waves Wind duration waves Wind direction = wave direction
Distance travelled	100m	1km	100s–1000s km	100s–1000s km
Time required	seconds	minutes	hours to days	hours to days
Wave profile				
Water depth	1.5 x water depth	<100m	>>100m	>>100m
Wave character	wave breaks wave bore swash	higher shorter steeper same speed	regular lower longer flatter faster	variable height high short steep slow
Example; height(m) period(s) length(m) speed(km/hr)	2.5–3m 12s 50–0m 15–0	2–2.5m 12s 220–50m 66–15	2m 12s 220m 66km/h	3–5m 6–8s 50–100m 33–45 km/h
distance travelled (km/day)			1600 km/day	800–1100 km/day

Figure W12 Ocean waves begin life as "sea waves" produced by strong winds blowing over the surface of the deep ocean. When they leave the area of wave generation they transform into lower, longer, faster, and more regular "swell" which can travel for hundreds to thousands of kilometers. As waves reach shallow water they undergo a process called "wave shoaling" which causes them to slow, shorten, steepen, and finally break. This figure provides information on the characteristics of each type of wave (from Short, 1993).

but also the shoaling processes, which can reduce wave height from between 0% and 100% (Figure W12).

WAVE FOCUSING

Swell waves traversing the inner shelf and shoreface undergo shoaling and refraction processes around seafloor topographic highs, such as offshore reefs or transverse sand ridges. These seafloor topographic irregularities act as a "bathymetric lens" (Speranski and Calliari, 2001) inducing refraction processes such that the wave orthogonals become compressed in the lee (shoreward) of the seafloor topographic high, that is, energy along the wave front becomes concentrated, resulting in a localized greater wave heights (Healy, 1987; Calliari *et al.*, 1998). Away from the zones of wave energy concentration the refraction may spread the wave orthogonals, dispersing the wave energy, and resulting in lower wave heights. As a result of this process, localized zones of higher wave energy may be concentrated or *focused* at the coastline (Finkl and Bruun, 1998). This feature of enhanced

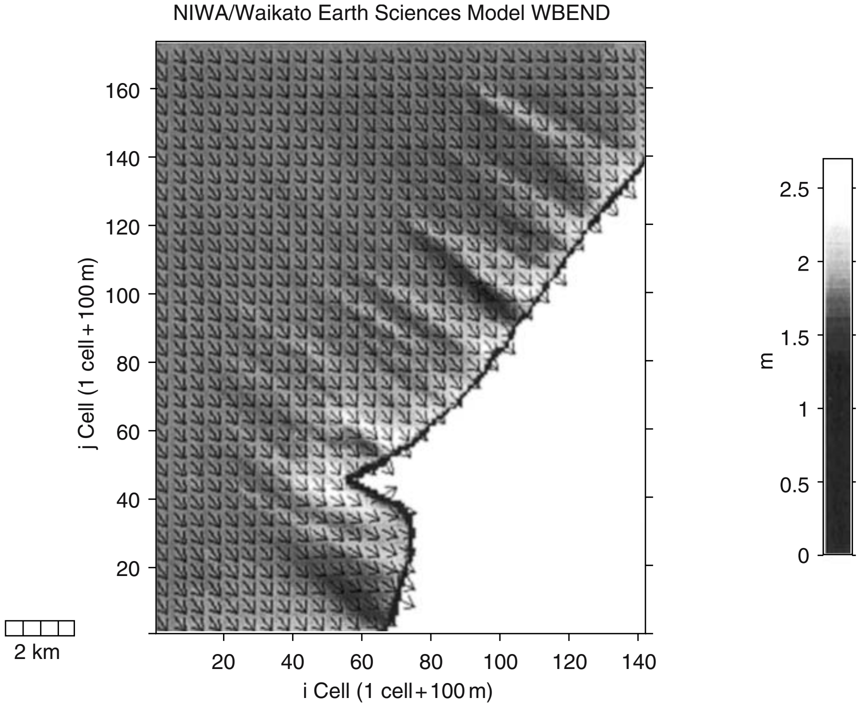

Figure W13 Wave refraction simulation commencing with deepwater wave height H_o = 1.63 m, and period T = 10.64 s. Note the general focusing of energy around the headland where the light patches show wave heights reach 2.5 m, and at various focused sectors further along the coast where waves reach 2.5 m at breaking. In between the major wave-energy focus zones are sectors of lower wave heights (*Source*: H. Easton, personal communication).

wave heights is well-known at headlands, but is not often recognized along sandy beach coastlines (Figure W13). Relatively short swell waves ($T \sim 7$ s) undergo little refraction when crossing the shoreface, but longer period waves ($T \geq 10$ s) may undergo marked refraction and focusing in water depths less than 50–60 m.

Some remarkable erosion and geomorphic effects may result from wave energy focusing along a sandy coastline (Finkl and Bruun, 1998). Sectors of beach subject to wave focusing exhibit localized higher breaking waves, resulting in enhanced wave set-up and run up, and thus are the zones where accelerated dune erosion or dune overwash occurs during episodic storm events. Local variation in littoral drift gradients result. Healy (1987) demonstrated from several examples of numerical wave refraction simulation that wave energy focusing exacerbated rates of erosion along sectors of frontal dune on generally long straight beaches. These sectors of "accelerated" erosion created "arcuate duneline embayments" of order 200–500 m long and 10–20 m amplitude which are cut into the dune face (Stephens *et al*., 1999). Similar effects have been reported along the coast of Brazil (Speranski and Calliari, 2001). Wave focusing has also been demonstrated as a fundamental cause of barrier spit breaching and breakthrough during a storm, and was identified as a factor in coastal hazard zone assessment (Healy, 1987).

On the inner shelf or shoreface seafloor, the zones of focused wave energy (higher waves) are subjected to greater bottom orbital velocities, and therefore potentially greater scour. These are the zones where side-scan sonar surveys demonstrate that large-scale ripples (often termed *"megaripples"* or *"coarse grained ripples"*) are formed in zones of otherwise fine sands (Healy *et al*., 1991; Bradshaw *et al*., 1994).

WAVE HINDCASTING

Definition

Wave hindcasts refer to the predictions of wind waves on the water surface for a past event. Wave nowcasts and forecasts similarly refer to the predictions in real time and in the future, respectively. But the relations or models used for predictions for a past, present, or future event are the same. The wave parameters of interest are wave height and period, and the required wind parameters for predictions are wind speed (U) and duration (t). Wind speed should represent an average, typically over a timescale of 1–15 min. Since wind waves represent an irregular undulated water surface comprising a multitude of superimposed wave frequencies, rather than a monochromatic wave, its parameters are best described in statistical terms. These terms are significant wave height (H_s) and significant wave period (T_s), which represent the average of the highest one-third of the parameters. However, in spectral-based computations, H_{mo} is used to represent wave height related to the total energy density as given by the zero-th moment of the wave spectrum. H_s is slightly larger than H_{mo} on most occasions, but they are equivalent for deepwater waves (Goda, 1974; Thompson and Vincent, 1985; Sorensen, 1993). Depth (d) and fetch (F) are the two water body variables required to compute wave parameters. Fetch is defined as a region of the water surface over which wind blows with speeds and directions that vary within a specified limit. The accepted limit for wind speed variation is 2.5 m/s (or 5 knots), and the same for wind direction is 45° (U.S. Army Coastal Engineering Research Center, 1984). In lakes and coastal water bodies, the fetch is often limited by land boundaries. The limiting lengths of fetch and duration give rise to three wave-generating conditions for a particular wind speed. A *fetch-limited* condition applies when the wind duration exceeds the wave travel time over the fetch. When the opposite happens, a *duration-limited* condition applies. If both the fetch and the wind duration are sufficiently large, a *fully arisen sea* develops for a particular wind speed. Depth of the water body is only important for shallow water wave hindcasts.

Wind waves or seas are distinct from swells. Swells are smooth undulations representing decayed and dispersed wind waves that have traveled out of their generating area, and are no longer subject to wind input. A typical ocean wave climate during a windstorm comprises both wind waves and swells.

Wind waves are generated by a complex interaction between the blowing wind and the water surface with the transfer of energy from the former to the later. Two wind-wave generation theories, both based on resonance phenomenon, were pioneered by Phillips (1957) and Miles (1957). The model proposed by Phillips (1957, 1960) is based on a resonant interaction between the forward moving turbulent pressure fluctuations and the generated free waves that propagate at the same speed as the pressure fluctuations. The pressure fluctuates with a varying magnitude and frequency, and is generated by turbulent eddies in the wind field. Phillips' model gives rise to a linear growth of the wave spectrum in time, and best explains the initiation and beginning stages of wave generation. A shear flow model proposed by Miles (1957) provides for a useful mechanism of momentum transfer. It considers the resonant interaction between the wave-induced pressure fluctuations and the free surface waves. An elaborate review of the wave generation processes can be found in an article by Janssen (1994).

In the following sections three methods of wave hindcasting, empirical relations, spectral models, and numerical models are discussed, with a brief history of the development of wave hindcasting methods.

Wave hindcasting methods

History

Probably, the earliest wave hindcasting method started with the pioneering works of Admiral Sir Francis Beaufort of the British Navy in 1805. His devised scale is popularly known as the Beaufort Wind Scale, and gives a qualitative description of winds and visible wave features. The modern history of the quantitative methods of wave hindcasting dates back to World War II. To forecast conditions during landings with amphibious vehicles, H.V. Sverdrup and W.H. Munk (1947) developed methods that related wind speeds to the higher and more distinct oscillations on the sea surface. The waves were characterized using the terms *significant wave height* and *significant wave period*. Statistical analysis of waves, later showed that these characteristic terms were equivalent to the average of the highest one-third of the wave parameters. More works followed with compilations of wave data, statistical analyses and derivation of refined relations (Bretschneider, 1952; Darbyshire, 1952; and Longuet-Higgins, 1952). Neumann (1953) derived wave spectral relations relating significant wave heights and periods. This was followed by the works of Pierson *et al.* (1955) that used Neuman spectra to derive graphical methods for engineering applications. Further developments are covered in the following sections and interested readers could consult Sylvester (1974) for more on historical developments.

Empirical relations

Using a simple wave energy growth concept and an early prediction method developed by Sverdrup and Munk (1947), Bretschneider (1952, 1958) refined the method by an improved calibration with a large amount of field data. It is known as the SMB (Sverdrup–Munk–Bretschneider) method. Deepwater (depth/wavelength >0.5) wave parameters that can be read graphically to establish a relationship between dimensionless significant wave heights and periods with dimensionless fetch and windstorm duration. In functional relationship, this means,

$$\frac{gH_s}{U^2} \quad \text{and} \quad \frac{gT_s}{2\pi U} = f\left[\frac{gF}{U^2}, \frac{gt}{U}\right], \qquad \text{(Eq. 1)}$$

where U is wind speed, F is fetch, t is windstorm duration, g is acceleration due to gravity, and H_s and T_s are significant wave height and period, respectively. With known wind speed, fetch, and duration, H_s and T_s could be read from graphs. In deepwater, the celerity of wave is $C = gT/2\pi$, and the ratio C/U is known as wave age, an important parameter defining the wave growth. The deepwater graphical relations were later presented as equations by Bretschneider (1970).

For a circular wind field such as a hurricane, Bretschneider (1957) proposed relations based on an analysis of 13 hurricanes in the Atlantic Ocean off the US East Coast. The relations are given as follows (U.S. Army Coastal Engineering Research Center, 1984):

$$H_{sp} = 16.5e^{0.01R\Delta P}\left[1 + \frac{208\alpha V_F}{\sqrt{U_R}}\right] \qquad \text{(Eq. 2)}$$

and

$$T_{sp} = 8.6e^{0.005R\Delta P}\left[1 + \frac{104\alpha V_F}{\sqrt{U_R}}\right], \qquad \text{(Eq. 3)}$$

where H_{sp} (feet) and T_{sp} (seconds) are peak significant deepwater wave heights and periods, respectively. R is distance (nautical miles) from the center out to the point of maximum wind velocity, ΔP is pressure difference (inches of mercury) from the center to the periphery of the hurricane, V_F is forward speed (knots) of the hurricane, U_R is maximum wind speed (knots) at R, and α is a correction factor based on the hurricane speed and is equal to 1 for a slow-moving hurricane. The calculated H_{sp} and T_{sp} develop in the vicinity of the point of maximum wind velocity.

Spectral models

Based on empirical fits to measured waves, three one-dimensional deepwater spectral models have been proposed. These three models assume wave growth in the direction of the wind. The Bretschneider Spectrum (Bretschneider, 1959) shows a period spectrum as a function of wind speed, fetch, and wind duration. The spectrum can be used to hindcast wave height and period, as also mentioned earlier for significant wave parameters. Pierson and Moskowitz (1964) proposed a wave frequency spectrum based on analysis of wave and wind records from British weather ships operating in the North Atlantic. Their analysis considered fully arisen sea for wind speeds (estimated at an elevation of 19.5 m) ranging from 20 to 40 knots. The wave frequency spectrum known as Pierson–Moskowitz Spectrum, representing only the fully arisen sea provides wave frequency as a function of wind speed. The JONSWAP (Joint North Sea Wave Project) Spectrum (Hasselmann *et al.*, 1973) is developed from wave and wind measurements with sufficient wind duration and provides a fetch limited spectrum. The spectrum gives a relation between wave frequency, and wind speed, and fetch. The *Shore Protection Manual* (U.S. Army Coastal Engineering Research Center, 1984) recommended a parametric method based on the JONSWAP spectrum for deepwater wave prediction, and replaced the earlier recommended SMB method. According to this method, the following relations are used for both fetch and duration limited conditions.

$$\frac{gH_{mo}}{U_A^2} = 0.0016\sqrt{\frac{gF}{U_A^2}}, \qquad \text{(Eq. 4)}$$

$$\frac{gT_p}{U_A} = 0.286\left(\frac{gF}{U_A^2}\right)^{1/3}, \qquad \text{(Eq. 5)}$$

and

$$\frac{gt_d}{U_A} = 68.8\left(\frac{gF}{U_A^2}\right)^{2/3}. \qquad \text{(Eq. 6)}$$

The adjusted wind speed, U_A is given by

$$U_A = 0.71U_{10}^{1.23} \qquad \text{(Eq. 7)}$$

where U_{10} is wind speed at 10 m above mean sea level, T_p is peak wave period, and other notations are as before. The significant wave period T_s is estimated from T_p as, $T_s = 0.95T_p$. If the actual wind duration (t) is greater than the calculated limiting wind duration (t_d), a fetch-limited case applies. A duration limited case applies if the converse is true, and an effective fetch is computed using equation 6 by replacing t_d with the actual duration of the storm, t. With the known effective fetch, equations 4 and 5 are used to estimate H_{mo} and T_p.

For fully arisen sea when $gt/U_A \geq 71{,}000$ and $gF/U_A^2 \geq 22{,}800$, the deepwater wave parameters are estimated as,

$$\frac{gH_{mo}}{U_A^2} = 0.243 \qquad \text{(Eq. 8)}$$

and

$$\frac{gT_p}{U_A} = 8.13. \qquad \text{(Eq. 9)}$$

If wind speed (U_z) is measured at a height z above mean sea level, the velocity at 10 m (U_{10}) can be estimated using one-seventh power law profile,

$$U_{10} = U_z\left(\frac{10}{z}\right)^{1/7}. \qquad \text{(Eq. 10)}$$

JONSWAP spectrum can also be used to estimate wave parameters resulting from a circular wind field such as a hurricane using a method developed by Young (1988). An equivalent hurricane fetch is first estimated using hurricane forward velocity and maximum wind velocity. This is then used to estimate wave parameters using the above equations.

For shallow water (depth/wavelength <0.5) applications, U.S. Army Coastal Engineering Research Center (1984) recommended the use of the following equations pertaining to the JONSWAP spectrum.

$$\frac{gH_{mo}}{U_A^2} = 0.283 \tan h\left[0.53\left(\frac{gd}{U_A^2}\right)^{3/4}\right]\tan h\left[\frac{0.00565(gF/U_A^2)^{1/2}}{\tan h\left\{0.53(gd/U_A^2)^{3/8}\right\}}\right], \qquad \text{(Eq. 11)}$$

$$\frac{gT_s}{U_A} = 7.54 \tan h\left[0.833\left(\frac{gd}{U_A^2}\right)^{3/8}\right]\tan h\left[\frac{0.0379(gF/U_A^2)^{1/2}}{\tan h\left\{0.833(gd/U_A^2)^{3/8}\right\}}\right], \qquad \text{(Eq. 12)}$$

$$\frac{gt_d}{U_A} = 537\left(\frac{gT_s}{U_A}\right)^{7/3}, \qquad \text{(Eq. 13)}$$

where d is water depth. However, shallow water wave parameters can best be estimated from deepwater waves using wave transformation techniques.

Numerical models

The above wave hindcasting methods do not give directional distribution of the wave field. The directional spectra are basically one-dimensional spectra corrected by a dimensionless directional spreading function that depends on the wave frequency and direction. The directional spectra can best be hindcasted by numerical models. Numerical models are used to forecast, nowcast, and hindcast waves or wave climates. The models are based on numerical integration of the spectral energy balance equation over a spatial grid. The general expressions for the source functions (Hasselmann, 1962) are the wind energy input, the nonlinear transfer of energy from one frequency to another by wave–wave interaction, and the energy dissipation by wave breaking, turbulence, and bottom friction. These source functions are then allowed to result growth of the wave spectrum as a function of time and space.

The SWAMP (Sea Wave Modeling Project) Group—a group of 10 institutes from Germany, Italy, Japan, the Netherlands, Norway, United Kingdom, and the United States—has examined and tested 10 numerical models on a common platform and has published their findings in 1985 (The SWAMP Group, 1985). They classified the existing models into three groups: Decoupled Propagation (DP) models, Coupled Hybrid (CH) models, and Coupled Discrete (CD) models. DP is a first generation wave model in which the spectral components evolve independent of each other in accordance with the linear input of source function. CH models work on the basis of a hybrid combination of parametrical wind-sea models with the standard discrete spectral representation for the swell components. The limitations of DP and CH models are eliminated in the CD models, which are based on discrete spectral representation for the entire spectrum of windsea and swell. WAVEWATCH III (Tolman, 1999) is a third generation model of this type developed at NOAA/NCEP in the spirit of WAM (Wave Modeling Group) model (WAMDIG [Wave Model Development and Implementation Group], 1988; Komen *et al*., 1994). It represents a further development of the original WAVEWATCH I model developed at Delft University of Technology (Tolman, 1991).

The best reference texts for wave hindcasting are *Shore Protection Manual* by U.S. Army Coastal Engineering Research Center (1984), *Basic Wave Mechanics for Coastal and Ocean Engineers* by Sorensen (1993), *Basic Coastal Engineering* by Sorensen (1997), *Coastal Engineering: An Introduction to Ocean Engineering* by Horikawa (1978), and *Dynamics and Modelling of Ocean Waves* by Komen *et al*. (1994). A brief review of wave prediction methods (Bishop and Donelan, 1989) can also be found in chapter 4 of *Applications in Coastal Modeling* by Lakhan and Trenhaile (1989).

WAVE POWER

Of the "implemented" systems to extract energy from the ocean, power from the waves is perhaps the one that has received most attention during the 20th century, from Pacifica (California) to Royan (France). The number of patents taken out, and of systems proposed, is impressive. Projects are being examined in several locations in Asia and the Pacific Ocean, in Canada and in Europe. Waves are considered a "small energy source" that can be profitably tapped by industrialized and less-developed countries alike.

Extraction systems utilize either the vertical rise and fall of successive waves in order to build water- or air-pressure to activate turbines, or take advantage of the to-and-fro, or rolling, motions of waves by vanes or cams which rotate turbines. Still another approach concentrates incoming waves in a converging channel, thus allowing the buildup of a head of water, which then makes it possible to operate a turbine. Wave refraction effects can be used to focus wave energy and they have played an expanding role in current wave-energy conversion thinking. However, in shallow waters the amount of such energy available is reduced due to shoaling and seafloor friction.

Most recently proposed schemes show economic feasibility. Japanese and British researchers have been in the forefront of research, though the Japanese have been closer to implementation, and Scandinavians have overtaken the British.

Conversion devices

Systems involve a movable body, an oscillating column, or a diaphragm and the "object" that moves floats is anchored on the seabed. Attenuator type devices in a two-dimensional case will provide only a 50% efficiency, unless dispersion waves strike the object only on one side. A superior apparatus must have a high absorption efficiency for a wide range of wave frequencies. Most currently considered primary wave converters are linear, two- or three-dimensioned. Among the latter are those systems known as Kaimei, Flexible Bag, and National Electronic Laboratory's Oscillating Water Column (NEL's OWC). Converters involving a movable body use vertical, rotational, lateral, coupled movable bodies or a raft or float. They include, respectively, the Point Absorber, Salter Duck (Figure W14), Wave Power Water Turbine, Bristol Cylinder, and Cockerell Raft. There are systems that double as breakwaters, such as the Pendulum and NEL's OWC. Some apparatus are moored, fixed on the shore or on the seabed. The Focusing Wave Energy System is in a somewhat separate category.

Based on *uses* energy conversion devices can be grouped into four "classes:" propulsion, buoy power supply, offshore plants, shore-based power plants. Another grouping considers rather conversion *methods:* utilization of the rise and fall sequence, of the rolling motion, or convergence to create a hydraulic head. A "*physics principles*" classification recognizes: intervention in wave orbits, utilization of the pressure field, acceleration devices, and use of the horizontal transport from breaking waves. A much older (1892) classification was based on *mechanical concepts*: motors operated by the rise and fall of a float, by to-and-fro wave movement, by the varying slope of wave surface, and by impetus of waves rolling up a beach. With about 40 different *systems* proposed over time still another grouping is possible: surface profile variations of traveling deepwater waves, subsurface pressure variations, subsurface fluid particle motion, and naturally or artificially induced unidirectional motion of fluid particles in a breaking wave.

Systems may intervene in the wave orbits, utilize the pressure field, be accelerative or utilize the water mass horizontal displacement. They may involve flaps and paddles; heaving, pitching and rolling bodies, pressure devices, rotating outriggers, pneumatic or cavity resonators, or be waves focusing, surging, or mixed systems.

Performance of systems

Satisfactory performance and economically sustainable results appear to have been achieved by several systems. Charlier and Justus (1993) list an air turbine driven by water oscillation in a vertical borehole (Royan, France, Gironde River estuary), floats activated by horizontal and vertical motion attached to a pier (Atlantic City, New Jersey and Pacifica, California—USA), a Savonius rotor operating pump (Monaco, Musée Océanographique), pump operated by a rising and falling heavy float (Monaco), low-head hydroelectric plant supplied from a forebay with converging channels (Pointe Pescade and Sidi-Ferruch, Algeria), air turbine buoys (Japan, United States, United Kingdom), air turbine generator (Osaka, Japan), Kamei barge with compressed-air chambers (Japan), hydraulic pumping over pliable strips in a concrete trough (Boston, MA, USA), autobailer bilge pump (Sweden), and a sea-lens concentration scheme (Norway). Still other schemes which either function or show promise are utilized in bouys and desalination plants.

The machine must be able to amplify the relatively low water head, have a broad range of response, be nonresonant, and have the capacity of responding to smaller waves, while simultaneously be able to withstand the effects of large storm waves.

Recent developments

Just before the dawn of the 19th century a patent was taken out in France to turn wave energy into mechanical energy by using a float. Several wave motors were patented in the 19th and 20th centuries which supplied electrical energy for buoys, pumps, lighthouses, and even small residences. Duckers (1989), Scheer and Gandhi (1994), Charlier and Justus (1993), Ross (1985, 1987), and Salter (1975a,b, 1976) among others, discussed the more recent devices tested and put into service. OWCs are perhaps the most promising scheme; indeed, being robust and utilizing relatively conventional, proven technology.

In 1990, Wave Energy Inc. took out patents contracts (hydraulic method) on the heels of several successful tests carried out at Scripps Institution of Oceanography for a wave pump and energy extraction system. Norwave conducted a feasibility study for a 5 MW plant on Java. Sixteen prototypes and ten "future prototypes" were listed by Duckers for the period 1965–92; several were operational for a while, but eventually abandoned; they were mostly installed in Japan, with one each in Great Britain, Denmark, Norway, and India, or planned for Japan, Scotland, the United States, among other locations. Eire has concentrated on devices and so have Korea and China; a small power

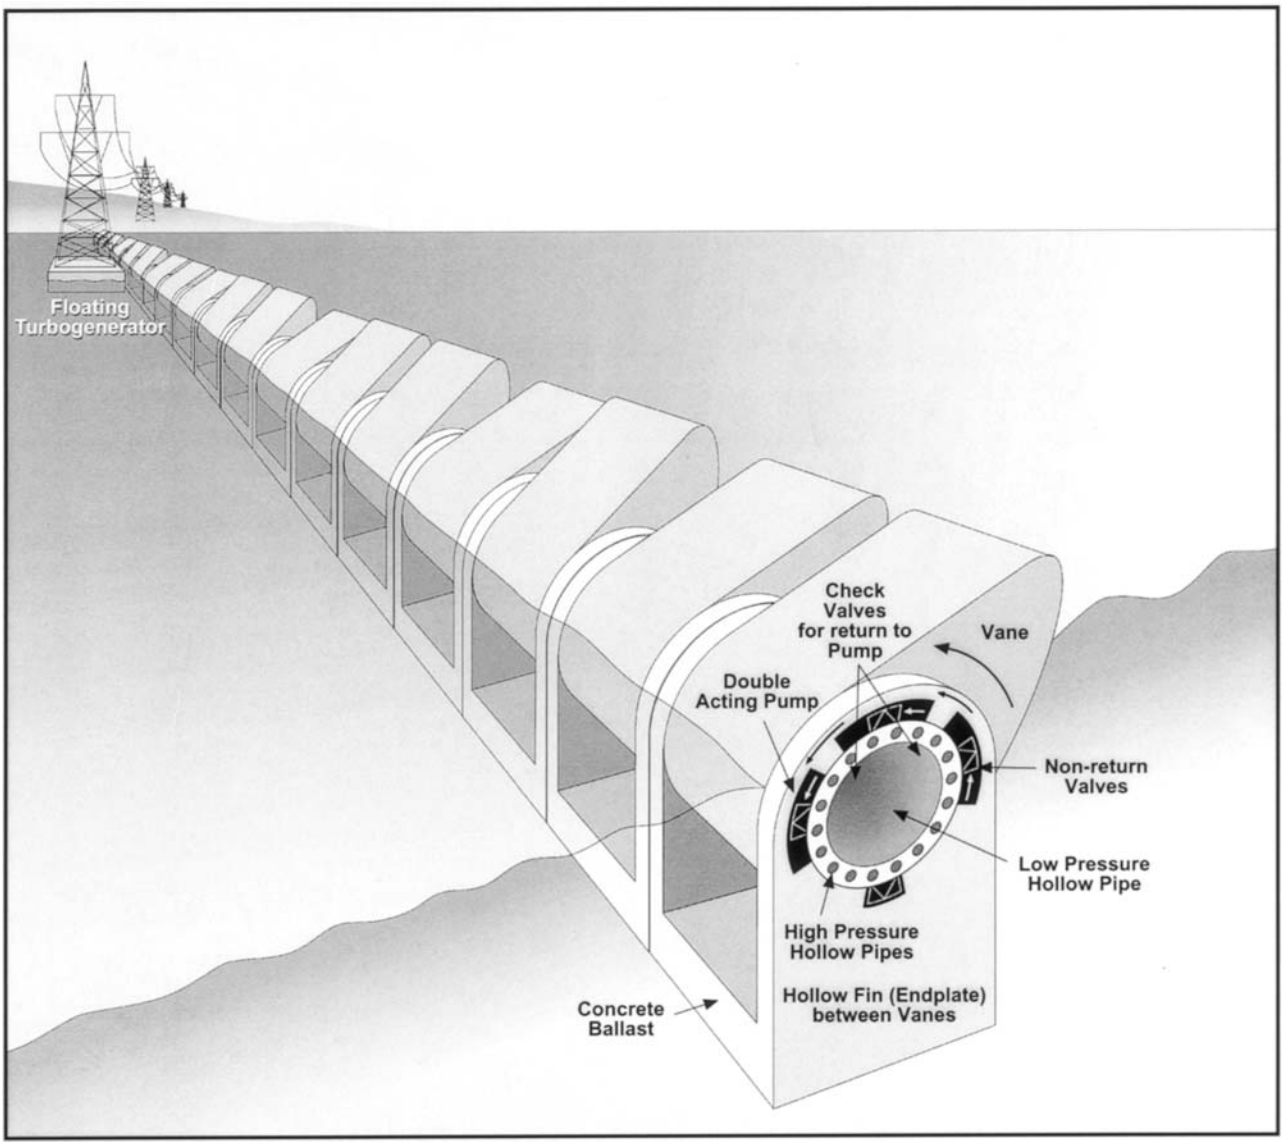

Figure W14 Schematic view of "Salter's Duck" (from Charlier and Justus, 1993, with permission from Elsevier Science).

plant (8 KW) was installed in the Pearl River estuary around 1991. China's interest in wave power has not diminished (Zhi, 1993; You and Zhi, 1995) and India has conducted surveys and tests (Sivaramakrishnan, 1992; Raju and Ravindram, 1996). Ocean Power Technology (USA) developed in 1995–96 a power system using the piezoelectric effect to generate electricity from waves; the bending of laminated sheets suspended from rafts secured on the seafloor generate electricity. The European Union supported in 1994 the construction of a full-scale 2 MW converter of the OWC type in Scotland (You and Zhi, 1995).

Mighty Whale is a Japanese constructed offshore floating wave power device, 50 m long and 30 m wide, the world's largest. It was moored in late 1998 off Gokasho Bay. Resembling a whale, it transforms wave motion into high velocity oscillating airflow, achieved near the "mouth," by three chambers; waves enter and exit through these ducts at their top, with air turbines driving electric power generators (one each of 10 and 50 kW and two of 30 kW). Electricity drives the air compressors.

Environmental impact

Wave energy is clean, safe, environment friendly, but its harnessing affects beaches, marine life, fishing, shipping, coastal tourism and recreation, and should be viewed in the overall picture of integrated coastal management.

Though limited, wave-energy utilization has thus some environmental consequences, biological, physical, and social. Marine organisms will be moderately affected, but may pose biofouling problems for the system. Fisheries will be impacted, differently according to species, though floating structures may act as a fish reef. More severe impact on fisheries is caused by seabed fixed apparatus.

Longshore currents may be rerouted, tidal currents influenced, particularly with apparatus fixed on the seabed, and coastlines may consequently be modified. Navigational problems may arise. Wave absorbers alter wave patterns and drift patterns of sand, thus possibly causing coastal erosion.

Production of electricity at an affordable cost, particularly in power deprived developing countries areas, may lead to implantation of new industries, and/or improvement of existing ones. A social and developmental "plus" may flow forth.

The future

If wave energy is to make a significant contribution to national energy demand, sustained research is needed into its application to the offshore production of hydrogen. Wave power has also been proposed for use in communications and spacecraft propulsion (Korde, 1990) and continues to be eyed for desalination plants (Crerar and Pritchard, 1991). In some countries, for example, Norway, successful plants have been abandoned because of the availability of huge oil reserves; only when these will have dwindled, will new enthusiasm for alternative sources of energy be rekindled there.

Further reading on this subject may be found in the following bibliography.

WAVE REFRACTION DIAGRAMS

Wave refraction diagrams are used to illustrate and predict the refraction of waves approaching the shoreline. They are an invaluable tool for understanding coastal morphology and processes, and their construction is practically standard practice in coastal engineering applications. Amongst others, wave refraction diagrams can be used to compute alongshore variations in wave energy and breaker angles, and subsequently longshore sediment transport rates and directions (see *Longshore Sediment Transport*). Wave refraction diagrams are also used to indicate the stability of embayed beaches (see *Headland Bay Beach*). A good summary and comparison of techniques to construct wave refraction diagrams is given in Wiegel (1964).

Theoretical background

The theoretical background to the wave refraction process is discussed in the section on *Waves*. Briefly, wave refraction is the bending of wave rays that occurs in intermediate and shallow water depth. As a result of wave refraction, wave crests become increasingly lined up with the bottom contours, thereby reducing the angle of wave approach. The refraction of waves is similar to the bending of light rays and the change in direction is related to the change in the wave celerity C through the same Snell's law

$$\frac{\sin\alpha_1}{C_1} = \frac{\sin\alpha_2}{C_2} = \text{constant}, \qquad \text{(Eq. 1)}$$

where α_1 is the angle of a wave front with the depth contour h_1 over which the wave is passing, α_2 is a similar angle measured as the wave front passes over the second depth contour h_2, C_1 is the wave celerity at the depth of the first contour, and C_2 is the wave celerity at the second contour (refer to Figure 7a in the section on *Waves*).

Wave refraction for coasts with parallel bottom contours

Changes in wave direction due to wave refraction on a straight coast with parallel bottom contours can be determined analytically using

$$\sin\alpha = \frac{C}{C_o}\sin\alpha_o, \qquad \text{(Eq. 2)}$$

where α is the angle between wave crest and depth contour at an arbitrary depth, α_o is the angle between wave crest and depth contour in deepwater, C is the wave celerity at an arbitrary depth, and C_o is the deepwater wave celerity. Computing sin α for different water depths simply involves solving equation 2. The relevant equations to do this computation are given in the section on *Waves*. Alternatively, a nomograph can be used to determine changes in wave height and direction due to refraction (Figure W15). For example, for a deepwater wave angle α_o of 60° and a deepwater wave length L_o of 100 m, the wave angle α in 10 m water depth is 38° and the refraction coefficient K_r is 0.79. Table W6 lists an example of wave refraction (and shoaling) over a bathymetry with parallel depth contours. It can be seen that wave shoaling results in an increase in wave height with decreasing depth ($K_s > 1$), whereas wave refraction reduces the wave height ($K_r < 1$).

Wave refraction for coasts with complex bottom contours

In reality, parallel depth contours rarely exist and in this case the wave refraction pattern has to be determined manually. Refraction diagrams for such conditions can be constructed in two ways. The first, known as the "wave-front method," is essentially a map showing the wave crests at a given time or the successive positions of a particular wave crest as it propagates shoreward (Johnson *et al*., 1948). Wave rays or orthogonals can then be drawn perpendicular to the wave crests to indicate the direction of wave travel. In the second method, known as the "orthogonal method," the wave rays are drawn directly (Arthur *et al*., 1952). The orthogonal method is considered the most practical, quickest, and widely used technique at present and will be discussed here.

A number of assumptions underly the orthogonal technique: (1) wave energy between wave rays remains constant, that is, there is no leakage

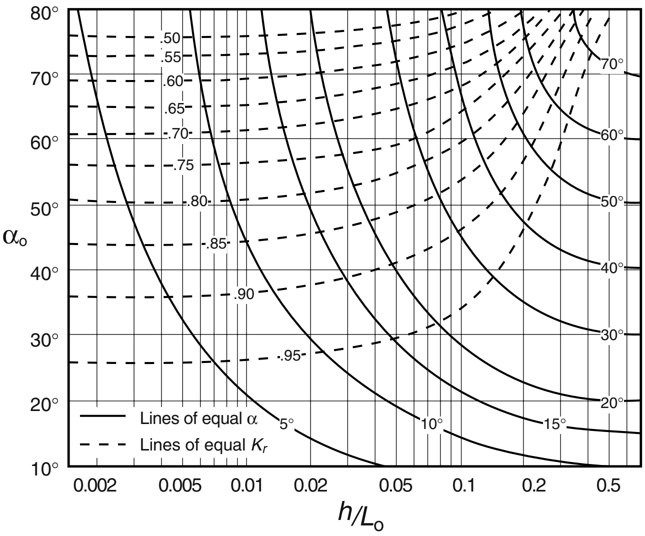

Figure W15 Change in wave direction and height due to refraction on a straight coast with parallel bottom contours (after CERC, 1984) (h = water depth, L_o = deepwater wave length, α_o = deepwater wave angle, α = wave angle, K_r = refraction coefficient).

of wave energy perpendicular to the direction of wave travel; (2) the direction of wave advance is parallel to the wave rays; (3) the celerity of a wave of a given period depends only on the water depth at that location; (4) changes in seabed topography approaching a coastline are gradual; (5) waves are long-crested, constant period, small amplitude, coastline and monochromatic; and (6) other factors that may affect wave refraction, such as currents, winds, and reflected waves are ignored.

Before constructing the wave rays, a tracing paper overlay is placed on the bathymetric chart. The shoreline and the bottom contours are then traced with all bottom irregularities within a local spatial scale of five wave lengths smoothed out. Mid-contour lines are then drawn between the existing contour lines. Subsequently, a set of evenly spaced and parallel wave rays from the chosen direction of wave approach are plotted up to the bottom contour closest to $0.5L_o$ and extended to the first mid-contour line. The number of wave rays should be selected to sufficiently cover the coastline. The closer the spacing between the rays, the greater the resolution when estimating wave energy at the coastline. Finally, for each mid-contour line the C_1/C_2 ratio should be computed, where C_1 represents the wave celerity of the deeper depth contour and C_2 represents the wave celerity of the shallower depth contour.

Table W6 Wave transformation characteristics for an incident wave with a deepwater wave height of 1 m, a wave period of 8 s and a deepwater wave angle of 45°

h, water depth; L, wave length; C, wave celerity; n, coefficient; α, wave angle; K_s, shoaling coefficient; K_r, refraction coefficient; H, wave height.

Starting with any one wave ray the following steps are taken in extending the wave ray from offshore to the coastline (Figure W16).

1. Extend the incoming wave ray to the mid-contour and determine the intersection point P.
2. Construct a tangent line to the mid-contour at point P.
3. Measure the angle α_1 between the tangent line and wave crest 1 (normal to wave ray 1) using a protractor.
4. Compute the angle α_2 between the tangent line and wave crest 2 using equation 1 and the C_1/C_2 ratio.
5. Using a protractor, construct wave ray 2 which is the line normal to wave crest 2 going through the intersection point.
6. Repeat the procedure for successive contour intervals and all incoming orthogonals.

Manually measuring and plotting wave angles using a protractor can be quite cumbersome. Templates have been constructed that preclude the manual measurement of wave angles. The template shown in Figure W17 is most commonly used and will be described here. The template should be constructed such that the length of the template is about 25 cm long and should be printed or copied on transparency paper. The following steps are taken in extending the wave ray from offshore to the coastline (Figure W18).

1. Extend the incoming wave ray to the mid-contour and determine the intersection point P.
2. Construct a tangent line to the mid-contour at point P.
3. Place the line on the template labelled "wave ray" along the incoming wave ray with the point representing C_1/C_2 1.0 at point P.
4. Rotate the template about the turning point R until the C_1/C_2 value corresponding to the contour interval being crossed intersects the tangent to the mid-contour at point S. The refracted wave ray now lies in the direction of the turned wave ray on the template.
5. Construct a line parallel to the turned wave ray on the template from P representing the refracted wave ray.
6. Repeat the procedure for successive contour intervals and all incoming wave rays.

Strictly speaking, point P is not the correct intersection point between the incoming and refracted wave ray. The "true" intersection point P′ is found by moving parallel to the turned wave ray until the distance AP′ is equal to the distance BP′ (Figure W18). This ensures that the distances travelled by the incoming and refracted wave rays within the contour interval C_1–C_2 are equal. However, if the change in depth between the

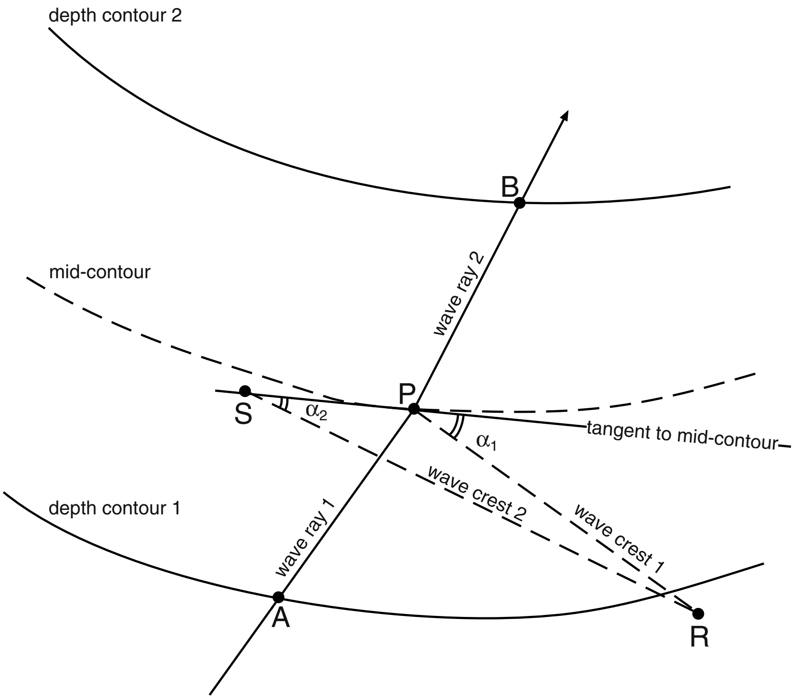

Figure W18 Construction of wave rays using a template (α_1 wave angle of the incoming wave, α_2 = wave angle of refracted wave).

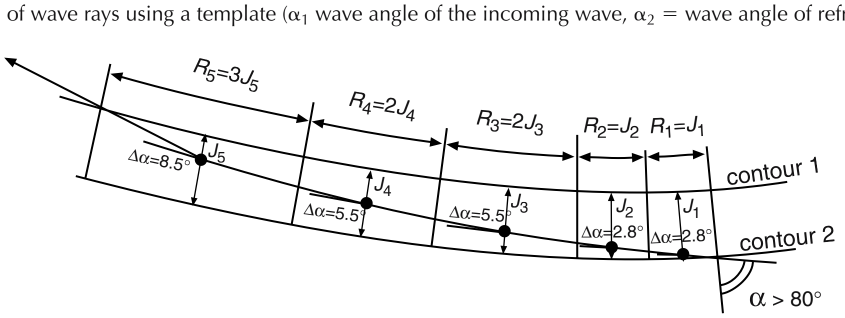

Figure W19 Construction of wave rays using the *R*/*J* method when the wave angle α is larger than 80° (after CERC, 1984). The wave ray has been constructed assuming $C_1/C_2 = 0.95$ (R = distance along wave ray, J = distance between contours, $\Delta\alpha$ = turning angle of the wave ray).

two contours is small and $C_1/C_2 < 1.2$, P and P′ will almost coincide and it is permissable to construct the refracted wave ray from P rather than P′.

For wave angles larger than 80°, the orthogonal method is no longer reliable and an alternative method of constructing wave rays must be used. The *R*/*J* method is generally used for this purpose and consists of the following steps.

1. Divide the contour interval to be crossed (from h_1 to h_2) into segments by transverse lines drawn perpendicular to the contours (Figure W19). The spacing R of the transverse lines is arbitrarily set at some small number times the distance J between the contours.
2. Determine the turning angle of the wave ray $\Delta\alpha$ from the *R*/*J* nomograph (Figure W20).

3. Turn the wave ray by the angle $\Delta\alpha$ and extend it to the middle of the segment.
4. Repeat the procedure for each segment in the sequence.

Once the wave ray crosses a new contour and the wave angle α is less than 80° the R/J method should be replaced by the orthogonal method.

Both the orthogonal and the R/J method can be used to construct orthogonals from shallow to deepwater. In this case, the same procedure can be employed, except that the ratio C_1/C_2 (>1) is replaced by C_2/C_1 (<1).

