Encyclopedia of Earth Sciences Series

ENCYCLOPEDIA OF COASTAL SCIENCE

Volume Editor

Maurice Schwartz is Professor Emeritus, Department of Geology at Western Washington University, Bellingham, Washington, United States; where he served near the end of his tenure as Dean of the Graduate School and Bureau for Faculty Research. As well as being an author of numerous articles which have appeared in the coastal geology literature he was the editor of *Spits and Bars* (Dowden, Hutchinson & Ross, 1972), *Barrier Islands* (Dowden, Hutchinson & Ross, 1973), *Encyclopedia of Beaches and Coastal Environments* (Hutchinson Ross, 1982), and co-edited with Eric Bird *The World's Coastline* (Van Nostrand Reinhold, 1985).

Advisory Board

Aim of the Series

The Encyclopedia of Earth Sciences Series provides comprehensive and authoritative coverage of all the main areas in the Earth Sciences. Each volume comprises a focused and carefully chosen collection of contributions from leading names in the subject, with copious illustrations and reference lists.

These books represent one of the world's leading resources for the Earth Sciences community. Previous volumes are being updated and new works published so that the volumes will continue to be essential reading for all professional earth scientists, geologists, geophysicists, climatologists, and oceanographers as well as for teachers and students.

See the back of this volume for a current list of titles in the Encyclopedia of Earth Sciences Series. Go to www.eseo.com to visit the "Earth Sciences Encyclopedia Online"—the online version of this Encyclopedia Series.

About the Editors

Professor Rhodes W. Fairbridge has edited more than 30 Encyclopedias in the Earth Sciences Series. During his career he has worked as a petroleum geologist in the Middle East, been a WW II intelligence officer in the SW Pacific and led expeditions to the Sahara, Arctic Canada, Arctic Scandinavia, Brazil and New Guinea. He is currently Emeritus Professor of Geology at Columbia University and is affiliated with the Goddard Institute for Space Studies.

Professor Michael Rampino has published more than 100 papers in professional journals including *Science*, *Nature*, and *Scientific American*. He has worked in such diverse fields as volcanology, planetary science, sedimentology, and climate studies, and has done field work on six continents. He is currently Associate Professor of Earth and Environmental Sciences at New York University and a consultant at NASA's Goddard Institute for Space Studies.

Airborne Laser Terrain Mapping and Light Detection and Ranging

Foreword

As millions of people move toward the coastline, the rise in sea level is moving the coastline toward them. Anxious for a good view of the sea, property owners crowd the retreating beaches and governments seek the advice of coastal scientists and engineers to find a way to control the erosion problem. As a consequence, the study of sea level change, the greenhouse effect, the coastal processes and ways to respond to retreating coastlines have become paramount priorities. Coastal science has benefited tremendously.

For example, the search for sand used for beach nourishment, currently a favored erosion control approach, is pouring millions of dollars into the hands of those who operate vibracores, side-scan sonar, and shallow seismic devices. The applied science that is carried out to find sand is almost exactly the same as the preferred basic science approach to determine the recent history of shorefaces, coasts, and islands, and to discern the processes that have shaped them. This combined need-to-know and funding bonanza are in significant part responsible for a leap in our comprehension of nearshore processes in the last two decades. So, Maurice Schwartz's enormous effort in bringing us this new *Encyclopedia of Coastal Science* is most timely.

Specialty encyclopedias, especially one concerned with a fast moving science, such as this, provide a contemplative ledge, a place to pause and consolidate recent accomplishments. Inclusion of almost all of the seasoned practitioners of coastal earth science as contributors adds significantly to this volume's usefulness and credibility as well as its potential as a point of consolidation for our science.

This volume is replete with essays on a great number of topics that incorporate the most recent illations, judgments, and discoveries in coastal studies. What are these great advances, especially those that have occurred in coastal science in the 20 years since the Schwartz-edited *Encyclopedia of Beaches and Coastal Environments* hit the book stores? This question, a perennial favorite in Ph.D. exams, will be answered differently according to one's subspecialty. My first choice is the push forward in understanding the shoreface processes, the all-important link between the subaerial beach and the continental shelf. The topic is covered in at least half a dozen articles in the encyclopedia including those by Ed Clifton, Miles Hayes, Robert Dean, Alan Niedoroda, and Victor Goldsmith. There are also articles on the major technological advances that have fueled the advance of coastal science, including photogrammetry, side-scan sonar, synthetic aperture radar systems, and LIDAR among others (R. Thieler, Doug Inman, Keith Raney, and Stephen Leatherman).

A global perspective is furnished in separate articles about the coastal geomorphology of each continent, including the Antarctic, with companion articles on the ecology of the same coasts. A different approach to the big picture is provided through articles on coastline types such as tide- and wave-dominated (Miles Hayes), ice-bordered (Jess Walker), bay beaches (Karl Nordstrom), vegetated coasts (Denise Reed), muddy coasts (Terry Healy), chalk coasts (Vincent May), karst coasts (Roland Paskoff) and uplift coasts (Terry Healy). This small sampling of authors is indicative of the care that editor Schwartz has taken to fill the contributor slots with the "right" people with appropriate specialties.

Maurice Schwartz presents us with his second coastal encyclopedia. The first one, *The Encyclopedia of Beaches and Coastal Environments* (Hutchinson Ross, 1982) became the reference bible for coastal geologists and geomorphologists. At least it was for me. Not surprisingly, in this fast moving specialty, it is now out of date. I believe this new encyclopedia will prove to be equally important, but to a broader spectrum of coastal specialists.

The *Encyclopedia of Coastal Science* follows true to the title and cuts a broad swath. Titles are more sweeping. Individual entries are mostly topical essays rather than the dictionary-like definitions of the earlier encyclopedia. For example, instead of individual short definitions and descriptions of bulkheads, groins, jetties, seawalls, offshore breakwaters and the like, Nick Kraus has contributed two entries: Shore Protection Structures and Navigation Structures. The range of article topics is huge. Some of the outliers include coastal warfare, cleaning beaches, sand rights, oil spills, setbacks, polders, and tourism.

I believe the *Encyclopedia of Coastal Science* will prove to be a priceless resource for both educators and researchers in the coastal sciences as well as for those who use science in managing our nearshore resources. I would even like to see it on the bookshelves of beach cottages, although the volume is not intended for a lay audience. This resource is perfect for those who need succinct and authoritative information on most aspects of coastal science.

Orrin H. Pilkey
Duke University

Preface

Map measurements of the world's coastline length have yielded a figure of 500,000 km. However, when all of the very real and intricate coastal crenulations are considered, the actual length is probably closer to 1,000,000 km. Added to this is the fact that 40% of the 6,000,000,000 people presently inhabiting the earth live within 100 km of a coastline. From these observations, it can be seen that coasts are a very major geomorphic and social feature on the face of the planet. And for this reason, scholars in a multitude of disciplines have long been studying the many facets of the zone where the land meets the sea.

In this collected volume, authorities in many fields expound on certain aspects of their expertise, not so much in a dictionary of terms sense as in a series of essays that may be broken down into such categories as: atmosphere and oceanography, ecology, engineering and technology, geomorphology, and human activities related to the coasts (see Appendix 6: Topic Categories). The reader may not completely agree with some of their views; in fact, some of the authors do not agree entirely with each other. Perusing through professional journals in these fields would show the same variety of opinions on a given topic. For that is the nature of science, holding forth on a subject as interpreted by long and careful study of the evidence. What is then to be found here, between the covers of this volume, are 306 entries that contain a wealth of information on different aspects of the world's coast, which we all hold so dear. If there are any questions of omissions or judgment, the fault then lies entirely with me, the editor.

In a similar vein, one would expect the terminology of a science to have universal acceptance; but, sadly, that is not the case. For example, the ubiquitous term "shoreline" can be employed in the historical geomorphic sense of the line formed by the edge of the water against the land as it rises and falls through tidal cycles or atmospheric changes; or as it has been defined by the US Coast and Geodetic Survey for mapping purposes as the high-tide line, high-water line, or wet–dry boundary. In order for the term to mean the same thing wherever it appears in this volume the geomorphic meaning has been adopted, or clarified where it has deviated from that. For further clarification of this dichotomy, the reader is referred to the entry titled Coasts, Coastlines, Shores, and Shorelines.

Though there have been many trials and tribulations during the four to five years that it has taken to bring this volume to publication, there have also been moments of humor that lightened the load along the way. While explanations for late contributions ran rampant, none was more acceptable than that from the contributor down-under who, while working on a major topic, brought forth two "bubs" (a girl and a boy) to add to an already large family. For sheer inventiveness to a contributor who did not want to repeat a previously published survey, that progressed around a continent in a clockwise fashion, there was your editor's suggestion that he simply proceed in a counter-clockwise direction. In the end it came out only halfway there. Then too, probably the best single line in any entry contained here is the quote to the effect that a certain coastal feature is "… rather like pornography—difficult to define, but you know it when you see it!" That could only be topped by correspondence from another down-under contributor who used wildly colorful expressions that can not even be repeated here.

Of course, I am most appreciative to all of the very many people who have been involved in this project. However, two individuals stand out most significantly. The first and foremost is the editor-in-chief of this earth-science encyclopedia series, Rhodes Fairbridge, who has been my teacher, mentor, and friend for the past 40 years. The second is Peter Binfield, my editor at Kluwer Academic Publishers, who has guided me through this project with expertise, patience, and humor. To both of these gentlemen, I offer my most profound gratitude. Thanks are also due to Russ Burmester, Vicki Critchlow, Gene Hoerauf, Larry Palmer, Kevin Short, and Chris Sutton, at Western Washington University, for considerable technical support.

Sadly, media specialist Kevin Short, who worked his computer magic on many graphics in the volume including the cover photo, passed away suddenly in January of 2004 at the age of 44. Colleagues and friends alike will miss Kevin and remember him for his kindness, humor, and creativity.

Maurice Schwartz

A

ACCRETION AND EROSION WAVES ON BEACHES

An accretion/erosion wave is a local irregularity in beach form that moves along the shore in the direction of net littoral drift. The initial irregularity may be caused by a wide variety of events such as the bulge from an ephemeral stream delta, the material from the collapse of a sea cliff, erosion or accretion associated with convergence and divergence of wave energy over an offshore bar, erosion downdrift of a structure such as a groin, sudden loss of sand by slumping at the head of a submarine canyon, or rapid accretion due to beach nourishment as when dredge spoil is placed on a beach. Given the wide variety of causes leading to local beach irregularities, accretion/erosion waves are common transport modes along beaches.

The wave-like form of an accretion/erosion wave is related to the change in sediment transport rate along the beach (divergence of the drift). Specifically, an irregularity in beach topography along an otherwise straight beach produces wave refraction and diffraction that locally modifies the littoral drift system. Wave convergence at an accretionary bulge reduces the littoral drift passing the bulge, causing downcoast erosion. Consequently, the accretionary bulge moves downdrift with an erosional depression preceding it. An initial erosional depression in beach form, as in the lee of a groin, moves downdrift as a traveling sand deficit because the transport potential of the downdrift side of the depression is always greater.

Accretion and erosion waves are best observed from the air or by comparison of beach profiles with time and distance along the beach. The associated change may be several hundred meters in beach width, but more typically is about 10–20 m over a distance of about 1–2 km and may be masked locally by cusps and other small-scale beach features.

Background

The concept of an accretion/erosion wave was developed to account for the downdrift movement of a sand delta deposited across the beach by an ephemeral stream (Inman and Bagnold, 1963). It was observed that the downdrift movement occurred as an accretionary bulge preceded by an erosional depression (Figure A1). The net littoral drift perturbs deltaic accretion through a series of spit extensions (t_2). Over time, the cumulative spit extensions will progressively displace the accretionary bulge in the downdrift direction, while local wave refraction and refraction-induced divergence of the littoral drift cause erosion downdrift of the bulge (t_3). The areas of accretion and erosion migrate downdrift together in a phase-locked arrangement referred to as an accretion/erosion wave. The movement of the accretion/erosion form was quantified by surveys of the flood delta of the San Lorenzo River in central California (Hicks and Inman, 1987), and further evaluated from the sudden release of sand at the San Onofre power plant in southern California (Inman, 1987).

The propagation rate of the accretion/erosion wave form is slow initially because the on–offshore dimensions and volume of sand to be moved are at a maximum, and a significant fraction of that volume remains outside the region of rapid transport by waves (Figure A1; t_1). Once the material enters the surf zone, the longshore transport rates are much higher and the entire accretion/erosion form moves faster, spreads out along the beach, and decreases in cross-shore amplitude. Measurements near the sand release at San Onofre, CA, showed that the form of the accretional wave initially traveled with a speed of about 0.6–1.1 km/yr in the 1.8 km near the release point (nearfield) and much faster farther from the release (farfield). The delta from the Santa Cruz River floods of 1982/83 was large (800,000 m^3) and extended offshore to depths of over 10 m, and that material moved about 0.5–1.5 km/yr during the first year (Hicks and Inman, 1987). Subsequently, the downdrift erosion and accretion waves from the delta moved with speeds of 2.2–2.8 km/yr (Table A1).

It has been observed that any structure that interrupts the littoral drift of sand along a beach results in an erosional chain reaction traveling downdrift from the structure (Inman and Brush, 1973). The propagation rates of the downdrift erosion wave was evaluated from beach

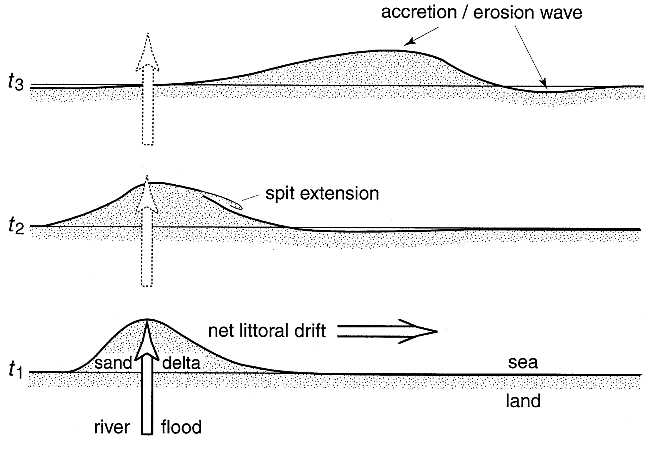

Figure A1 Formation of accretion/erosion wave downdrift from an episodically formed sand delta at time t_1, where $t < t_2 \ll t_3$ (modified from Inman and Bagnold, 1963).

Table A1 Propagation speeds of accretion/erosion waves

Location	Type/cause	References	Net downdrift transport rate 10^3 m^3 yr^{-1}	Speed of accretion/erosion wave (km yr^{-1}) Nearfield[a]	Farfield
Santa Cruz, CA	Accretion from San Lorenzo River Delta	Hicks and Inman (1987)	268	0.5–1.5	
Santa Cruz, CA	Erosion and bypass accretion from Santa Cruz Harbor	Hicks and Inman (1987)	268		2.2–2.8
Santa Barbara, CA	Erosion from harbor and bypass accretion	Inman (1987)	214		2.5–2.8
San Onofre, CA	Accretion from sand release	Inman (1987)	200	0.6–1.1	
Oceanside, CA	Erosion from harbor	Inman and Jenkins (1985)	200		2.2–4.0
Assateague Island, MD	Erosion from jetties at Ocean City Inlet	Leatherman *et al.* (1987)	153	~0.3	
Outer Banks, NC	Migration of Oregon Inlet	Inman and Dolan (1989)	590	0.023	
Nile Delta, Egypt	Accretion wave from onshore migration of sand blanket	Inman *et al.* (1992)	1,000		0.5–1.0

[a] Nearfield is within 1–2 lengths of the perturbing feature such as a sand delta.

surveys following the construction of the harbor jetties at Santa Barbara, CA (Inman, 1987), and the enlargement of the harbor at Oceanside, CA (Inman and Jenkins, 1985). Once in the farfield of the structure, the erosion wave, followed by the accretion wave moved downdrift at 2.5–2.8 km/yr at Santa Barbara and 2.2–4.0 km/yr at Oceanside (Table A1).

Accretion/erosion waves also occur along beaches and barriers downdrift of tidal inlets (e.g., Inman and Dolan, 1989). The erosion wave from the jetties at Ocean City, MD, is a well-known example. The inlet between Fenwick and Assateague barrier islands was stabilized by jetties in 1935. The jetties trapped the littoral drift and caused an erosion wave to travel downdrift along Assateague Island, resulting in a landward recession of the entire barrier island of 460 m in 20 years (Shepard and Wanless, 1971).

The Nile Delta experiences accretion/erosion waves driven by the currents of the east Mediterranean gyre that sweep across the shallow shelf with speeds up to 1 m/s. Divergence of the current downdrift of the Rosetta and Burullus promontories entrains blankets of sand that episodically impinge on the beach. These sand blankets cause shoreline irregularities with average amplitudes of 100 m and wavelengths of about 8 km that travel along the shore at rates of 0.5–1 km/yr as accretion/erosion waves (Inman *et al.*, 1992) (see entry on *Littoral Cells*).

A related example of a traveling accretion/erosion feature occurs when the littoral drift impinges on an inlet causing it to migrate downdrift (Figure A2). The migration proceeds as an accretion of the updrift bank in response to positive fluxes of sediment delivered by the net littoral drift Q_ℓ, while the downdrift bank of the inlet erodes due to a negative divergence of drift across the inlet, $\partial Q_\ell/\partial \ell < 0$. The negative divergence of the drift across the inlet is caused by wave refraction over the ebb-tide bar and by a loss of a portion of the drift to flood-tide entrainment at the inlet, ΔQ_t. Also the offshore tidal bar, maintained by the ebb-tide flow, moves downdrift with the inlet migration. Although the migration rates of the up- and downdrift banks of the inlet and the tidal bar are phase-locked, they are out of phase with the local net sediment changes in the shorezone bordering the inlet. The inlet banks and channel form an accretion/erosion sequence that travels along the beach and surf zone while the ebb-tide bar forms an accretion wave that moves along the shore in deeper water. Their relative on/offshore positions depend on the inlet tidal velocities that are functions of the size of the inlet and the volume of tidal flow through it (Inman and Dolan, 1989; Jenkins and Inman, 1999).

Accretion/erosion waves associated with river deltas and migrating inlets are common site-specific cases that induce net changes in the littoral budget of sediment. However, it appears that accretion/erosion waves in some form are common along all beaches subject to longshore transport of sediment. This is because coastline curvature and bathymetric variability (e.g., shelf geometry and offshore bars) introduce local variability in the longshore transport rate.

Mechanics of migration

An accretion/erosion wave is a wave- and current-generated movement of the shoreline in response to changing sources and sinks in the local balance of sediment flux along a beach. The downdrift propagation of the wave form is driven by advective and diffusive fluxes of sedimenb mass (Figure A3(a)). For convenience, these processes are usually expressed in terms of the longshore flux of sediment volume Q_ℓ into and out of a control cell (Q_{in}, Q_{out}; Figure A3(b)). By convention, fluxes of sediment into the cell are positive and fluxes out are negative. The net change of the volume fluxes between the updrift and downdrift boundaries of the control cell ($Q_{in} - Q_{out}$ = divergence of drift) will result in a net rate of change in the position of the shoreline $\partial x/\partial t$. Shifts in shoreline position will in turn cause the beach profile within the control cell to adjust to new equilibrium positions (Figure A3(b)). The new profile positions alter local wave refraction causing adjustments in the flux of sediment leaving the control cell (Q_{out}). The variation in Q_{out} will alternately accrete and erode the beach downdrift of the control cell. As a consequence, propagation of the accretion/erosion wave involves

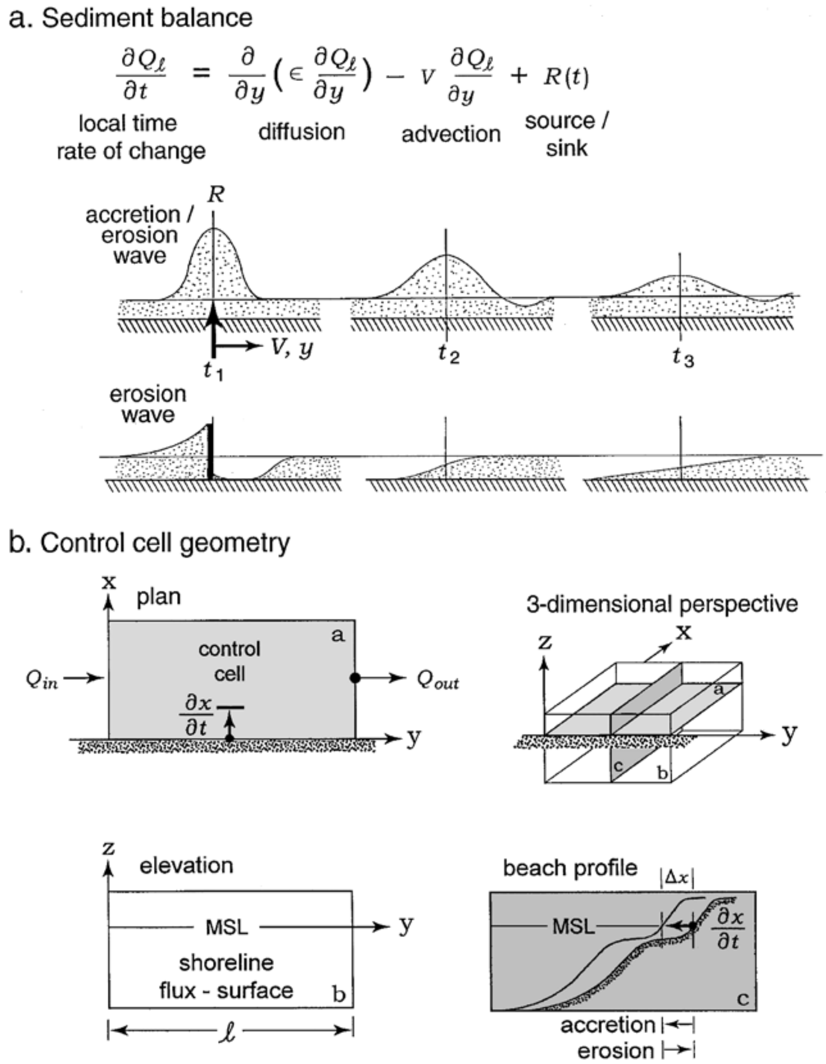

Figure A3 The balance of sediment for a propagating accretion/erosion wave (modified from Inman and Dolan, 1989).

a chain reaction in the local sediment flux balances. The reaction is set off by a disturbance on the updrift side of the control cell that yields a shoreline response on the downdrift side.

At a tidal inlet, these dynamics are impacted by additional fluxes of sediment into or out of a control cell centered at the inlet. When the tidal transport of sediment is ebb-dominated ($\Delta Q_t > 0$), the sediment flux into the control cell builds the ebb-tide bar and increases the rate of sediment that passes over the bar to the downdrift side of the inlet (Figure A2). This stabilizes the inlet position by decreasing deposition on the updrift side and erosion on the downdrift side. Flood-dominated tidal transport ($\Delta Q_t < 0$) has the opposite effect and will cause the inlet to migrate faster (Jenkins and Inman, 1999).

AFRICA, COASTAL ECOLOGY

Introduction

The continent of Africa straddles the equator and extends to about 35° latitude both north and south. It is, therefore, dominated by warm water regions and its coastline includes environments such as coral reefs and mangroves, except at the northwest and southwestern extremes, where temperate environments occur. The African coastline, excluding Madagascar (4,000 km), totals 35,000 km. A review of the literature dealing with sandy beaches in Africa (Bally, 1986) found the earliest paper to have been published in the 1880s and, of more than 1,000 papers published over 100 years, 19% concerned north Africa, 16% west Africa, 15% east Africa and Madagascar, and 55% southern Africa, particularly South Africa. Early papers were primarily taxonomic but later publications were mainly ecological. English was the language of 59% of the papers, followed by French (29%), German (7%), and Italian (3%). This sketch for literature on sandy beaches is probably representative of all papers dealing with coastal ecology in Africa. If so, it can be concluded that coverage of coastal ecology in Africa is patchy and, whereas the coastal ecology of South Africa has been extensively researched, most other regions are less well known.

The physical environment

Precipitation along the African coast is mostly low, with the exception of Madagascar, central east Africa, and west Africa, where rainfall is high (Figure A4). It is in central to northwest Africa that the largest rivers enter the sea, whereas greatest evaporation occurs in northwest Africa and in the Red Sea. Lowest salinity in coastal waters is therefore in the Gulf of Guinea and highest values are in the Red Sea. The coasts of Africa experience semi-diurnal tides, with the exception of the east coast of Madagascar, the horn and the Mediterranean coast of Egypt, where tides are mixed. Spring tide range mostly approximates 2 m, except in the Mozambique Channel where it is larger and can exceed 4 m, and along the Red Sea and Mediterranean coasts where tides are small (Davies, 1972). The entire east coast experiences temperatures permanently above 20°C, as does the central west coast. Upwelling in the southwest and northwest lowers temperatures regionally. Major currents are the Somali and Mozambique/Agulhas in the east and the Benguella, Guinea, and Canary currents in the west. Wind and wave energy is greatest in the south and lowest in the equatorial regions, the Mediterranean and the Red Sea.

Regional descriptions

West Africa

The northwest coast, from Morocco to Senegal, is sandy and relatively unindented, but from Dakar southeast to Monrovia it becomes very indented and there are numerous offshore islands. Moving further south, the coast becomes low lying and sandy and more deltaic in nature, with large lagoons further east. The eastern area is dominated by the delta of the Niger River. Further south, the Congo River has a major influence and freshwater can extend far offshore. High precipitation and numerous rivers in central west Africa result in warm, low salinity water, known as Guinean waters, circulating in the Gulf of Guinea.

The most notable feature of this coast is the extent of mangrove forests, estimated at 28,000 km^2 or 15% of the world's mangroves. Coastal lagoons range from tidal swamps and seasonal marshlands, associated with the river deltas and estuaries, to extensive coastal lagoons, which are typical of the Guinea coast. Sea grass beds are not well developed and there are no true coral reefs due to the cool waters of the Benguela and the Canary currents. Sandy beaches occur throughout the coast, particularly along the coast of Mauritania and northern Senegal. There are permanent areas of upwelling off Senegal, Zaire, and Namibia, coupled to the Canary and Benguela currents.

The marine resources of the west African region are important in the local and regional economies. Although seaweeds are not diverse, invertebrates (lobsters and shrimps) are exploited and there is a rich icthyofauna with about 250 species and high levels of endemism. Five species of marine turtles nest along the coast and on the islands and there are three species of crocodiles. Millions of migratory birds, especially waders, visit the coast seasonally. The northwest African manatee occurs in suitable habitats from Senegal to Angola.

The coastal human population in west Africa exceeds 50 million and the rate of industrialization and urban population growth is accelerating along the coastal zone. Oil production has increased markedly in Nigeria, Angola, and Gabon. Tourism is an important earner of foreign exchange in the economies of several countries including Gambia and Guinea Bissau. Increased fishing effort and the introduction of more efficient technologies has led to over exploitation of fisheries resources.

East Africa

Oceanic current patterns and monsoon seasons have a major influence on the biogeography and biodiversity of east Africa. The main oceanic currents are the Somali, Madagascar, and Mozambique/ Agulhas currents. The continental shelf is mostly narrow, varying from a few kilometers off Pemba to nearly 145 km in the Bight of Sofala, Mozambique. The shelves and banks are areas of intensive biological activity and productivity; in general, the narrower the shelf, the less productive the sea area. The western Indian Ocean is fairly poor in fisheries compared with other regions. The mainland coast is relatively unindented due to the absence of large rivers and coastal waters are moved by coast parallel currents. Much of the Mozambican coastline consists of low coastal plains forming long stretches of sand beaches and dunes interspersed with muddy rivers. North of the Zambezi estuary, many small coral islands fringe the shore. To the south, the islands of the Bazaruto group and Inhaca are mainly sand.

The total area of mangrove coverage in east Africa is about 10,000 km^2 or 5% of the world mangrove. Diversity of mangrove communities in east Africa is higher than in the west, with 10 species compared with only 7. Sea grass beds are found in all countries where there are low energy environments. The east African coast features fringing and patch reefs along the coastline from Somalia to Mozambique. Sandy beaches are well developed throughout. Small-scale local upwelling occurs seasonally, particularly in the waters off Somalia.

The coast of east Africa supports an enormous diversity of life. More than 350 marine algal species and more than 135 species of coral are known and there are more than 900 fish species, mostly associated with coral reefs. The five marine turtles are abundant. The region has a varied assemblage of seabirds, including frigate birds, tropic birds, boobies, shear-waters, terns, noddies, and gulls. The dugong is present, but its distribution and migration along the mainland coasts is not known. At least 15 species of cetaceans occur along this coast.

The coastal human population in east Africa is about 80 million. Shipping/port development and tourism are the fastest growing industries in the east African coastal zone. These industries are becoming incompatible with conservation in areas where pollution threatens to destroy the scenic beauty of beaches and coral reefs.

Red Sea

The Red Sea, over 2,000 km long and up to 360 km wide, is an important repository of marine biodiversity on a global scale. It features a range of coastal habitats including coral reefs, mangroves, salt marshes/sabkhas, rocky and sandy beaches, dune systems, and sea grass beds. These habitats accommodate more than 500 species of seaweeds, 1,000 fish species, 200 species of stony coral, 130 species of soft corals, more than 200 species of echinoderms, and 200 species of birds. There is a considerable variety of coral reef types with great structural complexity. The diversity and the number of endemic species of corals are extremely high.

The coastal human population is about 5 million. Urbanization, oil and other industries are developing rapidly in the Red Sea and tourism plays a major role in the economy of several countries. Pressures from recreation and tourism are high in the northern part and in the Gulf of Aqaba. Much of the oil produced in the Middle East is transported through the Red Sea and land-based activities (e.g., power and desalination plants, sewage treatment plants, industrial facilities, solid, wastes, and others) are adversely affecting the coastal and marine environment.

North Africa

The north African part of the Mediterranean is warm and arid. While it exhibits a low level of biological productivity, the Mediterranean Sea, as well as the surrounding land, is characterized by a moderate degree of biological diversity. Among the ecosystems that occupy coastal marine areas, the rocky intertidal, estuaries, and sea grass meadows (*Posidonia*

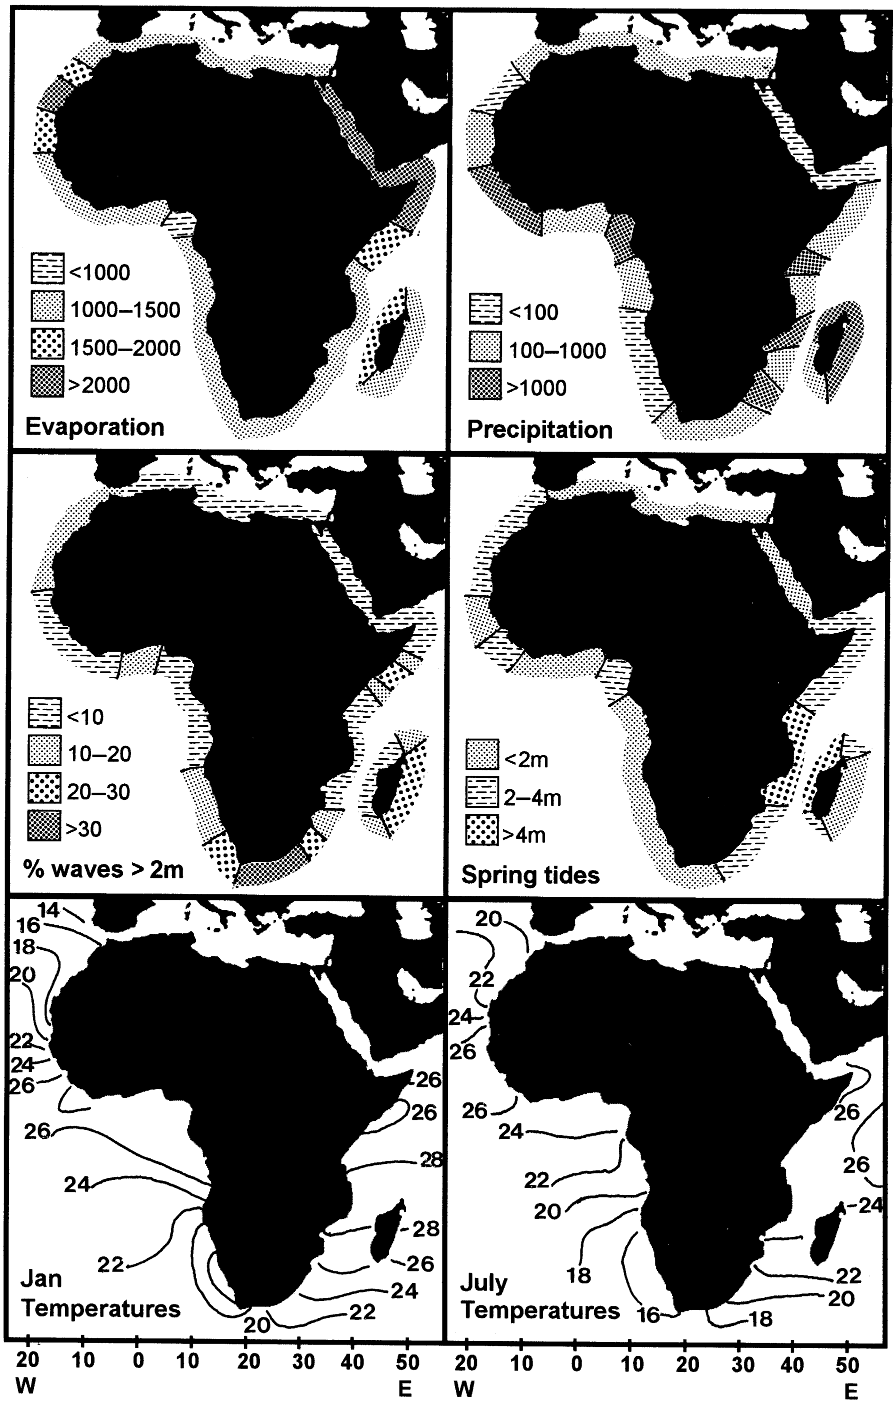

Figure A4 Physical features of African coasts.

beds, especially in Libya and Tunisia) are of significant ecological value. The Nile delta is a major feature of this area. Endangered species include the Mediterranean monk seal, marine turtles, and marine birds. It has been estimated that 500 species from the Red Sea have entered the Mediterranean through Suez, since damming the Nile has reduced the freshwater barrier (Por, 1968). The coastal population is about 40 million and human impacts are considerable. Tourism is of great importance in several areas.

Southern Africa

This region, including South Africa and Namibia, is subtropical to temperate, with cool upwelling waters in the west. It mostly consists of open high-energy coast receiving swell from the Southern Ocean. There are numerous large zetaform bays on the exposed south coast and few sheltered waters. The west is arid and the east is moist. Sandy beaches and rocky shores dominate and there are many small estuaries. Large volumes of sand transport characterize the south, with extensive, coupled dune and beach systems. Rocky shores are notable for their diversity of large limpets. Productive kelp beds occur on the west coast, and salt marshes are typical of estuaries and lagoons in the south and west. Biodiversity is highest in the east and decreases towards the west coast. Fur seals and penguins occur around the islands and two species of turtles breed on the east coast of South Africa.

There are a number of invertebrate fisheries: in addition to abalone in the southwest and subsistence fishing on the east coast, lobsters are exploited in the south and west, and penaeid prawns on the east coast. Demersal and seine fisheries are well developed, especially on the west coast. The coastal population is about 15 million and there are five major harbors. A wide range of activities impinges on the coast: besides recreation, tourism and industry, these include dune mining for heavy minerals, beach mining for diamonds, and damming of rivers.

Biogeography

The "shallow water" or coastal marine biogeography of Africa is dominated by warm water regions (Figure A5), the Indo-Pacific component on the east coast and the Atlantic component on the west coast. The Red Sea and Mediterranean coasts have distinctive, warm water faunas, which may be considered tropical and subtropical, respectively. Their marine boundaries are at Gibraltar and at the entrance to the Red Sea. Southern Africa harbors three provinces in addition to the Indo-Pacific component to the east: a warm temperate region on the extreme south coast and two temperate regions, the Namaqua and Namib provinces on the southwest. The eastern boundary between the southern warm temperate region and the Indo-Pacific is a broad transition region spanning the Eastern Cape and Natal coasts of South Africa. The junction between the Namaqua and Namib provinces, both influenced by upwelling, lies in southern Namibia near Luderitz and the boundary between the Namib and the Guinean is in southern Angola. The boundary between the tropical Guinean province and the north African

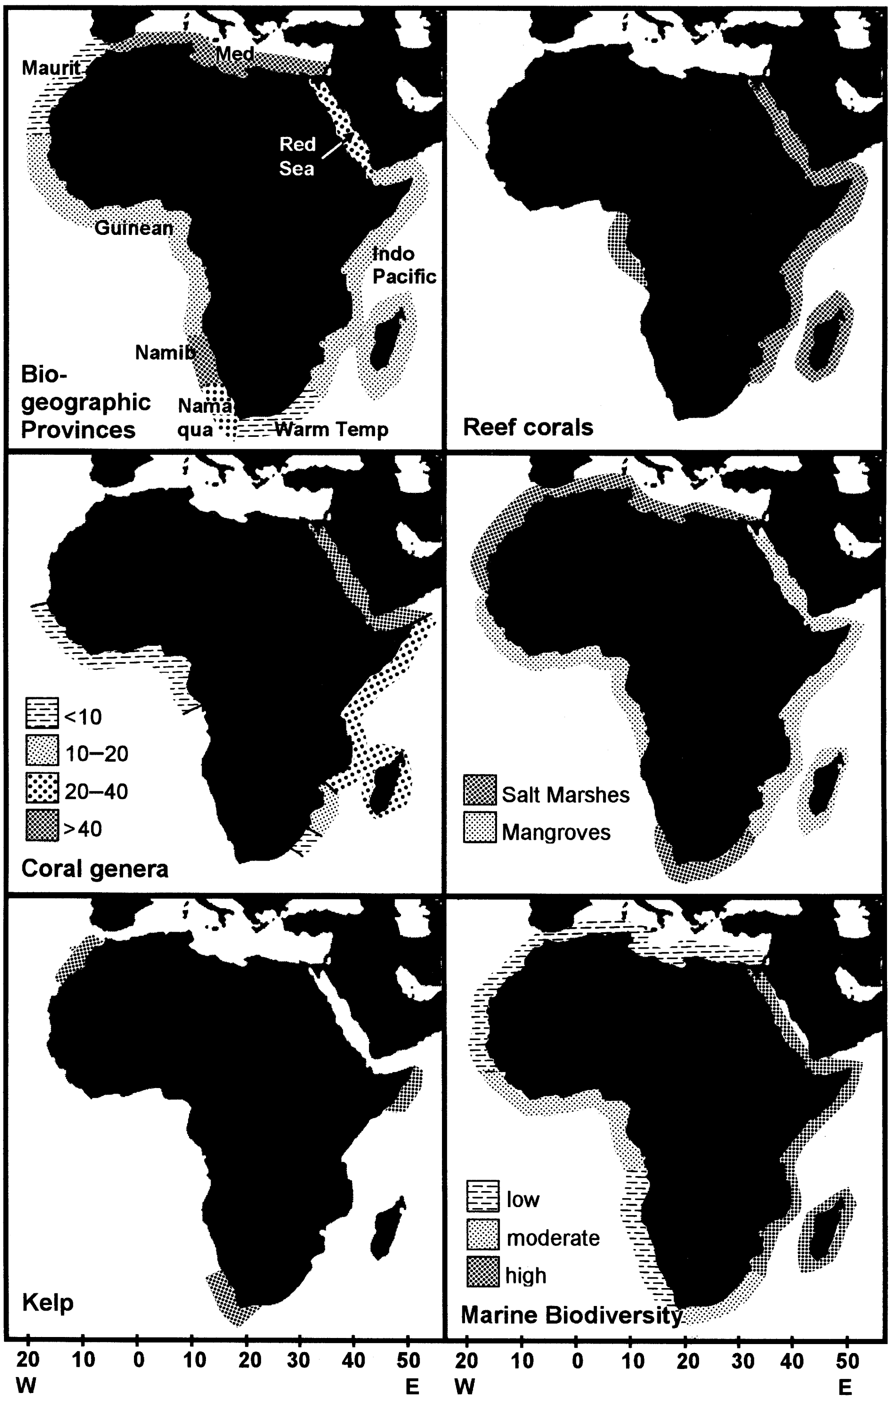

Figure A5 Biogeographic features of African coasts.

Mauritanian province lies around 15°N. Biodiversity is greatest in the Indo-Pacific province and in the Red Sea on the east coast and lowest in the temperate provinces in the southwest and northwest (Namaqua, Namib, and Mauritanian) and the Mediterranean.

Environments

The warm water provinces are characterized by corals, mangroves and, in some cases, sea grass beds, whereas the temperate provinces harbor kelps, where there is upwelling, and salt marshes. Sandy beaches and associated dunes, rocky shores and estuaries occur throughout.

Coral reefs

True coral reefs occur around Madagascar and along the African east coast from the Red Sea to Mozambique with some reef forming (hermatypic) corals extending further south into South Africa. On the west coast, the influence of upwelling restricts corals to a more limited region around the equator and islands off the northwest, but these are not true coral reefs. Those on the east coast are much richer in genera, being a part of the Indo-Pacific region (Figure A5). Coral reefs are mostly of the fringing type and occur predominantly in two provinces, the Red Sea and East Africa/Madagascar (Sheppard *et al*., 1992). Reef development in between, around the horn and Gulf of Aden, is limited by upwelling. In the northern Red Sea reefs are well developed and drop into deep, clear water, whereas in the south they occur in shallower, more turbid water and are less well developed. Besides fringing reefs, barrier reefs, patch reefs, and even atolls can occur. Coral diversity in the Red Sea is high and there is a clear north/south zonation into 13 communities. Coral reefs also display a depth zonation with maximum coral diversity at 5–30 m depths, depending on exposure and water clarity. Coral cover is mostly less than 50% on slopes but in sheltered areas *Porites* can attain 80% cover. Coral reefs support a diverse associated fauna of cryptic invertebrates and fishes, which play a variety of roles in these complex communities. The Red Sea harbors more than 1,000 species of fishes, many associated with coral reefs. Greatest fish abundance occurs near the reef top, whereas greatest species richness tends to occur at depths of 10–15 m.

Sandy beaches

Sandy beaches, backed by dunes, are the dominant coastal form, comprising as much as 70% of the coastline, and have been well studied in South Africa. Beach form is controlled by the interaction between sediment particle size and wave and tide energy. Conditions of high wave energy, large tide ranges, and fine sand give rise to wide flat beaches referred to as dissipative; whereas, narrow steep beaches, called reflective beaches, develop under conditions of low wave and tide energy and coarse sand. African beaches range from high-energy dissipative systems on the southwest tip of the continent, through intermediate types to microtidal reflective beaches in the Mediterranean and Red Sea. Macrotidal beaches and sand flats occur in the Mozambique Channel. High-energy dissipative systems have been shown to be richest in terms of productivity, with large populations of filter feeders (Brown and McLachlan, 1990). Such beaches, together with macrotidal flats, support diverse benthic faunas. Reflective systems, which are typical of tropical regions with modest tide ranges, generally support lower diversity and lack surf zones. Temperate high-energy beaches with extensive surf zones often develop blooms of surf zone diatoms, which fuel rich food chains. Besides meiofauna and microfauna, beaches support a macrofauna of scavenger/predators, filter feeders and deposit feeders. Among the macrofauna, donacid clams, gastropods of the genus *Bullia*, ghost crabs (*Ocypode*), cirolanid isopods, mysid shrimps, and polychaete worms are typical. The species richness per beach ranges from less than 10 species on reflective beaches to more than 30 on tropical dissipative beaches and tidal flats. Zonation on sandy beaches is less marked than on rocky shores and throughout most of Africa consists of three zones: ghost crabs at the top of the shore, cirolanid isopods on the midshore, and a variety of species lower down. In the temperate areas, sandhoppers (talitrid amphipods) and/or oniscid isopods occur at the top of the shore. Beach fauna is, therefore, controlled primarily by physical factors and beach type, with biogeography and climate playing a lesser role.

Sea grass beds

In the Mediterranean, the Red Sea and throughout the western Indian Ocean, sea grass beds are common in intertidal areas, coastal lagoons, shallow sandy bottoms with good light penetration and sandy areas adjacent to shallow reefs. At least 10 species are common and include members of the genera *Possidonia*, *Thalassia, Halodule, Syringodium, Halophila, Cymodocea*, and *Thalassodendron*. Sea grasses are not true grasses but are closer to pondweeds. They are aquatic plants with leaves above the surface and rhizomes and stems buried in the sand. Sea grass beds create habitats distinguished by high primary productivity, enhanced by encrusting algae epiphytes. However, there is limited direct herbivory, probably due to distasteful compounds and indigestibility of seagrasses. Instead, seagrasses are consumed via detritus food chains after processing by microorganisms. Sea grasses stabilize the sediment, create habitat, and serve as nursery areas and support a high diversity of associated species, especially molluscs, polychaets, crustaceans, and fishes. Many commercial fishes utilize them as nursery areas. Ten species occur in the Red Sea, *Halodule* and *Halophila*, being the commonest.

Dunes

Dune forms depend on rainfall (vegetation growth) and sediment transport (supply X wind) and are closely coupled to beach type. Simple vegetated foredune ridges and hummocks are the most widespread type. Such dunes typically occur behind low energy and reflective beaches and are characteristic of the moist tropics. Transgressive dune sheets occur in windy areas with large volumes of sand transport, for example, the south coast of South Africa, and parabolic dunes occur in places with predominantly unidirectional winds. Coastal dunes are rapidly colonized by plants, *Ipomoea* and *Scaevola* being typical foredune pioneers. These may be followed by scrub and thicket until climax forest is reached. In the arid southwest and north of Africa coastal dunes are highly mobile and support limited vegetation. Climax dune vegetation may be scrub in arid areas, or even pioneers in hyperarid situations. In the moist tropics, forest may extend right down to the beach. Coupled to landward succession in dune vegetation is a change in animal communities: bird diversity increases as vegetation structure becomes more vertical; insects and small mammals also respond to this gradient. In general, therefore, coastal dune ecology is a function of dune forms and vegetation succession, which in turn are controlled by sand supply and climate.

Rocky shores

Rocky shores form about 30% of the coastline of Africa. Intertidal rocky-shore organisms are exposed to a wide range of physical conditions. Unlike the situation on sandy beaches, organisms on rocky shores cannot burrow to escape adverse conditions: they must simply be tough enough to tolerate the fluctuations. Tides establish a gradient of physical stress, with the high-shore being sun-baked and desiccated, and the low-shore more mild. This gradient leads to a distinctive vertical zonation of organisms, with the top of the shore characterized by a small number of species, low biomass and productivity, and progressive increases in all these variables as one moves down the shore. Physical stress tends to limit the extent to which species can advance up the shore, but biological interactions between species often set limits to how far they extend down the shore. For example, competition from mussels ousts barnacles; grazers, such as limpets and chitons, control the growth of algae; predators, such as whelks, crabs, fish, and birds, limit the zonation of their prey. Moving horizontally along rocky shores, different gradients come into play. The first of these is wave action, which operates on a scale of meters to kilometers. Mobile predators and grazers tend to be inhibited by waves, whereas algae benefit from a reduction in grazing and from an increase in the turnover of nutrients. Filter feeders, such as mussels, are enhanced because waves import the organic particles that comprise their food. The overall effect is that biomass and productivity are highest on wave-beaten shores, such as those occurring on the south coast of Africa (Branch and Griffiths, 1988).

At larger scales of 100s to 1,000s of kilometers, there are gradients of productivity. High nutrient levels associated with upwelling accelerate algal growth, supporting high biomass of grazers and predators but a low diversity of species. On a similarly large scale, there are climatic gradients from temperate to tropical conditions. High temperatures in the tropics lead to greater physical stresses, so that rocky shores there tend to be sparsely occupied, with low biomass and productivity, but high levels of species diversity. Tough coralline turfs become a dominant element among the seaweeds. Grazers and sedentary predators are often confined to shelters during low tide to avoid potentially lethal conditions. On the other hand, mobile predators, such as crabs and fish, are more abundant in the tropics than on temperate shores. In sum, vertical changes in community structure on rocky shores are dictated by gradients of physical stress overlain by biological interactions. Moving horizontally along rocky shores, community patterns and processes controlling them change radically in response to wave action, productivity, and climate.

Kelp beds

Kelps are large and complex in structure, with a root-like holdfast, a long stipe and frond-like blades. Kelps are fast growing plants and are restricted to coastal areas where sunlight is readily available and nutrient levels are high. In Africa, they are confined to zones of upwelling, where cool and nutrient-rich water is brought to the surface by winds that drive surface waters offshore. Upwelling is concentrated on the west coast of southern Africa, off west Africa and in the region of the Somalian horn of Africa, where the world's only tropical upwelling areas can be found. Kelp forests thus occur in the southwest in the Namaqua and Namib provinces (*Ecklonia, Laminaria, Macrocystis*) and in the northwest in the Mauritanian province (*Laminaria*) and off Somalia. Kelp plants are of direct economic significance because they produce alginic acid, widely used in food and other products.