The variation in wave height due to wave refraction can be determined based on the principle that the transported energy between two adjacent wave orthogonals is conserved. By measuring the width between two orthogonals at depth h and in deepwater the refraction coefficient K_r is given by

$$K_r = \left(\frac{b_o}{b}\right)^{0.5}, \qquad \text{(Eq. 3)}$$

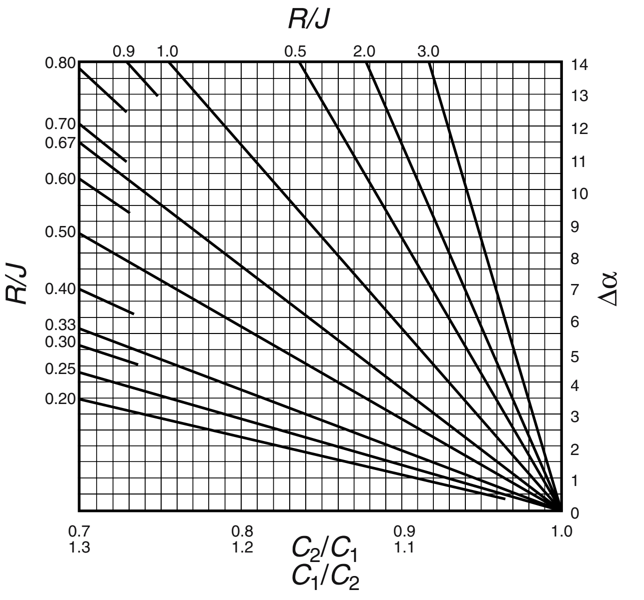

Figure W20 Nomograph to determine the turning angle of the wave ray $\Delta\alpha$ from the ratios R/J and C_1/C_2 (after CERC, 1984) (R = distance along wave ray, J = distance between contours, C_1 = wave celerity at contour 1, C_2 = wave celerity at contour 2).

where b and b_0 are the width between two wave rays at depth h and in deepwater, respectively.

An example of a wave refraction diagram in shown in Figure W21 which indicates the refraction pattern associated with submarine canyons. Note that the spacing of the wave rays is not constant; where more detail is required, such as in the vicinity of the canyons, the wave rays are spaced closer together. Strong focusing of the wave rays, known as wave convergence, occurs at the headland. At this location, $K_r > 1$ and relatively energetic wave conditions will prevail. Spreading of the wave rays, known as wave divergence, takes place at the heads of the canyons. As a result, $K_r > 1$ and the coastline landward of the canyons will experience relatively calm wave conditions.

Numerical wave refraction models

In the past, wave refraction diagrams were invariable constructed manually. Currently, numerical models are often used to construct wave refraction diagrams (e.g., Dalrymple, 1988). Such models, which often include the effects of wave diffraction, are much faster and more accurate than the manual method, but require considerable technical expertise and preparationary work (e.g., digitising the bathymetry). Rather than yielding orthogonals, the numerical analyses obtain solutions for wave direction and wave height for a finite number of grid cells that cover the area of interest. The obvious advantage of numerical wave refraction models is that once the model has been set up and found to perform satisfactory, a large number of scenarios (different incident wave direction and period) can be investigated with relative ease.

Waves

WAVES

In most coastal regions, waves provide the dominant source of energy to the nearshore. Although part of the incident wave energy is converted into heat or sound, or is reflected at the shore, a significant proportion of the energy is used for sediment transport and ensuing morphological change. An understanding of wave processes is therefore of fundamental importance when investigating nearshore sediment transport processes and morphology.

The characteristics of natural waves have received much attention in the oceanographic and coastal engineering literature. The classic book by Kinsman (1965) summarizes much of what was known about ocean waves in the early 1960s and remains authoritative. In the last three decades, advances in instrument design and data handling have considerably improved our knowledge of natural wave processes as described in Massel (1996). A succinct, but comprehensive overview of our current understanding of wave processes is provided by Komar (1998).

Wave analysis and statistics

An important characteristic of natural waves is that they are often highly irregular and made up of a range of wave heights and periods (Figure W22(A)). Hence, statistical techniques are required to properly describe the sea state in quantitative terms. Wave-by-wave analysis is one of the most common approaches to describe irregular waves. This technique consists of identifying the individual waves in the wave record using the zero-downcrossing method (IAHR, 1989) and determining representative wave parameters from the subset of wave heights and periods (Figures W22(B), (C)). An alternative method to describe the properties of irregular waves is spectral analysis (Figure W22(D)). The wave spectrum plots wave energy (variance) as a function of frequency (inverse of period) and can readily be used to identify the dominant wave frequencies in the wave record. In addition, the wave spectrum is useful for determining the partitioning of wave energy over distinct frequency bands (e.g., wind and swell waves). The directional wave spectrum can also be computed and plots spectral energy as a function of wave direction and frequency.

The two most common wave parameters to describe an irregular wave field are the significant wave height H_s and the peak wave period T_p. The significant wave height is sometimes denoted by $H_{1/3}$ and represents the average wave height of one-third of the highest waves in a wave record. The significant wave height approximately corresponds to visual estimates of wave heights. The peak period is derived from the wave spectrum and is defined as the wave period associated with the maximum wave energy. Other frequently used wave parameters to be derived using wave-by-wave analysis include $\overline{H}$ (mean wave height), H_{rms} (root mean square wave height), $H_{1/10}$ (average wave height of one-tenth of the highest waves), H_{max} (maximum wave height), T_z (mean wave period), T_s (mean wave period associated with H_s), $T_{1/10}$ (mean wave period associated with $H_{1/10}$) and T_{max} (maximum wave period associated with H_{max}).

Longuet-Higgins (1952) suggested that the probability distribution of wave heights in an irregular wave field can be described by the Rayleigh distribution (Figure W23)

$$P(H) = \frac{2H}{H_{rms}^2}\exp\left[-\left(\frac{H}{H_{rms}}\right)^2\right]. \quad \text{(Eq. 1)}$$

According to equation 1, the probability that a particular wave height has a value in the range $H + \delta H$ is given by the product $P(H)\delta H$. Thus, the probability of occurrence in a certain class range increases for increasing width of the class ranges. The probability that a particular wave height exceeds a prescribed value H_* is given by

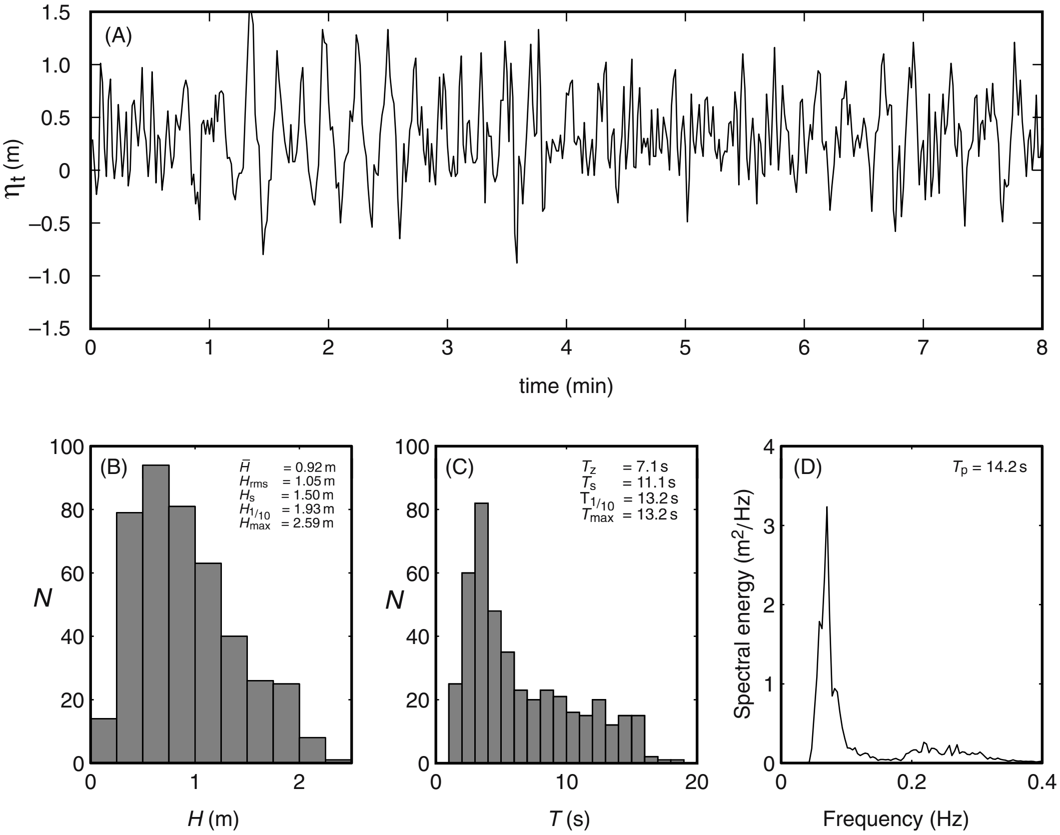

Figure W22 Analysis of 1 h of irregular offshore wave data: (A) time series of 8-min section of demeaned water surface elevation η_t; (B) frequency distribution of wave heights H; (C) frequency distribution of wave periods T; and (D) wave spectrum. The wave field represents a combination of wind waves and swell as indicated by the bimodal wave spectrum. The data were collected in 48 m water depth off the coast of Perth, Western Australia.

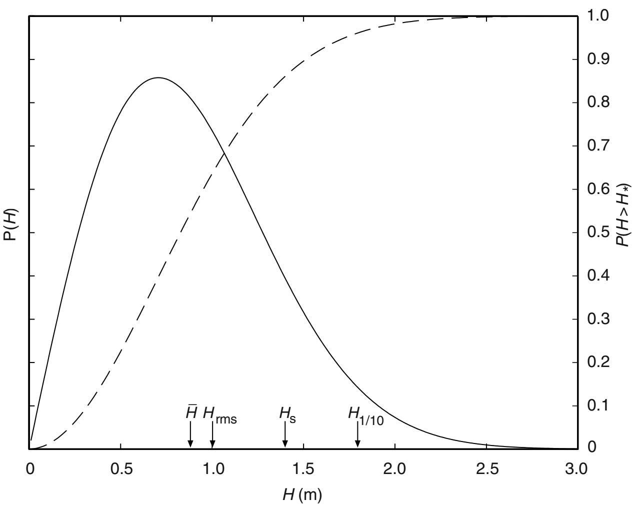

Figure W23 Relative (solid line; equation 1) and cumulative (dashed line; equation 2) probability density functions for wave heights according to the Rayleigh distribution for a root mean square wave height of H_{rms} = 1 m.

$$P(H > H_*) = \exp\left[-\left(\frac{H_*}{H_{rms}}\right)^2\right]. \quad \text{(Eq. 2)}$$

Based on the Rayleigh distribution, various wave height measures can be determined from the standard deviation of the water surface elevation record σ_η

$$\overline{H} = 2.505\sigma_\eta \quad \text{(Eq. 3a)}$$

$$H_{rms} = 2.828\sigma_\eta \quad \text{(Eq. 3b)}$$

$$H_s = 4.004\sigma_\eta \quad \text{(Eq. 3c)}$$

$$H_{1/10} = 5.090\sigma_\eta. \quad \text{(Eq. 3d)}$$

Equation 3 enables direct determination of representative wave height parameters from the wave record (through the standard deviation) without the need to conduct wave-by-wave analysis.

The periods of individual waves generally show a narrower distribution than that of the wave heights and are in the range of 0.5–2 times the mean wave period T_z. The smallest waves in a record often have the shortest wave periods and site-specific correlations between the wave height and period can be derived empirically. For example, wave records from the North Sea suggest that $T \approx 4H^{0.4}$. One of the main problems with determining the characteristic wave period of a wave field is that natural waves generally consist of more than one wave field (refer to Figure W22), rendering a single wave period statistic not very useful.

An important application of statistical analysis of wave conditions is the estimation of extreme wave conditions on the basis of short-term wave records. This involves choosing a suitable probability distribution to fit to the available data and then extrapolating to obtain the probability of occurrence of extreme wave conditions. The probability distribution that is commonly used for this is a lognormal, Gumbel or Weibull distribution (Massel, 1996).

Wave generation

Waves are generated by wind acting on a water surface. In physical terms, the formation of waves constitutes a transfer of energy from wind to waves. At present, the generally accepted theory to account for the growth of wind waves is the combined Miles–Phillips mechanism. The mechanism incorporates two distinct phases of energy transfer from wind to waves: (1) an initial, linear growth phase that accounts for the formation of waves on a calm water surface (Phillips, 1957); and (2) an ongoing, exponential growth of the waves due the interactive coupling between wind and waves (Miles, 1957). An additional process that occurs within a developing wave field is the transfer of energy from high to low frequencies (Stewart, 1967; Longuet-Higgins, 1969). This process may occur when short-period waves steepen and break on the crests of the long-period waves. Since the long-period waves are traveling faster in deepwater than the short-period waves, they sweep up the energy and momentum contained within the short-period waves that are being overtaken. Thus, in a developing wave field both the wave energy level and the dominant wave period progressively increase. Wave growth is not infinite and when waves reach their limiting steepness (H/L = 1/7 in deepwater, where H is wave height and L is wavelength) they break in the form of white caps. An equilibrium can eventually be achieved whereby the energy losses by wave breaking are balanced by the addition of new energy being transferred from the wind to the waves. Such an equilibrium wave field is referred to as a fully arisen sea.

Wave conditions can be predicted as a function of wind speed, wind duration, and fetch length. This technique is known as wave forecasting when predicted wind data are used, or wave hindcasting when historical wind data are used. There are two main approaches to wave prediction: (1) the significant wave approach; and (2) the wave spectrum approach. The former approach is relatively simple and aims to predict wave statistics such as significant wave height and spectral wave period from wind conditions (CERC, 1984). The latter approach is more sophisticated and characterizes the predicted wave field by their spectra. One of the most common spectral formulations to parameterize the growth of a wave field is the JONSWAP spectrum which is based on extensive field measurements conducted in the North Sea (Hasselmann *et al.*, 1976).

Wave theories

Wave theories are mathematical formulations that predict the change in wave properties, such as water particle velocity, wave height, and wave energy, with depth. A basic assumption of linear and nonlinear wave theory is irrotational flow, that is, bed friction is neglected and there are no internal shear stresses. Under this assumption, the full momentum equations, the Navier–Stokes equations, reduce to the Euler equation of motion that contains only terms for the water particle velocities and local pressures. A second relation that must be included in the analyses of wave motion is the continuity equation to ensure conservation of mass. To provide an analytical solution to these equations, additional simplifying assumptions are required. The greater the number of assumptions, the simpler the resulting equations, but the greater the departure from the actual wave motion one is trying to describe. A large number of wave theories have been developed with different levels of complexity and accuracy.

Airy (or linear) wave theory (Airy, 1845) gives the least complicated expressions for wave motion and is therefore the most widely used wave theory. The simplicity of Airy wave theory is attained by making a number of assumptions. Most significantly, it is assumed that the wave amplitude is negligibly small compared with water depth. This is not a problem for waves in deepwater, but the theory is less suitable for waves in shallow water. Stokes wave theory (Stokes, 1847) was developed to overcome this main limitation of Airy wave theory and is a theory for waves of finite height (i.e., wave height is not negligible). Stokes wave theory is essentially Airy wave theory with nonlinear terms added to the equations. The additional terms have the effect of enhancing the crest amplitude and subtracting from the trough amplitude. The resulting wave profile is characterized by narrow wave crests and wide wave troughs which provides a more realistic wave shape of waves as they enter shallow water. When waves are in very shallow water, their crests peak up and are separated by wide, flat troughs, very much resembling solitary waves. Although solitary waves are not oscillatory waves and do not have a wave length or period, solitary wave theory (Boussinesq, 1872) can be used to determine properties of waves very close to breaking. The most sophisticated wave theory available is cnoidal wave theory (Korteweg and de Vries, 1895) and has potentially the widest range of application. In deepwater, the cnoidal wave solution reduces to the Airy wave theory, whereas in shallow water the wave period and length become infinite such that the cnoidal waves become equivalent to solitary waves. Cnoidal wave theory provides the most accurate description of the wave profile but is also the most cumbersome to use. A final wave theory that deserves mention is stream function wave theory (Dean, 1965) which resolves water motions associated with waves numerically without the need for simplifying assumptions required to obtain analytical solutions.

Selection of the appropriate wave theory depends upon the intended application. Figure W24 suggests the fields of application in terms of the ratios H/h and h/L. In the construction of this graph, the widest possible regions are given to the simpler wave theories. For example, the difficult cnoidal wave theory is given only a restricted region of application within its potentially much greater field. An important consideration is that Airy wave theory predicts water motions that are symmetrical, that is, onshore velocities are identical to offshore velocities. The nonlinear wave theories, on the other hand, predict water flows that are distinctly asymmetric in shallow water depths. This flow asymmetry is consistently directed landward whereby the onshore stroke of the wave motion is stronger, but of shorter duration than the offshore stroke. An accurate description of the flow asymmetry under waves is of

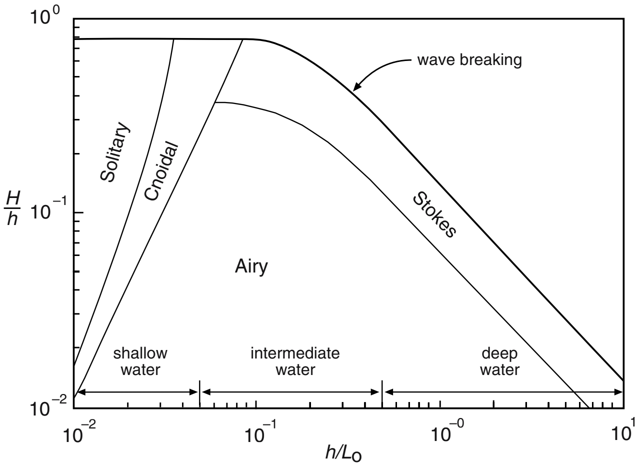

Figure W24 The areas of applications of the various wave theories as a function of the ratios H/h and h/L_o, where preference is given to the simpler theories such as Airy wave theory (after Komar, 1998).

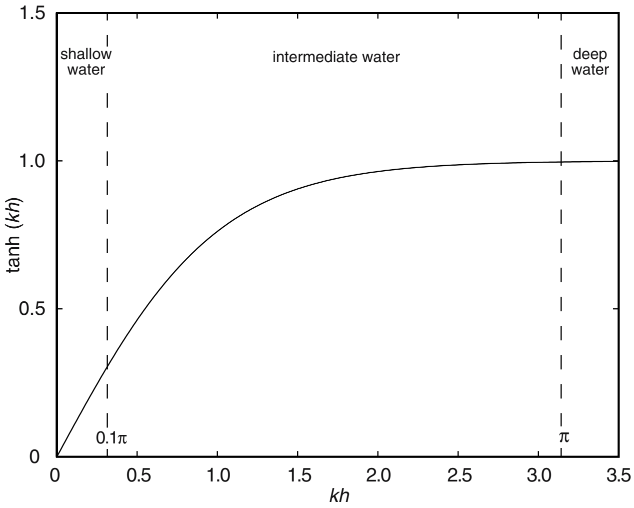

Figure W25 Properties of the tan h function.

fundamental importance for modeling wave-driven sediment transport processes (see *Cross-Shore Sediment Transport*).

Airy wave theory

Airy wave theory is still the most widely used wave theory in oceanographic research and important wave processes such as shoaling and refraction are adequately described by treating ocean waves as Airy waves. According to Airy wave theory the water surface elevation $\eta(x, t)$ is described by

$$\eta(x, t) = \frac{H}{2}\cos(kx - \sigma t), \qquad \text{(Eq. 4)}$$

where x is the coordinate axis in the direction of wave advance, t is time, H is the wave height, $k = 2\pi/L$ is the wave number (L is the wave length), and $\sigma = 2\pi/T$ is the radian frequency (T is the wave period). An important relationship to emerge from Airy wave theory is the dispersion equation which expresses the functional relationship between the wave period and the wavelength,

$$\sigma^2 = gk \tan\mathrm{h}(kh), \qquad \text{(Eq. 5)}$$

which can be rewritten as

$$L = \frac{g}{2\pi}T^2 \tan\mathrm{h}\left(\frac{2\pi h}{L}\right), \qquad \text{(Eq. 6)}$$

where h is the water depth and g is the gravitational acceleration. From equation 6 the wave celerity C can be derived:

$$C = \frac{L}{T} = \frac{g}{2\pi}T \tan\mathrm{h}\left(\frac{2\pi h}{L}\right). \qquad \text{(Eq. 7)}$$

The wave celerity is also referred to as the wave phase velocity and represents the propagation speed of individual waves.

The dispersion equation can not be solved explicitly because it contains L on either side of the equation and therefore has to be solved numerically (iteratively). However, a convenient function which is accurate to 0.1% is given by Hunt (1979)

$$(kh)^2 = y^2 + \frac{y}{1 + 0.666y + 0.355y^2 + 0.161y^3 + 0.0632y^4 + 0.0218y^5 + 0.00654y^6} \qquad \text{(Eq. 8)}$$

where

$$y = \frac{\sigma^2 h}{g} = \frac{4\pi^2 h}{gT^2} = 4.03\frac{h}{T^2}. \qquad \text{(Eq. 9)}$$

At present, the use of computers makes computations involving the general dispersion relationship a relatively painless task, especially if equations 8 and 9 are used. In the past, however, further simplications to the dispersion relationship were desirable and these were made possible due to the characteristics of the tanh function (Figure W25). If $kh = 2\pi h/L$ approaches zero, $\tanh(kh) \approx kh$ and equations 6 and 7 reduce to

$$L_s = T\sqrt{gh} \qquad \text{(Eq. 10)}$$

and

$$C_s = \sqrt{gh}. \qquad \text{(Eq. 11)}$$

Equations 10 and 11 are known as the shallow-water approximations, hence the use of the subscript "s," and are valid for $kh < 0.1\pi$ (or $h/L < 0.05$). If, on the other hand, $kh = 2\pi h/L$ becomes large, $\tan\mathrm{h}(kh) \approx 1$ and equations 6 and 7 reduce to

$$L_o = \frac{gT^2}{2\pi} \qquad \text{(Eq. 12)}$$

and

$$C_o = \frac{gT}{2\pi}. \qquad \text{(Eq. 13)}$$

Equations 12 and 13 are known as the deepwater approximations and are valid for $kh > \pi$ (or $h/L > 0.5$). Commonly, the subscript "o" is used to denote deepwater conditions and is therefore used here. Intermediate depth conditions prevail for $0.05 < h/L < 0.5$ and here the general equations 6 and 7 should be used because the errors in the deepwater and shallow-water approximations will exceed 5%.

Waves have potential and kinetic energy associated with the deformation of the water surface and the orbital motion of the water particles, respectively. According to Airy wave theory, the two energy forms are equal and the energy density E (in Newtons per unit area) is given by

$$E = \frac{1}{8}\rho g H^2, \qquad \text{(Eq. 14)}$$

where ρ is the density of water. The rate at which the energy density is carried along by the moving waves is the wave energy flux P and is given by

$$P = ECn \qquad \text{(Eq. 15)}$$

where

$$n = \frac{1}{2}\left[1 + \frac{2kh}{\sin\mathrm{h}(2kh)}\right]. \qquad \text{(Eq. 16)}$$

The velocity Cn is the speed at which the energy density is carried along and is referred to as the group velocity C_g since it is the movement of groups of waves as distinguished from individual waves that travel according to the wave celerity C. In deepwater $n \approx 1/2$ but n increases in value as the waves travel into water of intermediate depth, becoming $n = 1$ in shallow water. The implication is that in deepwater, individual waves travel at twice the speed as the wave groups, whereas in shallow water, individual waves propagate at the same speed as the wave groups.

Airy wave theory also provides a description of the movement of water particles associated with wave motion (Figure W26). In deepwater, water particles move in a circular path with the radius of the circles decreasing with increasing depth beneath the water surface. The wave motion of deepwater waves is not felt at the seabed. In intermediate water depths the water particles follow an elliptical path with the ellipses

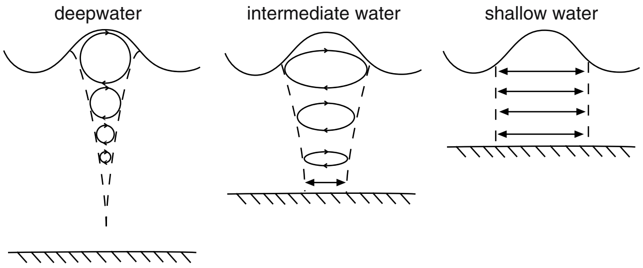

Figure W26 Description of the orbital motion of Airy waves in deep, intermediate, and shallow water.

becoming flatter and smaller as the seabed is approached. At the bottom, the water particles undergo a to-and-fro motion with a horizontal extent of the water motion d_0

$$d_0 = \frac{H}{\sin h(kh)} \qquad \text{(Eq. 17)}$$

and a maximum near-bed velocity u_m

$$u_m = \frac{\pi H}{T \sin h(kh)}. \qquad \text{(Eq. 18)}$$

In shallow water, Airy wave theory predicts that all water motions consist of to-and-fro horizontal movements uniform with depth with

$$d_0 = \frac{HT}{2\pi}\sqrt{\frac{g}{h}} = \frac{H}{kh} \qquad \text{(Eq. 19)}$$

and

$$u_m = \frac{H}{T}\sqrt{\frac{g}{h}}. \qquad \text{(Eq. 20)}$$

Parameters d_0 and u_m are important with respect to the bed morphology (wave ripples) and sediment transport processes. It should be emphasized that nonlinear wave theories such as Stokes theory provide a better description of water particle motions in shallow water than Airy wave theory.

Wave dispersion

A developing wave field is characterized by a broad-banded wave spectrum, indicating that a large range of wave periods are represented in the wave field. Such waves are referred to as sea. According to Airy wave theory, the wave celerity in deepwater C_o increases with wave period T (equation 13). In a broad-banded wave field, therefore, waves propagate at a range of wave celerities with the longer-period waves traveling faster than the short-period waves. Given sufficient time, the longer-period waves will outrun and leave behind the shorter-period waves. This sorting of the waves by period is termed wave dispersion and results in the transformation of broad-banded and confused sea into regular swell. The longer the distance of travel from the area of wave generation, the more effective the wave sorting process and the narrower the wave spectrum becomes. If a wave field is generated by an offshore storm, wave disperion causes the longest-period waves within this storm-wave field to reach the coast first. These first waves, the so-called storm-forerunners, will then be followed by waves of progressively decreasing shorter periods.

Wave groups

Ocean waves often occur in successive groups of higher or lower waves. Using linear wave theory, Longuet-Higgins and Stewart (1964) demonstrated that a small lowering of the mean water level accompanies groups of high waves, whereas a small rise in mean water level occurs under groups of small waves. This leads to the development of the group-bound long wave which has the same wave length and period as the incident wave group, but is 180° out of phase with the group. Offshore-directed currents of the long wave are maximum under groups of high waves and may constitute an important mechanism of offshore transport under shoaling waves (see *Shelf Processes*). Wave groups and the group-bound long wave are also of interest through their link with infragravity wave motion in the surf zone (see *Surf Zone Processes*).

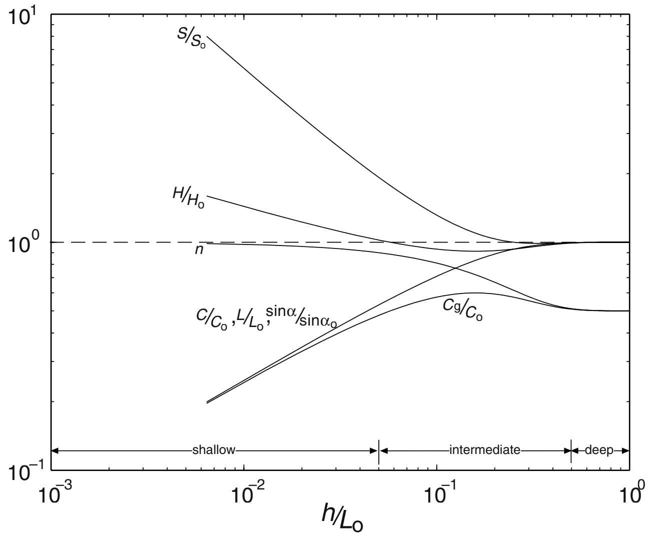

Figure W27 Shoaling transformations for Airy waves as a function of the ratio h/L_o.

Wave shoaling

As waves propagate from deep to shallow water they undergo a number of transformations which can be predicted using Airy wave theory. Some of these variations in wave properties have been plotted in Figure W27 and indicate that both the wavelength L and the wave celerity C systematically decrease with decreasing water depth. The wave period is the only variable that remains constant. Similarly, there are variations in n and hence changes in the wave group velocity C_g as the depth decreases.

The variation in the heights of the shoaling waves can be calculated from a consideration of the energy flux. Assuming energy losses due to bed friction and reflection can be ignored, the wave energy flux $P = ECn$ remains constant during wave propagation. This can be expressed as:

$$P = E_2C_2n_2 = E_1C_1n_1 = \text{constant}, \qquad \text{(Eq. 21)}$$

where the subscripts "1" and "2" indicate two different locations along the path of wave travel ($h_1 > h_2$). Inserting $E = 1/8\rho g H^2$ in equation 21 yields

$$H_2 = \left(\frac{C_1n_1}{C_2n_2}\right)^{0.5} H_1. \qquad \text{(Eq. 22)}$$

The ratio of the local wave height H (i.e., H_2) to the deepwater wave height H_o (i.e., H_1) can easily be derived from equation 22

$$\frac{H}{H_o} = \left(\frac{1}{2n}\frac{C_o}{C}\right)^{0.5} = K_s, \qquad \text{(Eq. 23)}$$

where K_s is referred to as the shoaling coefficient. Equation 23 is plotted in Figure W27 and it can be seen that during wave shoaling, the wave height initially decreases slightly while entering intermediate water depth followed by a rapid increase.

The wave steepness $S = H/L$ also varies in the shoaling waves. Because the increase in H during shoaling is accompanied by a decrease in L, the wave steepness shows a dramatic increase during shoaling, especially over the shallow water region (Figure W27). It is the steepening of the waves that ultimately results in wave breaking.

Wave refraction

When a wave approaches the coast with its crest at an angle to the bottom contours, the water depth will vary along the wave crest. If the wave is in intermediate or shallow water, the wave celerity C will also vary along the wave crest with the deeper part of the wave propagating at a faster rate than the shallow part of the wave (equations 7 and 11). This results in a rotation of the wave crest with respect to the bottom contours, or in other words a bending of the wave rays or wave orthogonals. This processes is known as wave refraction (see *Wave Refraction Diagrams*) and is of great relevance to nearshore currents, sediment transport, and morphology (see *Beach Processes*, *Headland Bay Beach*, *Longshore Sediment Transport*, and *Surf Zone Processes*).

The refraction of waves is similar to the bending of light rays and the change in direction is related to the change in the wave celerity C through the same Snell's law

$$\frac{\sin \alpha_1}{C_1} = \frac{\sin \alpha_2}{C_2} = \text{constant}, \quad \text{(Eq. 24)}$$

where α refers to the angle between the wave crest and the bottom contours and the subscripts "1" and "2" are used to indicate two different locations along the path of wave travel ($h_1 > h_2$) (Figure W28(A)). For a straight coast with parallel bottom contours, the angle at a given depth can be related to the angle of wave approach of the wave in deepwater

$$\sin \alpha = \frac{C}{C_o} \sin \alpha_o. \quad \text{(Eq. 25)}$$

The expression shows that as the wave celerity decreases in shallow water, the angle made by the wave with the bottom contour also decreases.

The refractive bending of the wave rays also causes the wave rays to spread out, that is, the distance between rays increases as the waves are being refracted. If b_1 and b_2 are the spacing of the rays at two consecutive depths then the energy flux between the wave rays at these two depths should be constant:

$$P = E_1 C_1 n_1 b_1 = E_2 C_2 n_2 b_2 = \text{constant}. \quad \text{(Eq. 26)}$$

Inserting $E = 1/8 \rho g H^2$ in equation 26 then yields

$$H_2 = \left(\frac{n_1 C_1}{n_2 C_2}\right)^{0.5} \left(\frac{b_1}{b_2}\right)^{0.5} H_1. \quad \text{(Eq. 27)}$$

For straight coasts with parallel contours, simple geometry considerations give

$$\frac{b_1}{b_2} = \frac{\cos \alpha_1}{\cos \alpha_2}. \quad \text{(Eq. 28)}$$

The ratio of the local wave height H to the deepwater wave height H_o can easily be derived from equation 27

$$\frac{H}{H_o} = \left(\frac{1}{2n}\frac{C_o}{C}\right)^{0.5} \left(\frac{b_o}{b}\right)^{0.5} = K_s K_r, \quad \text{(Eq. 29)}$$

where K_r is referred to as the refraction coefficient.

Irregular bottom topography can cause waves to be refracted in a complex way and produce significant variations in wave height and energies along the coast (Figure W28(B)). Waves diverge over relatively deepwater (e.g., depression in the seafloor), resulting in a spreading of the wave rays ($K_r < 1$) and a decrease in wave energy and wave height. In contrast, wave rays converge over relatively shallow water (e.g., shoal on the seafloor), resulting in a decrease in the spacing of the wave rays ($K_r > 1$) and an increase in wave energy and wave height.

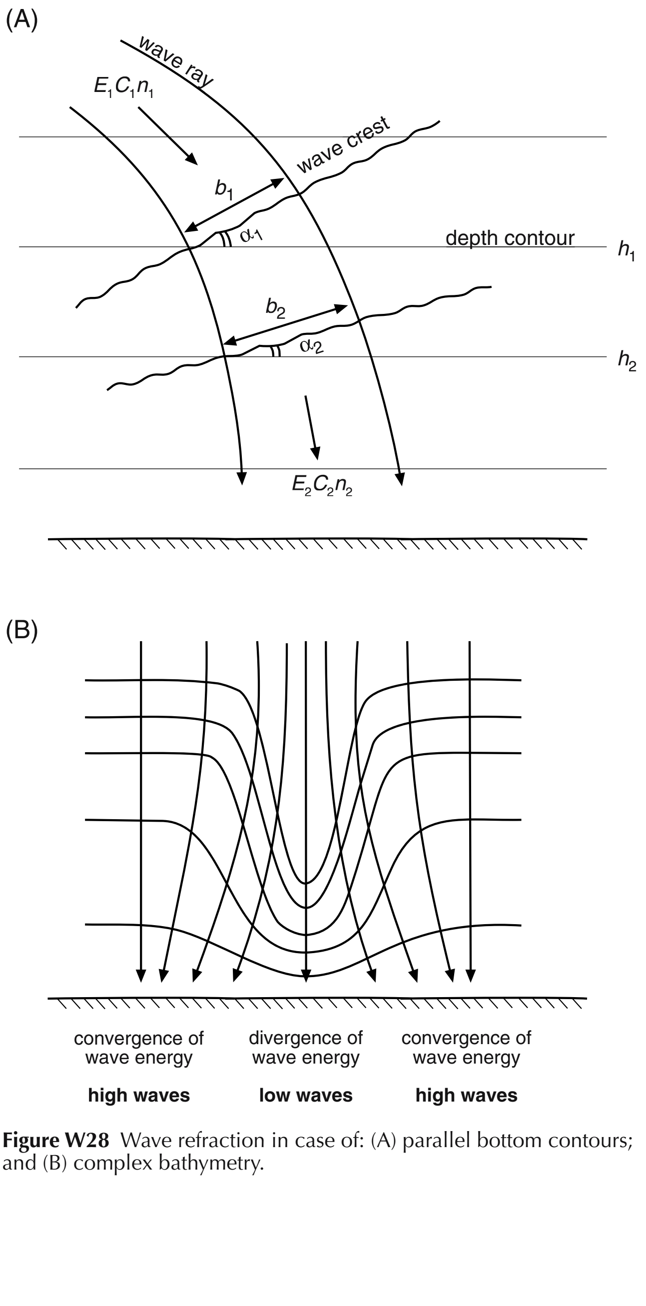

Figure W28 Wave refraction in case of: (A) parallel bottom contours; and (B) complex bathymetry.

Wave diffraction

Wave diffraction is the process of wave energy transfer in a direction other than the wave propagation direction and occurs irrespective of water depth. As such, diffraction is fundamentally different from wave refraction, although both processes often operate in concert. Wave diffraction occurs when an otherwise regular train of waves encounters an impermeable structure, for example, an island. A wave shadow zone will be created behind the obstacle, but wave diffraction will cause wave energy to leak into the shadow zone. Wave diffraction also enables wave energy to enter into narrowly confined bays and harbors.

Wave breaking

At some point during wave transformation, the water depth becomes too shallow for a stable waveform to exist and the waves break (Figure W29). The mechanism of wave breaking is that the horizontal velocities of the water particles in the wave crest exceed the phase velocity of the wave. Consequently, the water particles leave the waveform, resulting in a disintegration of the wave into bubbles and foam. The breaking wave height is related to the water depth by the breaker index γ according to

$$H_b = \gamma h_b, \quad \text{(Eq. 30)}$$

where H_b is the height of the breaking wave and h_b is the mean water depth at the point of breaking. When the height-to-depth ratio of the wave exceeds the breaker index, breaking will occur. Solitary wave theory prescribes that $\gamma = 0.78$ and this provides a good first-order approximation.

Komar and Gaughan (1972) obtained a useful expression of the breaker height as a function of the deepwater wave height and steepness by applying linear wave theory (and ignoring energy losses by bed friction) to evaluate the wave energy flux from deepwater up to the breakpoint and using $\gamma = 0.78$,

$$\frac{H_b}{H_o} = \frac{0.563}{(H_o/L_o)^{1/5}}. \quad \text{(Eq. 31)}$$

The value 0.563 was determined empirically from laboratory and field data. Due to wave shoaling, the height of the breakers always exceeds that of the deepwater waves and the ratio H_b/H_o increases with decreasing wave steepness H_o/L_o.

A continuum of breaker shapes occur in nature. However, three main types of breakers are commonly recognized: spilling, plunging, and surging (Galvin, 1968). Spilling breakers are characterized by a gradual peaking of the wave until the crest becomes unstable, resulting in a gentle forward spilling of the crest. Plunging breakers are distinguished by the shoreward face of the wave becoming vertical, curling over, and plunging forward and downward as an intact mass of water. In surging breakers,

Figure W29 Plunging breaker.

the front face and crest of the wave remain relatively smooth and the wave slides directly up the beach without breaking. Spilling and plunging breakers occur in the surf zone, whereas surging breakers are restricted to the swash zone. The transition from one breaker type to another is gradual and in natural surf zones, a mixture of breaker types is often present.

The breaker type principally depends on the beach gradient and wave steepness, which may be expressed by the surf similarity parameter

$$\xi_b = \frac{\tan\beta}{\sqrt{H_b/L_o}}, \qquad \text{(Eq. 32)}$$

where tan β is the beach gradient and the subscripts "b" and "o" indicate breaker and deepwater conditions, respectively. Spilling breakers occur for $\xi_b < 0.4$, plunging breakers occur when $\xi_b = 0.4$–2 and surging breakers occur for $\xi_b > 2$ (Battjes, 1974).

WEATHERING IN THE COASTAL ZONE

Weathering, anywhere on the earth's surface, is a destructive process whereby preexisting rocks, boulders, pebbles, or smaller particles are altered in composition, texture, color, and/or hardness with little or no transport from their original *in situ* positions, except as mediated by chemical solutions. In soil science, it is the initial step in a long and complex process (Merrill, 1897/1921; Carroll, 1962; Barshad, 1972; Yatsu, 1988; Birkeland, 1999). As a process in physics, this rock decay follows the Second Law of Thermodynamics, as positive entropy, in which systematic ordering of chemical elements is progressively broken down. In a mineral petrological sense, the Bowen reaction series is reversed (Colman and Dethier, 1986).

The *agencies of weathering* are multiple, often operating in a synergistic way, and rarely in total independence. The net product contributes to the

"*Mantle*" or "*Regolith*," the term coined by Merrill (1897/1921, p. 299) for unconsolidated material without specifying genesis (Fairbridge, 1968; Gale and Hoare, 1991). The agents of weathering are threefold: (1) *Physical weathering*, such as thermoclastic processes ("thermoclasty"), involving expansion and contraction, operating both in low latitudes (notably the hot deserts) and mid- to high-latitudes (due to freeze and thaw). There is also "Fretting," a process of weathering by wetting and drying (especially by sea spray). The scale ranges from granular-sized disintegration ("granulation") to the splitting of giant boulders, 3–5 m in diameter. (2) *Chemical weathering*, operating principally in the humid climates, both warm-wet and cool-wet types. The weathered material is termed *Saprolite* (literally "rotted rock"). Chemical susceptibility depends partly on the nature of the solvent (the pH of the ground or seawater, acidic or alkaline), and on the minerals themselves, the solubility of which may be positively or inversely related to temperature, for example, the calcite or aragonite of limestone dissolves more freely as the temperature falls, but the K-feldspars of granite dissolve more readily with a rise in temperature and at low pH, but quartz (SiO_2) dissolves faster at a high pH. The progressive nature and stage is referred to in terms of "*Weathering Maturity*" (Garner, 1974, p. 269). Under warm freshwater conditions the ultimate mineral product of granitoid weathering is *kaolinite* (which has a group formula of $Al_2Si_2O_5(OH_4)$ and has the lowest cation exchange capacity). In the warm coastal zone the littoral belt is often marked by mangrove swamps. There, the decaying leaves and organic debris forces the normally high pH seawater to an acidic range (pH 4–6), creating mud-filled pools. This acidification favors removal of SiO_2 and concentration of *bauxite* (ideally $Al_2O_3 \cdot 2H_2O$; but more often a mixture of aluminous laterite). Commercial bauxites on the seaward side of the Guyana Shield and of the West-Australian Shield appear to mark former (pre-Quaternary) eustatically high sea levels. (3) *Biological weathering* relies largely on the presence of liquid water (at equable temperatures), and is thus inhibited by the hot-dry climates of deserts and by the cold-dry climates of the very high latitudes. The synergism of plant roots is particularly significant, for example, the thermoclastic crack in a mineral is exploited by root penetration. But the physical expansion of the root opens the crack still further, accelerating the disintegration process. Contributing also is the chemical (biochemical) role of decaying organic matter, and root "exudation" or granulation. Mineral diagenesis that involves hydration leads to expansion and thus further accessibility for groundwater (and roots). Animals play an important role, especially in limestones, which often favor the roots of plants or algae that crabs, gastropods, bivalves, and ecninoids like to eat. "Lithophagous" mollusca do not actually "eat" the limestone, but mechanically bore into it for the algae living in it. The byssus of *Mytilus*, and related bivalves, is an anchoring device, but is often torn away to expose fresh rock to weathering.

In the coastal zone, weathering is an essential forerunner to the various processes of *Erosion* (*q.v.*) which shifts or displaces the original material that has been made softer or more "erodable" by the loosening or softening effects of weathering. The process may be (1) subaerial, or (2) marine in its action, but for most rock material the rates involved are generally about five or six orders of magnitude less for the latter. The boundary between these two realms is accentuated by the action of tides, waves, and spray, and as a rule-of-thumb the level of mean low tide may be taken as the lower limit of subaerial processes. As an exception to this rule may be the occasion of a tropical hurricane on a coral-reef coast, when a meteorological blocking leads to a dead calm with three days or so of steady rain creating an aerated freshwater layer up to about 60 cm deep, effectively killing the surface reef.

Normally speaking, the low-tide boundary means that coastal rocks are made systematically more erodable, while their submarine extensions are differentially preserved. Depending upon the lithology, there is often a littoral bench or platform produced, the loose weathering products having been removed by mass wasting, wave action, or floating ice.

Lithology of the coastal belt plays a critical role in the effectiveness, style, and rate of weathering. Bearing in mind that since the last glacial phase most of the world's coastlines in the more stable regions have only been exposed to marine forces for about 6,000 yr, the rate of weathering is often critical. Important for this rate three lithic categories may be noted:

1. Massive plutonic rocks of granitic, dioritic, and gabbroic types, together with deeply crystallized metamorphics of granitoid types.
2. Feldspathic volcanics, pyroclastics, and derivative sandstones, including some graywackes.
3. Limestones, beachrocks, calcareous eolianites or calcarenites, algal and coral breccia.

These three categories need to be taken in conjunction with the long-term geological history of a given coastline, in other words, its paleoclimatic inheritance. Among the three categories listed above, rates of weathering are difficult to determine but certainly vary greatly with latitude in view of the physical processes introduced (Loughnan, 1969; Ollier, 1969a; Colman and Dethier, 1986; Birkeland, 1999).

Shore platforms develop mainly in the (2) and (3) categories (Stephenson, 2001). Important also is the role of inheritance, former climates and eustasy, and also the role of sea ice which develops *well before* the glacier buildup causing sea-level fall (Fairbridge, 1971, 1977).

For category (1), the massive plutonic rocks, weathering of a chemical nature is most evident in equatorial and temperate latitudes, where it penetrates the rock along major joint planes which in uncomplicated structural examples tend to produce cube-shaped blocks. Sharp corners and intersections became gradually rounded off until a so-called "woolsack" is created. Around the fractured borders of Gondwanaland, much of this weathering began in the early or mid-Mesozoic (200–150 Myr ago). In the tropics and subtropics the repeated eustatic fall of sea level during the Quaternary glaciations led to brief episodes of torrential precipitation and giant mudflows, which transported the unweathered crystalline blocks to the coast, where recent and present-day wave action is removing the weathered "rind," exposing totally unweathered, rounded boulders (Fairbridge and Finkl, 1984). Fine examples can be seen around Africa, Brazil, and Australia. Where the massive crystalline rocks are still *in situ*, for example, in the Recherche Archipelago, off S.W. Australia, the smooth surfaces of unweathered material plunges directly from the coastal hills well far below present mean sea level (MSL). Little trace of an intertidal notch is seen, and present rate of intertidal coast retreat (over the last 6,000 yr) is almost zero.

In the same category of massive plutonic rocks, but in the intermediate latitudes of the high-pressure belts, a strong alternation of wet and dry seasons prevails. During the Quaternary glacial stages, however, total aridity often prevailed, with seasons of cold-fog ("Atacama Desert" type). Also seen in the Namib desert of SW Africa, weathering pits develop on various scales (Goudie and Migon, 1997). The process is called "exudation." This is also the setting for a peculiar geomorphic form of pitting, *tafoni* (Fairbridge, 1968). Its classic setting is on the island of Corsica in the Mediterranean; the mountains there were not glaciated but subjected to severe frost action and cold dry winds blowing off the Alps. Fine examples may be seen on the south coasts of Australia, South Africa, and South America. The mechanism appears to be a process of weathering pit development. On the shady side of the outcrop, the daily dew precipitation leads to chemical weathering of feldspar minerals. Wind action removes the insolubles but diffusion and evaporation leads to the strengthening of a hard rim. The pit progressively deepens in size to cave where a human being can stand up in it.

Yet a third type of weathering of the first category appears on the coasts of the high latitudes, where alternate wet-dry, freeze-melt conditions apply. These have been studied particularly in Quebec and eastern Canada (Dionne and Brodeur, 1988); as well as in the southern Baltic where the clays become winnowed to concentrate the boulders. Winter freeze-up combined with tides and current action creates a mixture of frost debris, till clays and boulders that the French call *glaciel*. Freeze-thaw, combined with shore-ice pushed by currents and tides, is also seen on the coasts of Norway, where a prominent feature, the *strandflat* (*q.v.*) has long been a problem, a product of multiple cycles, involving both glacio-isostasy and glacio-eustasy.

The second weathering lithic type is that dominated by feldspathic minerals, which are susceptible to slow dissolution in acid groundwater (high levels of CO_2). This form of weathering is most apparent around volcanic centers that have erupted with the andesitic-rhyolitic lava suites, that are typical of the circum-Pacific "Ring of Fire." Weathering platforms are typically swept clean by wave action, and in places display the very evocative patterns of truncated pillow lavas.

Arkosic sandstones (i.e., rich in K-feldspars) are particularly common in the *flysch*-type facies and graywackes that are a feature of the great orogenic belts near former plate boundaries. These rock types are often heavily folded, but in coastal sectors they may be dramatically transected by contemporary (or at least Quaternary) marine erosion. That erosion involves a differential truncation made possible by the subaerial "preparation" by chemical weathering (Stephenson, 2000). The role of subaerial weathering in the development of the Kaikoura Peninsula shore platforms on the south island of New Zealand has been studied in depth by Stephenson and Kirk (2000), who have comprehensively studied the roles of both animal and plant types as well as their interactions with the results of wave energy. A useful review of the whole topic of shore platforms was issued separately by Stephenson (2000), with the question of platform width (Stephenson, 2001).

Finally, there are the limestones, along with beach rock, calcareous eolianites (calcarenites), coral and algal reef rock, and their breccias (Fairbridge, 1968; Miller and Mason, 1994). These are susceptible to solution in CO_2 rich (acid) waters, but seawater is alkaline (pH ca. 8), so at first sight this would not appear to be an effective process.

The explanation lies in the development of biochemical microenvironments. Tide pools disclose an extraordinary range of pH (5–10) in 24 h periods. During hours of darkness, CO_2 production and cooling cause the pH to fall into the acid range and the pool margins become undercut (helped by gastropoda). The next morning, the pool warms and solar evaporation shifts the pH quickly to the alkaline range. A white precipitate (aragonite) is often seen, and the pure spaces in the country rock are tightly cemented. The limestone shores are commonly marked by nearly horizontal intertidal platforms with undercut notches (and possibly overhanging visors) on the landward side (Fairbridge, 1968, p. 653). Tidal action is constantly saturating this undercut which is populated by unicellular blue-green algae which bore into the rock to depths up to 2–3 mm. The platform, for its part, is differentially hardened by interstitial precipitation of $CaCO_3$, in a plane approximating mean low tide (higher on exposed points). A limestone shore platform is thus a product of differential biochemical weathering and lithic hardening. An outer rim of algal construction (the so-called "Lithothamnion Rim" often forms a massive protective barrier on the seaward edge of the platform. Measurements of Holocene platforms suggest their landward growth is often at a rate of >1 mm/yr. When measuring Holocene changes of relative sea level it is found the limestone shores provide the clearest evidence, even to cm-precision in favored places.

As to the *agents of weathering*, to say mechanical, chemical, and biological is simplistic, because in most settings there is synergistic interplay, so that there is commonly a highly complex sequence of reactions. In many standard works on coastal science, the subject is not a even listed in the index. (Nevertheless, it gets 20 citations in Fairbridge, 1968.) It became a topic of debate during the mid- to late-19th century, particularly in Britain, when the physiographic questions of landscape came under consideration. The prominent action of marine (wave) erosion in western Europe tended to overwhelm the associated agencies and was favored by major physical geographers of the 19th century (e.g., Von Richthofen, 1870–72). The role of weathering particularly chemical weathering, was able to gain ground in some circles (e.g., Whitaker, 1867), and notably in New Zealand during the next century (Bartrum, 1926). In the South Pacific, the "Old Hat" phenomenon, observed by Dana in the previous century on the US Exploring Expedition, was a critical factor, although little noticed in the Northern Hemisphere. Thus, it was mainly in Australia and New Zealand during the 20th century that weathering became recognized as the key agency in coastal erosion.

Anomalies abound in coastal weathering situations. Disharmonic climatogenetic features are commonly sources of controversial interpretations. A classic example is at the Giant's Causeway in Northern Ireland, to be seen repeated on the opposing shores of Scotland (Fingel's Cave on Staffa), where the same Cenozoic basalts display spectacular columnar jointing. Paradoxically, the boulder beaches nearby are not characterized by sharply edged pentagonal or hexagonal blocks, but by well-rounded boulders. Their source is evident in the deeply weathered tropical soil that forms a transition zone above the fresh basalt, showing the progressive weathering of the columns into spheroidal "core stones" analogous to those of Devon's well-known granite tors.

Differential hardness of the parent rock material is the explanation for the sorting and concentration of the Upper Cretaceous chert (flint) horizons of the Chalk, as notably developed along the English Channel coast of Dorset where it forms a massive boulder beach, the Chesil Bank. The soft chalk has been lost to weathering. Another process involving Upper Cretaceous chalk is observed on the Baltic coastal cliffs of eastern Germany and Poland. Frozen spray in winter constitutes a powerful weathering agent.

Salt spray is effective in all latitudes, leading to "haloclasty", or what E.S. Hills called "fretting," besides simple wetting drying, that is a grain-by-grain disintegration of the coastal rocks, most typical of sandstones. Due to inhomogeneities to the rock, cavities develop and the result is a network or lace-pattern, that is generally known as *honeycomb* or *alveolar weathering* (see numerous illustrations in Fairbridge, 1968). As in the case of tafoni, noted earlier, extra-large examples are attributed to a dew-plus-chemical action that can operate far inland from the coastal zone (e.g., in the mid-Sahara), but the typical spray-activated alveolar weathering is most typical of the salt-crystal expansion in the supratidal zone. Ice-crystal expansion takes its place in the high latitudes (e.g., the "dry valleys" of Antarctica). Yet another agency in the coastal zone is biological where crabs and gastropods loosen mineral grains as they browse on algae.

Landsliding in the coastal zone is particularly evident in the "*Zone of Weathering*," label introduced by Ruxton and Berry (1957) after a survey undertaken in the territory of Hong Kong which displayed weathering on a scale unfamiliar to eyes accustomed to the landscapes of NW Europe or eastern North America where repeated Quaternary glaciations and periglacial activity has greatly modified the warm-wet products of what is "normal" weathering in much of the world far removed from the direct influences of glaciation over the last l–2 Myr. In the deeply dissected coastal areas of Hong Kong, likewise in the Seychelles and eastern Brazil, particularly in granite or granitoid rocks, the zone of weathering is commonly 50–80 m thick. Deforestation and other human activities have helped to accelerate landscape modification by massive landsliding. The latter, while not a weathering process itself, may be greatly enhanced by the preparation and lubrication provided. Even in a temperate zone like the south coast of England, landsliding of coastal cliffs is particularly prevalent, thanks to the action of groundwater in the porous stratified formations.

A combination of deep weathering and landsliding is also observed in the region of Rio de Janeiro on the coast of Brazil, but here it has been accelerated by differential uplift following the plate-tectonic separation from Africa. Granite plutons form "sugar-loaf" mountains (inselbergs) that in a relative sense have grown progressively higher through time, aided by eustatic fluctuations and secular lowerings of the water table (Bremer, 1999).

Weathering profiles exposed in deeply dissected volcanic rocks such as in Fiji or in New Guinea (Ollier, 1969b) may frequently exceed 100 m. However, if the volcanic necks are traced eastwards into the Louisiade Archipelago, they are often seen to have been completely isolated from their weathered mantle and the waves beat against a vertical wall of unweathered igneous rock.

An unusual volcanic landform results from the weathering of a porous pyroclastic lithology that is rich in K-feldspars. The result is a so-called "volcano-karst" which includes weathering pits, caverns, and gullies reminiscent of limestone karst.

Important for shore platform development is the "*Weathering Front*," a concept introduced in Australia by Mabbutt (1961), and now adopted worldwide for the interface between fresh and weathered rock, to replace an earlier term "basal surface." In crystalline rocks it represents the ultimate saturation depth of groundwater, and therefore of atmospheric gases such as CO_2 and O_2. In porous, sedimentary sequences its definition is less straightforward, and in artesian basins the term has little use. On the contrary, in the ancient cratons it is very instructive, especially where such features reach the present-day coast.

For the Gondwanaland cratons such weathering fronts may be traced back many million years in time to the initiation of subaerial exposure. Over broad areas this zero date was in the Late Permian with the retreat of the last Late Paleozoic ice sheets about 250 Myr ago. A comparable date in the regions of the Laurasian glaciations would be only about 6,000 yr ago, but nevertheless in some exceptional spots, for example, in eastern Quebec pre-Cretaceous weathering fronts are known. In extensive areas of South America, South Africa, Antarctica, and Tasmania the last major defining events were the basaltic lava and diabase intrusions that ended in the Early Jurassic about 200 Myr ago. In the Indian peninsula the same type of eruption, marked the Cretaceous/Tertiary boundary, was 65 Myr ago.

In each region the "geomorphic clock" started ticking at a different point in time. With the far-reaching taphrogeny that marked the breakup of Gondwanaland came isostatic adjustments and drainage system reorientations. Rivers do not rapidly abrade their beds in fresh crystalline rocks, but where the "bedrock" has been preconditioned by a deep weathering front, that stream bed will be rapidly incised.

One might contrast the interior Guyana Shield in South America (Garner, 1974) and its limited weathering of sandstones, with the deep weathering front of the West Australian Craton where it is often situated at a depth of about 100–120 m (Finkl and Fairbridge, 1979). In this case, the boundary can be directly inspected by taking one of the gold mining elevators in the region of Kalgoorlie. The mean surface elevation of the craton is about 400–500 m, but the highest eustatic level of the Late Cretaceous was nearly 300 m, so there has been progressive lowering of the streambeds in the major rivers, but only near the cratonic margins. A mean rate of cratonic lowering over much of Gondwanaland has been 10–100 cm Myr. This snail's pace constitutes the "primary weathering cycle" on Gondwanaland. Only in the water-saturated stream beds approaching the grade dictated by sea level is chemical weathering feasible. And that MSL has fluctuated markedly, but shown a secular fall during the last 65 Myr.

Where the deeply weathered margin of the Deccan Plateau in India can be seen at the present-day coast, for example, around Goa and Kerala, the unsilicified latosol is terraced by marine erosion. The soft paleosols in the intertidal and supratidal zones there is subject to a *secondary weathering cycle* under its exposure to sea spray, tidal action, and biological agencies, further supplemented by the mechanical role of wave action. This exemplifies the predominant role of weathering, on every scale, in predicting the erosion of coastlines.

WETLANDS

Wetlands are neither terrestrial nor aquatic systems and at the coast form part of a continuous gradient between upland and ocean. The most obvious characteristic of all wetlands is continuous, seasonal, or periodic standing water or saturated soil. However, the increasing understanding of wetlands as important ecosystems and the parallel recognition of the threats posed to them by urban development, drainage for agriculture, and other human pressures has led to the need for clearer definitions and classifications. Conservation and management measures focused at wetlands often involve restriction or regulation of activities at the site, and so the need for "delineation" or defining the boundaries of individual wetlands has become of concern to landowners, managers, and political leaders.

While much of the ongoing debate over "what is a wetland?" encompasses a range of environments from peat bogs to vernal pools to cypress swamps, the focus here will be on wetlands found in coastal areas—where the "wet" aspect of the wetland is specifically associated with tidal action, but not necessarily saline tidal waters. These would be classified as part of the marine, estuarine, and riverine-tidal systems under the classification methodology of Cowardin *et al*. (1979) or the marine and coastal section of the wetland classification approach adopted by the Ramsar Convention Bureau (Scott and Jones, 1995). There are many excellent texts which describe the range of processes and characteristics of wetlands around the world including Mitsch and Gosselink (2000), Finlayson and van der Valk (1995), and Mitsch (1994).

Here we will discuss the definitions that have been used to delineate wetlands and how these may be used relative to coastal wetlands, assess the functions and values of various types of coastal wetlands, and evaluate some of the current threats to coastal wetlands and the management measures that are needed to appropriately respond.

Definitions

Although most definitions encompass three fundamental characteristics of wetlands—the presence of water at or near the surface, soil conditions different from those in upland areas, and vegetation dominated by hydrophytes—the diversity of wetland types means that the combination of these three elements into a meaningful definition has been challenging. The purpose of such a definition should be to readily distinguish wetlands from other ecosystems. In some cases the definitions used have emphasized characteristics of the wetland that serve particular purposes or interests. An example is an early definition, the first in the United States, by the US Fish and Wildlife Service (Shaw and Fredine, 1956):

> The term "wetlands" … refers to lowlands covered with shallow and sometimes temporary or intermittent waters. They are referred to by such names as marshes, swamps, bogs, wet meadows, potholes, sloughs, and river-overflow lands.

This definition goes on to encompass shallow lakes and ponds but not deepwater areas and permanent streams. Also excluded are areas that are flooded on such a temporary basis that the area does not support "moist-soil" vegetation. This on the basis that they were of little value to the wildlife species of concern at the time.

Under the Convention on Wetlands of International Importance Especially as Waterfowl Habitat, a global environmental treaty signed in Ramsar, Iran in 1971 and commonly known as the Ramsar Convention, "wetlands" were defined as:

> … areas of marsh, fen, peatland or water, whether natural or artificial, permanent or temporary, with water that is static or flowing, fresh, brackish or salt, including areas of marine water the depth of which at low tide does not exceed six metres.

The Ramsar Convention also provides that wetlands "may incorporate riparian and coastal zones adjacent to the wetlands, and islands or bodies of marine water deeper than six metres at low tide lying within the wetlands." This very broad definition encompassed many areas, such as rice fields, that although technically wetlands, were unlikely to be considered of conservation value under Ramsar. While this definition still officially defines wetlands under the treaty, the Contracting Parties have adopted a classification system based loosely on that developed in the United States in the mid-1970s. The Cowardin Classification (Cowardin *et al*., 1979) divided wetlands into systems, subsystems, classes, and subclasses in combination with a series of modifiers that describe water regime, water chemistry (e.g., salinity), and soil. The definition of wetlands used by Cowardin *et al*. (1979) includes descriptions of vegetation, hydrology, and soil:

> Wetlands are lands transitional between terrestrial and aquatic systems where the water table is usually at or near the surface or the land is covered by shallow water .... Wetlands must have one or more of the following three attributes: (1) at least periodically, the land supports predominantly hydrophytes, (2) the substrate is predominantly undrained, hydric soil, and (3) the substrate is nonsoil and is saturated with water or covered by shallow water at some time during the growing season each year.

In an attempt to convey the ecosystem concept of wetlands, and to ensure that the essential role of hydrology as a driving force behind the physical, chemical, and biological features of the system is retained, the US National Research Council Committee on Characterization of Wetlands (NRC, 1995) developed a broad reference definition of a wetland:

> A wetland is an ecosystem that depends on constant or recurrent, shallow inundation or saturation at or near the surface of the substrate. The minimum essential characteristics of a wetland are recurrent, sustained inundation or saturation at or near the surface and the presence of physical, chemical and biological features reflective of recurrent, sustained inundation or saturation. Common diagnostic features of wetlands are hydric soils and hydrophytic vegetation. These features will be present except where specific physicochemical, biotic or anthropogenic factors have removed them or prevented their development.

At the coast, the flood and ebb of the tide will usually be the controlling factors in determining soil inundation or saturation. Importantly, while many coastal wetlands support halophytic vegetation, the presence of salt is not an essential feature of a coastal wetland. They also include areas further inland and the landward limit can be defined by the limit of tidal fluctuation. According to Field *et al*. (1991) there are over 4.5 million ha of coastal wetlands in the conterminous United States of which only 16% are salt marshes. The remainder are forested and shrub-scrub wetlands and fresh marsh areas. There may be some uncertainty in determining the boundary between tidal and nontidal wetlands and Mitsch and Gosselink (2000) note that tidal freshwater marshes can be described as intermediate in the continuum from coastal salt marshes to freshwater marshes. Similarly, freshwater woody wetlands or swamps, can occur in fresh nontidal waters and in areas influenced by the tide. This tidal–inland boundary has received less attention than that between wetlands and their adjacent uplands, likely because there is no jurisdictional difference between wetlands on either side of it. However, in some areas lands flooded by the tide are in public ownership by statute and it is likely, as this "tidal" boundary changes with sea-level rise, that criteria for the discernment of tidal versus nontidal wetlands in the coastal zone may be required.

Functions and values of coastal wetlands

Coastal wetlands are valuable ecosystems. By providing refuge and forage opportunities for fishes and macrocrustaceans, swamps, marshes, and mangroves around the world are the basis of many communities' economic livelihoods. Shallow ponds and seed producing vegetation provide overwintering habitat for millions of migratory waterfowl, and the structure of trees and forests is vital to songbirds and waders alike. The role of wetlands in uptaking nutrients and reducing loading to the coastal ocean is widely recognized, as is their value for protecting local communities from flooding—either by damping storm surges from the ocean or providing storage for riverine flood-waters. The economic value of tidal marshes and mangroves has been estimated at $9,990/ha/yr in a recent assessment of ecosystem services (Costanza *et al*., 1997).

According to Mitsch and Gosselink (2000) coastal wetlands include tidal salt marshes, tidal freshwater marshes, and mangrove swamps. Tidal swamps will also be considered here as they are extensive at the heads of estuaries and in coastal plain environments where tides influence water levels at great distances from the coastline.

Salt marshes

While saline marshes around much of the United States are dominated by *Spartina alterniflora*, regional variations include *Salicornia virginica* and *Spartina foliosa* in California and southern Oregon, to more diverse assemblages including *Distichlis spicata, Triglochin* spp., and *Plantago maritima* in the Pacific Northwest. In the west, these native halophytes are being supplanted at low tidal elevations by invasive *S. alterniflora* which can grow vigorously on open mudflats unavailable to the native species. Salinity typically varies between 15 and 33 ppt depending on coastal physiography and the level of freshwater inputs to the coastal ocean. Coastal salt marshes are highly productive systems. Tides, nutrients, and regular flushing offset the stresses associated with salinity, fluctuating temperatures, and alternate wetting and drying of the substrate. The detritus derived from this primary productivity supports higher trophic levels both via direct consumption and through microbial degradation which enhances the food value of the detritus. By providing shelter and refuge from predation, salt marsh margins are important nursery habitats for many fisheries species. For more detail see *Salt Marsh*.

Mangroves

Mangroves, comprising approximately 60 species of trees and shrubs, are the predominant form of vegetation in the intertidal zone of tropical estuaries, lagoons, and sheltered coastlines. They are largely confined to latitudes between 30°N and S of the equator, with a few notable exceptions that may be explained by the occurrence of warm ocean currents or by the presence of relict populations of more poleward past distributions (Duke, 1992). According to one recent estimate, the total area of mangroves in the world is 181,000 km^2 (Spalding *et al*., 1997). While mangrove trees are notable for their characteristic adaptations to anoxic soil environments, such as prop roots and pneumatophores (see *Vegetated Coasts*), their ecological function is very similar to coastal salt marshes. For more detail see *Mangroves*.

Tidal freshwater marshes

Inland from salt marshes but still close enough to the coast to experience tidal fluctuations in water level are wetlands dominated by a variety of grasses and annual and perennial broadleaved aquatic plants. This wetland type is found most commonly in the mid- and south-Atlantic coasts and in Texas and Louisiana. No known plant species appears exclusively in tidal freshwater areas. Most marshes are dominated by a combination of annuals and perennials most of which also occur in inland freshwater wetlands. Plant diversity is much higher than in salt marshes and on much of the Atlantic coast of the United States there are substantial seasonal changes in plant coverage (Odum *et al*., 1984). In the late winter and early spring there is a period of almost bare mud with some remaining stubble from previous years growth, followed by coverage with broad leaved plants in the late spring. By late summer the marshes are dominated by grasses and herbaceous plants. The soil conditions and hydrology of these marshes are very dependent on local conditions; although Odum *et al*. (1984) note that they are most likely fine mineral soils or peats.

In the Mississippi River delta plain a particular type of tidal freshwater marsh has developed in which, rather than being rooted in sediment, the plants live in an organic mat composed of live roots and decomposing litter. The level of this mat rises and falls with the tide. These marshes are termed "flotant." While Mitsch and Gosselink (2000) noted similar floating marshes in the Danube Delta and in lakes around the world, in coastal Louisiana O'Neil (1949) reported 100,000 ha of freshwater and brackish floating wetlands. Flotant is described by Sasser *et al*. (1994) as "wetlands of emergent vegetation with a mat of live roots and associated dead and decomposing organic material and mineral sediments, that moves vertically as ambient water levels rise and fall." Sasser *et al.* (1994) suggests that the floating marshes of the Mississippi delta plain have most likely developed in fresh marshes removed from riverine sediment inputs. There are several possible explanations for the formation of floating marshes. O'Neil (1949) suggests that floating marshes form when natural "attached" organic marshes are subjected to subsidence or sea-level rise and the buoyant organic mat is subjected to increasing upward tension. It eventually breaks free from its mineral substrate and floats (Figure W30(A)). Alternatively, the floating mat could grow and expand out into open water areas from existing marshes (Figure W30(B)).

Tidal freshwater marshes support a variety of waterfowl and animals from alligators to nutria. Their high primary production is only partly consumed directly with most being available to consumers through the detrital foodchain where benthic invertebrates play an important role. Mitsch and Gosselink (2000, p. 279) note that "of all wetland habitats, coastal freshwater marshes may support the largest and most diverse populations of birds." These include wading birds, dabbling ducks, birds of prey, and shorebirds, and the structural diversity of the wetland vegetation interspersed with shallow ponds is an important factor in their use of these wetlands.

Freshwater forested wetlands

Coastal wetland forests frequently have an extremely diverse flora of tree, shrub, and herbs. They can be roughly divided into deepwater swamps, in the southeastern United States dominated by bald cypress (*Taxodium distichum*) and tupelo gum (*Nyssa aquatic*), with a red maple (*Acer rubrum*) and buttonbush (*Cephalanthus occidentalis*) understory; and seasonally flooded bottomland hardwood forests dominated by several oak species (*Quercus* spp.), green ash (*Fraxinus pennsylvanica* var. *lanceolata*), and other hardwood species.

The character of coastal wetland forests is very sensitive to water level conditions, influenced in many areas by the tidal and gradual changes in sea level; as well as seasonal changes in riverine water levels at the heads of estuaries. Increases in freshwater discharge during floods are unlikely to result in any deleterious effects to freshwater forested wetlands as long as seasonal low-water periods allow for substrate drainage and forest regeneration. Bald cypress regenerates well in swamps where the substrate is moist and competing species are unable to cope with flooding. Seedlings must experience dry periods long enough to allow growth and survival of future flooding. However, prolonged flooding, associated with sea-level rise or a major change in riverine discharge regime, can result in changes. DeLaune *et al*. (1987) recognized gradients in seedling survival for both *T. distichum* and *Quercus lyrata* along an elevation gradient in a Louisiana coastal swamp. Increased flooding will thus reduce the area of appropriate elevation for seedling survival, and the findings of Rheinhardt and Hershner (1992) suggest that increased saturation of substrate will alter species composition in freshwater swamps. They found *Fraxinus* spp. and *Nyssa sylvatica* in wetter areas compared to *A. rubrum* and *Liquidambar styraciflua* within swamps of the Virginia coastal plain.

Sensitivities, threats, and management approaches

Coastal wetlands are undoubtedly some of the most valuable ecosystems in the world and also some of the most threatened. Climate change and variability compound existing stresses from human activities such as dredging and/or filling for development, navigation or mineral extraction, altered salinity and water quality resulting from watershed management and non-point source contamination, and the direct pressures of increasing numbers of people living and recreating in close proximity.

The survival of coastal wetlands under conditions of altered climate really depends primarily on the ability of the plants to survive. The biogeomorphic processes which control the wetland landscape may produce gradual changes, for example, from marsh to mangrove swamp, as long as the environmental thresholds which control plant survival are not crossed. The challenge in predicting coastal wetland response, either the nature of the gradual change, or when and where the thresholds are exceeded, depends upon interactions among the responses to various climate forcing. The very low gradients of coastal wetlands make them particularly susceptible to changes in water level and any adjustments in the hydrodynamic forcing from both ocean and watershed. While submergence associated with sea-level rise is frequently considered a serious threat to coastal systems, their inherent adaptation to coastal hydrology makes them perhaps less sensitive than terrestrial ecosystems

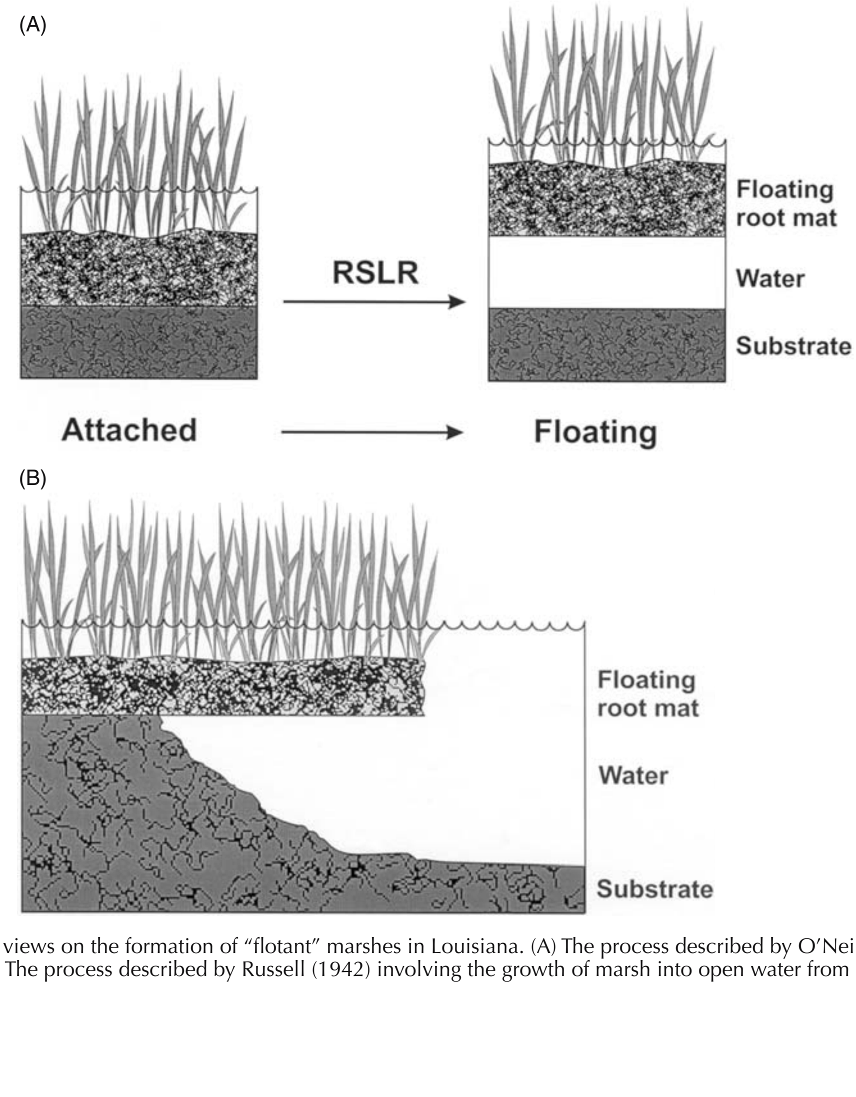

Figure W30 Alternative views on the formation of "flotant" marshes in Louisiana. (A) The process described by O'Neil (1949) involving relative sea-level rise (RSLR). (B) The process described by Russell (1942) involving the growth of marsh into open water from an existing stand.

subjected to frequent flooding by the encroaching sea. An examination of the response of various coastal wetland environments to climate change forcing illustrates the resilient nature of these systems and the complex biogeomorphic interactions that sustain them.

Increased freshwater is generally beneficial to coastal wetlands and a decrease may result in salinity stress for some communities. However, a gradual change does not necessarily result in plant death and wetland loss, and salt and brackish marshes may replace freshwater marshes and swamps. For example, the variation in salinities found by Visser *et al.* (1998) in marshes dominated by *Spartina patens* was so wide (average salinity 10.4 ± 5.8 ppt), and overlapped with the zone dominated by *S. alterniflora* (average 17.5 ± 5.9 ppt) that it seems likely that an increase of more than 1–2 ppt in salinity would be required to result in a significant change in habitat types in the more saline marshes. Decreases in salinity will likely increase the productivity of salt marsh plants as osmotic stresses are decreased. However, the salinity data of Visser *et al.* (1998) suggest that decreases in salinity of more than 5 ppt might be required for *S. alterniflora* to be replaced by more brackish marsh species.

Most coastal wetlands already cope with gradual sea-level rise. During the last 100 years, globally averaged sea level has risen at about 1–2 mm/yr. In most instances, these changes have not produced dramatic changes in coastal wetlands and accretionary processes have maintained wetland elevation and hydroperiod. Increased sediment delivery to coastal systems, resulting from future increased frequency of high intensity rainfall events, enhances sustainability by providing for vertical accumulation of substrate. Catastrophic sediment delivery could increase elevation sufficiently to convert coastal wetlands to areas of upland vegetation. However, unless the net effect is greater than the cumulative effects of sea-level rise, the effect should be seen as a type of dynamic equilibrium where episodic inputs counter long-term but low-level rise in sea level. Indeed it appears that many coastal wetlands in areas of high subsidence—and thus high relative sea-level rise—maintain their elevation through the episodic input of sediments associated with moderate-low frequency storms such as frontal passages and hurricanes (Reed, 1989; Cahoon *et al.*, 1995).

Coastal storms can bring more than beneficial sediments. The resilience of coastal wetlands to storm effects likely varies with salinity. Fresher systems are more susceptible to saline incursions during storms. For example, in South Carolina the storm surge caused by Hurricane Hugo flooded some low-lying coastal forests greater than 3 m deep with saltwater, and the surge carried saline water (> 20 ppt) along waterways up to several hundred kilometers inland (Blood *et al.*, 1991). Elevated soil salinity levels lingered for months after Hugo, and had adverse affects on tree survival and growth, as well as on nutrient cycling processes. The effect of tropical cyclone activity on forested wetlands can be structural as well as hydrologic. Low salinity and freshwater forested wetlands differ in their susceptibility to tropical storm wind impacts, with damage to forest types generally greatest to pines, least to swamp, with hardwoods intermediate (Conner, 1998). In the Atchafalaya River basin in south Louisiana, Hurricane Andrew caused little damage to cypress-tupelo communities but caused significant damage and mortality to bottomland hardwood forests (Doyle *et al.*, 1995). However, in some areas in the vicinity of Cape Cod, MA, USA, Atlantic white cedar wetlands were more severely affected by blowdowns from Hurricane Bob than adjacent upland forests, a fact attributed to their relatively shallow root systems (Valiela *et al.*, 1998). The long-term effect of storms on coastal wetlands depends upon the recovery time and the return interval of the storms. Increased frequency, if not intensity, of storm impact may therefore result in irreversible damage to forested systems or fragile organic substrates. For minerogenic salt marsh soils, however, storms can provide inputs of sediment essential to vertical sustainability.

It is important to recognize that these various responses may interact in ways that are difficult to predict, and that climatic and other stress factors and their interactions may result in a host of indirect effects on coastal wetlands, such as changes in patterns of herbivory or the rise in importance of alien species.

Management measures adopted to remediate loss of coastal wetlands must emphasize future sustainability of existing systems rather than re-creation of lost, impaired, or threatened habitats. The fisheries productivity, storm protection, and avian habitat provided by wetlands is dependent upon their landscape configuration, their internal structure, and their linkages with other coastal and marine resources. Such architecture is challenging to recreate and likely impossible to recreate given the other changes occurring at our coasts. Thus, management and planning strategies that provide for sustainable vertical accumulation, biodiversity, and linkages, both internally and with watershed and coastal ocean, are essential to wetland survival in the face of climate variability and long-term change. Climate change will continue to occur and it seems unlikely that development pressures will diminish in the near future (Nicholls and Small, 2002). Appropriate planning and management to facilitate change and adjustment of the coastal wetland landscape, rather than total loss of this valuable habitat, must be implemented to ensure the wetlands have a fighting chance (see *Coastal Zone Management*).

Summary and conclusions

Coastal wetlands occur at the transition from terrestrial to aquatic ecosystems and on the topographic gradient between upland and sea. Their definition on the ground has been a topic of much discussion in recent decades but importantly, this discussion has clearly identified fundamental wetland characteristics that vary in nature from place to place but which can be used to successfully distinguish wetlands from adjacent lands or waters. At the coast, important gradients in salinity and tidal inundation control the specific ecology and geomorphology of wetlands. When combined with climatic factors these drivers result in environments as different as low salt marshes to cypress-tupelo swamps. Coastal wetlands are undoubtedly among the most productive and valuable ecosystems on earth.

The vital role of vegetation in the form and function of coastal wetlands makes them particularly susceptible to pressures associated with urbanization and industrial development at the coast (see *Vegetated Coasts*). However, coastal wetlands are able to withstand disturbances and stresses associated with climate variability and in most cases future changes in climate will result in transitions and adjustments between and within coastal wetlands rather than the catastrophic loss sometimes projected. Most mangrove and freshwater forested wetland plant species are millions of years old, and therefore have survived through numerous and very large-scale changes in climate and sea level, including several ice ages and changes in sea level on the order of 100 or more meters. Survival under such circumstances generally depended on the ability to migrate, rather than on the persistence of individual wetlands. Individual coastal wetlands today can either accumulate vertically to maintain their position in the coastal zone or migrate as in the past. Both can occur—where conditions are favorable.

Wetlands Restoration

WETLAND RESTORATION

Wetlands are usually thought of as vegetated habitat on land that is flooded for at least part of each year. However, specific definitions vary. For example, the Canadian Wetland Registry defines wetlands as "land having the water table at, near, or above the land surface or which is saturated for a long enough period to promote wetland or aquatic processes as indicated by hydric soils, hydrophytic vegetation, and various kinds of biological activity which are adapted to the wet environment" (Mitsch and Gosselink, 1993, p. 26). In contrast, the Convention on Wetlands of International Importance Especially as Waterfowl Habitat (also known as the Ramsar Convention) defines wetlands as "areas of marsh, fen, peatland or water, whether natural or artificial, permanent or temporary, with water that is static or flowing, fresh, brackish, or salt including areas of marine water, the depth of which at low tide does not exceed 6 meters" (Mitsch and Gosselink, 1993, p. 26). While the first definition includes only vegetated habitats, the second definition includes nonvegetated habitats such as mudflats and shallow reefs. In a narrow sense, then, wetlands include salt marshes, mangrove forests, swamps, bogs, fens, marshes, muskegs, playas, moors, vernal pools, wet meadows, and similar areas, but in a broader sense wetlands also include sea grass beds, mudflats, coral reefs, shallow lakes, and shallow rivers (see bogs, mangroves, salt marsh, and wetlands).

Restoration can be defined as "the process of repairing damage caused by humans to the diversity and dynamics of indigenous ecosystems" (Jackson *et al*., 1995, p. 71). Thus, wetland restoration is the repair of anthropogenic damage to habitat that is saturated or flooded by shallow water for at least part of the year. Related terms include construction, creation, enhancement, mitigation, and rehabilitation (Table W7). Approaches to restoration include activities such as planting hydrophytes, control of invasive plants, grazing control, removal of fill, removal of structures that restrict water flow, and placement of dredged material to provide elevations suitable for wetland establishment.

Why restore wetlands?

In some areas, such as California in the United States and Java in Indonesia, more than 90% of the historic area of wetlands has been lost (Dahl, 1990; Crisman and Streever, 1996). Although estimates are influenced by many factors, most estimates suggest that about 50% of the world's wetlands have disappeared in the past few hundred years. Recognition of these losses, along with recognition of the economic and ecological value of wetlands and a general increase in environmental awareness, has inspired interest in wetland restoration. This interest is reflected in community action, incentive measures, and laws that require restoration under some circumstances.

Community action is often catalyzed by the efforts of nonprofit organizations, including relatively small organizations that operate locally or within a single country, such as the Yadfon ("Raindrop") Association in Thailand, and larger organizations that operate internationally, such as the Mangrove Action Plan and Wetlands International (Quarto, 1999). In some cases, community action manifests itself in the efforts of individuals undertaking restoration on their own property. For example, Kym Denver and his family have made extensive efforts to restore wetlands on their 1,200-ha farm near the mouth of the Murray River in South Australia (Denver, 1999) (Figure W31).

In some nations, government-backed incentive plans provide the impetus for restoration. These incentive plans usually involve direct payments or tax relief for landowners participating in restoration programs. For example, in southwest England the Environment Agency has paid about £450 per ha per year to landowners for participation in the Levels and Moors Strategy, which seeks to restore and maintain wetland habitat (Jenkins and Sturdy, 1999). Similarly, the Wetland Reserve Program in the United States pays farmers to restore wetlands on marginal croplands (Gaddis and Cubbage, 1998). For government projects, policies, and funding packages provide incentives for restoration. Examples include the Commonwealth Wetlands Policy in Australia, which encourages government agencies to consider restoration opportunities, and the Coastal Wetlands Planning, Protection, and Restoration Act in the United States, which provides millions of dollars for restoration of wetlands. At the international level, Resolution VII.17 of the Ramsar Convention encourages signatory nations to incorporate wetland restoration as an element of national planning.

Some nations also have laws that can require wetland restoration to compensate (or "mitigate") for destruction of wetlands that occurs as the result of development. In New South Wales, Australia, *State Environmental Planning Policy Number 14—Coastal Wetlands* can require restoration as compensation for the destruction of wetlands. Similarly, Section 404 of the Clean Water Act in the United States can require restoration to compensate for wetland losses caused by filling of wetlands.

Approaches to wetland restoration

There are dozens of approaches to wetland restoration, ranging from planting hydrophytic vegetation to constructing substantial earthworks to using innovations that set the stage for natural processes to restore wetlands. Often, different approaches are used together, in a single project. In all cases, restoration should begin with consideration of the impacts that caused degradation followed by development of specific objectives for the restoration project. In addition to ecological knowledge, successful restoration requires an understanding of hydrology and engineering as well as coordination among stakeholders that may include landowners, funding sources, nonprofit organizations, government agencies, and the local community. Although many handbooks provide guidelines for restoration, these guidelines are neither universally applicable nor definitive—every restoration project is to some degree unique, and every project requires some level of innovation and creativity.

One approach to restoration involves little more than planting. In the tropics, thousands of acres of mangroves have been planted, leading to

Table W7 Definitions of terms related to wetland restoration

Constructed wetland: Increasingly used to refer to wastewater or stormwater treatment wetlands, but occasionally used interchangeably with "created wetland."
Created wetland: Usually refers to a wetland built in an area that did not previously support a wetland.
Enhancement: An attempt to improve a specific wetland function, such as the ability of the wetland to support ducks.
Mitigation: Literally refers to the reduction of some impact, but is commonly used to describe a wetland that was restored or created to replace a wetland destroyed by development, especially under Section 404 of the US Clean Water Act.
Rehabilitation: Sometimes used to refer collectively to restoration, creation, and enhancement, but also used to refer to improving aesthetic qualities of a wetland.

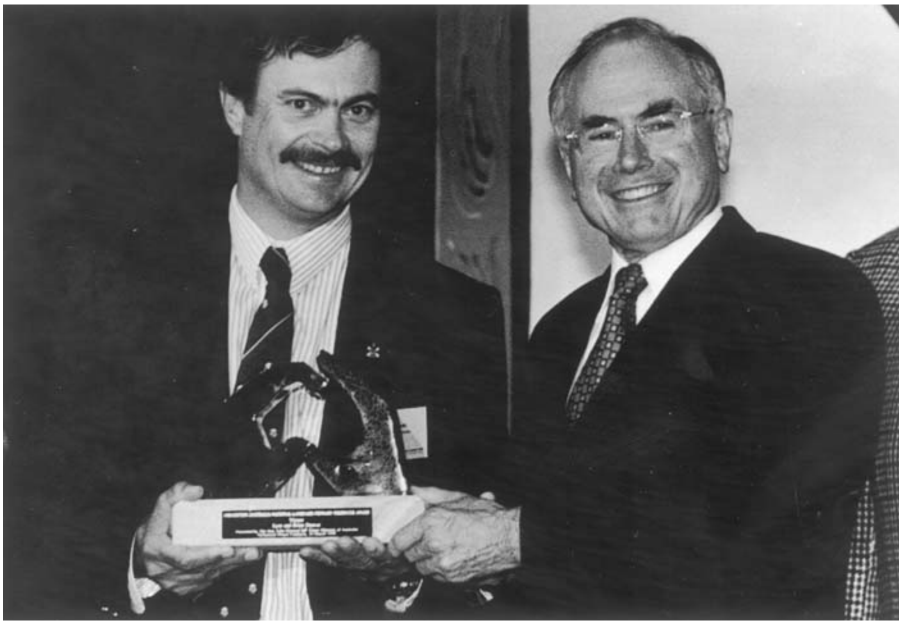

Figure W31 Australian Prime Minister John Howard (right) awards Kym Denver the 1998 National Landcare Primary Producer Award, in recognition of Denver's efforts to restore wetlands on his family's property in South Australia (from Streever, 1999; with permission of Kluwer Academic Publishers).

reestablishment of mangrove forest that had been cut for production of charcoal or for building materials (see mangrove restoration). When vegetation has been removed from a wetland but hydrological conditions remain unchanged, planting may be all that is required to meet restoration objectives. Often, however, construction of dikes or other activities change hydrological conditions, rendering planting alone insufficient as a means of restoration.