Kelps form dense underwater forests, which break the force of wave action. They are themselves, however, powerfully influenced by waves, which tangle and tear out swathes during storms. Whole kelp plants wash ashore on sandy beaches where they contribute substantially to energy flow. Sandy shores "supplemented" in this way have high levels of biomass and productivity, and their life is concentrated at the top of the shore where the kelp deposits. Surprisingly little kelp is directly eaten by herbivores; most is abraded from the growing plants and contributes to a pool of organic matter that fuels particle-feeders and filter feeders, such as sea cucumbers, mussels, ascidians, and sponges that dominate much of the floor of kelp beds. Large fragments of kelp also break off and support urchins and abalone. Intertidal grazers also benefit: the highest biomasses of grazers ever recorded in the world occur on rocky shores on the west coast of South Africa. Their existence depends on the vital "subsidy" they receive in the form of drift from adjacent subtidal kelp beds. Clearly, kelp beds play significant ecological roles that extend well beyond their confines. They are commercially valuable in their own right, but also sustain other species of commercial importance, such as abalone.

Estuaries

Estuaries, lagoons, and river mouths are highly variable around the coasts of Africa, depending on climate. Other than for the Zambesi in the east, all the major rivers (Kunene, Orange, Congo, Niger, Volta) drain to the west and the Nile empties into the Mediterranean. The Nile (20,000 km^2), Zambesi (700 km^2), Volta (9,000 km^2), Senegal (8,000 km^2), Oueme (1,000 km^2), and Niger (36,000 km^2) have extensive delta systems. Large coastal lagoons occur in west and in southeastern Africa and many wetlands are of considerable conservation value. In the arid areas of southern and southwest Africa, the Red Sea and the Mediterranean coast, most estuaries are ephemeral and close during the dry season. Many estuaries have been impacted by damming of rivers, in some cases the reduction in freshwater supply eliminating normal salinity gradients and/or reducing floodplains (e.g., Niger). Mangroves, salt marshes, and phytoplankton contribute to primary production and support benthic fauna of high abundance but low diversity. Estuaries are important nursery areas for penaeid prawns and a variety of fishes.

The regulation and impoundment of freshwater in river systems is probably the single most important threat to natural functioning of estuarine systems in many parts of Africa. Most of these estuaries are classified as temporary open/closed. Floods, in particular, are important in maintaining functional links between the estuaries and the sea, but because of impoundment schemes, changes in the frequency and intensity of flood events is becoming evident. Many estuaries close more frequently and for longer periods since the removal of accumulated sediment in marsh channels by floods is not as effective as before. Thus, many estuaries are beginning to function differently compared with the natural state. Not only do freshwater abstraction schemes lead to negative downstream impacts, but they also have the capacity to influence the marine nearshore. Major regulations along the Zambesi river (Kariba and Cahora Bassa dams) are having a negative influence in coastal waters, with die back of mangroves and a collapse of the coastal prawn fisheries (Davies *et al*., 1993).

Salt marshes

Salt marshes are temperate habitats, mostly associated with estuaries. African salt marshes occur in the Mediterranean, on the northwest and on the south and southwest coasts. Most African salt marshes are of limited extent; for example, total salt marsh area in South Africa is 1,700 ha, most of which is confined to five systems. There is clear zonation of the marsh flora from the subtidal to the top of the intertidal zone, *Spartina*, *Zostera*, *Sarcocornia*, and *Limonium* are the most typical genera. These African salt marshes are distinguished from those elsewhere by their warm temperate character and limited size. Associated fauna includes a variety of marsh crabs and shrimps, wading birds and, at high tide, fishes.

Mangroves

Total world mangrove area is 181,000 km^2 and 20% of this is in Africa, 15% on the west and 5% on the east coasts (Spalding *et al*., 1997). On the east coast, in the Red Sea and Madagascar, they form part of the Indo-Pacific province; there are 10 species and the most widespread are *Avicennia marina, Rhizophora mucronata*, and *Sonneratia alba*. On the west coast of Africa their affinities are with New World tropical regions and, of the seven indigenous species, *Avicennia germinans, Rhizophora racemosa*, and *Laguncularia racemosa* are widespread. Distribution may be as much limited by aridity as temperature. Estuaries may harbor large mangroves systems but they can also occur as narrow strips along the coastline where rivers are absent. Associated fauna includes mudskippers *Periopthalmus*, mangrove snails *Cerithidea*, fiddler crabs, *Uca*, and oysters. Fishes and penaied prawns utilize mangroves as nursery areas. Mangroves are important sources of detritus for estuarine food chains. Wood collection threatens mangroves in several areas (e.g., Mozambique).

Islands

Coastal islands form important rookeries for seals and nesting sites for seabirds. Colonies of Cape fur seals, Jackass penguins, Cape gannets, cormorants and other seabirds occur on numerous coastal islands, especially off South Africa and Namibia. Socotra is also an important breeding area for boobys and terns and also harbors six endemic species of birds and eight endemic reptiles. Red Sea islands support colonies of gulls and terns. Islands off Mauritania are important for migratory birds and support large breeding colonies of gulls and terns.

Utilization

Coastal resources are extensively utilized throughout Africa. These activities range from subsistence gathering of shellfish and mangrove wood to commercial exploitation of abalone, kelp, lobsters, and inshore fishes. Subsistence utilization can cause degradation and damage to coastal habitats. Dynamite fishing also threatens Africa's coastal ecosystems in some localities as it disturbs coral reefs and lagoon systems. Nonliving resources that are exploited include oil (Angola, Nigeria), diamonds in beach and nearshore sediments (Namibia), heavy minerals in dune sands (South Africa), sand, rock, and groundwater. The coast is also a focal point for recreational activities including swimming, surfing, angling, and diving. Indeed, the African coastline is becoming as important as its game reserves and ancient civilizations in attracting tourism. For most recreational activity, sandy beaches are focal points. One third of the coastline is considered to be under threat from developments and other human activities.

Conservation and management

Marine and coastal resources contribute significantly to African economies, especially through fisheries (e.g., Namibia) and tourism (e.g., Mauritius). Current development trends and pressures from increasing urbanization and industrialization are steadily degrading fragile ecosystems. Pollution, mining, and oil exploration are also threatening coastal ecosystems. Oil spills due to well blowouts have caused serious problems in the Niger delta, decimating "black water" biodiversity. In addition, toxic wastes from developed nations have been illegally dumped along the coasts of poor African nations. Many industries dispose of untreated wastes directly into rivers running into the sea. In the Red Sea and in north Africa there is an increasing risk of pollution as over 10^9 tons of oil are transported through the area annually and there are limited maritime traffic regulations. The coastal countries of Africa are also susceptible to the problem of accelerated coastal erosion. This is driven by natural processes that are exacerbated by sea-level rise, upstream construction of dams, other coastal infrastructure, and clearing of mangrove systems.

In recent years, Africa has seen major political, economic, and social changes and has transformed from a rural society to a complex modern region whose ties to natural capital remain strong despite economic development. Population growth (2.8%) is almost twice the global average (1.5%), far in excess of the average rate of economic growth. In many African countries, national parks and conservation areas include parts of the coast as increasing human impact necessitates protection and management. Coastal reserves, which have been established in a number of areas to afford protection or control utilization, need to be expanded, to involve the local populations and to be better managed. Important resources/habitats requiring protection are dunes, mangroves, coral reef, and islands. Integrated coastal zone management, in its infancy or absent in most of Africa, is essential for the future well-being of these spectacular coasts.

AFRICA, COASTAL GEOMORPHOLOGY

The African continent measures 30×10^6 km^2 and its relatively unbroken coastline is 30,000 km long, compared with the 70,000 km coast of Asia, which is only 1.5 times larger than Africa, and the 76,000 km coast of smaller North America (24×10^6 km^2) with its numerous Arctic islands. Over long distances, the African coast is unbroken by sizable inlets, and its major river mouths, except the Congo, are either deltaic or blocked by sand barriers. Excepting Madagascar (587,000 km^2), no large islands lie off the African coast.

Offshore, Africa's continental shelf covers only 1.28×10^6 km^2, compared with 9.39×10^6 km^2 for Asia and 6.74×10^6 km^2 for North America. The shelf averages only 25 km in width, wider off southern Tunisia, Guinea, and major deltas, and reaching 240 km wide across the Agulhas Bank, but narrowing to 5 km off Somalia, northern Mozambique, and Kwa-Zulu. This narrow shelf and paucity of sheltering islands allow deep-water waves and surface ocean currents to approach unmodified close to the mainland shore where they are unusually influential in moving sediment (Orme, 1996).

Explanations for Africa's relatively smooth coastline and narrow continental shelf are to be found in the tectonic processes that triggered the rupture of Gondwana in Mesozoic time and in the geomorphic processes that have shaped the coast more precisely during later Cenozoic time.

Coastal origins

The broad outlines of Africa's coastal margins may be explained in terms of plate-tectonic events over the past 200 Ma (million years before present). Africa's margins were initially blocked out by the rupture of Gondwana in Mesozoic time, and further modified during the progressive opening of the Atlantic and Indian Oceans, the gradual closure of the Tethys Ocean, and the Cenozoic opening of the Red Sea (Figure A6; Orme, 1996; Summerfield, 1996).

Prior to these events, Africa's cratonic nucleus had been fused during the Panafrican–Brasiliano orogeny in later Neoproterozoic time (650–530 Ma) with cratons from other southern continents to form the supercontinent of Gondwana. Later, towards the close of Paleozoic time (330–260 Ma), Gondwana became joined to the supercontinent of Laurussia to form a vast single landmass, Pangea, a suture marked prominently by the Appalachian (Alleghanian) and Atlas collisional orogens of North America and northwest Africa, respectively (Ziegler *et al*., 1997; Orme, 2002). Compared with Gondwana, however, Pangea did not last long. Following Triassic crustal extension (248–206 Ma), North America began separating from Africa along the Appalachian–Atlas suture and, by mid-Jurassic time (180–160 Ma), an incipient north-central Atlantic Ocean, underlain by oceanic basalts spewing from a spreading center beneath the Canary Islands, lay off northwest Africa (Steiner *et al*., 1998). The later development of this coastal margin reflects variable rates of sea-floor spreading, epeirogenic flexuring, marginal basin development, and sedimentation.

The continent's western margin farther south was initiated by sequential events, which caused South America to separate from Africa over a period of 100 Ma, from early Jurassic to middle Cretaceous time (Uchupi and Emery, 1991; Milani and Filho, 2000). In the north, following Triassic crustal extension, sea-floor spreading in the early Jurassic (190–180 Ma) introduced ocean waters to the Guinea–Sierra Leone margin. In the south, the Malvinas (Falkland) Plateau, which had formerly wrapped around Africa's southern tip, began shearing westward in the early Jurassic (200–180 Ma), causing the continent's west-facing margin to unzip progressively northward from eastern Brazil. Later, in response to these stresses, right-lateral wrenching along a massive transform system began separating northern Brazil from the south-facing Guinea coast in middle Cretaceous time (120–100 Ma). Throughout this Atlantic margin, initial crustal extension and enhanced magmatism were followed by basin formation along the rifted margin and then, as sea-floor spreading moved Africa farther from the Mid-Atlantic Ridge, by widening oceanic tectonic and sedimentary regimes. Thus, magmatism at a common eruptive center on the Mid-Atlantic Ridge generated early Cretaceous volcanic rocks at Etendeka in northern Namibia and the Paraná flood basalts of southern Brazil, which on subsequent rifting and sea-floor spreading have since separated (Glen *et al*., 1997). The Liberian coastal margin off Cape Palmas reflects fracture zones that developed around 140 Ma, since when some 8,000 m of sediment have blanketed the shelf and slope. Farther south, the deep Angola and Cape basins developed during Cretaceous time to the north and south of the Walvis Ridge, respectively. South of this ridge, the western continental margin consists of downdropped basement blocks, aligned NNW and overlain by a prograded sediment wedge formed by debris brought down by the Orange River and other streams that have been eroding the Great Escarpment since it was first tilted upward in early Cretaceous time (Dingle and Scrutton, 1974; Summerfield, 1996). Islands such as Ascension and Tristan da Cunha in the central South Atlantic Ocean mark continuing hotspot volcanism on the Mid-Atlantic Ridge at the western edge of the African plate. At Africa's southern tip, the Malvinas Plateau sheared westward from the Hercynian Cape Fold Belt (280–230 Ma) along major transform structures during Jurassic time. Since then, and notably since epeirogenic uplift of the southern Great Escarpment in Cretaceous time, terrigenous debris has crossed the narrow continental shelf to blanket the continental slope and adjacent basins. Farther out, the submarine Agulhas Plateau was probably created by volcanism in fracture zones vacated by the Malvinas Plateau (Barrett, 1977).

Following Permian tensions and Triassic saltwater intrusion, much of Africa's eastern margin was blocked out during earlier Jurassic time (200–160 Ma). In Mozambique, early tensional rifting produced N–S horst and graben that were later buried beneath debris from the Limpopo and Zambezi river systems (Dingle and Scrutton, 1974). The N–S segments of coast south of the Zambezi and Limpopo river mouths reflect these structures, whereas the NE-trending coasts north of these rivers reflect right-lateral offsets of basement cratons, bringing Precambrian rocks close to shore in northern Mozambique. Some 6,000 m of Cretaceous and Cenozoic terrigenous sediment have since accumulated in offshore basins, including the massive Zambezi cone. Madagascar is a large fragment of continental crust that probably lay

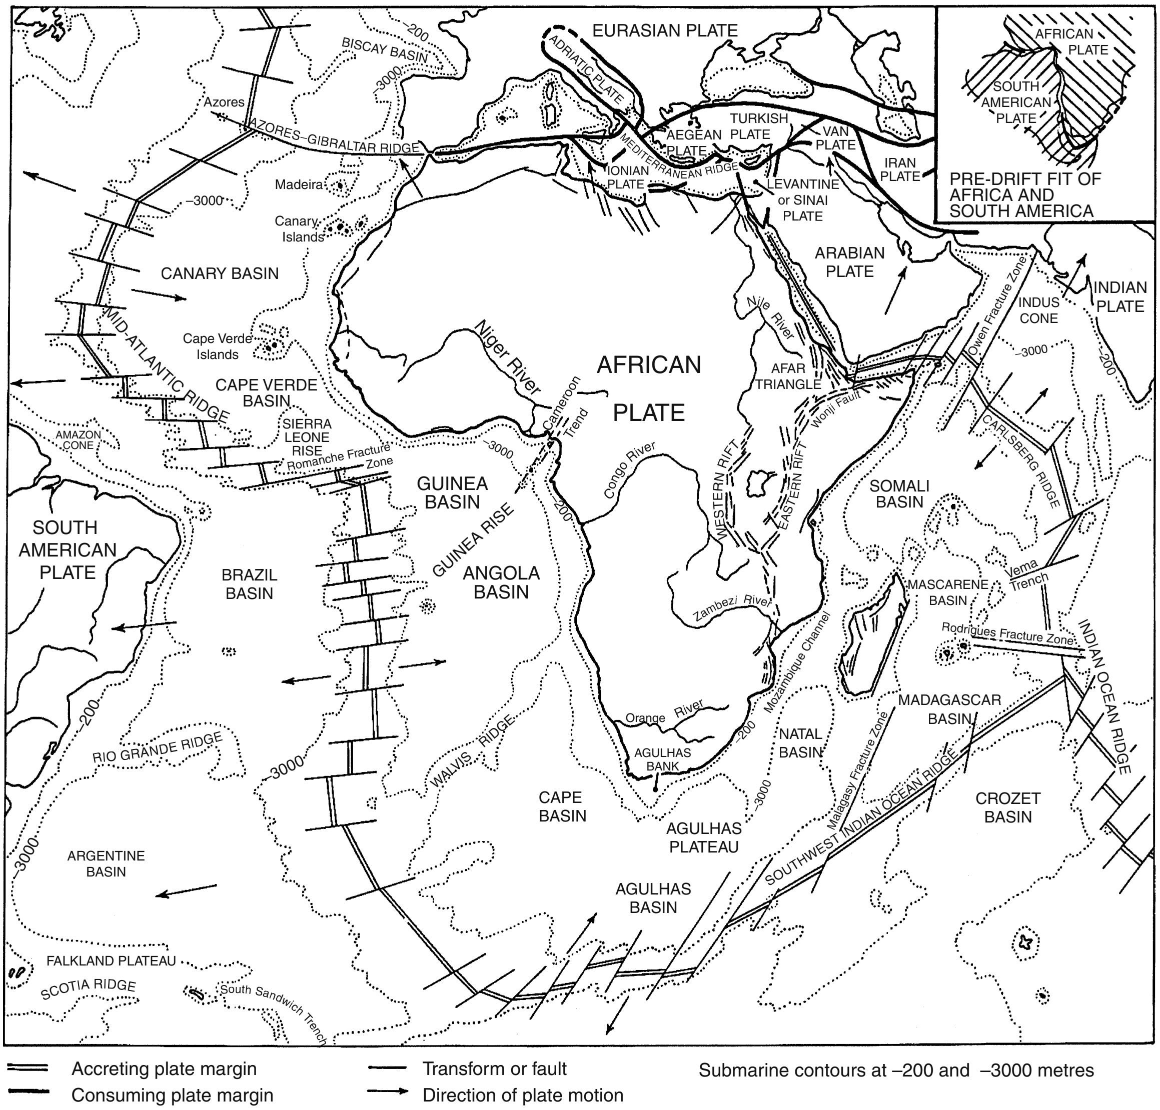

Figure A6 Tectonic relations of the African Plate (from Orme, 1982, with permission of Kluwer Academic Publishers).

alongside western India before the latter began separating from eastern Africa in Jurassic time. Although Madagascar's place in Gondwana has been much debated, it probably translated southward to its present location from Tanzania and Kenya, with the reef-capped Comoro volcanic archipelago extruding along resultant fracture zones (Maugé *et al.*, 1982; Ziegler *et al.*, 1997). Farther north, the southeast margins of Somalia and Arabia also formed from the Jurassic rupture of Gondwana.

The Red Sea and Gulf of Aden coasts reflect relatively late intraplate separation of the African–Arabian portion of Gondwana along extensions of the East African Rift system. In early Cenozoic time, after prolonged stability, the region became the site of intensive magmatic and tectonic activity. By late Eocene time (~35 Ma), vertical uplift had produced a massive Afro-Arabian dome which subsequently broke into Somali, Nubian, and Arabian segments. The Somali segment was bounded to the north and west by crustal flexures and tensional faults along which lateral displacement began in the Miocene, forming the discrete Somali plate. Since then, as the Arabian segment has moved north and east away from the Somali and African plates, new oceanic crust up to 200 km across has formed in the widening Gulf of Aden and Red Sea.

The Mediterranean coastal margin reflects a long and complex relationship with the European portion of the former supercontinent of Laurussia. The rupture of Pangea that began in late Triassic time, sometime before 200 Ma, permitted a large tropical ocean, the Tethys, to intervene between central Europe and north Africa at a time when the African plate lay wholly south of the Equator. As Africa subsequently moved northward and rotated anticlockwise across the Equator, transpressional tectonics reshaped the Tethys into several microplates and convoluted mid-Cenozoic (Atlas–Alpine) collisional orogens, which today form southern Europe and underlie the Mediterranean Sea. The effects of the Atlas orogeny are well revealed along the north African coast between Agadir and Gabes. Farther east, the situation is less clear because regional tectonism involves both transpressional and transtensional interactions between several microplates, activities that yield frequent earthquakes and volcanic events in southern Europe but not in north Africa. In the Aegean subduction zone, for example, the African plate is presently moving under the Aegean microplate at a rate of 2.7 cm yr^{-1}.

In summary, Africa's Atlantic and Indian Ocean coasts reflect divergent or passive plate margins inasmuch as the African plate has diverged from oceanic spreading centers from which the continent is now separated by vast expanses of post-Gondwanan basaltic ocean floor variably mantled with marine and terrigenous sediment. In embryo form, the Red Sea and Gulf of Aden coasts are also divergent margins but continuing crustal adjustments and volcanism belie the term passive. In contrast, the western Mediterranean margin is an active margin, but this categorization is less easily applied farther east.

Coastal and offshore geology

Tectonic origins apart, the present shape of the African coast also reflects the character of the rocks and structures introduced to the coastal zone during and since the breakup of Gondwana. The principal rocks influencing coastal features may be grouped into Precambrian basement, consolidated Phanerozoic platform covers, and poorly consolidated late Cenozoic sediments.

Precambrian rocks outcrop over 57% of Africa's surface, reflecting numerous sedimentary cycles whose deposits were intensely folded and fractured, metamorphosed, and often granitized during at least eight orogenic cycles. Gneiss, schist, quartzite, and migmatite are important but post-orogenic molasse deposits and tabular to strongly folded platform covers of sandstone, limestone, tillite, and volcanics also occur. Today, these basement rocks reach the coastal zone in the Anti-Atlas of Morocco, the Guinea coast between Monrovia and Accra, at intervals from Angola to Cape Province, and again in northern Mozambique, eastern Madagascar, and the Red Sea. Because intense fracturing favors deep weathering, these rocks rarely form high cliffs.

Phanerozoic rocks occur mostly as tabular platform covers occupying large basins between swells in the basement complex, but folded cover rocks form the Cape Fold Belt (Hercynian) of South Africa and the Atlas Fold Belt (Hercynian and Alpine) from Morocco to Tunisia. In Africa as a whole, the great extent of continental deposits and the paucity of marine sediment are noteworthy. The continental rocks include the Nubian Supergroup (Cambrian–Cretaceous) which straddles the Red Sea, and the 7,000 m thick Karroo Supergroup (Carboniferous–Triassic) of southern Africa whose tillites, shales, sandstones, and basalts form bold escarpments inland and sea cliffs at the shore.

In contrast, late Cenozoic sediments within the coastal zone are mostly marine sediments or fluvial deposits reworked by waves, currents, and winds. These materials are often poorly consolidated and thus erodible but, except in the Mozambique coastal plain, rarely extend far inland. More resistant late Cenozoic rocks include coral-reef limestones and aeolianites.

Offshore, there are about a dozen major basins around Africa, formed following the rupture of Gondwana and now partly filled with late Mesozoic and Cenozoic sediment. Where these basins straddle the present coast, both marine and terrigenous sedimentation have occurred, leading to epeirogenic seaward subsidence of the coastal margin which in turn favors more sedimentation (Orme, 1996). The contrast between sedimentation in these basins and denudation in their hinterland has caused significant isostatic responses to loading and unloading, leading, for example, to 600 m of uplift inland from the southwest coast and adjustments to the Orange River below Augrabies Falls (Gilchrist and Summerfield, 1990). Continued deformation and volcanism have complicated coastal evolution, notably in coastal extensions of the 7,000 km long East African Rift system and the Cameroon volcanic line.

Moving clockwise from Ras Asir at the Horn of Africa, the first basin encountered is the 7,000 m deep Somali Basin which merges south with the 8,000 m deep Kenya and 3,000 m deep Dar es Salaam Basins. When the Somali Basin formed along Gondwana's rifted margin, marine transgressions and carbonate deposition followed, but late Jurassic uplift of the Bur basement complex along NE-trending faults separated the interior of this basin from continuing carbonate deposition at the coast. Cenozoic rejuvenation of these faults has largely defined the east coast from Ras Asir to Tanzania (Orme, 1985, 1996). Farther south, the 4,000 m deep Mozambique Basin has also been broken by N–S faults at the south end of the East African Rift system. The 7,000 m thick sedimentary cover of the Madagascar Basin has also been severely faulted.

Along the west coast, a more or less continuous embayment of folded sediments and salt domes is represented by the 4,000 m deep Luanda Basin, the 3,000 m deep Cabinda Basin, and the 8,000 m deep Gabon Basin. The Niger Basin, the seaward extension of the Benue graben, contains up to 10,000 m of Cretaceous and Cenozoic deposits, including important petroleum resources beneath the Niger delta. The narrow Ivory Coast Basin is faulted to depths of 4,000 m and the Senegal Basin reaches depths of 7,000 m at the coast. The Tarfaya Basin farther north, bounded inland by the Zemmour Fault, contains 10,000 m of Mesozoic and Cenozoic deposits beneath Cape Juby.

Early evolution of the Mediterranean coast differed from other coasts because sediments in its developing marginal basins became involved in mid-Cenozoic orogeny, as seen in the mountain arcs and deep sedimentary basins of the Algerian coast. Farther east, the 5,000 m deep Tripoli Basin is separated by NW-trending faults from the extensive 8,000 m deep Sirte Basin of Cyrenaica.

Relative sea-level change

Since the rupture of Gondwana, continuing tectonic, isostatic, and eustatic forces have left their imprint on Africa's emerging coastal margins. For example, sea-level relations have been strongly impacted by Atlas tectonism along the continent's northwest margin during and since mid-Cenozoic time, while late Cenozoic rifting has impacted the Red Sea coast. Isostatic adjustments of Africa's plate margin to denudational unloading and sediment loading have also affected sea levels. Further, the eustatic high sea levels of mid-Cretaceous time caused shallow seas to transgress north Africa and link the Tethys with the Gulf of Guinea. After Paleocene regression, Eocene seas again flooded the Sahara and a shallow gulf persisted into Miocene time (~20 Ma) in Libya and Egypt.

Relative sea-level changes over the past few million years, and especially for the Quaternary, have been the focus of much research, in part because they aid prediction of future coastal behavior. In general terms, tectonism, isostasy, and eustasy may have combined locally to force Quaternary sea-level changes ranging from 300 m above to 200 m below present levels. Along the Moroccan coast, for example, a deformed Pliocene marine surface up to 20 km wide, the Moghrebian rasa, has been raised between 100 and 600 m above sea level, providing a useful measure of Alpine tectonism (Weisrock, 1980). Flights of deformed Pleistocene coastlines also occur along the western Mediterranean coast, notably at Algiers, Bizerte, and Monastir, while raised coral reefs occur along deformed Red Sea and northern Somali coasts. Elsewhere, the stability of much of the African plate relative to high last interglacial seas (~125 ka) is indicated by little deformed coastlines and coral reefs a few meters above present sea level, notably along southern coasts (Orme, 1973; Hobday and Orme, 1975). Offshore, former sea cliffs, beaches, aeolianites, and river valleys, now submerged on the continental shelf, testify to low late Pleistocene sea levels (Orme, 1974, 1976).

The last major global sea-level change, the Flandrian transgression which accompanied the melting of the last Pleistocene ice sheets and culminated around 5 ka (thousand years before present), initiated the present phase of coastal erosion and deposition. Locally, this transgression may have risen a few meters above present sea level, as suggested by the Nouakchottian deposits in Mauritania and Senegal, but such evidence for seemingly high Holocene sea levels may also be explained by local epeirogenic forcing or by climate-induced changes in hydrology and sediment delivery (Ausseil-Badie *et al.*, 1991). Relative sea-level rise during historic times is reflected in submerged Phoenician tombs and Roman ports along the Mediterranean coast, by submerged Arab legacies along the east coast, and more recently by tide-gauge records.

Coastal processes

Climatic factors

Directly or indirectly, climate affects most processes shaping the coast. As elsewhere, Africa's coastal climates reflect the impact of seasonal changes in Earth–Sun relations on the Intertropical Convergence Zone (ITCZ), air masses, and wind regimes. During the southern summer, the ITCZ shifts southward with the Sun to a zone running from the Guinea coast to Madagascar. Excepting the influx of cool moist maritime polar air masses from the Atlantic into the Mediterranean, most of north Africa is covered by warm dry outflowing air associated with continental tropical air masses over the Sahara and southwest Asia, promoting the dust-laden Harmattan over the Guinea coast and the northeast monsoon along the east coast, respectively. During this, the *jilaal* season in Somalia, warm northeasterly winds up to 30 km hr^{-1} drive ocean waters and aeolian sands southward along the coast (Orme, 1985). Farther south, warm rainy conditions and onshore winds linked to inflowing marine air or local thermal convection cells prevail.

During the northern summer, the ITCZ shifts northward to the Sahel. Hot wet conditions prevail over central Africa and the Guinea coast, Saharan aridity reaches the Mediterranean, and, although much of southern Africa is dry, cool maritime air masses and storms from the Southern Ocean impact the southern coast. This, the *hagaa* season in Somalia, sees southwest monsoon winds with mean velocities over 40 km hr^{-1} move aeolian sand and surface waters northward along the east coast, while the hot desiccating dust-laden *kharif* wind invades the Gulf of Aden from northern Somalia.

Oceanic factors

Excepting the Mediterranean and northwest coasts where northwesterly swells predominate, the African coast is dominated by southerly swells generated by storms in the Southern Ocean (Figure A7). From Cape Vert to Cape Agulhas, these swells are mostly southwesterly, decreasing in height northward and from southern winter into southern summer. Along the Guinea coast, these swells are reinforced by southwesterly monsoon winds during the northern summer. Because of the orientation of Africa's west coast, the southwesterly swells generate mainly east-flowing longshore currents in the Gulf of Guinea and mainly north-flowing longshore currents along the west-facing coast farther south. This nearshore wave-driven circulation is reinforced

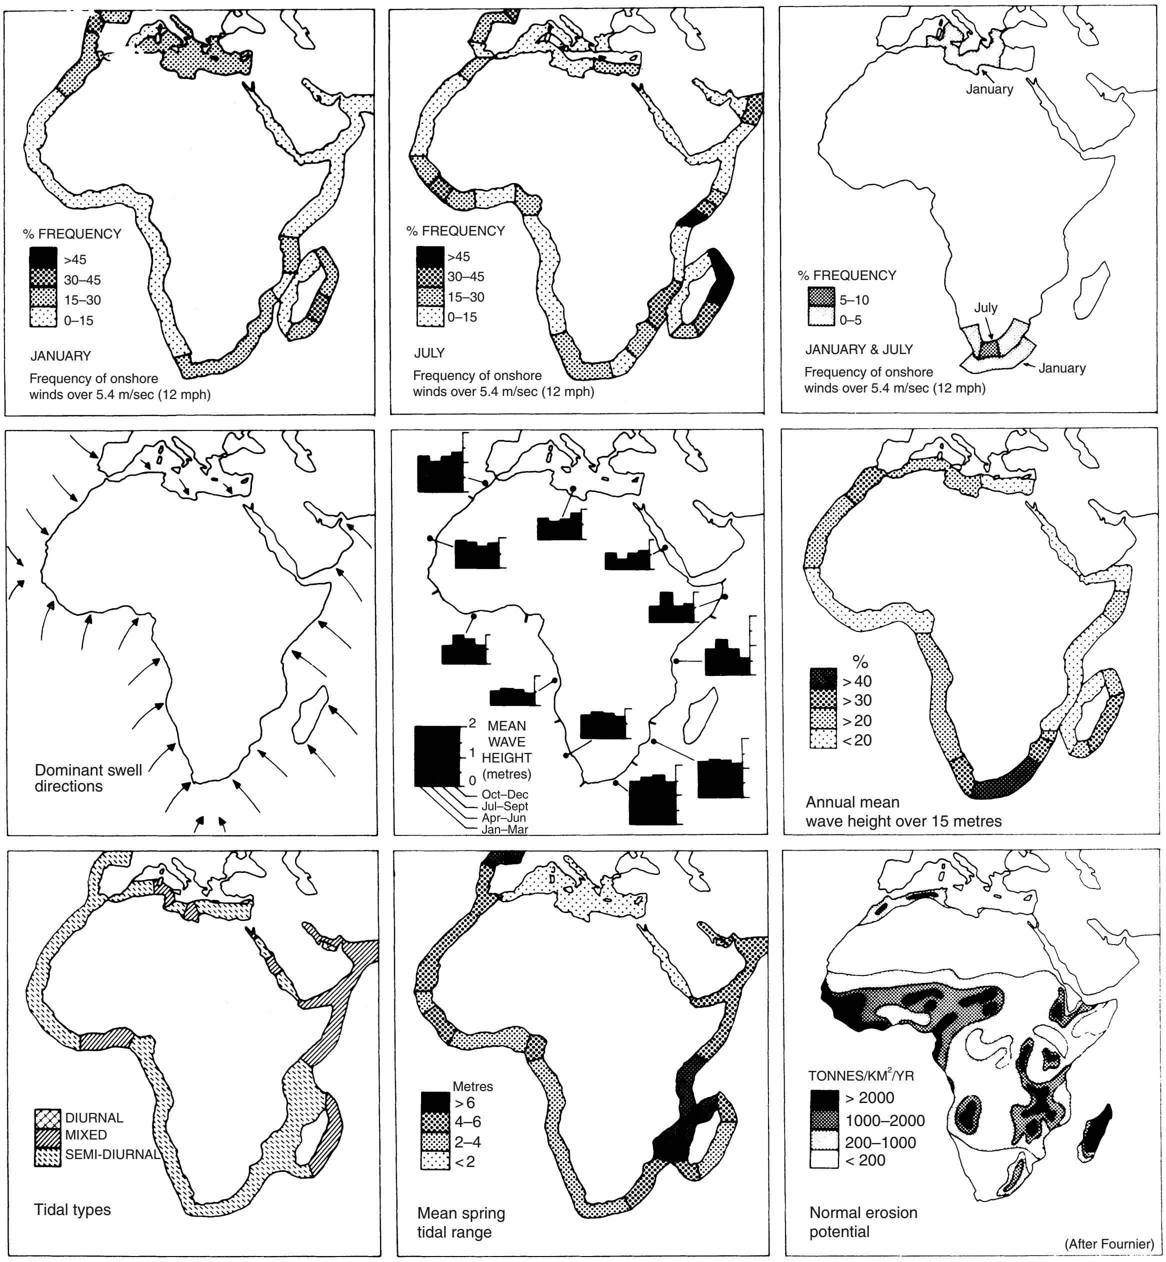

Figure A7 Selected processes affecting the African coast (in part after Hayden *et al.*, 1973; Davies, 1977; from Orme, 1982, with permission of Kluwer Academic Publishers).

offshore by the Guinea and Benguela Currents. Exceptions to these patterns occur in the lee of major promontories such as the Niger delta. Throughout the Atlantic coast, wave erosion and longshore sediment transport are strongest and most frequent when swells are highest—from December to March north of Cape Vert, and from June to September farther south (Davies, 1977).

Along the east coast, from Cape Agulhas to Ras Asir, most swells also originate from the southwest but are strongly refracted to reach the coast from the southeast (Figure A7). This circulation is further complicated by reversing monsoonal winds and currents off Somalia, by westward-moving cyclones and tropical easterlies off Madagascar, and by the south-flowing Agulhas Current farther south. Under the influence of the southwest monsoon, for example, the Somali Current reaches surface velocities of 3.7 m s^{-1} and the uppermost 200 m of its water column transports 60×10^6 m^3 s^{-1} northward. Along the KwaZulu coast, littoral transport of coarser terrigenous sediment is commonly northward within the surf zone, but finer sediment that is flushed farther seaward is carried south with the Agulhas Current (Orme, 1973). Onshore winds are stronger and more frequent during the southern winter, when winds exceeding 60 km hr^{-1} may drive powerful surf against the continent's southern tip.

Highest wave energy occurs around the southern tip, from Cape Point to Durnford Point, and moderately high wave energy prevails from the Orange to Limpopo river mouths, along Madagascar's east coast, and along Morocco's Atlantic coast (Figure A7). Lower wave energy occurs in the Red Sea, the Mozambique Channel, the Gulf of Guinea, and eastern Mediterranean.

Semidiurnal tides predominate around Africa, with mixed regimes confined to the central Mediterranean, Red Sea, Guinea, Somali, and eastern Madagascar coasts (Figure A7). Mean tidal range is less than 2 m throughout the Red Sea and Mediterranean, over 6 m along the Mozambique Channel, and 2–6 m elsewhere.

Hydrologic factors

The continent's hydrologic regimes are important because they deliver freshwater and sediment to the coast, which in turn influence coastal ecology and sediment budgets (Orme, 1996; Walling, 1996). Sediment delivery is highest in areas of rugged relief and/or high rainfall, at least seasonally (Figure A7). Thus, the many small rivers that drain steeply from the mountains of Algeria and Morocco to the Mediterranean may have only modest sediment loads but large sediment yields per unit area of their basins, often >1,000 tonnes (t) $km^{-2}\,yr^{-1}$ (Milliman and Syvitski, 1992). Sediment yields may also be high where open forest or savanna vegetation has been modified or destroyed by human activity, for example, along the coast of Guinea, east Africa, and Madagascar. Sediment yields are lower where luxuriant vegetation inhibits surface erosion or where rivers have long run-out reaches across coastal lowlands, and lowest where heavy rainfall is lacking, notably in desert areas.

Most larger rivers have lower sediment yields because they often cross different climatic regimes and broad floodplains, both of which afford opportunities for floodplain storage. However, because their drainage basins are large, they may deliver substantial sediment loads to the sea annually. Thus, the Congo and Limpopo, respectively, carry average loads of 43×10^6 t and 33×10^6 t to the sea annually (Milliman and Syvitski, 1992). Of particular importance to the present coast are the reduced sediment loads in rivers that have been dammed upstream. Thus the Orange, which formerly transported 89×10^6 t of sediment annually, now moves only 17×10^6 t to the sea. The Zambezi, which once transported 48×10^6 t annually, now carries only 20×10^6 t, largely owing to construction of the Cabora Bassa Dam upstream. Most dramatically, annual sediment loads from the Nile and Volta, formerly 120×10^6 t and 19×10^6 t, respectively, have diminished to virtually zero as a result of construction of the Aswan High Dam (completed 1964, capacity $162 \times 10^6\,m^3$) and earlier structures on the Nile, and of the Akosombo Dam (1961) on the Volta. These structures have major consequences for coastal sediment budgets.

Despite high sediment yields from seasonally wet areas and high sediment loads from many larger undammed rivers, Africa's vast internal drainages and the relatively aridity and low gradient of most external basins restrict sediment yields to the coast (Walling, 1996). Thus, compared with other continents, direct wave attack on coastal cliffs and carbonate reefs is a more important source of sediment. Further, the wide extent of seasonally dry climates means that, for much of the year, ocean processes predominate over fluvial processes around river mouths. Thus, many mouths are closed during drought and partially blocked by coastal barriers at other times.

Human factors

Although the African coast has suffered less from human activity than that of Europe or North America, some historic impacts are noteworthy and the rate of human-induced change has accelerated in recent decades. Apart from the construction of major dams inland, noted above, land-use practices inland have often led to extensive soil erosion and increased sediment yields (Stocking, 1996). In Kwa-Zulu, for example, recent sediment yields are two to three times the average for the past 5,000 years, owing in large measure to overgrazing and accelerated erosion in coastal basins (Orme, 1973). Along many parts of the African coast, increased sediment yields have clogged estuaries while sediment plumes have been worked onshore to form new beach-dune ridges. Conversely, along Somalia's east coast, Pleistocene dunes have been reactivated and gullied by overgrazing of vegetation by cattle, goats, and camels, aggravated by tillage practices of an increasingly desperate refugee population (Orme, 1985). Elsewhere, beaches and dunes have been mined for diamonds and heavy minerals, respectively, while beaches and wetlands near major ports have been consumed by harbor and urban development. Pollution and recreation are also beginning seriously to impact coral reefs in east Africa.

The Mediterranean coast

Africa's 5,000-km long north coast is divisible into two contrasting segments (Figure A8). The 3,300 km eastern segment from Sinai to the Gulf of Gabes features low cliffs of little deformed Cenozoic sedimentary rocks interspersed with barrier beaches, lagoons, and dunes. The 1,700 km western segment from Cape Bon to Cape Spartel reflects Alpine tectonism in its rugged coastal mountains and deep coastal basins. Throughout this coast, prevailing northwest winds generate northwesterly swells and wind waves, strongest in winter, which in turn promote net littoral drift eastward. With a mean tidal range of 0.2–0.5 m, but 1.8 m in the Gulf of Gabes, tidal forcing is weak. Wave energy, littoral drift, annual rainfall, and fluvial sediment inputs, diminish eastward.

The 12,500 km^2 Nile delta fronts 280 km of the Egyptian coast. Although fluvial sediment rich in Fe and Al from the Ethiopian Highlands may still be found in beaches east of the delta, water and sediment delivery by the Nile have been much reduced by irrigation diversions and dams built since the 1880s. Of the six or more distributaries used by the Nile some 2,000 years ago, only the Damietta and Rosetta branches still function. Further, because longshore currents continue to move sediment eastward, the delta's seacoast is suffering severe erosion, at rates up to 60 m yr^{-1}, leaving high-density magnetite, ilmenite, zircon, and garnet as black-sand placers while moving lighter minerals downdrift (El-Ashry, 1985; Frihy and Komar, 1991). A 40 km deep littoral zone, the *barari* (barren) fronts the delta, comprising barrier beaches and back-barrier marshes, salt flats, and lagoons of which the largest are Manzala (1,450 km^2) and Burullus (560 km^2). Over the past 8,000 years, delta subsidence has ranged from 1 mm yr^{-1} near Alexandria to 5 mm yr^{-1} near Port Said (Stanley, 1990). During historic time, while delta subsidence was offset by sedimentation, coastline location did not change much but, with sediment delivery now curtailed, several areas have subsided to below sea level. Farther east, the Sinai coast is a broad sandy plain with bold dunes and a 100 km long, 500 m wide barrier beach fronting Bardawil Lagoon along whose shallow hypersaline margins gypsum and halite readily precipitate. The ephemeral Wadi el Arish is the only sizable stream course to reach this coast.

Westward from the delta, dark Nile sediment is replaced by carbonate grains from local sources. Several beach-dune ridges backed by elongate sabkhas parallel the coast, reflecting episodic barrier formation during late Quaternary time. In Cyrenaica, the Jebel el Akdar limestone plateau generates higher rainfall and greater surface runoff, and reaches the coast in rocky cliffs and narrow terraces that leave little room for coastal plain. From Benghazi to Cape Bon, the coast is again dominated by barrier beaches, dunes, sabkhas, and salt marshes. The 150 km^2 Sabkha el Melah in southern Tunisia exemplifies Holocene evaporite sedimentation in which marine detrital limestones, euxinic beds, magnesium carbonates, gypsum, polyhalite, and halite have successively accumulated over the past 6,000 years (Busson and Perthuisot, 1977).

From northern Tunisia westward, coastal character changes as mid-Cenozoic (Atlas) and neotectonic structures form prominent cliffs, marine terraces, and subsiding basins, and as the seasonally wetter, stormier climate mobilizes coastal and fluvial sediment. Quaternary tectonic and eustatic forces are reflected in suites of deformed marine terraces rising to over 200 m above sea level near Monastir and Bizerte, and in 400 m of littoral sediments beneath the subsiding Medjerda delta whose outlet has changed frequently in response to historic floods (Paskoff, 1978). Farther west, along the Algerian Tell and Moroccan Rif, structural basins floored with Quaternary sediment open through swampy lowlands into Skikda, Bejaia, and Arzew Bays. Wadis discharge abundant sediment to the coast in winter, to be partly reworked onshore in aeolian dunes. The Isser and Soummam rivers have a mean yield of 6.1×10^6 and 4.2×10^6 t yr^{-1}, respectively, while sediments carried by the Moulouya from the High Atlas contribute to impressive shingle beaches east of Nador, Morocco. Alpine massifs up to 1,000 m above sea level reach the shore in active sea cliffs involving crystalline basement, Mesozoic limestones and sandstones, and Cenozoic molasse and volcanic rocks, and then descend across a narrow shelf down the 2,000 m Habibas submarine escarpment.

The Atlantic coast

The Atlantic coast of Africa may be divided into three segments: the semiarid to arid coast from Cape Spartel to Cape Vert characterized by the cool Canaries Current, northwesterly swells and south-flowing littoral drift; the humid tropical coast from Cape Vert to beyond the Congo River, dominated by the Guinea Current, southerly swells and east-flowing littoral drift; and the sub-humid to arid coast from Angola south to the Cape characterized by the cool Benguela Current, southwesterly swells and strong north-flowing littoral drift (Figure A9).

From Cape Spartel to Cape Dra, the Moroccan coast is underlain by Hercynian and mid-Cenozoic structures that have been planed off by later marine erosion, forming the Pliocene Moghrebian *rasa* and sequences of Pleistocene marine terraces, all since deformed. The continental margin offshore has seen episodic sedimentation and subsidence since the break-up of Gondwana. Winter floods transport large sediment loads from the Atlas Mountains down the Sebou, Rharb, Sous, and other rivers to feed beach-dune complexes up to 80 m high which, shaped by northwest winds in winter and northeast trade winds in summer, enclose many lagoons and sabkhas.

From Cape Dra to Cape Vert, the coast overlies the Tarfaya and Senegal structural basins whose post-Gondwana cover rocks, planed by episodic marine transgressions, form low coastal cliffs and a relatively smooth continental shelf. Saharan sands blanket this coast along a broad front. Extensive late Cenozoic dune systems show that aeolian processes have long dominated the region. Saharan sands are driven seawards by the

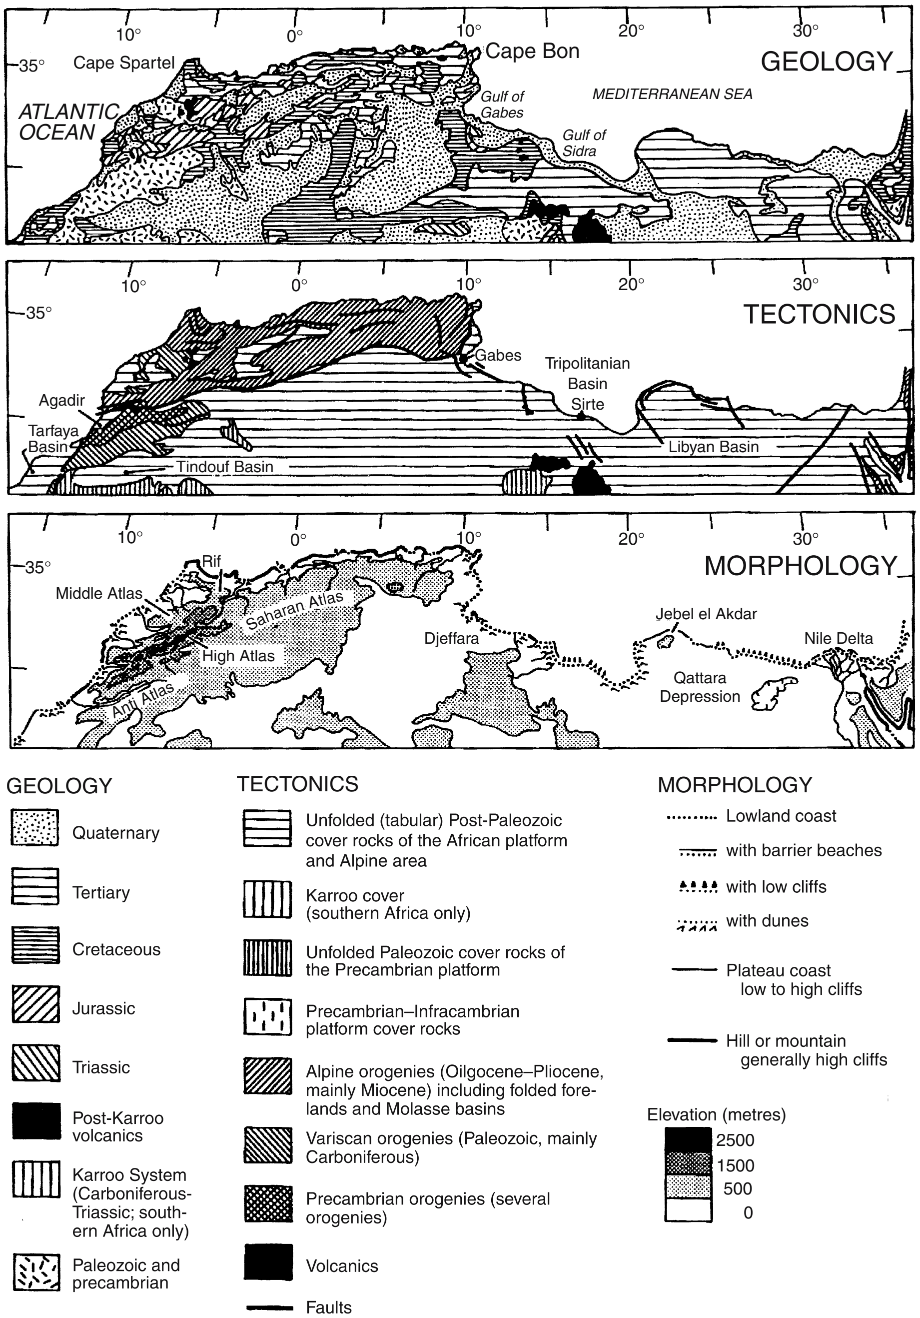

Figure A8 The Mediterranean coast: geology, tectonics, morphology (from Orme, 1982, with permission of Kluwer Academic Publishers).

irifi, a hot easterly wind, to form the great red *draas* and superimposed barchans that trend obliquely across the Mauritanian coast between Cape Blanc and the Senegal River, notably in the Azefal and Akchar ergs (Kocurek *et al*., 1991). The Sahara now contributes 13×10^6 m^3 of quartz sand to the continental shelf annually, but this amount may have been much larger in the past (Sarnthein and Walger, 1974). Late Pleistocene aeolianites occur to at least -50 m off Cape Vert while Saharan dust is found in deep ocean sediments far beyond the shelf. Coastal sands are reworked onshore by the *alisio*, a persistent northerly wind, to form dunes ridges up to 2,000 m wide and 40 m high, which in turn trap sabkhas (*niayes*) seaward of Saharan draas in Mauritania and Senegal. Lacking rainfall and a mountain backdrop, stream flows and fluvial sediment discharge are now negligible, except during rare rain storms, along the coast between Cape Dra and the Senegal River, but relict fluvial sediments on the continental shelf, including detrital phosphatic placers derived from onshore phosphorites, show that fluvial processes were more important during Pleistocene time.

The 4,250 km^2 Senegal delta forms the outlet for a 196×10^3 km^2 drainage basin whose mostly summer rains average 1,381 mm annually. Despite significant evaporative loss, annual discharge through the delta averages 870 m^3 s^{-1}, ranging from negligible during prolonged drought to 3,700 m^3 s^{-1} during floods (Guilcher, 1985). The delta formerly entered a bay created by the Flandrian (Nouakchottian) transgression but, as the delta plain accreted, marine processes deflected the river mouth 120 km southward behind a massive barrier spit. The distal end of this barrier, the unstable 30 km long Langue de Barbarie, has been breached 25 times by storm waves or river floods since 1850. Although spring tidal range is only 1.2 m, the low gradient of the Senegal River allows tidal influences to penetrate over 400 km upstream. Southward littoral drift along the open coast ranges from 0.5×10^6 to 1.0×10^6 t yr^{-1}, part of which is lost down Kayor submarine canyon off Cape Vert.

From Cape Vert to the Niger delta, cliffed coasts formed in Precambrian basement and Phanerozoic sedimentary rocks alternate with lowlands underlain by Cretaceous and Cenozoic sediments and

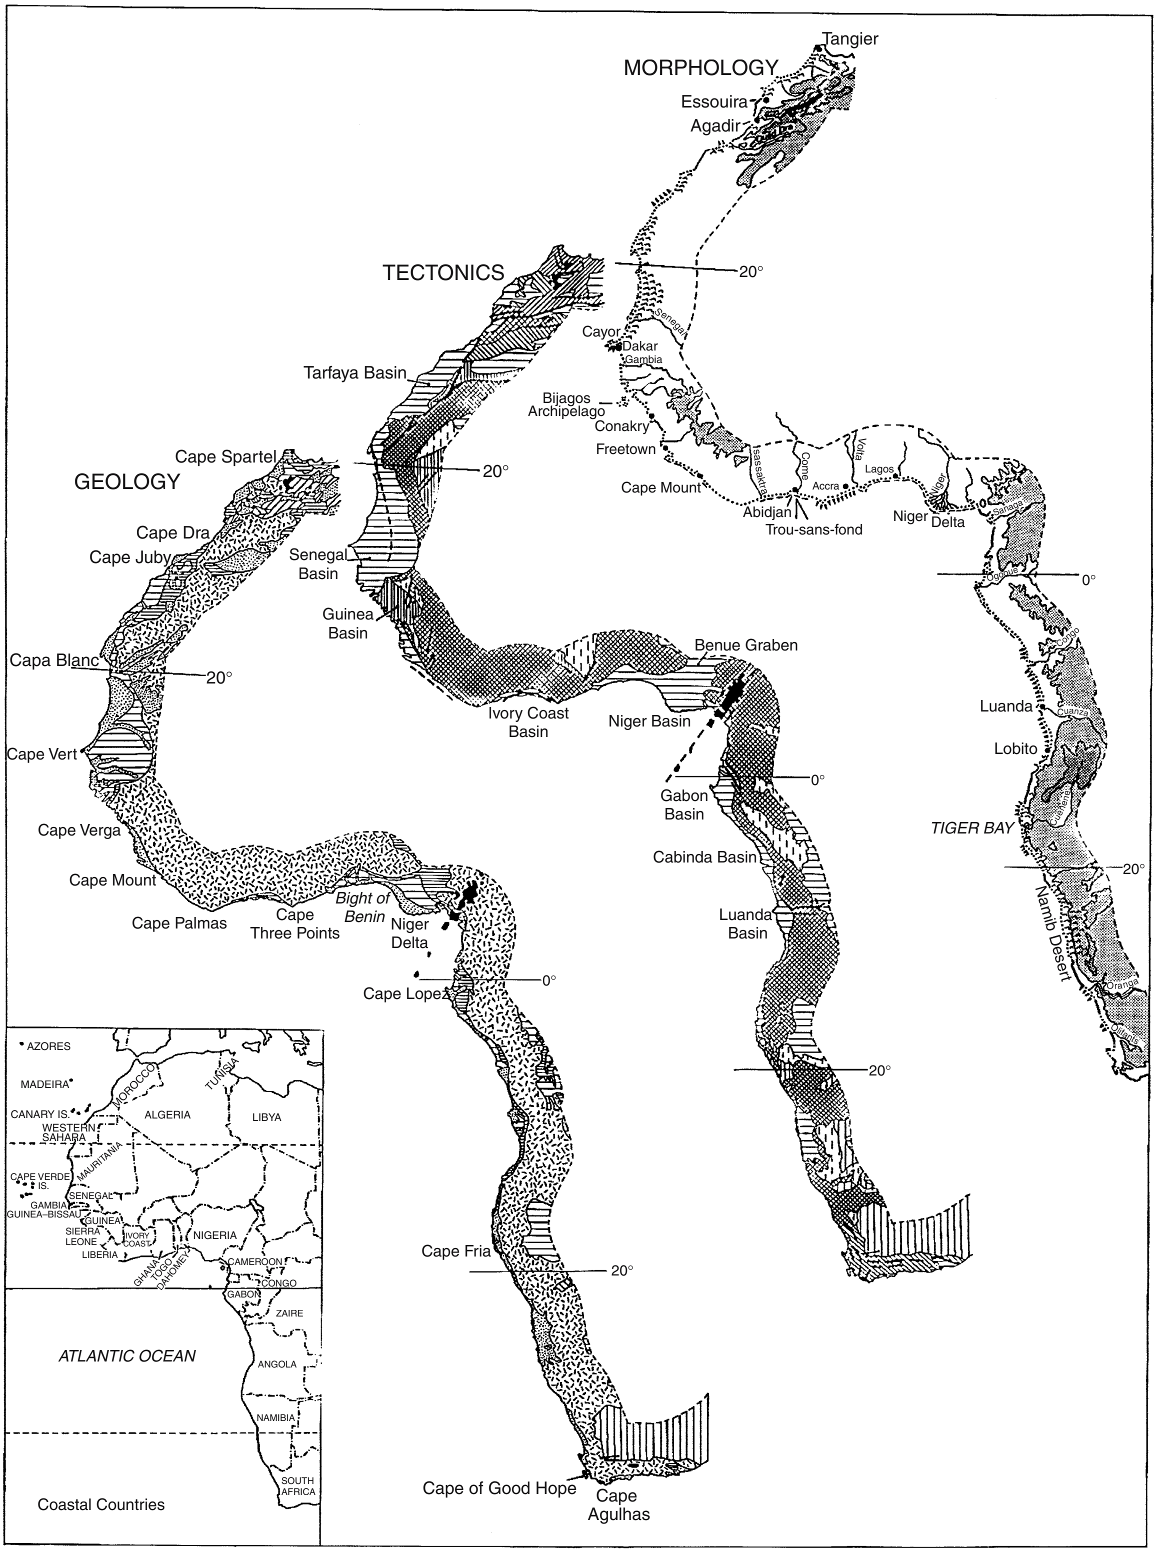

Figure A9 The Atlantic coast: geology, tectonics, morphology (see Figure A8 for key) (from Orme, 1982, with permission of Kluwer Academic Publishers).

fronted by beach ridges and mangrove swamps. Paleozoic rocks emerge along the south coast of Guinea-Bissau and at Cape Verga; basic intrusives form the Kaloum and Freetown peninsulas; Precambrian granite and gneiss underlie the coasts of Liberia and western Ivory Coast, and reappear with Paleozoic sandstone in low cliffs from Cape Three Points nearly to the Volta delta. In contrast, the subsiding and downfaulted Ivory Coast Basin and the larger Niger Basin are underlain by great thicknesses of Cretaceous and Cenozoic sediment overlain by coastal barriers, lagoons, and swamps.

The southwest-facing coast between Cape Vert and Cape Palmas, tropical rains of 2,000–3,000 mm yr^{-1}, enhanced by inland relief and southwest winds drawn onshore during the northern summer, is reflected in abundant discharge of water and sediment from short coastal rivers. Broad deltaic estuaries, such as those of the Casamance, Geba, Konkoure, and Scarcies rivers, reach the sea through intricate networks of tidal creeks, mangrove swamps, and supratidal mudflats or *tannes*. While most estuaries remain open throughout the year, barrier beaches locally front coastal swamps and lagoons in southern Sierra Leone and Liberia. Modern beaches and Holocene beach ridges farther inland, notably on Sherbro Island and the Turner Peninsula testify to abundant sediment supplies, powerful onshore swells, and seasonally reversing littoral drift. Offshore, the continental shelf ranges from 200 km wide on the shallow Great Geba Flat around the Bijagos Archipelago to <20 km wide at Cape Palmas. This shelf contains many submerged river channels, deltas, coral reefs, and shoreline sequences to depths of -90 m, all evidence of low Pleistocene sea levels (McMaster *et al*., 1971). Fine sediment is readily swept southward across shelf by the surface Canaries Current and tidal ebb currents, and then returned northward by strong bottom countercurrents.

East from Cape Palmas, the south-facing Guinea coast causes south-westerly swells to promote east-flowing littoral drift, aided for fine sediment by the Guinea Current. Littoral drift reflects sediment availability. Thus, resistant Precambrian rocks east of Cape Palmas and again east of Cape Three Points restrict littoral drift to around 0.2×10^6 m^3 yr^{-1} but, where Cenozoic basinal and recent fluvial sediments reach the coast east of Fresco and again east of Accra, littoral drift reaches 0.8×10^6 m^3 yr^{-1}, forming massive barrier beaches across the mouths of many rivers. Where sediment supplies have been curtailed, notably by construction of the Akosombo Dam (1961) across the Volta River, or where littoral drift is interrupted, for example, by jetties off the Vridi Canal and Lagos Harbor, downdrift beach erosion occurs. Offshore, the continental shelf is relatively narrow (10–70 km) and featureless but exceptions occur in the Trou-sans-Fond, a massive submarine canyon that heads at -10 m off Abidjan but descends to $-2{,}000$ m and traps 4,000,000 m^3 yr^{-1} of littoral drift; the large Volta submarine delta; and submerged beach–aeolianite ridges that indicate a late Pleistocene regression to the shelf edge at -120 m.

The Niger delta is the outlet for a 1.11×10^6 km^2 drainage basin whose main artery, the 4,460-km Niger River rises in the Guinea Mountains only 250 km from the Atlantic. Following mid-Cretaceous separation of South America from Africa in this locality, and subsequent crustal adjustments and sea-level changes, the delta began forming in Eocene time when the coastline lay near Onitsha, 250 km inland from the present coast. The basin began acquiring its present form during a later Pleistocene pluvial stage when the NE-flowing Soudanese Niger overflowed into the SE-flowing Nigerian Niger. The Flandrian transgression later drowned the outer 50 km of the delta's late Pleistocene distributary system. The delta now comprises 500,000 km^3 of Eocene–Holocene sediment, up to 8 km thick, and covers 28,827 km^2, of which two-thirds lie above sea level (Hospers, 1971). Present annual discharge of freshwater into the delta is about 200×10^9 m^3 and of sediment about 18×10^6 m^3, mostly as silt and clay that radiate unequally through a dozen major distributaries into the Gulf of Guinea. Depositional environments and sedimentary facies are distributed concentrically within the delta (Allen, 1970). The deltaic plain comprises upper and lower floodplains, tidal creeks, and mangrove swamps fronted by barrier beaches. The submerged delta comprises river-mouth bars, delta-front ramps, pro-delta slope, open shelf, and relict Pleistocene littoral deposits. Prevailing southwesterly swells strike symmetrically against the nose of the delta, promoting divergent littoral drifts east toward the Cross River and west toward the Benin River. Submarine canyons channel about 1×10^6 m^3 of sediment from these drifts into fans beyond the delta foot. The delta mass is broken by arcuate gravity faults downthrown toward the gulf and also affected by compaction and subsidence of its constituent sediments, aggravated in recent years by extensive subsurface oil and gas withdrawal. Subsidence and mangrove clearance have in turn increased erosion to 40 m yr^{-1} along the exposed muddy coast northwest of the Benin River (Ebisemiju, 1987).

The west-facing coast of Africa south of the Mount Cameroun volcanic pile (4,070 m) comprises several post-Gondwanan basins containing Cretaceous and Cenozoic sedimentary and volcanic, rocks separated by Precambrian basement, all variably mantled by recent marine, fluvial, and aeolian deposits. The Niger Basin extends through the Cameroun volcanics into the swampy and deltaic Sanaga coastal plain. The Gabon Basin is fronted by barrier-lagoon complexes and north-oriented spits terminating at Cape Lopez. In contrast, the Cabinda Basin has active sea cliffs north and south of the Congo estuary. South of Precambrian outcrops near Ambriz, the Luanda Basin is fronted in part by 100–150 m sea cliffs cut in Cretaceous and Cenozoic rocks and in part by *restingas*, north-oriented barrier spits enclosing bays and lagoons, notably the Luanda spit (12 km long), Lobito spit (9 km long), and the spit enclosing Tiger Bay (37 km long, before breaching in 1962; Guilcher *et al*., 1974). These barrier spits form in response to powerful southwesterly swells and predominant north-flowing littoral drift. However, littoral processes are incapable of closing the mouth of the Congo River where powerful discharge annually jets up to 50×10^6 m^3 of sediment seaward into a submarine canyon, denying most of this load to the littoral drift. This submarine canyon descends to $-2{,}700$ m before spilling across an abyssal fan with leveed distributaries to $-4{,}900$ m.

Farther south, although Precambrian basement and Cretaceous basalts form cliffs locally, the coast from southern Angola through Namibia to northern Cape Province is largely mantled by relict and active coastal dunes, including the Kunene Sand Sea and the 400 km long Namib Sand Sea (Lancaster, 1996), and by relict alluvial fans. The perennial Kunene River along Namibia's northern boundary sheds much terrigenous debris onto the continental shelf. Similarly, the Orange River along the country's southern border, though blocked by sand during the dry season, has long been the source of the beach and dune sand that moves north with the dominant southwesterly winds and swells, prograding the coast and deflecting the mouths of the Swakop and Kuiseb rivers. The diamantiferous marine-terrace deposits of the Sperrgebeit, ranging from 90 m above to -60 m below sea level, originate from switching late Cenozoic outlets of the Orange River. The shelf here varies from <30 km wide off rocky coasts to >160 km wide where terrigenous Orange River sediments have built a broad submarine delta. Where aeolian sand seas block lesser streams, however, shelf sediments are composed mainly of diatomaceous muds, foramineriferal sands, and skeletal clasts.

The southern tip

Between the Olifants and Tugela rivers, strong southerly swells and winter storms have fashioned a rugged cliffed coast interspersed with sandy bays from Precambrian and Paleozoic rocks of the Cape Fold Belt (280–230 Ma) and the thick formations of the Karroo Supergroup. Thus, massive sandstone-on-granite cliffs of the Cape Peninsula are separated from fold mountains farther east by the broad dune-mantled Cape Flats. From Cape Agulhas to Algoa Bay, the coast cuts across the easterly strike of the Cape Fold Belt, causing cliffed anticlinal ridges to alternate with synclinal corridors fronted by barrier beaches and extensive dunefields. In the Alexandria Basin, a transverse dunefield is moving inland along a 50 km wide front driven by WSW winds off Algoa Bay. Sand enters this dunefield at a rate of 375,000 m^3 yr^{-1} and leaves at 45,000 m^3 yr^{-1} for a net gain of 330,000 m^3 yr^{-1} (Illenberger and Rust, 1988). Farther northeast, gently tilted rocks of the Karroo Supergroup are exposed in majestic cliffs fronting coastal plateaus.

Quaternary marine terraces rise at intervals to over 60 m along this coast, while beachrock, related to both high interglacial and Holocene sea levels forms a broken pavement along much of the immediate shore. Beachrock typically consists of quartz sand and shell fragments cemented by micrite or aragonite overlain by laminated calcrete. Relict beachrock and aeolianite are often exposed along the coast and also form submerged ridges offshore (Figure A10). Off Cape Agulhas, the continental shelf forms the 240 km wide Agulhas Bank, relatively featureless except for the shelf edge between -110 and 380 m which is cut by several canyons. The bank is formed from over 6,000 m of post-Gondwanan sediments lying on basement rocks and, during low Pleistocene sea levels, was exposed over 22,500 km^2 (Dingle, 1973).

Compared to Africa's great rivers, the Gourits, Sundays, Great Kei, Mtamvuna, and other rivers are relatively short but, in descending swiftly from the Cape fold mountains and the Great Escarpment, they transport large sediment loads seasonally (Figure A11). In the Mediterranean-type climate of Cape Province, maximum flows occur in the southern winter (May–August) but farther north, in Natal-Kwa-Zulu, summer (December–March) thunderstorms are more important. Rivers draining the bold Drakensberg (3,482 m) enter the sea through Pleistocene channels excavated to -100 m below sea level, now partly filled with Holocene estuarine sediment (Orme, 1974, 1976; Cooper, 1993). Over the past 200 years, sediment yields have been accelerated by soil erosion but diminished by dam construction.

The Indian Ocean coast

Africa's mostly low-lying east coast, from the Tugela estuary to Ras Azir, straddles post-Gondwanan coastal basins filled with several thousand meters of Mesozoic and Cenozoic sediments the 4,000 m deep Mozambique Basin in the south, characterized by north–south faults at the south end of the East African Rift system, and the 3,000–8,000 m

Figure A10 Pleistocene raised beach deposit overlying Pleistocene aeolianite, Durban Bluff, South Africa (from Orme, 1982, with permission of Kluwer Academic Publishers).

Figure A11 Mtamvuna river mouth and wet (summer) season sediment plume, Transkei-Kwa-Zulu border (photo: A.R. Orme).

deep Dar es Salaam–Kenya–Somali Basin continuum farther north (Figure A12).

The onshore portion of the Mozambique Basin forms a coastal plain 300 km wide in central Mozambique but pinches out southward near the Tugela estuary and northward at Mocambo Bay. Its 2,100 km-long shoreline is characterized by long barrier beaches topped by parabolic and lobate dunes up to 180 m high, behind which lie shallow lagoons, extensive swamps, old coastal barriers, and extensive aeolian cover sands (Orme, 1973). In Kwa-Zulu, the massive coastal barrier, although veneered with Holocene sands, is superimposed upon remnants of a major late Pleistocene barrier-lagoon complex, the Port Durnford Formation, whose nearshore, beach, and swamp facies were probably deposited during the last interglacial around 125 ka (Figure A13; Hobday and Orme, 1975). A similar scenario seems likely along much of the Mozambique coast. The

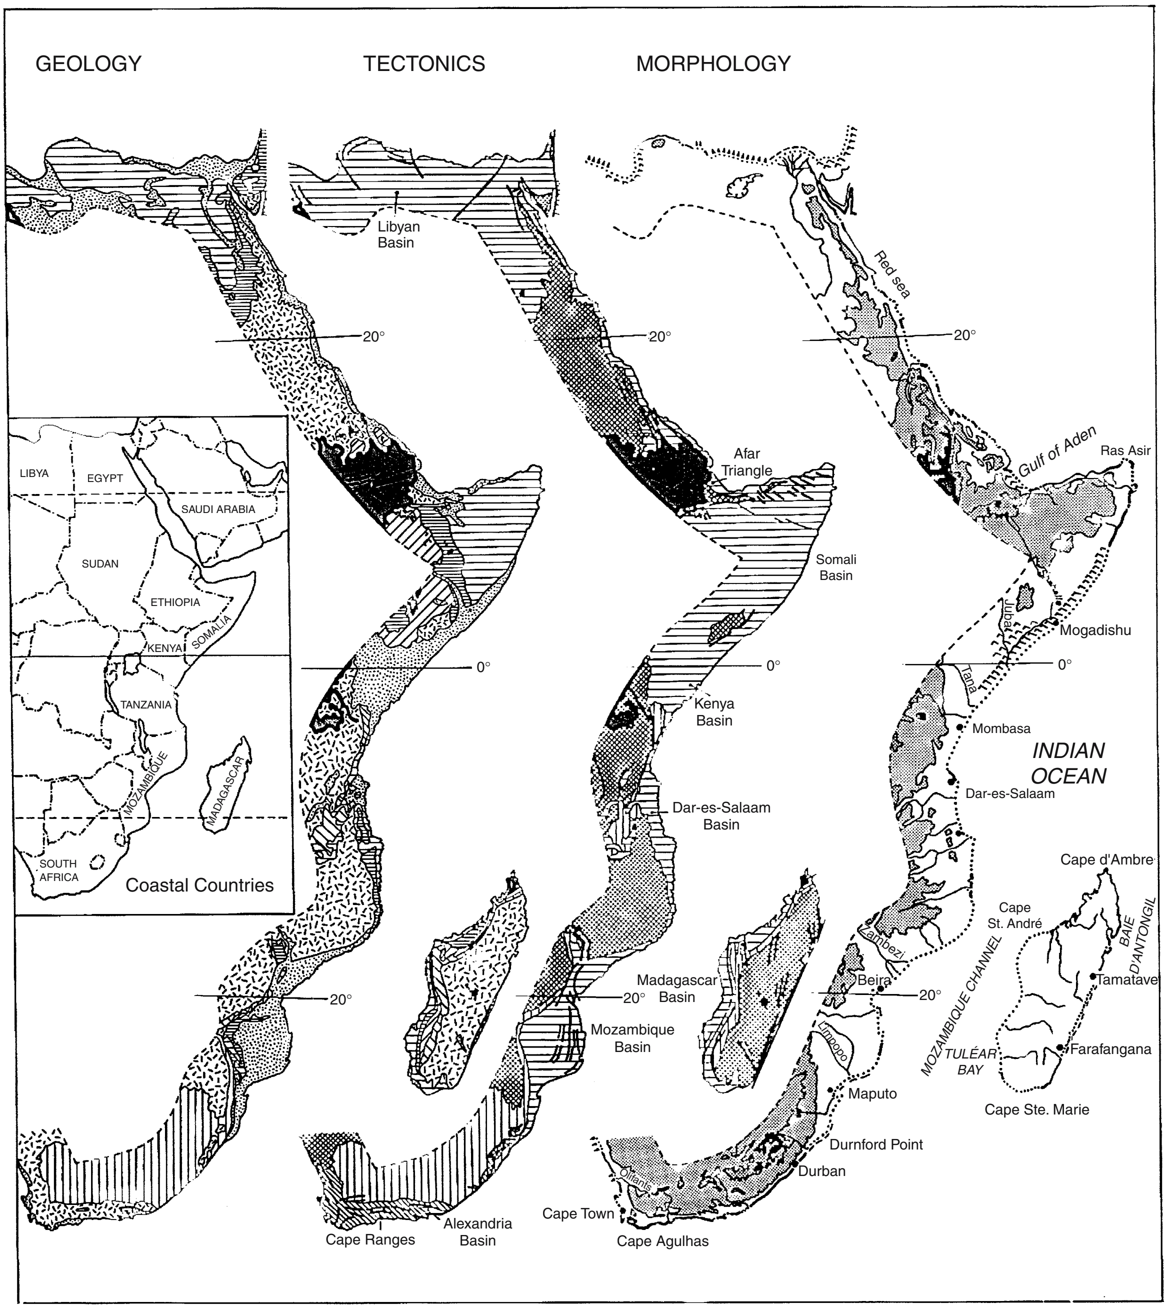

Figure A12 The Indian Ocean and Red Sea coasts: geology, tectonics, morphology (see Figure A8 for key (from Orme, 1982, with permission of Kluwer Academic Publishers).

older coastal barrier was subsequently breached by rivers draining to lowered late Pleistocene sea levels and then invaded by the Flandrian transgression, for example, forming Lake St. Lucia in Kwa-Zulu and Delagoa Bay behind Inhaca Island in Mozambique (Figure A14). Late Pleistocene estuaries excavated to more than -55 m below sea level are now choked by complex sequences of Holocene marine, estuarine, and fluvial sediment (Orme, 1974, 1976). Offshore, beachrock and aeolianites towards the edge of the continental shelf testify to the magnitude of late Pleistocene drawdown.

Shorezone dynamics along the coast of the Mozambique Basin are conditioned by prevailing northeasterly and southwesterly winds, by powerful swells from the Southern Ocean, by longshore currents up to $2\ \mathrm{m\,s^{-1}}$, by reversing coastal flows related to the Agulhas Current that parallel the shore with surface velocities up to $0.8\ \mathrm{m\,s^{-1}}$, and by seasonally high discharges from coastal drainage basins. The Tugela River brings 10.5×10^6 t of sediment to the coast annually and its sediment plume, like those of neighboring rivers, may be traced far out into the Agulhas Current. Owing to unwise land use and increased erosion inland, recent sediment delivery rates to the coast have greatly exceeded prehistoric rates, leading, for example, to accelerated beach-ridge and dune formation north of the Tugela estuary (Figure A15). The 7,150 $\mathrm{km^2}$ Zambezi delta forms the outlet for a $1.33 \times 10^6\ \mathrm{km^2}$ savanna drainage basin and a 3,540 km mainstream. Discharge through the delta averages 7,000 $\mathrm{m^3\,s^{-1}}$, and sediment that is not trapped within coastal swamps and lagoons, or transported coastwise as littoral drift, is flushed over the continental shelf onto the Zambezi cone. North of the Mozambique Basin, from Mocambo Bay to Kisware Bay, faulted Cretaceous and Cenozoic rocks underlie an embayed cliffed coast fronted by raised coral bluffs and fringing reefs. The continental shelf here is often only a few hundred meters wide, plunging to $-2{,}500$ m within 10 km of the shore.

The coastal zone of Tanzania and Kenya comprises numerous, deformed and faulted Pleistocene marine terraces supporting relict

Figure A13 Port Durnford Formation, Kwa-Zulu, showing basal fossiliferous interglacial swamp peat overlain by transgressive beach sands, buried beneath weathered aeolianites (photo: A.R. Orme).

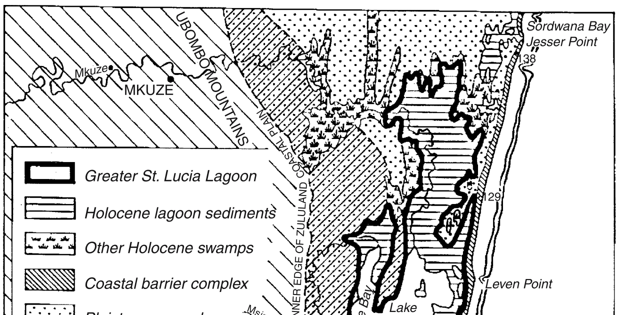

Figure A14 Greater Lake St. Lucia lagoon, Kwa-Zulu, on the site of a late Pleistocene barrier–lagoon complex, was reformed by the Flandrian transgression and has since been largely filled with Holocene lagoonal sediment.

barrier beaches and coral reefs, as well as active Holocene barrier beaches, mangrove swamps, offshore bars, and coral reefs. Three late Quaternary beach ridges surmount the lowest terrace between Dar es Salaam and Tanga, reflecting an abundant sediment supply worked onshore by strong swells, modified by wind action, and then stabilized by vegetal growth (Alexander, 1968). Raised coral reefs rise to 140 m along the Kenya coast but their margins are often obscured where cliffing was inhibited by the presence of wide lagoons and coral growth during marine regressions (Hori, 1970). The offshore islands of Zanzibar (1,660 km^2), Pemba (984 km^2), and Mafia are also relict coralline structures. All three islands are defined eastward by massive faults and Pemba is separated from the mainland by a 700 m deep graben. The Rufiji River, draining a 0.18×10^6 km^2 drainage basin, transports an average sediment load of 17×10^6 t to the sea annually (Milliman and Syvitski, 1992).

From the Tana River for 1,600 km northward to Gifle in Somalia, although fringing reefs persist, the coast is dominated by massive aeolian deposition promoted by semiarid conditions, strong monsoon winds, and episodic supplies of fluvial sediment. The Tana delta is blocked seaward by dunes, while complex Quaternary dune complexes up to 200 m high have deflected the Shebele River for 400 km parallel with the present coast, allowing it to reach the sea through the Juba estuary only after heavy rains (Orme, 1985). Paleodunes along this coast have been widely destabilized and gullied as a result of overgrazing and poor tillage practices, most recently by a population swelled by refugees from strife farther inland. Dune stabilization efforts have so far met with only limited success. From Gifle to Ras Asir, Cenozoic carbonate rocks form rocky marine terraces and sea cliffs 100–300 m high. The 1,100 km long *guban* (sunburnt plain) coast of the Gulf of Aden is partly cliffed, partly backed by alluvial plains, sabkhas, and marine terraces. Thick Plio-Pleistocene marine sequences and coral reefs raised 180–280 m above sea level around Berbera emphasize the recent tectonic emergence of this coastal zone. No perennial rivers reach Africa's east coast north of the Shebele River.

Madagascar

The coast of Madagascar reflects the structural and topographic asymmetry of this large island. The linear, fault-controlled east coast is broken by only one major embayment, the Baie d'Antongil graben (Figure A14). Basement rocks plunge from 2,000 m highlands onto a narrow coastal plain and shelf underlain by Cretaceous sediments. Persistent southeast trade winds, storms in the Southern Ocean, high average wind velocities, and west-moving cyclones from December to March all promote strong wave action. In response, barrier beaches and shallow linear lagoons have formed along 800 km of coast from Fénérive southward to Port Dauphin. These lagoons, separated from one another by low rises or *pangalanes*, are used by coastwise traffic.

In contrast, the west coast fronts a broad alluvial lowland underlain by thick post-Gondwanan sediments and the shelf widens to 150 km off

Figure A15 The Tugela River drains the east face of the Drakensberg and much of Kwa-Zulu. Driven by prevailing southerly swells, its sediment plume provides abundant material for coastal beach and dune formation farther north (photo: A.R. Orme).

Cap St. André and on the Leven Bank. Along the northwest coast between Cap St. André and rugged Cap d'Ambre at the island's northern tip, the Flandrian transgression breached a barrier system to produce complex rias, partly drowned cuestas, deltas, mangrove swamps, and islands. The Isles Glorieuses northwest of Cap d'Ambre, contain coral reefs, now 3 m above sea level, which formed around 150 ka. The semi-arid southwest coast is dominated by active parabolic dunes and oxidized paleodunes shaped by prevailing southerly winds. The shelf is narrower here and in Tuléar Bay is notched by massive submarine canyons, that off the Onilahy River descending to $-2{,}600$ m. Coral reefs of many ages and types occur: barrier reefs, fringing reefs, coral banks, and islets. Because muddy detritus inhibits reef growth, these reefs occur between major estuaries. Relative sea-level change since the last interglacial ($\sim$125 ka) is reflected in the barrier beach 8–12 m above sea level behind east coast pangalanes, in raised coral reefs at the northern tip, and in submarine coastlines and aeolianites elsewhere (Battistini, 1978).

The Red Sea coast

The Red Sea extends 2,000 km NNW from the narrow Bab el Mandeb, ranges from 150 to 300 km in width, and deepens to over $-2{,}300$ m along its central axis (Figure A14). This embryo ocean occupies a complex rift system between the African and Arabian plates. Separation began with left-lateral transtension in Cretaceous–Eocene time but accelerated with a 7° counter-clockwise rotation of the Arabian block after Oligocene time. The Red Sea opened to the Indian Ocean in Miocene time but this link has not been continuous. It remained open to the Mediterranean until the early Quaternary. Then, with closure of the Mediterranean link and eustatic and tectonic changes at Bab el Mandeb, the Red Sea became isolated from time to time during the later Quaternary. With potential evaporation approximating 2,000 mm yr^{-1} but rainfall ranging from only 3 mm yr^{-1} in the north to 150 mm yr^{-1} in the south, episodic closure of the Red Sea from the Indian Ocean has had a dramatic impact on water volume and thus coastal environments.

Owing to the recency of separation, faulted Precambrian basement rocks lie close to the coast and dissected mountains plunge toward a narrow ribbon of coastal plain underlain by later Cenozoic sediments. The northern Red Sea, together with its northern arms in the 10–25 km wide, $-1{,}800$ m deep Gulf of Aqaba and shallower Gulf of Suez graben, reflect mainly normal tensional faulting of continental margins. South of Ras Banas, however, the Red Sea is structurally more complex and falls stepwise into a narrow central trough where ascending volcanics have overlapped the continental margins.

The African coast of the Red Sea is characterized by a faulted staircase of coral reefs that form wedge-like plates up to 10 m thick, several kilometers wide, and range from 50 m above to -100 m below present sea level. Onshore, these reefs are mantled by aeolian sand, lagoonal evaporites, estuarine deposits, and alluvial gravels. The coastal plain widens only where major valleys reach the coast, as in the Tokar delta into which the Baraka River flows between June and September, or where structural troughs occur, such as the Dallol Basin, a saline depression that descends to -116 m below sea level where the Red Sea rift turns inland south of Massawa. Offshore faulted paleoreefs form the Dahlak Archipelago at the northern end of the Danakil horst. The paucity of blanketing terrigenous sediment allows modern fringing reefs to thrive in warm transparent waters. Reef margins are dominated to windward by *Acropora* associations, to leeward by *Porites* associations (Braithwaite, 1982). Lateral reef growth of several centimeters annually even occurs in front of now dry early Holocene river deltas and abandoned *marsas* (*sharms*), corridors cut by wadis draining to low Pleistocene sea levels. Barrier reefs and atolls are less common but are found overlying subsiding fault blocks from Port Sudan to Ras Hadarba (Mergner and Schuhmacher, 1985).

AIRBORNE LASER TERRAIN MAPPING AND LIGHT DETECTION AND RANGING

Introduction

Recent advances in the technology known as airborne laser altimetry or Light Detection and Ranging (LIDAR) allow us to map shoreline (hereinafter the term "Shoreline" generally refers to the "high-water line") position and coastal topography promptly and accurately in order to provide erosion rate updates. Precise measurement of beach and dune dimensions relative to beachfront development can also be obtained in order to determine coastal vulnerability. Overflights can be scheduled after major storm impact to assess quantitatively the amount of beach erosion, dune scarping, and overwash deposition. Considering the U.S. trend of pervasive coastal erosion and ever-increasing beachfront development, punctuated by storm impact, this new technology will fill a major void in terms of providing timely and accurate data for scientific assessments and management programs. In summary, the airborne laser altimetry represents a quantum step forward in mapping coastal erosion and flood hazard zones.

The coastal zone, which represents the interface between the land and sea, is one of the most dynamic areas on Earth. Change is occurring at all time scales from hours (with storm impact) to decades and longer (due to sea-level rise). Therefore, topographic base maps rapidly become outdated as the coastline is continually adjusting to a combination of natural forces and human modifications. At the same time there is continued population growth in the coastal zone and increasing demand for beachfront development (Cullinton *et al*., 1990). It is estimated that there is already $3 trillion of development along the U.S. coast vulnerable to erosion and storm flooding. This same trend of coastward migration is manifested worldwide.

Beach erosion is a significant and growing problem. It is estimated that 70% of the world's sandy beaches are eroding (Bird, 1985); in the United States it approaches 90% along the Atlantic coastal plain. The worldwide extent of erosion strongly suggests that eustatic sea-level rise is an important underlying factor, although many other natural processes can locally contribute to the problem. Human intervention alters these natural processes through such actions as dredging of tidal entrances, emplacements of groins and jetties, hardening of shores with seawalls or revetments, and beach nourishment (Leatherman and Dean, 1990). Therefore, erosion rates vary widely on a geographic basis, ranging up to 5 m/yr along the Cape Hatteras, North Carolina shoreline.

Coastal vulnerability

Coastal vulnerability in response to storm impact can be assessed by obtaining accurate and up-to-date measurements of beach and dune dimensions in relationship to the position of buildings. The Federal Emergency Management Agency (FEMA) spent over $1 billion acquiring topographic data for the coastal and riverine floodplains of the United States in order to generate 100-year flood maps (Flood Insurance Rate Maps or FIRMs). But these data are much out-of-date and often inaccurate for coastal areas where beach and dune dimensions are affected by long-term coastal recession as well as short-duration storm impact. FEMA's data requirements are for 15–20 cm vertical accuracy.

The width of the dry sand beach (or beach backshore), which extends from the berm to the dune, is a measure of coastal vulnerability. In addition to the large seasonal fluctuation in width, most beaches are narrowing through time in response to a long-term erosional trend. As the beach narrows, storm waves can eventually reach the barrier dunes, causing vertical scarping (erosion) while the surge persists. FEMA uses the "540 rule" in combination with a height criteria to determine if a sand dune can withstand a 100-year storm and hence whether the landward-flanking houses are safe from flooding (A-Zone) or subject to attack by waves, requiring (V or velocity) Zone designation. The insurance rate for a particular property varies greatly, depending upon which zone a house is located. The "540 rule" refers to the volume of sand (540 ft^3) per foot of shoreline, but the status of the barrier dunes (e.g., volume and height) is not presently known because of continued storm impact and long-term erosional trends.

Coastal mapping technology

The approach of using classical transit and rod surveys to map shorelines was initiated in the mid-1800s by the National Ocean Service (and its forerunners) of NOAA (Figure A16). While field surveys of this type provide the most accurate information, this approach is time consuming and expensive, making these traditional surveys impractical for large areas (e.g., 10s km of shoreline). These data have been augmented and updated with historic aerial photography since the 1940s, but such hard-copy imagery must be corrected for distortion using stereoplotters or other computer-assisted photogrammetric techniques at considerable cost (Leatherman, 1983). Satellite imagery collected since the early 1970s has provided a synoptic view of coastal processes. Unfortunately, for most applications, this imagery cannot provide the level of detail necessary for precise measurement of shoreline change (Leatherman, 1993). More recently, kinematic global positioning system (GPS) surveys have been made by driving a truck-mounted receiver along the high-water line (HWL) (Morton *et al*., 1993; French and Leatherman, 1994). While this method allows much more rapid surveying of the shoreline than conventional techniques, it is limited by access restrictions and still allows only kilometers of shoreline to be mapped per day.

Recent advances in microcomputers, laser ranging technology, and GPS have resulted in the development of compact and lightweight airborne laser terrain mapping (ALTM) systems which can inexpensively acquire shoreline topographic data of unprecedented detail and accuracy. These systems, also known as LIDAR represent a tremendous advancement in our capability not only to map the shoreline but also to obtain digital elevations for critical coastal features (e.g., sand dunes) for determining coastal vulnerability.

Modern ALTM systems are able to map an area several hundred meters wide and hundreds of kilometers long with a nominal spacing of 2–3 m and an accuracy of ±15 cm in a few hours. The existing database

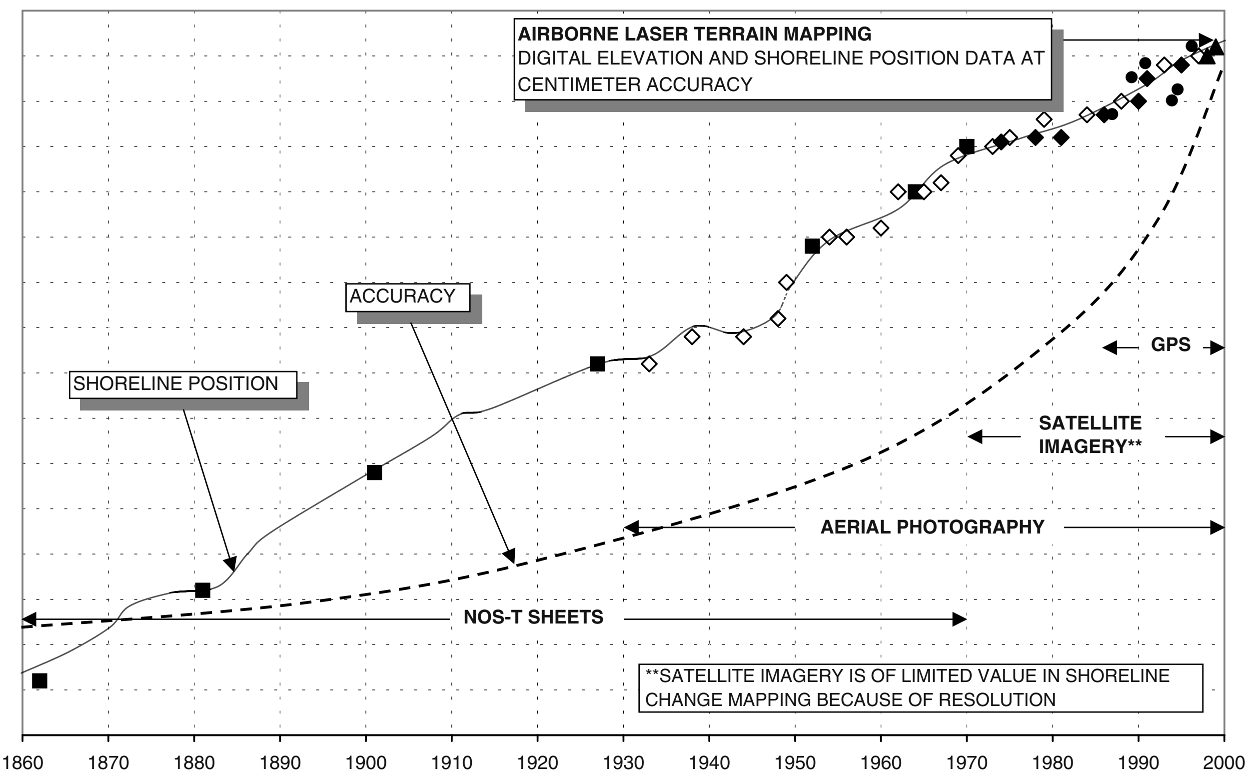

Figure A16 Evolution of shoreline mapping technologies.

of shoreline locations over time can be easily updated by using this new technology. The entirety of Pinellas County Florida of 717 km^2 was mapped in a week (Carter *et al.*, 1998). Comparison of the airborne measurements with surveyed ground control points showed a mean difference of less than 10 cm. Pre- and post-storm airborne laser data can be collected to obtain highly detailed and accurate topographic information on coastal changes (beach erosion, dune destruction, and overwash deposition) resulting from hurricane landfall or winter northeastern impact.

ALTM system

There are several different ALTM systems, but the basic working principles of these systems are similar. Three basic components: the laser scanner, a kinematic GPS, and Inertial Navigation System (INS) are employed simultaneously to determine the ground elevation. The laser scanner detects the range from aircraft to ground by recording the time difference between laser pulses sent out and reflected back. In addition, many systems allow the recording of multiple returns and the return intensity for each laser pulse. Pulse repetition rates of most ALTM systems range between 2 and 25 kHz. A rotating or oscillating mirror mounted in front of the laser causes the laser to scan back and forth, allowing the coverage of a wide swath beneath the flight path. This oscillation of the scanner mirror, in combination with forward motion of the aircraft, typically results in a zigzag scan pattern beneath the flight path (Figure A17).

For most shoreline mapping applications the ALTM system is deployed on a fixed wing aircraft at heights ranging from 350 to 1,000 m above the ground surface (Figure A17). Aircraft positions are recorded continuously by a GPS receiver mounted in the aircraft. A second GPS station situated at a known ground position provides differential corrections for more accurate estimation of the aircraft trajectory. The roll, pitch, and heading of aircraft are continuously recorded by the INS from 10 to 100 times per second.

After the flight, a precise aircraft trajectory is determined by post-processing the aircraft and ground station GPS carrier phase data. This trajectory is then combined with the laser range data, scanner mirror angle, and the INS measurements to determine the precise horizontal coordinates and vertical elevations of each laser reflection. Commonly, the irregularly spaced elevations are interpolated onto a regularly spaced grid to produce a digital elevation model (DEM). Reflection intensity measurements can also be gridded to produce an image similar to a digital photograph.

Applications

Several recent studies have demonstrated the use of LIDAR technology for mapping shoreline morphology and hazard (Carter *et al.*, 1998; Sallenger *et al.*, 1999; Krabill *et al.*, 2000). Studies of coastal vulnerability require coverage of beach and dune dimensions relative to beach-front development. To survey barrier beaches at 1 m resolution using the ALTM system, usually a pair of parallel passes is made along the shore with 20% overlap, yielding an approximately 400 m wide swath of data. In addition, a digital camera system is often installed in the aircraft. Such systems are valuable for comparison of historical shoreline markers such as the HWL or dry/wet boundary with the laser measurements.

Shoreline surveys can be scheduled seasonally or after the passage of major storms such as hurricanes or northeasters to assess quantitatively the amount of beach erosion, dune scarping, and overwash deposition. For example, an ALTM survey was conducted along the central-east coast of Florida immediately before and after the passage of Hurricane Floyd in September 1999 (Figure A18). This airborne laser technology will literally revolutionize our data collection efforts and permit a much better scientific understanding of how beaches change seasonally and annually as well as respond to storm impact.

In summary, this new and important technology represents a quantum step forward in mapping the coastal erosion hazard zones and provides a chance for breakthrough science in terms of understanding shoreline changes relative to the forcing functions, including storm impact.

ALGAL RIMS

History

Since the beginning of coral reef studies algal formations of various sizes and shapes, made of coralline algae and other organisms and generally associated with coral reefs, have been described under various names (algal ridges, crests, mounds, reefs, etc.). They were described as being developed upon the windward edge of reefs, but mention of algal mounds, crusts or rims developed on rock also exist in the early literature. A detailed description of algal rim structure was given by Tracey *et al.* (1948) on Bikini atoll.

Locations were mainly Pacific, but analogous formations were also described in the Atlantic, such as the "boilers" of Bermuda (Agassiz, 1895). Later papers (Kempf and Laborel, 1968; Gessner, 1970; Glynn, 1973; Adey and Burke, 1976; Focke, 1978; Jindrich, 1983; Bosence, 1984) dealt with algal and animal populations associated with Atlantic rims, and demonstrated their identity with Indo-Pacific rims, and their independance from coral reefs proper, since algal rims can develop directly upon littoral rock, or in regions where corals do not thrive.

Definition and morphology

Algal rims are reef-like structures (bioherms or biostromes, following their size, development, and influence on local sedimentation processes) developing on the outer edge of reef-flats as well as on rocky coasts submitted to permanent, strong surf (trade winds). They exist both in Atlantic and Indo-Pacific regions but rim-like formations have also been described in the Mediterranean (Blanc and Molinier, 1955).

They are built mainly by massive or encrusting coralline algae (mostly *Porolithon*), associated with Hydrocorals (*Millepora*), and Vermetid Gastropods (*Dendropoma*), with a few sturdy corals. Specific composition varies with exposure, slope, and nature of substrate (Focke, 1978); coralline algae replacing vermetids when wave energy increases.

Rims are often built-up upon the inner parts of spur-and-groove systems by fusion of algal heads (Tracey *et al*., 1948). In extreme surf conditions, upward water movement leads to algal terraced pinnacles or blowholes.

Rim populations gradually mingle seaward with populations of the outer slope, rich in coralline algae down to several meters deep but enriched in corals (such as Atlantic *Acropora palmata*).

In weaker surf conditions, the rim gradually passes into a spur-and-groove reef edge or to thin rim-like formations along rocky coasts. Algal rims or equivalent structures may develop in tideless as well as in tidal conditions.

An often overlooked fact is that structures with algal rim or rimmed terrace morphology may be formed not by constructional evolution but by an erosive process. The Bermudian "boilers" may thus be divided into "erosive boilers" generated by erosion of an emerged stack of soft rock, the edge of which is protected by a thin organic cover (original description of a Bermudian boiler) and into "constructive boilers" obtained by the upward growth of a coral patch, covered by a surface layer of vermetids (Ginsburg and Schroeder, 1973).

Relation with past sea levels

Some components of algal rims (*Dendropoma* vermetids, some *Lithophyllum*) have a narrow repartition range around MSL and their presence in cores or on elevated coastlines is a precise indicator of ancient sea levels, with an approximation of less than 1 m (Jindrich, 1983; Laborel, 1986; Laborel *et al*., 1994). Conversely, corals such as *Acropora palmata*, having a vertical range of 5–10 m are less precise indicators (Lighty *et al*., 1982) unless a true rim may be recognized in the core.

Further study of algal rims is nevertheless needed to obtain better biological indications of past sea level stands.