If hydrological conditions have been changed, restoration should address the hydrological change. Complete restoration of hydrology is not always possible because of constraints related to urban infrastructure, flood control, and other factors, but partial restoration of hydrology can contribute substantially to wetland restoration (Streever, 1998). For example, industrial and agricultural development has significantly affected the entire Hunter River Estuary in New South Wales, Australia, but replacement of small-diameter culverts with bridges in selected locations has led to increased tidal flushing and subsequent increases in wetland area (Streever and Genders, 1997). Similarly, in Florida, USA, dikes constructed as part of a mosquito-control program led to severe degradation of wetland habitat, but breaching of dikes to allow some tidal exchange led to rapid recovery of vegetation and fish populations (Brockmeyer *et al.*, 1997). However, even if hydrological conditions can be restored, impacts resulting from drainage may be difficult to overcome. In some coastal areas that have been temporarily drained for farming or other purposes, oxidation and subsidence can lower elevations or oxidation of naturally occurring pyrite can result in soil acidification so severe that substrates will not support plants even after the land is reflooded (White *et al.*, 1997).

Removal of fill has been undertaken at several locations to restore wetlands. In the Gog-Le-Hi-Te Wetland, in the Puyallup River estuary in Washington, USA, removal of about 55,000 m^3 of dredged river sediments and solid waste contributed to partial restoration of a 2.2-ha area (Simenstad and Thom, 1996). Other examples include the Tourle Street Bridge site near Newcastle, New South Wales, Australia, where slag from the iron-smelting industry was removed to restore intertidal wetlands (Day *et al.*, 1999), the Sweetwater River Wetlands Complex near San Diego, California, USA, where fill was removed to mitigate for wetland losses resulting from highway construction (Pacific Estuarine Research Laboratory, 1990), and numerous sites on the Alaskan North Slope, where gravel fill has been removed to promote recovery of tundra near the Beaufort Sea (Jorgenson and Joyce, 1994) (Figure W32). In some cases, natural habitat is excavated to create wetlands. For example, on the Grand Bay-Bangs Lake Estuary in Mississippi, USA, about 10 ha of salt marsh was created by excavating sediment from a pine forest (LaSalle, 1996).

In contrast to fill removal for wetland restoration, sediment dredged from navigation channels is sometimes placed in shallow water to restore or create vegetated wetlands (Streever, 2000). Typically, hydraulic dredges remove sediment from a navigation channel and pump it through a pipeline to the wetland project site. Fine sediments must be contained within earthen berms or other structures to allow consolidation, while sandy sediments can be placed on shallow bay bottoms without confining structures. In the 1970s, when technology for dredged material wetlands was in the early stages of development, success was typically defined by establishment of vegetation, but in recent years increased emphasis has been placed on maximizing all aspects of similarity between natural and dredged material wetlands. For example, in the Atchafalaya Delta, Louisiana, USA, attempts have been made to build dredged material marshes with geomorphology similar to that of naturally accreting deltaic marshes (Figure W33).

Restoration sometimes requires removal of contaminants, including contaminants from oil spills and industrial development. In some cases, contaminants enter groundwater. For example, the Jauá Lake wetlands, a system of freshwater wetlands sitting between an extensive stretch of sand dunes and the Atlantic Ocean in Bahia, Brazil, were contaminated when domestic and industrial waste infiltrated into groundwater, and restoration required removal of contaminated groundwater (da Silva *et al*., 1999) (Figure W34).

Figure W32 Bill Streever points to peat exposed by removing gravel from an abandoned work pad near the Beaufort Sea on the North Slope of Alaska. Gravel removal is the first step in tundra rehabilitation.

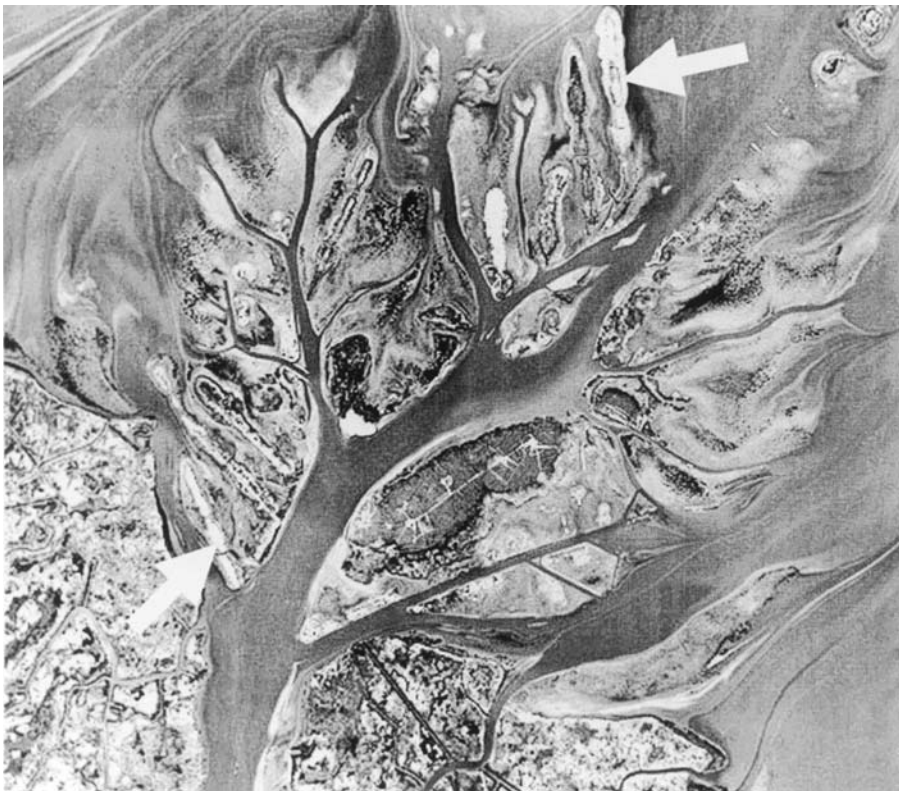

Figure W33 Arrows point to recently created dredged material wetlands built to mimic the natural geomorphology of the Atchafalaya Delta, Louisiana, USA.

For large-scale restoration, costs can prohibit extensive on-the-ground activities. This reality has prompted development of methods that rely on natural processes to restore wetlands. For example, in Louisiana, USA, natural levees have been intentionally breached to facilitate deposition of Mississippi River sediments on shallow bay bottoms, leading to development of vegetated wetlands at costs as low as US$54 per ha by mimicking the natural delta-building process of crevasse-splay formation (Turner and Boyer, 1997) (Figure W35).

Key research issues

As the number of restoration projects has increased over the past few decades, the amount of research on restoration has also increased, but the majority of this research has been recorded in reports with limited distribution. Most research consists of site-specific attempts to track wetland development, but some research has attempted to assess restoration efforts by looking at collections (or "populations") of restored wetlands. Most research, whether it is site-specific or more

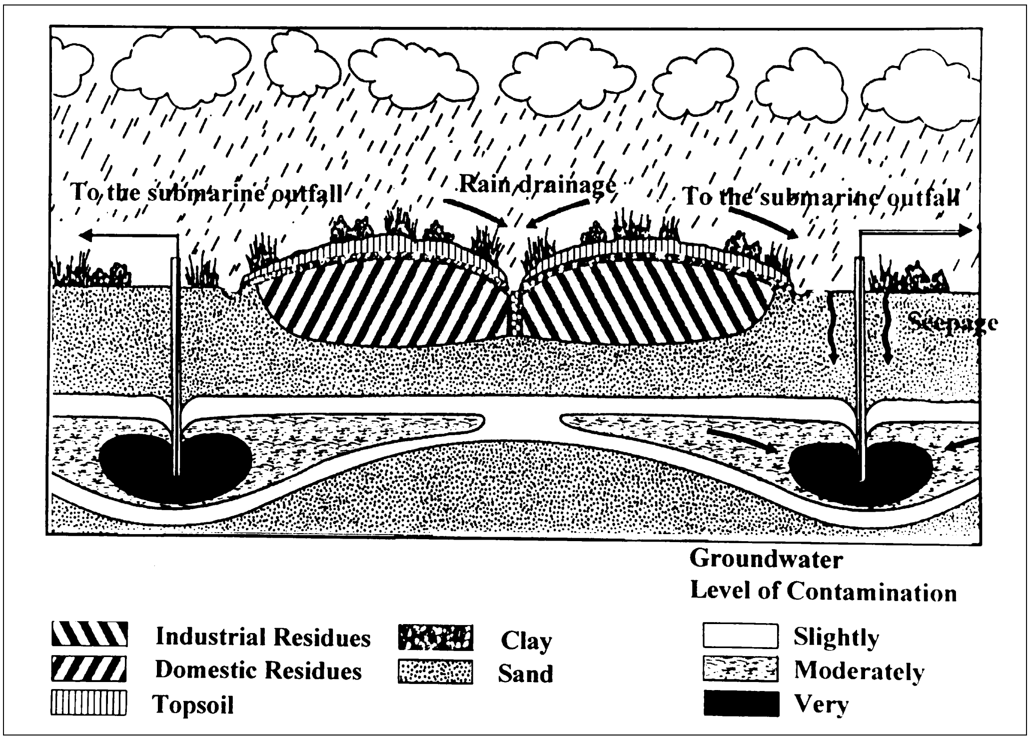

Figure W34 The Jauá Lake wetlands in Brazil (top) were degraded by spills that contaminated the groundwater, leading to a need for restoration that included groundwater withdrawal (bottom) (from Streever, 1999; with permission of Kluwer Academic Publishers).

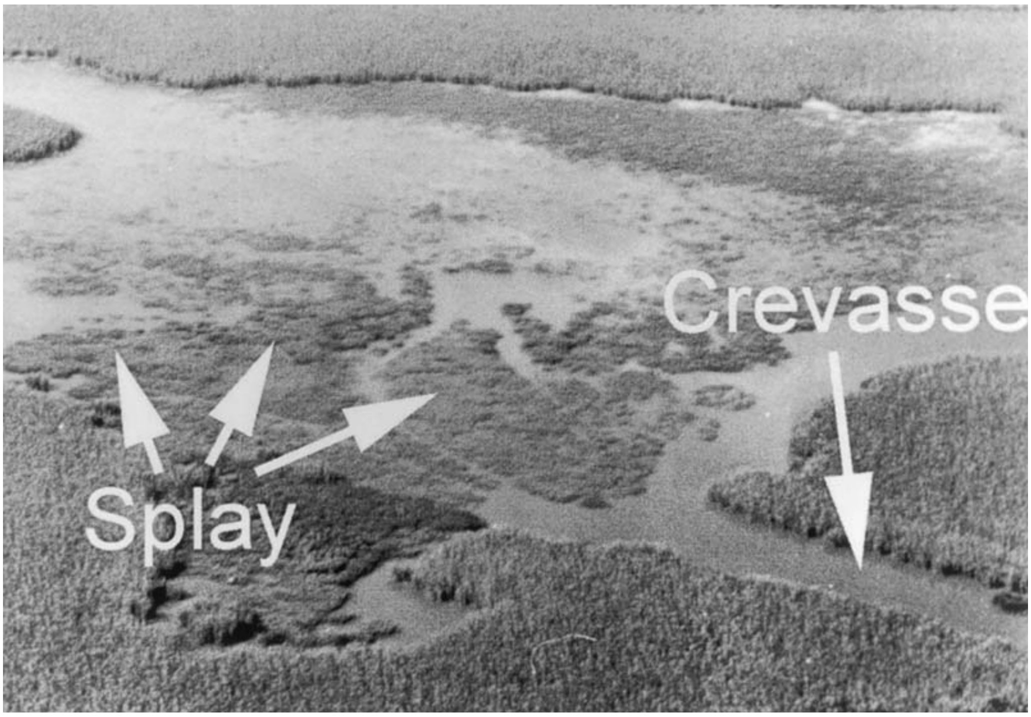

Figure W35 Crevasse splay restoration project near the mouth of the Mississippi River.

broad, addresses two questions. First, how do restored wetlands compare to natural wetlands? And second, do restored wetlands follow a developmental performance curve, or trajectory, leading to increased similarity with natural wetlands over time? In addition to addressing these questions, restoration research has contributed to improved methods of plant establishment, development of engineering alternatives for shore protection, a better understanding of relationships among physical and biological components of wetlands, and other topics. Despite the amount of research that has been completed, useful broad generalizations about wetland restoration remain elusive.

Studies comparing natural and restored wetlands often suffer from pseudoreplication (in the sense of Hurlbert (1984)), in which conclusions about all natural and restored wetlands are generalized from data based on replicate samples collected from a single natural reference wetland and a single restored wetland. However, over time data have accumulated from hundreds of studies comparing pairs of natural and restored wetlands. Cumulative results from these studies and from studies of populations of wetlands clearly indicate that restored wetlands often do not have all of the same structural and functional attributes found in nearby natural wetlands, even many years after restoration efforts have been completed. That is, some attributes of restored wetlands, such as percentage cover by vegetation and abundance of invertebrates, may be indistinguishable from those of natural reference wetlands, but other attributes of restored wetlands, such as soil organic content and rates of nutrient cycling, may be clearly different from those of natural reference wetlands. Furthermore, some differences may persist indefinitely. Zedler (1999) noted that similarity between restored and natural wetlands depends on the degree of degradation at the beginning of the restoration project as well as the degree of effort invested in restoration.

When variables such as abundance of invertebrates or organic content in soils are plotted against time, the resulting curve is sometimes called a "performance curve" or "trajectory." However, because the term "trajectory" implies a specific type of curve (i.e., the curve described by a projectile moving through space, or a curve that passes through a set of points at a constant angle), the phrase "performance curve" may be more appropriate for describing plots that illustrate wetland development over time. Performance curves can be plotted in at least two ways: as measured values plotted against time, or as relativized values plotted against time. Relativized values are measured values that have been standardized against values found at a natural reference site or sites, usually by dividing the measured value from the restoration site by the measured value of the natural reference site or sites. Relativized values help account for intra- and inter-annual variability in measured values. Because there are few long-term data sets for individual restored wetlands, some researchers have endeavored to analyze data from multiple restored wetlands of different ages, making it possible to plot performance curves across time but adding the confounding factor of site-to-site variability. Simenstad and Thom (1996) described five types of performance curves, including curves that (1) converge with the mean found for reference wetlands, (2) approach and surpass the mean found for reference wetlands, (3) develop toward the mean found for reference wetlands but then stabilize at a level lower than that of reference wetlands, (4) follow a sigmoidal trend that reaches an asymptote at the mean found for reference wetlands, and (5) decline from a level higher than that of reference wetlands to a level below the mean of reference wetlands. In keeping with results of studies comparing natural and restored wetlands, currently available research clearly shows that different wetland attributes can have different performance curves even within an individual wetland. For most restored wetlands that have been closely examined, performance curves for at least some attributes have not reached levels found in natural reference wetlands even after many years of development.

The future of wetland restoration

Research illustrating the shortcomings of restoration approaches may eventually lead to a reduced willingness to trade natural wetlands for restored wetlands, as is frequently allowed under legislation such as Section 404 of the Clean Water Act in the United States. However, wetland restoration has a short history, and current trends indicate that interest in restoring wetlands will continue to increase dramatically around the world. Research and experience will continue to contribute to improvements in restoration approaches, and innovative techniques are likely to reduce costs per area. The scale of some restoration efforts is also likely to increase, as exemplified by efforts to restore parts of the Florida Everglades and Louisiana's coastal wetlands in the United States. Techniques for wetland restoration used in wealthy nations are increasingly exported and adapted for use in the developing world. Although it is unlikely that restoration will ever lead to complete replacement of wetlands destroyed over the past two centuries, it is becoming increasingly likely that restoration efforts will complement preservation efforts and one day stem the ongoing loss of wetlands around the globe.

APPENDIX 2: JOURNALS

Professional journals, periodicals, gazetteers, government publications, and trade magazines are a primary means of communicating information among coastal scientists. These information sources are usually provided to users as hard copy on paper stock, but there is an increasing trend toward dual publication with electronic versions becoming more widely available. Consideration of the topic in terms of content, availability, and cost is, however, not as simple as it might first appear. There have been many recent changes in the media of communication. Most senior researchers are familiar with paper copy volumes that were searched via perusal of tables of contents in various research publications (e.g., *Current Contents*) or by tracking down references cited in research papers. Prior to the last decade, journals were generally inexpensive enough for most professionals to subscribe on a personal basis. Many researchers built up a personal research library comprised by books and journals, the latter supplying the most recent cutting edge information. These private libraries were often conveniently located at a university or home office. Notes kept on index cards or bookmarks often signaled important articles or passages in journals. The coastal researcher was conversant with the literature and it often was mostly at hand for immediate perusal in the office or research laboratory.

Sometimes professional organizations publish lists of citations in specialized fields for specific time frames, as a means to facilitate or expedite the compilation and perusal of the coastal literature. Examples include supplements to the *Annotated Bibliography of Quaternary Shorelines* published by the Academy of Natural Sciences of Philadelphia (e.g., Special Publication No. 6, 1965; Special Publication No., 10, 1970; Special Publication No. 11, 1974), GeoAbstracts (East Anglia, UK) (*Third Supplement*, 1979), and *Journal of Coastal Research* (*Fourth Supplement*, 1986). The *International Bibliography of Coastal Geomorphology* (Sherman, 1992; Kelletat, 1996), published by the *Journal of Coastal Research* and the International Geographical Union (Commission on Coastal Systems), is another example of efforts to summarize a great literature of coastal research in comprehensive bibliographic lists for specialized fields. Such efforts are noteworthy in themselves because they are not common. When available in electronic format on a CD, for example, the search capabilities are enormously increased and the research value of the compendium is substantially increased over paper copy.

The convenience and familiarity of yesteryear is but a memory of the past. Research procedures and access to information was changed forever with the advent of the modern personal computer. With the development of online databases and electronic libraries, it became possible to conduct global searches via the Internet without leaving the office. With advances in modern technology came many innovations that assisted the document search process, but there were also downsides. With declining numbers of subscribers, journal costs increase to the point where it becomes impossible for individuals to maintain complete personal libraries of hard (paper) copies. Publishers, responding to declining subscriberships thus offer electronic copies of individual articles or entire issues. Most journals now provide access to free abstracts of papers in an effort to encourage purchase of the article for a royalty or access fee. There are also service bureaus and search services that provide electronic summaries of search results that list papers in a wide range of journals. Not only has the shelf space in the professorial office shrunk, but libraries as well often do not subscribe to hard copies of journals because they rely on a central source for interlibrary loan or use electronic services to order requested papers. This is an increasingly electronic age where much research is conducted in front of a computer screen.

There are pros and cons in these new venues for dissemination of information related to coastal research. There are many physical and psychological disadvantages to spending long hours in front of computer screens. Back radiation from monitors, eyestrain, carpal tunnel syndrome, and lack of physical exercise are but a few of the drawbacks. Positive aspects focus on access to vast amounts of information not heretofore possible to the average person. But, again there are pros and cons to the flood of data offered by computer searches. Search results require much sifting of data for relevancy and computer searchers often miss critical, nonmainline sources of information. It is a trade-off, computer searchers versus perusal of personal hard copies or visits to the stacks in libraries.

Journals, the basic resource for armchair research, cover all aspects of coastal research but inclusion of all relevant or pertinent journals becomes problematic depending on the definition of coastal research (see Introduction; Management) and specific fields of interest. Even more basic is consideration of what is "coastal" from a definitional point of view, at least as far as reporting research results is concerned. Greater diffusivity of the concept of what constitutes a *coastal topic* relates to viewpoints, perspectives, and orientation of study problems. The focus or content of journals is relatively clear-cut for the basic sciences (e.g., biology, geology) but becomes blurred in applications (e.g., coastal engineering, ecology, geophysics, geochemistry, geotechnique, biogeochemistry, hydrophysics, hydrochemistry, hydrobiology, sedimentology, remote sensing), and extremely broad ranging in the management subfields (e.g., coastal environments; marine pollution; use of maritime and marine resources; legal, political, social, and economic analyses). Although studies in the pure sciences (e.g., physics, chemistry) can be very specific, coastal research is mostly conducted from the purview of some application or for greater understanding of coastal shape or configuration due to wave action (e.g., coastal morphodynamics). The scope of coastal science is thus potentially vast and the possibilities of research materials are almost limitless. As an example of the wide range of source materials for coastal research, Table A2.1 is the result of a partial and edited printout of holdings in the coastal library at NOAA's Coastal Services Center (Charleston, South Carolina). This eclectic assemblage of journals represents one perspective of what constitutes a useful public research library in the coastal sciences. Even though data fields in the compilation are sometimes incomplete, the list illustrates a broad interest base for a national coastal service center. Fortunately, the central core of coastal science clumps together lines of research that focus on biological and geological principles, engineering practices, and to a lesser extent various management issues and mathematical modeling. The objectives, goals, and interests of the supporting organization thus restrain the universe of serials retained in any library devoted to coastal research. If nothing else, the list in Table A2.1 emphasizes the wide range of subject matter that must be considered in a government service center library. Some holdings in the library are mainline professional journals, as listed in Table A2.2,

Table A2.1 List of some journal holdings by the Coastal Services Center (NOAA, National Ocean Service, Charleston, South Carolina), illustrating the diverse range of information sources that are required to support coastal research interests

[2] Based on computer searches during the compilation of this table, it was not possible in some cases to locate ISSN numbers or a Website contact. Further information can be obtained from the NOAA Coastal Services Center Library at www.csc.noaa.gov/library/. Conventional contact information for the center is as follows: 2234 South Hobson Avenue, Charleston, SC 29405-2413.

Table A2.2 Select list of primary international, national, and regional coastal science journals, based on relevance of subject matter and orientation of readership, published on a regular basis in English

Journal	Content, scope, or society affiliation	Publisher	ISSN	1st issue	Frequency/cost	Description and notes
Primary sources of academic and scientific coastal research information						
Bulletin of Marine Science	International journal: marine science	Rosensteil School of Marine and Atmospheric Science (Miami, Florida)	0007-4977	1951	6/year $225 Institution $85 personal	All aspects of marine science are included: marine biology, biological oceanography, fisheries, marine affairs, applied marine physics, marine geology and geophysics, marine and atmospheric chemistry, and meteorology and physical oceanography.
Coastal Engineering	International journal: engineering applications	Elsevier (The Netherlands)	0378-3839	1977	12/year $1207 Institution	Combines practical application with modern technological and scientific achievements in fundamental studies and case histories for coastal, harbor and offshore engineering: studies on waves and currents; coastal morphology; estuary hydraulics; harbor and offshore structures.
Coastal Engineering Journal	International journal: coastal, harbor, and offshore engineering	World Scientific (USA)	0578-5634	1959	4/year $292 Institution	Deals with waves and currents, sediment motion and morphodynamics, predictive methods for environmental processes, hard and soft technologies related to coastal zone development, shore protection, and prevention and mitigation of coastal disasters.
Coastal Management	International journal: marine environment, resources, law, and society	Taylor & Francis (USA)	0892-0753	1973	4/year $335 Institution	Explores the technical, legal, political, social, and policy issues surrounding the utilization of valuable and unique coastal environments and resources.
Continental Shelf Research	International journal	Elsevier Science (The Netherlands)	0278-4343	1982	15/year $216 Institution	Presents research results in physical oceanography, chemistry, ecology, sedimentology, and applied aspects of continental shelf research.
Coral Reefs	International Coral Reef Society	Springer-Verlag (Germany)	0722-4028	1982	4/year $468 Institution	Covers reef structure and morphology, biogeochemical cycles, behavioral ecology, sedimentology, and evolutionary ecology of the reef biota.
Estuarine, Coastal and Shelf Science	Estuarine, Coastal, and Shelf Science Society	Academic Press (United Kingdom)	0272-7714	1973	12/year $1524 Institution	Devoted to the analysis of saline water phenomena ranging from the outer edge of the continental shelf to the upper limits of the tidal zone.
Estuaries	International journal: estuarine and coastal waters	Estuarine Research Federation (USA)	0160-8347	1978	6/year $320 Institution	Includes papers on any aspect of research on physical, chemical, geological, or biological systems, as well as management of those systems, at the interface between the land and the sea.
Geo-Marine Letters	International journal: marine geology	Springer-Verlag	0276-0460	1981	4/year $496 Institution	Publishes papers dealing with all marine geological aspects including: (1) marine geology, (2) marine geophysics, (3) marine geochemistry, (4) marine geotechnique, (5) environmental problems where geo-marine studies play a role, (6) new techniques or modifications, and (7) applications.
Journal of Coastal Conservation	International conservation	European Union of Coastal Conservation (Sweden)	1400-0350	1995	4/year $200 Institution	A scientific journal for integrated research and management of the coastal zone. Emphasis is on natural resources and their sustainable use in the context of past and future social and economic developments.

Table A2.2 (*Continued*)

Journal	Content, scope, or society affiliation	Publisher	ISSN	1st issue	Frequency/cost	Description and notes
Journal of Coastal Research	International forum for the littoral sciences	The Coastal Education & Research Foundation (USA)	07049-0208	1985	4/year $145 Institution $75 Personal	Dedicated to all aspects of coastal (marine) research. Encourages dissemination of knowledge and understanding of the coastal zone by promoting cooperation and communication between specialists in different disciplines.
Marine Geology	International journal: marine geology, geochemistry, and geophysics	Elsevier Science	0025-3227	1964	28/year $2768 Institution $167 Personal	Original research and comprehensive reviews in the field of marine geology, geochemistry, and geophysics.
Marine Georesources and Geotechnology	International journal: seabed resources, methods of exploration and extraction	Taylor & Francis	1064-119X	1993	4/year $275 Institution $146 Personal	Devoted to all scientific and engineering aspects of seafloor sediment and rocks.
Marine Mammal Science	International journal: marine mammals	Society for Marine Mammalogy (USA)	0824-0469	1985	4/year $18 each issue	Presents original research and observations on marine mammals, their evolution, form, function, husbandry, health, populations, and ecological relationships.
Marine Policy	International journal: ocean law and policy	Elsevier	0308-597X	1977	6/year $723 Institution	Offers researchers, analysts and policy makers a unique combination of legal, political, social, and economic analysis.
Marine Pollution Bulletin	International journal: pollution in estuaries, seas, and oceans	Elsevier	0025-325X	1970	6/year $942 Institution	Concerned with the rational use of maritime and marine resources in estuaries, the seas and oceans. Documents marine pollution and new forms of measurement and analysis. Includes research reports on effluent disposal and pollution control.
Ocean and Coastal Management	International journal: all aspects of ocean and coastal management	Elsevier Science	0964-5691	1973	12/year $1138 Institution $107 Personal	Covers all aspects of ocean and coastal management at local, regional, national, and international levels.
Ocean Engineering	International journal: research and development	Elsevier Science	0029-8018	1968	8/year $1798 Institution $223 Personal	Covers the design and building of ocean structures; submarine soil mechanics; coastal engineering; ocean energy; underwater instrumentation, marine resources and other related issues.
Shore & Beach	American Shore & Beach Preservation Association	ASBPA (USA)	0037-4237	1926	4/year $250 Institution	Deals with shore protection measures, coastal engineering, beach nourishment, methods and techniques, and beach management.
Secondary sources of academic and scientific information related to coastal research						
Acta Oceanologica Sinica	Chinese Society of Oceanography	China Ocean Press	0253-4193	1979	4/year $420 Institution	Publishes scholarly papers on marine science and technology, including physics, chemistry, engineering, remote sensing, and instrumentation. (Text in English)
ASLO Bulletin	American Society of Limnology and Oceanography	ASLO (USA)	0024-3590	1990	3/year $75 Members	Informs members of society events and provides a forum to discuss issues.
Australian	Commonwealth	CSIRO (Australia)	0067-1940	1950	8/year	Presents research in physical oceanography,

Marine and Freshwater Research	Scientific & Industrial Research Organization				$650 Institution $165 Personal	marine chemistry, marine and estuarine biology, and limnology.
Chinese Journal of Oceanology and Limnology	National research journal	Science Press (China)	0254-4059	1982	4/year	Covers hydrophysics, hydrochemistry, hydrobiology, geomorphology, apparatus research and manufacture, comprehensive reviews, and academic activities.
Helgoland Marine Research	Alfred-Wegener-Institute for Polar and Marine Research	Springer-Verlag	1438-387X	1946	4/year $169 Institution	Publishes original research papers, invited reviews, and comments on any aspect and level of the biology of marine and brackish water organisms.
ICES Journal of Marine Science	International Council for the Exploration of the Sea	Academic Press	1054-3139	1926	4/year $527 Institution	Contains original papers within the broad field of marine and fisheries science. References subjects including ecology, population studies, plankton research, and physical and chemical oceanography.
Indian Journal of Marine Science	Indian National Science Academy	CSIR (India)	0379-5136	1972	4/year $100 Personal	Publishes mainly papers and scientific articles in coastal and all fields of marine sciences about India, Oceania, and Red Sea regions.
Journal of Ecology	International journal: marine and terrestrial ecology	British Ecological Society (England)	0022-0477	1996	6/year $550 Institution	Publishes original research papers on all aspects of ecology of plants (including algae) in both aquatic and terrestrial ecosystems.
Journal of Geophysical Research—Oceans	International journal: geophysical research in the oceans	American Geophysical Union (USA)	0148-0227	0148-0227	12/year $120 Members	Covers physical, biological, and chemical oceanography.
Journal of Physical Oceanography	American Meteorological Society	American Meteorological Society (USA)	0022-3670	1971	12/year $445	Publishes research related to the physics of the ocean and of the processes operating at its boundaries.
Journal of Waterway, Port, Coastal and Ocean Engineering	American Society of Civil Engineers	American Society of Civil Engineers (USA)	0733-950X	1956	6/year $220 Institution $74 Personal	Presents information regarding the engineering aspects of dredging, floods, ice, pollution, sediment transport, and tidal wave action that affect shorelines, waterways, and harbors.
Marine Environmental Research	International Journal	Elsevier	0141-1136	1978	12/year 1196.00 Institution	Publishes original research papers on chemical, physical, and biological interactions in the oceans and coastal waters.
Marine Technology Society Journal	International journal: ocean and marine engineering, science, and policy	Marine Technology Society (USA)	0025-3324	1963	4/year $50 Membership	International interdisciplinary journal devoted to the exchange of information in ocean and marine engineering, science, and policy.
Netherlands Journal of Sea Research	Netherlands Institute for Sea Research	Netherlands Institute for Sea Research (The Netherlands)	0077-7579	1961	8/year $453 Institution $112.00 Personal	Contains papers on marine research with emphasis on non-applied aspects and contributions to the understanding of the functioning of marine ecosystems, including abiotic systems.
Oceanologica Acta	Review of European Oceanology	Gauthier-Villars (France)	0399-1784	1978	6/year $386 Institution	Presents results of works in all sections of oceanography and from all parts of the oceans and their adjacent estuaries and brackish water systems.
Photogrammetric Engineering and Remote Sensing	American Society for Photogrammetry & Remote Sensing	Potomac Publishing Services (USA)	Not listed	1996	12/year $160 Institution	Commonly referred to as *PE&RS*, the journal for imaging and geospatial information science and technology, is the flagship publication of the Society.

Table A2.2 (*Continued*)

Journal	Content, scope, or society affiliation	Publisher	ISSN	1st issue*	Frequency/cost	Description and notes
Remote Sensing of Environment	International journal: multidisciplinary remote sensing	Elsevier	0034-4257	1969	12/year $1896 Institution $115 Personal	Serves the remote sensing community with the publication of scientific and technical results on theory, experiments, and applications of remote sensing of earth resources and environment.
Tertiary sources of information that are occasionally relevant						
Acta Hydrochimica et Hydrobiologica	European focused journal	John Wiley & Sons, Ltd. (United Kingdom)	0323-4320	1972	6/year $698 Institution	Reports on the latest from all areas of water and environmental research.
Aquatic Conservation: Marine and Freshwater Ecosystems	International journal	John Wiley & Sons, Ltd.	1099-0755	1990	6/year $630 Institution	Dedicated to publishing original papers that relate specifically to freshwater, brackish, or marine habitats and encouraging work that spans these ecosystems.
Earth Surface Processes and Landforms	British Geomorphological Research Group	John Wiley & Sons	0197-9337	1976	9/year $1920 Institution	Contains important research papers on all aspects of geomorphology interpreted in its widest sense, including both pure and applied.
Environmental Pollution	International journal	Elsevier	0269-7491	1970	12/year $3111 Institution $98 Personal	Addresses issues relevant to the nature, distribution, and ecological effects of all types and forms of chemical pollutants in air, soil, and water.
Geology	Geological Society of America	GSA (USA)	0091-7613	1973	12/year	Topical scientific papers on all earth science disciplines worldwide.
Hydrobiologia	International journal	Kluwer Academic Publishers (The Netherlands)	0018-8158	1973	12/year $7216 Institution	A wide range of papers is published, including ecology, physiology, biogeography, methodology, and taxonomy.
International Journal of Marine and Coastal Law	International journal	Kluwer Law International (The Netherlands)	0927-3522	1985	4/year $377 Institution	Addresses all aspects of marine (maritime) and coastal law.
International Journal of Remote Sensing	International journal for remote sensing	Taylor & Francis	0143-1161	1980	18/year $2567 Institution	Is concerned with the science and technology of remote sensing and the applications of remotely sensed data in all major disciplines. Principal topics include: data collection; analysis, interpretation and display; surveying from space, air, and water platforms; sensors; image processing; use of remotely sensed data; economic surveys and cost–benefit analyses.
Journal of Geology	International journal: geological sciences	University of Chicago Press (USA)	0022-1376	1893	6/year $113 Institution $48 Personal	Publishes original contributions dealing with any aspect of geology including space science. Contributions should have wide appeal to geologists, present new concepts, and/or derive new geological insights through the use of new approaches and methods.
Journal of Great Lakes Research	International Association for Great Lakes Research	IAGLR (USA)	Not listed	1974	4/year $100.00 Institution $70 Personal	A eclectic mix of papers from various scientific, management, and policy perspectives all focused on a single topic: large lakes of the world.

Journal of Sea Research	International journal	Elsevier	1385-1101	1997	6/year $453 Institution $112 Personal	An international and multidisciplinary periodical on marine research, with an emphasis on marine ecosystems, including both biotic and abiotic aspects of all types of marine and estuarine systems, benthic as well as pelagic.
Journal of Marine Science and Technology	International journal	Springer-Verlag	0948-4280	1996	4/year $180 Institution	Provides a forum for the discussion of current issues in marine science and technology by publishing original, full-length, refereed contributions on research and/or developments in this field.
Journal of Marine Systems	International journal	Elsevier	0924-7963	1990	12/year $1789 Institution $102 Personal	Provides a medium of exchange for those engaged in marine research where there exists an interplay between geology, chemistry, biology, and physics.
Journal of Oceanography	Oceanographic Society of Japan	Kluwer Academic Publishers	0916-8370	1942	6/year $479 Institution $288 Personal	This bimonthly journal is published in English, in order to promote the research in pure and applied oceanography internationally.
Journal of Sedimentary Research	International journal: sediments and sedimentary rocks	Society for Sedimentary Geology (USA)	1073-130X	1926	6/year $195/year Nonmembers and institutions	Includes research papers, perspectives, and methods in any area of sedimentary geology.
Marine Biology	International journal: life in coastal and ocean waters	Springer-Verlag	0025-3162	Not listed	6/year $4028 Institution	Publishes articles in plankton research, experimental biology, molecular biology, biochemistry, physiology and behavior, biosystem research, evolution, theoretical biology related to the marine environment, methods and others.
Marine Chemistry	International journal	Elsevier	0304-4203	1973	12/year $1670 Institution $282 Personal	An international medium for the publication of original studies and occasional reviews in the field of chemistry in the marine environment, with emphasis on the dynamic approach.
Marine and Freshwater Research	Regional journal: Australia Academy of Sciences	Commonwealth Scientific & Industrial Research Organization (Australia)	1323-1650	1949	8/year $550 Institution $150 Personal	The broad subject scope imparts a particular strength in publishing multidisciplinary papers such as those in biogeochemistry.
Marine Geophysical Researches	International journal: study of the earth beneath the sea	Kluwer	0025-3235	1970	$583/volume Institution	Emphasizes the description and analysis of structures that can be investigated with geophysical methods only, and the study of the physical processes that led to the origin of these structures. Includes fundamental studies and case histories coastal, harbor, and offshore engineering: waves and currents; coastal morphology; estuary hydraulics; harbor and offshore structures.

Table A2.2 (*Continued*)

Journal	Content, scope, or society affiliation	Publisher	ISSN	1st issue*	Frequency/cost	Description and notes
Progress in Oceanography	International journal	Elsevier	0079-6611	1963	8/year $1962 Institution $162 Personal	Publishes the longer, more comprehensive papers that most oceanographers feel are necessary, on occasion, to do justice to their work.
Sea Technology	News magazine	Compass Publications (USA)		1965	12/year $35 in USA $115 Foreign	Provides current information on the worldwide marine/ocean industry through state-of-the-art and application articles.
Sedimentary Geology	International journal: pure and applied sedimentology	Elsevier Science	0037-0738	1967	24/year $2347 Institutional $156 personal	Provides a forum for the publication of research across the entire spectrum, from analytical techniques to regional or geodynamical aspects of sedimentary systems and basin analysis.
Sedimentology	International Association of Sedimentologists	Blackwell Scientific Publications (United Kingdom)	0037-0746	1952	6/year $835 Institution	Promote the study of sedimentology, interchange of research and international cooperation between sedimentologists.
Zeitschrift für Geomorphologie	International journal: geomorphology	K. Triltsch, Wuzburg (Germany)	0044-2798	1957	12/year	International journal for geomorphology.

(1) Prices are quoted on an annual basis, unless otherwise noted, for institutions. Personal rates are given for some journals, if available on the journal Website. Because some journals offer reduced personal rates for members of socities, these rates are not always readily available.
(2) Journal prices are quoted in US$ on a 2000–2001 volume cost basis, unless otherwise noted. Most journals are published in volume-years, one volume to one year, but some journals produce more than one volume per year. The price noted thus includes variable numbers of issues per volume on an annual basis.
(3) This list of journals is based on Internet-based computer searches initiated by general and specific titles, key words, or subject areas. Additional information was secured from the publisher's Website and used to fill out comments concerning scope and orientation, the ISSN number, date of first issue, frequency and cost, and ancillary comments or notes about the journal.

but there are also a large number of "soft" information sources that are required for effective coastal zone management. Even though some of these tertiary information sources have a definite corporate bias (e.g., *ARC News*, *Calypso Log*, *Geo Info Systems*, *GIS World*, *GPS World*, *Meeting News*, *Publish!*, *Spotlight*, *Successful Meetings*, *Sun Expert*, *UNIX Review*, *Visual Developer*), they provide practical information to coastal researchers who require expertise in diverse technical and socioeconomic fields to supplement their professional or academic expertise.

There are thus many different possibilities for the organization of a journal list. One approach might be to list journals alphabetically without comment or consideration of frequency of use, relative importance, by coastal researchers. The choice of what journal should be listed in a "coastal" list thus becomes subjective and some criteria must be applied for selective inclusion, in preference to personal impressions or bias. Another approach might be to organize the list in terms of frequency of citation in articles relating to the coast. Such an effort would be tedious to do by hand, but could be accomplished by a commercial citation indexing service. Criteria for selection would be difficult to set up and would, of course, again be subjective. Another approach would be to rely on the expertise of seasoned (longtime) researchers who could lend professional opinions to the selection. This approach is clearly subjective but no approach identified here can be regarded as unambiguous. The approach that I have adopted is to use the *Journal of Coastal Research* (JCR) as a baseline that is fairly representative of the central tendency of scientific research in the coastal zone. Although the JCR considers all aspects of coastal research, experience has shown over the years that most papers feature coastal aspects of biology (incl. ecology), geology (incl. geomorphology, hydrology, sedimentology), physical geography (incl. classification and mapping, GIS/LIS/MIS), littoral oceanography, hydrography, coastal hydraulics, environmental (resource) management, engineering, and remote sensing. Policy and legal aspects of are most often appropriately considered in other journals (e.g., *Journal of Coastal Conservation*, *Coastal Management*, *Marine Policy*, *Coastal and Ocean Management*). Even though the basis of the journal selection process is biased, it is hoped that it represents a fair appraisal of primary sources. Another limitation is language; this list features journals where papers are primarily published in English.

Although definition of the term "coastal" is specifically avoided here, the reader is referred to topics in this volume that provide insight into the scope and dimension of the subject area (see types of coasts, management and engineering topics, ecology of specific geographic regions). The list of professional (academic) journals presented in Table A2.2 is not comprehensive in the sense that it contains all journals that may contain papers related to some aspect of the coast. Journals listed here will direct neophytes to a spectrum of coastal journals and as such it serves as an introduction. This is a starting point that will get the interested coastal researcher into the literature. Professionals who have been conducting specialized coastal research for many years will know of more obscure sources that are useful in narrow lines of inquiry. The list points to journals that essentially deal with coastal topics on a regular basis or those that occasionally contain relevant articles. Journals listed in Table A2.2 are broadly organized into three categories that indicate whether the journal provides primary, secondary or tertiary support to the average coastal researcher. Some journals are dedicated to coastal research whereas others might have a different primary focus (e.g., oceanography, ecology, marine mammals, marine technology, ocean law and policy, seabed resources, fisheries science, meteorology, engineering) but often include coastal-based subject matter. The secondary journals are mostly based in the marine realm whereas those considered to be tertiary sources are primarily focused on other disciplines where the subject matter might occur in the coastal zone or be related to coastal processes in some way (e.g., journals dealing with biological, geological, or engineering topics). The listings in Table A2.2 are thus not an endorsement of journal contents or a reflection of citability or credibility. It is benign in the sense that it tries to steer interested readers to sources most likely to contain information related to the coast.

Most of the journals listed in Table A2.2 have international audiences in mind, but the scope of coverage may be limited to biophysical or geographic subdivisions of the coastal zone, define rather specific subject areas, or narrowly focus on legal or conceptual issues viz. *Continental Shelf Research, Coral Reefs, Estuaries, Helgoland Marine Research, International Journal of Marine and Coastal Law, Journal of Great Lakes Research, Marine Biology, Marine Chemistry, Netherlands Journal of Sea Research, International Journal of Remote Sensing*. On the other hand, some journals offer a wide-ranging approach to many different considerations in the coastal zone, for example, *Bulletin of Marine Science, Journal of Coastal Research, Journal of Marine Science and Technology, Geo-Marine Letters, Ocean and Coastal Management*. The scope and interests of journals covering the coastal zone are thus focused and yet multidisciplinary in approach.

Coastal science, as a discrete subject area, is a relatively young discipline. Recognition of diverse subject areas as a coherent corpus is evidenced in the journals themselves, the oldest continuously surviving primary journal being *Shore & Beach* (established in 1926). Some of the other older primary journals include, for example, *Australian Marine and Freshwater Research* (1950); *Bulletin of Marine Science* (1951); *Coastal Engineering Journal* (1959); *Journal of Waterway, Port, Coastal and Ocean Engineering* (1956); and *Marine Geology* (1964). A recent primary player is the *Journal of Coastal Conservation* (1995), the official publication of the European Union of Coastal Conservation. Papers of interest to coastal researchers appear in other venerable journals, listed in Table A2.2 as secondary or tertiary journals, which have broad-ranging interests that overlap or subsume the coastal zone as aspects of it, as for example, *Journal of Geology* (1893); *Journal of Oceanography* (1942); *Journal of Sedimentary Research* (1926); and *Sedimentology* (1952). A relative newcomer to the field is the *Journal of Coastal Research* (1984) which covers a wide range of topics that include but are not limited to geology, biology, geomorphology (physical geography), climate, littoral oceanography, hydrography, hydraulics, environmental (resource) management, engineering, and remote sensing. The *Journal of Coastal Research* invites contributions dealing with theory, methodology, techniques, and field or applied topic studies on interdisciplinary issues within the broad subject areas listed above.

To assist the researcher in gaining access to the journals, the list in Table A2.2 highlights critical information such as publisher, ISSN, and frequency of publication. A brief description of journal content has been abstracted from the journal itself, a journal or professional society Website, or from *Ulrichs International Periodicals Directory* (New Providence, New Jersey: R.R. Bowker).

APPENDIX 3: ORGANIZATIONS

In the last two decades there has been an explosion of organizations dealing with the coast. Most coastal researchers probably initially think in terms of scientific groups that consider academic, theoretical, or practical applications of scientific principles or engineering practices. With coastal populations increasing worldwide (e.g., Culliton *et al.*, 1992), there have been a number of movements that attempt to organize political and public opinion in favor of limiting overexploitation of coastal resources (see discussions in Clark, 1996). Disregard for the coast is not a new trend, but public awareness is increasing as coastal living space becomes more limited and use of coastal environments becomes more belligerent. In many ways, the coastal zone is becoming a battleground (Finkl, 1997) for different interest groups. In many places, coastal environments have been totally replaced by urbanization and industrialization, seriously degraded by overuse and effluent disposal, or are presently threatened by various facets of human action. There are now many conservation groups interested in organizing various types of resistance to degradation of coastal and marine resources.

Today the coastal zone is seen from many divergent points of view ranging from commercial and industrial use (e.g., ports and harbors, petroleum tank farms, transportation facilities, free trade zones), tourism, urban, and suburban living space, waste disposal sites, land reclamation (e.g., drainage of coastal wetlands), parks and reserves (including marine parks), military installations, and finally as political and military battlespace (e.g., strategic choke points, sites for amphibious landings, approachways for invasion from the sea). With all of these diverse, and often conflicting, uses of coastal space, it would be a disservice, to perception of the problems and potential remedies, to list only organizations of interest to academic researchers. Indeed, many of the most exciting and important considerations of the coast reside in nontraditional organizations that have as agendas the protection and preservation of coasts through avenues of public information campaigns, education, and private or nongovernmental organizations (NGO). Response to issues of coastal use is, unfortunately, largely not met by public agencies responsible for the care and protection of coasts. Leaders of coastal protection are thus often found in nonauthoritarian organizations that do not pander to political whims or inaction. On the other side of the coin, there are many examples of government agencies that have taken appropriate steps to better understand coastal environments and the natural processes responsible for them. By and large, however, the response by governments worldwide is too little too late, except possibly in North America and Western Europe, and Oceana.

Presentation of the organizations dealing with coastal issues requires organization because their number is legion. A mere decade ago if one were to conduct a computer search on the Internet by requesting a search based on the word "coastal," the response would have been minimal. Today, it is a different story. An Internet search using the word "coastal" as a key term would return literally hundreds of hits (e.g., web pages containing that word or access to other sources of information). With such vast amounts of information now readily available, it is clear that many organizations are involved with coasts in a way that was unimaginable in the recent past.

Before the widespread use of the Internet, it was possible to keep track of coastal-marine researchers through printed directories such as the *International Directory of Marine Scientists* (UNESCO, 1983), *Orbis Geographicus* (IGU, 1992), or to locate major repositories of information as listed, for example, in the *International Directory of Marine Science Libraries and Information Centers* (IAMSLIC, 1987). Organizations could be gleaned from these kinds of source materials (i.e., from their contained institutional lists) but there was no easy way to compile lists of coastal organizations. With the development of digital information systems, access changed and large amounts of information became available and retrievable to coastal researchers almost instantly. Because there is no comprehensive published list of coastal organizations worldwide, these lists are conceived as part of an attempt to indicate the range of organizations, public and private, that provide services to researchers of the coastal zone. Addresses, phone and fax numbers, e-mail addresses or websites are provided when available in the following lists. Statements of purpose, objectives or goals, mottoes or slogans, or advertizing self-images of various organizations are listed in table format as examples. The information provided here is not to be inclusive, but it is comprehensive and global in perspective. If there are organizations that are not listed in the following tables (1–16), it is an oversight resulting from the vagaries of computer searches on the net. All reasonable efforts were made to include as many organizations as possible but, of course, no list can be complete in a subject area where groups come together for a period of time and then disperse or where there are name changes, as so frequently happens in government with changes in political parties. In any case, the tables presented here are submitted in good faith in the belief that they represent a fair and unbiased summary of what can be found on the Internet. Access to these organizations is thus possible through traditional means by mail, telephone, or fax. The Internet offers new possibilities for rapid personal interaction and a means of rapidly acquiring information without much effort on the part of the searcher. The collection and availability of data more or less dictated organizational groupings, which turn out to be quite subjective. Mostly, the assembly of organizations was by continental or subcontinental geographic regions but sometimes a hemispheric approach was more convenient whereas some other organizations are essentially global in focus. It is thus anticipated that most readers will have interests in specific geographic regions rather than an organizational focus.

Table A3.1, for example, lists some of the main North American agencies that are maintained by federal governments. In some cases it is not entirely logical nor convenient to list subdepartments and so parent organizations are indicated viz. the National Science Foundation (NSF), US Department of the Navy (USN), National Oceanographic and Atmospheric Administration (NOAA), US Army Corps of Engineers (USACE). For these larger organizations, some of the larger coastal programs and projects are indicated. In the United States there are 33 state coastal zone management programs (Table A3.2). Alaska and Hawaii probably come readily to mind as programs separated from the conterminous United States but territories and commonwealth programs are also included in the number of "state" programs, viz. Guam, Northern Mariana Islands, Puerto Rico, and the Virgin Islands. Indiana, Michigan, Ohio, Pennsylvania, and Wisconsin have coastal management programs for management of Great Lakes shores. Other organizations having responsibility for management of freshwater and marine shores include government agencies and quasi-government bodies that feature concerted efforts to manage wildlife (e.g., Florida Fish and Wildlife Conservation Commission), protect natural coastal resources (e.g., Columbia River Estuary Study Task Force, San Francisco Bay Conservation and Development Commission), or restore coastal areas (e.g., Office of Coastal Restoration Indiana, Plan to Restore America's Everglades) (Table A3.3).

Some worldwide government agencies and programs related to the coastal zone are listed in Table A3.4. Some entries here appear to be national, and they are, but affiliated agencies also work overseas in a related capacity (e.g., Coastcare or the Coast Protection Board in Australia) as for example seen in the Australian Antarctic Division (AAD) as part of the Australian Government's Department of the Environment and Heritage. The European Union for Coastal Conservation (EUCC) attempts to ensure wise use and protection of Baltic Sea coasts and makes concerted efforts to ensure cooperation between government and non-government organizations viz. local communities, scientific organizations, and individuals involved in conservation of the coastal zone. The EUCC fosters participation in intergovernmental movements connected with coastal conservation and management as well as the integration of science and management in the coastal zone. Another example listed in Table A3.4 is the Intergovernmental Oceanographic Commission (IOC) of UNESCO that promotes marine scientific investigations and related ocean services. The Eastern African Coastal Area Management effort strives to assist East African countries to implement and coordinate coastal management activities as follow-up to the Arusha Resolution and the Seychelles Statement on Integrated Coastal Zone Management.

The main North American research and educational institutions that deal with coastal zone management and related topics are listed in Table A3.5. This sort of table is problematic because it is impossible to include every institution that deals with coasts. This table is thus the result of a computer search that turned up more than 60 organizations that conduct coastal research or instruction in coastal zone management related topics. Even though the list is not complete, it provides entry into the sphere of coastal zone research and education in North America. Some organizations, although they are part of state or private university systems, can be obscure (e.g., the Center for Coastal and Land-Margin Research (CCALMR) is part of the Oregon Graduate Institute of Science and Technology, Oregon Health and Science University, Beaverton, Oregon) or well known as part of major research centers of long-standing excellence (e.g., Center for Coastal Studies, Scripps Institution of Oceanography, University of California, La Jolla, California; Department of Earth, Atmospheric, and Planetary Sciences, Massachusetts Institute of Technology, Cambridge, Massachusetts). Although some organizations do not grant academic degrees as from colleges and universities, they do provide useful short courses, study groups and projects, applied research, and in-service training as, for example, seen at the US Army Coastal and Hydraulics Laboratory (Engineer Research and Development Center, Vicksburg, Mississippi). Other organizations function as clearinghouses for digital information (e.g., Oregon Coastal Geospatial Clearinghouse) or as providers of overarching regional research guidance and facilitation (e.g., Regional Association of Research on the Gulf of Maine) as associations of institutions or organizations of organizations (e.g., Coastal Resources Research Network based at Dalhousie University, funded by the International Development Research Centre, and working with partners in South East Asia).

Similar comments could be made with regard to Table A3.6, which lists some of the main European research and educational institutions that deal with the coastal zone. For convenience, the institutions here are listed in alpha-order by host country. The list contains organizations of international renown (e.g., Danish Hydraulics Institute, Institut Oceanographique, Delft Hydraulics Institute, Netherlands Institute for Sea Research, Cambridge Coastal Research Unit, Plymouth Marine Laboratory, Proudman Oceanographic Laboratory) as well as those that are perhaps less well known (e.g., Center for Marine Research, Zagreb, Croatia; Sandgerdi Marine Centre, Sandgerdi, Iceland). In either case, these organizations enjoy "hits" from web searches due to their websites. Last among the tables listing the main research and educational institutions that deal with the coastal zone is Table A3.7, which takes a hemispheric perspective in Australia, Brazil, New Zealand, and South Africa. Additional short listings are included for Argentina, Chile, southern India, and the Philippines.

Proprietary consulting companies provide useful services to both public and private sectors in the coastal zone (Table A3.8). These organizations are mostly "for profit" but they often provide information to the public in the form of competitive bidding for projects, reports, public debates and journal publishing, and participation in public meetings and forums. Nevertheless, these kinds of organizations provide many useful functions in the coastal zone that are not available from governmental organizations. Again, this list is not comprehensive and represents the kinds of results that can be obtained from simple computer searches based on critical key words. Most of the consulting companies deal with environmental issues and coastal engineering, although some consultants are lawyers (e.g., Conservation Law Foundation) or lobbyists (e.g., The Coastal Advocate). A related list contains coastal consulting companies based in the United States but with branches or additional offices overseas (Table A3.9). These are listed in alpha-order with indications of overseas location where the companies are active. Some consulting companies listed in Table A3.10 are truly worldwide in scope and operations. Clearly, there are many other consulting companies that deal with coastal conservation, shore protection, dredging, and so on, but they do not show up in this computer search as the main focus was not engineering, dredging, etc.

Other kinds of organizations active in the coastal zone that have not yet been considered include those that are comprised by professional societies, either governmental or private, that can include societies, federations, coalitions, campaigns, associations, not-for-profit corporations, foundations, alliances, clubs, projects, etc. These organizations listed in Table A3.11, include a broad range of interests in the coastal zone. Primary here are groups that have interest in protecting or preserving coastal resources such as beaches (e.g., American Shore and Beach Preservation Association, Florida Shore and Beach Preservation Association), habitat (e.g., American Littoral Society; Canadian Ocean Habitat Protection Society, Newellton, Nova Scotia, Canada), rivers and estuaries (e.g., Clean Annapolis River Project, Annapolis Royal, Nova Scotia, Canada; Clean Water Fund, Washington, DC), and historic cultural sites (e.g., Coastal America, Washington, DC). Some groups appeal to professional coastal researchers and academics rather than lay people and they attempt to foster study and research of coastal problems and issues (e.g., American Geological Institute, American Society of Civil Engineers, American Society of Limnology and Oceanography, The Coastal Education & Research Foundation, the Coastal Research and Education Society of Long Island, Marine Technology Society). Different examples are found in other kinds of organizations that fight coastal erosion (e.g., Beach Erosion Authority for Clean Oceans and Nourishment, Ventura, California), or strive to revitalize ocean resources (e.g., American Oceans Campaign) or which focus on maintaining sustainable tourism (e.g., Bay of Fundy.com, Chance Harbour, New Brunswick, Canada). There are thus many different orientations and the scope of effort is great in professional organizations that have the wellbeing of the coastal zone at heart. Those organizations listed in Table A3.11 are but a few of the many different kinds of organizations that can be accessed via the Internet.

Table A3.12 continues the previous line of inquiry but the organizations noted here are for coastal regions beyond the shores of North America. Some of these organizations have a global outlook (e.g., Estuarine and Coastal Sciences Association, Greenpeace International, Seas at Risk, Surfers Against Sewage, United Nations Environment Programme) while others have a national perspective (e.g., Asociación Oceánica de Panamá, Australian Coral Reef Society) or regional charge (e.g., European Artificial Reef Research Network, European Coastal Association for Science and Technology). These interest groups outside North America have similar orientations and thrusts of purpose as those listed in Table A3.11.

Asian groups that focus their attention on coastal research in general and marine science specifically are listed in Table A3.13. This regional listing is given as an example of concern for the coast in one of the most densely populated regions on earth. Oceanographic organizations and institutes of marine science conduct most of the coastal effort here. In a similar vein, Brazilian coastal organizations are listed separately in Table A3.14. There is concern in Brazil for maintaining clean coasts and there are numerous state divisions of IBAMA, the Brazilian environmental protection agency. Fisheries research institutes are listed here as well because of their concern for maintaining good coastal environmental quality that will support coastal fisheries, which in turn provide employment for small villages and towns along the coast.

By way of an example of another very specialized list, Table A3.15 lists coastal resource management companies in Hawaii. The island is clearly a Mecca for coastal consulting companies due to its strategic geographic location. Companies based here have ready access to North America, especially the West Coast, and to the eastern Asian continent and Oceana. Full contact information is provided for most of these companies based in Hawaii. Some of these companies are also listed in Tables A3.11, A3.12 or A3.13, depending on the location of their home office or branches. Others are not listed in these previous three tables because they did not show up in the computer search for those listings. The list in Table A3.15 is particularly comprehensive and complete and is a good example of an effort to provide useful information for a specific region, in this case the State of Hawaii. A smaller complimentary list is found in Table A3.16, which summarizes coastal resource management companies in Hawaii based on nonprofits.

Table A3.1 Primary North American agencies and programs related to the coastal zone, as maintained by federal governments in the United States and Canada

Canadian Hydrographic Service (Canada)
615, Booth Street
Ottawa, Ontario K1A 0E6
Phone: (613) 995 4413
Fax: (613) 947 4369

Canadian Ice Service (Canada)
373, Sussex Drive
Block E, Third Floor
Ottawa, Ontario K1A 0H3

Coastal America (USA)
Coastal America Reporters Building
300, 7th Street, SW Suite 680
WA 20250
Phone: (202) 401 9928
Fax: (202) 401 9821
E-mail: wanda.brown@usda.gov

A Decade of Commitment to Protecting, Preserving, and Restoring America's Coastal Heritage

Department of Fisheries & Oceans—Maritimes Region (Canada)
P.O. Box 1035
Dartmouth, Nova Scotia B2Y 4T3
Phone: 1 800 782 3058
E-mail: info@dfo-mpo.gc.ca

Environment Canada (Canada)
45, Alderney Drive
Dartmouth, Nova Scotia B2Y 2N6
Phone: (902) 426 7231
Fax: (902) 426 6348
E-mail: 15th.reception@ec.gc.ca

EPA (Environmental Protection Agency)—Office of Water (USA)
Deals with coastal waters and related aspects, has sub-offices of wetlands, oceans, and watersheds.

Contacts—Headquarters:

Rick Hoffmann
USEPA, 1200 Pennsylvania Ave. NW-4305
WA 20460
Phone: 202 260 0642
Fax: 202 260 9830
E-mail: hoffmann.rick@epa.gov

Charles Kovatch
USEPA, 1200 Pennsylvania Ave. NW-4305
WA 20460
Phone: 202 260 3754
Fax: 202 260 9830
E-mail: kovatch.charles@epa.gov

Promotes a watershed approach to manage, protect, and restore the water resources and aquatic ecosystems of our marine and fresh waters. This strategy is based on the premise that water quality and ecosystem problems are best solved at the watershed level and that local citizens play an integral role in achieving clean water goals. Through its many programs, OWOW provides technical and financial assistance and develops regulations and guidance to support the watershed approach.

Fisheries & Oceans Canada (Canada)
Communications Branch
200, Kent Street
13th Floor, Station 13228
Ottawa, Ontario K1A 0E6
Phone: (613) 993 0999
Fax: (613) 990 1866
TDD: (613) 941 6517

The CCG will ensure the safe and environmentally responsible use of Canada's waters, support understanding and management of oceans resources, facilitate the use of our waters for shipping, recreation and fishing, and provide marine expertise in support of Canada's domestic and international interests.

Fleet Numerical Meteorology and Oceanography Center (US Department of the Navy)
Commanding Officer: cdo@fnmoc.navy.mil
Executive Officer: cdo@fnmoc.navy.mil
Command Master Chief: fn-cmc@fnmoc.navy.mil
Public Affairs: fn-pao@fnmoc.navy.mil

National Marine Fisheries Service (NMFS) (USA)
NOAA Fisheries
1315, East West Highway
SSMC3, Silver Spring, MD 20910

The NMFS administers NOAA's programs which support the domestic and international conservation and management of living marine resources.

National Ocean Service (NOAA, National Oceanography & Atmospheric Administration) (USA)
National Ocean Service
1305, East West Highway
Silver Spring, MD 20910
Phone: (301) 713 3074

As the nation's principal advocate for coastal and ocean stewardship, the National Ocean Service develops the national foundation for coastal and ocean science, management, response, restoration, and navigation. The National Ocean Service maintains its leadership role in coastal stewardship by bridging the gap between science, management, and public policy.

Naval Meteorology and Oceanography Command (US Department of the Navy)
1100, Balch Boulevard
Stennis Space Center MS 39529
Phone: (228) 688 4187
Fax: (228) 688 5743
E-mail: pao@cnmoc.navy.mil

The Naval Meteorology and Oceanography Command's mission is to collect, interpret and apply global data and information for safety at sea, strategic and tactical warfare, and weapons system design, development, and deployment. The command provides meteorological, oceanographic, and geospatial information and services to increase the effectiveness of our Navy in both peacetime and in war.

Naval Oceanographic Office (US Department of the Navy)
N24 Customer Service Division
1002, Balch Boulevard
Stennis Space Center, MS 39522-5001
Phone: (228) 688 5661/5216/5382
DSN: 828 5661/5216/5382
Fax: (228) 688 4688
E-mail: wsc@navo.navy.mil

Naval Research Laboratory (US Department of the Navy)
4555, Overlook Ave., SW
WA 20375

The Naval Research Laboratory (NRL) is the Navy's corporate laboratory. NRL conducts a broadly based multidisciplinary program of scientific research and advanced technological development directed toward maritime applications of new and improved materials, techniques, equipment, system, and ocean, atmospheric, and space sciences and related technologies.

NOAA Coastal Service Center (USA)
2234, South Hobson Avenue
Charleston, SC 29405-2413
Phone: 843 740 1200
Fax: 843 740 1224

The mission of the NOAA Coastal Services Center is to foster and sustain the environmental and economic wellbeing of the nation's coast by linking people, information, and technology.

Table A3.1 *Continued*

NOAA Coral Health Program (USA)

Located at NOAA's
Atlantic Oceanographic and Meteorological Laboratory
4301, Rickenbacker Causeway
Miami, FL 33149-1026

The mission of the Coral Health and Monitoring Program is to provide services to help improve and sustain coral reef health throughout the world.

NOAA Office of Public Affairs (USA)

14th Street & Constitution Avenue, NW
Room 6013
WA 20230
Phone: (202) 482 6090
Fax: (202) 482 3154

NSF (National Science Foundation) Division of Ocean Sciences (USA)

4201, Wilson Boulevard
Room 725, Arlington, VA 22230
Phone: 703 292 8580
Fax: 703 292 9085

The Division of Ocean Sciences (OCE) supports basic research and education to further understanding of all aspects of the global oceans and their interactions with the earth and the atmosphere. The division also offers opportunities to participate in global change research programs and other focus programs.

Topographic Engineering Center (US Department of the Army)

Tammy Scroggins, CEERD-TG-S
Alexandria, VA
Phone: (703) 428-6902
E-mail: tscroggi@tec.army.mil

TEC's Mission is to provide the Warfighter with a superior knowledge of the battlefield, and support the Nation's civil and environmental initiatives through research, development, and the application of expertise in the topographic and related sciences.

US Army Corps of Engineers (USACE) (USA)

Headquarters:
441, G. Street, NW
WA 20314
Phone: 202-761-0008

US Coast Guard (USA)

Headquarters:
2100, Second Street, SW
WA 20593-0001
Website: www.uscg.mil

US Fish & Wildlife Service (USA)

Information about the Coastal and National Coastal Wetlands Conservation Grant Programs, contact:

US Fish and Wildlife Service, Branch of Habitat Restoration
4401, N. Fairfax Drive, Arlington, VA 22203
Phone: (703) 358 2201
Fax: (703) 358 2232

Information about the Coastal Barrier Program, contact:

US Fish and Wildlife Service, Branch of Federal Activities
4401, N. Fairfax Drive, Arlington, VA 22203
Phone: (703) 358 2183
Fax: (703) 358 2232

The US Fish and Wildlife Service is working to conserve coastal resources to benefit present and future generations. Three programs form the core of these coastal conservation efforts which are: The Coastal Program, the Coastal Wetlands Conservation Grants, and the Coastal Barriers Resources System.

Table A3.2 US state coastal zone management programs

Alabama Coastal Area Management Program

ADECA, Coastal Programs Office
1208, Main Street
Daphne, AL 36526
Phone: (334) 626 0042
Fax: (334) 626 3503
E-mail: buddy.sullivan@noaa.gov

Alabama's coastal program balances coastal activities to ensure that the environment on which Alabama business depends remains healthy for generations to come. Alabama's coast faces wetlands loss; coastal erosion; residential, commercial, port, and industrial development; population growth; and nonpoint source pollution problems.

Alaska Coastal Management Program

Division of Governmental Coordination
P.O. Box 110030
Juneau, AK 99811-0030
Phone: (907) 465 3562

With key industries like timber harvesting, oil and gas development, mining, and seafood processing, Alaska's coast faces pressures from resource development and subsistence use of resources. The coastal program balances these uses and the needs of the environment for the long-term health of the state's coastal industries.

California Coastal Management Program

California Coastal Commission
45, Fremont Street, Suite 2000
San Francisco, CA 94105
Phone: (415) 904 5200

For California's extensive coast, resource management and conservation means minimizing the impact of port and residential development, oil transportation, and runoff pollution. To deal with coastal problems, the program oversees almost all activities on the coast, from adding a deck to a private home to building a new refinery.

Connecticut Coastal Management Program

Connecticut DEP
Office of Long Island Sound Programs
79, Elm Street
Hartford, CT 06106-5127
Phone: (860) 424 3034

Connecticut's coastal management program addresses water quality issues including runoff pollution, habitat protection and restoration, public access to the coast, and the use of public lands and waters. The state manages its coastal resources by applying coastal policies to land uses, by overseeing activity in fishery habitats and coastal waters, and by demanding consistency between local, state, and federal actions.

Delaware Coastal Management Program

Delaware DNREC
89, Kings Highway
Dover, DE 19903
Phone: (302) 739 3451

To keep Delaware's coast healthy and productive, the state coastal program monitors activities in the coastal zone. Major challenges are runoff pollution and cumulative and secondary impacts of population growth and urban development.

Florida Coastal Management Program

The Department of Community Affairs
Florida Coastal Management Program
2555, Shumard Oak Boulevard, Tallahassee, FL 32399-2100
Phone: (850) 922 5438
Fax: (850) 487 2899

The Florida Coastal Management Program (FCMP) coordinates among local, state, and federal entities involved in coastal

Table A3.2 *Continued*

management activities. In addition to working with DCA's programs, the FCMP coordinates among the eight state agencies, five water management districts, and local governments that have responsibilities for coastal management under the federally approved Florida Coastal Management Plan. The FCMP also develops partnerships with local communities to actively solve problems related to coastal development.

Georgia Coastal Management Program
Georgia DNR
Coastal Resources Division
One Conservation Way, Suite 300
Brunswick, GA 31520-8687
Phone: (912) 264 7218

Georgia's major coastal issues include pollution, a rapidly growing coastal population, and erosion on the state's developed barrier islands. To deal with these and other issues, the state has developed a federally approved coastal zone management program.

Guam Coastal Management Program
Bureau of Planning
Coastal Management Program
P.O. Box 2950
Agana, Guam 96910
Phone: (617) 472 4201

Coastal hazards, public access, urban growth, and wetlands degradation are some of the key issues for Guam's coastal management program. In an effort to combat coastal problems, the program cooperates with other territory agencies that require permits for coastal activities.

Hawaii Coastal Management Program
Hawaii Office of Planning
Hawaii Coastal Zone Management Program
Hawaii Department of Business, Economic Development, and Tourism
P.O. Box 2359, Honolulu, HI 96804
Phone: (808) 587 2846

With no point in Hawaii more than 29 miles from the shore, almost any activity that accurs inland will impact Hawaii's coastal and ocean resources. Hawaii's coastal program balances the needs for economic growth, a clean environment on which that growth depends, and a vibrant local culture that reflects Hawaii's uniqueness.

Indiana Coastal Coordination Program
Indiana DNR
Division of Water
402, W. Washington
Room W264
Indianapolis, IN 46204-2748
Phone: (317) 233 0132

Indiana's most challenging coastal issues include public access to the shore, beach closures, water quality, brownfields dredging, shoreline erosion, and preservation of natural areas.

Louisiana Coastal Resources Program
Louisiana DNR
Coastal Management Division
P.O. Box 44487
Baton Rouge, LA 70804
Phone: (225) 342 7591

To ensure the environment on which its industry depends is healthy for generations, Louisiana's coastal program must turn around declining fishery habitats, such as wetlands, and reduce erosion. The coastal resources program works with parishes to design programs which resolve conflicting local uses of the coast.

Maine Coastal Management Program
Maine State Planning Office
Coastal Programs
State House Sta. 38
Augusta, ME 04333
Phone: (207) 287 3261

Maine's coastal managers contend with challenges of population growth, water quality, public access, and the impacts of development. The coastal management program manages activities in or on wetlands, flood plains, sand dunes, and other coastal resources.

Maryland Coastal Zone Management Program
Maryland DNR
Coastal Zone Management Division
580, Taylor Avenue
Annapolis, MD 21401
Phone: (410) 974 2784

Maryland's coastal program encourages sound economic development and minimizes the impact people have on vital coastal resources, such as fisheries.

Massachusetts Coastal Zone Management Program
Massachusetts Office of Coastal Zone Management
251, Causeway Street, Suite 900
Boston, MA 02114-2119
Phone: (617) 626 1200
E-mail: mczm@state.ma.us

Because of the beauty and bounty of the coast, many different interests compete for use of coastal resources. Massachusetts' coastal program must balance the competing demands of dredging and dredge material disposal, coastal erosion, runoff pollution, public access, ocean resource management, port revitalization, and harbor planning.

Michigan Coastal Zone Management Program
Michigan DNR
Land & Water Manangement Division
P.O. Box 30028
Lansing MI 48909
Phone: (517) 373 1950

With coasts on four Great Lakes, Michigan has the world's largest freshwater coastline. The state uses coastal management to encourage responsible growth and development along the coast, improve public access to the coast, and aid winter navigation. The program manages coastal activities such as shipwreck salvaging, building piers and marinas, development, and changes to the coast. The program is working creatively to find solutions to the loss of agricultural land and wildlife habitat to sprawling development.

Minnesota Coastal Program
Minnesota DNR, Division of Waters
1201, E. Highway 2
Grand Rapids, MN 55744
Phone: (218) 327 4417

Minnesota is considering participation in the federal Coastal Zone Management program through the program development process. The 4-year process is addressing concerns and evaluating benefits of the program. Local issues which the program could help to address include: shoreline erosion, inadequate sewage and stormwater systems, local watershed and land use planning, habitat restoration, waterfront revitalization, and water access.

Mississippi Coastal Program
Mississippi Department of Marine Resources
1141, Baywiew Avenue
Suite 101
Biloxi, MS 39530
Phone: (228) 374 5000
Fax: (228) 374 5008

Wetlands preservation and restoration is a key issue for Mississippi coastal management, as are dockside gambling and casinos. Construction, public access, land acquisition, and fisheries are some of the coastal activities supervised by the state agencies watching out for the state's coast.

New Hampshire Coastal Program
NH Office of State Planning
Coastal Program Office
2-1/2 Beacon Street
Concord, NH 03301
Phone: (603) 271 2155

Table A3.2 *Continued*

New Hampshire's coastal program strives to protect and improve water quality, restore fishery habitat (wetlands), and balance coastal resource use. The program monitors coastal and estuarine waters to identify the runoff pollution in the state. As a result, some of the clam flats in the Hampton-Seabrook estuary have been conditionally reopened for recreational clamming.

New Jersey Coastal Management Program

New Jersey DEP
Office of Coastal Planning and Program Coordination
401, East State Street, Box 418
Trenton, NJ 08625
Phone: (609) 777 3251

A densely populated coast brings challenges of water quality, overdevelopment, coastal hazards, and runoff pollution to the forefront of coastal management in New Jersey. Barnegat Bay, for example, loaded with fish and plant life, faces intense fishing, recreational uses, and polluted runoff.

New York Coastal Management Program

New York Department of State
Division of Coastal Resources
41, State Street
Albany, NY 12231
Phone: (518) 474 6000

New York's coast faces issues such as wildlife habitat protection and coastal hazards such as floods and erosion. The coastal management program does not directly restrict any activities on the coast, but it does work with other state agencies to make sure the permits they issue comply with coastal management efforts.

North Carolina Coastal Management Program

North Carolina DENR
Division of Coastal Management
1638, Mail Service Center
Raleigh, NC 27699-1638
Phone: (919) 733 2293

Wetlands loss, coastal hazards, and the impacts of population growth and development are among the pressures confronted by the North Carolina coastal management program. The state ensures responsible development and the use of the coast by overseeing coastal activities. Setback laws keep property out of harm's way during storms, and a prohibition on erosion structures keeps the beaches, vital for tourism, from starving.

Northern Mariana Islands Coastal Resources Management Program

Coastal Resources Management Office
Office of the Governor
2nd floor, Morgen Building
San Jose Saipan, Mariana Islands 96950
Phone: (670) 234 6623

Solid waste disposal and water pollution are two of the major threats to the Northern Marianas' coasts. To combat these threats, the program oversees activities along the shoreline, in lagoons and reefs, in wetlands and mangrove swamps, and for port and industrial activities.

Ohio Coastal Management Program

Ohio DNR
Office of Real Estate and Land Management
1952, Belcher Drive
Building C-4
Columbus, OH 43224
Phone: (614) 265 6413

Managing activities in erosion-prone areas and restoring and enhancing coastal marshes are the major challenges facing the Ohio coast. Coastal managers in 1997 completed a program for federal approval to deal with these and other coastal issues.

Oregon Coastal Management Program

Coastal and Ocean Management Program
Oregon Department of Land Conservation and Development
800, NE Oregon Street #18
Portland, OR 97232
Phone: (503) 731 4065

Oregon is nationally recognized as a leader in coastal ocean planning. Two major initiatives for Oregon's coastal managers are mitigating coastal hazards and managing Pacific Ocean resources. Oregon's waters, which extend 3 miles from the coast, include intertidal areas, offshore rocks, and reefs—wildlife habitat susceptible to damage from human recreation. Local governments oversee activity along the state's coast by following local land use plans that are consistent with statewide goals for the coast.

Pennsylvania Coastal Zone Management Program

Pennsylvania DEP
Coastal Zone Management Program
P.O. Box 8555
Harrisburg, PA 17105
Phone: (717) 787 5259

Pennsylvania's Lake Erie and Delaware Estuary coasts face threats from runoff pollution, shoreline erosion, bluff recession, and wetlands loss. The state oversees construction and other activities that alter wetlands. The coastal program also offers free site analysis and recommendation services to coastal property owners. The services include site inspections and recommendations on surface and groundwater control, stabilizing bluffs, and the use of vegetation to stabilize loose soil.

Puerto Rico Coastal Management Program

Puerto Rico DNER
Bureau of Reserves, Refuges, and Coastal Resources
Department of Natural and Environmental Resources
Pda. 3-1/2, Ave. Munoz Rivera
Puerta de Tierra, Box 9066600
San Juan, Puerto Rico 00906-6600
Phone: (787) 721 7593

Puerto Rico's coastal program confronts the challenges of sedimentation, erosion, coastal hazards, and illegal use of the island's maritime zone (its shoreline, territorial waters, and submerged lands).

Rhode Island Coastal Management Program

Coastal Resources Management Council
4808, Tower Hill Road
Stedman Building
Wakefield, RI 02879
Phone: (401) 783 3370
Fax: (401) 783 3767

The Coastal Resources Management Council is an environmental regulatory and management agency responsible for the preservation, protection, development and where possible the restoration of the coastal areas of the state.

South Carolina Coastal Management Program

South Carolina DHEC
Office of Ocean and Coastal Resource Management
1362, McMillan Avenue
Suite 400
Charleston, SC 29405
Phone: (843) 744 5838

South Carolina's coastal program protects marine resources from declining water quality, protects fish habitats such as wetlands, and reduces the risk to coastal property from storms and other hazards. To meet these challenges, the program oversees wetlands filling and commercial and residential construction, including docks and piers. The program also sets construction back a safe distance from the ocean.

Texas Coastal Management Program

Texas GLO
Coastal Division
1700, North Congress Street
Austin Building
Austin, TX 78701
Phone: (512) 463 5054

Texas coastal managers are confronting issues of dredging, erosion, beach access, and wetlands and dune protection. The coastal resources

Table A3.2 *Continued*

program seeks to balance commercial and recreational activity with preservation of its unique coastal resources.

Virgin Islands Coastal Zone Management Program

Virgin Islands Department of Planning & Natural Resources
Coastal Zone Management Program
Cyril E. King Airport
2nd Floor
St. Thomas, US Virgin Islands 00802
Phone: (809) 774 3320
Fax: (809) 775 5706

To keep the islands beautiful and a source of pride and productivity into the next generation, the Virgin Islands emphasizes the importance of healthy terrestrial and coastal resources as development takes place. The territory's coastal program oversees construction and other coastal uses throughout the territory to meet these goals.

Virginia Coastal Resources Management Program

Virginia Coastal Program
Virginia Department Of Environmental Quality
629, East Main Street, 6th Floor
Richmond, VA 23219
Phone: (804) 698 4320

Virginia's coastal zone encompasses the eastern third of the state including the Chesapeake Bay and its tributary rivers, part of the Albemarle-Pamlico watershed, and the Atlantic coast with its vast barrier island lagoon system. The Virginia Coastal Resources Management Program supports its coastal residents and industries, and the plants and animals that rely on these coastal habitats.

Washington Coastal Zone Management Program

Washington Department of Ecology
P.O. Box 47600
Olympia, WA 98504-7600
Phone: (360) 407 6000

Wetlands degradation, population growth, and coastal erosion and flooding are among the major challenges facing the Washington coastal management program. To counter these problems, the program oversees most activities on the state's shoreline except agriculture and activities related to single-family homes.

Wisconsin Coastal Management Program

Wisconsin DOA
Wisconsin Coastal Management Program
P.O. Box 7868
Madison, WI 53707
Phone: (608) 267 7982

To balance competing uses of its Great Lakes coast, Wisconsin's coastal management program encourages wetlands protection and awareness; solutions to runoff pollution, primarily from agriculture; greater public access to the shoreline; solutions to erosion; and resolving water quality threats from failing septic systems.

Table A3.3 Other US state agencies, programs and organizations within the coastal zone (cf. Tables A3.1 and A3.2)

California Coastal Commission

Headquarters:
45, Fremont Street, Suite 2000
San Francisco, CA, 94105-2219
Phone: (415) 904 5200
Fax: (415) 904 5400

The California Coastal Commission was established by voter initiative in 1972 (Proposition 20) and made permanent by the Legislature in 1976 (the Coastal Act). The primary mission of the Commission, as the lead agency responsible for carrying out California's federally approved coastal management program, is to plan for and regulate land and water uses in the coastal zone consistent with the policies of the Coastal Act.

California Coastal Conservancy

1330, Broadway
11th Floor
Oakland, CA 94612
Phone: (510) 286 1015
Fax: (510) 286 0470

Works to preserve, improve, and restore public access and natural resources along the California coast and on San Francisco Bay.

California Department of Boating and Waterways

2000, Evergreen, Suite 100
Sacramento, CA 95815-3888
Phone: (888) 326 2822
(916) 263 4326
Fax: (916) 263 0648

Protect[s] significant natural resources through its programs to provide for public access to the waterways, and promot[es] recreational boating safety. These programs include funding and designing the construction and improvement of boating facilities, beach erosion control, aquatic weed control, boating safety education, and supporting and training local boating law enforcement officers.

California Department of Fish and Game

1416, Ninth Street
Sacramento, CA 95814
Phone: (916) 653 7664
Fax: (916) 653 1856

The Mission of the Department of Fish and Game is to manage California's diverse fish, wildlife, and plant resources, and the habitats upon which they depend, for their ecological values and for their use and enjoyment by the public.

Columbia River Estuary Study Taskforce

750, Commercial Street, Room 205
Astoria, OR 97103
Phone: (503) 325 0435
Fax: (503) 325 0459 (please call first)
E-mail: crest@columbiaestuary.org

CREST is Council of Governments that includes the local counties, cities, and port districts surrounding the Columbia River Estuary in both Oregon and Washington. CREST is not a regulatory agency. It is a regional organization providing a forum for members to identify and discuss issues of regional importance; to monitor and comment on governmental activities related to the development and management of the natural, economic, and human resources of the Columbia River Estuary; and to improve communication and cooperation between member governments.

Michigan Department of Environmental Quality

P.O. Box 30458
Lansing, MI 48909-7958
E-mail: deq-lwm-webmaster@state.mi.us

The core programs of the Land and Water Management Division protect Michigan's sensitive natural resources and the public trust at the land/water interface. Development and construction activities are regulated on the Great Lakes, on inland lakes and streams, floodplains, wetlands, and sand dunes to minimize environmental disruption and to protect the public health and safety. Information and technical assistance are also provided to the public and to the private sector. The programs promote wise management and use of the State's natural resources for present and future generations.

Minnesota's Lake Superior Coastal Program

DNR Information Center
500, Lafayette Road
St. Paul, MN 55155-4040

This plan is a work in progress. Technical studies and more detailed designs, involving several pilot projects will come next. We will continue to involve the public throughout the process of implementing the Comprehensive Plan. Find out more about the plan and help us improve it. Help us to better involve your community in this effort. Please contact us for information.

WA State Department of Ecology

Mailing Address: P.O. Box 47600, Olympia WA 98504-7600
Physical Address: 300, Desmond Drive, Lacey WA 98503

Shorelands and environmental assistance program: Works to protect and enhance Washington's shorelands, wetlands and other land resources through education, technical assistance, and collaborative environmental management.

Table A3.4 A brief overview of worldwide government agencies and programs related to the coastal zone

Australian Antarctic Division (Australia)

Headquarters:
Australian Antarctic Division
Channel Highway
Kingston Tasmania 7050
Phone: +613 6232 3209
Fax: +613 6232 3288
E-mail: information@aad.gov.au

Administering Australia's wide-ranging activities in Antarctic and subantarctic regions is the responsibility of the Australian Antarctic Division (AAD), a part of the Australian Government's Department of the Environment and Heritage.

Table A3.4 *Continued*

Coastcare (Australia)

Marine and Water Division
Environment Australia, G.P.O. Box 787
Canberra Act 2601
Phone: (02) 6274 1967
Fax: (02) 6274 1006

Coastcare is a national program that encourages community involvement in the protection, management and rehabilitation of our coastal and marine environments. The program assists local communities to form partnerships with local land managers to undertake projects that aim to improve and protect our coastal and marine habitats.

Coast Care (South Africa Coastal Information Center) (South Africa)

Zain Jumat, Project Manager
Coastal Management Office
Department of Environmental Affairs and Tourism
Private Bag X2, Roggebaai 8012
Phone: (+27 21) 402 3030
Fax: (+27 21) 418 2582
E-mail: mzjumat@mcm.wcape.gov.za

The Coastal Management Office of the Department of Environmental Affairs and Tourism recognizes that the more the people are informed about our coast, the easier it will be to protect it and ensure that its development is to the benefit of current and future generations. To this end, it established a special programme, CoastCARE, to assist in the education and exchange of information about coastal issues.

Coast Protection Board (Australia)

Office for Coast and Marine
Department for Environment and Heritage
6th Floor, Australis House
77, Grenfell Street
Adelaide SA 5000, Australia

The Coast Protection Board is specifically responsible under the Coast Protection Act (1972).

Danish EPA (Denmark)

29, Strandgade, DK-1401 København K
Phone: +45 32 66 01 00
Fax: +45 32 66 04 79
E-mail: mst@mst.dk

The Danish Environmental Protection Agency (EPA) spheres of activity are concentrated on preventing and combating water, soil, and air pollution. The Agency belongs under the Danish Ministry of Environment and Energy and some 425 employees.

Environmental Protection Agency (Ireland)

P.O. Box 3000
Johnstown Castle Estate, Co.
Wexford, Ireland
Phone: +353 53 60600
Fax: +353 53 60699

Mission: To promote and implement the highest practicable standards of environmental protection and management which embrace the principles of sustainable and balanced development.

European Union for Coastal Conservation (Poland)

Europejska Unia Ochrony Wybrzeza—Polska ul. Wąska 13
71-415 Szczecin, Poland
Phone/fax: (0 91) 421 00 97
E-mail: szakow@sus.univ.szczecin.pl

Established at 1996 to realize the following most important aims: strengthening the importance of Baltic Sea coasts and solving problems connected with wise using and protection; creating platforms for cooperation between G.O., NGOs, local communities, scientific organizations and individuals involved in conservation problems of coastal zone; participation in international movements connected with coastal conservation and management; integration science and management in the coastal zone.

Federal Waterways Engineering and Research Institute, Coastal Division (Germany)

BAW—Dienststelle Hamburg
Wedeler Landstraße 157
D-22559 Hamburg
Phone: [+49] 40 81908 0
Fax: [+49] 40 81908 373
E-mail: postmaster@hamburg.baw.de

The department Hydraulic Engineering in Coastal Areas is consultant for the coastal offices in the Federal Waterways and Shipping Administration in the field of hydraulic, soils, and foundation engineering. It carries out field measurements, laboratory investigations and theoretical studies, operates physical and numerical models of the large German estuaries and does standardization work. It is also engaged in research and development projects.

Forum Skagerrak (Sweden)

Pege Schelander, Project Leader
BOSAM, Box 305,
S-451 18 Uddevalla
Phone: +46 522 15980
Fax: +46 522 511796
E-mail: pege.schelander@bosam.se

Forum Skagerrak is a common initiative of the regions surrounding Skagerrak, in Denmark, Norway, and Sweden, to find solutions to prioritized environmental problems where cooperation can lead to effective measures.

Gerência Executiva do Ibama no Distrito Federal (Brazil)

Eulália Arlete Machado de Carvalho
SAS, Qd. 05, Lote 05, Bl. "H", 1° Andar
70.070 000, Brasília/DF.

Swedish Environmental Protection Agency (Naturvårdsverket),
SE-106 48 Stockholm
Phone: +46 8 698 10 00
Fax: +46 8 20 29 25
E-mail: natur@environ.se

A governmental authority which coordinates and promotes environmental work.

Table A3.5 Overview of some main North American research and educational institutes (academic units) that deal with the coastal zone

Acadia Centre For Estuarine Research (Canada)

Acadia University
Wolfville, Nova Scotia B0P 1X0
Phone: (902) 585 1113
Fax: (902) 585 1054

The primary objective of the Centre is to focus research attention on the estuaries and nearshore coastal waters of Eastern Canada, with emphasis on the estuarine systems of the Bay of Fundy and the hydrographically related Gulf of Maine and Georges Bank.