ALLUVIAL-PLAIN COASTS

Alluvial-plain coasts are prograding shore systems "formed where the broad alluvial slope at the base of a mountain range is built out into a lake or the sea" and are part of a "neutral" coast (Johnson, 1919, p. 188). This term is little used in modern publications, but is still a useful classification of coastlines built by interaction of river and coastal processes where sediment input and relative sea-level change are relatively balanced, producing a coastline that neither progrades nor retreats rapidly. Alluvial-plain coasts may be closely associated with deltas, estuaries, beach-ridge plains, barrier–lagoon systems, and in some settings glacial outwash plains. Variations in geomorphology and process responses among these coastal environments are determined by the ratio of relative sea-level change to sediment supply, as well as by climate, wave and tidal energy, and underlying geologic controls such as relief, complexity of coastline shape, and tectonic setting.

In sequence stratigraphic terminology, alluvial-plain coasts are expected within a highstand systems tract (Posamentier *et al*., 1988; Posamentier and Vail, 1988) or falling-stage systems tract (Plint and Nummedal, 2000). These systems tracts form during rising to highstand sea level and highstand to falling sea level, respectively. However, the use of these interpretations clearly requires an understanding of rates of sediment influx and the influence of local basin subsidence or tectonic uplift.

Low-relief alluvial plains are built by fluvial processes such as meandering stream pointbar accretion, deposition on levees, over-bank flood deposition, and a variety of channel avulsion processes that create oxbow lakes, flood chutes, and crevasse-splay deposits. In higher-relief coastal settings fan deltas may develop. Fan deltas are sloping alluvial sediments deposited in a sweeping arc where mountain streams flow out onto lowlands and into a sea or lake, with a substantial subaqueous extent (Holmes, 1965; Prior and Bornhold, 1989). Their subaerial portions are alluvial fans, that is, they are dominated by braided stream and sediment gravity flows in irregular flow conditions. Their subaqueous portions include fan-shaped deltaic and prodelta facies, usually with only a narrow shelf. Alluvial-plain coasts are influenced by littoral processes, either by the reworking by waves and tides of fluvial sediments brought into the coastal setting, or by the gradual infill of pre-existing embayments.

Wave-dominated alluvial-plain coasts occur on relatively simple coastlines, where there is sufficient fetch and wave energy to prevent the outward building of a distinct delta form. The coast may be somewhat tectonically influenced and of moderate relief, such as the Mediterranean Valencia coast of eastern Spain (Figure A19) (Viñals and Fumanal, 1995). The very low relief Texas coast has alluvial-plain coastal segments at High Island, and on the Brazos River delta (Rodriguez *et al*., 2000, 2001). The Peruvian coast is battered by higher wave energy and has steep cliffs in many sectors. However, valley mouths receive abundant coarse and fine sediment from rivers heading in the foothills of the Andes, modulated by the important climatic variability of the El Nino–Southern Oscillation as well as earthquake destabilization. Fluvial reworking and resurfacing creates alluvial-plain coasts near river mouths, while sand and gravel are reworked into well-developed beach ridge plains northward (downdrift) of the Santa, Piura, and Chira rivers in northwestern Peru (Richardson, 1983; Sandweiss, 1986; Wells, 1996).

Embayment-infill alluvial plains occur on complex coast-lines with higher relief. Sediments are trapped in coastal compartments with relatively limited fetch and lower wave energy. The coastal valleys of western Turkey (Figure A20) and Greece are excellent examples of this type of coast. The coastlines in these embayments have prograded many kilometers in historic times, with the result that famous archaeological sites such as Troy and Thermopylae are now well inland of the coastal settings described in antiquity (Kraft *et al*., 1980, 1983, 1987). Figure A20 shows

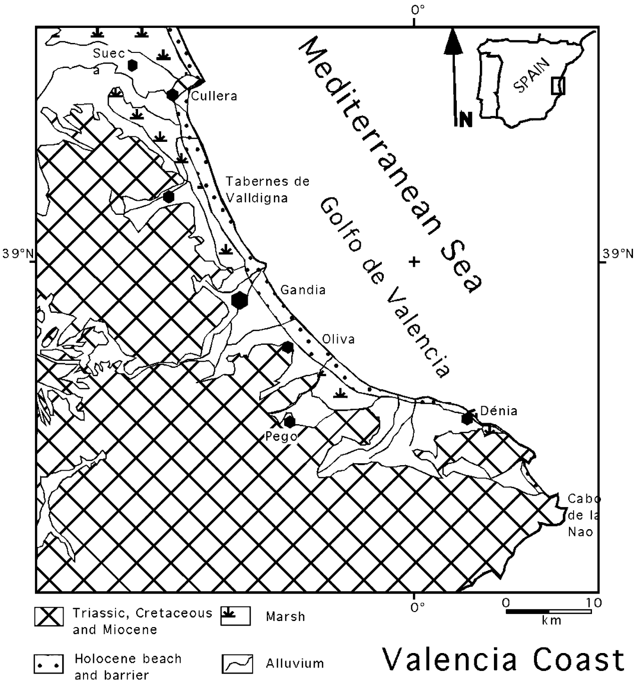

Figure A19 Alluvial-plain coast of eastern Spain, the Valencia Coast (after Viñals and Fumanal, 1995, figure 1).

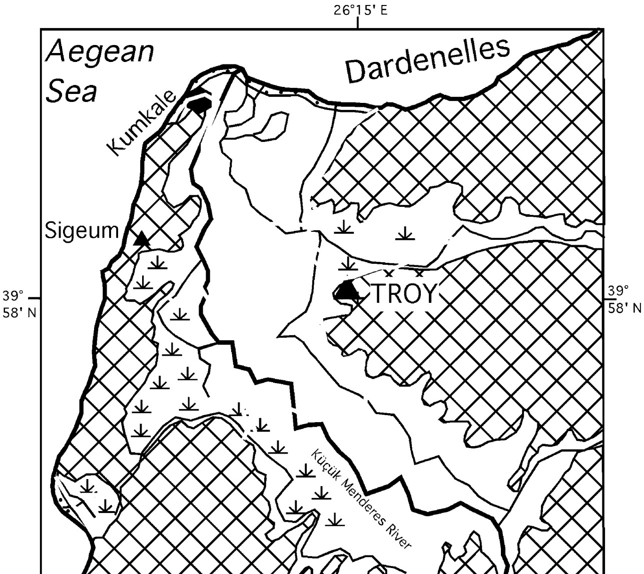

Figure A20 Alluvial-plain coast of northwestern Turkey, the Trojan plain of the Küçük Menderes River (after Kraft *et al.*, (2003, figures 1 and 4–6).

the progradation of the Küçük Menderes alluvial plain 7 km from a coastline within a protected embayment at 5,000–5,500 yr BP, more than 5 km since the Trojan war 3,250 BP, and more than 3 km since Roman times 2,000 BP. These reconstructions are based on interdisciplinary coastal geology, geoarchaeology, and written records (Kraft *et al.*, 2003). Recognition of the potential for coastline change is crucial to interpretation of archaeological sites on alluvial-plain coasts.

Alluvial-plain coasts associated with large rivers may grade into delta systems, representing an inactive lobe of a delta cycle (Coleman, 1988) or distant from the primary river influx. The Huanghe (Yellow River) entering the Bo Hai Sea of northeastern China has an active modern birdsfoot delta, but there are also broad stretches of alluvial-plain coast on the Bo Hai coast that formed by coastal reworking of former fluvial/deltaic environments (Saito *et al.*, 2001). Marsh and swamp environments, represented by coals in ancient sequences (e.g., Fielding, 1987) are commonly associated with delta plain and alluvial-plain coasts.

Recognition of alluvial-plain coasts in ancient rock sequences may be challenging, particularly to distinguish from delta plain and barrier–lagoon systems. However, the Cretaceous Mesaverde Group littoral facies provide clear examples of alluvial-plain coasts on the margin of the interior seaway of Colorado and Wyoming (Hollenshead and Pritchard, 1961; Kraft and Chrzastowski, 1985). This succession includes transitions from fluvial delta plain (Menefee Fm.) with associated coal and carbonaceous shales, to the Lookout Point Fm. sandstone, in a regressive succession, overlain by the Cliff House Fm. sandstone, in a transgressive succession. Determining the relative influences of eustatic sea-level fluctuations and rates of sediment supply, as well as climate, subsidence, and local process variations, can be even more challenging in the ancient rocks, than in Holocene systems, where geomorphology and geologic settings are more completely understood.

Alluvial-plain coasts may be underrepresented in the literature because they are combined with delta, barrier, or estuarine environments. They represent intermediate conditions of balance between sediment accumulation and sea-level change. They are neither strongly prograding, like deltas, nor transgressed like estuaries. They reflect primary fluvial processes of deposition, but also significant reworking by littoral processes. They may be recognized by the lack of distinct barrier and lagoon environments and close juxtaposition of alluvial and beach systems.

ALTIMETER SURVEYS, COASTAL TIDES, AND SHELF CIRCULATION

Satellite altimetry produces unique global measurements of instantaneous sea surface heights relative to a reference surface, and is one of the essential tools for monitoring ocean surface conditions and conducting physical oceanographic research. So far, scientific results from altimetric data have significantly improved our knowledge of global ocean tides and mesoscale circulation variability in the deep ocean. However, the application of altimeter data to coastal waters has been limited (Han, 1995). This article briefly discusses issues related to applications of satellite altimetry to coastal tides and subinertial shelf circulation.

Satellite altimetry

A radar altimeter aboard a satellite is a nadir-looking active microwave sensor. Its signal pulse, transmitted vertically downward, reflects from the ocean surface back to an altimeter antenna. The round-trip time and the propagation speed of the electromagnetic waves are used to compute the range between the antenna and the ocean surface.

From the altimeter-measured range, the instantaneous sea surface relative to a reference surface, such as an ellipsoid, can be determined if a satellite orbit relative to the reference surface is known. With the knowledge of the oceanic geoid, the sea surface topography relative to the geoid due to ocean dynamic circulation including the temporal averages can be mapped. Although the geoid is not well determined yet, repeated observations can provide a measurement of the temporal variability of the sea surface height since the geoid can be treated as time-invariant for oceanographic applications.

Oceanographic applications of satellite altimetry require an accuracy of a few centimeters. This requirement constrains not only the altimeter sensor, but also pertinent atmospheric and oceanographic corrections that have to be made, the satellite orbit, and, in some applications, the reference geoid. One-second data are provided to the science community as the Geophysical Data Records (GDR). So far, the accuracy of altimetric sensors has steadily improved to a few centimeters. The atmospheric corrections consist of ionospheric delay and wet and dry tropospheric delays; the oceanographic effects are composed of the sea state bias, inverse barometric response, the elastic ocean tides, solid Earth tides, and pole tides. The radial uncertainty of the orbit has long been one of the largest error sources in satellite altimetry until the TOPEX/Poseidon (T/P) mission. The root mean square accuracy of the orbit used for producing T/P GDRs is estimated to be 3.5 cm (Fu *et al*., 1994). At present, the geoid errors occurring at various spatial scales are the largest error source, and the major obstacle to the derivation of the mean current from altimeter data.

Because almost all radar altimeter missions use a repeating orbit, repeat track analysis or collinear analysis becomes a conventional approach for application of altimeter data in physical oceanography. A mean at a location is calculated from data available, and then the mean is removed from the data to produce sea surface height anomalies relative to the mean. Thus, the repeat track analysis eliminates the geoid and its errors, the mean sea surface, and a portion of the orbit error. There are three variants from the standard approach. One is to subtract a selected instantaneous sea surface instead of the mean sea surface; another calculates the along-track slope deviations instead of sea level deviations. For a tidal analysis, collinear differences are usually calculated to bypass the uncertainty associated with the mean sea surface.

Coastal tides

Coastal tides are forced by adjacent deep-ocean tides which themselves are generated by the tide-generating potential associated with the motion of both the moon and the sun. The tidal waves in coastal seas propagate as trapped Kelvin waves, subject to significant amplifications in magnitude and reductions in wavelength.

Several empirical methods can be used to derive tides from altimetric time series. These include but are not limited to harmonic analysis, response analysis, and the inverse method. The first two methods are applied to each geographical location, and the last method considers the spatial correlation as defined by *a priori* spatial covariance in the tidal signal.

Both harmonic and response analyses are purely temporal analyses, common in the analysis of hourly tide-gauge data. The methods are suitable for either coastal seas (Woodworth and Thomas, 1990; Han *et al*., 1996) or deep oceans (Cartwright and Ray, 1990), not constrained by large satellite track intervals. However, an assimilative model in which altimetric tidal information is optimally blended with a dynamical model would be a great benefit in providing spatial interpolation and extrapolation of tidal fields (Han *et al*., 2000).

Tides in altimetric data have aliasing periods longer than their physical periods due to the altimeter sub-Nyquist sampling. Consequently, it may be difficult to resolve all leading tidal constituents using the harmonic analysis because of the limited duration of the altimeter data. This difficulty can be mitigated by the response analysis. Once the response weights of a tidal species have been determined, a solution for any tidal constituent in this species can be derived from the response analysis, even though some of these constituents are not resolved at all, given the satellite-sampling period (Cartwright and Ray, 1990).

The inverse method is a joint analysis in time and space, in which the spatial and spectral properties of tides and associated errors are considered using *a priori* covariance explicitly estimated from all the available information for the tides and various altimetric data errors. Several tidal constituents are simultaneously derived by an inversion of the data and the corresponding errors associated with these constituents by computing *a posterior* covariance (Mazzega and Berge, 1994). However, the inverse method is not applicable if the tidal correlation scales are smaller than satellite track intervals.

Subinertial shelf circulation

Another important application of satellite altimetry in physical oceanography is to subinertial variability over a continental shelf. A key component of the geophysical corrections is the removal of oceanic tides.

In coastal seas, tides are often larger than subinertial variability and have horizontal scales of ~100 km owing to the local coastline and bottom topography. Global tidal models may not be adequate for shallow waters; for example, the M_2 amplitudes and phases in Geosat GDRs are significantly different from both tide-gauge and altimeter data over the Scotian Shelf and the Grand Banks (Han *et al*., 1993) and in the Amazon mouth (Minster *et al*., 1995). The tide model in T/P GDRs was found not sufficient over the Canadian Pacific shelf (Foreman *et al*., 1998).

Because the semidiurnal and diurnal constituents are aliased into fluctuations with longer periods, their errors may obscure subinertial fluctuations of interest. For example, the K_1 has an aliasing period of 173 d in the T/P data, close to a semiannual cycle. One way to reduce the tidal correction errors is to use regional tidal models that have higher accuracy (Han *et al.*, 1993). The separation of the low-frequency variability of interest from the aliased tidal constituents can also be achieved using harmonic analysis. The results may be subject to notable statistical uncertainties, depending on the length of data, magnitudes of tidal errors, and error correlation.

The altimeter data can be used to study sea surface height variability directly and to calculate sea surface slopes and thus to derive geostrophic surface currents. The geostrophic currents at depth can be determined when combined with interior density structure. Han and Tang (1999) combined the T/P data with density and wind data to study seasonal variability of current and transport in the Labrador Current. T/P sea level anomalies are being used to examine seasonal and interannual variability of coastal sea levels.

The spatial sampling resolution is critical for shelf circulation. Dynamic models are needed for a space–time interpolation to make the best use of the information. The assimilation of altimeter data into numerical models is one of the most promising approaches to study subinertial shelf circulation.

Discussion: challenges and opportunities

Application of satellite altimetry to coastal tides and shelf circulation is more challenging than to similar problems for the deep ocean (Han, 1995). The reasons are multifold. First, dynamic features in coastal seas are strongly influenced by the complex coastline and bottom topography, and have temporal scales of several days to weeks and spatial scales of tens of kilometers. A satellite altimeter is not good at sampling these small-scale features. Second, an altimeter is subject to tracking problems upon crossing the land–sea boundary; useful data may not be available within tens of kilometres from the land. Third, atmospheric and oceanographic corrections are more uncertain for coastal waters than for the deep ocean.

High temporal and spatial resolutions are very important, particularly in the coastal seas. Unfortunately, they are incompatible, and a reasonable compromise must be made. Consequently, the cross-track spatial resolution is often low relative to the small-scale nature of the coastal processes. Dynamical models with data assimilation are useful for optimally blending the model dynamics with altimetry. Only dynamical models may be able to recover the deep ocean conditions from their sea surface manifestation observed by an altimeter.

A temporal and spatial blending of multi-mission altimeter data can provide a partial solution to the poor spatial resolution and an unprecedented opportunity of studying coastal climate change and its impacts, especially when combined with prognostic models. In particular, the availability of near-real-time satellite altimetry data will be very useful for nowcasts and forecasts of coastal ocean conditions.

ANTARCTICA, COASTAL ECOLOGY AND GEOMORPHOLOGY

Ecology of coastal Antarctica

Antarctica covers an area of 14 million km^2 and has a coastline over 32,000 km long (Figure A21). However, more than 80% of this coastline is comprised of ice cliffs formed by either glaciers or the polar plateau. On average, the continental shelf is both narrower and deeper than other continents, averaging more then 600 m deep.

Marine life in Antarctic waters is controlled by the presence of sea ice. This ice, which can be more than 2 m thick, grows out from Antarctica each year until it covers approximately 20 million km^2; more than doubling the area of the continent. It reaches its maximum extent by late October but by late January it has retreated to the coast. The ice affects Antarctic life in two main ways. Most importantly, it reduces the amount of light reaching the underlying water column and so reduces the primary productivity and secondly, together with icebergs, the sea ice also disturbs and scours much of the shallow coastal zone.

The first explorer to sail south of the Antarctic Circle was secondly Captain James Cook in 1773. He noted the abundant seal and whale life but concluded "that no good would come of it" (Antarctica). His observations on the abundant seal and whale life, however, were to have a profound impact on the ecology of the Southern Ocean as it led to the focus of the whaling and sealing industries moving from the Northern to the Southern Hemisphere. Over the subsequent 150 years these industries effectively removed the higher order predators from the

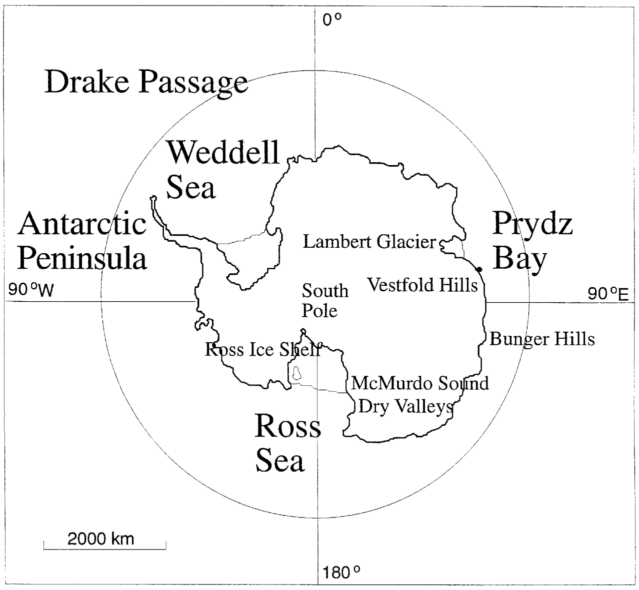

Figure A21 Map of Antarctica.

ecosystem and only now is there evidence that seal and whale populations are beginning to recover from their early savage onslaught. The first record of penguins was much earlier and surprisingly, by Sir Francis Drake in 1644. He commented

> Wee found great store of strange birds, which could not flie at all, nor yet runne so fast as they could escape with their lives; in body they are less than a goose and bigger than a mallard, short and thicke sett together, having no feathers, but insteed thereof a certaine hard and mattered downe; their beaks are not much unlike the bills of crowes, they lodge and breed upon the land, where making earthes, as the conies doe, in the ground, they lay their egges and bring up their young, their feeding and provision to live on is the sea, where they swimm in such sort, as nature may seeme to have granted them no small prerogative of swiftnesse.

Many of the early explorers had biologists aboard and by the beginning of the 20th century most of the important components of the marine ecosystem had been described. Research over more recent years has concentrated on the significance of the microbial ecosystem, specific adaptations to the unique characters of the Antarctic environment, and the effects of human impacts, such as global warming, the ozone hole, over fishing, and pollutants.

The base of all marine food chains is comprised of algae. In the open ocean this is comprised exclusively of phytoplankton. In coastal areas seaweeds and benthic microalgal mats are also important. In Antarctica, a forth and often dominant component is contributed by the sea ice algae.

Phytoplankton in the waters around Antarctica are comprised of the same basic algal divisions as elsewhere. Diatoms are particulary prominant but summer blooms are often comprised of phytoflagellates such as Prymnesiophytes (*Phaeocystis* in particular), Cryptophytes, Prasinophytes, and dinoflagellates.

The largest size class of phytoplankton, that is, the net plankton (20–200 μm), is dominated by diatoms and these comprise most of the large spring algal blooms. The nanoplankton (2–20 μm), unlike most other areas is also dominated by diatoms, *Fragilariopsis cylindrus* in particular, but *Phaeocystis* and Parmales can also form large blooms. Cyanobacteria (i.e., blue green algae) characterize the picoplankton (0.2–2 μm) in most other areas but these are almost completely absent from Antarctic waters.

Each year as the ice melts and the pack ice retreats, it leaves behind it a surface layer of slightly fresher water. Algal cells fall out of the melting ice and contribute to a major annual algal bloom which tracks the retreating ice edge back to the continent. When it reaches the continent a major summer coastal phytoplankton bloom results. This bloom can account for more than 60% of the annual primary productivity and has a similar biomass concentration to phytoplankton blooms elsewhere in the world (up to 10 μg Chla l^{-1}). At other times of the year the phytoplankton biomass is very low (<0.1 μg Chla l^{-1}) but comparable to many other remote ocean sites. In most oceanic areas of the world the availability of nutrients (i.e., nitrate, phosphate, and silicate) limits the growth of algal blooms. In Antarctica, however, this is rarely the case and nutrients are nearly always present in excess. Here phytoplankton growth is usually limited by low light levels and deep mixing. Limited iron (Fe) availability is now also thought to reduce phytoplankton productivity over large areas of the Southern Ocean, but this is unlikely to be the case in coastal areas where iron is available from both the sediments and wind-blown dust. Early explorers often noted the teeming wildlife of Antarctic waters and concluded that it was an area of high productivity but in fact more recently we have found that the reverse is the case. The explorers typically sailed south as the ice was retreating in spring and early summer, a time that coincides with the one time in the year when the melting ice creates the conditions that allow a transient algal bloom. This bloom in turn attracted the abundant zooplankton, birds, whales, etc. The rest of the year the Southern Ocean is remarkably unproductive.

Seaweeds make only a minor contribution to Antarctic primary productivity, first because there is little rocky substrate and second because of the disturbance caused by sea ice and icebergs. Diversity is relatively low and is dominated by red algae. Marine benthic algal mats have not received much attention although it is likely that they contribute up to 50% of the primary production in many shallow marine areas. They are dominantly comprised of diatoms.

When the sea ice reforms in autumn phytoplankton cells are taken up into the ice. The few species that are able to survive do well and grow to be released as an innoculum when the ice again melts the following spring.

The algae form communities either at the top of the ice, within the interior or on the bottom. In late winter and spring in coastal areas the most important communities grow as either encrusting or hanging communities on the bottom of the ice. It is only these bottom communities that are available as food to grazing invertebrates and fish. The algal biomass growing on the bottom of the ice is so high (380 mg Chla m^{-2}) the undersurface of the ice often appears dark brown to black and has a biomass approaching the theoretical maximum for the available sunlight. In coastal areas the dominant species are the diatoms *Nitzschia stellata, Entomeneis kjellmannii, Berkelaya adeliense*, and *Thalassiosira australis*.

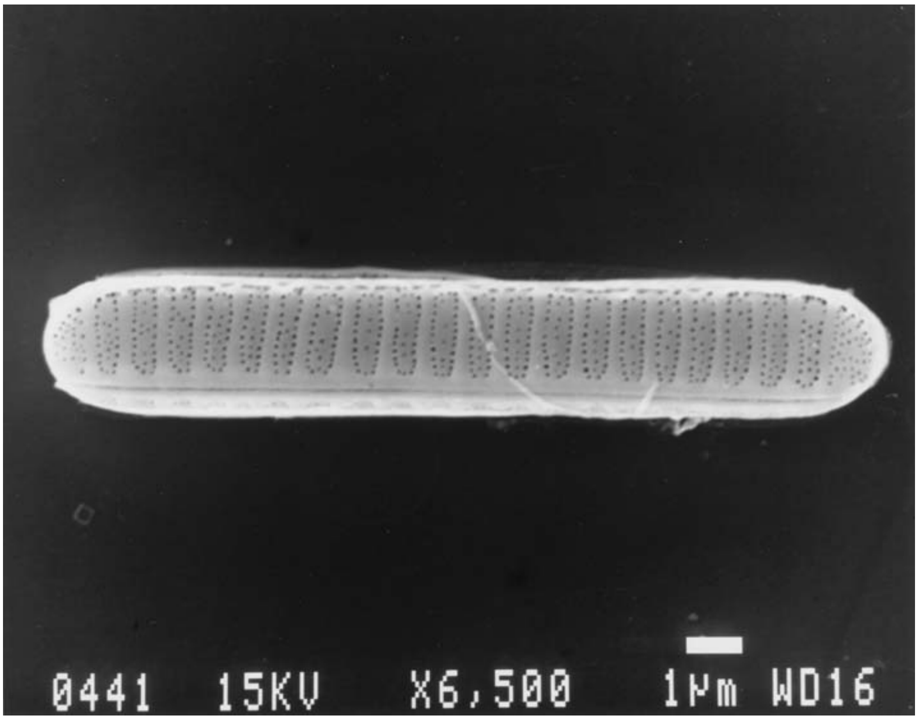

Figure A22 Scanning electron microscope photograph of *F. cylindrus*, an important diatom species in both the phytoplankton and sea ice. It also comprises a major proportion of many bottom sediments.

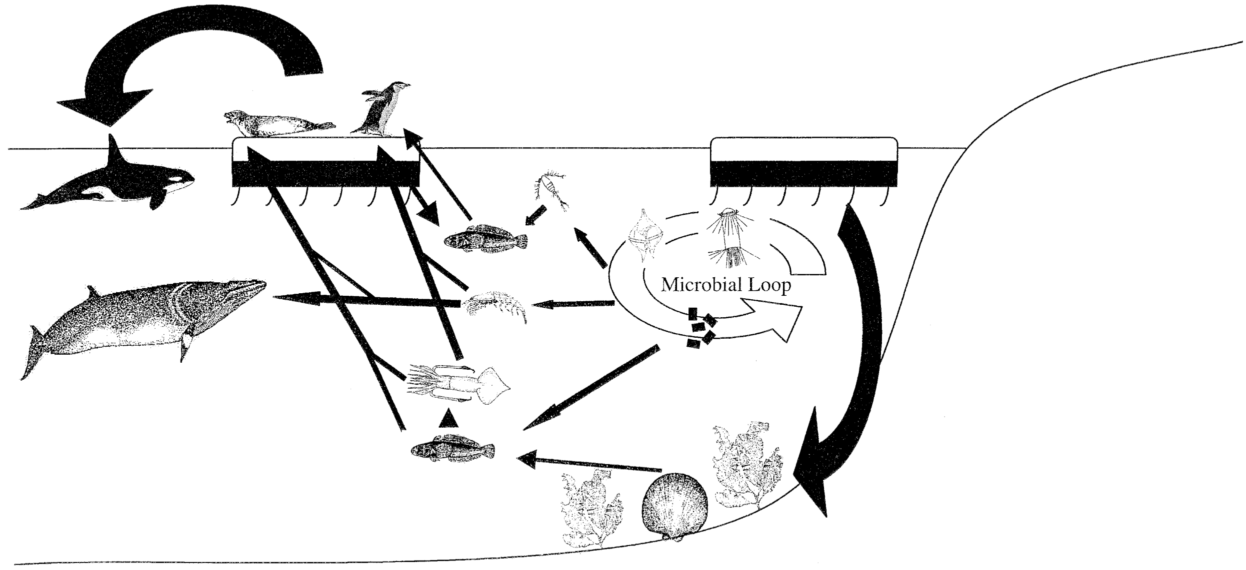

Figure A23 Simplified food web diagram of Antarctic coastal communities. Arrows indicate that an organism is eaten by the animal that is being pointed at. Diagram shows the importance of the microbial loop and sea ice communities to the whole ecosystem. The large arrow from the sea ice to the bottom indicates that most ice algal production falls to the bottom where it is grazed by invertebrates.

Further off shore in the pack ice, the ice communities are dominated by the diatoms *Fragilariopsis curta* and *F. cylindrus* (Figure A22).

With the arrival of warmer temperatures in late spring, melt pools develop on the surface of the ice. These are predominantly colonized by a dinoflagellate, *Polarella*, and chrysophytes. These organisms are released into the water column when the ice finally melts or breaks out in late December or January.

The seafloor, sea ice, and the water column all contain abundant and diverse communities of bacteria and protozoans. These organisms, together with the phytoplankton, comprise the elemensts of the microbial loop (Figure A23). The loop is so named because it describes the route taken by the organic material which is created by the phytoplankton. Phytoplankton use the sun's light energy to synthesize organic matter which they use to grow and reproduce. These cells are gazed on by heterotrophic protists, which in Antarctic coastal waters are mostly dinoflagellates, amoebae, and choanoflagellates. These organisms either die or are attacked by bacteria or viruses, which then decompose to become nutrients for the phytoplankton. It has been estimated that as much as 50% of the energy, which has been harvested from the sun by the phytoplankton, is circled around this loop and thus not made available to multicellular grazers.

The sea ice algae is directly grazed on by small crustaceans such as amphipods, krill, and copepods. These are able to consume up to 2% of the total biomass per day. The other main grazer on sea ice algae is the ice fish, *Pagothenia borchgrevinki*. Much of the primary production of the sea ice falls to the bottom when the ice begins to melt. Here it becomes available as food, together with the benthic algal mats, to the benthic invertebrate community. This community is comprised of a diverse range of sponges, starfish, sea urchins, sea slugs, worms, and shellfish.

The best known invertebrate of the Southern Ocean is the Antarctic krill, *Euphausia superba*. This shrimp-like crustacean, which is up to 20 cm long, forms incredibly large aggregations of up to 100 million individuals and is arguably the most abundant multicellular organism on earth. However, it is not usually a creature of coastal areas; there, it's smaller cousin *Euphausia crystallorophius*, takes over. These creatures together with smaller zooplankton such as copepods and fish larvae comprise the main herbivorous grazers of the phytoplankton.

Zooplankton

The herbivorous zooplankton is composed largely of heterotrophic protists (e.g., dinoflagellates), pelagic crustaceans (e.g., copepods, amphipods, and euphasids), laval fish, and salps. Compared to most other areas the biodiversity of the Antarctic coastal zooplankoton community is relatively low although the biomass is high. Diversity tends to increase with depth. Salps, gelatinous zooplankton, are very significant filter feeders in pelagic waters around Antarctica but their role in coastal communities is unknown.

Biomass and reproduction is strongly seasonal with the peaks coinciding with the development of the maximum phytoplankton bloom soon after the disappearance of the secure. Zooplankton biomass in McMurdo Sound in February has been estimated at 1.5–3.4 g dry weight m^{-3}, a biomass toward the top of the range for coastal communities elsewhere.

Fish and squid

Compared to most other areas the diversity and biomass of Antarctic coastal fish is very low. There is only one common truly pelagic fish, the Antarctic Silverfish(*Pleuragramma antarcticum*), and this commonly comprises more than 90% of the pelagic fish biomass. This species has been found in the diet of all fish that live above the bottom, Weddell Seals, whales, and both Emporer and Adelie Penguins. The diet of *Pleuragramma* itself is comprised largely of copepods, mysids, and other fish.

There is a community of fish associated with the underside of the sea ice. This community is characterized by *Trematomus* spp. and *P. borchgrevinki*. These fish feed directly on the sea ice biota. Other fish species live and feed near the bottom.

Many species of Antarctic fish have developed remarkable adaptations to help them survive in the Antarctic marine environment. The body fluids of most fish have a salinity which would freeze at approximately $-0.7°$. Since the water temperature is usually around $-1.8°$ they would freeze solid unless they had a mechanism to deal with it. Many, such as *P. borchgrevinki*, have evolved antifreezes comprised of glycoproteins. These depress the freezing point of the fish by inhibiting the growth of ice crystals as contact will cause damage as they get larger. Fish which do not possess antifreezes, such as *P. antarcticum*, must avoid coming into contact with ice crystals as contact will cause snap freezing.

Squid almost certainly comprise a critical component of the Antarctic coastal ecosystem and yet very little is known about them. Approximately, 72 species occur south of the Antarctic convergence but only a relatively small number are thought to live near the coast. They are known to feed on krill but also feed on a variety of other zooplankton and fish species. They themselves comprise an important component of the diets of several whale species (e.g., Sperm Whale, Killer Whale), seal species (Weddell Seals, Ross Seals, and Elephant Seals), and birds (particularly Emperor Penguins and albatrosses).

Benthic communities

Antarctic coastal benthic environments are characterized by both stable low temperatures and the effects of ice. Seasonal changes in water temperature are small compared to most temperate areas with a range of only 2–3°, from $-2°$ in winter to approximately $+1°$ in summer. Melting ice in spring and summer reduces the salinity of surface waters. Conversely, forming ice in autumn and winter expels salt producing water of higher salinity, which then sinks to the bottom.

Sea ice can affect benthic communities down to at least 10 m. The moving ice scours and abrades littoral and sublittoral areas. Icebergs disturb the seafloor down to depths of over 150 m. These bergs, driven by currents and winds can scour rocky surfaces and plough into sediments.

Benthic microalgal mats grow in most shallow nearshore environments. These mats, which are mostly dominated by diatoms, can account for up to 50% of the annual primary productivity. The biomass of these mats is strongly seasonal and is governed by the amount of light reaching the bottom. In winter, when the sun either does not rise or is low on the horizon for only a few hours each day biomass is at a minimum. The amount of light reaching the bottom is usually further reduced by a cover of sea ice up to 2 m thick.

Over 700 species of seaweed are known form the southern Ocean of which approximately 35% are thought to be endemic. Seaweeds are uncommon down to a depth of 5 m due to the scouring action of the sea ice. In McMurdo Sound *Iridaea cordata* is dominant at shallow depths, *Phyllophora antarcica* at intermediate depths and *Leptophyllum coulmanicm* below 20 m. At all locations the diversity increases with depth.

The equable but cold marine environment of Antarctica has led to the development of benthic communities characterized by high biomass but low growth rates. Biodiversity is similar to benthic communities elsewhere but endemism in most major groups, for example, echinoderms, bryzoa, polychaetes, amphipods, etc, is between 50% and 90%

Epibenthic (i.e., those living on the surface rather than within the substrate) invertebrate communities are also strongly influenced by the actions of sea ice. The upper zone, 0–15 m is almost devoid of animals but is briefly colonized by detritus-feeding echinoids (*Sterechinus neumayeri*) and starfish (*Odonaster validus*), isopods, and small fish. An intermediate zone, 15–33 m is characterized by abundant soft corals, sponges, anemones, hydroids, and ascidians. Fish, mostly *Pagothenia bernachii* and *Trematomus centronotus*, are also conspicuous. The lower zone, below 33 m and down to approximately 200 m is characterized by a diverse community of sponges. Infaunal communities (i.e., those living within the sediment) are dominated by polychaetes (worms) and crustaceans; mollusks, unlike temperate areas contribute less than 5% of the total number of individuals. The number of species found is relatively low, usually less than 100, but the number of individuals can be enormous with over 155,000 individuals per meter square found in McMurdo Sound.

A characteristic of Antarctic benthic communities is the high proportion of suspension feeders. This is thought to be a response to the short period of phytoplankton availability during the short summer ice-free period. This has also led to an increasing prevalence of scavenging and opportunistic feeding strategies compared to elsewhere.

Penguins and other sea birds

The abundance of birds in many areas of Antarctica gives a deceptive impression of their biodiversity. Thirty-eight bird species are known to breed south of the Polar Front but only ten actually breed on the Antarctic continent. This level of diversity is very low compared to most other natural areas. Penguins comprise approximately 90% of the Antarctic avian biomass. Four species, the Emperor (*Aptenodytes forsteri*), Adelie (*Pygoscelis adeliae*), Gentoo (*Pygoscelis papuaa*), and Chinstrap (*Pygoscelis antarctica*) breed on the Antarctic continent, but of these the Gentoo and Chintrap Penguins are restricted to the Antarctic Peninsula area. The Emperor Penguin is the largest of the penguins. It alone of all the vertebrates winters on the continent. All other birds and mammals migrate north for the winter. The Adelie Penguin is the most abundant penguin and colonizes areas of bare rock on the coast or on nearby offshore islands. Colonies can be up to several hundred thousand in size. All penguin diets are dominated by krill, although squid and fish supplement the diets to varying degrees depending on location and seasonal abundance.

Most of the remaining birds breeding on the Antarctic continent belong to the petrel family (Procellariiformes). These include the Wilsons Storm Petrel, Snow Petrel, Antarctic Petrel, Cape Petrel, Antarctic Fulmar, and Giant Petrel. The Southern Skua, a large gull-like bird is an aggressive predator at many bird colonies. Although rarely taking adult birds, it feeds on eggs, chicks, and sick individuals. The only other species is the Blue Eyed Cormorant, which is restricted to northern areas of the Antarctic Peninsula.

Bird distribution patterns and breeding cycles are strongly influenced by the short intense pulse of marine primary production between December and February. As this is the only time when food is abundant, the breeding cycle of all birds, except the Emperor Penguin, must be rushed to coincide with maximum food availability. It is essential that the chicks are fledged by the end of summer so they can migrate north before the growing sea ice prevents them access to their food supply.

Seals and whales

Six species of seals are found around Antarctica, the Weddell Seal, the Ross Seal, the Crabeater Seal, the Leopard Seal, the Antarctic Fur Seal, and the Elephant Seal. However, of these only the Weddell Seal actually breeds on the Antarctic continent. This species, which breeds close to the continent on the fast ice and feeds mostly on fish, squid, and krill, forms groups of up to several hundred. Leopard Seals, together with the Killer Whale, are the main top-order predators. These species both feed on penguins and other seals. The Ross and Crabeater seals (the world's most abundant large mammal) spend their entire lives in the pack ice and never venture to shore. The Elephant and Fur seals are mostly creatures of the sub Antarctic and only juveniles or vagrants make appearances on the Antarctic coast.

Twelve species of toothed whale and seven species of baleen whale are present in the Southern Ocean. None are endemic to the region and most have widespread migration patterns. As a result of the whaling impact most of the larger whales are uncommon, with Blue Whale numbers probably down to only a few hundred. However, the smallest of the baleen whales, the Minke Whale, was never seriously harvested and is possibly more abundant than ever. This species is common in coastal areas. All baleen whales feed on zooplankton, predominantly on krill.

Of the toothed whales, the Killer Whale is the most abundant. It is common throughout the pack ice zone and when the ice retreats from the coast in summer, is also a common visitor to coastal areas. It feeds on most larger animals including fish, penguins, and seals. There are no known human deaths attributable to Killer Whales although there are numerous stories of near misses.

The ecosystem of the Antarctic is often seen as pristine and untouched but this is not the case. The whaling and sealing industries of the 19th and early 20th centuries massively depleted the numbers of top-order predators and effectively removed an important component of the ecosystem. Similarly, in the 1970s, over-fishing led to the commercial extinction of most of the more abundant fish species. National bases have degraded areas of the coastline and dumped waste into the nearby ocean. PVCs, DDT, and other toxic compounds have been found in the tissues of most animals. Introduced diseases (e.g., Newcastle disease, canine distemper) have caused widespread deaths among bird and seal populations. The ozone hole and global warming threaten to make even more significant changes. In spite of all these factors, Antarctica is still one of the least impacted ecosystems.

Antarctic geomorphology

Antarctica is simultaneously both the highest and driest continent on earth. It covers an area of approximately 14×10^6 km^2 and has a coastline approximately 32,000 km long. The average elevation is over 2,300 m but this is largely made up of an ice cap that is over 4,000 m thick near its center close to the south Pole. The ice cap contains 90% of the world's freshwater reserves and covers more than 95% of the continent. The remaining ice-free areas are mostly small, scattered, and located near the coast. The Antarctic coastline itself is predominantly ice bound. Over 38% of its length is comprised of ice cliffs where the ice cap terminates abruptly at the sea. A further 44% of the coast is associated with floating ice shelves, large areas where the polar ice cap extends from the continent and floats on the sea. The largest of these, the Ross Ice Shelf, covers an area of 536,000 km^2; an area larger than the U.S. state of Texas or the country of France. About 13% of the coast is occupied by glaciers and only 5% of the coastline is ice-free and even in these areas sea ice covers the sea surface for up to 11 months of the year.

Much of the land surface of Antarctica is currently below sea level, with the ice cap grounding at depths of up to 1,200 m. Were the ice cap to melt, the land surface would rebound by up to several hundred meters but more than 50% of the current land surface would still be under water and the Antarctic Peninsula would become a chain of islands.

Geological investigations of Antarctica have been closely associated with its exploration history. Of particular interest was the position of the South Magnetic Pole. The British explorer, James Clarke Ross, had this objective in mind when he entered what is now known as the Ross Sea in 1841. However, as he sailed southeast he was confronted by the Transantarctic Mountains blocking his way to the Magnetic Pole. Disappointed, he sailed south reaching 76°S and in the process discovering amongst other things the Ross Ice Shelf and Mount Erebus. Most of the subsequent expeditions of the late 19th and early 20th centuries, which often had funding and backing from scientific associations such as the British Royal Society or Royal Geographical Society, took geological and geographical scientific parties along. Both of Robert Falcon Scott's expeditions included geologists as did those of Shackleton, Mawson (himself a geologist and also searching for the South Magnetic Pole), Drygalski, and others. On Scott's fateful return trip from the Pole, the explorers never considered discarding their heavy load of geological specimens even though they probably contributed to their demise. The single most important event in the scientific understanding of Antarctica was the International Geophysical Year in 1957. This led to the establishment of a large number of permanent bases on the Antarctic continent with the specific aim of investigating the structure and evolution of Antarctica.

The present shape of the Antarctica continent is profoundly influenced by its geological past. Antarctica was an integral part of the ancient supercontinent of Gondwana. This continent started to break up in the Jurassic (approximately 200 million years ago) but the last major segments, that is, Australia and South America, did not finally break from Antarctica until the Oligocene, approximately 40 million years ago. For virtually all of this time Antarctica was situated over the South Pole. The northward movement of Australia and South America away from Antarctica led to the development of Drake Passage beneath South America and the Macquarie Passage beneath Australia. This opening ocean led to the progressive thermal isolation of Antarctica and the onset of continental glaciation. As the Southern Ocean widened, Antarctica continued to cool and a permanent ice cap developed, a feature of Antarctica that has been present ever since. The stability of the ice cap, however, has varied and there is now strong evidence for major periods of ice cap shrinkage and expansion through the Pliocene and early Pleistocene (5.1 million years ago).

The erosive and depositional action of ice is almost entirely responsible for the topography, landforms, and continental shelf bathymetry of Antarctica. While melt water streams are seasonally present in some areas they have been inconsequential in either landscape evolution or marine processes. In Antarctica, ice either covers the surface or is responsible for its features. Less than 5% of the surface area of Antarctica is ice-free. These ice-free areas are small and clustered around the coast. The largest of these is the Dry Valleys of the McMurdo Sound area followed by the Bunger Hills and Vestfold Hills of eastern Antarctica. These areas typically show many of the classical features of recently glaciated terrains, including moraines, striated surfaces, drumlins, etc. Many of these areas are also characterized by rich lake provinces. The Vestfold Hills, for instance, an area of only approximately 400 km^2 contains more than 200 lakes, many of which are hyposaline reflecting a marine origin and subsequent stranding by isostatic sea-level rise. Lakes in the Vestfold Hills area are less than 12,000 years old but some lakes in the Dry Valleys may be as old as 500,000 years. Some of these lakes are permanently ice covered (e.g., Lake Hoare and Lake Fryxell in the Dry Valleys), while some are so saline that they never freeze (Deep Lake, Lake Stineer, Vestfold Hills). One of the more unusual features of many of these lakes is that they are permanently stratified (meromictic), that is the water column is layered with zones of increasing salinity with depth. These layers have typically been undisturbed for thousands of years.

Soft sediment shores are uncommon around Antarctica. This is largely because of the absence of significant river action. Small local deltaic features are sometimes present but these are always of very limited extent. Sandy beaches are particularly uncommon in Antarctica as there is rarely sufficient water action to provide the necessary sorting.

The continental shelf of Antarctica is generally narrow, varying in width between 64 and 240 km wide. However, its most distinguishing features are its irregular topography and its great depth, which averages over 500 m; a depth which is more than five times the global average. The outer shelf is typically 400–500 m depth but, unusually, has a landward sloping profile that deepens toward the coast. Depths of 100–1,200 m are common close to the coast in many areas around Antarctica. The reasons for this unusual profile have been speculated on since the late 1920s. It has been shown that glacial isostasy, that is, the effect of the heavy ice cap depressing the crustal surface, can account for up to 150 m of this depth but the remainder is almost certainly due to the effects of glacial erosion at times of low sea-level stand and glacial advance. In some areas during periods of lower sea level, glaciers carved channels far out onto the continental shelf. These drowned fjords are often beneath the effects of modern iceberg scouring and contain basins with restricted circulation. This has led to the preservation of very well-preserved late Quaternary sequences that have a remarkably good time resolution. Such sequences can be found off the Antarctic Peninsula and on the MacRobertsonland Coast. These glacial troughs are usually associated with modern major ice streams and outlet glaciers and they are likely to be the result of multiple glacial advances. Geomorphic landforms associated with these troughs include megascale glacial lineations, striations, and drumlins.

Sedimentation on the continental shelf is dominated by biogenic and glaciomarine processes. Biogenic sediment is comprised of the remains of animals and plants, predominantly from the plankton, while glaciomarine sediment is sediment-derived originally from glaciers but subsequently deposited in the ocean. In offshore areas up to 50% of the sediment can be of biogenic origin. This is overwhelmingly composed of diatom remains. Diatoms are microscopic plants, 2–100 μm in diameter, with siliceous cell walls. Diatom diversity in these sediments is relatively low due to extensive silica dissolution, a factor that becomes more pronounced with increasing water depth. Dominant species include *F. curta, F. cylindrus, Fragilariopsis kerguelenensis, Thalassiosira lentiginosa*, and *Eucampia antarctica*. Other biogenic components include minor quantities of silicoflagellates, Parmales, and foraminera. The remaining sediment is predominantly of glaciogenic origin, although a small component is also of eolian origin.

Around Antarctica, icebergs influence sedimentation up to a distance of several hundred kilometers from the continent. Sediment entrained in a basal debris zone is transported towards the coast. Sediment enters the sea by one of three principal processes; either at ice shelves, ice cliffs, or via glaciers. Ice at the edge of ice shelves calves into icebergs, which drift out to sea and drop their sediment often far from the coast. Most of the sediment, however, is deposited in the grounding zone (i.e., where the ice shelf begins to float). Ice at ice cliffs is eroded and drops its sediment load in close proximity. Most sediment reaches the coast by glaciers, which calve rapidly into small sediment-laden icebergs. It has been estimated that 62% of the ice transported to the coast of Antarctica is calved as icebergs from ice shelves, 22% from glaciers, and 16% from ice cliffs (Drewry and Cooper, 1981).

Most of the continental shelf, at least down to 400 m, is affected by icebergs. These regularly plough into the sediment, disrupting any bedding and causing the sediments to become well mixed and unlaminated. These sediments are sometimes referred to as iceberg turbate. Calcareous sediments are rare on the Antarctic continental shelf but have been recorded on the shelf break in Prydz Bay. Here the dominant component is barnacle shells.

In Antarctica glaciers are by far the most important contributors of terrestrial sediment to the marine environment. Compared to many glaciers in temperate or Arctic areas, they are predominantly sluggish-moving, very cold, and usually extend out to sea as a floating ice tongue. Most Antarctic glaciers are classified as "cold glaciers," that is the temperature of the ice is below the pressure melting point. This results in a glacier that is dry and frozen to the bed. On the Antarctic Peninsula, where the temperatures are higher and the precipitation is much greater they are more dynamic and the glaciers extend to near the mouths of short fjords. These glaciers which often undergo substantial melting in summer are often classified as "subpolar" glaciers. In cold glaciers, where the ice is frozen to the bed, there is comparatively little erosion of bedrock or deposition of sediment. Furthermore, there is rarely any glaciofluvial sediment.

Glaciers enter the sea via fjords, deep usually linear embayments with shallow sills at their entrance. In most temperate areas the glaciers have retreated leaving a deep marine embayment. In Antarctica, however, the glaciers mostly reach the sea and then extend as a floating ice tongue. Minor glaciers are present in areas where the ice cap has retreated such as in the Vestfold Hills and Dry Valleys. The world's largest glacier is the Lambert Glacier in eastern Antarctica. This glacier drains approximately 25% of the eastern Antarctic ice cap and occupies a trough up to 80 km wide and 800 km long. This glacier has retreated in the geological past and would have left the world's largest fjord.