Bay of Fundy Marine Resource Centre (Canada)

Bay of Fundy Marine Resource Centre
P.O. Box 273
Cornwallis Park, Nova Scotia CANADA B0S 1C0
Phone: 902 638 3044
Fax: 902 638 3284

Table A3.5 *Continued*

Website: http://www.bfmrc.ns.ca/

The Bay of Fundy Marine Resource Centre is a community-based nonprofit, nongovernmental organization offering services, facilities, and technical support to all sectors of the marine economy and ecosystem. The MRC was established in 1997 through the efforts of the Western Valley Development Authority and the Fundy Fixed Gear Council in order to give the Digby and Annapolis region the capacity to take on a greater role in the integrated management of its coastal resources.

Belle W. Baruch Institute (USA)

Belle W. Baruch Institute for
Marine Biology and Coastal Research
University of South Carolina
Columbia, SC 29208
Phone: (803) 777 5288
Fax: (803) 777 3935
E-mail: fletcher@biol.sc.edu

The Belle W. Baruch Institute conducts basic and applied research in marine and coastal environments—research that addresses the critical need for knowledge and improved understanding of these essential ecosystems.

Bodega Marine Laboratory (USA)

2099, Westside Road
P.O. Box 247
Bodega Bay, CA 94923-0247
Phone: (707) 875 2009

California Environmental Education Interagency Network (USA)

Gray Davis, Governor 2000, State of California.
Consortium of environmental educators representing California agencies with oversight responsibilities to protect California's environment.

Center for Alaskan Coastal Studies (USA)

P.O. Box 225, Homer, AK 996003
Phone: 907 235 6667
E-mail: cacs@xyz.net

The Center for Alaskan Coastal Studies' mission is to foster responsible interaction with our natural surroundings, and to generate knowledge of the marine and coastal ecosystems of Kachemak Bay through education and research programs.

Center for Applied Coastal Research, University of Delaware (USA)

Ocean Engineering Laboratory
University of Delaware
Newark, DE 19716
Phone: 302 831 6531
Fax: 302 831 1228
E-mail: rad@udel.edu

This interdisciplinary center provides a focal point for research in coastal processes and coastal engineering. Members of the center are coastal engineers, coastal geologists and oceanographers, primarily from the University of Delaware and the Middle-Atlantic region.

Center for Coastal and Land-Margin Research, Oregon Health & Science University (USA)

Department of Environmental Science and Engineering
OGI School of Science and Engineering
Oregon Health & Science University
20000, NW Walker Rd. Beaverton, OR 97006
Phone: (503) 690 1147
Fax: (503) 690 1273

The Center for Coastal and Land-Margin Research (CCALMR) of the Oregon Graduate Institute of Science & Technology addresses, through advances in scientific understanding, technology, and education, society's need to manage increased development and manipulation of coasts and landmargins while preserving and enhancing their environmental integrity, and protecting human populations from natural and man-made hazards.

CCS—Center for Coastal Studies (USA)

Center for Coastal Studies
59, Commercial St., Provincetown, MA 02657
E-mail: ccs@coastalstudies.org

A private nonprofit organization for research, conservation, and education in the coastal and marine environments. For 25-years, CCS has worked to increase our understanding and protection of coastal and marine environments.

Center for Coastal Studies (CCS), Scripps Institution of Oceanography (USA)

Center for Coastal Studies
Scripps Institution of Oceanography
University of California, San Diego
La Jolla, CA 92093-0209
Phone: (858) 534 4333
Fax: (858) 534 0300

The Center for Coastal Studies (CCS) is a research division of Scripps Institution of Oceanography (SIO), University of California, San Diego (UCSD). Located adjacent to the SIO pier, the Center engages in worldwide scholarly studies of the coastal environment, the development of data acquisition systems and research instrumentation, and advising on coastal protection and sediment management.

Centre for Earth and Ocean Research, University of Victoria (Canada)

Petch Building, Room 169
P.O. Box 3055, Victoria, British Columbia, V8W 3P6
Phone: (250) 721 8848
Fax: (250) 472 4100

The Centre for Earth and Ocean Research (CEOR) was established in 1987 to initiate, foster, promote, and coordinate research in earth, ocean, and atmospheric sciences at the University of Victoria and to engage in collaborative projects and programs with other institutions and agencies.

Center for Marine Science, University of NC at Wilmington (USA)

5600, Marvin K. Moss Lane
Wilmington, NC, 28409
019.052.2300

CMS General Information:
Nancy Stevens
Phone: 910 962 2300
E-mail: stevensn@uncwil.edu

Dedicated to providing an environment that fosters a multidisciplinary approach to questions in basic marine research. The mission of the center is to promote basic and applied research in the fields of oceanography, coastal and wetland studies, marine biomedical and environmental physiology, and marine biotechnology and aquaculture.

Center for the Study of Marine Policy, University of Delaware (USA)

301, Robinson Hall, University of Delaware, Newark, DE 19716
Phone: 1 302 831 8086
Fax: 1 302 831 3668
E-mail: bcs@udel.edu

The Center conducts a broad range of research and policy studies emphasizing the application of policy analysis and other analytical tools to the management of ocean and coastal areas on national, regional, and global scales. A major emphasis of the Center has been on integrated coastal and ocean management, particularly on the development of governance approaches that move beyond present single-sector approaches toward multiple-use management regimes.

CEROS—National Defense Center of Excellence for Research in Ocean Sciences (USA)

73-4460, Queen Kaahumanu Highway, Suite 111
Kailua-Kona, HI 96740
Phone: (808) 327 4310
Fax: (808) 327 4320
E-mail: info@ceros.org

CEROS' mission is to support the Department of Defense technology requirements; encourage leading edge R&D in ocean sciences and technology in Hawaii; foster use of ocean R&D facilities in Hawaii; provide an interface between specialized small businesses with expertise in ocean-related R&D and DoD users of advanced technology and

Table A3.5 *Continued*

develop avenues to ocean science expertise and facilities at the University of Hawaii (UH).

Chesapeake Bay Research Consortium (USA)

Chesapeake Research Consortium
645, Contees Wharf Rd.
Edgewater, MD 21037
Phone: 410 798 1283
Fax: 410 798 0816

The Scientific and Technical Advisory Committee (STAC) provides scientific and technical guidance to the Chesapeake Bay Program on measures to restore and protect the Chesapeake Bay. As an advisory committee, STAC reports quarterly to the Implementation Committee and annually to the Executive Council.

Coastal and Hydraulics Laboratory (USA)

Coastal and Hydraulics Laboratory
Engineer Research and Development Center
3909, Halls Ferry Road, Vicksburg, MS 39180
Phone: (601) 634 3111

Coastal Morphodynamics Laboratory, Louisiana State University (USA)

Coastal Studies Institute
336, Howe-Russell Geoscience Complex
Louisiana State University, LA 70803
Fax: 225 388 2520

The Coastal Morphodynamics Laboratory (CML) was founded in 1991 to facilitate graduate student and faculty research in coastal morphodynamics. The CML offers a wide range of state-of-the-art field, laboratory equipment and computers for research in coastal processes including wave hydrodynamics, hurricane impacts, sediment transport, beach and nearshore profile measurements, GIS/RS, mapping, database, and sedimentology.

Coastal Ocean Observation Lab, Rutgers University (USA)

Rutgers University
Institute of Marine and Coastal Sciences
Coastal Ocean Observation Lab
71, Dudley Road
New Brunswick, NJ 08901-8521
Phone: (732) 932 6555
Fax: (732) 932 1821

COOL's research focus is on New Jersey coastal waters, primarily within an area we call "LEO-15." Since 1996 we have been acquiring data from above and below the ocean. Below is a table of contents for the site, beginning with the real-time ocean data that we know you will love if you are planning on spending any time in or on the ocean.

Coastal Resources Research Network (Canada)

1321, Edward Street
Halifax, Nova Scotia B3H 3H5
Phone: (902) 494 1842
Fax: (902) 494 1216

The Coastal Resources Research Network (CoRR) supports researchers in developing countries in their efforts to research and promote Community Based Coastal Resources Management (CBCRM). The Network is based at Dalhousie University, is funded by the International Development Research Centre (IDRC, Canada) and is primarily working with partners in South East Asia.

Coasts Under Stress (Canada)

Dr. Rosemary E. Ommer, Director
Phone: (403) 220 7238
Fax: (403) 282 7822
E-mail: cus@mun.ca

The Calgary Institute for the Humanities
2500, University Drive NW
Calgary, Alberta T2N 1N4

Analyzes the Impact of Social and Environmental Restructuring on Environmental and Human Health in Canada.

Our goal is to identify the important ways in which changes in society and the environment in coastal British Columbia and coastal Newfoundland and Labrador have affected, or will affect, the health of people, their communities and the environment over the long run.

Columbia River Estuary Study Taskforce (USA)

750, Commercial Street, Room 205
Astoria, OR 97103
Phone: (503) 325 0435
Fax: (503) 325 0459 (please call first)
E-mail: crest@columbiaestuary.org

CREST is Council of Governments that includes the local counties, cities, and port districts surrounding the Columbia River Estuary in both Oregon and Washington. CREST is not a regulatory agency. It is a regional organization providing a forum for members to identify and discuss issues of regional importance; to monitor and comment on governmental activities related to the development and management of the natural, economic, and human resources of the Columbia River Estuary; and to improve communication and cooperation between member governments.

NL-1790 AB Den Burg, Texel
Phone: (+31) (0)222 369300
Fax: (+31) (0)222 319674

The Netherlands Institute for Sea Research (NIOZ) was founded in July 1876 as the Marine Zoological Station and is presently one of the major European oceanographic institutes. NIOZ is a research institute under the Netherlands Organization for Scientific Research (NWO). Its mission is to pursue multidisciplinary marine research related to phenomena and mechanisms in coastal and shelf seas as well as the open ocean and involves close cooperation between physicists, chemists, geologists, and biologists.

NORWAY

Coastal and Ocean Engineering

Coastal and Ocean Engineering
NO-7465 Trondheim
Phone: +47 73 59 23 38
Fax: +47 73 59 23 76

European Artificial Reef Research Network

Dr. Antony Jensen
School of Ocean and Earth Science
University of Southampton, Southampton Oceanography Centre
European Way, Southampton SO14 3ZH
Phone: +44 1703 593428
Fax: +44 1703 596642
E-mail: a.jensen@soc.soton.ac.uk

The European Artificial Reef Research network (EARRN) formed in May 1995 with funding from the European Commission (EC) AIR programme. The 51 scientists from 36 laboratories that formed EARRN were all active in artificial reef research and the network has provided recommendations for the direction of future research to the EC. The formal EC funding has finished but EARRN continues its activities using Internet, e-mail (discussion groups) and "meetings of opportunity" to continue its work; expanding its membership beyond the original 51 members. Building on the professional relationships and friendships developed between 1995 and 1998 members will undoubtedly prepare proposals for Framework V. EC-funded collaborative research between members will be the next goal for EARRN.

Institute of Marine Studies, University of Plymouth

Drake Circus, Plymouth

Anchor is an environmental science and engineering firm whose expertise and focus is shoreline projects, addressing issues in sediment management, environmental review, natural resources, and waterway, coastal, and geotechnical engineering. It has offices in Seattle (WA), Long Beach, Oakland and San Francisco (CA), and College station (TX).

Andrews, Miller & Associates, Inc. (USA)
401, Academy St.
Cambridge, MD 21613
Phone: 410 228 7117
Complete coastal & civil engineering services.

Applied Coastal Modeling (USA)
Consulting Services
Jon M. Hubertz, Ph.D.
2733, Deborah Drive
Punta Gorda, FL 33950-8182
Phone/Fax: 941 505 4079
A resource for the expert application of numerical models to coastal problems, analysis of data, display, and interpretation of results.

Applied Coastal Research and Engineering, Inc. (USA)
766, Falmouth Rd.
Building A, Unit 1-C
Mashpee, MA 02649
Phone: (508) 539 3737
E-mail: info@appliedcoastal.com
Applied Coastal Research and Engineering, Inc. focuses on developing and implementing scientifically defensible solutions to problems in the marine environment.

Applied Fluids Engineering, Inc. (USA)
Private Mail Box #237
5710 E, 7th Street
Long Beach, CA 90803
E-mail: phil.watts@appliedfluids.com
A consulting firm specializing in: air and water motion, suspension dynamics, rapid phase change, and vertebrate locomotion.

Aqua Solutions (Canada)
Judy Sullivan, P.Eng.
3405, Greenwood Road
Greenwood, Ontario L0H 1H0
Phone/fax: 905 428 3365
E-mail: judy.sullivan@sympatico.ca
Coastal & river engineering coastal zone management planning, environmental hazard management & planning, flooding & erosion evaluation, project management guidelines & criteria development.

ASL Environmental Sciences (Canada)
1986, Mills Road
Sidney, BC V8L 5Y3
Phone: 1 877 656 0177
When it comes to physical aquatic measurement problems, whether it is wave, ice, current or flow, ASL is uniquely qualified to meet the challenge.

AXYS Environmental Consulting Ltd. (Canada)
Head Office:
600-555, Fourth Ave. SW
Calgary, Alberta, T2P 3E7
Phone: (403) 269 5150
Fax: (403) 269 5245
As one of Canada's leading environmental consulting firms, we have consistently applied innovative and precise science in achieving balanced solutions. Since 1974, our professional staff has been offering clients a range of experience and knowledge to meet the diverse needs of each project.—Robert H. Seager, President.

Baker Coastal Services (USA)
Alexandria, VA
Phone: 703 960 8800
Annapolis, MD
Phone: 410 571 8706
Virginia Beach, VA
Phone: 804 468 8243
Elmsford, NY
Phone: 914 333 5300
Tampa, FL
Phone: 813 2897546
Deals with port & harbor engineering, coastal engineering, coastal zone management, dredging strategies & disposal designs, marina planning & design, and hydrografic surveying/digital mapping.

Cammaert Consultants—Newfoundland (Canada)
Dr. Gus Cammaert
Cammaert Consultants
1, Winter Place
St. John's, Newfoundland A1B 1J5
Phone: (709) 738 3581
Fax: (709) 738 3588
Cammaert Consultants provides specialized consulting and testing services in the field of coastal engineering for the fishing, aquaculture, and boating interests. The company offers design and analysis of coastal facilities and prediction of wave and ice climates.

Canadian Hydraulic Centre (Canada)
Ottawa, Ontario, K1A OR6
Phone: (613) 993 2417
Fax: (613) 952 7679
For all physical & numerical modeling and analysis needs in the general fields of hydraulics.

Table A3.11 North American professional societies, nongovernmental, and nonprofit organizations active in the coastal zone

American Coastal Coalition (USA)

American Coastal Coalition
5460, Beaujolais Lane
Fort Myers, FL 33919
Phone: (941) 489 2616
Fax: (941) 489 9917
E-mail: kategapr@cs.com

The American Coastal Coalition is a national membership organization composed of governmental entities, government officials, business people, academics, national and regional interest groups and advocacy organizations, property owners' associations, individual coastal community residents, and others. It has been organized to serve as the voice of the nation's coastal communities in Washington, DC. ACC's goals are to preserve the role of the federal government in shore protection; support policies and programs which promote travel and tourism to coastal regions of the United States; promote the preservation, protection, and restoration of sandy beaches along America's coastline, including the Great lakes; foster public understanding of the importance of well-maintained beaches to the national economy and to national disaster protection policy; and support these objectives in an environmentally and fiscally sound manner.

American Fisheries Society (USA)

5410, Grosvenor Lane
Bethesda, MD 20814
Phone: (301) 897 8616
Fax: (301) 897 8096
E-mail: main@fisheries.org

The mission of the American Fisheries Society is to improve the conservation and sustainability of fishery resources and aquatic ecosystems by advancing fisheries and aquatic science and promoting the development of fisheries professionals.

American Geological Institute (USA)

American Geological Institute
4220, King Street

Table A3.11 *Continued*

Alexandria, VA 22302-1502

The American Geological Institute is a nonprofit federation of 37 geoscientific and professional associations that represent more than 100,000 geologists, geophysicists, and other earth scientists. Founded in 1948, AGI provides information services to geoscientists, serves as a voice of shared interests in our profession, plays a major role in strengthening geoscience education, and strives to increase public awareness of the vital role the geosciences play in mankind's use of resources and interaction with the environment.

American Littoral Society (USA)

Building 18, Sandy Hook
Highlands, NJ 07732
Phone: (732) 291 0055

The American Littoral Society (ALS) is a national, not-for-profit, membership organization, dedicated to the environmental wellbeing of coastal habitat.

American Oceans Campaign (USA)

600, Pennsylvania Ave SE, Suite 210
Washington, DC 20003
Phone: (202) 544 3526
Fax: (202) 544 5625
E-mail: info@americanoceans.org

American Oceans Campaign is working in Washington (DC), Los Angeles (CA), and in coastal communities across the country to revitalize the nation's oceans and coastal waters. AOC has two primary goals: restore and protect ocean habitats and ensure clean, safe beach water.

American Society of Civil Engineers (USA)

1801, Alexander Bell Drive
Reston, VA 20191
Phone: (800) 548 2723

Founded in 1852, the American Society of Civil Engineers (ASCE) represents more than 123,000 members of the civil engineering profession worldwide, and is America's oldest national engineering society. ASCE's vision is to position engineers as global leaders building a better quality of life.

Fax: 254 776 3767
E-mail: business@aslo.org

The purposes of ASLO are to promote the interests of limnology, oceanography and related sciences, to foster the exchange of information across the range of aquatic science, and to further investigations dealing with these subjects. ASLO is best known for its journal, *Limnology and Oceanography* (L&O), its interdisciplinary meetings, and its special symposia.

America Shore & Beach Preservation Association (USA)

Gregori Wodell, President
1724, Indian Way
Oakland, CA 94611
Phone: (510) 339 2818
Fax: (510) 339 6710
E-mail: president@asbpa.org

ASBPA dedicated to the sound, far-sighted and economical development and preservation of the shore of our oceans, lakes and rivers which will aid in placing their benefits within the reach of the largest possible number of people in accordance with the ideals of a democratic nation.

Association of Coastal Engineers (USA)

P.O. Box 7800
Alexandria, VA 22307

Founded in 1999 to promote excellence in coastal engineering practice, education, and research. The Association of Coastal Engineers is a professional organization dedicated to the advancement of excellence in education, research, and the practice of coastal engineering.

The Association recognizes Coastal Engineering as the skills, knowledge, expertise, and theory associated with purposeful engineering intervention in the coastal system.

Atlantic Coastal Action Program Saint John (Canada)

76, Germain Street,
P.O. Box 6878, Station A
Saint John
New Brunswick
E2L 4S3
Phone: (506) 652 2227
Fax: (506) 633 2184
E-mail: acapsj@fundy.net

ACAP Saint John is a nonprofit community-based environmental management and research organization. In this capacity, we represent all of the interests in the Saint John community and work with the stakeholders to move toward better management of our local environment.

Atlantic Coastal Watch (USA)

Sustainable Development Institute
3121, South St., NW
Washington, DC 20007
Phone: (202) 338 1017
E-mail: susdev@igc.org
Website: www.susdev.org

Bay of Fundy.com (Canada)

P.O. Box 243
Chance Harbour
New Brunswick E5J 2B8
Phone: (506) 659 2044
E-mail: bof@nbnet.nb.ca

Bay of Fundy.com is distinctive because it is dedicated to sustainable tourism—tourism that enables visitors to experience and enjoy the natural and cultural attractions of Fundy in ways that do not exhaust the resource and which generate income for those who are stewards of the region.

Beach Erosion Authority for Clean Oceans and Nourishment (USA)

800, South Victoria Avenue
Room L1050
Ventura, CA 93009

105, East Anapamu St
Suite 201, County Counsel
Santa Barbara, CA 93101
E-mail: staff@beacon.dst.ca.us

The Beach Erosion Authority for Clean Oceans and Nourishment (BEACON) is a California Joint Powers agency established to deal with coastal erosion and beach problems on the Central Coast of California. The agencies making up BEACON are Santa Barbara and Ventura Counties and the cities of Port Hueneme, Oxnard, San Buenaventura, Carpinteria, and Santa Barbara.

California Shore and Beach Preservation Association (USA)

250, W. Wardlow Road
P.O. Box 7707
Long Beach, CA 90807
Phone: (310) 426 9551 Ext. 294
Fax: (310) 424 7489
E-mail: cwebb@moffattnichol.com

State chapter of the American Shore and beach preservations association. CSBPA is an educational and professional association with members from government, academics, coastal engineering, and other professions, as well as property owners and individuals and groups interested in the coast of California.

California Coastal Coalition (CalCoast) (USA)

1133, Second Street, Suite G
Encinitas, CA 92024
Phone: (760) 944 3564
Fax: (760) 944 7852
E-mail: steveaceti@calcoast.org

The California Coastal Coalition (CalCoast) is a nonprofit advocacy group comprising 28 coastal cities; six counties; AMBAG, BEACON, SANDAG, and SCAG; along with business associations and allied

Table A3.11 *Continued*

groups committed to restoring California's shoreline through sand replenishment, increasing the flow of natural sediment, wetlands recovery, and improved water quality. CalCoast was the cosponsor, with the CA Shore and Beach Preservation Association, of the CA Public Beach Restoration Act (AB 64-Ducheny) which was signed into law in October, 1999.

Canadian Ocean Habitat Protection Society (Canada)
Box 13, Newellton,
Nova Scotia
BOW 1PO
E-mail: dkpjones@klis.com
Exploring, understanding, protecting, and restoring eastern Canada's incredible northern coral forests & those fisheries that can coexist with them.

Caribbean Conservation Corporation (USA)
4424, NW 13th St., Suite #A1
Gainesville, FL 32609
Phone: 1 800 678 7853; (352) 373 6441
Fax: (352) 375 2449
E-mail: ccc@cccturtle.org
Caribbean Conservation Corporation is a not-for-profit 501(c)(3) membership organization based in Gainesville, Florida. CCC was founded in 1959 by Mr. Joshua B. Powers in response to renowned ecologist Dr. Archie Carr's award-winning book, The Windward Road, which first alerted the world to the plight of sea turtles. Since its founding, CCC has been dedicated to the conservation of sea turtles and related marine and coastal wildlife through research, training, advocacy, education, and protection of natural areas.

CERF—Coastal Education and Research Foundation, Inc (USA)
P.O. Box 210187
Royal Palm Beach, FL 33411
CERF is a nonprofit corporation dedicated to the advancement of the coastal sciences. The foundation is devoted to the multidisciplinary study of complex problems of the coastal zone. The purpose of the foundation is to help translate and interpret coastal issues for the public and to assist professional research and public information programs. CERF is the publisher of the international *Journal of Coastal Research* (JCR), a coastal-marine science research journal that deals with all aspects of the coastal zone.

Charlotte Marine Research Team
Phone: (813) 571 9750; 626 5478
The Charlotte Marine Research Team (CMRT) is a nonprofit corporation established in 1999 and composed of volunteer citizens.

Clean Annapolis River Project (Canada)
P.O. Box 395,
Annapolis Royal Nova Scotia
BOS 1A0
Phone: (902) 532 7533
E-mail: carp@fox.nstn.ca
The Clean Annapolis River Project (CARP) is a charitable, community-owned corporation created to work with the community and interested organizations to foster conservation, restoration, and sustainable use of the freshwater and marine ecosystems of southwestern Nova Scotia's Annapolis River and its watershed.

Clean Water Fund (CWF) (USA)
4455, Connecticut Ave.
NW, Suite A300-16
Washington, DC 20008
Phone: (202) 895 0432
Fax: (202) 895 0438
E-mail:cwf@cleanwater.org
Clean Water Fund (CWF), a national 501(c)3 nonprofit, brings diverse communities together to work for changes that improve our lives, promoting sensible solutions for people and the environment.

Clean Water Network (USA)
1200, New York Avenue
NW, Suite 400,
Washington DC 20005
Phone: (202) 289 2395
Fax: (202) 289 1060
E-mail: cfw@cleanwater.org
The Clean Water Network (CWN) is an alliance of more than 1,000 organizations that endorse its platform paper, the National Agenda for Clean Water, which outlines the need for strong clean water safeguards to protect human health and the environment.

Coalition to Restore Coastal Louisiana (USA)
200, Lafayette Street
Baton Rouge, LA 70801
Phone: 188-LA-COAST
Early in 1988, the Coalition to Restore Coastal Louisiana was incorporated to address and advocate for the restoration and preservation of the only great delta ecosystem in North America—the Mississippi River Delta. A land of extraordinary riches, the area supplies a large portion of our nation's commercial fish landings—oysters, blue crabs, menhaden, and shrimp, to name a few.

Coast Alliance
600, Pennsylvania Ave.
SE, Suite 340
Washington, DC 20003
Phone: (202) 546 9554
E-mail: coast@coastalliance.org
The Coast Alliance is a nonprofit organization, formed in 1979 by a number of groups and individuals concerned about the effects of unprecedented development pressure and pollution on the coasts.

Coastal America (USA)

Phone: (850) 224 7121
E-mail: fes@fleng.org

Florida Oceanographic Society (USA)
890, NE Ocean Boulevard,
Hutchinson Island
Stuart, FL
Phone: (561) 225 0505

Florida Oceanographic Society is a non-profit 501C(3) organization established in 1964, and is "Dedicated to the preservation and enhancement of Florida's Coastal Ecosystems, through education, research, personal stewardship and fun!"

Florida Shore & Beach Preservation Association, Inc. (USA)
2952, Wellington Circle
Tallahassee, FL 32308
Phone: (850) 906 9227
Fax: (850) 906 9228

The Florida Shore & Beach Preservation Association is a very different kind of state association, which is the source of our effectiveness. On the one hand, we function as a "league of cities and counties" on beach and coastal issues. Most coastal cities and counties are members. This gives us enormous clout in the Florida Legislature. On the other hand, FSBPA represents more than 1,000 private citizens concerned about beach preservation. We provide these citizens with a forum and a strong voice. This public–private partnership is vital to get local beach projects off the ground. FSBPA is a nonprofit corporation with offices in Tallahassee close to the state capital. We enjoy 501 (c) (3) tax exempt status with the I.R.S. as an educational organization.

Marine Technology Society (USA)
1828, L Street, NW #906
Washington, DC, 20036-5104m
Phone: (202) 775 5966
Fax: (202) 429 9417
E-mail: mtspubs@aol.com

As a professional society, we are constantly striving to rise to the challenges and changes within our ocean professions. We do this by ongoing examination of the services we offer our members, by increasing our cooperative efforts with other societies, by expanding our international presence, and by fostering education of the public and our youth.

National Parks Conservation Association (USA)
1300 19th St.
NW, Suite 300,
Washington, DC 20036

Since 1919, the National Parks Conservation Association has been the sole voice of the American people in the fight to safeguard the scenic beauty, wildlife, and historical and cultural treasures of the largest and most diverse park system in the world.

North Carolina Coastal Federation (USA)
North Carolina Coastal Federation
3609, Highway 24 (Ocean)
Newport, NC 28570
Phone: (252) 393 8185; 800 232 6210
Fax: (252) 393 7508

"Citizens working together for a healthy coastal environment" best summarizes the North Carolina Coastal Federation's mission. NCCF is a nonprofit, tax exempt organization which seeks to protect and restore the state's coastal environment, culture, and economy through citizen involvement in the management of coastal resources.

Ocean Conservation Society (USA)
P.O. Box 12860
Marina del Rey, CA 90295
Phone: (310) 822 5205
Fax: (310) 822 5729
E-mail: info@oceanconservation.org

Ocean Conservation Society is a 501 (c) (3) nonprofit corporation engaged in marine biology research, conservation education, public outreach, and the protection of our oceans.

Oceanic Society (USA)
Headquarters:
Fort Mason Center
Building E
San Francisco, CA 94123

The Oceanic Society is a nonprofit, membership organization founded in 1969 to protect the marine environment.

Ocean Voice International (Canada)
P.O. Box 37026,
3332, McCarthy Road
Ottawa, ON K1V 0W0
Phone: (613) 721 4541
Fax: (613) 721 4562

Ocean Voice International is a nonprofit membership-based marine environmental organization dedicated to the harmony of humankind, sea and its life.

Table A3.11 *Continued*

Stamford, CT 06902
Phone: (203) 327 9786
Fax: (203) 967 2677
E-mail: membership@savethesound.org
Save the Sound is a bi-state, nonprofit membership organization dedicated to the restoration, protection, and appreciation of Long Island Sound and its watershed through education, research, and advocacy.

SeaWeb (USA)
1731, Connecticut Ave.
NW, 4th Floor
Washington, DC 20009
Phone: (202) 483 9570
SeaWeb is a project designed to raise awareness of the world ocean and the life within it. The ocean plays a critical role in our everyday life and in the future of our planet. We believe that as more people understand this and begin to appreciate the earth as a water planet, they will take actions to conserve the ocean and the web of life it supports.

St. John's Harbour ACAP (Canada)
6, Bruce Street
Mount Pearl
Newfoundland A1N 4T3
Phone: (709) 747 4973
Fax: (709) 772 6309
St. John's Harbour ACAP, Inc. was founded in early 1993 by a group of citizen and government stakeholders. It is a nonprofit organization with a mandate to implement a community directed, concensus-based Comprehensive Environmental Management Plan (CEMP)for the Harbour and its related environs. This CEMP represents a major step toward fulfillment of that mandate.

Surfrider Foundation (USA)
122, S. El Camino Real #67
San Clemente, CA 92672
Phone: (949) 492 8170
Fax: (949) 492 8142
The Surfrider Foundation is a nonprofit organization dedicated to protecting our oceans, waves, and beaches.

Tampa BayWatch, Inc. (USA)
8401, Ninth Street North,
Suite 230-B
St. Petersburg, FL 33702
Phone: (727) 896 5320
Fax: (727) 896 5325
Tampa BayWatch, Inc. is a nonprofit stewardship program dedicated exclusively to the charitable and scientific purpose of protecting and restoring the marine and wetland environments of the Tampa Bay estuary, the largest open water estuary in the State of Florida.

The American Littoral Society (USA)
28, West 9th Road,
Broad Channel, NY 11693
Phone: (718) 634 6467
E-mail: donriepe@aol.com
We are an environmental organization concerned about issues that affect the littoral zone: that area on the beach between low and high tide. The American Littoral Society (ALS) is a national, nonprofit, public-interest organization comprising over 6,000 professional and amateur naturalists, with headquarters in Sandy Hook, New Jersey.

The Chesapeake Bay Foundation
Headquarters:
Philip Merrill Environmental Center
6, Herndon Avenue
Annapolis, MD 21403
Phone: (410) 268 8816; (410) 269 0481 (from Baltimore); (301) 261 2350 (from D.C. metro)
As you wander through this site, you will see concrete examples of how CBF is helping to restore the tapestry that is the Bay. Our efforts are organized under the headings of "resource protection and restoration" and "environmental education."

Table A3.11 *Continued*

The Coastal Society (USA)

The Coastal Society
P.O. Box 25408,
Alexandria, VA 22313-5408
Phone: (703) 768 1599
Fax: (703) 768 1598
E-mail: coastalsoc@aol.com

The Coastal Society is an organization of private sector, academic, and government professionals and students dedicated to actively addressing emerging coastal issues by fostering dialogue, forging partnerships, and promoting communication and education.

The Fishermen and Scientists Research Society (Canada)

P.O. Box 25125 (Canda)
Halifax, Nova Scotia B3M 4H4
Phone: (902) 876 1160
Fax: (902) 876 1321
Website: www.fsrs.ns.ca

The Fishermen and Scientists Research Society (FSRS), a nonprofit organization, is an active partnership between fishermen and scientists. The objective of this partnership is to establish and maintain a network of fishermen and scientific personnel that are concerned with the long-term sustainability of the marine fishing industry in the Atlantic Region.

The Marine Technology Society (USA)

1828, L Street
NW, #906
Washington, DC 20036-5104
Phone: (202) 775 5966
Fax: (202) 429 9417
E-mail: mtspubs@aol.com

From its inception in the early 1960s, the Marine Technology Society has embraced a charter of inclusiveness. We support all the components of the ocean community: marine sciences, engineering, academia, industry, and government. The core objectives of our society remain valuable in today's rapidly changing world: we are dedicated to the development, sharing, and education of information and ideas.

The Sea Turtle Restoration Project (USA)

P.O. Box 400,
Forest Knolls, CA 94933
Phone (415) 488 0370

The Sea Turtle Restoration Project fights to protect endangered sea turtles in ways that make cultural and economic sense to the communities that share the beaches and waters with these gentle creatures. With offices in California and Costa Rica, STRP has been leading the international fight to protect sea turtle populations worldwide.

The Wildlife Conservation Society (USA)

2300, Southern Boulevard
Bronx, NY 10460
Phone: (718) 220 5100

Since 1895, WCS has worked from our Bronx Zoo headquarters to save wildlife and wild lands throughout the world.

World Aquaculture Society (WAS) (USA)

143, J. M. Parker Coliseum
Louisiana State University
Baton Rouge, LA 70803
Phone: +1 225 388 3137
Fax: +1 225 388 3493

The World Aquaculture Society (WAS) is an international nonprofit society with over 4,000 members in 94 countries. Founded in 1970, the primary focus of WAS is to improve communication and information exchange within the diverse global aquaculture community.

1000 Friends of Florida (USA)

926, East Park Avenue
P.O. Box 5948
Tallahassee, FL 32314-5948
Phone: (850) 222 6277
Fax: (850) 222 1117

Table A3.12 Worldwide societies, nongovernmental, and nonprofit organizations active in the coastal zone

AINCO—Interocean

Costa Rica 11 (1, A-26),
28016 Madrid, Spain
Phone: 34 91 350 4394
Fax: 34 91 350 2414

AINCO7-Interocean is an independent nonprofit organization founded in 1985, with the principal goal of developing Oceanographic and Environmental Sciences in Spain and the rest of the world.

Asociación Oceánica de Panamá

6-2305 El Dorado, Panamá,
República de Panamá
6-3998, El Dorado, Panamá,
República de Panamá
Phone: (507) 226 2020; (507) 260 8265

La Asociación Oceánica de Panamá (AOP), es la organización no gubernamental (ONG) panameña sin fines de lucro que desde su fundación en enero de 1991 se dedica a la investigación, protección y conservación del medio ambiente marino panameño. Esta integrada en su mayoría por jóvenes buzos y personas que se sienten atraídas por la belleza de nuestros océanos y que han decidido unir esfuerzos para proteger y preservar nuestros recursos marinos.

Association of Marine Scientists

Room B19, New Academic Complex
University of Mauritius
Réduit, Mauritius
Phone: 4541041 Ext: 1409
Fax: 3952005
E-mail: ams.mauri@intnet.mu

The Association of Marine Scientists (AMS) is a nongovernmental organization which aims at providing a common platform for marine scientists in Mauritius to interact with each other. AMS also acts as the local chapter of the Western Indian Ocean Marine Science Association (WIOMSA).

Australian Coral Reef Society

66, Oogar Street
Alexandra Headland
Queensland 4572, Australia
Phone: (07) 5443 6565
E-mail: acrs@jcu.edu.au

The ACRS plays a key role by promoting scientific research on Australian coral reefs. It is a forum for discussion and information transfer among scientists, management agencies, and reef-based industries that are committed to ecological sustainability. Because it is not aligned to any vested interests, the Society's views are sought by government policymakers, conservationists and all those interested in coral reefs who need impartial and expert advice.

Australian Marine Sciences Association (AMSA)

P.O. Box 902
Toowong
Queensland 4066, Australia
E-mail: amsa@uq.edu.au

Table A3.12 *Continued*

The Australian Marine Sciences Association (AMSA) is a national nonprofit organization dedicated to promoting marine science and coordinating discussion and debate of marine issues in Australia.

Australian Meteorological and Oceanographic Society (AMOS)

Phone: +61 (0)2 9296 1618
Fax: +61 (0)2 9296 1657
E-mail: m.speer@bom.gov.au
Website: www.amos.org.au/sydney

The Australian Meteorological and Oceanographic Society (AMOS) is an independent Australian society that supports and fosters interest in meteorology and oceanography through publications, meetings, courses, conferences, grants, and prizes. It also represents the views of its members to various institutions and the public.

Cape Nature Conservation (CNC)

Phone: + 27 21 426 0723
Fax: + 27 21 426 4266
E-mail: cncinfo@cape-town.org

Cape Nature Conservation (CNC) is concerned with the conservation of our natural environment within the western Cape, South Africa (see our mission statement below). This area includes the fynbos biome—one of the six plant kingdoms of the world. Cape Nature Conservation manages nature reserves and wilderness areas in the Western Cape, and invites you to experience and revel in their pristine natural beauty.

Conference of Peripheral Maritime Regions of Europe

CRPM, 6 Rue Saint-Martin 35700
Rennes, France
Phone: +33 2 99 35 40 50
Fax: +33 2 99 35 09 19

CERM—Consortium for Estuarine Research and Management

University of Port Elizabeth
P.O. Box 1600
Port Elizabeth, South Africa
Phone: +27 (0) 41 5042877
Fax: +27 (0) 41 5832317
E-mail: btagcb@upe.ac.za

Organizations of South African scientists collaborate in promoting the wise management of estuarine systems trough joint participation in direct research, training, and technology transfer.

Dorset Coast Forum

C/o Dorset County Council,
County Hall
Dorchester, Dorset, DT1 1XJ, UK
Phone: 01 305 225 132

The Dorset Coast Forum was established in 1995 to look at the long-term strategic issues facing the Dorset coast. The overriding aim of the Forum is to promote a sustainable approach to the management, use, and development of Dorset's coastal zone, which will ensure that its inherent natural and cultural qualities are maintained and enhanced for the benefit of future generations.

ESPO (European Sea Ports Organisation)

Avenue Michel-Ange, 68
B-1000 Brussels
Phone: 32 2 736 34 63
Fax: 32 2 736 63 25
E-mail: mail@espo.be

ESPO's mission is twofold. It aims at influencing public policy in the European Union and to achieve a safe, efficient, and environmentally sustainable European Port sector, operating as a key element of a transport industry where free and undistorted market conditions prevail, as far as practicable.

Estuarine and Coastal Sciences Association

Department of Biological Sciences
University of Hull
Hull HU6 7RX, UK
E-mail: t.c.telfer@stir.ac.uk

ECSA is an academic organization, with a worldwide membership, which promotes research and study of all aspects of estuarine and coastal regions. The Association was founded in 1971, as the Estuarine and Brackish-Water Biological Association, to promote production and dissemination of scientific knowledge and understanding of estuaries and coastal waters, in order to encourage resource management for the public benefit.

European Aquaculture Society

Slijkensesteenweg 4
B-8400 Oostende, Belgium
Phone: +32 59 32 38 59
Fax: +32 59 32 10 05
E-mail: eas@aquaculture

The European Aquaculture Society (EAS) was established on April 30, 1976 as an international, nonprofit association, with the principal objective of being the European forum for contacts and information exchange between all actors within the aquaculture industry.

European Artificial Reef Research Network

Dr. Antony Jensen
Southampton Oceanography Centre
European Way
Southampton SO14 3ZH, UK
Phone: +44 1703 593428
Fax: +44 1703 596642
E-mail: a.jensen@soc.soton.ac.uk

Artificial reef research programs exist in Italy, Spain, Portugal, the UK, the Netherlands, France, Greece, Norway, Israel, Monaco, Russia, Poland, Turkey, and Finland. Denmark has an interest in artificial reefs, although no structures have yet been placed. European reef research is varied; from biofiltration through habitat protection to fishery enhancement.

European Coastal Association for Science and Technology

Jeanette Owen
Department of Maritime Studies and International Transport
Cardiff University
P.O. Box 907
Cardiff CF1 3YP, UK
Phone: +00 44 2920 874271
Fax: +00 44 2920 874301
E-mail: eurocoast@cardiff.ac.uk
owenJ4@cardiff.ac.uk

EUROCOAST was established in 1989 as an association of scientists, engineers, and decisionmakers within the European community.

European Union for Coastal Conservation

P.O. Box 11232
2301 EE Leiden
The Netherlands
Phone: +31 71 5122900
Fax: +31 71 5124069
E-mail: admin@eucc.nl

EUCC is dedicated to the integrity and natural diversity of the coastal heritage and to ecologically sustainable development. EUCC is the largest coastal network in Europe, with 750 members and member organizations in 40 countries, 14 active National Branches, and 7 professional offices.

EUCC bridges the gap between scientists, ecologists, conservation site managers, planners, and policy makers, especially at an international level.

Fiskardo's Nautical and Environmental Club and Ionian Sea Research Centre

28084 Fiskardo
Kephalonia, Greece
Phone: 00 30 (0) 674 41182
Fax: 00 30 (0) 674 41182

Table A3.12 *Continued*

E-mail: fnec@otenet.gr
fnec@otenet.gr

FNEC is a nonprofit making and nongovernmental organization conducting environmental activities in Kephalonia. FNEC'S main aims are to provide an informal environmental information center, promote environmental education & conservation and encourage youth exchanges for community development. The Ionian Sea Research Centre (ISRC) is an independent scientific body within the club FNEC carrying out marine research, recording marine sightings and promoting marine conservation. The ISRC possesses a number of permits from the Ministry of Fisheries and Forestry to carry out research in the Ionian Sea.

Fundação sos Mata Atlântica

Rua Manoel da Nóbrega, 456
CEP 04001-001
São Paulo/SP, Brazil
Phone: (0XX11) 3887 1195
Fax: (0XX11) 3885 1680
E-mail: smata@ax.apc.org
Website: www.sosmatatlantica.org.br

A Fundação SOS Mata Atlântica é uma entidade privada, sem vínculos partidários ou religiosos e sem fins lucrativos. Seus principais objetivos são defender os remanescentes da Mata Atlântica, valorizar a identidade física e cultural das comunidades humanas que os habitam e conservar os riquíssimos patrimônios natural, histórico e cultural dessas regiões, buscando o seu desenvolvimento sustentado.

Greenpeace International

Kiezersgracht 176

Phone: +31 20 523 6222

I Love the Ocean—Philippines

Blue Seas, Inc., 5/F CIFC Towers
J. Luna cor. Humabon Sts.
North Reclamation Area
Cebu City, Philippines
Phone: (32) 232 1821 22 412 0487 89
Fax: (32) 232 1825

The "I Love the Ocean" Movement is a recognition of the need to approach the problem of sustainable coastal resource use from all angles. It recognizes that all individuals have a stake in what happens to our marine resources, and that each individual, from the president of the country to the company executive to the nameless man on the street, has an important role to play in saving these precious gifts of nature.

Instituto Ecológico Aqualung

Rua do Russel, 300, grupo 401
Glória, Rio de Janeiro, RJ, Brazil, CEP: 22210-010
Phone: (021) 558 3428; (021) 558 3429
Fax: (021) 558 3419; (021) 558 1233
E-mail: instaqua@uol.com.br

O instituto ecológico aqualung é hoje uma das maiores e mais atuantes entidades preservacionistas brasileiras. Atuando na área de preservação e educação ambiental, criando e implantando ações concretas de forma a arrecadar maiores recursos para patrocinar diversas entidades e organizações ambientalistas, divulgando a informação e o conhecimento sobre as causas ecológicas, criando publicações sobre o meio ambiente e a fauna marinha e lançando campanhas de conscientização da importância de se preservar o meio ambiente, o instituto ecológico aqualung vem desenvolvendo um trabalho moderno e eficiente de inestimável valor para as gerações futuras—a preservação do nosso planeta.

KIMO, UK

Mr. Rick Nickerson, KIMO Secretariat
Shetland Islands Council, Infrastructure Services
Grantfield, Lerwick
Shetland ZE1 0NT UK
Phone: +44 01595 744800
Fax: +44 01595 695887

KIMO is an international association of Local Authorities, which was formally founded in Esbjerg, Denmark, in August 1990 to work toward cleaning up pollution in the North Sea. It has over 100 members in 8 countries including the United Kingdom, Norway, Sweden, Denmark, the Faeroes Islands, and the Netherlands, the Republic of Ireland with associate members in Germany. KIMO's primary objective is the cleaning up of the existing pollution in Northern Seas and coastal waters, of preventing future pollution and of working to preserve and enhance them and to leave them in a fit and healthy state for the wellbeing of future generation.