Global warming resulting from the current accumulation of greenhouse gases is already having a major impact on Antarctic glaciers and ice shelves. Temperatures over the Antarctic are predicted to rise faster than most other places on earth. This is leading to an increase in the rate of disintegration of major ice shelves, particularly evident on the Antarctic Peninsula. A major focus of recent research has been to establish the natural limits of Antarctic climate fluctuations in the recent and more distant past. Minor warming and cooling trends of a few degrees have been identified since the end of the last ice age (i.e., over the last 10,000 years) which have led to small scale advances and retreats of the ice cap and glaciers. However, during the Pleistocene (i.e., 1.6 million to 10,000 years) the ice cap at times extended to the edge of the continental shelf. Periods of increased temperature, comparable to those predicted for Antarctica, have been identified in the Pliocene (i.e., 1.6–5 million years ago). During these times there is strong evidence of major ice cap retreat; indicating a possible warm future for Antarctica.

AQUACULTURE

Definition and history

Aquaculture can be most simply defined as underwater agriculture. It is the rearing of aquatic plants and animals through some type of intervention by humans. Aquaculture is conducted in freshwater and saltwater. The term mariculture is often used in relation to marine aquaculture. Aquaculture involves plants and animals produced for human food, as ornamentals, for bait, and in recent years, as sources of nutritional supplements and pharmaceuticals. Some plants and animals are also grown as foods for other aquaculture species. For example, shrimp hatcheries typically grow one or more species of algae to feed brine shrimp (*Artemia salina*), which are fed upon by larval shrimp.

While there is some production of rooted aquatic plants, echinoderms (e.g., sea cucumbers), tunicates (e.g., sea squirts), amphibians (frogs), and reptiles (turtles and alligators), the majority of the world's aquaculture production comes from seaweeds, molluscs (e.g., abalone, clams, oysters, scallops), crustaceans (e.g., shrimp, crawfish), and finfish.

Aquaculture is widely acknowledged to have been born in China, perhaps as long as 4,000 years ago (Avault, 1996) when carp culture was developed. The first written document on aquaculture, a very short book by Fan Li, entitled *Fish Breeding*, appeared in 475 BC in China (Borgese, 1977). Carp culture was also developed in Europe, possibly during the Middle Ages. Tilapia, a type of fish native to north Africa and the Middle East, is depicted on the tombs of the Pharaohs in ancient Egypt. Whether tilapia was being cultured or not is unclear. Oyster culture appears to have been practiced during the days of the Roman Empire, while shrimp were being produced in China by AD 730 (Borgese, 1977). Native Hawaiians constructed fishponds and apparently developed a primitive form of aquaculture at least several hundred years ago. Thus, aquaculture in one form or another has a long history.

By the mid-19th century, trout culture had become a well-developed art in both Europe and North America (Kirk, 1987; Stickney, 1996). In the United States, brook trout were being produced and at least a few commercial fish farms had been established.

Overfishing in the United States was first reported in the 1750s, but it was not until 1871, when Spencer F. Baird convinced Congress to create the US Fish and Fisheries Commission (Stickney, 1996), that any attempt to rebuild wild fisheries was made. Baird enlisted the best fish culturists of the time and put them to work learning how to spawn an array of fishes and invertebrates with the goal of restocking both the inland and marine waters of the nation. In addition, the Commission shipped fish to foreign countries (e.g., establishing populations of rainbow trout in Europe and both rainbow trout and chinook salmon in New Zealand). Fish such as brown trout and common carp were introduced to the United States by the Commission.

While in most cases the stocking of eggs or newly hatched larvae by the Commission did little more than provide food for wild fishes, a significant amount of information and technology were developed, remnants of which can be seen in the most up-to-date of modern hatcheries. Techniques were developed for successfully producing fingerlings of many recreationally and commercially important species, including largemouth bass, channel catfish, walleye, striped bass, and Pacific salmon to name but a few.

The Commission was responsible for producing and distributing the eggs and larvae of hundreds of millions of fishes and invertebrates. Attempts were made to establish Atlantic salmon on the Pacific coast and Pacific salmon in the waters of New England. Both attempts failed, though not because of a lack of effort. Millions of eggs were shipped over a number of years to accommodate the program. Pacific salmon were ultimately established in the Great Lakes, but not until the 1980s.

Ultimately, attempts to enhance marine fisheries through stocking by the Commission and its successor organizations were terminated, though new enhancement programs, largely by the various individual states, have been initiated in recent years. Stocking programs for inland waters, by both state and federal agencies have continued.

Modern commercial aquaculture can arguably be attributed to have its origins in one or more of several countries and decades within the 20th century. For instance, breakthroughs that made possible the development of commercial shrimp culture occurred in Japan during the 1930s, though the industry did not develop significantly until the 1980s after which considerably more information had been developed in Japan, Taiwan, the United States, and other nations; information that was critical to move the technology beyond the research and demonstration phase.

The late 1960s and the 1970s serve as a benchmark period during which commercial aquaculture developed rapidly and began making significant contributions to the world's foodfish supplies. Fish farmers in the southern United States initially produced buffalo (*Ictiobus* sp.), but soon turned to channel catfish (*Ictalurus punctatus*). While the potential for rearing catfish to food size profitably was demonstrated in the 1950s (Swingle, 1956, 1958), commercial activity did not expand from producing and selling catfish fingerlings to growout of foodfish until the mid-1960s (Wellborn and Tucker, 1985).

During the same two decades (1960s and 1970s), commercial crawfish culture developed in Louisiana and rainbow trout production increased dramatically, particularly in the Thousand Springs area of Idaho (Stickney, 1996).

Marine shrimp research with various species in the former genus *Penaeus* (which has recently been split into several genera) was being conducted in both the United States and Taiwan, which led to two different types of larval rearing systems, both of which have been employed extensively. Taiwan and Japan were leading shrimp producing nations in Asia until the 1980s when Thailand, China, Indonesia, the Philippines, India, and others developed active industries. In the Western Hemisphere, the shrimp industry began in the 1980s and was centered in Ecuador, which continues to dominate Latin American production, though many other nations are now involved. The 1970s saw a great deal of interest in the culture of freshwater shrimp, *Macrobrachium rosenbergii*, but for various reasons, there are very few farms currently producing that species.

Also, during the 1980s, the feasibility of producing salmon in net-pens placed in the marine environment was demonstrated (Stickney, 1994). Much of the initial work was conducted on the west coast of the United States with coho (*Oncorhynchus kisutch*) and chinook (*Oncorhynchus tshawytscha*) salmon, and some commercial production occurred in both the United States and Canada. However, it soon became apparent that Atlantic salmon (*Salmo salar*) was more amenable to culture and the industry concentrated on that species, with Norway becoming the dominant salmon-growing nation. Chile became a major salmon-producing nation in the 1990s. Canada continues to produce significant quantities of salmon, and Maine has become the dominant salmon producing state in the United States, though there is still some production in the state of Washington. Large hatchery programs to produce Pacific salmon for release into the wild continue in the Pacific Northwest.

Many other aquatic species have been commercially produced within the past few decades. At present, there are well over 100 species under culture around the world, with more being developed each year. In Europe, sea bass (*Dicentrarchus labrax*) and sea bream (*Sparus aurata*) are being produced in the Mediterranean region, while Atlantic halibut (*Hippoglossus hippoglossus*) are cultured in Norway and Scotland along with the previously mentioned Atlantic salmon. Plaice (*Pleuronectes platessa*) and sole (*Solea solea*) are also among the fishes cultured in Europe.

Popular marine fishes in Japan are salmon (*Oncorhynchus* spp.), red sea bream (*Pagrus major*), and yellowtail (*Seriola quinqueradiata*). Milkfish (*Chanos chanos*) are produced primarily in the Philippines, Thailand, and Indonesia.

Tilapia (*Oreochromis* spp.) are being reared in both salt and freshwater throughout the tropical world and indoors in some temperate areas. Their fast growth and excellent flavor make them excellent aquaculture species.

Among the invertebrates being reared around the world are oysters (e.g., *Crassostrea* spp. and *Ostrea* spp.), including of course, pearl oysters, mussels (primarily *Mytilus* spp.), abalone (e.g., *Haliotis* spp.), and scallops (e.g., *Pecten* spp. and *Patinopecten yessoensis*).

Then there are the plants, dominated by red and brown seaweeds, but including green seaweeds (all of which are forms of algae), but also including higher plants such as water chestnuts, watercress, and such ornamental plants as water lilies, to name but a few. A wide variety of microscopic single-celled algae are produced as food for larval stages of aquacultured animals and, in the case of species such as *Spirulina*, as nutritional supplements for humans (*Spirulina* is also used as a food additive to produce color in fish). Extracts from aquatic plants are also being developed into pharmaceutical products.

Global production

Seaweed aquaculture comprises nearly one-quarter of total world production (New, 1999). Seaweeds play a large role in Asian cuisine, particularly that of Japan. Extracts from seaweeds, including agar and carageenin, are components of products utilized by people around the world. Seaweed extracts are used in automobile tires, toothpaste, ice cream, pharmaceuticals, and a wide variety of other commonly employed products.

By 1996, total world aquaculture production exceeded 34 million metric tons (mmt), with nearly 11 mmt coming from seaweeds (FAO, 1998). A breakdown of production by type of organism is presented in Table A2.

Table A2 World aquaculture production for various groups of organisms in 1996 (data from FAO, 1998)

Organism group	Production (mmt)
Freshwater finfish	14.4
Diadromous finfish[a]	1.7
Marine finfish	0.6
Crustaceans	1.1
Molluscs	8.5
Seaweeds	7.7
Micellaneous[b]	0.1
Total	34.1

[a] Includes fishes that spend part of their life cycle in freshwater and part in saltwater or that can live in either medium throughout their lives. Examples are salmon, eels, and milkfish.
[b] Includes amphibians, reptiles, tunicates, and other minor species.

Table A3 World aquaculture production in 1996 by continent and the top 10 nations in terms of total aquaculture production (data from FAO, 1998)

	Percentage of world total
Continent	
Asia	88.9
Europe	6.0
North America	2.3
South America	1.6
Oceania	0.3
Former USSR	0.4
Africa	0.4
Nation	
China	45.7
India	7.4
Japan	7.0
Republic of Korea	4.5
Indonesia	3.6
United States	3.6
Philippines	3.2
Taiwan	2.8
Spain	2.6
France	2.2

The most widely produced finfish are various species of carp, with the vast majority of that production occurring in China. In fact, China was responsible for 45.7% of the world's aquaculture production, excluding seaweeds, in 1996. When Asia is compared with other regions, the dominance of that continent in terms of aquaculture production is even more impressive (Table A3). Comparison of the top 10 countries in terms of aquaculture production also demonstrates the dominance of China, but also the important contributions of other Asian nations (Table A3).

The world's capture fisheries peaked and now hover around 80 mmt, while demand continues to increase. Aquaculture expansion has been identified as the only means of meeting that demand, and currently available data show that aquaculture production has rapidly increased in recent years. New (1999) developed a comprehensive overview of global aquaculture production that includes a comparison of data between 1987 and 1996. Production over the period covered increased from 13.4 mmt in 1987 to 34.1 mmt in 1996. That rate of expansion cannot be maintained indefinitely, however. Many of the best places to conduct aquaculture are currently being utilized, while various constraints mitigate against aquaculture development in regions where climate might be conducive to good growth of aquatic species. Water supply and quality are constraints in many areas. In the coastal zone, the high cost of land and competition with other users often mitigate against using it for aquaculture.

One approach is to establish fish farms in the open ocean. The costs and logistics associated with that idea present significant problems, but at least some success has been realized. Enhancement stocking, first undertaken by the US Fish and Fisheries Commission over a century ago, is currently being re-evaluated. Revitalization of the red drum (*Sciaenops ocellatus*) fishery in Texas through an aggressive stocking program coupled with strict fishing regulations (including a ban on commercial fishing) provide an indication that such programs have potential and may be cost effective. One approach would be to pay for the programs through license fees, which would apply to commercial and/or recreational fishermen depending upon the species employed.

Much of the increase in aquaculture production over the years, at least in developed nations, can be attributed to increased knowledge that has led to improved technology. One example is the channel catfish industry in the United States. When the industry was in its infancy, a profit could be made if the fish were sold at $1.10/kg. Forty years later, a profit can still be made when catfish prices to the producer are in the range of $1.65–1.80 per kg. The reason that catfish farmers can still realize a profit given the small increase in price per unit weight over nearly a half century of production is related to increases in production per hectare, which is a function of improvements in management of water quality, improvements in the food provided, and to a lesser extent, selective breeding programs.

In the 1950s, when catfish farming was in its infancy, a production level of about 500 kg/ha was considered credible. By the late 1960s that had increased to 1,500 or even 3,000 kg/ha. Currently, some catfish farmers produce as much as 10,000 kg/ha in ponds. Without those increases in production, the catfish industry would have probably collapsed.

Culture systems

The vast majority of aquaculture species are grown in ponds, though a number of other types of culture systems are also in use. They include linear and circular raceways (the latter are also known as tanks), cages, and net-pens. Specialized culture systems for molluscs and seaweeds include bottom culture in bays, pole culture, net culture, basket culture, and raft culture (Stickney, 1994).

Culture systems are often classified as extensive or intensive, though in reality the intensity of culture occurs along a continuum and relates to the complexity of the culture system. An example of a highly extensive system would be the culture of oysters in natural waters by spreading shell (cultch) material on the bottom and allowing larval oysters (spat) to settle and grow. Very little intervention by humans, other than preparation of the bottom and the spreading of shell is involved.

At the other extreme are high-intensity closed-recirculating water systems. Such systems employ raceways as culture chambers. Water is continuously exchanged in each raceway. Exiting water is treated, at a minimum to remove solids (usually by settling or mechanical filtration) and convert ammonia (NH_3 or NH_4^+) and nitrite (NO_2^-) to less toxic nitrate (NO_3^-) in a unit called a biofilter. Additional components that maintain temperature in the desired range, remove foam, convert nitrate to nitrogen gas (N_2), and remove other nutrients, may also be present. Most closed systems, receive supplemental aeration to maintain a high level of dissolved oxygen in the culture chambers. In truly closed systems, new water is added only to replace that lost to splashout, evaporation, or to flush solids from the system. Systems that have the same basic components but in which some percentage of the water is routinely or continuously changed by adding new water, are called semi-closed.

Between the extremes are the other systems mentioned above. Culture ponds, unlike most farm ponds, are most commonly rectangular in shape, are usually no more than 2 m deep, have a drain structure of some type incorporated into them and are, in most cases, located in an area where there is a reliable source of water. While some culture ponds depend on rainwater runoff to fill them, most ponds, at least in the developed world, employ well water or water from a stream, lake, or reservoir for filling and maintenance. Culture ponds come in many sizes, but most used for commercial production range from about 0.1 to 10 ha, with those between about 1 and 5 ha being the most commonly seen. Small ponds are used most often for breeding and rearing of early life stages, while the growout commonly occurs in larger ponds.

If two or more species are reared in the same culture unit—a process known as polyculture—that unit is most likely a pond. The Chinese have a very long history of carp polyculture, which involves different species with different feeding habits. Different species are stocked to consume phytoplankton, zooplankton, benthic invertebrates, and rooted aquatic plants. Benthic feeding carp may specialize on worms and insect larvae or molluscs. Today, the Chinese may also provide agricultural byproducts and prepared feeds. They, like aquaculturists in many other countries, maintain a high level of pond fertility to encourage the growth of natural food organisms. Cattle, swine, and poultry manure are common sources of fertilizer. Livestock are routinely seen being reared adjacent to ponds into which they deposit fresh manure. Rearing livestock adjacent to fishponds is common in many countries, particularly in the developing world.

The majority of raceway systems are of the flow-through variety. That is, water is continuously exchanged. Depending on stocking density and water quality, the exchange rate may range from several times an hour to several times a day.

Cages are relatively small structures with ridged walls, commonly made of welded wire or rubber-coated wire. Cages are used to contain fish in water bodies that are not enclosed (bays, rivers), and in those which are too large, too deep, or have some physical impediment to harvest (such as standing dead timber). Many reservoirs and lakes are good examples. Cages are not usually more than one to a few cubic meters in volume. Cages may be taken to the shoreside to facilitate harvesting.

Net-pens are large cages where nylon netting is employed for the sides and bottom instead of ridged material. The standard design most commonly used in protected marine waters where the net-pens are not exposed to high waves is typically $20 \times 20\ m^2$ on a side and can be 20 or more meters deep. Both cages and net-pens are provided with floats to keep them at the surface. Cages usually sit low in the water and are fitted with tops, while the sides of net-pens typically extend above the water surface sufficiently to prevent fish from jumping over the open top. Walkways around the perimeter of each net-pen allow access for feeding and harvesting.

Recently, there has been a move toward rearing fish in offshore locations. Net-pens designed for the open ocean are usually fully enclosed by netting because they may be subjected to storms. Some are designed so they can be totally submerged throughout the growing cycle or during stormy periods.

Oysters, mussels, clams, and scallops are less susceptible to predation by starfish and other organisms if they are grown off the bottom. Poles, lines, and baskets have been used in conjunction with off-bottom culture. In Spain, for example, ropes to which oysters or mussels are attached are suspended from large rafts.

Enhancement, as previously mentioned, is an option that deserves further consideration. While the culturists associated with the US Fish and Fisheries Commission in the latter half of the 19th century failed in their efforts to increase the numbers of fish in the sea, advances since that time greatly increase the potential for success.

Hatchery technology has developed to the point where the larvae of many species of interest can be reared from egg to appropriate stocking size economically. Enhancement efforts need to be conducted in an environmentally sound manner, however. Fish and invertebrates should not be stocked in such numbers that they overwhelm the available food supply; they should not cause declines in the populations of other valuable species in the community; and their genetic composition should reflect that of wild populations, to name but a few considerations.

Getting started

Several steps should be taken in advance of actually establishing an aquaculture facility. First, the prospective culturist should determine what species will be produced and type of water system to be employed. A suitable location should also be identified. All three factors tend to be co-dependent. Sometimes, the prospective aquaculturist will own property selected as the site of the new facility. If that property is in a subtropical area and there is no suitable source of cold water, it would be undesirable to attempt to produce trout or salmon. Similarly, if the property is distant from the coast and there is no convenient source of saline groundwater, producing marine fish might not be wise. The exception to those examples might be employment of a closed water system within which temperature and salinity could be controlled. Economic analyses of each option under consideration should be conducted to help determine the best course of action.

Once the above matters have been resolved, it is necessary to produce a business plan. Such a plan will be required by lending institutions and venture capitalists. The plan should include a complete financial analysis showing all costs associated with constructing, equipping, and operating the facility over a period of several years, along with an estimate of profit or loss for each year projected. All estimated costs and income should be based on information that can be documented. The culturist should provide a listing of the permits that may be required for the facility as well as a timetable for obtaining those permits and the fees that are associated. Conceptual drawings, or even better, detailed engineering blueprints, should be included with the business plan.

The prospective aquaculturist should determine what, if any, local, state, or national governmental permits are required. In some instances, the permitting process can be long and arduous. It may also be costly, particularly if the applicant is required to battle opponents within the legal system and conduct an extensive environmental impact study prior to establishing a facility. In general, inland aquaculture sites and those located along the coast that employ recirculating technology or other water systems that do not impact the marine or estuarine environment are more easily permitted than those that are established in public waters.

Facility management

On the surface, aquaculture is a biological discipline. In reality, like terrestrial farming, aquaculture involves a variety of sciences as well as engineering, business management, and such skills as plumbing, welding, carpentry, and electrical wiring. In the science arena, while expertise in biology is critical on any fish farm, an understanding of chemistry may be even more important. As the size and intensity of aquaculture operations increase, so does the need for additional and better-trained personnel. A subsistence culture operation in a developing country might be operated by an individual or a family, with perhaps a few additional laborers. A large pond operation that involves a hatchery, larval rearing, and production facilities, or an intensive raceway operation may require a large number of unskilled laborers as well as employees proficient in various specialties. Some of the technical aspects associated with operation and management of an aquaculture facility are discussed in the following subsections.

Water quality

Maintenance of good water quality is critical in any aquaculture facility. There are virtually hundreds of thousands of chemicals that can be found dissolved in water. In addition, there are physical characteristics such as temperature and transparency that can affect performance of organisms in an aquaculture facility. It is neither possible nor necessary to monitor all aspects of water chemistry. In most culture systems, after an initial screening of the water supply for toxicants (e.g., herbicides, pesticides, high levels of trace metals), routine monitoring involves only a few variables. Water temperature and dissolved oxygen, and in marine systems, salinity are typically measured at least several times a week and records of them are maintained. Some culturists employ sensors that constantly monitor those parameters and download the information into computers. Water transparency monitoring is also conducted in pond systems and provides a simple means of determining the state of plankton blooms. This is particularly important in systems that employ fertilization to provide natural food.

In high intensity systems, ammonia may be routinely monitored. Nitrite levels might also be tracked, particularly during colonization of biofilters with bacteria, since the types of bacteria that convert nitrite to nitrate tend to lag behind those that convert ammonia to nitrite. Thus, if only ammonia is measured, the culturist may get the impression that the water is not toxic, when in fact, it may contain a high level of nitrite. Toxic nitrite levels have occurred in heavily stocked catfish ponds in the United States during the late summer, so routine monitoring during that critical period is often undertaken. While ponds are not equipped with biofilters, the bacterial conversion of ammonia to nitrite and nitrate does occur.

Water temperature is of critical importance because it controls metabolic rate in the species being cultured. Aquatic animals can often be categorized as being warmwater or coldwater species. Warmwater animals are those that have an optimum temperature for growth of 25°C or higher, while coldwater species have an optimum below about 15°C. There are some animals, such as walleye (*Stizostedion vitreum vitreum*) and northern pike (*Esox lucius*) that have an optimum between 15°C and 25°C. Such animals are sometimes referred to as midrange species.

Most species have a broad tolerance for environmental temperature. Many species of fish live over a range of temperatures from near 0°C to somewhat above 30°C. Channel catfish and largemouth bass (*Micropterus salmoides*) are but two examples. Many coldwater species, such as trout and salmon, cannot tolerate warm temperatures, while many tropical fishes, such as tilapia, die at temperatures where trout and salmon thrive. Tilapia grow most rapidly when the water temperature is about 30°C, show significantly reduced growth at about 25°C, and stop growing around 20°C. Below the latter temperature tilapia lose their disease resistance and will die when temperatures fall much below 15°C (Avault and Shell, 1968).

Terrestrial animals live in an atmosphere that contains some 20% oxygen, while aquatic species live in a medium that contains only a few parts per million (ppm) of the same essential element. Depending on species, the minimum level of dissolved oxygen in the water that should be present to ensure that the animals have a sufficient supply varies from about 3 ppm (e.g., for catfish) to 5 ppm (e.g., for salmon and trout). From a practical standpoint, it is always desirable to have dissolved oxygen at saturation.

The amount of oxygen that water can hold (the saturation level) varies with temperature, salinity, and altitude. As each of those variables increases, the ability of water to hold oxygen decreases. Thus, warm, saline water at high altitude would hold less oxygen than cool, freshwater at sea level. In virtually all locations where aquatic animals are cultured, dissolved oxygen saturation level reaches or exceeds 5 ppm.

Dissolved oxygen follows a diurnal (daily) cycle. During daylight hours, phytoplankton and other types of vegetation in the aquatic environment produce oxygen as a result of photosynthesis. As a result, the oxygen level in water tends to increase during the daytime. Oxygen is also introduced into water through diffusion from the atmosphere, a process that is enhanced through wind turbulence or mechanical aeration. At night, both plants and animals respire, thereby consuming oxygen during a period when no photosynthesis is occurring (though diffusion is still operating). The result is a cycle in the availability of oxygen in the water. The cycle is also influenced by weather conditions and season of the year. During cloudy days, the rate of photosynthesis is reduced (because of reduced light level), while during clear weather the rate of photosynthesis is accelerated. Recall that temperature plays a role in the saturation level of dissolved oxygen in water; thus the seasonal variation. In most cases, problems associated with low dissolved oxygen occur during warm weather after a period of cloudy days. This often occurs during the late summer or early fall in temperate areas (the time just prior to harvest).

Aquaculturists routinely measure dissolved oxygen in pond systems early in the morning, particularly during the time of year when depletions are likely. Dissolved oxygen level typically peaks in the late afternoon before dusk and gradually falls during the night, and begins to increase after dawn. The lowest dissolved oxygen level will usually occur just prior to dawn, so the aquaculturist needs to check conditions at that time and determine which, if any, ponds may be approaching critically low oxygen levels.

When oxygen levels are low, the culture animals may alert the observant culturist. Fish may swim at the surface with their mouths open. They appear to be gulping for air. Shrimp may climb above the water level on rooted plants to expose their gills to the atmosphere. By the time such signs are noted, the animals may have already been severely stressed. It is much better to routinely measure dissolved oxygen during the night and take action to prevent severe depletions before they occur.

Under moderate stocking regimes only a few ponds on a given aquaculture facility will experience oxygen depletions on the same day and it is not necessary to have each pond provided with emergency aeration equipment. In many cases today, however, stocking densities are so high that oxygen depletions may occur with some frequency in nearly every pond. Such facilities may have aeration equipment permanently assigned to each pond. Paddlewheel aerators are commonly seen in culture ponds. They may be turned on only when the oxygen level falls below a specific level, or they may routinely be run during the night, or in some cases, continuously.

Mechanical aeration is not the only means of aerating ponds. New, oxygen-rich water can be added, though that can be expensive. Mechanical aeration is not inexpensive, however. It requires the equipment and the electricity or fuel required to operate that equipment.

Aquatic animals may have a wide range of tolerance for salinity (euryhaline) or may be restricted to a rather limited salinity range (stenohaline). Salinity is measured in parts per thousand (ppt). The salinity of freshwater is typically about 0.5 ppm, while full strength seawater is usually about 35 ppt. The optimum salinity for an aquatic species may be constant throughout the life cycle or it may change at various life stages. Salmon, for example, spawn and their eggs hatch in freshwater where the larvae live for a few weeks to two years before migrating to the ocean. Fish that spawn in freshwater but grow to adulthood in seawater are called anadromous. Those that spawn in the ocean and migrate to freshwater to grow to adulthood, such as eels, are catadromous.

While most aquatic organisms survive and grow well at a constant optimal salinity, it may be necessary to change the salinity when rearing certain species. It is important to know when those salinity changes should be made and the extent of the changes.

Ammonia is produced by many aquatic species as a metabolic waste product. Ammonia enters the water through the gills. As previously indicated it can be present in the water in two forms: ionized (NH_4^+) or unionized (NH_3). It is the unionized form is highly toxic to aquatic animals. The ratio between the two forms is determined by factors such as water temperature and pH. As either or both temperature and pH increases, the amount of unionized relative to ionized ammonia increases. Under most conditions, total ammonia concentration should not exceed about 1 mg/l. That will ensure that the level of unionized ammonia is not excessive.

Water pH can undergo fairly dramatic changes diurnally, particularly when there is a strong algae bloom present. As plants and animals respire at night in the absence of sufficient light to promote photosynthesis, the increased level of carbon dioxide in the water causes the pH to drop unless the system is well buffered. During the daytime, carbon dioxide is removed from the water by photosynthetic organisms and pH may rise. Carbonate (CO_3^{2-}) and bicarbonate (HCO_3^-) ions make up the foundation of the buffer system. They can absorb hydrogen ions (H^+) or in the case of bicarbonate, act as a source of H^+. If the supply of bicarbonate becomes exhausted, pH can change dramatically. Poorly buffered systems can be as acidic as pH 6 in the early morning and as basic as pH 10 in the afternoon if the buffer system is weak. In recirculating systems, pH will tend to drop over time as organic acids become concentrated in the water. Most aquatic species cannot tolerate such swings in pH. Calcium carbonate in the form of limestone or crushed oyster shell can be employed in the water system to help maintain pH by providing a source of carbonate ions.

Routine measurement of pH and alkalinity (a measure of carbonate and bicarbonate ions) every few days is common on aquaculture facilities. Hardness (a measurement of the calcium plus magnesium level in the water) may also be monitored. Some species, such as the euryhaline red drum that can be found in estuaries as well as in the coastal ocean of the southeastern Atlantic and Gulf of Mexico coasts of the United States, can survive and grow well in hard freshwater, but performance is not as good in soft freshwater.

Genetics and reproduction

Most species being successfully produced by aquaculturists can be maintained throughout their life cycles. Closing the life cycle has been relatively simple for some species, but very difficult for others. Aquatic animals with large eggs, such as salmon, trout, catfish, and tilapia—each of which has eggs 3 mm or larger in diameter—readily spawn in captivity. Their eggs can be incubated relatively easily and the newly hatched fish will consume prepared feeds as first food after yolk sac absorption.

Many aquatic animals of aquaculture interest have very small eggs and larvae so small as to be nearly invisible to the naked eye. The larvae tend to be very fragile and often have extremely limited swimming ability. If exposed to water currents in a hatchery raceway, they may become impinged on screens and killed. For many species, providing a complete feed that will be accepted has proved difficult so it is often necessary to culture living zooplankton as first food.

The most simple approach is to allow the animals to spawn naturally. Providing the proper conditions for spawning is not always possible, and in some cases, culturists still do not know how to duplicate what the animals experience in nature. Hormone injections are sometimes used to induce spawning. In the case of marine shrimp, removal of an eyestalk from females can trigger ovulation.

Fertilized eggs may be allowed to incubate naturally or they may be taken to a hatchery for artificial incubation. Various types of specialized hatching facilities have been developed. Not only is the survival rate generally higher in a hatchery than in a pond, but the culturist can get a good estimate of the number of offspring that have been produced since they are easy to observe in the hatchery as compared with an outdoor pond situation.

Only a few aquatic animals have been truly domesticated through many generations of selective breeding. Most are still only a step or two removed from their wild counterparts. In some cases, for example, in conjunction with hatcheries that produce fish for stocking into nature, a conscious effort is made to maintain the genetic integrity of the wild stock. For animals bred to be reared in captivity only, selection of brood stock for rapid growth, improved body configuration, disease resistance, and other desirable qualities may be employed.

The use of genetic engineering in conjunction with aquaculture species is in its infancy, but there has been some research activity in that controversial arena. Researchers have successfully incorporated selected genes from one species into another, but there do not appear to be any commercially produced transgenic aquatic animals in the market.

Nutrition and feeding

Feed represents the largest variable cost for most types of aquaculture. The exception is mollusc culture where wild phytoplankton is fed upon in most instances (cultured algae is used in mollusc hatcheries and fertilization of ponds is widely used in China and other countries to produce natural food). Many fishes and crustaceans are provided with commercial feeds. When prepared feeds are employed, they often represent nearly half of the variable costs associated with operating the aquaculture facility.

Most fishes and crustaceans will either accept prepared feeds upon first feeding or can be weaned from natural foods within a few weeks after first feeding. Prepared feeds may be a mixture of ground and mixed feedstuffs that are fed directly, or the ingredients may be formed into pellets. Feed pellets can be made in a variety of sizes and shapes; they can be dry, moist, or semi-moist; they may be hard or soft, and they may either sink or float depending upon the species being fed, local ingredient availability, and the type of equipment used in feed manufacture.

For some species, the nutritional requirements have been determined in some detail. Examples are salmon, trout, catfish, tilapia, carp, and to a lesser extent shrimp, striped bass, red drum, and a number of others (Wilson, 1991; D'Abramo *et al*., 1997). Depending upon the species, requirement information may be available on dietary energy, protein and amino acids, lipids and fatty acids, carbohydrates, vitamins, and minerals.

Feeds may contain animal protein from a few percent (channel catfish) to one-third or more of the diet (some salmonids), or they may be made up entirely of plant feedstuffs with or without added vitamins and minerals. Most of the animal protein in aquaculture feeds comes from fish meal, though poultry byproduct meal, and meat and bone meal are among the other options. Locally available ingredients are typically employed when possible. Fish feeds in Asia, for example, often contain relatively high percentages of rice bran, which has limited nutritional value but is readily available. Soybean meal is a major ingredient in many fish feeds in the United States. Diets may also contain corn meal, cottonseed meal, and/or peanut meal depending on availability and cost. A wide variety of other ingredients are also used.

Aquatic animals on prepared feeds are usually fed once or twice daily during the growout period. The total amount of feed provided on a daily basis is usually not more than 3–4% of the biomass of the animals being fed. Young animals are usually fed at a higher rate (as much as 50% of body weight initially, and declining as the animals become more proficient at finding feed and their relative growth rate slows). Young animals may be fed more frequently. Some carnivorous species may be offered small amounts of feed as often as every few minutes to keep them satiated and reduce cannibalism.

Feeding may be done by hand, though increasingly, automated feeding systems are being employed. Such systems have been developed for virtually every type of water system. Some feed automatically when activated by timers, while others may be activated when animals go to the feeder. The latter, called demand feeders, are used in conjunction with some finfish rearing operations and feature a rod or plate that is suspended in the water which when bumped by the fish causes a few feed pellets to be released.

Diseases

Aquatic animals are susceptible to a wide variety of diseases. Organisms responsible for disease in aquatic species include fungi, bacteria, nematodes, cestodes, trematodes, as well as parasitic protozoans, copepods, and isopods. Some can cause death while others may stress the affected animal to the point that it becomes more susceptible to additional diseases. Not all aquatic animal diseases are caused by other organisms. Some, such as gas bubble disease, are caused by water quality problems (in this case gas supersaturation). Nutritional deficiency diseases also exist. For example, vitamin C deprivation can lead to decalcification of bone, which can lead to spontaneous fracturing of the vertebral column.

While a variety of disease treatments have been developed and are in widespread use around the world, only a very small number of drugs have been approved for use on aquatic organisms in the United States. The US Food and Drug Administration must approve each drug utilized on foodfish. Because the industry is relatively small, the market for drugs often does not justify the financial investment required by the pharmaceutical companies to obtain clearance.

Controversies in aquaculture

In recent years, aquaculture has come under increasing criticism from environmentalists. Particularly heavy criticism has been leveled against aquaculture being conducted in pubic waters. The conduct of aquaculture on private land has received less opposition, except in cases where effluents from such facilities enter public receiving waters.

Salmon net-pen culture in Washington and Maine, and marine shrimp culture in Texas are two examples of aquaculture activities that have been targeted by anti-aquaculture groups. The net-pen industry in Puget Sound, Washington was initially objected to because upland landowners felt the net-pens represented visual pollution. That objection failed to gain traction in the courts, but many other criticisms followed (Stickney, 1990). Included were claims of:

- Waste feed and feces causing dead zones under net-pens
- Nutrients released from decaying feed and feces leading to eutrophication
- Antibiotics in feed entering the food chain leading to the development of resistant bacterial strains
- Net-pens interfering with recreational and commercial fishing
- Net-pens interfering with navigation
- Fish in net-pens transmitting diseases to wild fish
- Escapees from net-pens interbreeding with wild fish, or in the case of nonnative Atlantic salmon successfully colonizing and displacing wild salmon
- Net-pen aquaculture operations being noisy and producing noxious odors.

Many of the claims have at least some basis in reality or hold the potential of becoming problems, though each can be effectively dealt with if the net-pen facility is properly constructed and placed in the proper location (Parametrix, 1990).

If located in areas where tidal exchange and currents are insufficient to carry away waste products, an anoxic zone can occur. In Japan, uncontrolled development of net-pen facilities in several bays led to so-called self-pollution that resulted in heavy mortalities. Strict regulations on the number of net-pens per unit area are now in force in Japan and the problem has been resolved.

Salmon farmers, as other aquaculturists, are dedicated to maintaining the highest possible water quality and other environmental conditions for the animals under their care. Degradation of the culture environment causes stress and can lead to disease. If disease does occur, an approved antibiotic may be employed, but only for 10 days at recommended rates, so large amounts of such pharmaceuticals are not used.

Atlantic salmon have been known to escape but they cannot interbreed with Pacific salmon (the situation is different in Maine where Atlantic salmon are native). Many attempts were made to establish Atlantic salmon in the Pacific Northwest by the US Fish and Fisheries Commission over a century ago. All of those attempts failed. Atlantic salmon that have escaped into the waters of the Pacific Northwest in North America do not seem to compete well with native Pacific salmon.

Proper siting will help avoid problems with nutrient concentration and interference with other users. Excessive noise is not a valid criticism of net-pen operations and there would only be noxious odors in the event of a fish kill that was not immediately cleaned up.

The Texas shrimp farming industry has come under criticism for releasing sediment and nutrient-laden water into adjacent public waters. In one part of the state the suspended solids load from shrimp pond effluents has been blamed for heavy siltation of navigable waters, while nutrients in the effluent are blamed for harmful algae blooms. There has also been concern expressed that diseases in cultured shrimp could spread to wild populations. The industry is dealing with the situation by constructing wetlands through which water exiting the production ponds passes. Solids can settle and nutrients can be taken up by the wetland vegetation. The water may then be recirculated back to the ponds rather than released to the environment. Significant improvements in water quality have been achieved and production costs reduced when constructed wetlands are employed.

The other major criticism of the shrimp industry in Texas and other states involves the use of exotics. Most of the shrimp raised on farms in the United States are exotics from Asia or Latin America. Research on native species was all but halted in the 1970s, but many feel that attempts should be initiated to solve some of the problems so the industry can move away from exotic or nonindigenous species.

The development of extensive pond culture for shrimp has led to destruction of mangrove areas in many tropical countries. Some nations have recognized the importance of mangroves as habitat for marine organisms and wildlife and as buffers that can dampen the effects of storms on upland regions. As a result, mangrove habitat destruction has been outlawed or significantly reduced due to governmental regulation. In addition, mangroves grow in acid soils, which are not as conducive to supporting aquaculture operations as other soil types.

Many countries have brought in nonindigenous species and introduced them into culture. Besides Atlantic salmon and marine shrimp as previously discussed, examples include tilapia in North, Central, and South America as well as throughout much of tropical Asia; Latin American species of marine shrimp in the United States; various species of carp in the United States and Latin America; and walking catfish (*Clarias* spp.) in Europe. For species which have only recently been introduced into aquaculture as exotics, there is concern about escapement and establishment of wild populations that could compete with and perhaps displace native species. The rapid spread of common carp throughout North America beginning in the 19th century and the dispersal and establishment of tilapia in parts of Asia (where tilapia are now considered native though they have been present in Asia only since the 1930s) and Latin America are good examples.

While transgenic fish are not apparently being commercially produced for sale, researchers have been able to incorporate growth hormone producing genes from one species into another and obtained an increased growth rate. Transgenic fish with so-called antifreeze genes that might, for example, allow tilapia to survive at much lower temperatures than normal have been discussed. This type of activity is controversial and there are many stories in the media that have convinced at least a portion of the public that transgenic fish are threats to the environment as well as to the health of consumers. A great deal of debate surrounding this activity will occur before transgenic fishes become commonplace in the market.

ARCHAEOLOGICAL SITE LOCATION, EFFECT OF SEA-LEVEL CHANGE

In the past, archaeologists often drew conclusions about prehistoric peoples' use of coastal areas and coastal resources from the observable archaeological sites along the existing coastline. However, as archaeologists began to understand the magnitude of sea-level changes associated with the Pleistocene glacial stages, it became apparent that archaeological sites reflecting coastal adaptations along the present coastline were representative of only those periods of time when the prehistoric coastlines coincided with their present positions.

The coastal sites from most prehistoric periods are now either submerged on the continental shelves due to post-glacial rises in eustatic sea level (see *Eustasy*), or located at elevations far above present sea level due to post-glacial isostatic rebound of the earth's lithosphere. In some areas, local tectonic movements have also affected the elevation of former coastal sites in relation to present sea level. Therefore, it is very important for archaeologists studying coastal archaeological sites to understand how the location of the coastline has changed throughout the prehistory of an area. Understanding these changes will help in reconstructing the proper paleoenvironmental setting of the archaeological sites at the present coastline, and in knowing where to look for former coastal archaeological sites.

Sea level changes

Since the mid-Pleistocene (approximately 900,000 years ago) (see *Pleistocene Epoch*), periods of glacial building have reduced the absolute amount of sea water in the ocean basins, lowering global sea levels on the order of 120 m below present levels during periods of maximum glaciation (Peltier, 1999). The most recent glacial stage, the Wisconsinan or Würm, began approximately 100,000 years ago. Data indicate that the early Wisconsinan maximum glacial advance probably occurred between 72,000 and 62,000 years ago (Ruddiman and McIntyre, 1981; Shackleton, 1987; Oldale and Colman, 1992) and resulted in a maximum lowering of global sea level of only 50 m below present sea level (Oldale and Colman, 1992). The late Wisconsinan glacial maximum occurred at approximately 21,000 BP (Fairbanks, 1989; Bard *et al*., 1990), and resulted in a lowering of global sea level to approximately 120 m below present sea level. These periods of lower sea level resulted in large areas of the continental shelves (see *Continental Shelf*) being exposed as dry land. During the glacial stages, most continental coastlines were far seaward of their present positions (see *Paleocoastlines*), and land bridges formed between some landmasses currently separated by the sea (Masters and Flemming, 1983).

Eustatic sea level refers to the absolute changes in sea level that result from water being removed from the ocean basins during glacial building, or added to the ocean basins during glacial melting (see *Eustasy*). Isostatic adjustments refer to the differential depression or uplift of the earth's lithosphere in response to the weight of glacial ice (see *Isostasy*), the amount of water in the ocean basins, and sediment loading. The lithosphere beneath the areas formerly covered by glacial ice rebounded as the ice melted. The area of uplift around the margins of the ice masses, known as the glacial forebulge area, collapsed as the weight of the ice was released. The ocean basins subsided as a result of water loading due to glacial meltwater and, in some locations, of sediment loading. The continental margins also may have uplifted in response to subsidence of the ocean basins (Walcott, 1972). When these isostatic adjustments of the earth's lithosphere are combined with the effects of eustatic sea-level change and with local tectonic factors, such as vertical movements along fault planes and plate boundaries, a very dynamic picture of global paleocoastline positions emerges. For any given area, the changes in the elevation of the coastline, through time, in relation to the present coastline are referred to as relative sea level.

Relative sea-level change

The graphic depiction of relative sea-level change, through time, is called a relative sea-level curve. Relative sea-level curves are based on radiocarbon-dated samples of *in situ* organic material taken from the seafloor or from shallow geologic cores (see *Sea-Level Indicators, Biologic*), or on geomorphic features indicative of relict coastline environments (see *Sea-Level Indicators, Geomorphic*). The organic materials selected for dating are those known to occur only within former coastline environments (e.g., shells in growth position, certain plant roots, undisturbed brackish-water peat deposits). Relative sea-level curves are constructed by plotting the age in radiocarbon years before present and the elevation (positive or negative) in relation to present sea level of these *in situ* organic materials.

In formerly glaciated areas that have experienced isostatic rebound, paleocoastline positions may be tens to hundreds of meters above present sea level. In areas far removed from the glacial ice masses, the paleocoastline positions may be well below present sea level. In areas not affected by isostatic adjustments or tectonics, the paleocoastline positions will reflect changes in eustatic sea level (Bloom, 1977; Stright, 1995).

Global models of relative sea-level change

Various researchers have been developing and refining global mathematical models to simulate the worldwide glacial isostatic adjustments resulting from the late Wisconsinan glaciation (e.g., Walcott, 1972; Clark *et al*., 1978; Tushingham and Peltier, 1991, 1992; Peltier, 1994, 1999). For example, in Tushingham and Peltier's ICE-3G and ICE-4G models, unknown parameters are estimated, such as the thickness of the earth's lithosphere, the thickness of the glacial ice, and the timing and history of deglaciation. Then the model is run and compared against the available relative sea-level data around the world. Systematic divergences in the actual relative sea-level data and the model's predictions are examined, and changes are made, if necessary, in the assumed glacial and lithospheric parameters of the model. In more recent studies, even the effect of the earth's altered rotation due to the deformation of the geoid from the weight of glacial ice has been factored into these models (Peltier, 1999).

These global models can be of great value to archaeology. If the relative sea-level history can be accurately predicted for any given geographic area, it can be used to determine where to find coastal archaeological sites for any given prehistoric period, and to understand the systematic biases that have been introduced into archaeological interpretations of human migrations and adaptations. The only factor that cannot be accounted for by such global models is the influence of local tectonic activity on prehistoric site locations.

Lateral changes in the position of the coastline

The position of the coastline may also change laterally through progradation (building seaward) or erosion landward, even in the absence of relative sea-level changes. A prograding coastline would tend to bury and protect archaeological sites (Coastal Environments, Inc., 1977) while an eroding coastline would tend to destroy archaeological sites and redistribute the more durable archaeological materials, such as stone and bone artifacts, along the shore (Stright *et al*., 1999).

Finding former coastal archaeological sites

To determine where former coastal archaeological sites might exist, it is first necessary, as discussed above, to consult local relative sea-level curves or the results of one of the global glacial isostatic adjustment models to determine which areas were above sea level and available for human habitation. Paleocoastlines that are now above present sea level can be surveyed using standard archaeological methods. However, paleocoastline environments that are now submerged require more specialized archaeological methods (Johnson and Stright, 1992).

Finding submerged archaeological sites

Although the physical and cultural remains of prehistoric people might occur anywhere along these submerged land surfaces, basic human subsistence needs for such things as freshwater, plant and animal food resources, shelter, and raw material for tool manufacture were often determinant in site selection by prehistoric human populations. Landforms such as rivers, lakes, and bays represent locations where one or more of these basic subsistence needs could be met.

Although the archaeological sites themselves are generally not of sufficient size or acoustic contrast to the surrounding sediments to be detected by acoustic remote sensing instruments, the landforms with which they are most likely to be associated can be detected by these instruments (see *Remote Sensing: Coastal Environments*). Those landforms still exposed at the seafloor can be detected either directly by diver surveys or remotely by side-scan sonar, a remote sensing instrument that transmits a high-frequency sound signal at an oblique angle to the seafloor. The returning signal's strength depends on the density of the object encountered at the seafloor. These signals can then be interpreted to infer the presence of relict geomorphic features at the seafloor. The seafloor landforms, thus detected, can then be further investigated by divers or remotely operated vehicles (ROVs).

Archaeological sites buried beneath the seafloor can be located using a high-resolution seismic system such as a subbottom profiler, which images the buried land surface and detects landforms with which sites are likely to be associated. A series of these profiles can then be interpolated into a topographic map of the former land surface. If the landforms are not too deeply buried, they can be investigated by using divers to excavate the overlying sediments. However, complete excavation of underwater sites is a very difficult process; the feasibility of which is dependent on the water depth, the depth of the potential site below the seafloor, the sediment type, and other site conditions. A more realistic approach is to conduct an initial investigation using a series of sediment cores. Standard sedimentary analysis techniques can detect indicators of a buried archaeological site, even in the absence of recognizable artifacts (Coastal Environments, Inc., 1982; Pearson *et al*., 1986; Stright, 1986).

Although sediment cores provide only a very limited subsurface sample, they can be used to establish the presence or absence of an archaeological site. If it is determined that a site is present at the sampled location, transects of sediment cores can then be used to delineate the aerial extent of the site and depth of the site deposits. Analysis of the sediments in the cores can be used to reconstruct the paleoenvironmental context of the site, determine the subsistence resources that may have been available at the site, and may even provide sufficient organic material to allow radiocarbon dating of the site (Pearson *et al*., 1986).

Conclusions

Archaeological sites now submerged on the continental shelves are important because they can provide information on prehistoric human adaptations, migrations, and cultural contacts that may not be available from terrestrial sites. Many of the earlier archaeological interpretations, based on data from coastal archaeological sites, need to be carefully reexamined because the major changes in coastline positions caused by glacial advances and retreats may not have been taken into account. Most sites that would demonstrate early prehistoric human adaptations to coastal environments are now submerged. Likewise, land bridges that would have provided easy migration routes between current landmasses are also now submerged. Although raised paleocoastlines do exist, there may be few archaeological sites associated with these features, because the rapid rate of isostatic rebound may have precluded the development of stable coastal ecosystems necessary to support human populations (Oldale, 1985). The bias to our understanding of the archaeological record caused by the shifting positions of paleocoastlines is perhaps that we have thought coastal environments were not as important in the prehistoric past as they likely were, and perhaps we have underestimated prehistoric human migration pressures, opportunities, and contacts.

ARCHAEOLOGY

Humans have inhabited coastal areas and made use of their resources for hundreds of thousands of years. The richness of the coastal zone, the overlapping of maritime, littoral and inland resources, the ease of transportation along it, have led people to cluster along shores, including the people of today who are destroying much of the record of past inhabitants. However, coastlines are also the most dynamic environments on earth. Tides and currents effect daily and seasonal changes in the shore margin; storms dramatically resculpt the shore; isostatic, eustatic, and tectonic changes (cf. *Isostacy, Eustacy, Tectonics and Neotectonics*) can result in former coastlines being located far inland or far out to sea.

In trying to understand human use of coastlines, it is necessary first to discover where the coast was at the time the site one is interested in was occupied. Due to the ever-changing relationship between the land and the sea, sites of past coastal people may be well inland, well submerged under the sea or still coastal. To discover past coastal sites, it is essential that archaeologists work in cooperation with geologists and other coastal scientists, and take into account both local and global factors which influence relative sea level (cf. *Archaeological Site Location*). Once sites are located, and are determined to be cultural rather than natural features, archaeologists turn to more culturally interesting questions about human adaptation to the coastline and how it changed with time. For example, were these people simply living by the sea, like summer beach residents today or in Pompeii, or were they using marine resources? If they were using marine resources, was their primary focus on industrial or alimentary needs? If the latter, were they littoral hunter-gatherers, who made use of coastal and nearshore resources, or were they maritime hunter-gatherers, who had boats from which to gather creatures of the deep sea?

To understand human adaptation to coastal environments, archaeologists in all parts of the world have looked particularly closely at diet, at the season of occupation of sites, and at relationships between coastal and inland peoples. Changes in adaptation can be forced by changes in the environment, by cultural change and development or, most likely, by a complex interaction between culture and environment. In the short term, archaeologists consider the human response to disaster: for example, if their settlement is destroyed by a *tsunami* (*q.v.*), do people move away or do they reestablish themselves in the same place? One can examine changes through time in coastal occupation, both those forced in some way by environmental changes, for example, rising or falling sea levels, changes in ocean temperatures, which affect littoral or maritime resources, and those caused by social, political, or demographic changes in the human populations of the coast. In the following pages, studies from various parts of the world will be used as exemplars of current examinations of these issues.

Historical development

The archaeology of coastlines has a long history, with some of the earliest studies in archaeology focusing on the Danish *kjokken-möddings*, or shell middens, of the Mesolithic period. These were recognized as cultural by 1837 and shortly thereafter, the Royal Danish Academy of Sciences established a commission to study them, directed by Jens J.A. Worsaae, who was the world's first professional prehistoric archaeologist. In the 1850s, Worsaae and his colleagues published six volumes on their studies, which established that the Danish middens were cultural and had developed through time, that the only domesticated animal the people possessed was the dog, and that these middens were occupied in all seasons of the year but summer. They also identified the plants of the paleo-environment and studied the distribution of cultural features within the mounds. Finally, they initiated experimental archaeological studies: they gave bones to dogs to chew on to determine why there was a preponderance of bird long bone mid-shafts in the middens. This work was highly influential, stimulating scientists to study local shell middens on both coasts of the United States, and in Japan, Brazil, and Southeast Asia. By 1911, shell middens had been examined from the Aleutian Islands to South Africa (Trigger, 1989). The study of coastal sites has not slowed down, since: a 1991 bibliography of coastal and maritime archaeology, admittedly incomplete, contains 2,800 entries (Kerber, 1991).

Finding coastal sites

Finding coastal archaeological sites can be very difficult due to isostatic, eustatic, and tectonic forces that change the location of the sea relative to the land. The west coast of North America is an area in which all of these forces have been active to varying degrees during the period of human occupation. Fedje and Christensen show that, in the Queen Charlotte Islands, coastlines dating from 13,000 to 9,500 BP [uncorrected radiocarbon dates] are deeply drowned while those dating from 9,200 to 3,000 BP are stranded in the rainforest up to 15 meters above modern levels. Coastlines have been approximately coincident with the current position for only the last two to three millennia and for a century or two centered around 9,400 BP." (1999, p. 635). Modeling these *paleocoastlines* (*q.v.*) allowed them to discover a number of coastal archaeological sites in both drowned and uplifted zones and they are confident that more will be discovered. From southern Washington to northern California, on the other hand, late prehistoric coastal sites have been drowned due to earthquake-induced subsidence (cf. *Subsiding Coasts*) along the Cascadia subduction zone, seriously biasing our understanding of Washington's prehistory (Cole *et al*., 1996). While many sites thus drowned may be lost, the authors have found a number of examples buried under tidal mud along coastal *estuaries* (*q.v.*). In southern California, Waters *et al*. (1999) have identified a complex series of terraces along streams that are caused both by global patterns of sea-level fall and rise and by local climatic factors, possibly in response to an *El Niño-Southern Oscillation* (*q.v.*) event. These events have caused pre-4,000-year-old sites to be deeply buried and consequently difficult to find. The later sites, which are closer to the surface, have an advantage over many southern California sites in being below the bioturbation layer. Waters and his colleagues have found large late marine oriented sites in these channels, which are changing our understanding of late prehistoric cultural development in this area.

Determining site function

Natural/cultural

In many parts of the world, shell midden sites have been quarried out for fertilizer or to use as fill. Thus, many midden deposits may be lost or exist in places far removed from their original deposition. Even in remote places like the Shumagin Islands south of the Alaska peninsula, people have moved midden from one island to another to serve as fertilizer for gardens. Thus, merely finding on shore shell deposits, even when it can be determined that they are of human creation, does not mean that one has found an archaeological site *in situ*.

In Sri Lanka, the lowering of sea level has led to shellfish dying and their shells being washed and blown into windrows on beaches, lagoon and lake bottoms, sand dunes, and headlands. These are often difficult to tell from cultural deposits although artifacts found among the shells suggest that people were responsible for some of the deposition (Katupotha, 1995). In southwestern Louisiana, Henderson *et al*. (1998) also wished to determine whether shell rich deposits on coastal beach ridges were natural or cultural. In this case, the archaeological deposits were found lying on or actually constructed out of reworked *chenier* (*q.v.*) deposits. The authors discovered a suite of taphonomic, sedimentologic, and stratigraphic methods, which served to distinguish the cultural deposits from the natural chenier deposits.

Butler and her colleagues have been working during the past decade to discover how natural deposits of salmon differ from those left by human hunter-gatherers. This is a particularly important problem in the Pacific Northwest where the harvesting and storage of vast quantities of anadromous salmon is thought to underlie the development of the cultural complexity for which the area is famous. Butler has looked at a particular site, the Dalles Roadcut on the Columbia River and concluded that the deposition is probably cultural; has considered the varying natural decay of different salmon bones, and has investigated whether fish bones that have passed through mammalian digestive tracts bear recognizable marks (cf. Butler and Schroeder, 1998). All of these studies aid archaeologists in determining whether salmon deposits are natural or cultural.

An ethnoarchaeological study of fish middens on the coast of Senegal showed that caught and filleted fish mimicked natural fish deposits as the heads were not removed in filleting and, therefore, the entire skeleton remained (Van Neer and Morales Muñez, 1992). On Lake Turkana in Kenya, on the other hand, investigators could distinguish base camps, fish processing camps and fish waste discard sites from each other and from natural death assemblages by the nature and number of bones remaining (Stewart and Gifford-Gonzales, 1994). Both of these ethnoarchaeological studies can aid archaeologists in interpreting prehistoric shell deposits.

Related to the problem of distinguishing natural from cultural deposits is that of determining why species representation and shell size of shellfish found in middens might change through time. In looking at middens on the West Coast of Southern Africa, Jerardino (1997) determined that changes in species were due to humans exploiting different tidal zones, while size changes in individual species were due to a combination of water conditions and human exploitation.

Industrial

The industrial use of coastal resources by prehistoric peoples has not received much attention in recent years, though the attention it has received has been widespread. For example, working in the Sinai, Bar-Yosef Mayer (1997) demonstrates that shells entered sites as raw materials for beads rather than as food remains, while in the Arctic, Savelle (1997) notes that whale bones are often more indicative of housing needs than diet. Most investigators look at shellfish gathering as an enterprise that requires few or no tools aside from a container in which to carry the collected goods. However, Johnson and Bonsall (1999) note that in both the Shumagin Islands in Alaska and in Scotland, tools are found in shell midden contexts which appear to have been used in the collection and processing of shellfish. Wedge-ended rods of stone or sea mammal bone are used for prying limpets from rocks and, possibly, for digging the animal out of its shell, while small splinters of bird bone are used to pry periwinkles and other small snails loose from their shells, developing worn points in the process.

Coastal adaptation

Once coastal sites have been located and identified, archaeologists attempt to discover what people were doing at the sites. This involves figuring out what foods they were eating, by examining both the food remains left at sites and the bones of the humans, which reflect the nature of their diets. In looking at the food remains, it is necessary to figure out what the dietary implications are of, for example, ten bivalve shells versus two salmon bones versus one sea lion femur. Archaeologists are also interested in discovering whether people were using this site year-round or only seasonally, whether they were littoral gatherers or maritime hunters and fishermen, and what their relationship with other groups might be. Finally, archaeologists look both at individual sites occupied for a long period of time and at the pattern of sites within an area to discover how human adaptation to the coastline changed through time.

Diet

The most direct means of discovering what people ate is to examine their bones. Analyses of trace elements and stable isotopes can distinguish between diets rich in marine foods and those rich in terrestrial foods. Low Ba/Sr and Ba/Ca ratios and high $\delta^{13}C$ values in bones indicate a diet rich in marine foods, while the reverse is true for terrestrial diets. High $\delta^{13}C$ values also occur when plants such as maize, which use a C4 metabolic pathway, are eaten, but maize and marine foods in the diet can be distinguished by examining $\delta^{15}N$ and $\delta^{34}S$ values.

Gilbert *et al*. (1994) examined modern plants and animals of the western Cape of South Africa in order to determine marine and terrestrial signatures for Ba/Sr and Ba/Ca ratios, finding distinct differences in both edible tissue and bone. Re-analyzing bones, which had already been tested for $\delta^{13}C$ values, led to the conclusion that both methods worked, but that stable isotopes revealed more subtle differences.

Aufderheide and his colleagues (1994) had the advantage of working with mummified human remains from northern Chile. Here, they were looking at recent immigrants to the coast from the highlands and discovered that the community appeared to have split into two different groups, one right on the coast subsisting almost entirely on marine foods, and the other in the mid-valley eating both marine foods, probably supplied by the coastal community, and valley bottom foods. These results were supported by the presence of external auditory canal extoses, formed due to prolonged cold water diving, in the coastal population.

Human remains are not always available in the sites or levels where archaeologists would like to find them, and the prehistoric people's descendants are often not pleased to have their ancestors subjected to scientific analysis. Cannon *et al*. (1999) have demonstrated at the site of Namu on the British Columbia coast that dog bones can serve as surrogates for human bones in analyzing diets. It is probable that in most prehistoric coastal settlements the diet of dogs was very similar to that of their masters, thus providing archaeologists a much wider sample of bones to analyze for dietary information.

Another approach to dietary reconstruction is to estimate the amount of food represented by the remains present in a site. James Savelle has been particularly active in deriving meat utility indices for marine mammals (cf. Diab, 1998). This also relates to issues of variable preservation, discussed above, and to recovery methods. Fish bones are often underrepresented in archaeological assemblages because of a lack of screening of excavated materials or of using screens with too large a mesh. Ross and Duffy (2000) have demonstrated that a 1 mm mesh screen results in considerably greater recovery of fish bones from an Australian site and have also developed deflocculation and flotation techniques, which make sorting the screened remains practical in the real world: sorting remains from a 100 ml dry screened sample took 20 h, whereas the deflocculated and floated sample was sorted in only 2.5 h. Moreover, the chemical added to water for flotation was sugar and an excellent deflocculant was baking soda, making the procedure inexpensive and safe as well. The result of the 1 mm screening was to verify the reports of southeast Queensland Aborigines that both fishing and shellfishing had been important to them since time immemorial in contrast to prior archaeological investigations in which the paucity of fish remains recovered had led to a hypothesis of a late introduction of fishing to this coast.

Analysis of midden materials also gives rise to problems concerning how to quantify the materials recovered. Faunal analysts now tend to provide both number of identified specimens (NISP) and minimum number of individuals (MNI) data for mammal and fish remains, but the quantification of shellfish remains is a thornier issue. Shells appear in sites in the thousands and are often broken into small fragments. Because shells vary in size and in friability, NISP is not a useful figure. MNI is often used, but ignores a great deal of the data since only the hinge areas of bivalves can be counted. Thus archaeologists have attempted to use the weight of shellfish remains as a proxy for the importance of various species in past diets. This is an area of active discussion at present (cf. Claassen, 2000).

Season of occupation

Coastal settlements can be year-round residences or can represent part of a seasonal round, being occupied for one or two periods during the year while the people live elsewhere, exploiting other resources, during the rest of the year. Determining seasonality from the middens themselves requires some means of discovering when animals were killed, which has proven possible for mammals, fish, and shellfish. Marine mammals are born at particular times during the year, so the age at death of immature animals can indicate when a site was occupied: if all of the young animals found in a site died at the same age, it suggests that the site was occupied for only that season. The analysis of seal bones in South Africa indicated that early in the Holocene people exploited seals periodically throughout the year, while in the late Holocene they restricted this activity to the spring (August to November; Woodborne *et al.*, 1995). A similar pattern of change from year round to seasonal occupation is seen in New Zealand through the analysis of seasonal and annual growth rings on Cod otoliths (earbones; Higham and Horn, 2000). Shellfish, such as oysters and clams, also possess seasonal and annual growth rings, which have been used to analyze site seasonality. In Mexico, oxygen isotope ratios in marsh clams record large-scale salinity fluctuations in the marshes caused by alternating wet and dry seasons. Therefore, the oxygen isotopes in clams from midden sites can be used to determine the season of shellfish harvesting (Kennett and Voorhies, 1996).

Littoral or maritime

In trying to understand Mesolithic coastal sites in western Scotland, Bonsall (1996) makes use of ethnographic data which indicate that the Australian Aborigines had three recognized types of shell middens: processing camps, where shellfish were removed from their shells and prepared for transport elsewhere; dinnertime camps, where people involved in other activities stopped, collected shellfish and enjoyed a meal, and home bases. In Scotland, given the generally inclement weather, remnants of the first two types of camp would probably be found in shelters or other protected locales. Bonsall hypothesizes that the Obanian sites found around the western coast of Scotland are probably the remnants of processing and dinnertime camps occupied by gatherers whose base camps were located inland. The latter had a much richer artifact inventory, including the quintessential Mesolithic microliths, which are not found in the coastal sites.

In the much more complex society of Inka Peru, the fishermen of the Chincha Valley formed a separate community from the valley farmers and overlords whose protein they supplied. Specialized fishing communities seem to have existed in coastal Peru before the Inka took the area over and the Inka probably incorporated these communities into their empire with little change except for skimming the fish off for their own use rather than allowing the valley paramount lord to do so. The fishing here was primarily, if not entirely, littoral netting of small fish such as anchovies and anchovetas, which were then dried for exchange with other members of the valley and imperial communities (Sandweiss, 1992).

In contrast to these littoral adaptations, the residents of the Hoko River site in Washington state possessed a full-scale maritime adaptation. Due to half of the site being waterlogged, there is excellent preservation of organic artifacts, including numerous fishhooks, landing skids for canoes, pack baskets for transporting the fish, primarily halibut, and mats to protect the canoes and keep them from drying out between fishing trips. Around 3,000 years ago, the site was seasonally occupied for a number of years, "mainly in the spring/summer season, when [the people] focused on offshore hook-and-line fishing for bottom fish, and particularly flatfishes" (Croes, 1995, p. 229).

Coastal/inland relationships

Many studies look at the relationships between coastal people and their inland neighbors, or between coastal sites and the inland sites, which formed other parts of their seasonal round. Kennett and Voorhies used the oxygen isotope information from marsh clams, discussed above, to determine changes in the relationship between people and their environments. During the early late Archaic period, people collected clams year round, though they focused on the dry season.

> Through the late Archaic period a general trend occurred toward wet season use of these locations. This culminated at the end of the late Archaic period with the exclusive use of the littoral zone during wet season months. These data indicate a fundamental shift in the way these estuarine locations were being used. We argue that people living in this region altered their overall subsistence strategy during the late Archaic period due to scheduling conflicts that occurred with the adoption of maize agriculture. (Kennett and Voorhies, 1996, p. 689)

A similar process appears to have taken place in the Southeastern United States. Here ranked societies developed which took advantage of both coastal and interior resources. The origins of these societies are not well known, but evidence from Chesapeake Bay suggests that a pattern of springtime collection of oysters for local consumption was replaced, as maize arrived, with intensive spring harvesting and preserving of oysters. Anadromous fish and shellfish were major sources of protein along the coastal plain, where interior mammals such as white tailed deer were rare. Farther south, in Florida, the development of the Calusa cultural pattern is very imperfectly known, but maritime and littoral resources were clearly of major importance (Waselkov, 1997).

On Kodiak Island, Alaska, the permanent settlements are on the shore and sites in the interior tend to be summer salmon fishing camps. The interior Outlet Site, while it was primarily a fishing camp, also showed evidence of fall/winter bird hunting, and boasted substantial houses. Steffian and Saltonstall (2000) hypothesize that, as the population on Kodiak grew, the period of use of interior resources was extended and the coastal people, needing to lay stronger claim to their summer settlements, built substantial houses to serve as signs of ownership when they were absent.

Change in coastal adaptation

The majority of archaeological studies of coastal societies focus on change through time as people adjust to the constantly changing physical and cultural environment. Studies of the changing relationships between people and coasts have taken place in all parts of the world and only a few can be highlighted to give the flavor of current research on this topic.

The classic, and in many ways still unmatched study of human reaction to changing coastlines is Shackleton's study of Franchthi Cave in Greece (cf. 1988). During the 20,000 years the cave was occupied, sea level rose from −115 m to its present level. At varying times in the past the shore in the vicinity of the cave supported different shellfish communities. By comparing the proposed communities to the shellfish remains in the cave, Shackleton was able to hypothesize that the people selectively gathered these resources rather than merely collecting the closest available species.

A short distance to the north of Franchthi Cave, near Volos, Greece, Zangger (1991) has studied changes in settlement along a prograding rather than submerging coastline. At ca. 6000 BP, Holocene sea levels reached their maximum height, and the shore in the vicinity of Volos was 3 km farther inland than it is today. Combined archaeological and geological investigation has shown that during the following 6,000 years coastal cities followed the coastline as it prograded to the east.

In many urban coastal areas, engineers have captured land from the sea, using dikes and landfills to increase human living space. Nowhere did this process begin earlier or proceed further than in Holland. By 1984, Dutch archaeologists were already involved in detailed geoarchaeological studies looking at the changing relationships between people and the land. Brandt, van der Leeuw and van Wijngaarden-Bakker (1984) showed how rising sea level changed the configuration of the land west of Amsterdam and, thus, its use by early settlers. By the early Iron Age, at least, human livestock was also changing the land, simplifying its ecology and creating a human dominated landscape, a process that continued as people began to enclose the land with dikes.

On the Texas Gulf Coast, Archaic Period habitation closely followed relative sea-level rise. When sea-level rise was rapid, estuarine resources were impoverished, and humans abandoned the region. When sea-level rise slowed, "the emergence of highly photosynthetic bay/lagoon shallows support[ed] nutrient-rich shoreline vegetation [which] provided the basis for a rich, exploitable aquatic biomass" (Ricklis and Blum, 1997, p. 287), which the people proceeded to exploit. In the past 10,000 years, this cycle repeated itself three times, with settlements between 7,500 and 6,800 BP, between 5,900 and 4,200 BP and between 3,000 BP and the late Prehistoric Period, and abandonments between 6,800–5,900 BP and 4,200–5,900 BP. During the first two occupations the people focused on shellfish; during the course of the last,

> ongoing sedimentation under conditions of stable sea level led to formation of the continuous modern barrier island chain by ca. 2,500–2,000 BP. As the disconnected barriers coalesced, back-barrier lagoons became very extensive vegetated shallows, providing protective and nutrient-rich habitats for important fish species, with a resultant increase in estuarine fish biomass. A marked increase in fish remains in archaeological contexts, beginning at the time, indicates the emergence of intensive fishing as a major subsistence focus. (Ricklis and Blum, 1997, p. 306)

Short- and long-term responses to environmental disaster

Many coastal changes are gradual and may take generations to make themselves felt. As Brandt *et al.* state, people "perceive slow, continuous changes as unchanged, as similar until so much change has occurred that it is clearly seen. Then, they … change … much more drastically than the circumstance requires" (1984, p. 14). Other changes, on the other hand, such as hurricanes, tornadoes, earthquakes, and tsunamis are sudden, dramatic, and disastrous. Human response to sudden disaster varies according to the circumstances and can be looked at on various scales (Johnson, 2002).

Two recent studies of North Pacific coastal peoples come to quite different conclusions concerning human response to catastrophic change. Jordan and Maschner (2000) have studied the western end of the Alaska Peninsula, where isostacy, eustacy, tectonics, and volcanoes have served as a dynamic stage for human settlement. The cultural phases they have identified mark changes in village organization and subsistence orientation in the area and reflect some combination of environmental, social, economic, and political change. The dominant factor in the environmental history of the area has been isostatic recovery, but Jordan and Maschner argue that two large or great earthquakes have had major effects on regional prehistory. The first, in ca. 2,200 BP, led to coseismic subsidence which increased site erosion and submergence. No sites are dated in the area between 2,400 and 2,100 cal yr BP suggesting that sites occupied shortly before the earthquake were destroyed and the area was abandoned for a century following the earthquake. In the following cultural period there is a major change in village organization and subsistence. The most radical change in village organization took place about 850–950 cal yr BP in concert with changes in almost all the eastern Aleutian arc. There does not seem to be any local environmental instability correlated with these changes. However, there was a great earthquake in the Gulf of Alaska between 700 and 900 BP. Environmental recovery probably took a relatively short period of time, but cultural disruption may have lasted considerably longer. Jordan and Maschner argue that the displacement of populations from the region of the epicenter may have triggered the cultural changes in the wider area.

On the south side of the Alaska Peninsula, Johnson does not see as strong a reaction to catastrophe. The initial occupation of the islands appears to have been rapid, following a major uplift episode, which substantially increased terrace living space in the islands. The immigrants may have been fleeing from areas where the effect of the earthquakes was subsidence rather than uplift. Johnson concludes that "for maritime hunter-gatherers like the Shumagin Islanders, earthquakes are terrifying occurrences which may slow cultural development and force populations to move their settlements, but they do not seem to have a major effect on cultural development. Shumagin history, like ours, is more affected by human events than by natural events, however catastrophic" (Johnson, 2002).

Archaeology in service to geology

While archaeologists most often use the results of other scientists to help interpret their sites, occasionally archaeological data are used to help interpret geological data. The majority of these studies concern sea-level change. Since people do not live underwater, sites found beneath the sea are clear evidence of rising sea level or sinking land; sites with clear maritime focus located well away from the shore, on the other hand, indicate lowered sea level or rising land. These sites can often be dated, using either cultural or geophysical means, with more precision and certainty than natural deposits, allowing geologists to pinpoint the changes of interest to them more precisely.

In a major review, Owen Mason (1993) looked at the geoarchaeology of *beach ridges* (*q.v.*) and cheniers on prograding coastlines worldwide. He looked at studies in which archaeologists and geologists working cooperatively achieved a thorough understanding of the chronology of these features as well as those in which a lack of cooperation between the two has led to less satisfactory results for both. In using archaeological sites to date beach ridge formation, one must first carefully evaluate cultural adaptation of the past people to be certain that site location is closely tied to the position of the sea relative to the inhabited ridge.

An example of the study of rising sea levels is that of Morhange *et al.* (1996) which used archaeological, biological, and sedimentary data to model the sea level at Marsielles over the past 4,000 years. In this area, the archaeological indicators of sea level include objects such as wrecks, which were originally deposited below sea level, the walls of quays and wharf pilings found at sea level, and roads and room floors which were originally above sea level. Using these urban features in combination with barnacles and beach indicators led to a detailed and well-supported sea-level record. On a much broader scale, Flemming (1998) reviews drowned sites worldwide that indicate Paleolithic, Neolithic, and Bronze Age sea levels.

Archaeological sites can also provide evidence of falling sea level. In a non-civilized, shell midden context on the Northwest Coast, Cannon (2000) used coring to recover samples from the surface to the base of the cultural deposits in a series of sites. By dating the basal cultural deposits and establishing their relationship to present sea level, he was able to identify steady sea level decline over the past 10,000 years in this region.

Finally, relative sea levels may change in a complex and irregular manner. In the Shumagin Islands, Alaska, where episodic tectonic uplift is coupled with interseismic downwarping and post-glacial sea-level rise over the past 10,000 years, archaeological site locations served to constrain geological modeling, since occupied sites could not be located under water (Winslow and Johnson, 1988).

Intensive studies

North Pacific

Integrated studies of North Pacific prehistory are descendants of 19th century studies of Arctic cultures crystallized in Gjessing's formulation of the Circumpolar Stone Age concept. Early studies of northern maritime adaptations were much too broad and general and have been replaced by more focused studies of particular regions. In the north Pacific, the opening of the "Ice Curtain" led to increased contact between New World and Russian archaeologists interested in the North Pacific. As these studies progressed, links to more southern Pacific cultures became obvious, drawing in Japanese scholars, who have studied both their own and New World cultures. A major focus of these studies has been the inhabitation of the Americas in the terminal *Pleistocene Epoch* (*q.v.*). Additional studies have been concerned with issues of culture contact and influence around the North Pacific Basin, with initial adaptations to the coastline, both littoral and maritime, and with interrelationships between Pacific coastal peoples and their interior neighbors. There has also been concern about the fidelity of representation of cultural components, given post-glacial sea-level changes, but not as much as there probably should have been.

Channel islands

A nearby area in which there has been an explosion of archaeological research in the last few years is the Channel Islands area in southern California. In this region, prehistorically, there was a mainland adaptation, which often, if not always, included both coastal and inland facies, and an island adaptation, which, perforce, was always primarily littoral or maritime, though sometimes provided with inland resources through trade with the mainland people. Archaeologists and geologists working in this area have been trying to determine environmental changes in the area, how these changes affected the marine and shore-based resources, and what effect these changes had on cultural development and change. Also of concern is whether the whole area can be treated as a unit for paleoecological and paleocultural studies or whether subdivisions, between the southern and northern islands or between the islands and the mainland, are significant enough to make conclusions derived from one zone inapplicable in the other. In the process of arguing these various positions, local scholars have significantly advanced our understanding of the factors involved in both ecological and cultural development in highly variable coastal environments (cf. Kennett and Kennett, 2000).

Future work

"Interdisciplinary efforts to reconstruct shoreline history and associated environmental parameters could significantly raise the potential of locating early postglacial archaeological sites" (Fedje and Christensen, 1999, p. 650). More modeling of past environments, both on large- and small-scales, is necessary, as well as additional detailed studies of regions and sites. More bathymetric studies are needed in many areas: in coastal Alaska, for example, bathymetric charts are very general and not useful for detailed coastal studies, even where they do not meander off into dotted lines. Given the maritime focus that the majority of coastal peoples developed, sooner or later, and the freedom of movement boats provided, regional studies are essential (Waselkov, 1997). As detailed understanding of local sea level variation increases, we will be better able to understand how prehistoric people adapted to and used these changes in cultural development.

Conclusions

Absence of evidence is not necessarily evidence of absence, particularly in coastal environments. A dictum all coastal archaeologists should repeat when going to bed and upon arising in the morning: Consider the absent! In modeling past coastal subsistence/settlement systems, archaeologists must take account of sites that are gone! What we don't know will hurt us! Archaeologists should use all methods available, particularly modern tools like *Geographic Information Systems* (*q. v.*), to predict site loss, to get a handle on how much of the archaeological record is actually left in any particular area. Prehistoric coastal peoples saw their settlements disappear in storms just as present coastal people do, and the effect of these disappearances on the archaeological record is something coastal archaeologists ignore at their peril.

ARCTIC, COASTAL ECOLOGY

Unlike Antarctica, which is an ice-covered continental plateau surrounded by oceans, the Arctic is made up of a central ocean nearly enclosed by land. This entry will mainly focus on the coastal ecology of the Canadian Arctic (Nunavut and Northwest Territories), northern Alaska (United States), Norway, Greenland, and Iceland, as well as the islands of the Barents, Kara, Laptev, and Siberian seas (Figure A24). The intertidal zone, the benthic, and pelagic subtidal communities and the ecosystems associated with the ice itself will be discussed, as well as the ecological importance of polynyas, which are characteristic habitats of the Arctic.

Basic characteristics of the Arctic

The major marine ecosystems of the Arctic include the High Arctic oceanic region, which comprises the deep sea; the High Arctic coastal region between the abyss and the shore; the High Arctic brackish water subregion surrounding the shores of northern Russia, Canada, and Alaska, where the fauna must adjust to seasonal changes in temperature and salinity; and the boreal littoral region of Norway influenced by warmer currents which favor a faunal penetration from the south. Lastly, the Low Arctic shallow region marks the transitional area between the boreal Norwegian fauna and the High Arctic fauna.

The Arctic coastlines of Greenland, northern Iceland, Svalbard, northern Norway, Novaya Zemlya Islands, Murman coast, eastern Siberia, and Arctic archipelago of Canada are generally steep and deeply cut by fjords. However, the northern coast of Alaska, the Canadian Northwest Territories mainland, and most of the Arctic Russian coast are low relief coastal plains. The southern part of the Arctic coasts is characterized by the tundra biome where only grasses, mosses, lichens and about 400 flowering plants grow on a permanently frozen soil during short summers. Most of the biomass is in the root systems. The northernmost portions of Arctic landmasses, consisting mainly of the northeastern islands of Nunavut (Canada) and northern and central Greenland, lie under a permanent ice and snow cover.

Overall, much of the Arctic coastline is ice-covered for about seven months a year and the water temperature generally remains below 0°C. Air temperatures as low as −65 to −68°C have been recorded in Arctic Russia and Canada, and precipitation in the Arctic generally averages less than 250 mm per year. Melting and refreezing processes, wind-chill, runoff from the land and ice movement generate temperature and salinity variations in the upper water layer. The extreme seasonal oscillation in light is an additional factor affecting the biotic components of the Arctic ecosystem.

Due to its particular structure as a semi-enclosed sea (Figure A24), the Arctic Ocean is fairly isolated from the other major oceanic masses, except through the Bering Strait, the Denmark Strait, and the Barents and Norwegian Seas. However, no invertebrate genus is endemic either to the Low or High Arctic. This suggests that most Arctic genera are distributed worldwide or at least found in the Atlantic, the Pacific, or both. Moreover, 77% of the Arctic genera are also common to the Antarctic.

The marine Arctic environment is generally perceived as stressful to the fauna and flora that live there (Menzies, 1975). Low temperature is apparently not the primary factor that has shaped the Arctic marine ecosystem, but rather the marked seasonal oscillation of other physical components. Among the most important characteristics of the Arctic are reduced light, seasonal darkness, prolonged low temperature and icy period, which result in impoverished fauna and flora and low seasonal productivity. Contrary to habitats of lower latitudes, including coral reefs, where biodiversity is, generally, inversely proportional to the respective biomass of each species present, the Arctic is characterized by the dominance of a few species both in abundance and biomass.

From mid-November to late January, the sun is not seen above the horizon in the far North, whereas from mid-May to late July, the sun does not set. However, owing to its geographical position, the Arctic receives an overall low input from the slant illumination of the sun in summer. Moreover, on the polar sea itself, the permanent pack ice reflects 60–90% of the meager incoming radiation. When there is constant heat during the summer, widespread melting of snow and ice occurs, uncovering the seas and land surfaces. The weak organic production is in particular contrast to the high productivity of adjacent subarctic and boreal regions. Production in Arctic waters is probably below an average of 50 g of carbon per square meter of sea surface a year, and mainly concentrated in summer. Phytoplankton peaks in August in northern Canada, while polar zooplankton counts increase by tenfold in July compared with values in the winter dark. Because of this seasonal production, fish feeding on the lower elements of the food chain must glean most of their food in a short period and be able to subsist on small amounts of ingested food and stored energy for long periods. The phases of high productivity and feeding coincide with higher temperatures, which allow higher metabolic rates and levels of activity. Alternatively, when productivity is low, colder temperatures occur and hence, metabolism and energy consumption are low. When and where resource turnover and availability are sufficiently high, the systems may be relatively productive and sustain complex trophic levels, composed of numerous production and consumer organisms (Figure A25).

Supralittoral, littoral, and sublittoral zones

A bar of coarse sediment can form by waves or ice scouring on certain Arctic shores of Alaska and Canada. Pools of brackish water and typical marsh vegetation, including *Carex* spp., *Pucinellia*, mats of mosses, blue-green algae and diatoms, often occur behind these beaches. These supralittoral Arctic marshes can sustain populations of cladocerans, copepods, branchio-pods, dipteran larvae and oligochaete worms, numerous insects, shorebirds, and caribou herds (Broad, 1982).

The intertidal and shallow subtidal areas are relatively barren, at least on the surface. For instance, the Arctic coasts of Alaska and western Canada have no littoral flora and only sparse vegetation in the supralittoral (Broad, 1982). The virtual absence of intertidal fauna, which results in the absence of a fauna in the upper littoral zone, may be attributed to the freezing air and low humidity. However, the barrenness is usually explained, according to many authors, by the mechanical action of ice on the shores and/or to the weak tidal amplitude itself.

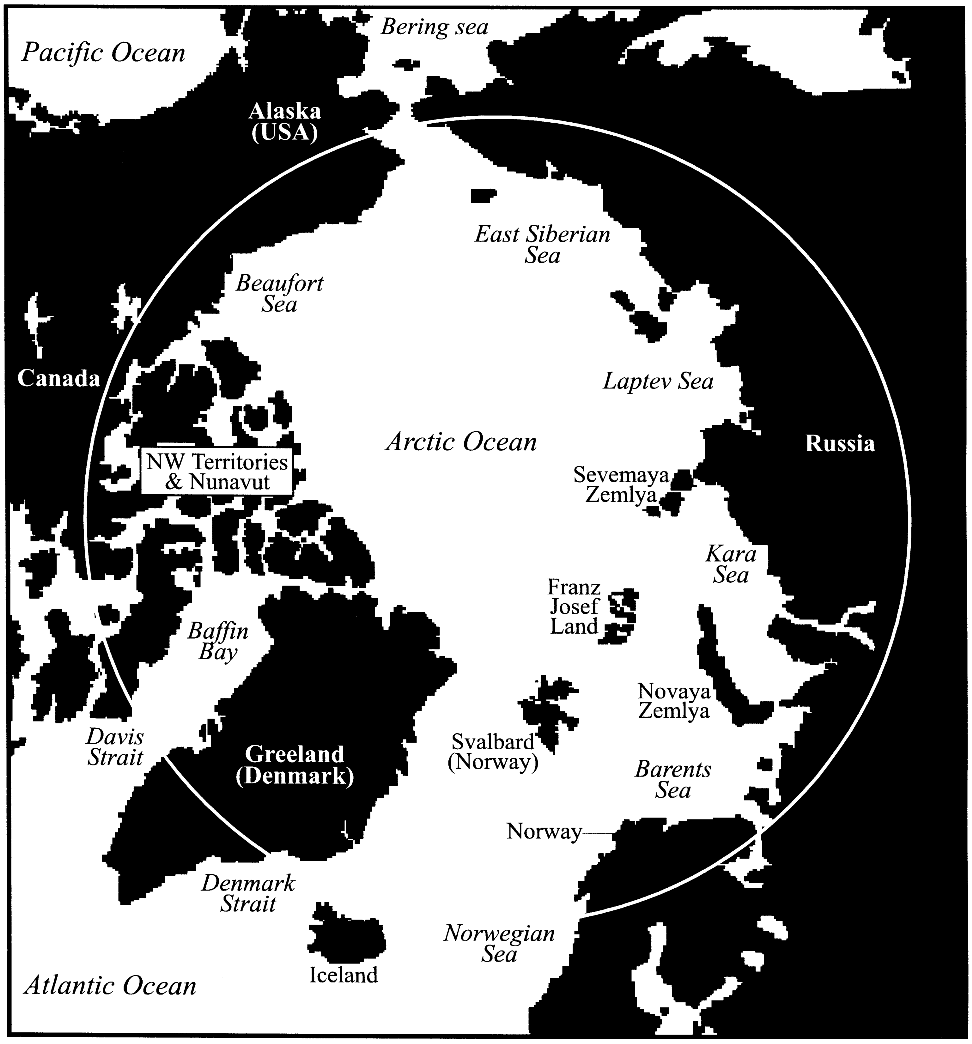

Figure A24 Continental boundaries, major islands and seas of the Arctic. The approximate limits of the Arctic circle (66° 30′N) are shown in white.

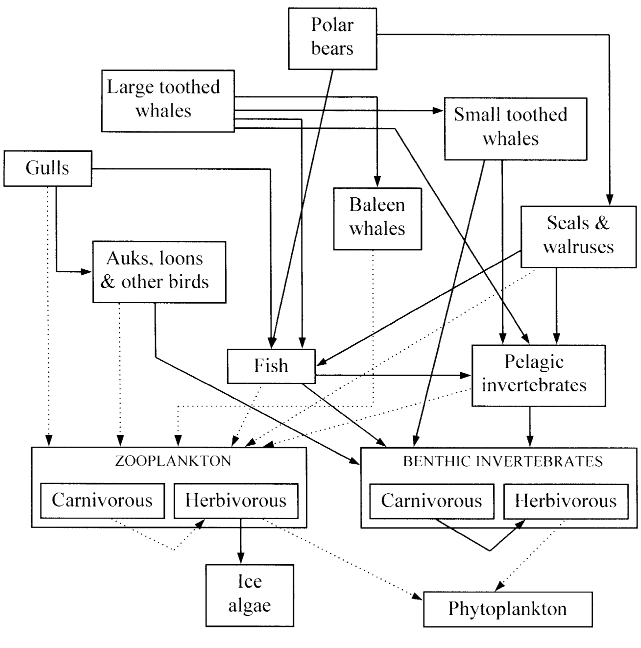

Figure A25 Schematic Arctic food chain.

When wind, current, and tide drive ice floes against the shore, bottom sediments, rocks, and benthic fauna and flora are mixed, overturned, and ground together. The resulting clouds of mud may extinguish the life of nearby organisms under a blanket of mud and smother filter-feeders hundreds of meters away. Consequently, when they are present in the Arctic, the intertidal species found in the Atlantic or Pacific are usually located in the subtidal area.

While sparse, the littoral fauna of the High Arctic is characteristic. In Alaska, the shore to a depth of about 2 m, the approximate depth of seasonal ice, is probably colonized by less than 50 species of macrobenthos, mainly oligochaete worms, midge larvae, amphipods (*Gammarus setosus* and *Onisimus litoralis*) and the isopod *Saduria entomon*, which form nearly the entire biomass (3 ± 5 g m^{-2}; Broad, 1982). The sublittoral fauna beyond the depth reached by ice is more diverse, including species such as mysid shrimps (*Mysis relicta* and *Neomysis rayii*), polychaete worms (*Scolecolepides arcticus, Ampharete vega, Prionospiro cirrifera, Terebellides stroemi* and others), bivalve mollusks (*Cyrtodaria kurriana* and *Lyocyma fluctuosa*), the priapulid *Halicryptus spinulosis*, amphipods (*Pontoporeia affinis* and *Calliopus laevuisculus*), and the four-horned sculpin *Myoxocephalus quadricornis* (Broad, 1982). The boundaries between Arctic and Subarctic shores of northern Canada and Greenland can be determined by the sudden disappearance in the northern parts of three common invertebrates, *Mytilus edulis, Littorina saxatilis* var. *groenlandica*, and *Balanus balanoides*. The last two are the most decisive indicators as their disappearance is more abrupt. In northern Iceland, the littoral zone is characterized by the succession of different species of *Fucus*, from *Fucus spiralis* in the upper section to *Fucus edentatus* in the lower littoral (Munda, 1991).

The sublittoral of Alaskan shores harbors benthic macroalgae, including 3 species of Chlorophyta, which infrequently grow in the littoral zone, 14 species of Phaeophyta and 11 species of Rhodophyta. The intertidal and subtidal zones are feeding grounds for about 30 species of fish, including anadromous salmonids, typically marine gadids, pleuronectids, cottids and a few freshwater species (Broad, 1982).

The Arctic shores of eastern Greenland are similar to those of Alaska. A few algae occur on rocks with *Fucus inflata* in the lower littoral. The fauna of the littoral consists of mostly oligochaete worms (*Enchytreaus albidus* and *Lumbricella lineatus*), mites *(Molgus littoralis* and *Ameronothrus lineatus*) and sublittoral crustaceans (*Gammarus wilkitzkii* and *Mysis oculata*) (Broad, 1982). Warm currents along some coasts of Norway, Iceland, Greenland, and other regions of the Barents and Norwegian Seas promote the occurrence of a boreal biota along Arctic shores. In such environments, the most common species of the mid-littoral and continuing subtidal are the blue mussel *M. edulis*, the gastropods *L. saxatilis*, with some *Buccinum groenlandicum, Margarita helcina* and crustaceans of the genera *Balanus, Gammarus, Caprella* and *Ischyrocerus*. Some species, such as the polychaete worm *Spirorbis spirium* and certain gastropods also colonize floating thallus of *Fucus* and other macroalgae. Jorgensen *et al*. (1999) indicated that 387 species were observed in the Kara Sea, Arctic Russia, with predominance for polychaetes, crustaceans and mollusks. Boreal–Arctic species clearly dominate this area. The sedimentation rate, as well as depth, sediment structure, and salinity apparently influence the faunal distribution.

Studies performed in southern Baffin Island indicated that numerous pelagic and benthic invertebrates were found below ice-covered sea. The fauna and flora in the long lasting ice cover, the small tides and the reduced wave action allow fine sediments to settle and produce low oxygen concentrations near the bottom. The brittle star *Ophiura sarsi*, shrimp *Sclerocrangon boreas*, sea cucumber *Chiridota laevis*, starfish *Crossater papposus* and *Leptasterias groenlandicus* are observed commonly. Rocks deposited by ice and human artifacts provide a scattered hard substrate, which supports a kelp community of *Laminaria* and *Agarum*. Barnacles, ascidians, sea cucumbers, sea anemones, gastropods are also observed abundantly on rocky bottoms.

Bluhm *et al*. (1998) indicated that the sea urchin *Strongylocentrotus pallidus* was considered an important part of the benthic standing stock and carbon flux in the northern Barents Sea. Holte and Gulliksen (1998) noted that macrofaunal dominant species in the sediment of the north Norwegian coast were detritivorous and carnivorous polychaetes, and detritivorous bivalves. Sponges, bivalves, polychaetes, and nematodes are common in the Svalbard waters (Strömberg, 1989).

Primary production (phytoplankton)

The algae that grow on the under-surface of the ice, the phytoplankton and the benthic macroalgae, produce biomass that feeds numerous animals. Together, these plants are called the primary producers. Among them, phytoplankton produces the majority of the edible material, although ice-associated algae are of equal importance in some areas (see Sub-ice flora and fauna section below).

The onset of ice cover and the loss of winter solar radiation have the clearest impact on the primary production in the Arctic. Although, the level of incident radiation in the polar summer is high, much of it is lost by the high reflectivity from the snow and ice. This restricts the production and leads to extreme seasonal oscillation in both phytoplankton and herbivorous zooplankton. The onset of seasonal production is clearly linked to the melting of snow from the ice surface and the subsequent melting of the ice. The annual primary production in polar regions varies from one area to another and ranges from 5 to 290 g C m^{-2} (Sakshaug, 1989). Blooms are formed mainly in spring or summer when nutrient supply is adequate and vertical mixing is restricted to the upper 30–50 m. They are particularly frequent at the ice edge because melting generates water column stability (Alexander, 1980). In the northern waters of Iceland, spring growth of phytoplankton begins in late March and culminates during mid-April (Gislason and Astthorsson, 1998).

According to Zenkevitch (1963), more than 200 species of phytoplankton are present in the Barents Sea. About 80% are diatoms, 20% are dinoflagellates and flagellates. During winter and early spring, phytoplankton biomass is small (<0.5 mg chlorophyll *a* m^{-3}) and mainly composed of small flagellates. The spring bloom gives place to the growth of larger groups, such as diatoms and dinoflagellates. During summer, two main composition patterns are found. One is dominated by microflagellates in the upper oligotrophic layers and diatoms and other large groups dominate the other, in the sub-surface chlorophyll maximum. Toward autumn, the chlorophyll sub-surface maximum tends to disappear and most of the phytoplankton comprises microflagellates (Loeng, 1989).

Small flagellates dominate the first phase of the phytoplankton bloom in ice-covered water. The main spring bloom occurs in the surface layer close to the ice edge and is usually dominated by diatoms, although flagellates can also be abundant. Toward the end of the diatom bloom, the maximum phytoplankton biomass is found at the nutricline, located below the pycnocline. After the bloom, the major part of the diatoms sink out of the euphotic zone (Loeng, 1989).

Strömberg (1989) indicated that as the ice melts in the Svalbard waters, a very active pelagic primary and secondary production begins, which follows the ice-edge as it retreats. Horsted (1989) noted that there are generally two maxima of primary production from April and from August to September in Greenland waters.

Sub-ice flora and fauna

Wherever a sufficient amount of light penetrates the ice and enough nutrients are present, ice algae develop. These algae make ice-covered seas unique. The ice-edge phenomena are closely linked to the cryopelagic organisms. Thus, one of the short food chains is: primary production (ice-algae, phytoplankton), sea ice amphipods (*G. wilkitzkii, Apherusa glacialis*), polar cod (*Boreogadus saida*), sea birds, or mammals. The biomass of the cryopelagic fauna is high close to the ice-edge and decreases with increasing distance from it.

Daily and seasonal melting and formation of the ice has a thermostatic effect, so that the temperature of the water immediately below the ice is almost constant. It is also often of low salinity, hence the ice biota have evolved as euryhaline and stenothermal organisms. Mel'nikov (1980) distinguishes an endemic or autochthonous flora, consisting of Chlorophyta and Cyanophyta, present year-round and developing each spring in the snow above the ice and gradually leaching downward through the ice; and a non-endemic flora dominated by diatoms. This latter flora develops at the bottom of the ice, is planktonic in origin, and is carried upward as the ice thickens in the fall. He indicated that when diatoms die, they become a source of food for the endemic species of flora. The associated fauna is endemic, *G. wilkitzkii*, *Mysis polaris*, *Derjugina tolli*, *Tisbe furcata* among others, or non-endemic.

The brown zone forming the bottom layer of sea ice is dominated by pennate diatoms, but contains other algae and several species of small invertebrates. Chlorophyll measurements in Arctic Canada show that production of the ice diatoms peaks in mid-June before the phytoplankton blooms in the water below the ice, at a time when the sea ice is still snow-covered (Mansfield, 1975). As soon as the snow melts this ice flora disappears, suggesting that it is adapted to low light intensities. It extends the season of production by preceding the normal phytoplanktonic bloom. These algae also provide a source of food for benthos and fish in coastal waters, especially with the cods *B. saida* and *Arctogadus glacialis* (Mansfield, 1975).

Werner and Arbizu (1999) noted that the lower part of the ice in the Laptev Sea, northern Russia, showed an accumulation of organic matter, mainly composed of organic carbon and chlorophyll, that could provide a food source to the fauna living below the ice in the pelagic habitat, and to the underlying benthos. In fact, they found that large quantities of nauplii, copepods, foraminifers and pteropods were common. Poltermann (1998) found that the Franz Josef Land islands sea ice was inhabited by several amphipods species. Abundance, biomass and small-scale distribution of these cryopelagic amphipods reached 420 ind m^{-2}. Amphipods were concentrated at the edges of the ice floes and were less frequent in areas further away under the ice. Species such as *G. wilkitkzii* were dominant with the less abundant *Apherusa glacialis*, *Onisimus nanseni*, and *Onisimus glacialis*.

Secondary production (zooplankton)

Water near the surface of the Arctic Ocean supports the greatest summer biomass of zooplankton, the abundance generally decreasing with increasing depth. At least 158 species of zooplankton are known to be found in the central Arctic and adjacent seas including Kara, Laptev, East Siberian, and Beaufort. Crustacea, Ctenophora, Molluska, Annelida, Ostracoda, and Chaetognatha are the most common (Grainger, 1989).

Like phytoplankton, zooplankton shows an extreme annual oscillation in Arctic Canada. This is mainly due to the increase in populations of the herbivorous species, particularly copepods, which are the dominant species. As phytoplankton grows, copepods grow and reproduce, and then as their food supply comes to an end, they gradually die off. In contrast, the primarily carnivorous zooplankton species show relatively little change in numbers throughout the year and no particular period of reproduction (Mansfield, 1975).

Gislason and Astthorsson (1999) indicated that the seasonal variation in biomass and abundance of zooplankton in the waters north of Iceland were low during the winter and peaked once during spring in late May. The principal constituents were *Calanus finmarchicus*, *Pseudocalanus* spp., *Metridia longa*, *C. hyperboreus*, chaetognaths and euphausid larvae. Kosobokova *et al*. (1997) studied the composition and distribution of zooplankton in the Laptev Sea where total biomass ranged between 0.1 and 7.9 g m^{-2}. The dominant species were *Calanus glacialis*, *Calanus hyperboreus*, and *M. longa*. Copepods are also the most important grazers in the Barents Sea with ca. 38 species, *C. glacialis*, *C. finmarchicus*, and *C. hyperboreus* being among the most common (Loeng, 1989). Euphausids as *Thysanoessa* spp. are the most important grazers. Among carnivorous zooplankton species, the chaetognaths *Sagitta elegans* and *Eukrohnia hamata*, together with ctenophores are considered to be important (Loeng, 1989).

Dunbar (1989) and Grainger (1989) pointed out that diel vertical migration of zooplankton in the Arctic Ocean is rare, but seasonal vertical migration is fairly common. In the Barents Sea, larger zooplankton species, such as *C. glacialis*, are thought to overwinter in deeper layers, returning to the surface layer in early spring to mature and spawn. Spawning takes place during the diatom bloom and the new generation feeds on the remnants of this bloom and subsequent production of phytoplankton. Zooplankton in turn is preyed on by capelin, which during summer has a northward feeding migration (Loeng, 1989).