Marine Conservation Society, UK

Organizes the biennial Pacific Congress on Marine Science and Technology; promotes ocean education and ocean research; marine policy.

A great deal of information about coastal organizations is provided in these 16 tables. The information that is highlighted here could have been organized in many different ways. Due to the large number of organizations, it was convenient to present lists in a format that was similar to an Internet search result. The table thus compiled required minimal efforts at reworking the lists into usable summaries. Other methods could have been used to obtain this kind of information but due to time constraints and the great effort of hand searches in books, the results would not have been as comprehensive. Perusal of these 16 tables would suggest, even to a novice researcher first approaching the coastal realm of endeavor, that an enormous amount of information from a wide variety of coastal organizations that have interest in coastal topics is now available. This list can now serve as a "heads up" for academic coastal researchers who should now be aware of many brethren of the same ilk that they were not aware of previously. Besides university researchers, there are now many private nonprofit organizations and for-profit consulting companies that conduct research in the coastal zone. The past two or three decades have witnessed enormous increases in coastal populations, expansion of industry and commercial facilities into coastal zones, and tourism and recreation dependent on clean/safe environments and adequate support infrastructure. These coastal uses mostly conflict with one another and governmental oversight has not kept pace with the rapid urban–industrial–commercial development and associated environmental degradation. The large numbers of organizations that have concern for coastal issues evidences the expansion of private and public interest groups as well as service organizations into the coastal zone. It is hoped that these lists of coastal organizations indicate the importance and level of interest in this special part of the world, the thin interface between land and water that is coming under increasing threat from over use. The organizations listed here exist, in large part, to better understand natural coastal systems and to protect, preserve and manage coastal/marine resources.

APPENDIX 4: DATABASES

A database can be defined as a collection of interrelated data stored together with minimum redundancy to serve multiple applications. A common and controlled approach is used in adding new data or in modifying and retrieving the existing data within the database.

Proper coastal data management necessitates a comprehensive knowledge of the coastal environment, rapid access to required information, effective communication, and decision support tools. The development of a coastal data management system for multiple use spans a broad range of fields. In the last decades considerable changes have occurred in the methodology of storage and retrieval of data. In this presentation, information on bibliographic as well as numeric/textual databases relevant to coastal geomorphology has been included in tabular form. Databases cover a broad spectrum of related subjects like coastal environment and pollution aspects, coastline, elevation data, landscape and landform images, shore zone morphology, erosion, grain size, bathymetry, topography, hydrology, terrain, oil spills, coral morphology, coastal changes, coastal zone management, etc.

With increasing utilization of the coastal zone for various purpose the need for an Integrated Coastal Management (ICM) system has become necessary. The management of data requirements and compilation of coastal inventories are often among the first steps in ICM. In addition to contributing to the understanding of the environment and potential impacts of development, the compilation of an inventory also ensures a common information base for all decisionmakers. Once the problems of data access are overcome, building a coastal zone inventory involves constructing an intelligent and cohesive mosaic by integrating numerous separate data sources.

However, upon closer scrutiny, it is often found that the databases are incompatible and inconsistent, which hinders the process of inventory building. Differences in data collection equipment and protocol, scale, projection, temporal and attribute resolution, terminology and nomenclature, data gaps, problem solving approaches, and quality control standards, especially data validity, tolerances of error, and uncertainty need to be resolved before integrated databases are compiled. Problems of data inconsistency can supersede those of data availability, accuracy, geographic coverage, large data volume, and lack of structure. Traditional coastal inventories have been compiled as atlases and more recently digital coastal information systems. Further developments have culminated in the development of large digital atlases such as the North Sea Project Database and UK Digital Marine Atlas.

In recent times the more useful way of having a database in GIS (Geographic Information System) format has proved to have manifold support. GIS has emerged as a valuable media for coastal database management, most notably for the ability to store and analyze the diverse amount of data required for coastal management in an integrated format. The tremendous capabilities of GIS, such as infinite precision, the capability to change scale, the capability to combine and overlay data from various data sources, and the production of high-quality cartographic displays; which are most alluring, are also most deceptive. The ease with which one can create maps with GIS and the inexperience of many users in cartographic design can lead to the production of ineffective and misleading maps.

Advances in many technological fields have been well incorporated in development of coastal databases. Traditional digital atlases have been augmented with multimedia video, remote sensing images, photographic images, and hypertext medium. Traditional databases have been converted into CD-ROM databases and/or WEB databases.

Data management technology has advanced from tapes to index files, to hierarchical databases, to network database, to relational databases, to object databases, to object-related database, and finally web databases. Coastal databases have also grown through these stages and hence such databases are found in one of the above stages.

With advances in communication technology, local databases are now accessible through LAN (local area network), WAN (wide area network), Intranet, Internet (WEB databases), etc. Similarly, improvements have occurred in user's interface with database from character interface, Graphic User Interface, Object-oriented UI, Hypermedia, Hypertext mark-up language, and so on. Depending upon the need to resolve the coastal conflicts, using GIS technology, the databases have grown to Decision Support System (DSS), to Multi-criteria DSS, to Spatial DSS, to Collaborative DSS, to expert system, and so on.

Since database creation involves data from various sources, the issue of data quality is considered one of the main areas requiring attention while building databases. Of paramount importance is the need to assess the suitability and correctness of a data set to be incorporated in the database. Unfortunately the drive to build database applications often neglects the fabric of the data. Too often efforts are focused on "feeding the beast" and minimal regards to "what the beast is being fed."

Information on representative databases relevant to coastal geomorphology are presented in tabular form under:

Table A4.1: Bibliographic coastal databases;
Table A4.2: Numeric/textual coastal databases;
Table A4.3: Developer/provider's address.

Pravin D. Kunte

APPENDIX 5: GLOSSARY OF COASTAL GEOMORPHOLOGY

Abrasion - The wearing away of a rock surface by friction as a result of the impact of wind, wave, current, or ice action, particularly when these agents are armed with rock fragments (notably sand and gravel): sometimes termed *corrasion*. Abrasion of a rocky shore can form ramps or platforms, or excavate furrows or potholes, while abrasion of a cliff can result in the cutting of caves, clefts, and crevices. Submarine abrasion takes place on the nearshore seafloor, diminishing offshore as water depth increases; it becomes imperceptible at depths greater than half the wave length (Bradley, 1958). Rock fragments (such as quartz grains) can also be worn and pitted by abrasion when they are impacted against each other, or against a rock surface: this is known as mechanical abrasion, and is distinguished from etching produced by chemical solution (Corrosion, *q.v.*) (Margolis, 1968).

Abrasion notch - An elongated cliff-base hollow (typically 1–2 m high and up to 3 m recessed) cut out by abrasion, usually where Breaking Waves (*q.v.*) are armed with rock fragments.

Abrasion platform - A smooth, seaward-sloping surface formed by abrasion, extending across a rocky shore and often continuing below low tide level as a broad, very gently sloping surface (plain of marine erosion) formed by long-continued abrasion (Johnson, 1916). The intertidal section is typically 50–100 m wide, increasing with tide range.

Abrasion ramp - A smooth, seaward-sloping segment formed by abrasion on a rocky shore, usually a few meters wide, close to the cliff base.

Accretion - A gradual or intermittent natural process of deposition of sediment by wind, wave or current action, or by rivers, glaciers, solifluction or mass movement, resulting in the natural raising or extension of a land area.

Aeolian calcarenite, Aeolianite (Eolianite) - See Dune Calcarenite.

Abrasion notch at Cape Liptrap, Victoria, Australia.

Intertidal abrasion platform cut in Chalk near Birling Gap, Sussex, England.

Abrasion ramp at cliff base, North Island, New Zealand.

Aggradation - The raising of a land surface by deposition (vertical accretion) of sediment, as on a beach, dune, mudflat, marsh, coastal plain, or delta.

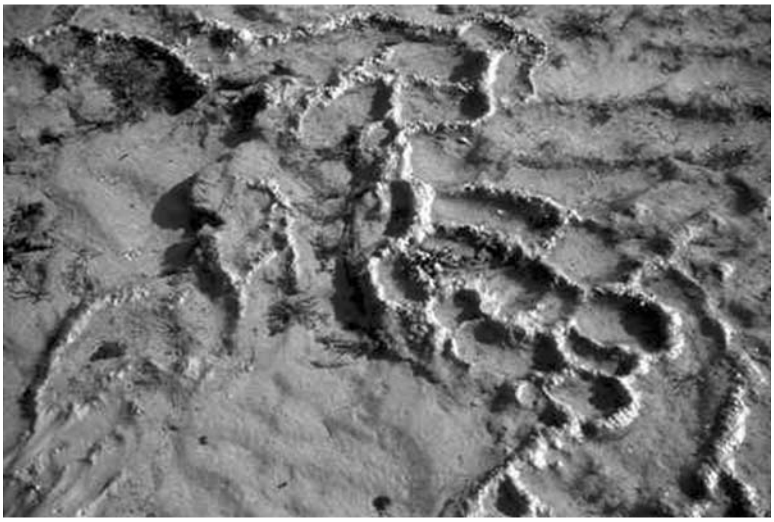
Algal mat - A carpet of blue-green algae (cyanophytes) that stabilize intertidal sediments and precipitate carbonates on the sheltered shores of hypersaline areas, found in the Arabian Gulf and the Red Sea, Shark Bay in Western Australia, the Bahamas, and Texas coast lagoons. See Stromatolite.

Algal rampart, Algal reef - A structure typically 10–20 m, occasionally up to 100 m wide, formed in shore and nearshore waters by the growth of calcareous algae (notably *Lithothamnion, Lithophyllum*, or *Porolithon* spp.).

Algal ridge - A structure built by calcareous algae on the surface of a reef or shore platform.

Algal rim - A ridge built on the more exposed (seaward) margins of coral reefs or shore platforms by encrusting calcareous algae, such as *Lithothamnion* or *Porolithon*; they are usually no more than 20 cm high. Networks of ridges constructed by algae may enclose shallow pools on coral reef flats and shore platforms.

Artificial beach - A beach emplaced by human action, as where sand brought from the land, or alongshore or offshore sources is dumped on the shore, strictly where there was no natural beach, but the term is often used where a natural beach depleted by erosion is restored or renourished (see Beach Nourishment).



Algal ridges on shore platform at Port Hedland, Western Australia.

Amirante Atoll, Seychelles, Indian Ocean.

Atoll - A ring-shaped coral reef structure (ranging from <1 km to >100 km in diameter), partly or wholly enclosing a lagoon (typically 30–100 m deep and several kilometers wide); the outer (seaward) slopes plunge steeply to the deep ocean floor (oceanic atoll) or to the continental shelf (shelf atoll). The term comes from the Maldives, where "atolu" are government districts, each being a circular reef enclosing a lagoon. Atolls with a central (noncoral) island, such as Bora Bora, are termed "almost atolls"; those with ring-shaped reefs enclosing remnants of an earlier atoll, as in Houtman Abrolhos off the coast of Western Australia, "compound atolls." Some compound atolls take the form of chains of small atolls (diameter about a kilometer), known as Faros, as in the Maldive Islands, Indian Ocean. Horsehoe reefs form where isolated reef platforms (patch reefs) have marginal spurs that have grown to leeward.

Attrition - The wearing down of rock fragments by friction when they are mobilized and thrown against a rock surface, or ground against other rock fragments by wind action, waves, or currents.

Avulsion - The separation of an area of land when a river or estuary channel suddenly changes its course, usually during floods, or when a meander is breached. The term has been used obscurely, mainly by lawyers, to describe rapid erosion of the shore by waves. Another interpretation may be the transference of land along a coast as a result of rapid erosion on one sector and nearby related accretion, but this is not strictly avulsion, the placing of an area of pre-existing land on the opposite side of an earlier channel as the result of river migration.

Backshore - The coastal fringe lying above (i.e., landward of) the normal high tide line, but occasionally inundated by exceptionally high tides or storm surges. Also known as the supralittoral or supratidal zone.

Backwash - The seaward (return) flow of water after the swash (uprush) produced when a wave breaks on the shore.

Bank - A localized broad elevation of the seafloor, smooth in profile, usually submerged even at the lowest tides, and composed of unconsolidated sediment (usually sand, sometimes glacial drift), subject to movement by waves or current action. Typically a few meters wide, but the term is used for larger features, such as the Dogger Bank in the North Sea or the Grand Bank of Newfoundland. See also Bar (shoal). A banner bank trails in the lee of an island or headland.

Bar - An elongated bank, ridge or mound of sediment (sand or gravel) a few meters wide, deposited and shaped by waves and currents, and submerged at least at high tide (i.e., can be partly or wholly exposed at low tide) (Shepard, 1952). Bars commonly form off beaches, but also

Sand bars on the southeast coast of Port Phillip Bay, Australia.

occur off river mouths and lagoon entrances. A break-point bar is a concentration of sediment formed by breaking waves where material that is being carried shoreward meets that withdrawn from the beach by backwash. Longshore bars are formed parallel to a beach, and at least partly exposed at low tide, while oblique bars run at an angle to the beach, and transverse bars at right angles to it. Bars may also occur in cuspate, lunate, looped, crescentic, reticulate, or chevron patterns. Multiple parallel bars and troughs form on gently sloping sandy shores where spilling waves break and re-form: they are exposed at low tide (see Ridge and Runnel). Trailing bars (banner banks) occur in the lee of headlands or islands, and become flying bars when they are disconnected (cf. trailing and flying spits, which differ in that they extend above high tide level). It should be noted that before Shepard defined bars, the terms such as offshore bar, bay bar, and looped bar (Johnson, 1919) were often used to describe features that would now be termed barriers.

Barchan - A dune form, an isolated, mobile crescentic mound of bare sand, typically up to 30 m high, with a steep advancing leeward slope and a gentler concave windward slope, flanked by lateral horns curving downwind and spaced at up to 350 m. Commonly found in deserts, barchans also form on extensive areas of bare drifting coastal dune sand, and on unvegetated backshores.

Barrier (Coastal barrier) - An elongated ridge of deposited sediment (sand, pebbles, occasionally boulders) that has been built up by wave action above high tide level along the coast or across an embayment (bay barrier): differing from a bar, which is submerged at least at high tide (Shepard, 1952). Typically a barrier is backed by a lagoon or swamp that separates it from the mainland or from earlier barriers, but this is not essential: some barriers abut older land surfaces. A barrier may be from a few meters to more than a kilometer wide and up to 100 km long, attached to the mainland at one end (see Barrier Spit) or both ends, or interrupted by tidal inlets (see Barrier Island).

Short (1999, p. 307): "A barrier is defined as a shore-parallel sub-aerial and sub-aqueous accumulation of detrital sediment (sand/boulders) formed by waves, tides and aeolian processes."

Barrier beach - A single, narrow (usually <200 m) elongated ridge built parallel to the coast, without surmounting dunes.

Barrier island - A barrier segment bordered by transverse gaps (tidal inlets, lagoon entrances, river outlets) which may be migratory and subject to closure; it usually bears beach ridges, dunes and associated swamps and minor lagoons. Barrier islands are typically 0.5–5.0 km wide, 1–100 km long and 6–100 m high.

Barrier lagoon - A lagoon extending roughly parallel to the coastline, behind a barrier or reef. See Coastal Lagoon.

Barrier reef - An elongated, narrow coral reef built up offshore and parallel to the coast, from which it is separated by a broad lagoon (which may be several kilometers wide), typically with extensive areas too deep for coral growth.

Barrier spit - A barrier attached at one end to the mainland, with or without recurves, and backed by a bay, lagoon or marshland (swamp).

Bay - A general term for a wide (typically >1 km) coastal re-entrant between two headlands, its seaward boundary generally wider than the extent of landward penetration. A small bay is termed a cove, a large bay a gulf. The term bay is also used in the United States for coastal waters largely or entirely cut off from the sea by spits and barrier islands (e.g., Netarts Bay on the Oregon coast) which elsewhere are called coastal lagoons, and for the ovoid depressions of uncertain origin that contain lakes or swamps on the coastal plain of South Carolina.

Beach - An accumulation on the shore of generally loose, unconsolidated sediment, ranging in size from very fine sand up to pebbles, cobbles, and occasionally boulders; often also containing shelly material. Conventionally, shores with silt or clay sediment are not regarded as beaches (but in some languages the terms beach and shore overlap, so that silt shores and clay shores may be translated as silt beaches and clay beaches). A distinction can sometimes be made between an upper

Coastal sand barrier at Marlo, southeastern Australia.

Barrier reef with storm-tossed boulders.

Barrier spit, Lake Onoke, North Island, New Zealand.

beach, often swash-built, around high tide level, and a gentler lower beach exposed as the tide falls.

Short (1999, p. 3) defined a beach as "a wave-deposited accumulation of sediment lying between modal wave base and the upper swash limit where wave base is the maximum depth at which waves can transport beach material shoreward." However, since wave base is conventionally where the water depth is half the wave length, this limit can be in water at least 50 m deep and perhaps several kilometers offshore. Most accounts of beaches admit their extension below lowest tide level and for some distance (usually not stated) beyond the breaker zone.

Beach berm - An ephemeral flat or landward-sloping step or terrace built on a beach face by swash action. On shingle beaches there may be several such berms, resulting from successive episodes of swash action at successively lower tidal levels. A berm built at the top of a beach may persist to become a Beach Ridge (*q.v.*).

Beach budget - The quantified gains and losses of sediment from a defined beach sector.

Beach compartment - A beach occupying a sector of coast bounded by rocky reefs, promontories or artificial structures such as breakwaters. See Coastal Sediment Compartment.

Beach cusps - Regular successions of half-saucer (crescentic) depressions opening seaward between cuspate points in the swash zone on the upper beach face, the points being of coarser material (shingle or coarse sand) than the intervening hollows. Also known as Swash Cusps.

Swash-built sand berm on the Ninety Mile Beach, southeastern Australia.

Shingle beach cusps at Ringstead, Dorset, England.

Beach drift (Beach drifting) - The zigzag movement of beach material along the shore in the swash zone when waves arrive at an angle to the shoreline, producing an oblique swash, followed by a Backwash (*q.v.*) that descends orthogonally from the beach face. The same waves generate a longshore current which carries sediment along the coast in the same direction in the nearshore zone. See Longshore Drifting.

Beach, drift-aligned (drift-dominated) - A beach with an orientation determined by the drifting of sediment alongshore in response to waves arriving at an angle to the coastline: they are aligned at an angle to the dominant direction of wave approach, with alignments parallel to the line of maximum longshore sediment flow, generated by obliquely incident (typically 40–50°) waves. Contrast Swash-Dominated Beach (*q.v.*), aligned parallel to the dominant waves.

Beach face - The seaward slope of a beach between the low tide line and the upper limit of wave swash.

Beach gravel - An American term describing beach sediment coarser than sand, ranging up to cobble size, and often (but not always) well-rounded: the British term shingle is similar.

Beach lobe - Roughly triangular or lobate protrusions from a beach that form and may migrate alongshore downdrift in response to oblique wave action.

Beach nourishment - The natural or artificial supply of sand or gravel to a beach. Also termed Beach Restoration, Beach Fill, and Beach Renourishment (*qq.v.*).

Beach, profile of equilibrium - A beach profile (concave, steepening upward past the high tide line and declining seaward to below the low tide line) that represents the attainment of an equilibrium with incident waves, whereby sediment gains and losses are balanced (Johnson, 1919). A cyclic equilibrium is attained where a succession of beach profiles corresponds with changing wave regimes through a Cut-and-fill (*q.v.*) sequence, and a dynamic equilibrium where the beach profile is maintained even though the beach may be prograding or retreating as the result of erosion.

Beach ridge - An elongated low ridge of beach material (sand, gravel, or shells) piled up above high tide level by swash action. Many beach ridges are surmounted by wind-deposited sand, which may develop into a Foredune (*q.v.*), but a beach ridge is strictly a feature built and shaped by wave action. Sandy beach ridges are typically 5–50 m wide, measured from bordering troughs (Swales, *q.v.*), shingle beaches usually narrower.

Beach ridge plain - A series of beach ridges formed successively, parallel, or roughly parallel to the coastline, and separated by elongated hollows or swales, each ridge marking a former position of the prograding coastline.

Sandy beach lobe at Lang Lang, Westernport Bay, Victoria, Australia.

Storm-piled shingle beach ridge at Redcliff Point, Dorset, England.

Shingle beach ridge plain at Hoed, Denmark.

Beach rock exposed on a sandy shore at Gili Bidara, Lombok, Indonesia.

Beach rock - A sandstone layer within a beach, formed by interstitial precipitation of carbonates (calcite or aragonite) to cement the beach sand in the zone of fluctuating groundwater levels, usually where the sediments are strongly calcareous, as on shelly, calcarenite, or coralline beaches (Stoddart and Cann, 1965). Where the material cemented consists of rounded pebbles the term beach conglomerate is used, while cementation of angular gravel yields beach breccia.

Beach scarp - A steep or vertical cliff cut in the beach face by large waves during a storm or tsunami.

Beach state - The state of a beach may be reflective (with a high proportion of wave energy reflected from beach face), dissipative (wave energy diminished through breaker and surf zones), or intermediate between these two.

Beach, swash-aligned (swash-dominated) - A beach formed where incoming waves are refracted into curved patterns that anticipate, and on arriving fit, its curved outline (Davies, 1980), so that the beach is parallel to incoming wave crests (particularly refracted ocean swell).

Beach system - Beaches and the processes at work on them, with adjustments in morphology in response to energy inputs from waves, currents, tides, and winds.

Bench - A flat or gently sloping rock ledge, terrace or platform, typically 5–50 m wide, but sometimes much wider, backed and fronted by steeper slopes. A structural bench coincides with the upper surfaces of a hard rock outcrop, formed where weaker overlying material has been removed by erosion, an erosional bench has been planed across tilted or

Scarp cut by storm waves, Ninety Mile Beach, southeastern Australia.

Structural benches on Bay Cliff, Wonboyn, New South Wales, Australia.

folded rocks by erosion. A bench between high and low tide levels is called a Shore Platform (*q.v.*).

Berm - See Beach Berm.

Beveled cliff - See Slope-over-wall Coast.

Bioconstruction - Formed by organisms (e.g., algae, corals, vegetation) that trap sediment, including the products of their own decay (e.g., shells, peat).

Biodeposition - A little used term for sedimentation generated by organisms, such as coral reefs and algal rims, shelly deposits or peat.

Bioerosion - Removal of rock material by the physical and chemical processes associated with the activities and metabolism of plants and animals that inhabit the shore, especially on limestone coasts (Healy, 1968).

Bioherm - A mound, bank, or (biogenic) reef built by sedentary organisms, such as corals, algae, foraminifera, molluscs or gastropods, or a reef built in the nearshore zone by oysters, mussels, gastropods

Beveled cliff on glacial drift over vertical Chalk, Flamborough Head, Yorkshire, England.

or worms (serpulid and sabellariid reefs). Vermetid reefs are built by long, coiled gastropods.

Blowhole - A hole or fissure in the roof of a cave on a rocky coast, usually steeply sloping or vertical, through which geyser-like fountains of water and spray are forced by the intermittent release of compressed air trapped in a cave by incoming waves.

Blowout - A small saucer-shaped hollow or trough excavated in vegetated dunes by wind action, with an advancing nose of sand spilling downwind. See Parabolic Dune.

Blue hole - A submerged sinkhole in a coral reef, generally formed by solution when the reef was subaerially exposed during a low-sea-level-stage.

Bluff - A bold, steep, sometimes rounded coastal slope on which soil and vegetation conceal, or largely conceal, the underlying rock formations, in contrast with a cliff in which these formations are exposed. Bluffs may be termed abandoned, degraded, or fossil cliffs. The term seems to have originated in North America for a headland that was rounded rather than cliffed. There is confusion when the term bluff has been used as a place name for a feature that is actually a cliff. Bluffs may form where cliffs stop retreating (as when basal marine erosion is halted by emergence, the Accretion (*q.v.*) of a protective beach, or artificial protective structures such as seawalls or rock ramparts): they may then become degraded by subaerial processes to gentler slopes on which a soil forms and vegetation establishes. Bluffs are generally relatively stable, in comparison with receding cliffs, but the steep forested slopes on the Pacific coast of Oregon and Washington have receded as the result of occasional slumping.

Bombora - Australian term for a bank or reef that causes local raising and steepening of waves moving through shallow water, producing wave fronts that are good for surfing.

Boulder - A rock particle with a diameter exceeding 256 mm (or about 25 cm). See Granulometry.

Breakaway - A fracture at the top of a cliff behind an area where a rock mass has subsided or slid seaward, leaving a small scarp.

Reef formed by calcareous tubeworms (*Galeolaria*) at Beaumaris, Victoria, Australia.

Blowhole at Quobba, west coast, Western Australia.

Bluffs on the southeast coast of Phillip Island, Victoria, Australia.

Breakaway on cliff top near Lyme Regis, Dorset, England.

Breakers, Breaking waves - When waves break they produce (1) surging breakers, which are low and gentle waves until they sweep up a relatively steep beach, (2) plunging breakers, with fronts that curve over and crash (producing little swash but a strong backwash), (3) collapsing breakers that subside as they move toward the shore, and (4) spilling breakers, which are short and high, and produce foaming surf as the swash runs up a beach of gentle gradient (Galvin, 1972). Alternatively, there are constructive breakers (which wash sediment up on to the beach) and destructive breakers (which cause beach erosion), depending on whether the swash and backwash achieve net shoreward or seaward movement of beach material.

Break-point bar - A bar built in the zone where waves break, deposition occurring where shoreward drifting beneath incoming waves meets seaward drifting by backwash, leaving a parallel trough to landward.

Breakwater - An artificial structure built into the sea, often curved, and designed to impede wave action so as to shelter a harbor or protect a stretch of coastline. The terms jetty and pier are sometimes used as synonyms.

Bund - A term used mainly in India and southeast Asia for an artificial embankment, usually of earth or gravel, built along the coastline or the banks of a river or estuary.

Cala, Calanque - A deep steep-sided marine inlet on a limestone coast: calas are found in the Balearic Islands and calanques on the coast of Provence.

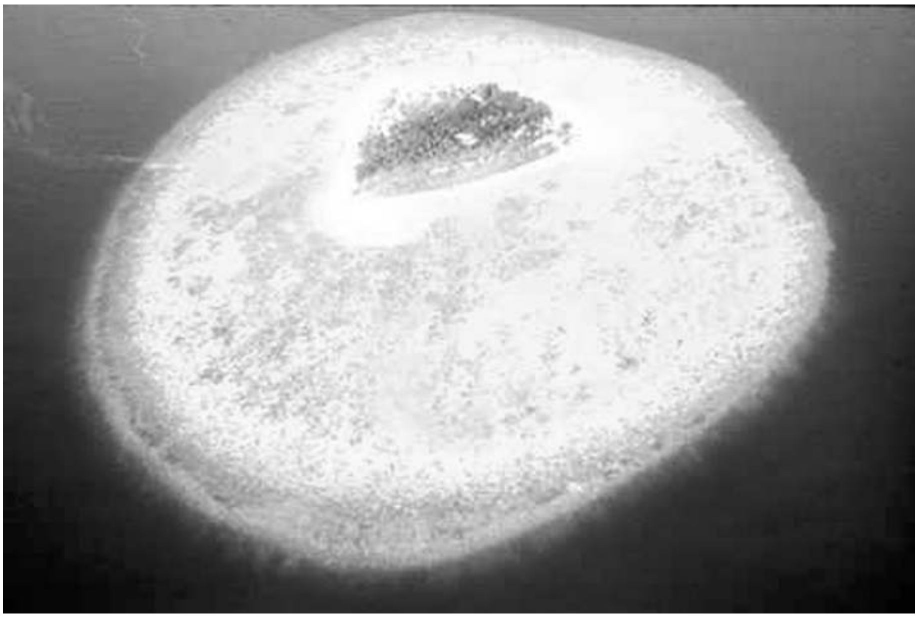
Calcified seaweed, grit - Coarse angular sand or gravel produced by *Lithothamnion calcareum*, which grows extensively on some seafloor areas, as in the western part of the English Channel.

Calcilutite - A fine-grained (silt-sized) calcareous formation with an admixture of clay, often coherent enough to stand as a vertical cliff. The Port Campbell Limestone formation (Miocene) in Victoria, Australia, contains calcilutite deposits that stand in spectacular vertical cliffs.

Calcirudite - A calcareous conglomerate or breccia, consisting of broken or worn fragments of coral, shells, or limestone cemented by precipitated carbonates, often occurring in layers in Dune Calcarenite (*q.v.*).

Calcrete (Caliche) - A hard rock calcareous formation cemented by precipitated carbonates; a limestone or calcareous duricrust usually

Calanque at Wied-il-Ghazri, Gozo, Malta.



Coral cay in the Maldive Islands, Indian Ocean.

formed on or immediately below the land surface in an arid or semiarid environment by precipitation of carbonates derived from groundwater that moved upward to an evaporation level. Calcrete can occur as a horizon within dune stratigraphy (usually formed on an old land surface subsequently buried by younger dune sand) or as a caprock (carbonates having been delivered in rising groundwater and precipitated near the drying surface). Known as kunkar in Australia. See Dune Calcarenite.

Can - A fan of beach material washed through a low permeable coastal barrier by Storm Waves (Storm Surges) (*qq.v.*) to form a delta-like projection into a lagoon or on to backing marshland. There are good examples behind the shingle barrier of Chesil Beach, Dorset.

Cape - A large, often rounded coastal protrusion, located where the coastline intersects a range of mountains, hills, or a plateau, usually where a drainage divide reaches the coast. However, some capes are low-lying (e.g., Cape Canaveral (Kennedy) and others on the American Atlantic coast).

Cay - A small low-lying depositional island of coralline sand or gravel (shingle cay) built up just above high tide level by wave action on a reef flat, usually toward the lee side. In the Caribbean a cay is termed a key.

Chenier - A long, low-lying narrow strip of sand, often shelly and typically up to 3 m high and 40–400 m wide, deposited in the form of wave-built beach ridge on a swampy (peat and clay), deltaic, or alluvial coastal plain by wave action. Many cheniers contain shelly sand and gravel. In Louisiana such ridges often have vegetation dominated by oak trees (chêne, hence chênière), emphasizing the contrast with the adjacent peat or clay terrain (Russell and Howe, 1935). Cheniers on the wide coastal plain east of Darwin, Australia, have pandanus palms: had they been originally studied here they may have been called pandaniers. Most cheniers have been deposited at the limit of storm surge swash, and may be termed transgressive, but some may have formed along the coast during a brief phase of raised sea level, followed by progradation that leaves them stranded inland: these may be termed regresssive.

A chenier plain is a coastal plain with several cheniers scattered across it, usually parallel or subparallel to the coastline. Cheniers may pass laterally into beach ridges where the fine-grained substrate becomes sandy or gravelly.

Chine - A deep and narrow ravine cut into soft rock on a cliffed coast by a stream descending steeply to the shore, often over waterfalls. A term used in the Isle of Wight and on the Hampshire coast in southern England.

Clastic - Consisting of broken and transported fragments of pre-existing rock. The term Coarse clastic beach has sometimes been applied to a beach of gravel or Shingle (*q.v.*).

Clay - A sediment consisting of particles with a diameter smaller than 1/256 (about 0.004) mm.

Cliff - A steep (usually >40°, often vertical and sometimes overhanging) coastal slope cut into (and thus exposing) rock formations,

Sandy chenier within mangroves, Karembé, New Caledonia.

Whale Chine, Isle of Wight, England.

produced by basal marine erosion (undercutting), but occasionally by faulting or earlier fluvial or glacial erosion. Cliffs cut in unconsolidated formations are sometimes known as Earth Cliffs (*q.v.*), and there are also Ice Cliffs (*q.v.*) at the seaward terminations of glaciers and ice sheets. Cliffs rising to 100–500 m above sea level are termed high cliffs, while those exceeding 500 m (as in Peru and Western Ireland) are termed megacliffs (Guilcher, 1966): the cliff at Enniberg on the north coast of Vidoy (Faerö Islands) is 725 m high. Coastal cliffs are generally receding as the result of marine erosion at their base, accompanied by subaerial erosion of the cliff face.

Cliff fall (Rock fall) - The collapse of the face of a rocky cliff into an apron of debris. On some cliffs columns of rock bordered by vertical joints may topple on to the shore.

Clifflet - See Microcliff.

Cliff-top dunes - Usually found where sand blown from a beach moved up and over a cliff, but the link between the beach and the dune has been removed by erosion, exposing the cliff; occasionally the dunes have arrived from inland (Jennings, 1967).

Coast - A zone of varying width where the land meets the sea, and where the lithosphere, hydrosphere, and atmosphere meet and interact. Some use the term as a synonym for shore, but generally it is taken to include the land margin, extending inland to the limit of penetration of marine processes or to the first major change in landform features, such as a rising slope, and the nearshore zone, out at least to the line where waves break. A wider definition includes the whole zone between the highest and lowest coastlines related to sea-level changes during the Quaternary (*q.v.*).

Cliff fall and scar on Chalk coast, North Foreland, Kent, England.

In American literature the coast is sometimes elaborated to the coastal zone.

Coastal barrier - See Barrier.

Coastal dimensions - Coastal morphology may be classified as follows:

First-order features - about 1000 km long, 100 km wide, and 10 km high (e.g., continental coasts, related to global tectonics).
Second-order features are about 100 km long, 10 km wide, and 1 km high (e.g., deltas, fiords).
Third-order features about 10 km long, 1 km wide, and 100 m high (e.g., coastal barriers).
Fourth-order features are about 1 km long, 100 m wide, and 10 m high (e.g., foredunes).
Fifth-order features are about 100 m long, 10 m wide, and 1 m high (e.g., beach berms, shore platforms, sand bars).
Sixth-order features are about 10 m long, 1 m wide, and 10 cm high (e.g., beach cusps).
Seventh-order features are about 1 m long, 10 cm wide, and 1 cm high (e.g., current ripples).

In each case the dimension given should be regarded as being within a range of from 50% to five times the figure given (i.e., Sixth-order features 5–50 m long, 0.5–5 m wide, and 5–50 cm high).

Coastal dunes - Hills, banks, or ridges of aeolian (wind-blown) sand backing present or former coastlines.

Coastal erratics - Large shore rocks that came from outcrops elsewhere, delivered to their present position on the coast or on the shore, usually by glaciers or icebergs.

Coastal gorge - See Geo.

Coastal lagoon (Barrier lagoon) - A shallow, often brackish (estuarine) water body formed where a coastal inlet, river mouth or embayment has been enclosed (or almost enclosed) behind a depositional barrier or barrier spit. Known as an étang in France, a haff in Germany, an estero in Portugal, a liman on the Black Sea coast and a pond in New England. A distinction is made between coastal lagoons enclosed by depositional barriers and lagoons backed by coral atolls, or standing between a barrier reef and the mainland coast.

Coastal land reclamation - The making of new land by enclosing or filling shore and nearshore areas. An alternative term land claim has been suggested, because this is not strictly reclaiming, but land claim risks confusion with territorial claims by political groups.

Coastal landslide - The movement of a mass of rock, earth or debris down a coastal slope. Also known as a landslip (Lyell, 1833). Where the coastal rocks are fine-grained, the downslope movement may be in the form of a mudflow lubricated by exuded groundwater or surface runoff after heavy rain or melting snow or ice.

Coastal plain - Low-lying coastal terrain, usually of depositional origin, but occasionally consisting of planed-off rock outcrops (see Strandflat), between the coastline and rising ground in the hinterland.

Coastal sediment compartment - A sector of coast within which sediment is largely or completely confined, delimited by rocky reefs, promontories, tidal inlets, river mouths, or artificial structures such as breakwaters (Davies, 1974). See Beach Compartment.

Coastal tors - Outcrops of harder or more massive rock protruding as buttresses (coastal tors) from a coastal slope.

Coastal waters - A general term for the sea area adjacent to the coast, comprising the nearshore and offshore zones. The seaward limit is usually indefinite, and an arbitrary distance (such as 3 nautical miles) has been used in Law of the Sea schedules.

Coastline - The edge of the land at the limit of normal high spring tides; the subaerial land margin, often marked by the seaward boundary of terrestrial vegetation. On cliffed coasts it is taken as the cliff foot at high spring tide level. Use of the term Shoreline (*q.v.*) as a synonym for Coast or Coastline is vague and misleading, and should be avoided—shorelines move to and fro as the tides rise and fall, whereas coastlines

Giant's Rock, a coastal erratic on the shore near Porthleven, Cornwall, England.

Coastal landslide at Blackgang, Isle of Wight, England.

Coastal tor (buttress) at Trewalvas Head, Cornwall, England.

are related to the high-spring-tide shoreline, and thus submerged only in exceptional circumstances (e.g., Storm Surges, *q.v.*).

Cobble - A rock particle with a diameter between 64 and 256 mm. See Granulometry.

Colk - A relatively deep circular or oval depression in the seafloor (or on the floor of an estuary or lagoon) excavated and kept clear of sedimentation by locally strong current action (including the siphoning that can occur beneath ice). Also known as a tidal colk or scour hole. Originally a pothole on a river bed.

Compound spit - A recurved spit with several recurves on the inner shore marking former terminations.

Concentric (Contraction) ridges - A series of small parallel beach ridges formed successively on the shore of a contracting shallow lake or lagoon by intermittent deposition along the margins of a prograding salt marsh, as described from Lake Reeve, Victoria, Australia, by Jenkin (1966).

Contraposed coast - A discordant coast developed on previously concealed rock formations where marine erosion has removed bordering and overlying weaker deposits (Clapp, 1913). Examples of contraposed coasts include sectors where Archaean gneiss has been exhumed from a Pleistocene dune calcarenite cover on the west coast of Eyre Peninsula, South Australia, and where Palaeozoic rocks have been exposed by the removal of a fringe of glacial drift on the coasts of the Lleyn Peninsula in North Wales. In southwest England the slope-over-wall profiles formed where a mantle of Pleistocene periglacial Head has been undercut by marine erosion to expose Devonian rocks could also be classified as contraposed.

Coral garden - An open structure built by branching (e.g., staghorn) corals.

Coral rampart - A depositional ridge of coral fragments built near the windward margin of a coral reef by storm waves or surges.

Coral reefs - A structure built in the sea by corals, which form the reef framework, together with algae and other organisms (such as algae, molluscs, crinoids, bryozoans) and precipitated carbonates to make rock formations sufficiently resistant to withstand normal wave action.

Corrosion - Dissolving of rock or minerals by chemical action in water (rain, sea, or spray).

Currents - Movements of water generated by one or more of the following: density currents occur where water of higher specific gravity (colder or more saline) moves to displace water of lower specific gravity; discharge (fluvial jet) currents occur where a river flows into the sea; ebb and flow (flood) currents are generated by falling and rising tides; wave-generated currents such as the longshore currents that develop when waves arrive at an angle to the shoreline; Rip Currents (*q.v.*) flow back into the sea through breaking waves at intervals along the shore; wind-generated currents flow in the direction of the wind; and ocean currents are slow mass movements of water in response to variations in water temperature and salinity, atmospheric pressure and wind stress.

Cuspate bar - A triangular depositional bank of sand or shingle, submerged, at least at high tide, extending out from the coast with straight or concave shores that meet in a seaward point, and enclosing a depression occupied by a lagoon at low tide.

Cuspate barrier - Similar to a cuspate bar, except that it has been built above high tide level.

Cuspate foreland - A triangular depositional area of sand or shingle with straight or concave shores extending out to a seaward point, with multiple beach ridges marking stages in progradation on one or both flanks. Cuspate forelands may migrate by erosion of one flank and the drifting of beach material to accrete on the other. Known in Britain as a ness (Dungeness and Duddon Ness).

Cuspate spit - A triangular spit that projects from the coast with straight or concave shores extending out to a seaward point. Often formed in the lee of an islet, stack, reef or shoal, or on the shores of a bay or lagoon as a result of convergent wave refraction. Formerly known as a cuspate bar, but this term is not applicable to a feature built above high tide level (see Bar).

Cut-and-fill - The cyclic sequence of changes on a beach profile resulting from erosion by storm waves (cut) and subsequent restoration by constructive waves (fill).

Delta - A depositional landform produced by sedimentation at and around the mouth of a river. Deltas usually protrude from the coast, and are typically triangular, named from the Greek letter "delta" applied to the Nile delta by Herodotus in ancient times, but they may alternatively be Digitate (finger-like, as in the Mississippi delta), Cuspate (Tiber delta), Arcuate or rounded (Niger delta), or Lobate (Rhône delta), in shape.

Coral garden, Great Barrier Reef, Australia.

Dungeness: a cuspate foreland in southeastern England.

Cuspate spit, Moreton Island, Queensland, Australia.

Dissipative beach - A beach where wave energy is greatly diminished as spilling breakers move in through shallow nearshore water.

Distributary - One of a number of channels formed in a delta region where the river branches downstream.

Drift-aligned beach - See Beach, Drift-Aligned.

Drowned valley-mouth - See Ria.

Dune - A mound or ridge of unconsolidated wind-blown sediment, usually sand but occasionally silt or clay (where the source area is a dry mudflat: crescent-shaped silt or clay dunes on the lee shore of a lake or lagoon are known as lunettes).

Dune calcarenite - A generally consolidated aeolian sandstone lithified by the cementation or partial cementation of dune sand by secondary internal precipitation of carbonates from groundwater. The proportions of carbonate vary, but are typically at least 50%, the dune sand being calcareous or partly noncalcareous (quartzose sandstones with less than 50% carbonate are termed quartz-arenites). Dune calcarenite is usually of Pleistocene age, and may be overlain by unconsolidated Holocene dune topography. Dune calcarenite is also known as Aeolian Calcarenite (*q.v.*), Aeolianite, Calcareous aeolianite, Dune limestone or Dune sandstone; American spelling: eolianite.

Dune swale - A hollow within dune topography, especially between parallel dune ridges. Wet swales (often with marsh vegetation) are termed *slacks* and deeper hollows may be seasonally or permanently occupied by *dune lakes*.

Earth cliff - A term used by May (1977) for a cliff cut in soft rock formations (sand, clay, and chalk) and subject to rapid recession and instability leading to recurrent mass movements.

Dune calcarenite cliff, Jubilee Point, Victoria, Australia.

Emerged beach, Falmouth Bay, Cornwall.

Edge waves - Standing oscillations that develop at right angles to the coastline as the result of resonance between waves approaching the shore and waves reflected from it.

Emerged beach - A beach that stands above the level at which it originally formed, on or behind the present shore. Known in the earlier literature as a Raised Beach (*q.v.*), when it was thought that upward land movement was necessary to produce such a feature, but it can also be formed as a result of a lowering of sea level, or some combination of land and sea-level change that has left the sea at a relatively lower level.

Emerged shore platform - A shore platform that stands above the level at which it originally formed (often with an emerged beach), on a coast where the land has been uplifted, sea level has fallen, or some combination of land and sea-level change that has left the sea at a relatively lower level.

Emergence - A rise in the level of the land relative to the sea, achieved by actual uplift of the land, a lowering of sea level, or some combination of land and sea-level change that leaves the sea at a relatively lower level. Also known as a negative change (or fall) in base level. An emerged coast (or feature) is one that stands at a higher level relative to the sea than when it originally formed; an emerging coast is one actually rising relative to sea level.

Epeirogenic movement - Upward or downward tectonic movements of large (continental) land masses.

Emerged shore platform (raised in 1855 earthquake), Wellington, New Zealand.

Escarpment cliff (bluff) - A steep coastal slope cut across rock formations that are horizontal, or dipping landward.

Estuary - The seaward end of a river, opening toward the sea, typically through a funnel-shaped inlet, and usually subject to tidal movements and incursions of salt water from the sea.

Estuary threshold - A bank of inwashed sand or gravel at the mouth of an estuary.

Eustasy (Eustatic movements) - Worldwide movements of sea level resulting from changes in the volume of water in the ocean basins. Such changes have occurred as a result of the waxing and waning of the Earth's glaciers, ice sheets, and snowfields (glacio-eustatic movements), but similar changes have taken place as a result of modification of the shape and capacity of the ocean basins by deposition of sediment (sedimento-eustatic movements), submarine vulcanicity (volcanic-eustatic movements) or tectonic deformation (tectono-eustatic movements). There are also *steric changes* due to expansion or contraction of the oceans with rising or falling temperatures.