Zenkevitch (1963) characterized the Svalbard water area in the same way as the Barents Sea, with a dominance of copepods *C. finmarchicus* making up 90% of the zooplankton biomass. The plankton biomass was reported to decrease in a northerly and easterly direction. In the area north of Svalbard, chaetognaths, ctenophores, and amphipods comprise most of the remaining biomass (Strömberg, 1989).

Horsted (1989) observed that zooplankton biomass in Greenland waters had its maximum in July at the same time as the second maximum of primary production, while macroplankton had a somewhat longer lasting maximum from June–July onward. Thus, the newly hatched cod larvae seem to depend heavily upon the availability of naupliar and copepodid stages of *C. finmarchicus*.

Polynyas

In the Arctic, there are ice-free areas in the proximity of completely ice-covered regions, so called polynyas. The correlation between areas of open water in ice-covered Arctic and increased biological productivity is clear (Bazely and Jefferies, 1997; Stirling, 1997).

Polynyas form where warm, upwelling sea currents prevent the water surface from freezing. They are either small and temporary or extensive and free of ice all winter. The largest ones appear at the same place every year. The biggest of all polynyas is located at the head of Baffin Bay, Canada, and can reach a surface area as large as Lake Superior. In the desert of floating ice, polynyas represent a rich feeding ground and ideal habitat for many tiny plants and animals at the base of the food web. They also represent a temperate environment that enhances survival of Arctic animals. For instance, the ice around polynyas is ideal for the growth of ice algae. Owing to this large amount of food, countless amphipods and larger crustaceans, squids, fishes and mammals can be observed. Ice algae develop soon in spring, as soon as the sun rises high enough to promote minimum photosynthesis, long before the weather begins to warm up. This early start of primary production and its effect on other levels of the food chain is important for seabirds that need time to build up their strength before they can lay their eggs. Moreover, since seabirds can only hunt for food in open water, they are largely dependent upon polynyas. Among them are fulmars, murres, guillemots, and gulls. Marine mammals such as whales, seals, polar bears, and walruses also converge at polynyas to take opportunity of the abundance of food. If no patches of open water existed in the winter pack ice, many animals could not survive.

Fish

There are no schooling pelagic fish, though the cryopelagic Atlantic cod (*Gadus morhua*) is known to occur in large numbers during the spring period in the Barents Sea, and the polar cod (*B. saida*) appears to form scattering layers. The giant among benthic fish is the Greenland shark (*Somniosus microcephalus*) long known for its scavenging behavior largely oriented on whale carcasses. Where the Bering Sea intrudes into the Beaufort Sea, abundant pelagic herrings (*Clupea harengus*) and capelins (*Mallotus villosus*) occur in the region of the Mackenzie delta. Demersal species such as the Arctic and starry flounders (*Liopsetta glacialis* and *Platichthys stellatus*) and the Greenland and saffron cods (*Gadus ogac* and *Eleginus gracialis*) are also common. Similarities exist in the southern part of Baffin Island where the Atlantic cod and several deepwater forms like the Greenland halibut (*Reinhardtius hippoglossoides*) and the rock and roughhead grenadiers (*Coryphaenoides rupestris* and *Macrourus berglax*) are observed. The Barents Sea is a feeding ground and nursery for large commercially important fish stocks such as Arctic cods, herrings, Greenland halibuts, haddocks, capelins, redfish, and saithes (Loeng, 1989).

Arctic fish must be able to live under conditions of reduced light and in total darkness. Air breathing predators, except for certain seal species, are displaced to gaps, leads and polynyas through interference with respiration. Ice also reduces avian predation to practically zero. In these conditions, ice may be considered advantageous for fish. Moreover, a new biological habitat that might be described as an inverted benthos is provided by ice for fish. A distinct phytoplankton flora occurs immediately below the ice and an abundant crustacean fauna may be tributary to this food source. This diatom-crustaceans community is an important one that supports the Arctic cod, which helps to sustain Arctic char, birds, seals, and belugas.

Birds

About 12 species of birds are known to live all year round in the Arctic, including the raven, gyrfalcon, willow and rock ptarmigans, snowy owl, redpoll, Ross's and ivory gulls, thick-billed murre, dovekie and the black guillemot. Most of them shift south slightly during the Arctic winter. All other birds, about 90 species, are migrants. Numerous species of birds nest in the Arctic, such as the fulmar *Fulmarus glacialis* and the kittiwake *Rissa tridactyla*. In the Greenland Sea, the most abundant species are the fulmar, little auk *Alle alle*, guillemot *Uria lomvia*, and kittiwake (Mehlum, 1997). The abundance of organisms that bloom during summer, including insect larvae, mollusks and crustaceans, are a substantial source of food. Lack of food rather than the cold itself is what makes the Arctic so inhospitable for birds in winter. Nevertheless, considering that the cold is fierce, some of the permanent residents have evolved special adaptation to cope with it.

Mammals

The generally scattered distribution of marine fish in Arctic waters has not prevented mammals from attaining a dominant position among the marine vertebrates, for they depend mainly on the larger invertebrates, both planktonic and benthic, for their food. Thus, most common mammals of the Arctic are either part of or dependent upon coastal ecosystems. They include polar bear, arctic foxes, wolverines, reindeer, musk oxen, lemmings, and many species of marine mammals.

Five species of seals spend at least part of the year in the Arctic. The bearded seal (*Erignathus barbatus*) and ringed seal (*Pusa hispida*) remain all year round. The others are the harp seal, hooded seal, and harbor seal. Except for the harbor seal, all species give birth to their pups on the ice. Most seals are important predators of benthic invertebrates and fish. The most thoroughly investigated species has been the ringed seal, the most truly Arctic of all the mammals. This species is able to survive under the winter fast ice by keeping open breathing holes. In spring, the pup is born in a cavern among rafted ice blocks or on the surface of the ice in a lair excavated in the overlying snow. Predation by the polar bear (*Ursus maritimus*) and Arctic fox (*Alopex lagopus*) can cause very high mortality of young in certain areas. In fact, the polar bears feed almost exclusively on seals. The ability of ringed seals to live under fast ice is not shared by any other Arctic pinnipeds, though the bearded seal is known to keep breathing holes in some areas.

Walrus (*Odobenus rosmarus*) live in the Arctic waters east of Somerset Island, notably in Baffin Bay, Davis Strait and Foxe Basin. Pacific walrus are found along the coast of Alaska and westward along the Arctic shores of Siberia. Walrus give birth on ice floes and, when not feeding, spend most of their time lolling on the ice floes in great numbers. Most of them are bottom feeders grazing on clams and others bivalves in shallow waters. They also eat whelks, sea cucumbers, and other benthic invertebrates.

Four species of whales may be encountered in Arctic waters. Three of them, the bowhead whale (*Balaena mysticetus*), beluga (*Delphinapterus leucas*), and narwhal (*Monodon monoceros*) are permanent residents. Like the walrus, narwhals and belugas are gregarious. Narwhals are found in large herds in the fjords of eastern and northern Baffin Island, Devon Island and Ellesmere Island. These whales occur in the High Arctic waters of the northern hemisphere, where they occupy the most northerly habitat of any cetacean species. The fourth whale species, encountered in summer, is the killer whale (*Orcinus orca*). Other species, such as right, gray, blue, fin, minke, and humpback whales move to the Arctic during their normal annual migration cycles (Gambell, 1989). Toothed whales like sperm, Baird's beaked, northern bottlenose, long-finned pilot, and beaked whales, among others, can also be observed in the Arctic.

The bowhead whale is the only plankton eater, its diet is focused on euphausids. The beluga and narwhal mostly prey on fish and squids as well as pelagic and benthic invertebrates. Killer whales largely prey on other marine mammals.

Human impact

The native people of the Arctic are at the top of the food chain and harvest fish, birds, and marine and terrestrial mammals. Inuits have their homeland stretched from the northern tip of Russia across Alaska and northern Canada to parts of Greenland, but their populations remain sparse.

In spite of its remoteness, the Arctic is threatened by airborne pollutants spreading from industrial areas in the lower latitudes, by growing mineral exploitations (coal, nickel, uranium, tin, gold) and also by natural gas and petroleum industries. As a result, Arctic ecosystems and Inuit populations are seriously endangered.

Moreover, during the course of the past century, there has been an overall increase in global temperature of some 0.5°C. The past decade has been the warmest of the past 100 years with the five warmest individual years having been recorded during it. The recent trends observed are generally consistent with those projected by the global circulation models under increased atmospheric CO_2 concentrations (Maxwell, 1997). Higher temperature is generally associated with less sea ice and snow cover extent. Thus, global warming could be one of the most important factors affecting the biodiversity, distribution, abundance, and seasonal cycles of Arctic species in the future.

ARCTIC, COASTAL GEOMORPHOLOGY

Introduction

The Arctic, long considered a ". . . region of darkness and mists, where sea, land and sky were merged into a congealed mass" (Nansen, 1911, p. 1), has subsequently been defined according to its astronomic, biotic, climatic, cryologic, geomorphic, and hydrologic characteristics (Walker, 1983). From the standpoint of coastal morphology, it is the juncture of whichever category is used with the coastline that is important. The determinant that provides the greatest extent to the coastline is sea ice. In the Northern Hemisphere using sea ice as the limiting boundary results in the inclusion of the coastlines of Hudson Bay, Labrador, and Newfoundland, the Sea of Okhotsk and most of the Baltic and Bering Seas (See *Ice-Bordered Coasts*). By many other criteria, most of these coastlines do not qualify as Arctic.

In this entry, the discussion centers on those coasts that border the Arctic Ocean and surround Greenland and the islands of the Canadian Archipelago. When the lengths of these coastlines are measured on the American Geographical Society 1 : 5,000,000 *Map of the Arctic Region*, they total 82,000 km, Greenland (16,000 km), the Canadian Archipelago (26,000 km) and the other arctic islands (9,000 km) (Figure A26). Other calculations, depending on the detail used, provide larger numbers. For example, Bird (1985) states that the coastline of the islands of the Canadian Archipelago is at least 90,000 km long and Nielsen (1985) reports that that of Greenland is some 40,000 km long.

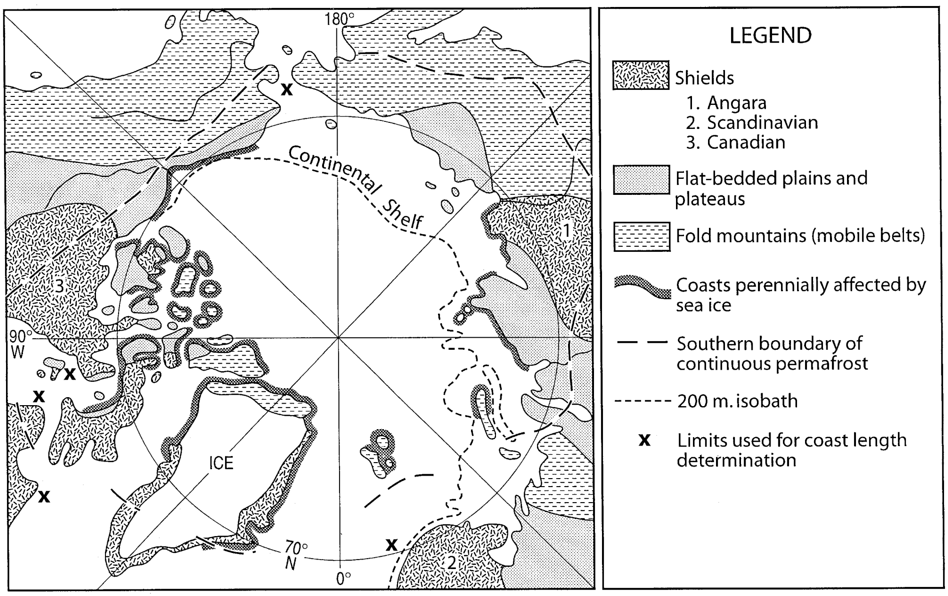

Figure A26 Geologic base, continental shelf and sea ice distribution in the Arctic (compiled from numerous sources including Sater *et al.* (1971); Péwé (1983); Walker (1998)).

The geologic base

Three large, stable shields composed of Pre-Cambrian rocks form the cornerstones of the Arctic, one each in Canada, Scandinavia, and central Siberia (Figure A26). The actual exposed lengths of these Pre-Cambrian rocks along the coast is less than what the size of the shields would lead one to believe because their margins have been buried under eroded shield materials. Between and adjacent to the shields, including their buried margins, are folded mountains (or portions of the so-called "mobile belts" of the Northern Hemisphere) some of which extend to the coast (Figure A26).

Like the embedded coasts surrounding the Atlantic Ocean, Arctic coastal margins are affected by minimal tectonic activity. Earthquakes do occur, as on the north coast of Baffin Island, north of the Mackenzie delta and in the northwest Canadian Archipelago, but they are of low magnitude.

The most recent major event to impact most of the arctic coastal zone is glaciation. The main coastal areas not directly affected by glacial ice during the Pleistocene include the east-central Siberian lowland, a small part of the western Canadian Archipelago and the north coast of Alaska. However, even those coastal zones, though never actually covered by ice sheets, were affected by drainage across them from glacial fronts and by the changes in location of the interface between land and sea due to changes in sea level as the continental glaciers waxed and waned. Today, only a small percentage of the arctic coastline is being modified by glaciers. Major segments are found on Greenland, Ellesmere Island, Novaya Zemblya, and Spitzbergen.

In addition to the direct modifications of the coastlines by glaciers in the form of moraines, drumlins, fiords and strandflats, the rebound that followed deglaciation has (and is) converted formerly submerged coastal belts into subaerial coastal plains. Such occurrences are especially common in northern Canada, the Canadian Archipelago, Scandinavia and the islands north of Siberia. In many locations former coastal features are found today at elevations of as much as 250 m. In the Canadian Archipelago and the Hudson Bay area rebound is continuing at rates of as much as 1 m/century (Andrews, 1970).

The continental shelf and the coastal plain

The two basic contrasting zones of coastal significance in the Arctic are its subaerial and subaqueous portions. These two zones are highly variable in width and in the forms and processes they possess. The continental shelf varies in width from a few kilometers, as off parts of Greenland, to more than 800 km in the East Siberian Sea. With sea-level rise and with coastal erosion, the width of the subaqueous portions of the Arctic Ocean has been increasing. Weber (1989, p. 815), for example, writes that "The Chukchi Shelf was eroded far into the continent and transects the principal mountain ranges of Northern Alaska." Much of the continental shelf of the Arctic Ocean is flat and shallow, cut only by a few submarine valleys such as those off rivers like the Kolyma and Indigirka and off Barrow, Alaska. Most of the smaller features on the shelves are the result of ice gouging and deltaic deposition or are remnants of subaerial erosion that occurred during lower sea levels (Reimnitz *et al.*, 1988; Weber, 1989).

The coastal plain, although not as extensive as the continental shelf, possesses a greater variety of forms and processes than the shelf it borders. Although, the coastal plain of today is subaerial much of it, as in Alaska and northwestern Canada, is the ". . . landward edge of a continental shelf that has experienced repeated transgressions and withdrawals of the sea . . ." (Bird, 1985, p. 243). It is comprised mainly of gravels, sands, and silts that presently are ice-bonded in the permafrost. In places it is low-lying and level. Near the Indigirka River mouth, for example, storm surges have reached as far as 30 km inland (Zenkovich, 1985).

The major forms of the coastal plain that border the ocean include barrier islands and lagoons, sand and gravel beaches, mudflats and marshes, sand dunes, low coastal bluffs, deltas and lengthy rias (*gubas* in Russian).

Among the arctic coast's most conspicuous and extensive features are its barrier islands and sandy spits. They are present along much of the coast of arctic Alaska and northwest Canada and along various parts of the Siberian coastline. Some barrier islands are remnants of the coastal plain whereas most are composed of gravel and sand which originated offshore.

Although, most of the deltas in the Arctic are small, they are sufficiently numerous to occupy a sizeable proportion of the coastline. For example, 135 km (or 9%) of the coastline of Alaska between Cape Lisburne and the Canadian border is deltaic (Wiseman *et al.*, 1973).

Some arctic deltas, like the Mackenzie, Lena, Indigirka, Kolyma, and Colville, face the open ocean, whereas others, such as the Yenisey and Ob, are located at the head of lengthy and narrow gubas (Figure A27). These two deltas, even though confined to the head of their estuaries, are the fourth and fifth largest deltas in Siberia. Among arctic deltas, that of the Lena River (Figure A28) is unique because its structure, shape, and relief appear to be the result of tectonic activity as well as modern hydrological processes (Aré and Reimnitz, 2000).

The deltas of the Arctic, like those elsewhere, are relatively young in that their present-day expression stems only from the time sea-level rise reached a nearly stillstand position about 5000 BP. All of the older deltas in the Arctic contain most of the features, such as distributaries, abandoned channels, lakes, sand bars, mudflats, and sand dunes, that are typical of deltas elsewhere. However, they also possess such cryospheric forms as ice-wedges, ice-wedge polygons, pingos, and thermokarst lakes.

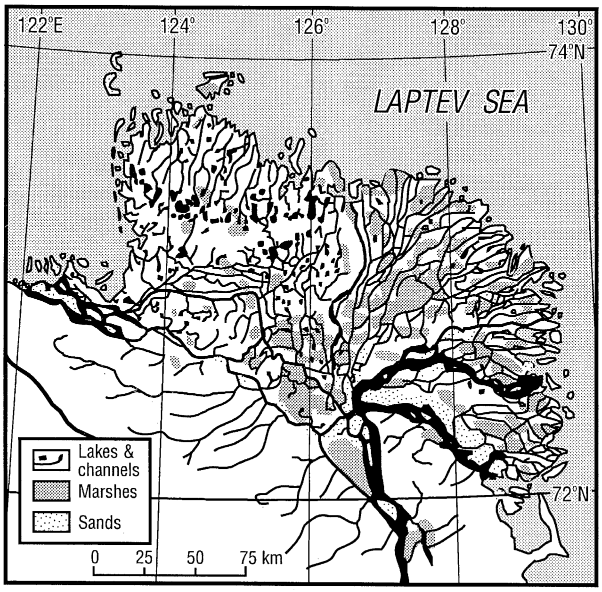

Figure A28 The Lena River delta, the largest at 32,000 km^2 in the Arctic.

Conditions, forms and processes

The present-day appearance of the arctic's coastline, like that of coastlines elsewhere, depends on modifications that have occurred to the geologic base it inherited. Along many coastlines, these modifications include those engineered by humans. In the case of the Arctic, however, human modifications are still minimal, although they do occur at the mouth of some rivers, adjacent to some coastal villages, and where mining operations, including petroleum exploration and production enterprises, have been developed.

Thus, most of the coastal forms in the Arctic, as is true also of the Antarctic, are the result of natural conditions and processes. Included are those conditions and processes associated with cold climates such as low temperature, snow, ice (river and sea) and permafrost with its many forms of ground ice as well as those of more universal occurrence like relief, structure, sediment type, river discharge, offshore gradient, wave action, currents, storm surges, and tides (Figure A27).

Cold climate processes are frequently divided into two types: glacial and periglacial (French, 1989). Although in the arctic of today glacial processes impact only short lengths of shore, periglacial processes are of major importance along the entire coastline (Harper, 1978) including those sections most recently deglaciated.

The *sine qua non* of periglacial processes is the freezing and thawing of the ground, which is mainly temperature dependent. The change from one state to the other may be daily, seasonal or over longer (thousands of years in some cases) periods of time.

Permafrost

Permafrost (a condition in which ground temperature remains below 0°C for more than two years) is present along most of the coastline of the Arctic from which it extends both landward and seaward (Figure A27). Although permafrost is defined by temperature, it is water in the form of ice that is especially critical in coastal modification (Figure A29). The included ice, which serves to bond unconsolidated sediments as long as they remain in a frozen state, makes the mass especially unstable when thawed. Ground ice is highly variable in type and quantity. In the upper few meters of permafrost it may account for more than half of the

Figure A29 Ice complex coast on Muostakh Island facing the Laptev Sea. The cliff is about 20 m high and is retreating at a rate of about 11 m/a (photo courtesy of Feliks Aré).

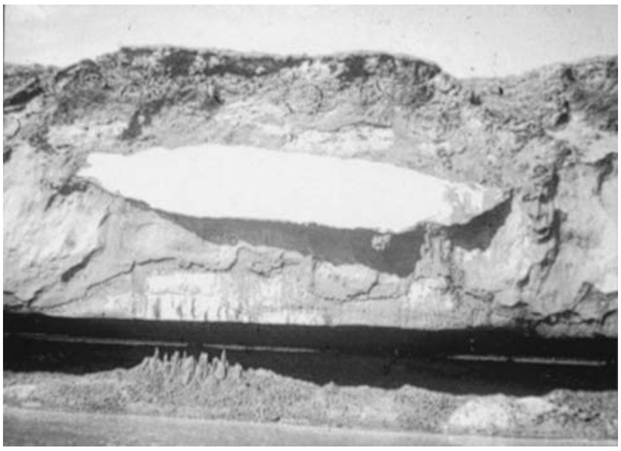

Figure A30 Thermoerosional niche in deltaic permafrost.

Figure A31 Example of block collapse and ice wedge from E. de K. Leffingwell's classic research monograph on permafrost and coastal morphology (1919).

volume whereas its presence in bedrock is minimal. It can range in form from microscopic pore ice to large segregated masses (Mackay, 1972).

Permafrost cliffs, which border much of the coastal plain of the Arctic, are relatively stable for 8–10 months of the year because they are protected from erosion by being in a frozen state, being covered by snowdrifts, and by facing a frozen, immobile sea. With snowmelt, an active layer (the thin layer that alternately freezes and thaws on the top of permafrost) begins to form and some surface flow is initiated. However, it is after the shore has become sufficiently free of ice that wave action can impact the base of the cliff and major erosion can occur. With wave impact, thawing at the base of the ice-bonded cliff occurs and with sediment removal a thermo-erosional niche (*termoerozionaja niza* in Russian) is created (Gusev, 1952) (Figure A30). The height of thermoerosional niches depends largely on the change in water level during wave attack and the depth of penetration varies with the stability of the sea cliffs.

The permafrost of the Arctic frequently supports other features such as pingos (Mackay, 1972) and ice-wedges which often express themselves at the surface in the form of ice-wedge polygons (Lachenbruch, 1962). Although their size varies, polygons are usually on the order of 10–30 m in diameter. Along the coastline, paralleling wedges serve as lines of weakness and often lead to block collapse (Figures A31 and A32) as thermoerosional niches develop. Those wedges that are perpendicular to the shore can serve as points of more rapid retreat, especially if the matrix is dominated by peat. Such coastlines are highly irregular

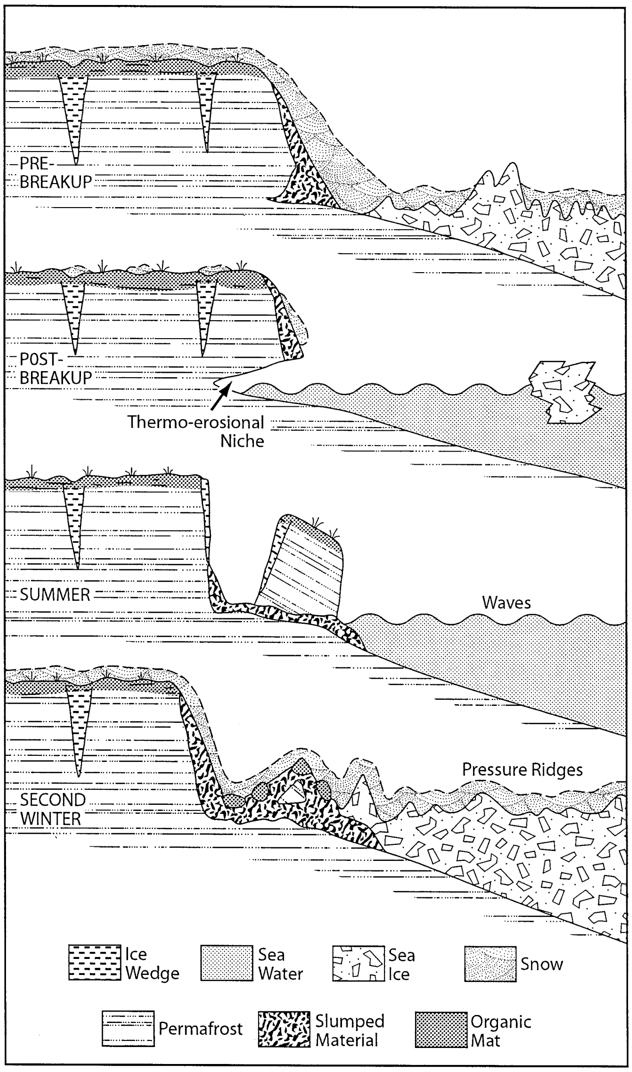

Figure A32 Block collapse and erosion along permafrost coastlines.

in detail. In addition to the large block falls that result from thermoerosional niche development, many coastlines exhibit thermokarst forms such as ground-ice slumps (creating what some have called thermocirques) and breached thermokarst lakes. Along hard rock coasts (which are in the minority in the Arctic) erosion of a cliff face appears to be mainly by frost wedging (Figure A33).

Sub-sea permafrost (offshore permafrost, submarine permafrost) occurs beneath the seabed of the continental shelves of northwest Canada, north Alaska, and Siberia (Figure A27). It is relic in that it formed when sea level was low and much of the present-day continental shelf was subaerial. It is of major interest today because of its importance to the petroleum industry and as a store of carbon dioxide and methane (Osterkamp, 2001).

Sea ice

Sea ice which borders virtually all of the arctic coast during winter, is present along some sections even in summer (Figure A26). During the time it is shorefast and bottomfast marine action along the coastline is nil. Also, during summer, much of the coastline is protected from wave attack because the presence of sea ice offshore reduces the fetch available to wind and dampens wave action. However, during these periods, often in the Fall of the year when the ice pack has been removed some distance offshore, storm waves may become powerful eroding agents. In 1986, strong winds over the Chukchi and Beaufort Seas resulted in severe erosion of low coastal cliffs impacting heavily the villages of Wainwright and Barrow, Alaska. Other erosive storms also occurred along these coasts in 1954, 1956, and 1963.

Some coastal specialists consider that the passive nature of sea ice is its most important role *vis-à-vis* the coastline. Nonetheless, sea ice is also an active agent in coastline and offshore modification. Ice push during the periods of freeze up and to a lesser extent during breakup create highly irregular surfaces on arctic beaches. Large pressure ridges formed during freeze up help protect the coastline during breakup because they may last well into the Fall. Although some of the reworked beach forms, including mounds, ridges and kettles, may last for years, depending mainly on how high up on the beach they developed, most tend to be ephemeral because they are removed by summer wave action. Large amounts of beach material (especially sand and gravel but also, in some locations, boulders) can be bulldozed, scoured, rafted, and resuspended by sea ice. In some instances, sea ice rides up on the shore and even overtops low cliffs. If rideup is over a snow bank or an ice foot it will cause minimal modification to the frozen ground beneath.

In addition to the shoreface itself, sea ice causes ice scour out to depths of more than 20 m often several kilometers from the coastline. Deep (2–3 m) gouges or trenches are created by the keels of drifting floes. Most floes eventually become grounded in which case current movement around them can resuspend bottom sediment and transport it elsewhere.

From the standpoint of the coastline, changes occurring to sea ice because of global warming are likely to be very important in the future. Recent data show that, not only is the ice pack thinning, but its seasonal regimen is changing (Parkinson, 2000). If such a trend continues, ice-free periods along coastlines will lengthen and the fetch will increase in length. Thus, both the intensity and duration of waves impacting the shore will also increase.

Snow

Although the amount of snow that falls in the Arctic is limited, partly because of low temperatures, it is an important factor in regard to the coastal zone. It accumulates as snow drifts against irregularities such as coastal bluffs and serves as protective ramps often until late summer (Figure A34). Snow also becomes incorporated in the icefoot in combination with seawater and freshwater ice, and organic and inorganic sediment where it becomes part of the beach (McCann and Taylor, 1975). Possibly the most important role of snow insofar as the arctic coastline is concerned is its service as the main source of water for the rivers that flow with their sediment load into the Arctic Ocean.

Impact of rivers on the Arctic coast

Four of the ten longest rivers of the world (Ob, Yenisei, Lena and Mackenzie) drain into the Arctic Ocean. In addition, there are numerous smaller rivers, some of which are confined to the zone of continuous permafrost. Many of these smaller rivers cease flow completely during winter. Even the larger rivers are highly seasonal with the major discharge of water and sediment occurring during the snowmelt season (Walker, 1998). Thus, the impact of rivers on the coast is confined, like that of most other arctic coastal modifiers, to a few months of the year. Nonetheless, during that restricted season river water impacts the sea ice over and under which it flows.

Floodwater aids in earlier melting of the sea ice at the mouth of the river than otherwise would be the case. Nearshore, much of the flood water flows over the top of the bottom/shore fast ice until it finds holes, as along pressure ridges, down through which it drains. From these discharge holes, which Reimnitz and Bruder (1972) call *strudel*, water continues to flow seaward beneath the ice (Figure A35). As the water pours through these holes in the ice, it creates depressions in the seafloor deposits below.

As sediment-laden floodwater spreads out over the sea ice, its velocity decreases and deposition occurs. Most of the sediment deposited on this bottomfast ice becomes a part of the subaqueous delta as the sea ice melts from under it (Walker, 1974). The sediment that is carried by floodwaters beneath the sea ice may be transported many tens of kilometers seaward and become incorporated in long-shore currents and therefore, lost to the deltas.

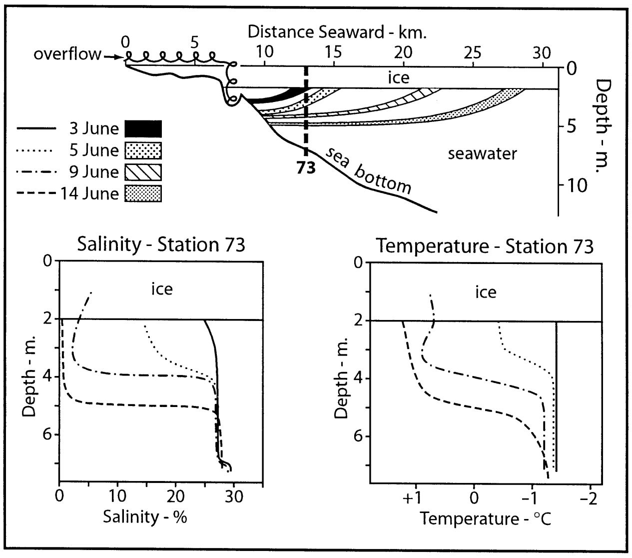

Figure A35 Floodwater overflow and the development of a freshwater wedge beneath sea ice during breakup.

Ocean currents, tides, and waves

"The Arctic Ocean, relatively isolated in terms of worldwide wind systems and partially or wholly covered with sea ice, depending on season, is a body of water in which low tides, slow-moving currents, and low-energy waves predominate" (Walker, 1982, p. 61).

Although there are a few locations in the Arctic where macrotides occur (e.g., off southeast Baffin Island, Canada, and in the Mezen Gulf, Russia, where ranges are more than 10 m), along most of the arctic coast tidal ranges are less than 2 m (Figure A27). Marshes are often associated with the high tide range locations. Despite low astronomic tidal ranges, storm "tides" occasionally result in deep intrusions of water over low coastal plain surfaces. The inner edge of surge lines are often delineated by the presence of driftwood which is a common contribution of the rivers that flow through the taiga of Asia and North America.

The dominant currents in the Arctic Ocean are the Beaufort Sea Gyre and the Transpolar Drift (Figure A27). They are the currents that provide the general direction of flow to pack ice and the occasional ice island that breaks off of Greenland and Ellesmere Island. There are other localized currents that affect the coastal zone by transporting sediments along shore and cause sea ice to impinge the coastline. Such ice movements are affected by wind as well as by ocean currents.

Waves, even though their formation is impossible for most of the year because of the canopy of sea ice that covers the ocean, are, nonetheless, the dominant agent in shore modification along most of the arctic coastline. The length of time, waves are effective, varies greatly ranging from several months along the longest-lasting ice-free zones to only occasionally or even rarely along coasts that are often ice-bound even during summer as exampled by parts of the northwest Canadian Archipelago.

Coastal erosion and climate change

Many of the coasts of the Arctic are retreating, some by tens of meters per year especially along some Siberian coastlines (Aré, 1988). Along the Beaufort Sea coast of Alaska, erosional rates have been such that since the sea reached its present level 4–5,000 BP, the coastline has retreated as much as 25 km (Reimnitz *et al*., 1988). Rates ranging from 1 to 5 m/a are common in the ice-rich permafrost bluffs bordering much of the Arctic Ocean. In areas north of the Siberian coast, erosion has resulted in the disappearance of some offshore islands.

As most of this retreat is the result of the combined effect of normal marine (wave action) erosion and the periglacial process of thermokarst collapse and thermal erosion, it appears that an increase in the rate of coastal retreat with any rise in sea level and sea-ice degradation is likely.

Such a change would increase the amount of sediment contributed to the shore from cliff erosion which by some calculations already exceeds that contributed by the rivers flowing into the Arctic Ocean (Brown and Solomon, 1999). However, it is likely that the same climate changes that affect sea level and sea-ice degradation will also increase permafrost thaw and river discharge and, therefore, the sediment loads of arctic rivers. Whether the relative proportions of the two sources will change is uncertain.

Conclusion

Although a number of localized programs have been undertaken in the last four decades, some of them out of research stations such as the Naval Arctic Research Laboratory, Barrow, Alaska; the Inuvik Research Laboratory, Inuvik, Canada; and the Permafrost Research Institute, Yakutsk, Russia, Arctic coastal research has generally been neglected.

In 1998, at the International Permafrost Conference, a Working Group on Coastal and Offshore Permafrost was formed. This led to the development of an Arctic Coastal Dynamics (ACD) project which has among its objective the establishment of rates of erosion and accumulation, the development of a network of monitoring sites along the coast and the initiation of research on critical coastal processes in the Arctic. The ACD is an international undertaking that bodes well for the future of arctic coastal research.

ARTIFICIAL ISLANDS

Introduction

Islands are defined as a relatively small landsurface, surrounded by water. The largest island, Greenland, has a surface, which is still four times smaller than that of the smallest continent, Australia. The total surface of the earth's islands approximates 10 million km^2, which is comparable to Europe's total surface area.

It is common to distinguish between continental and oceanic islands. Continental islands are considered part of a continent when they are located on the associated continental shelf. Oceanic islands, in contrast, do not belong to a continental shelf. The majority of oceanic islands are of volcanic origin. Some oceanic islands (e.g., Madagascar, Greenland) could be considered as subcontinents, which have been separated from larger continents through tectonic processes.

All realizations of artificial or man-made islands, as constructed so far, are close to shores on relatively shallow water either in intertidal zones, in bays, on the shoreface, or on the nearby shallow continental shelf, and most are located in a sheltered environment. Based on the above definition artificial islands belong to the class of continental islands. Because of their general close vicinity to the shore, artificial islands are very similar to land reclamations into the sea, certainly when such reclamation is separated from the existing land by a waterway or channel, which often has a water management purpose.

The history of island and land reclamation into the sea is some 2,000 years old, starting with dwelling mounds in floodprone areas (cf. Kraus, 1996; this reference provides historic context of works in Canada, Germany, Japan, the Netherlands, and Taiwan, described below). In the 16th and 17th century, land reclamations were becoming common practice in western Europe. In the 20th century, this practice has become worldwide. While this continues to be the case, the construction of islands or reclamations further offshore is only of recent times. Islands in support of a larger infrastructure or temporary islands for petroleum exploitation are of the last decades. Many feasibility studies on artificial islands with an intrinsic purpose (such as industry, urbanization, and airports) have been undertaken all over the world since the 1970s. However, it was not until 1994 that the first more offshore-located island was completed at Kansai International Airport in the Bay of Kobe of Japan.

Concepts and applications

Dwelling mounds

Historically, artificial islands and reclamations go back a long way (cf. Van Veen, 1962). The first known historic recordings of artificial islands are by the Romans. Plinius in 47 AD describes how the Friesians along the northern boundaries of the Roman empire lived on artificial mounds (called "terpen" in Dutch) in order to keep "their heads above the water" during spring tides and storm surges. In all they built 1,260 of these mounds in the northeastern part of the Netherlands, which still exist today, although by now situated in reclaimed land. The areas of the mounds vary from 2 to 16 ha, and their surface level may reach as high as 10 m above mean sea level. The volume content of a single mound may be up to 1 million cubic meters (Mm^3).

Poldertype reclamations

This period of family based shelter against high waters reverted into a more collective form of shelter by seawalls and associated reclamations. The start of these constructions is expected to have been shortly after the declaration of the Lex Frisonian in 802. In the 16th and 17th century all over western Europe, including Russia, polder-type reclamations have been realized both on seashores, estuaries and rivers, and lakes. A polder that is used to reclaim part of the sea bottom consists of an endiked continental shelf or intertidal basin area, with its surface, being the original sea bottom, below mean sea level which is maintained dry by the use of pumping stations (see entry on *Polders*).

One of the world's largest polder reclamations (Van de Ven, 1993) concerns that of the Zuiderzee in the Netherlands, which started in 1918 (with the main damming realized in 1932) and is not yet finalized today. The closing off and the partial reclamation of the Zuiderzee have resulted in the gain of 166,000 ha of new land distributed over four polders. This new land is used for agriculture, urban development, recreation, and nature conservation.

Elevated reclamations

The strong economic development over the last decades of Asian countries where the availability of land is scarce, for example, Japan, Singapore, Taiwan, and South Korea, has also resulted there in a series of reclamations. With the exception of South Korea the acceptation of the polder-type reclamation in Asia has shown to be low. Although the execution method initially is similar, viz. endiking the area first and then drying by pumping, there appears to exist a preference in Asia for elevating the reclamation to above mean sea level (see entry on *Reclamation*).

Examples of this practice are the recent realizations (mid-1990s) of the industrial reclamation estates Chang Hua and Yun-Lin on the west coast of Taiwan, comprising 3,000 ha and 10,000 ha, respectively. The fill of these reclamations amounted to 800 Mm^3 of sand, which was dredged by trailing suction hopper dredgers in the nearby offshore area. The reclamation locations were primarily on diluvial substrates formed by pre-Holocene ebb-tidal deltas, which implies that subsidence problems were virtually absent.

Petroleum exploration and exploitation islands

In the petroleum exploration and exploitation industry, there exist several examples of island reclamations. One such example concerns Rincon Island off California (U.S. Army Corps of Engineers, 1984).

Another important example concerns a series of artificial exploration drilling rig islands of temporary nature in the Beaufort Sea – McKenzie Delta region, Canada. Through the construction of a number of such islands in the period 1973 to 1986 the presence of oil and gas reserves was confirmed, but exploitation in this remote, arctic environment was costly. The decline of the oil prices had hampered exploitation. The islands, with an expected lifetime of 3 years, were constructed in water depths varying between 3 and 21 m, just before the frost and ice formation would set in. A total of eight exploration islands of the sacrificial beach type and nine exploration islands of the sandbag-retained type were constructed. In both cases a dense sediment core was placed, which provided the exploration space needed (surface areas of the order of 1 ha). The sacrificial beach type implied that the relatively steep slope of the core was protected with a gently sloping lower beach of less dense sediment, which would be able to withstand erosive forces by water (in summer) and by ice (in winter). The sandbag-retained type resolved the issue of required resistance by protecting the slopes of the core through geotextile sandbags (with volumes of 1.5–3 m^3). The issue of subsidence in this area is virtually absent because of the permafrost conditions.

Infrastructure supporting islands

Over the last decades, a number of islands have been reclaimed to support the construction of a larger infrastructure. An early example is the island Neeltje Jans in the mouth of the Eastern Scheldt estuary. This was created on a subtidal flat, separating the main estuarine channels, with a twofold purpose. The island served both as a working area for construction of the elements that were to form the Eastern Scheldt Storm Surge Barrier (completed in 1988) and to form part of the barrier itself.

Other examples concern the construction of islands in cases where the two banks of a waterway are connected by a combined bridge–tunnel connection. At the transition of the bridge to tunnel and vice versa the island serves as the connection area. One North-American example is the Chesapeake Bay bridge–tunnel connection, a European example is the Øresund bridge–tunnel connection between Denmark and Sweden.

Airport islands

It might be stated that the introduction of offshore artificial islands in larger depths with a ground level above mean sea level was benchmarked by the construction of Kansai International Airport, Japan (1994). Soon, this was followed by Chep Lap Kok International Airport, Hongkong (1998), and Inchon International Airport, South Korea (2001). A common problem to these three airport islands is formed by the foundation. Being international airports demands that important loading forces (400 metric tons for future intercontinental aircraft) need to be sustained. Since all of these islands are constructed in relatively sheltered areas, the local sea bottom commonly consists of alluvial clay, which calls for special measures.

Kansai International Airport, Japan: The main concern in creating the artificial island has been the foundation of the island. Not only was the local water depth some 18 m, but an alluvial clay layer of more than 20 m covered the geotechnically stable diluvial (Pleistocene) clay substrate. The alluvial clay layer was artificially compacted by about 1 million piles that were driven into the layer to drain the water out. Subsequently, a sea defense was constructed of some 11 km circumference, within which 178 Mm^3 of material was dumped. Because of the scarce availability of suitable sand dredge material the majority of the fill was taken from quarries near Osaka. Thus, an island was created which has an elevation of 33 m above the sea bottom. Since the construction, the subsidence has continued and is expected to continue another 30–50 years. In the next phase the surface area of the island will be extended.

Chep Lap Kok International Airport, Hong Kong: A quarter of the artificial island consists of the island of Chep Lap Kok (350 ha), three quarters consists of a sea reclamation. The average local depth was some 6 m. In contrast with the solutions for Kansai and Inchon, the alluvial clay layer of 10–15 m was removed. The reclamation consisted of a lower layer of rubble mound material quarried from Chep Lap Kok and supplemented with sand dredged in the nearby area. To avoid expensive layer gradation transitions between the rubble mound material and the sand geotextiles were applied. The fill quantities amounted to 350 Mm^3, of which two-third was dredged sand.

Inchon International Airport, South Korea: This airport site covers 5,600 ha in total, of which 4,700 ha consists of reclaimed land between the islands of Yongjong and Yongyu along with 900 ha of existing land. To endike the area between the islands, three dams of a total length of 17 km were constructed, varying in crest height between 7.5 and 9.4 m. Their widths at their foundations are 90–120 m and 20 m at the crest. The reclamation of the 4,700 ha required approximately 180 Mm^3 of fill. Around 80% of the fill was dredged from the sea and the remaining 20% was quarried from mountains and hills in the area. The top layer of the reclamation site, which is largely an intertidal area, is composed of a soft alluvial layer of 5 m average thickness. A sand drain technique was applied to achieve higher soil-carrying capacity. Vertical sand pipes of 400 mm diameter were driven into the soft soil every 2.8–3.8 m to drain pore water. The expected additional settlement is less than 0.5 m.

Conclusions

Although the history of artificial islands or island reclamations is long, it may be expected that the increasing pressure of urbanization, industry, and tourism in the densely populated coastal regions is yet to result in a boom of construction of such islands e.g., Palm and Globe islands (Dubai) under construction. The three main technical problems that one will generally face in the design and execution, are those of geotechnical foundation, of connection to the mainland and of availability of fill material. Besides this, one faces the important issue of environmental impact, where the aspects of impact minimization, nature substitution, and working in harmony with natural system forces are the keywords.

ASIA, EASTERN, COASTAL ECOLOGY

Coastal geography

Extending from Bangladesh in the west, to the Korean Peninsula and Siberia in the northeast (latitudes 89–129°E), Eastern Asia lies within the Indo-West Pacific Biogeographical region described by Ekman (1967). Eastern Asia contains diverse coastal land formations and habitats, ranging from rocky shores and sandy beaches, to coral reefs, seagrass beds, salt marshes, mudflats, and mangrove swamps. The main landmass of Eastern Asia includes long, uninterrupted coastlines, for example, the coast of Rhakine (Arakan) in Myanmar, the coastlines of central Vietnam and China, and the peninsulas of Malaysia and Korea. The region also supports immense archipelagoes, most notably those making up Indonesia and the Philippines, which comprise of more than 13,700 and 7,000 islands, respectively. Innumerable small islands make up the Mergui Archipelago extending from Myanmar to Thailand, the Andaman and Nicobar Islands, and several minor archipelagoes. Huge deltas have also been formed by some of the world's great rivers (the Ganges–Brahmaputra in Bangladesh, the Irrawaddy in Myanmar, the Red River and Mekong River in Vietnam, the Yangtze River and Yellow River in China).

Climate and ecology

Climatically, Eastern Asia features a tropical equatorial subregion consisting of Malaysia, Singapore, Sumatra, Java, and Borneo; and northern subtropical to temperate subregions, which include the Bay of Bengal, the South and East China Seas, and the Yellow Sea (Figure A36). The Malay-Indonesia region has a hot and humid climate and is bathed by shallow, highly productive seas overlying the Sunda Shelf (the submerged peninsula of Pleistocene Sundaland). Extensive coastal areas of the Sunda Shelf are less than 60 m in depth. The Philippines borders the eastern edge of the Sunda Shelf, with much deeper waters of the Pacific Ocean beyond. Although the southern archipelago of Indonesia lies mainly within the humid tropical zone, there are some subhumid to semiarid areas, particularly to the east, including the northeast coast of Java and the islands of Timor, Lombok, and Sumba.

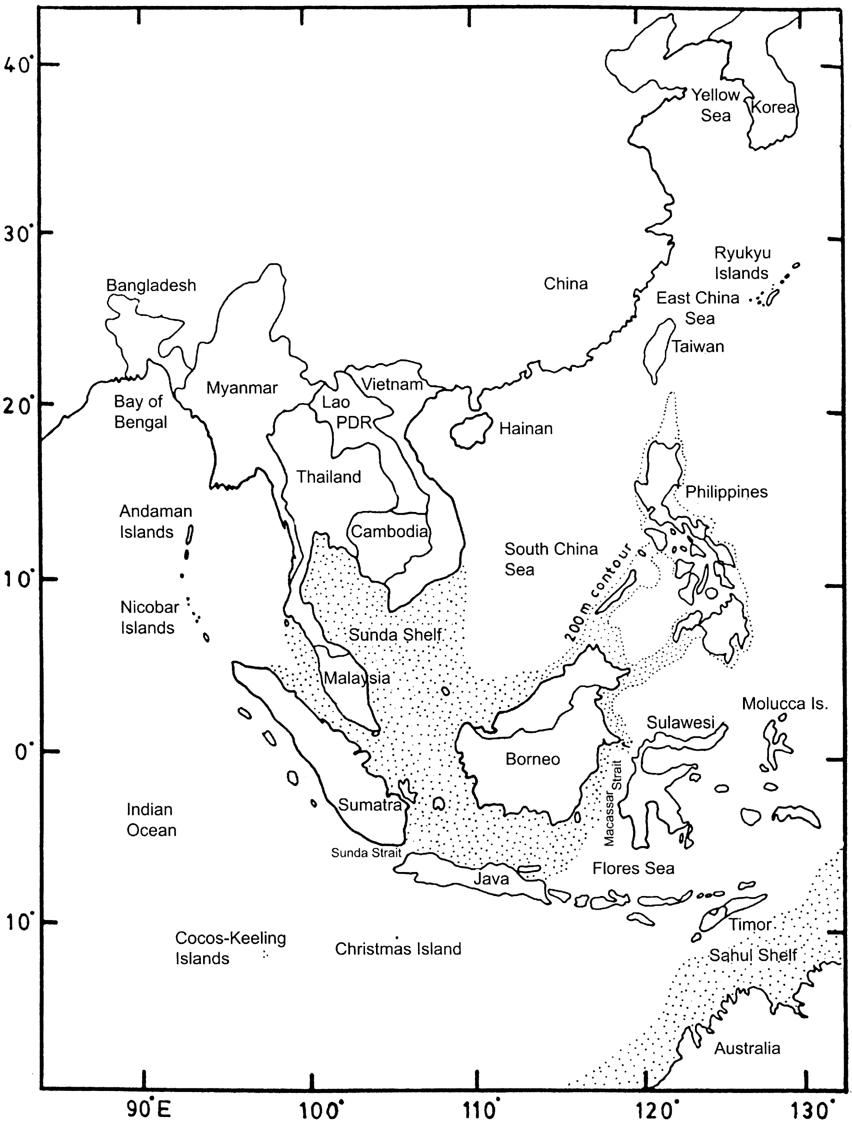

Figure A36 General map of Eastern Asia; the Sunda Shelf and Sahul Shelf regions are shaded.

North of the equatorial region, the NE and SW monsoons dominate the climate and surface ocean circulation. Rainfall becomes more and more seasonal eastwards and northwards from the equatorial subregion, with typhoons and cyclones (defined as storms with wind speeds exceeding 73 mph) associated particularly with the warm SW monsoon season. Typhoons originating in the Pacific pass through the Philippines before reaching the coastline of Vietnam and southern China. There is a "typhoon belt" from central Vietnam to Hainan Island where most of these typhoons strike land, causing wave surges of up to 2.5 m above normal sea level. Similar storms originating in the Bay of Bengal move northwards and commonly strike the coast of Bangladesh as cyclones. A key consequence of these monsoonal weather phenomena is that the most vulnerable coastal regions of Vietnam and Bangladesh are protected by man-made earthen sea dikes that have transformed the coastal ecology of the upper intertidal zone; these coastal defenses have also served to reclaim land for agriculture, salt-making, and aquaculture.