Fault coast - A steep or cliffed coast produced by faulting, where the seaward slope coincides with the plane of the fault, along which the land has been raised. Some coasts were initiated as fault coasts, but have been cut back by marine erosion and now stand landward of the fault.

Fault-line coast - A steep or cliffed coast following a fault line, where the seaward slope has been formed by differential erosion of rock formations juxtaposed by prior faulting.

Ferricrete - A sedimentary rock formation indurated by the precipitation of iron oxides or other iron compounds, usually derived from percolating groundwater.

Fetch - The distance of open water across which the wind generates waves approaching a coastline from a particular direction.

Fiard (Fjard) - An inlet formed by marine submergence of a river valley (or wide, shallow valley excavated by ice movement) incised in low-lying glaciated rocky terrain. Known in Scotland as a firth.

Fiord (Fjord) - A long, deep steep-sided marine inlet formed by submergence of part of a valley (U-shaped glacial trough) previously shaped by a glacier and incised into coastal uplands. Known in Scotland as a sea loch.

Escarpment cliff, Ballard Down, Dorset, England.

A fiard near Hjortholm, Denmark.

Fiord at Milford Sound, South Island, New Zealand.

Fitting boulders - Interlocking accumulations of blocks and boulders on the shore, resulting from the jostling of the rocks by wave agitation and their consequent abrasion until they have become mutually worn into a complex three-dimensional jigsaw pattern.

Flandrian marine transgression - The sea-level rise that began about 18,000 years ago, in the Late Pleistocene, and continued into the Holocene. This transgression was originally defined in Flanders, northeast France and southern Belgium (Dubois, 1924). See Late Quaternary Marine Transgression (*q.v.*).

Foredune - A ridge of wind-blown sand at the back of a beach, parallel to the coastline, and retained by vegetation. Some foredunes originate as a result of wind deposition of sand on a beach ridge (*q.v.*), but others may begin to form along an upper beach strandline that persists long enough for plants to germinate and intiate sand trapping. The terms primary dune and frontal dune are synonyms for foredune in Australia.

Foreshore - The shore zone, between high and low tide lines. In some countries there is confusion because the term has been used for the fringe of the land, which is really the backshore.

Fringing reef - A structure built adjacent to the coast by coral and associated organisms. A distinction may be made between a shore reef, built out as a prograded terrace from the coastline, and an attached reef, which originated a short distance offshore and became linked to the coastline by subsequent deposition. Some fringing reefs decline gently landward, passing beneath a shallow (ca. 1 m) lagoon or moat, sometimes called a boat channel.

Frost shattering - The disintegration of rock surfaces, notably on cliffs and shore outcrops, as a result of repeated expansion and contraction of the rock by freezing and thawing, particularly where contained moisture forms ice crystals as temperature ranges through 0–4°C. Also termed thermal abrasion.

Foredune at Seaspray, Ninety Mile Beach, Victoria, Australia.

Fringing reef on the southeast coast of Bali, Indonesia.

Gat - A channel cut or maintained across a bar by waves or (more often) currents.

Geo - A Scottish term for a long, deep, and narrow steep-sided inlet (coastal gorge or chasm) cut into rocky cliffs by marine erosion, usually along structural planes of division (joints, faults, bedding planes, cleavage planes). Known as a zawn or gut in Cornwall. A distinction may be made between geos, excavated entirely by marine erosion, and gorges that are the mouths of deeply incised steep-sided valleys invaded by the sea during the later stages of the Flandrian Marine Transgression (*q.v.*).

Geological column - The sequence of rock formations arranged by age (my = million years):

Geological structure - See Structure.

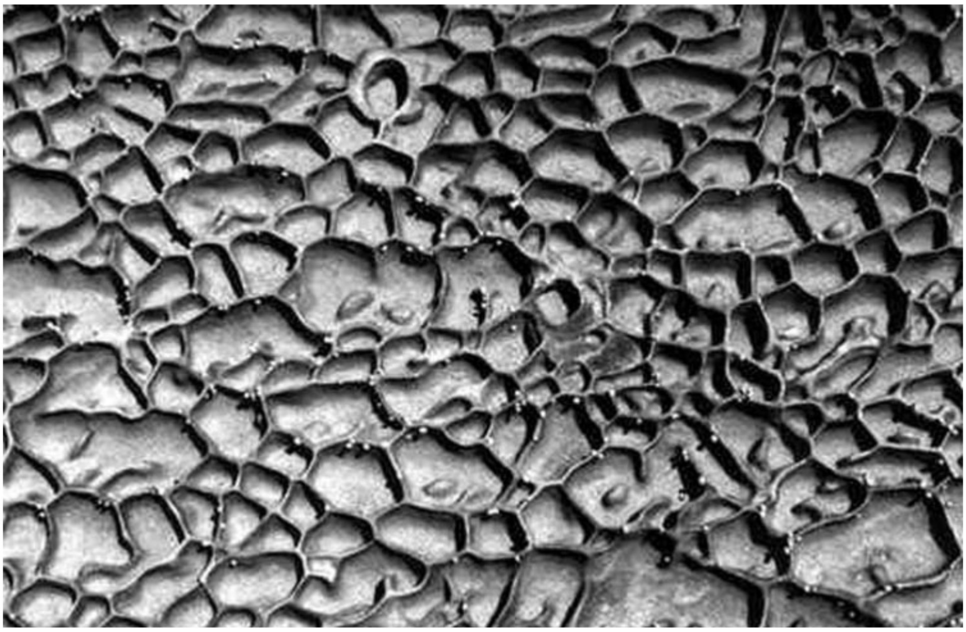
Giant waves - Exceptionally high waves generated by major disturbances (earthquakes, landslides, volcanic eruptions) on the coast or seafloor. See Tsunami.

Grain Size Categories - The Wentworth scale of particle diameters. The ø scale is based on the negative logarithm (to base 2) of the particle diameter in millimetres [$ø = \log_2 d$], so that coarser particles have negative values.

An alternative is a decimal scale centered on 2 mm, in which sand ranges from 0.2 to 2.0 mm, but this does not correspond well with generally perceived grain size categories. The sand range excludes sediment that would be generally classified as fine to very fine sand, and the coarser (>2.0 mm) and finer (<0.2 mm) divisions do not match widely accepted categories of pebbles and cobbles or of silt and clay.

Quaternary Period	Holocene (Recent)	10,000 years
	Pleistocene Epoch	2.3 my
Tertiary Period	Pliocene Epoch	5 my
	Miocene Epoch	23 my
	Oligocene Epoch	36 my
	Eocene Epoch	53 my
	Palaeocene Epoch	65 my
Mesozoic Era	Cretaceous Period	144 my
	Jurassic Period	213 my
	Triassic Period	248 my
Palaeozoic Era	Permian Period	290 my
	Carboniferous Period	360 my
	Devonian Period	405 my
	Silurian Period	436 my
	Ordovician Period	510 my
	Cambrian Period	560 my
Pre-Cambrian Era		

Wentworth scale category	Particle diameter (mm)	ø scale
Boulders	>256	below −8ø
Cobbles	64–256	−6ø to −8ø
Pebbles	4–64	−2ø to −6ø
Granules	2–4	−1ø to −2ø
Very coarse sand	1–2	0ø to −1ø
Coarse sand	1/2–1	1ø to 0ø
Medium sand	1/4–1/2	2ø to 1ø
Fine sand	1/8–1/4	3ø to 2ø
Very fine sand	1/16–1/8	4ø to 3ø
Silt	1/256–1/16	8ø to 4ø
Clay	<1/256	above 8ø



Honeycomb weathering on Cretaceous sandstone, Otways coast, Victoria, Australia.

Granule - A rock particle with a diameter between 2 and 4 mm. See Granulometry.

Granulometry - The measurement and classification of the size of sediment grains.

Groyne - A wall built out at right angles from the coastline, intended to intercept drifting beach material. American spelling: groin.

Gulch - A deep and narrow channel cut by abrasion into a cliff or shore platform or across a rocky shore, often extending below low tide level.

Hairpin dune - An elongated, narrow blowout or parabolic dune with parallel trailing arms, well developed in northeastern Tasmania.

Hanging valley - A valley truncated by cliff recession, so that the stream pours out as a coastal waterfall.

Headland - A high protrusion of the land into the sea, usually cliffed. Generally smaller than a Cape or Promontory (*qq.v.*).

Holocene epoch - The last of the geological epochs, which began about 10,000 years ago.

Holocene marine transgression - See Late Quaternary Marine Transgression or Flandrian Marine Transgression.

Honeycomb weathering (Alveolar weathering) - A process producing an intricate pattern of small cell-like cavities on a rock surface, often penetrating a harder (or indurated) crust.

Humate - A consolidated and indurated sandrock formed within a sandy formation (Dunes, Beach Ridges, *qq.v.*) by interstitial precipitation of iron oxides (derived from the thin coating of quartz sand grains by ferruginous material, responsible for their initial yellow or brown color, mobilized by percolating groundwater) and precipitation of organic matter (washed down from surface soil and decaying vegetation) within the zone where the water table rises and falls (seasonally or irregularly). Also known as coffee rock or hardpan.

Hutberge - A high, steep-sided hill rising abruptly from a Strandflat (*q.v.*), formed as a residual island in a shallow sea subject to intensive freeze–thaw processes accompanying tidal alternations. Similar in form, but not origin, to Old Hat Islands (*q.v.*).

Hydro-isostasy - Vertical movements of a coast and continental shelf in response to loading and unloading of water as sea levels rise and fall.

Cliffs cut in humate, Chatham Islands, New Zealand.

Ice coast/Ice cliffs - Steep cliffs up to 50 m high, formed where glaciers or ice sheets (ice shelves) reach the sea, and from which floes and icebergs become separated during summer melting. Where the ice is afloat the cliff is called an ice front; where it is grounded, an ice wall.

Ice rafting - The delivery of material (rocks, beach sediments, marsh fragments, driftwood) to the shore on or within layers of ice (often in icebergs detached from a glacier front), to be deposited when the ice melts in summer. See also Coastal Erratics.

Induration - The hardening of a rock surface by precipitation of material (carbonates, iron compounds, silica) from groundwater exudations, forming a resistant crust (case-hardening).

Intermediate beach - A beach state transitional between a dissipative and a Reflective Beach (*q.v.*).

Isostasy - An equilibrium between an area of the Earth's crust floating and the underlying plastic mantle, whereby areas loaded with sediment, volcanic deposits or ice subside, and areas unloaded (e.g., when an ice cover melts) rise (isostatic rebound).

Jetty - A solid structure built out more or less at right angles to the coastline or on either side of a river mouth or lagoon entrance. The terms breakwater and pier are sometimes used as synonyms.

Karst coast - A coast with landforms shaped by solution processes, notably on limestone, where the dissolving of the rock leads to the formation of surface depressions, sinkholes, caves, and underground drainage.

Klint - A term used for a cliff (generally in limestone) in the Baltic region. In some countries, notably Estonia, it describes an active cliff, but more generally it indicates an inland bluff that was an active cliff when sea level was higher.

Landlocked - An area of water (usually a bay or lagoon) surrounded or nearly enclosed by land.

Late Quaternary marine transgression - The worldwide rise of sea level that began about 18,000 years ago, when sea stood between 100 and 140 m below its present level, and the continental shelves were subaerially exposed, as the result of global warming and the release of water from melting glaciers, ice sheets, and snow fields. It came to an end about 6,000 years ago, but the history of sea-level change has been complicated on many coasts by accompanying and continuing uplift or depression of coastal land margins. See Flandrian Marine Transgression. Sometimes called the Holocene marine transgression, but the term Late Quaternary Marine Transgression (*q.v.*) is more accurate as the sea-level rise began late in Pleistocene times and culminated within the past 10,000 years (Holocene).

Lateral grading - A gradual change in the caliber of beach sediment along the shore. Grading is a condition; sorting and attrition are processes that may lead to a beach becoming graded.

Longshore current - The flow of water along the shore or nearshore as the result of oblique waves, often augmented by wind-driven and tidal currents.

Longshore (Littoral) drifting - The movement of beach sediment along the shore (and Nearshore, *q.v.*) by waves arriving at an angle to the coastline (Beach Drifting, *q.v.*) and by currents generated by such waves (nearshore drifting). Also known as Shore Drift (*q.v.*).

Lobate (Looped) bar, barrier - A depositional feature curving out from the coastline and back again, in such a way as to enclose a lagoon or swamp. A lobate bar is submerged at least at high tide, and a lobate barrier has been built up above high tide level.

Log-spiral beach - See Zetaform Beach.

Low islands (Low wooded islands) - Small low-lying depositional islands of coralline sediment, comprising a leeward sand Cay (*q.v.*), mainly of sand, a shingle rampart on the windward side, and an intervening depression occupied by a lagoon with mangroves.

Machair - A low flat or hummocky plain of calcareous sand, generally formed on the landward side of a coastal dune, as on the coasts of Scotland and Ireland.

Macrotidal - Where mean spring tide range is 4–6 m.

Mangrove - A type or community of halophytic trees and shrubs that can grow on shores sheltered from strong wave action (bays, inlets, delta, estuary, and lagoon shores) in the intertidal zone, subject to regular or frequent submergence of their root systems by brackish or seawater. Mangroves are found mainly on tropical and subtropical coasts, but extend locally into temperate latitudes.

Low Isles, low wooded islands off Port Douglas, Queensland, Australia.

Megaripples in the Bay of Fundy, Canada.

Megaripple - A large form or Ripple (*q.v.*) or sand wave with an amplitude of 0.1–1.0 m and length between 1 and 100 m. See Ridge and runnel.

Megatidal - Where mean spring tide range exceeds 6 m.

Mesa - A flat-topped, steep-sided residual hill. The term has also been used to describe small upstanding flat-topped rocks on a shore platform.

Mesotidal - Where mean spring tide range is between 2 and 4 m.

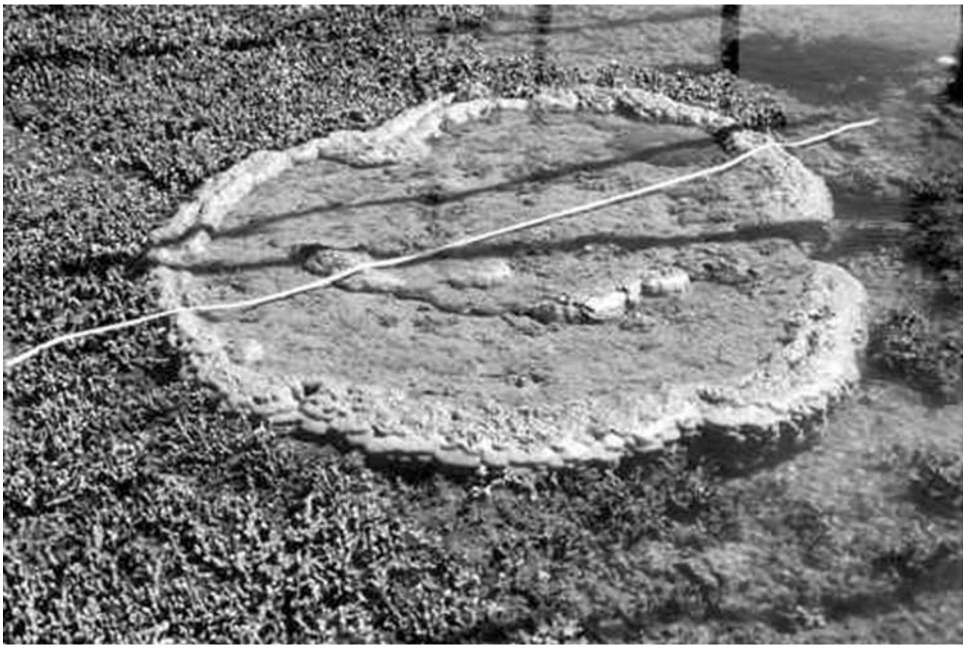
Microatoll - A circular organic reef structure (diameter 1–6 m) consisting of a raised rim built by coral (usually porites), algae and other organisms, surrounding a shallow depression on the shore or on a coral reef.

Microcliff - A small cliff, generally less than a meter high, found on the seaward margins of salt marsh and mangrove terraces, and sometimes in intertidal mudflats. Also known as a Clifflet (*q.v.*).

Microtidal - Where mean spring tide range is less than 2 m.

Mud - A sticky fine-grained sediment (silt, clay, sometimes with organic matter).

Mudflat - A relatively level unvegetated area of fine sediment on the shore, especially in sheltered inlets, estuaries, or tidal lagoons. Intertidal



Microatoll, White Lady Bay, Magnetic Island, Queensland, Australia.

Mushroom Rock on Pleistocene dune calcarenite, Sorrento, Victoria, Australia.

mudflats are commonly exposed seaward or salt marshes of mangroves at low tide, and supratidal mudflats (Tanns in West Africa) occur landward of salt marshes or mangroves on arid or semiarid coasts.

Mudrock - A massive or blocky rock composed of indurated fine-grained sediment (silt and clay), also termed siltstone or claystone, differing from a shale in being nonfissile.

Multicausality - Where similar coastal landforms (e.g., coastal barriers, cuspate forelands, laterally graded beaches) may be produced in different ways (Schwartz, 1971).

Muricate weathering - the intricate pitting of coastal rock surfaces in the spray zone, especially on limestones, calcareous sandstones, and dune calcarenites, as a result of physical processes (wetting and drying), chemical processes (corrosion by sea spray, i.e., aerated sea water; growth of salt crystals), and biological processes (corrosion by algae and other organisms; scraping and browsing by shore fauna).

Mushroom rock - A table-like stack that has been marginally undercut by abrasion, solution, or bioerosion so that it is surrounded by a notch and visor, and stands above a narrower pedestal.

Natural arch - A tunnel extending through a headland, island or stack, beneath a connecting bridge, usually formed where a cave has been enlarged by abrasion or solution. Also known as a Sea Arch (*q.v.*).

Natural arch, La Manne Porte, Etretat, France.

Old Hat island, Taylor Island, Paihia, New Zealand.

Neap tide - A diminished tide range when the sun and the moon are at right angles in relation to the earth, so that their gravitational effects are not combined.

Nearshore - The shallow water zone between the low tide line and the line where waves begin to break; a zone that migrates to and fro as the tide rises and falls.

Nearshore water circulation - An association of processes that operates as wave move through the nearshore zone to break on the Shore or Beach, generating Swash and Backwash (*qq.v.*).

Neotectonic - Movements that have produced existing landforms (e.g., fault scarps) and associated structures, generally within Quaternary (*q.v.*) Times.

Notch (Nip) - A narrow hollow excavated along the base of a cliff near high tide level by abrasion, solution or bioerosion, often with an overhanging rock visor (protruding ledge of rock). See Abrasion Notch, Solution Notch.

Old Hat island - A stack or islet surrounded by a flat or gently sloping shore platform, formed where much of a soft or weathered rock formation has been removed by erosion above a harder horizontal intertidal rock layer, which persists as a structural bench. Originally described from North Island, New Zealand.

Open coast - A coast unprotected by islands, promontories or reefs, and so exposed to the full force of wave action.

Overwash (Washover) - The washing of sediment over the crest of a beach or coastal barrier by exceptionally strong wave swash to form a depositional fan on the landward side. See Washover Fan.

Paired spits - Spits on either side of a coastal inlet, river mouth or lagoon entrance, or protruding toward each other between two islands or between the mainland and an offshore island. They have developed either by convergent longshore drifting or the breaching of a former coastal barrier.

Pan - A shallow steep-sided and flat-floored natural depression on a shore platform or in a salt marsh (see Salt Pan). A soil pan is a crust or subsurface horizon of compacted or indurated sediment (see Humate).

Parabolic dune - A dune with an advancing convex nose of spilling sand and trailing (roughly parallel) arms of partly vegetated sand on either side of an elongated low corridor formed or maintained by deflation. Typically its axial length is more than three times its mean width.

Paired spits, Shoal Inlet, Victoria, Australia.

Parabolic dune near Lakes Entrance, Victoria, Australia.

Parallel dunes near Robe, South Australia.

Parallel dunes - A succession of foredunes developed on a prograding coast (usually surmounting Beach Ridges, *q.v.*).

Pebble - A rock particle with a diameter between 4 and 64 mm. See Granulometry.

Periglacial (Paraglacial) - Processes and environments found beyond the limits of glaciation, typified by freezing and thawing, and frequent accumulation and melting of snow.

Pier - An open structure on multiple supports, usually designed to permit ships to berth: beneath it waves, currents and drifting sediment pass almost unimpeded. The term Jetty (*q.v.*) is sometimes used as a synonym. Occasionally these terms are used to describe solid stone structures.

Pit, Pitting - superficial indentations (typically up to 5 mm in diameter), etched on a rock surface by Weathering or Abrasion (*qq.v.*). See Muricate Weathering.

Plunging cliff - A steep or vertical cliff that descends into deep water inshore without any intervening Shore Platform, Rocky Shore, or Beach (*qq.v.*).

Point - A small protrusion of the land into the sea, usually sharp, tapering and low-lying, but sometimes a high headland (Hartland Point, Devonshire).

Progradation - The building seaward of a coastline by deposition of sediment, as on a beach or a dune, or where a marsh or mangrove shoreline advances.

Promontory - A coastal protrusion or headland, high and bordered by cliffs or bluffs, usually smaller than a Cape (*q.v.*).

Quaternary - The geological period which began about 2.3 million years ago. It comprises the Pleistocene epoch (2.3 million years ago to 10,000 years ago) and the Holocene or Recent epoch (the last 10,000 years).

Raised beach - A beach that has been uplifted by tectonic movements to stand above the level at which it originally formed, on or behind the present shore. See Emerged Beach.

Plunging cliff near Milford Sound, South Island, New Zealand.

Recurved spit near Mackay, Queensland, Australia.

Rampart - A slight rise or wall-like ridge up to 2 m high toward the seaward edge of a shore platform or reef, or toward the crest of a cliff. Some ramparts are residual rock features that have escaped weathering and erosion; others are constructional, formed by the growth of organisms (see Algal Rim) or depositional, as on the coaming found on some cliff crests. They may consist of boulders, cobbles, pebbles or sand, generally angular and often cemented. See Coral Rampart.

Recurved spit - A spit that ends in a landward hook or recurve. (e.g., Sandy Hook, New Jersey).

Reef - A bank, ridge or mound with a rocky structure, either an eroded rock formation or built by organisms such as corals and algae, usually irregular in outline (but often flat-topped), and not moved by waves or current action.

Reflective beach - A beach where wave energy is partly reflected seaward as plunging breakers move in through relatively deep nearshore water.

Relict features - Features that developed under different environmental conditions (climate, vegetation, sea level) in the past, and have persisted in the present coastal landscape, having not yet been destroyed by modern processes.

Reliction - The exposure of land as a result of seafloor emergence during a slow or gradual withdrawal of the relative fall in sea level, as around the Caspian Sea between 1930 and 1977.

Ria - A long, narrow, often branching inlet formed by marine submergence of parts of a river valley that had previously been incised to a lower sea level: a drowned valley-mouth. Cotton (1956) separated ria *sensu lato*, thus defined, from ria *sensu stricto*, where the inlet runs parallel to geological outcrops that run at right angles to the coastline, as in the Rias of Galicia, northwest Spain, which Richthofen (1886) quoted in the original definition. Some of the Galician rias are wide and deep, and the valleys that have been drowned may have been shaped partly by tectonic subsidence or by the recession of bordering scarps.

Ridge and runnel - Several subdued bars and troughs running parallel or nearly parallel to the coastline and exposed at low tide on a sandy shore. Also known as low and ball.

Ria (Aber Benoît) on the Brittany coast, France.

Ridge and runnel on the shore at Saltburn, Yorkshire.

Rip channel - A channel cut by the seaward flow of a Rip Current (*q.v.*) across the nearshore zone, usually through nearshore bars.

Rip current - A strong narrow current (up to two knots) flowing seaward through breakers at right angles or an oblique angle to the coastline.

Ripple marks - Undulations (ridges generally less than 10 cm high, and troughs a few centimeters long between successive crests, often exposed at low tide on the foreshore), formed on a sandy foreshore and nearshore area by waves and/or currents. Some are parallel, others form intersecting, sometimes rhomboidal patterns. They may be symmetrical in cross-section, but are usually asymmetrical with steeper slopes in the direction of wave or current flow and elongated at right angles to this direction.

Rocky shore - An irregular, rugged rocky area between high and low tide where shore platforms have failed to develop, or have been intricately dissected.

Round hole - An enlarged blowhole on coastal slopes above cliffs that have been penetrated by caves, notably in southwest England.

Sabkha - See Sebkha.

Salt marsh - a flat or gently sloping vegetated wetland in the upper intertidal zone on sheltered parts of the coast (estuaries, inlets, lagoon shores). Often in the form of a depositional terrace, periodically submerged, with halophytic grasses, herbs, and shrubs; dissected by tidal creeks, and may contain enclosed Salt Pans (*q.v.*).

Salt pan - An enclosed bare depression within a salt marsh, apt to dry out, leaving an algal or saline crust. The term is also used for shallow artificial basins in which seawater is trapped and concentrated by evaporation to brine, which crystallizes into salt for harvesting.

Salt weathering - Disintegration or decomposition of a rock surface by stress caused by the growth of salt crystallizing from sea spray, resulting in the formation of pits, cavities, or shallow basins.

Sand - A sediment consisting of rock particles with a diameter between 0.125 and 2.0 mm. Subdivisions are very coarse sand (1–2 mm), coarse sand (1/2 or 0.5–1 mm), medium sand (1/4 or 0.25–1/2 or 0.5 mm), fine sand (1/8 or 0.125–1/4 or 0.25 mm) and very fine sand (1/16 or 0.0625–1/8 or 0.125 mm). See Granulometry.

Sandflat - A relatively level unvegetated sandy intertidal area.

Rip currents (arrowed) on Woolamai Beach, Phillip Island, Victoria, Australia.

Round Hole at The Lion's Den, Lizard Point, Cornwall, England.

Seagrass - A marine grass that grows in the intertidal and shallow subtidal zones.

Sea level - The level at which the sea stands against the coast, conventionally taken as mean sea level, the arithmetic mean of the calm sea surface (excluding waves and oscillations related to winds and atmospheric pressure variations) measured at hourly intervals over at least 18.6 years.

Sebkha (Sabkha) - A low-lying very gently sloping saline area above normal high tide level on an arid coast, subject to occasional flooding by the sea or rain water, and prolonged phases of evaporation and dessication, resulting in hypersaline conditions. Some sebkhas have the branching form of rias. Some carry Salt Marshes (*q.v.*).

Sediment budget - The relative proportions of inputs, outputs and storage in a coastal sediment system (e.g., a Beach, *q.v.*).

Segmentation - The division of an elongated lagoon or bay into a chain of smaller, oval, or circular lagoons by the growth and coalescence of cuspate spits and forelands and the erosion of intervening embayments, usually with narrow connecting channels (Price, 1947; Zenkovich, 1959).

Seiche - Alternating, diminishing fluctuations of water level after a rapid change in atmospheric pressure or where strong wind action has built up water level downwind and lowered it upwind in a landlocked bay, inlet, or coastal lagoon.

Shale - A fine-grained stratified or laminated sedimentary rock which breaks readily into thin layers. Contrast Mudrock (*q.v.*).

Sharm - A long narrow marine inlet on an arid coast, usually at the mouth of a wadi (a generally dry valley in a coastal upland).

Shingle - A British term for Beach Gravel (*q.v.*), a coarse, loose deposit which may range from granules through pebbles to cobbles and small boulders, generally well-rounded particles that vary in shape from roughly spherical through ovoid to flat or platy. Shingle beaches are sometimes termed coarse Clastic Beaches, Clastic (*q.v.*) meaning consisting of rock fragments.

Shore - The zone between the water's edge (Shoreline, *q.v.*) at high and low tide. Sometimes referred to as tidelands.

Sebkha on the coast of King Sound, Western Australia.

Shore drift - See Longshore drift, which is more accurate because shore drift could include movements landward or seaward across the intertidal zone.

Shoreline - The water's edge, moving to and fro as the tides rise and fall, so that there is a low tide shoreline, a mid-tide shoreline, and a high tide shoreline. The term has been used as a synonym for Coastline (*q.v.*), but it is useful to maintain a distinction between the two terms, taking Coastline as equivalent to the high tide shoreline. Where the tide range is large and the shore profile gently sloping there is much variation in the position of the various shorelines.

In the United States the term Shoreline (*q.v.*) is defined legally as mean high water (MHW), as shown on nautical charts produced by the National Oceanic and Atmospheric Administration (NOAA), while shorelines at other levels are called lines (e.g., the mean lower low water line) which is a private-property seaward boundary in some eastern states. It should be noted that the American shoreline, thus defined, is submerged at high spring tides, and is not the margin of normally dry land.

Shore platform - A flat or gently sloping smooth or relatively smooth rock surface formed in the zone between high and low tide levels. The term is preferred to wave-cut platform, except on some soft rock outcrops where the platform has been literally cut by wave action alone. Some shore platforms are sub-horizontal, and may be *high tide shore platforms*, submerged only at the highest tides, or *low tide shore platforms*, exposed only at low tide. Others are seaward sloping intertidal platforms, extending down to below low tide level. Some are structural (coinciding with the upper surface of a seaward sloping hard rock formation), others erosional (cut across outcropping structures).

The term Beach Platform (*q.v.*) is not acceptable as an alternative to Shore Platform (*q.v.*) because of the risk of confusion with depositional terraces (e.g., Beach Berm, *q.v.*).

Shore pothole - A circular or oval depression scoured in a rocky shore platform by abrasion where sand or pebbles are circulated by wave motion (Wentworth, 1944). Similar features may occur on a limestone coast where soil pipes formed beneath an ancient soil (palaeosol) are exhumed and excavated by wave scour.

Shore potholes formed by abrasion, Pearce's Beach, Rye, Victoria, Australia.

Significant wave height - The average height of the highest one-third of waves measured over a 20-min observation period. As the number of waves within 20 min varies (240 5-s waves, but only 80 15-s waves) it may be preferable to measure the highest 33 of a set of 99 successive waves.

Silt - A sediment consisting of particles with a diameter between 1/256 (about 0.004) and 1/16 (0.0625) mm.

Skerry - A low, rugged rocky reef or scatter of reefs, generally intertidal but sometimes extending above high tide level, off a hard rock coast, particularly in Scandinavia and Scotland. Usually there are many skerries; the Norwegian term skjergaard has been wrongly translated as "skerry-guard" when in fact it means the area of calm water in the lee of skerries.

Slope-over-wall profile - A steep coast on which an upper, sloping facet descends to a steeper, often vertical, basal cliff. Such profiles are found on steep coasts where the rock formations dip seaward, on soft formations where a subaerial slope is recurrently undercut by marine erosion, and where a weak formation (such as glacial drift) forms a slope above a cliff in more resistant rock. On hard rock coasts that were periglaciated in Pleistocene times, as in southwest England, the upper slope is mantled by frost-shattered solifluction talus deposits (termed head) and the basal rocky cliff has been exposed by later marine erosion. Some slope-over-wall coasts have beveled slopes of uniform seaward gradient (Beveled Cliffs, *q.v.*), but many are convex (hogsback coasts) and some concave. Also known as two-storied cliff.

Solution notch - An elongated cliff-base hollow cut out near high tide level by solution (sometimes also bioerosion), often with an overhanging rock visor (protruding ledge of rock).

Solution pan - A flat-floored basin developed on a limestone shore platform by solution, bordered by a microcliff or a constructional rim of algae.

Solution pipe - A cylindrical depression formed on a limestone surface by the dissolving of carbonates, often beneath soil and around a root system. There may be no surface depression, but soil has often subsided into a deepening hollow, the margins of which may become case-hardened by secondary precipitation of the leached carbonates. On Dune Calcarenite (*q.v.*) coasts solution pipes (with encircling calcrete) may be exposed by wind erosion (as structures sometimes confused with petrified forests) or as shore platforms are cut, and the soil washed out to leave a protruding vase-shaped structure.

Sound - A narrow marine channel or strait between an island and the mainland, or between two islands, or between two land areas. A Strait (*q.v.*).

Spit - A finger-like ridge or embankment of beach material built up above high tide level and diverging from the land at one end (proximal) to terminate (distal end) usually in one or more recurves or hooks curving landward. See Recurved Spit.

Spring tide - An augmented tide range when the sun and the moon are in alignment with the earth, so that their gravitational effects are combined.

Squeaking sand - Beach or dune sand that emits sounds (squeaks, squawks, shrieks, sings, barks, booms, roars, or whistles) when walked upon, as the result of the mutual impact of sand grains. Sometimes called musical sand.

Stack - An isolated upstanding steep-sided rock pillar, column or pinnacle rising from the shore, a shore platform, or the seafloor close to a cliffed coast.

Stillstand - A condition of stability when the relative levels of land and sea remain the same for a prolonged period (several centuries), either because there has been no change in land or sea level, or because these levels have risen or fallen the same amount.

Slope-over-wall profile (periglaciated slope), Dodman Point, Cornwall, England.

Solution notch on a limestone coast, Baron, Java, Indonesia.

Stack at Sentinel Rock, Port Campbell, Victoria, Australia.

Storm surge - A temporary abnormal rise of sea level on a coast, as when an exceptionally high tide (often with sea level raised by low atmospheric pressure) is accompanied by strong wave action generated by an onshore gale (cyclone, hurricane, typhoon).

Storm wave - A short, steep high wave (wave period generally <10 s) generated by strong winds.

Strait - A narrow passage of water between two land areas. A Sound (*q.v.*).

Strand - See Shore or Beach.

Strandflat - An extensive shallow submarine and low-lying emerged coastal platform (up to 65 km wide and typically with transverse gradients of up to 10° and many surmounting mounds and hillocks that were formerly stacks and islands), sharply contrasted with a high and rugged hinterland.

Strandline - See Shoreline.

Stromatolite - A low calcareous sedimentary domal structure, formed in shallow water where a mat or assemblage of blue-green algae have trapped sediment and precipitated calcium carbonate. See Algal Mat.

Structure, Structural features - The assemblage of rock formations (their arrangement, disposition, nature, and form) upon which erosional processes are, or have been, at work in shaping a landscape or coastline.

Subdelta lobe - Portion of a delta formed around the mouth of a distributary channel.

Submergence - A fall in the level of the land relative to the sea, achieved by actual subsidence of the land, a raising of sea level, or some combination of land and sea-level change that leaves the sea at a relatively higher level. A submerged coast (or feature) is one that stands at a lower level relative to the sea than when it originally formed; a submerging coast is one actually subsiding relative to sea level.

Swale - An elongated hollow or low-lying area between dune ridges, usually running parallel to the coastline.

Swamp encroachment - The advance of sediment-trapping swamp vegetation (reedswamp, salt marsh, mangroves) into shallow nearshore water, notably in sheltered bays, inlets and coastal lagoons, resulting in progradation of the land.

Swash - The rapid flow (uprush) of a breaking wave up the beach face.

Swash bar - A nearshore bar built parallel to the shore by wave swash, with a steeper landward slope advancing into a shallow lagoon.

Swash (Swash-backwash) cusps - See Beach Cusps.

Swash-dominated beach - A beach shaped primarily by the action of swash generated by breaking waves that arrive parallel to the shoreline, so that the beach has an alignment at right angles to the dominant direction of wave approach. Contrast with Drift-Aligned Beach (*q.v.*).

Swashway - A low sector of a barrier through which storm waves or surges flow. Sand or gravel swept through a swashway is deposited as a Washover Fan (*q.v.*) on the inner shore of the barrier.

Swatchway - A channel cut and maintained across a bar or shoal by wave and current scour. A term used in a novel by Erskine Childers (1903).

Swash zone - The zone regularly covered and uncovered as breaking waves generate swash and backwash.

Sweep zone - The zone (vertical plane) between high (often summer) and low (often winter) beach profiles, surveyed at right angles to the coastline, and indicating the extent of loss and gain resulting from cut and fill sequences.

Swell - Long, low waves (wave period typically 12–16 s) generated by distant storms and transmitted across oceans and seas.

Tafoni - Large cavities excavated in a rocky cliff by weathering, notably where the rock surface has been indurated and the underlying material is softer.

Tectonic - Crustal movements that produce geological structures, notably folding and faulting.

Terrigenous sediment - Sediment derived from the land surface and delivered to the coast by runoff, landslides, rivers, glaciers, or wind action, in contrast with marine sediment supplied to the coast from the seafloor.

Threshold - A shallow area near the seaward end of a drowned valley. In fiords it is often a rocky sill (sometimes partly depositional), but in estuaries and inlets on high wave energy coasts it is commonly a bank of inwashed sand, prograding landward.

Tidal bore - A large turbulent wave that develops a steep advancing water slope (up to 5 m high) that moves rapidly (5–8 m/s) into a long

Swamp encroachment (reedswamp) on the shore of Lake Wellington, Victoria, Australia.

Tafoni on granite coast, Victor Harbour, South Australia.

shallow funnel-shaped inlet or estuary during a rising spring tide on a macrotidal or megatidal coast. Known as the mascaret on the Gironde estuary; eagre on the Trent and Humber; pororocas on the Amazon.

Tidal current - A current generated by the rise or fall of the tide.

Tidal delta - An intertidal or subtidal bar or shoal, typically triangular or lobate, formed on the inner (flood delta) and often also the outer (ebb delta) sides of a tidal inlet or gap between barrier islands. Usually of sand, sometimes gravel, with diverging channel systems.

Tidal divide - An intertidal isthmus that emerges between an island and the mainland, or between neighboring islands, as the tide falls. There are usually tidal creeks heading away on either side and converging downstream. Sometimes called a tidal watershed, but this is inappropriate as the term watershed can also indicate a catchment area.

Tidal environment - A Macrotidal (*q.v.*) environment where mean spring tide range is between 4 and 6 m; a Mesotidal (*q.v.*) environment where mean spring tide range is between 2 and 4 m, and a Microtidal (*q.v.*) environment where mean spring tide range is less than 2 m. The term Megatidal (*q.v.*) is used where mean spring tide range is more than 6 m.

Tidal flat - A depositional feature, usually with a very gentle intertidal slope, consisting of sand (Sandflat, *q.v.*) or finer sediment (Mudflats, *q.v.*).

Tidal prism - The volume of seawater that flows in and out of an estuary or lagoon as the result of the rise and fall of the tide; a process known as tidal ventilation. It is computed as the difference between high and low tide volume, or as mean tide range times the mid-tide area of the basin.

Tide-dominated morphology - Landforms such as intertidal Mudflats (*q.v.*), salt marsh, and mangrove swamp, shaped primarily by tides and tidal currents, rather than by wave action. Most intertidal mudflats and sandflats, and most salt marshes and mangrove swamps, have to some extent been shaped by occasional wave action (notably producing shoreward drifting of sediment). It is suggested that tide-dominated shore morphology occurs where significant wave height is less than 20 cm at high tide.

Tide range - Mean tide range is the difference between mean high and mean low tides; neap tide range the difference between mean high neap and mean low neap tides; spring tide range the difference between mean high spring and mean low spring tides.

Tombolo - A Ridge or Barrier (*qq.v.*) of sand (occasionally Shingle, *q.v.*) built above high tide level in such a way as to link a former island to the mainland, or unite two islands. Sometimes this Italian term (which actually means the sand dune on top of the barrier) is taken to include the island as well as the depositional linking feature. Where the connecting deposit is submerged at high tide the terms tie-bar or tombolino are used. The term usually indicates a constructional feature, but similar forms can develop as a result of erosion of weak or unconsolidated material in the lee of a Headland or Breakwater (*qq.v.*).

Trailing spit - A spit that runs out from the lee shore of a headland or island. Also termed arrow spit or comet tail.

Transgressive barrier - A barrier that is migrating landward as a result of overwash and the movement of dune sand by onshore winds, encroaching on the lagoon or swamp that lies behind it.

Transgressive dune - A dune migrating away from the prevailing wind, some of which may assume barchan form, with lateral arms pushed leeward, as in desert dunes.

Trottoir - A constructional bench formed by the growth of algae at about mid-tide level on cliffed coasts (notably limestones), particularly in the Mediterranean. In some places the algae have colonized a preexisting rock ledge. Trottoirs have also been described from the Mariana Islands in the western Pacific. The mearls of Brittany are similar features, built by *Lithophyllum*.

Tsunami - Long seismic sea waves, generated by a major disturbance within an ocean basin (mainly due to earthquakes, but sometimes explosive volcanic eruptions or submarine landslides). They are of subdued form in deep water, but on entering shallow nearshore areas their height increases greatly, and can exceed 30 m when they break over the coastline.

Undertow - Laminar basal flow of water seaward beneath incoming waves; a continuation of Backwash (*q.v.*) from the shore into the nearshore and offshore areas. However, seaward flow of water generally takes the form of segregated Rip currents (*q.v.*) rather than laminar basal flow.

Washover fan (Overwash fan) - A fan of beach material washed over low sectors of a coastal barrier by Storm waves (Storm surges) (*qq.v.*) to form a delta-like projection into a lagoon or on to backing marshland. See Overwash. In Texas the term washaround has been used for features produced by overwash on either side of a residual island or mound.

Wave diffraction - Increased curvature in the pattern of waves moving through a natural or artificial entrance to a bay or lagoon because of frictional retardation by bordering Headlands or Breakwaters (*qq.v.*).

Wave energy environments - High wave energy coasts are those exposed to strong ocean swell and large storms waves, with significant wave (Breaker, *q.v.*) heights of more than 1 m. Moderate wave energy coasts are where significant wave height is 0.3–1 m, and low wave energy coasts (where wave energy is limited by headlands, islands or reefs, or where there is extensive shallow water offshore), have significant wave heights of less than 0.3 m. The term zero wave energy is applied where wave action is completely absent.

Wave quarrying - Excavation or displacement of rock masses by wave impact.

Tombolo at Broulee Island, New South Wales, Australia.

Trailing spit, Halifax Island, Queensland, Australia.

Wave quarrying has disintegrated the shore platform at Tessellated Pavement, Tasmania.

Wave refraction from seawall, Black Rock, Victoria, Australia.

Wave reflection - Where waves breaking against a rock formation, steep beach or artificial structure return seaward.

Wave refraction - Changes in the pattern of waves moving toward a coast because of frictional retardation by the shallowing seafloor and bordering headlands; waves in deep water have parallel crests, but as they move into a gulf or bay these become curved, and may anticipate and fit the outline of a beach or a cliffed coastline cut in soft rock formations.

Wave sluicing - the washing away by waves of material disintegrated from the surface of a shore platform by Weathering (*q.v.*) or erosion.

Waves - Undulations produced on the sea surface by disturbance, generally the frictional drag of wind action, but see Giant Waves (*q.v.*). Wave height is the vertical distance between adjacent crests and troughs, wave length the horizontal distance between successive wave crests, wave period the time taken by successive crests to pass a fixed point, wave steepness the ratio of wave height to wave length, and wave velocity the speed at which a wave crest moves forward. Wave energy is taken as length multiplied by the square root of the height.

Weathering - The *in situ* disintegration or decomposition of rock surfaces exposed to the atmosphere and the upper part of an outcropping rock formation as the result of physical, chemical, and biological processes. It is usually indicated by changes in color, texture, composition, coherence, or firmness. Excludes erosion and induration. Residual rocks more resistant to erosion may produce strange forms (columns, pinnacles, pillow or cannon-ball structures, pillars and pedestals, sometimes termed hoodoo rocks).

Wetland - a general term describing swamps, bogs, marshes, and shallow (up to 5 m) lagoons and lakes. In coastal environments these include salt marshes, mangrove swamps, reedswamp, rush swamp, and seagrass beds.

Wind resultant - an expression of the long-term effect of winds of varying strength, duration, and direction, usually developed as a vector diagram from which a directional resultant may be determined.

Zetaform beach - an asymmetrical beach between headlands, where the outline is shaped by waves arriving obliquely, and refracted round

Wave refraction in Seven Mile Bay, Tasmania.

the headlands. Also known as a Log-spiral (*q.v.*) or half-heart beach, and sometimes as a Headland (*q.v.*) bay beach (but this term does not indicate that the beach outline is asymmetrical).