Further north, the coastlines of China and the Korean Peninsula are influenced by the East China Sea and the Yellow Sea. The latter is a productive, semi-enclosed water body with an average depth of only 44 m and a maximum of 100 m. The Yellow Sea is influenced strongly by several major rivers, especially the Huang He (Yellow River) and Yangtze River, which discharge more than 1.6 billion tonnes of sediments annually. Sedimentation and salinity, as well as seasonal temperature changes, control the ecology and productivity of the Yellow Sea ecosystem. The coastline of China consists mainly of mudflats and salt marshes. There are also large areas of intertidal mudflats and salt marshes along the west coast of the Korean Peninsula that provide an important ecological support function to migratory birds (including the very rare black-faced spoonbill *Platelea minor*: world population in 1998 only 613), as well as fisheries stocks (Kellerman and Koh, 1999).

Coastal habitats of Eastern Asia

This section describes the ecology of the main coastal habitats founds in Eastern Asia, particularly the mangrove forests, seagrass beds, and coral reefs of Southeast Asia which are the most productive and diverse in the world. However, Eastern Asia is a region where the natural ecology of the coast shows a complete spectrum of impacts due to human activities, from near pristine beaches and coral reefs on remote islands, to massive coastal land conversion for agriculture, aquaculture, and urban/industrial uses. The pressures from human population and development, particularly in heavily populated countries like Bangladesh, China, Indonesia, and Vietnam, have transformed or degraded the coastal zone at an alarming rate over the past 20 years.

Mangroves

Mangroves, or mangrove swamp forests, consist of trees and shrubs growing in the upper intertidal zone of muddy tropical and subtropical shores, including estuaries and lagoons. Mangroves develop best along sheltered shores where there is high and prolonged rainfall and an average temperature exceeding 20°C (Macnae, 1968). Mangrove forests provide important habitat and other ecological support functions for many terrestrial and aquatic animals, including both resident and visiting species, especially birds, as well as fish and shellfish populations that support substantial coastal fisheries (Macintosh, 1982). For this reason, it is usual today to regard mangroves as an ecosystem rather than simply a community of highly adapted plants and animals. The biology and ecology of mangroves has been reviewed in detail, notably by Macnae (1968), Tomlinson (1986), Robertson and Alongi (1992), and Hogarth (1998), while their traditional exploitation for forestry, fisheries, and aquaculture production is also well documented. An early account by Watson (1928) and a recent update by Gan (1995) describe the mangroves of Matang in Perak, Malaysia, which have been under management for wood production since the 1900s (mainly for charcoal). Matang is widely regarded as the best-managed mangrove forest ecosystem in the world. Schuster (1952) gives an excellent account of the partial conversion of mangroves in Java to integrated mangrove fishponds, or tambaks, for milkfish culture, with marine shrimps (Penaeidae) and mud crabs (*Scylla* spp.) being the secondary crop. The current tambak management system in Indonesia is described by Sukardjo (2000). While these represent good examples of the sustainable economic use of mangroves in Eastern Asia, it is really only within the past decade or so that all the functions, attributes, and values of mangroves (and other tropical coastal ecosystems) have become widely recognized and understood (e.g., White and Cruz-Trinidad, 1998).

According to the World Mangrove Atlas, 41.5% (75,173 sq. km) of the world's total mangrove area (181,077 sq. km) are found in South and Southeast Asia. Indonesia (42,550 sq. km of mangroves) dominates with 23% of the world resource (Spalding *et al.*, 1997). Mangroves occur throughout the tropical and subtropical regions of the world, but the Indo-Pacific region is clearly their center of diversity, with 63 out of the 90 or so genera of mangrove and associated plants occurring here. Mangrove forests extend into the colder temperate subregion of Eastern Asia as far as southern China (Hainan Island and Fujian Province), Taiwan, and the Ryukyu Islands of Japan (Figure A37). The Ryukyus (26–27°N) are the northern limit for mangroves; here temperatures in winter fall to 17–22°C. At these northern extremes, the mangrove vegetation is much more stunted and limited in species compared to the magnificent mangrove forests of tropical Asia. The drop-off in mangrove species with latitude is shown clearly in China's Fujian Province. In southern Fujian, there are six mangrove species (*Aegiceras corniculatum, Avicennia marina, Acanthus ilicifolius, Bruguiera gymnorhiza, Excoecaria agallocha*, and *Kandelia candel*); this falls to four species in central Fujian and to only one species (*K. candel*) in northern Fujian (Peng and Wei, 1983). Further north along the coastline of China, salt marsh vegetation, especially *Salicornia*, replaces mangrove as the dominant intertidal wetland community.

It is in Southeast Asia where mangroves have achieved their greatest development and diversity, especially along the sheltered shores bordering the shallow seas of the Sunda Shelf within the Malay–Indonesia subregion (Figure A38). This includes the coasts of Peninsular Malaysia and Sumatra adjoining the Melaka (Malacca) Straits, the Gulf of Thailand and the coast of Cambodia, the Mekong Delta of southern Vietnam, the northern coast of Java, and almost the entire coastline of Borneo (see Figure A37). The prolific reproductive capacity of the main forest-forming Asian mangrove species is one reason for their great success throughout Southeast Asia (Figure A39).

Under the more exposed conditions of the Bay of Bengal and South China Sea, it is in the great deltas of the Ganges–Brahmaputra

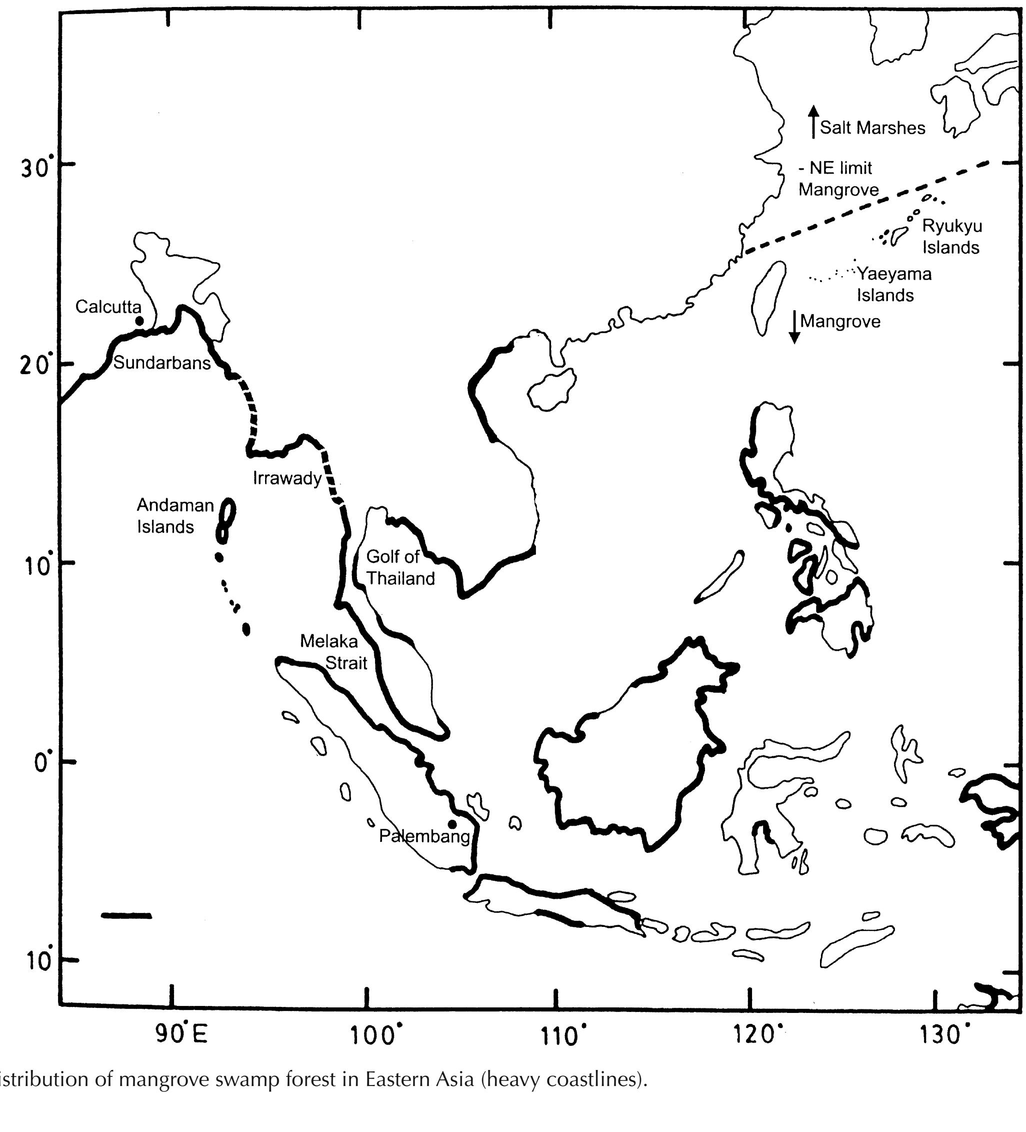

Figure A37 Distribution of mangrove swamp forest in Eastern Asia (heavy coastlines).

(Bangladesh), Irrawaddy (Myanmar), and Red River (northern Vietnam) where mangroves are most extensive and luxuriant. In each case, massive deposition of alluvial sediments from the river systems creates mud banks along the shallow coastal zone that enable mangrove forests to colonize and flourish. At the same time, the presence of mangroves affects the hydrological regime by modifying tidal flows and velocities, influencing sedimentation and erosion patterns, and reducing the impact of waves along the coast (Wolanski and Ridd, 1986; Kjerfve, 1990). Thus, mangrove systems are highly dynamic, both in the short-term and over longer time periods. The longer-term dynamic changes in coastal land formation resulting from these processes are well illustrated historically, especially in the Sunda Shelf subregion. Palembang was a thriving port city when Marco Polo visited Sumatra in 1292, but since then coastal accretion has left Palembang more than 50 km inland (Macnae, 1968).

The rates of “land-building” by mangroves are lower on more exposed coastlines due to less favorable current and/or climatic conditions. Mangroves rapidly colonize the mudbanks formed in the Irrawaddy Delta, but some sediments are carried away eastwards and offshore by coastal currents generated during the monsoons. In the Mekong Delta, there is a net flow of sediments from east to west, and consequently some parts of the eastern shore of the Cam Mau Peninsula are actually eroding, despite the great sediment loads being deposited by the Mekong River system. Moreover, Typhoon Linda, which struck southern Vietnam in November 1997, destroyed the last vestiges of the original mixed forest, as well as damaging many of the older mangrove forest plantations in Ca Mau. As in China, the colder climate in northern Vietnam, coupled with frequent typhoons, limit mangroves in the Red River Delta to low, shrubby vegetation (dominated by *Avicennia* spp. and *K. candel*). In contrast, the mangrove forests of southern Vietnam feature taller trees of *Rhizophora*, *Sonneratia, Brugueira*, and *Ceriops* spp., including large tracts of plantation mangrove consisting of a single commercial species, *Rhizophora apiculata* integrated with canals for aquaculture (Figure A40).

Nipa swamp forest

Along tropical riverbanks, and in low-lying muddy swamplands subjected to greater freshwater inundation, the nipa palm (*Nypa fruticans*) replaces mangrove forest as the characteristic plant community (Figure A41). Nipa palms often intergrade with mangroves in estuarine transition zones near the upper limit of saltwater penetration. Large areas of nipa swamp have been destroyed by land reclamation projects and for shrimp farming, but nipa remains an important wetland community in many Southeast Asian countries, both ecologically and economically. Nipa is still used widely in Southeast Asia as a traditional thatching material for house-building; it can also be processed for sugar and alcohol production (Chan and Salleh, 1987).

Figure A41 A dense stand of the palm *N. fruticans*, at the transition zone from mangroves to freshwater vegetation, Mekong Delta, Vietnam.

Salt marshes and mudflats

Salt marshes replace mangroves in the coastal ecology of the temperate subregions of Eastern Asia, especially along the sheltered western coastline of the Korean Peninsula. The southern portion of the Yellow Sea, including the entire west coast of Korea, is dominated by tidal flats up to 10 km wide, with an operating tidal range of 4–10 m. This forms the Yellow Sea ecoregion that includes an estimated 2,850 km^2 of tidal flats (Kellerman and Koh, 1999). Salt marsh vegetation characterized by *Suaeda japonica* once flourished on the upper part of the shore, but much of this has been lost through land conversion for agriculture.

The tidal flats of the Yellow Sea ecoregion contain muddy, sandy, and mixed sediments; these areas are highly productive, with a rich benthic fauna of polychaetes, bivalve and gastropod mollusks, crustaceans, holothurians, and branchiopods (Koh and Shin, 1988). The tidal flats are an extremely important habitat for migratory wading birds on their passage between Indonesia–Australia and Eastern Siberia–Alaska. Ecologically, the coastal habitats of the Yellow Sea have been likened to those in northern Europe, particularly the Wadden Sea (Kellermann and Koh, 1999).

Salt marsh plants also replace mangroves locally in more arid conditions, even within tropical Southeast Asia. On dry muddy soils above the mangrove zone, or where coastal dikes and embankments have been constructed, the salt-tolerant creeper *Sesuvium portulacastrum* often covers such exposed habitats, its fleshy leaves being capable of retaining water even during prolonged droughts. In Vietnam, where virtually all the mangrove zone has been disturbed by sea dike and shrimp pond construction, several other marginal species colonize the supralittoral zone, including the shrubs *Clerodendron inerme* and *Pluchea indica* and the tree *Thespesia populnea*, which produces a hibiscus-like flower. Such high, arid habitats are hostile to most marine animals, but fiddler crabs (*Uca* spp., Family Ocypodidae) and mangrove sesarmid crabs (Family Grapsidae) burrow deeply into the soil for protection. A few mangrove species, especially *E. agallocha* and *Lumnitzera racemosa* also tolerate the dry, acidic conditions on the slopes of coastal dikes. Local farmers in Vietnam often plant these mangrove trees, along with *Thespesia* and *Casuarina*, to provide shade and wind protection for their houses and farmland. Very poor people also gather *Sesuvium* for use as animal fodder.

Sandy beaches

Eastern Asia includes some of the most magnificent sandy beaches in the world, many of which are still unspoiled, particularly those fringing remote coral islands. The world's longest beach is located on the Arakan coast (now Rhakine) of Myanmar, while the powdery white beaches of Boracay Island (Western Visayas, the Philippines) are regarded by many to be the world's finest. Beautiful sandy beaches also make up 90% of the eastern coastline of Peninsular Malaysia. Not surprisingly, the sandy beaches of Indonesia, Malaysia, Philippines, Thailand, and more recently Vietnam, are promoted strongly as a key attraction to tourists. Particularly renowned are the beaches on many tropical islands such as Bali and Lombok (Indonesia), Penang and the Lankawi Islands (Malaysia), Phuket and Koh Samui (Thailand), Boracay (Philippines), and Phu Quoc (Vietnam).

Beach sediments of volcanic origin occur in parts of Indonesia, such as eastern Java, creating beaches of black or gray sand. Beach ridges and sand dunes are not well developed in the humid tropical regions of Asia, but examples occur in parts of southern Java and southwestern Sumatra; here a natural beach ridge and dune vegetation of *Casuarina, Pandanus, Calophyllum, Inophyllum*, and *Barringtonia* occurs, together with planted or self-established coconut palms. A similar sandy ridge and sand dune formation occurs much more extensively in monsoonal Asia, especially along parts of the coastline of Myanmar and Vietnam. Natural and planted *Casuarina equisetifolia* trees are a feature of the low sand ridges behind the beach slope. In many provinces of Vietnam planted *Casuarina* trees act as a wind break in front of coastal villages, as well as providing a traditional, and renewable, source of wood (Figure A42). The slender form of the branches and leaves of this native conifer enables *Casuarina* to withstand the arid conditions and strong winds associated with sea-facing sandy beaches.

Within the upper intertidal zone on exposed shores with strong surf, the sand is too dry and unstable for most marine animals, but burrows of the ghost crab *Ocypode ceratophthalma* are a common site on the upper beach slope. This large ocypodid crab burrows deeply for protection from the sun and desiccation. Ghost crabs emerge at low tide to scavenge from the sand line, or to chase and capture smaller fiddler crabs (*Uca* spp.) or soldier crabs (*Dotilla* spp.) which occupy the lower, less-exposed intertidal zone. As the fastest running land crustacean, *Ocypode* is particularly well adapted to catch its prey and to escape predators.

Of the seven species of sea turtles found in the world, four species visit sandy beaches in Malaysia to lay their eggs. The beaches of Rantau Abang, in Trengannu on the east coast of Peninsular Malaysia, are one of only four main nesting sites worldwide known for the giant leathery turtle, *Dermochelys coriacea*, and the only nesting site in Eastern Asia. This rare and endangered species is the world's largest living reptile, capable of reaching 2 m in length with a weight of more than 900 kg. It is also the only sea turtle without a hard shell; instead it has a leathery, ridged carapace. Although this unique species has a worldwide distribution, being found even in temperate seas, it only breeds in the tropics. After laying many large parchment-like eggs in a nest dug carefully in the sand at the top of the beach slope, the female turtle returns to the sea. As soon as the eggs hatch the baby turtles struggle out of the sand and crawl down the beach slope to enter the sea. Despite efforts to protect its nesting beaches in Malaysia, the giant leathery turtle has declined significantly over the past 30 years, disturbance to its nesting habitat being one of several critical factors.

The other turtles nesting on Malaysia's beaches are also endangered, having suffered severe decline due to egg harvesting and relentless fishing pressure because of their high value. It is also likely that their feeding habitats have declined significantly. The olive ridley turtle (*Lepidochelys olivacea*) is the world's smallest marine turtle; its diet includes crustaceans, mollusks, and jellyfish. The green turtle (*Chelonia mydas*) has a vegetarian diet of seagrasses and algae, though it may also consume sponges. The beautiful hawksbill turtle (*Eretmochelys imbricata*) also feeds on sponges. The hawksbill and ridley turtles are hunted for their shells, while the green turtle is prized for its meat and oil. The same four species of marine turtle occur in the Philippines (Gomez, 1980), but they have declined greatly in numbers, just as in Malaysia, despite conservation measures including closed seasons for turtle fishing and egg-collecting (Palma, 1993). Sea turtles are particularly difficult to conserve because of their precise habitat requirements, as well as their high

Figure A42 Planted *C. equisetifolia* trees serving to stabilize the upper beach zone and provide a windbreak, Nam Dinh Province, northern Vietnam.

Figure A43 A coral reef flat of hard and soft corals in Singapore; heavy coastal industries can be seen in the distance.

value to poachers. The disturbances to their historical breeding beaches, and the great decline in coral reefs and seagrass beds which provide sea turtles with feeding habitats, place these remarkable marine reptiles at great risk, even if hunting them can be controlled.

Coral reefs

There are almost 100,000 sq. km of coral reefs in Southeast Asia, representing about one-third of the world's total coral resource. Like mangroves, corals show their greatest diversity in Southeast Asia, with 600 of the almost 800 reef-building coral species found in this tropical subregion of Eastern Asia. The center of coral diversity is eastern Indonesia, the Philippines, and the Spratly Islands with over 70 genera of hard coral represented. Indonesia and the Philippines, alone contain 77% of the region's coral reefs due to their multitude of islands featuring the sheltered, clear water conditions corals require. Coral reef fishes, crustaceans, and mollusks also show their greatest diversity in this subregion and up to 3,000 animal species may be present on a single coral reef. A recent identification guide to corals of the world (Veron and Stafford-Smith, 2000) provides an excellent reference to the corals of Eastern Asia. Several new coral species are described and there are probably many more species still to be identified.

Notwithstanding their great beauty, diversity, and ecological importance, the world's coral reefs have suffered a dramatic decline in recent years. About 10% may already have been degraded beyond recovery; a further 30% are likely to decline seriously within the next 20 years. Recently, the World Resources Institute estimated the potential threat to coral reefs using standard criteria to calculate a "reefs at risk" indicator (Bryant *et al.*, 1998). The reefs identified as being at greatest risk are in South and Southeast Asia, East Africa, and the Caribbean. Specifically, over 85% of the reefs of Indonesia and Malaysia, and over 90% of those in Cambodia, Singapore, the Philippines, Taiwan, and Vietnam are threatened (Figure A43).

Seagrass beds

Seagrasses are distributed widely through tropical and subtropical Eastern Asia, mainly as low intertidal to subtidal beds in shallow sandy bays, lagoons, and around near shore islands. They often form an associated wetland community below mangrove-fringed shores with sandy sediments, or occur interspersed with coral reefs. Like corals, seagrasses do not tolerate the muddy or turbid habitat conditions typical of estuaries and mudflats. In Vietnam, for example, where more than 5,000 ha of seagrass beds containing 15 species have been identified, the main sites for seagrasses are north of the Red River Delta in Quang Ninh Province, in the central region of Vietnam (Hue and Khanh Hoa-Nha Trang) where there are many magnificent sandy bays and lagoons, and around the southern island of Phu Quoc (Vietnam Environmental Monitor, 2002). Seagrass beds in Vietnam have become heavily degraded due to excessive harvesting for animal food and organic fertilizer, as well as destructive fishing practices (use of dynamite and cyanide) in seagrass and coral habitats.

Coastal reclamation projects have also caused widespread loss of Eastern Asia's seagrass beds and coral reefs, but there is also growing evidence of decline due to natural causes, including coral bleaching associated with warming of the seas and "wasting disease" in seagrasses. Haynes *et al.* (1998) concluded that most seagrass losses, both natural and anthropogenic, stem from reduced light intensity due to sedimentation and/or epiphytic development caused by water nutrient enhancement.

Coastal development activities commonly increase sediment loading in the surrounding waters, causing great harm to seagrass beds and coral reefs. One well-documented example is Hong Kong's Chep Lap Kok Airport (Lee, 1997). Increased sediment levels caused by the airport's construction virtually wiped out the nearby beds of *Zostera japonica* and *Halophilia ovata*. While *Halophilia* has recovered well following the construction period, the *Zostera* beds have almost completely disappeared, although some transplanted patches have survived and enlarged. This difference between seagrass species may be explained by the observation that *Zostera* is mainly subtidal and intolerant of shading, whereas *Halophilia* also occurs in the lower intertidal zone and can survive in relatively low light intensity.

Seagrass beds play various ecological roles, including sediment adsorption and nutrient absorption from seawater; this may serve an important protection function for adjacent coral reefs, since corals are even more sensitive to sediment and nutrient loading. Seagrasses also provide important nursery habitats for many fish species, including groupers fingerlings, for example, which are heavily collected throughout Southeast Asia for aquaculture. Seagrass beds are also critical feeding areas for the green turtle (*C. mydas*) and the rare sea mammal, the dugong (*Dugong dugun*), which feeds almost exclusively and selectively on various seagrasses, especially *Halodule* and *Halophilia*. Dugongs may choose these particular grasses in preference to other genera (*Thalassia* and *Enhalus*) because they are easily digested (*Halophilia*) and rich in available nitrogen (*Halodule*). Dugongs are capable of digesting a large volume (8–15% of body weight per day) of low quality plant material (Reynolds and Odell, 1991), an observation that explains why the great loss of seagrass beds in Eastern Asia has been so damaging to the survival prospects for this unique mammal. It has also been reported that grazing by dugongs and turtles plays an ecological role in seagrass communities by stimulating the growth of new leaves, thereby changing the structure and nutritional status of the seagrass bed (Aragones and Marsh, 2000).

Exploitation of coastal resources

Human pressure

Eastern Asia is a region where the great natural diversity of coastal topography, biological communities, and species has been transformed in many countries by immense human population and development pressures. Although human occupation and economic use of the coastal zone have a long tradition in the region, dating back centuries in the case of coastal farming and aquaculture, the pace of coastal development has accelerated since the 1980s, raising the need for habitat conservation and integrated coastal zone management as never before.

The effects of high population growth in the coastal zone, unsustainable exploitation of coastal resources, and conversion of coastal habitat for agriculture, aquaculture, and urban and industrial development, have now reached crisis levels. In reviewing the threatened status of wetlands in Asia in 1989, Wetlands International (an international NGO) noted that Southern and Eastern Asia (including the Indian subcontinent) had an average population density about eight times that of the rest of the world and was increasing at a rate of 55 million people annually. This led Wetlands International to conclude that, "Most of the threats to wetlands in Asia are a direct consequence of the need to feed and house this massive and ever-increasing number of human beings." Unfortunately, this is a very accurate assessment of the problems facing Eastern Asia's coastal ecosystems in general.

Table A4 Estimated loss of the original mangrove forest area in different countries (based on data from World Resources Institute, 1996)

Country	Loss of mangrove forest (% loss by area)
Bangladesh	73
Brunei	17
Indonesia	45
Malaysia	32
Myanmar	58
Singapore	76
Thailand	87
Vietnam	62
Unweighted average for Asia	61

A good historical example is the Chakaria Sundarbans region of Bangladesh. Located on the eastern border of the Bay of Bengal, this is the eastern limit of the great Sunderbans mangrove forest shared between Bangladesh and India and the largest mangrove ecosystem in the world. One hundred years ago the Sundarbans was reserved forest, but over the next several decades the mangroves were exploited for wood and fishery products and then encroachment followed for human settlement and salt production. Mangrove conversion accelerated greatly during the 1980s due to the development of coastal shrimp farming, until by 2001 all the remaining mangrove had been converted to shrimp ponds and human settlements (Hossain and Kwei-Lin, 2001). Even by the 1980s, the Chakaria Sundarbans were considered too degraded to merit any special conservation efforts.

There has been a similar history of mangrove exploitation in Vietnam, where now less than 30% of the original mangrove area remains and virtually no pristine forest has survived. Only 60 years ago, mangroves in Vietnam covered an area of up to 400,000 ha (Maraund, 1943 cited by Hong and San, 1993), of which about 250,000 ha flourished in the Mekong Delta. The greatest concentration of mangrove (150,000 ha) was in the Minh Hai Peninsula at the southern tip of Vietnam (now divided into Ca Mau and Bac Lieu provinces). The most recent estimate for the total area of mangrove forest remaining in Vietnam is only 110,000 ha (Vietnam Environmental Monitor, 2002). Overall, the Eastern Asia region has lost more than 60% of its mangrove forest in just a few decades (Table A4).

It is not just Eastern Asia's fragile tropical mangrove forests, seagrass beds, and coral reefs that have become severely depleted or degraded. Approximately 600 million people live in the area around the Yellow Sea, including major cities such as Shanghai, Seoul-Inchon, and Pyongyang-Nampo. The Yellow Sea is among the most heavily exploited coastal and marine areas of the world, with more than 100 species of fish, crustaceans, and cephalopods captured by its fisheries. Today, coastal habitats and fishery resources in the Yellow Sea are threatened by both land-based and sea-based infrastructures, by pollution, and by overfishing and other forms of unsustainable resource exploitation. More than 100 million tonnes of domestic sewage and about 530 million tonnes of industrial wastewater are discharged annually into the nearshore areas of the Yellow Sea. These discharges come from large coastal cities, shipping, and oil exploration; they contain

Figure A44 Recreational use of a sandy beach in Johore, Pensinsular Malaysia, with dense surrounding urban infrastructure—a scene typical of many beaches near large cities throughout Eastern Asia.

many pollutants, including heavy metals (cadmium, lead, mercury), oil residues, and nitrogenous compounds.

Other economic uses of the coastal zone in Eastern Asia tend to reflect the stage of development of the countries concerned. Like Bangladesh and Vietnam, the more developed South-east Asian countries of Indonesia, Malaysia, Philippines, and Thailand have heavily exploited sheltered bays, lagoons, estuaries, and other mangrove and mud flat areas for coastal agriculture and aquaculture. There has also been localized industrial and urban development, as well as heavy investment in tourist infrastructure centered on islands and mainland sandy beach sites near major cities; for example, Pattaya and Hua Hin in Thailand, Port Dickson and Johore in Peninsular Malaysia (Figure A44). Estimates for Thailand made by the Royal Thai Forestry Department in 1993 revealed that, of the original 372,448 ha of mangrove forest (measured in 1961), 133,812 ha (35.9%) had been converted into salt pans, mining, agriculture, and infrastructure, 64,991 ha (17.5%) was occupied by coastal shrimp farms, and 4,961 ha (1.35%) had been converted to other uses (leaving only 45% undeveloped).

In the most populated and developed parts of Asia, especially Hong Kong, Singapore, and parts of Peninsular Malaysia, China, and Korea, coastal land is at such a premium that urban and industrial development (e.g., airports, container ports, oil-refineries) have almost completely replaced earlier natural resources use. Such economic developments have overtaken the coastal zone in a remarkably short period of time. Only 50 years ago Schuster (1952) noted "The greater part of down town Singapore is built on *Rhizophora* piles driven into the mud of the harbor region." Today only carefully conserved vestiges of the original coastal habitat remain in Singapore (e.g., Figure A43).

Coastal aquaculture

Of the many human uses of the coastal zone, aquaculture stands out not only in terms of its scale and importance throughout the Eastern Asia region, but also because of its interaction with the ecology of the coastal environment (e.g., Primavera, 1993). Unlike the conversion of coastal habitat to agriculture or urban and industrial uses, the production of human food by aquaculture is still critically dependent on the carrying capacity of the surrounding aquatic ecosystem. Where coastal aquaculture causes environmental degradation, there is a rapid negative feedback on the viability of the aquaculture production system itself, as the experiences with intensive shrimp farming in Eastern Asia show only too well (e.g., Smith, 1999). The term "self-pollution" is sometimes used to describe this problem in coastal aquaculture (Phillips and Macintosh, 1997).

Shrimp farming

Shrimp farming has had a dramatic impact on the coastal ecology of Eastern Asia over the past 20 years or so. Although coastal aquaculture has a long history of operation in Southeast Asia (Schuster, 1952; Macintosh, 1982), it was the commercialization of technology for breeding one particular species, *Penaeus monodon*, or the black tiger shrimp in Taiwan, which enabled shrimp seed (post-larvae) to be produced, then reared intensively in coastal shrimp farms. The world demand for farmed shrimp also rose significantly in the 1980s, led at that time by Japan, because the yields from shrimp capture fisheries had long since reached a ceiling level. From early pioneering research on the breeding of *Marsupenaeus japonicus* in Japan, research then developed in China involving the local species *Fenneropenaeus chinensis* and in Taiwan with *P. monodon*. Cool climatic conditions and high costs had mitigated against shrimp farming in Japan involving the local species *M. japonicus*, but the black tiger shrimp was readily accepted by the Japanese market and Taiwanese shrimp producers rapidly spread their knowledge to other parts of tropical Asia where conditions for farming *P. monodon* were much better. During the 1980s, investors in Thailand, Philippines, Indonesia, and Malaysia rushed to adopt the new technology, converting mangrove forests, traditional shrimp ponds, salt pans, coastal rice fields, and (in the Philippines) sugar plantations, into intensive shrimp farms. From Southeast Asia, "shrimp fever" as it became known (Primavera, 1993) spread to Vietnam and Bangladesh, countries with huge areas of coastal mangroves and mudflats considered more suitable for conversion to extensive, low-cost, shrimp ponds. Since 1995, records show that on average 138 million shrimp juveniles, or "seed" (mainly of *P. monodon* and *Macrobrachium rosenbergii*) have been collected annually from the Sundarbans reserve forest in Bangladesh to support coastal shrimp farming. Shrimp seed collecting is extremely destructive as many other species of fish and crustacean seed are caught and discarded by the shrimp fishers, but it is a form of livelihood for the great majority of families living in the Bangladesh Sundarbans and involve an estimated 225,000 shrimp seed collectors (Rouf and Jensen, 2001).

Shrimp farming was also promoted on a massive scale in China, with shrimp farms occupying 160,000 ha from Hainan Island in the south to Liaoning Province in the northern temperate zone. Production reached a peak of 200,000 tonnes in 1992 before coastal water pollution and

Figure A45 Intense use of the coastal zone for aquaculture; the photograph shows ponds and a complex of water pipes supporting fish and shellfish farming during the aquaculture boom in southern Taiwan in the 1990s.

shrimp diseases had a devastating impact on output (Smith, 1999). Shrimp farming has also developed in Korea, but as with its neighbors China and Taiwan, aquaculture has been badly affected by coastal industrialization and associated problems of water pollution (including self-pollution) and shrimp disease outbreaks (Figure A45). The shrimp farms in Korea are confined almost entirely to the west coast where it is more sheltered. The majority of farms are located within the intertidal zone or near to the coastline. Reflecting the colder operating conditions in Korea compared to Southeast Asia, the main species cultured are the local shrimp *F. chinensis* followed by *M. japonicus*. Annual production levels are rather low (less than 1 tonne/ha), but the environmental limitations on shrimp production in Korea are offset by the high price farmers can obtain for live shrimp delivered to the restaurant trade, including live sales to Japan.

Figure A46 A large mud crab (*Scylla paramamosain*) for sale in a local market in Vietnam. Mud crabs support important artisanal fisheries and coastal aquaculture production throughout Eastern Asia.

Mud crab culture

Poor coastal communities from Bangladesh to the Philippines are still heavily dependent on mangrove-based fisheries and aquaculture to support their livelihoods (Figure A46). This includes crab fishing for *Portunus* (blue swimming crab) and *Scylla* (mud crab), as well as shrimp fisheries and shrimp culture. Mud crab culture has also developed rapidly as a secondary activity to shrimp farming within the mangrove forest ecosystem. It carries much lower investment costs and risks than shrimp farming and is therefore more suitable for poor families (Overton and Macintosh, 1997). In the Lower Mekong Delta of Vietnam, farmers can now rear from 500 to 800 kg of mud crab per hectare in a simple mangrove pond (unpublished data). With a farm gate value of about USD3/kg, even a small crab pond can provide a poor Vietnamese family with an annual net income of USD200–300. This is a significant contribution to the economy of families living in remote coastal areas where the potential daily income from fishing, salt production, or agricultural laboring is only USD1–2.

Other forms of coastal aquaculture

Many other types of aquaculture are also economically and ecologically important in the coastal zone of Eastern Asia. Economically, caged fish culture for valuable species such as groupers (*Epinephelus* spp.) and snappers (*Lutjanus* spp.) appears to be very attractive, but it carries many risks, especially from fish diseases and can be highly polluting due to the use of trash fish as the main type of feed. The environmental damage stemming from large-scale collection of wild fingerlings (especially groupers) from coral reef and seagrass habitats to support aquaculture is another great cause of concern. For large-scale aquaculture

Figure A47 The ark shell, or "blood cockle" (genus *Anadara*), one of the many bivalve mollusks found abundantly on coastal mudflats throughout Eastern Asia and important in aquaculture, especially in Malaysia and China.

Figure A48 Tourists, long-tailed macaques, and mangrove forest in the Can Gio Biosphere Reserve, near Ho Chi Minh City, Vietnam. The reserve has conservation, sustainable development, education, and research functions.

production, and in terms of their ecological impacts, the culture of bivalve mollusks and seaweeds has many advantages over most fish and crustacean species. Mollusks and large seaweeds are cultured in huge quantities by both China and the Republic of Korea. For example, marine aquaculture production in China reached 10.6 million tonnes in 2000, with 93% of this total contributed by bivalve mollusks and seaweeds. The main species of mollusks include oysters (*Crassostrea*), mussels (*Mytilus*), hard clams (*Meretrix meretrix*), short-necked clams (*Mactra* spp.), scallops (*Clamys farreri*), and ark shells of the genus *Anadara* (Figure. A47). Gastropod mollusks of the genus *Haliotis*, better known as abalone, are more difficult to rear, but are in high demand as a delicacy. These snail-like animals occur naturally on subtidal rocks (especially in Korean waters) where they graze on algae. However, overfishing has decimated abalone populations because they are so valuable and easy for divers to harvest.

Seaweeds grow naturally on rocks in the lower intertidal and subtidal zones, especially in the warmer southerly regions of the Yellow Sea. The seaweed *Pelvetia siliquosa* occurs widely in the Shandong and Liadong regions of China, as well as around the Korean Peninsula. It grows most luxuriantly in Korean waters where it has been harvested for hundreds of years and exported to China. *Sargassum pallidum*, another edible seaweed, dominates in the west Yellow Sea, and *Plocamium telfairiae* is also common there. A cold water seaweed, the kelp *Laminaria japonica*, has become the most important seaweed cultured in China. Introduced from Japan, kelp farming now occupies more than 3,000 ha of China's coastal waters (yielding 10,000 tonnes dry weight/year) and is supported by hatcheries producing young plants for transfer to growing frames in the sea once the water temperature drops below 20°C.

Coastal habitat conservation and restoration

Given the already very high human population pressure in many Asian countries, it is difficult to be optimistic about the future for coastal habitats and the communities of plants and animals they support. Coral reefs and seagrass beds are particularly sensitive to destructive fishing methods, pollution, and any increased sedimentation caused by coastal construction or other development activities. Even mangrove forests, which are more robust and relatively easy to manage on a sustainable basis by tree replanting, have disappeared at an alarming rate (Table A4).

There are some positive indications that coastal protected areas (e.g., biosphere reserves, nature parks, and sanctuaries) can preserve habitat and protect species biodiversity. In addition, protected areas can play a valuable role in raising public awareness of the need for such conservation efforts (Figure A48). Habitat restoration, especially of mangroves, is also being supported very actively in several Asian countries. Thousands of hectares of mangrove have already been planted successfully in Bangladesh and in the Red River Delta and Mekong Delta of Vietnam in order to protect the coastal zone from storms, flooding, and erosion, and to accelerate the reclamation of land from the sea. Mangrove planting also leads to a higher diversity of animals and birds, and to improved fisheries production. However, the full ecological impact of mangrove reforestation need careful assessment, both in terms of the plant and animal communities that develop in mangrove plantations and the physical changes that take place in the ecosystem (Macintosh *et al.*, 2002).

In contrast to mangroves, it is very difficult to restore coral reefs and seagrass beds and most efforts to date have been only experimental in scale, involving, for example, the transplanting of healthy coral fragments or individual coral heads onto a degraded reef (e.g., Clark and Edwards, 1995; Rinkevich, 2000). For corals and seagrasses, strict conservation of the coastal habitats supporting these delicate plant and animal communities, including protection from pollution, should be the first priority. This is not simply a plea to protect these diverse coastal communities for biological interest; there are sound economic reasons for doing so. White and Cruz-Trinidad (1998), for example, estimated that the sustainable annual benefit from 1 ha of coral reef in the Philippines is in the range USD31,900 to USD113,000, including its fisheries, tourism, coastal protection, and biodiversity values. This suggests that, conservatively, coral reefs are contributing almost USD1 billion annually to the Philippines' economy, but equally such huge economic benefits will be lost if coral habitat continues to be destroyed.

ASIA, EASTERN, COASTAL GEOMORPHOLOGY

The shores of eastern Asia, extending from Thailand and Indonesia to eastern Siberia and including the Philippines, Taiwan, and Japan, largely follow the tectonically active zones along the eastern and northern sides of the Eurasian plate (Inman and Nordstrom, 1971). Large stretches of coastal area along Indonesia, the Philippines, Taiwan, Sakhalin, Kamchatka, and the East Asian island chains are therefore tectonically unstable. In these areas the structural trends are generally parallel to the coast, which was distinguished by Suess (1892) as the Pacific type. Outside these areas, away from the tectonically active collision zones, the coastal regions are generally more stable and the structural trends are usually not parallel to the coast, which corresponds to Suess' Atlantic type. This type is present along most of the Asian mainland from Thailand to Siberia.

Comparatively straight coasts, situated along mountain chains, sometimes with river deltas and local alluvial foreland, are found mainly in western Sumatra, southern Java, northern Vietnam, and the Pacific coast of Siberia. A drowned older topography with an irregular coastline is present along parts of southern Vietnam, the mainland coast north of the Red River, on the islands of eastern Indonesia, on northern Kalimantan (Borneo), the Philippines, the Shandong Peninsula in China, Japan, southern Sakhalin, and the eastern end of Siberia. These coasts are usually somewhat altered by the sea, with bays containing beaches, spits, and barriers, sometimes being filled up with sediment and partially surrounded by alluvial foreland. The main exceptions are the large river deltas, the west coast of Kamchatka that consists largely of sand barriers, some beach barriers in Japan and on Sakhalin, and some areas like eastern Taiwan where tectonic uplift matches the Holocene sea-level rise. Elsewhere the coast is predominantly depositional, consisting of beaches, spits, barriers, tombolos, mudflats, marshes, mangrove swamps, and coral reefs.

The general direction of beaches, spits, and barriers is related to the direction of the swell. Between northern Japan and Indonesia the swell comes chiefly from northern directions, and the beaches and spits face largely E–NE. Where the swell is southerly, as in the Indian Ocean and in the Pacific north of 45°N, the beaches face mainly SE–SW. A major distinction can be made between the coasts north and south of about 40°N (Davies, 1973). North of this latitude storm waves are predominant and pebbles form an important part of the beach material. During the winter, sea ice (pack-ice) borders the coast as far south as Vladivostok and northern Japan. Further north, along the northern shore of the Sea of Okhotsk and north of the Kamchatka peninsula, permafrost reaches the sea, and from the eastern Siberian coast ice cliffs have been reported. South of 40°N the ocean swell is more important, and large areas from southern Japan to Malaysia are affected by tropical storms. In this area, especially south of 25°N, sandy beaches are predominant while pebbles are relatively unimportant as beach material.

Coral reefs and beach rock are confined to the tropical and subtropical zones—they are not present north of 35°N. Mangrove grows south of 31°N (on the Asian mainland coast south of 26°N) and dominates large stretches of coast in Indonesia, Malaysia, and Thailand, especially in areas that are sheltered from the ocean swell. An important part of the East Asian coastline consists of several large river deltas (those of the Mekong, Yang-tse-Kiang or Chang Jiang, and the Hoang-Ho or Yellow river) and a large number of smaller deltas often of still appreciable dimensions such as the deltas of the Chao Phraya, the Red River, and the Si Kiang. This preponderance of deltas is due to the high mechanical erosion on the mainland between Thailand and Korea (>60 ton per km^2 per year), which, associated with the presence of large and numerous rivers, has resulted in extensive deltaic and estuarine deposition.

Tidal effects are especially important along the mainland coast from Taiwan to Kamchatka, where the tides have an appreciable range. Usually the tidal range in eastern Asia is less than 4 m (and around Japan mostly less than 2 m) but in the northern Sea of Okhotsk, in the Yellow Sea, and along the Chinese coast it reaches more than 6 m. Tidal marshes have been formed locally, as, for example, along the Gulf of Bohai, in southern Korea, and in Hangzhou Bay.

A striking feature on many coasts from Japan through southeast Asia to Indonesia is the evidence of raised coastlines at 0.5–1 m, about 2 m, and 5–6 m above present sea level. These are indicated by flat, sandy terraces, beach ridges, coral reefs, mollusks and/or barnacles, notches, benches, platforms, and beachrock. Similar raised coastlines are known from many other coasts in Asia, Africa, South America, and Australia (for references, see Tjia, 1975, and Clark *et al*., 1978). Daly (1934) and many others therefore assumed that during the Holocene, about 6,000–4,000 years ago, sea level stood about 5 m higher than at present. Others have contended that these features are related to temporary high water during storms, or to local uplift. Tjia (1975) has suggested that glacioeustatic uplift of the areas in the Northern Hemisphere that were glaciated during the Pleistocene, may account for the absence of any indications for high sea levels during the Holocene. C14 dates of raised reefs and mollusk shells from the Pacific and Indian Ocean, Southeast Asia, and Australia point to a slight Holocene transgression as well as to local uplift. Clark *et al*. (1978) indicate that regional differences in the Holocene sea-level rise are related to differences in crustal rebound after the Pleistocene through ice cap melting and the increasing water load of the oceans.

The general features of the east Asian coasts are summarized in Figure A49, which is based essentially on the world map given in Valentin (1952), but with emphasis on the coastline characteristics. More detailed knowledge, however, is still lacking for large stretches of coast, especially in eastern Siberia and Southeast Asia.

Siberia

The Siberian coast east of the Taymir Peninsula is flat up to the Kolyma River estuary and shows a drowned topography with only a higher coast at the Laptev Straits, where bedrock is exposed. The flat coast is locally raised a few meters and here small cliffs are formed by intensive thermal abrasion. This is caused by the regular melting of ice and frozen deposits (permafrost) along the cliffs and removal by waves of the loose sediment. The coastal flats are flooded over large distances (up to 30 km) during wind-induced surges. During offshore winds the muddy nearshore seafloor can be exposed over similar distances. Several large rivers reach the sea in this area such as the Lena, Indigirka, and Kolyma rivers, but only the Lena has a vast delta, which is largely a relict feature. The other rivers have long, partly filled-in estuaries and insignificant deltas. The islands off the coast (the New Siberian Islands and Wrangel Island) have a bedrock nucleus surrounded by loose but frozen sedimentary deposits. Thermal erosion is large and can annually remove up to 50 m from the cliffs.

East of the Kolyma River mouth the coast is partially rock, where the mountain ranges between Kolyma and the Bering Strait come near to the sea. There is usually a narrow coastal plain, several kilometers wide, and at Cape Billing a sand barrier extends for about 50 km into the sea with an up to 10 km wide lagoon on the landward side. Transverse sandbars divide the lagoon into several rounded lakes; their formation is related to the development of wind-induced circulation cells in the lagoon. The sand barrier has been formed in an area that is protected against pack-ice (probably by Wrangel Island). In general, longshore sediment drift is limited by the short period that the coast is free of ice. The sediment is mainly derived from reworked glacial deposits. The easternmost part of Siberian coast along the Bering Strait is characterized by high cliffs and fjords where the Chukhotsk range meets the coast (Zenkovich, 1985).

The Pacific coast of Siberia down to Korea extends from the arctic into the temperate zone and has complex tectonics with stable areas alternating with areas of emergence and subsidence. The coastal area is usually mountainous with rather short rivers (except the large Amur River) and narrow coastal plains. Waves and tides are variable: storm waves are up to 12 m in the Bering Strait and in the Sea of Okhotsk, while lower waves (normally up to 2–3 m, and up to 7 m during the winter) dominate in the other areas. Most of the coast is mesotidal, but locally, as in Penzinskaya Bay, becomes macrotidal (up to 12 m). There is a relatively large sediment supply to the coast, because of a wet, cold, or temperate climate in combination with easily weathered rock, such as volcanic deposits and Pleistocene fluvioglacial sediments. Barriers, coastal lagoons, and tombolos are common features, separated by promontories of rock or (unconsolidated) sediment (Kaplin, 1985). The largely drowned topography has for a large part been filled in during the postglacial period. Along Sikhote Alin the coast is relatively straight and uninterrupted because of a low mountain range that lies parallel to the coast.

Japan, Sakhalin

The shores of Sakhalin and Japan consist of large stretches of ria coast, alternating with many small and several large stretches of beaches, spits, barriers, sand dunes, lagoons, and river outlets. Especially on northern Sakhalin, but also on Hokkaido and along Honshu, large parts of the coast are depositional alternating with rocky promontories. Locally, volcanism close to the coast has resulted in cliffs and beaches of volcanic material. Most of the coastal lowland in Japan is intensively used so that a large proportion of the coast is man-made: less than 50% has remained natural. Coastal terraces are widely distributed in northern Japan; in the south they occur mainly on the promontories along the Pacific coast. The terraces are predominantly present on the more easily abraded Tertiary and Quaternary formations, whereas the indented ria coasts have been developed mainly in folded Palaeozoic and Mesozoic rock. The highest terraces have been found in southwestern Hokkaido at +585 m, but usually they reach to +150 m (Kosugi, 1971). Below present sea level submerged flat surfaces have been found to depths of −150 and −190 m.

The terraces as well as raised coral reefs (Yabe and Sugiyama, 1935) indicate that the Quaternary eustatic changes in sea level may have had an important effect on coastal development in Japan, but there is also much evidence for differential uplift, tilting, and local subsidence. Consequently, in an appreciable number of papers by Japanese authors the combined effects of both eustatic sea-level changes and crustal movements have been discussed (Richards and Fairbridge, 1965; Yoshikawa *et al*., 1965; Richards, 1970). The presence of ria coasts is generally seen as evidence of an overall subsidence since the Pleistocene, but narrow terraces scattered along the rias suggest a more recent emergence. Some terraces (at +40–+60 m) are widely distributed along the Japanese coast and are seen as the result of eustatic sea-level changes. Coastal terraces, formed at the same sea level, have also been found at different altitudes within short distances, even locally disappearing below present sea level, as a result of crustal movements. From this complex situation it has been deduced that the Holocene sea-level rise started around 18,000 BP and that between 6,000 and 3,000 BP sea level was 3–5 m higher than at present, which is indicated by former wave-cut notches, sea caves, benches, small terraces, marine deposits, and neolithic remains (Tada *et al*., 1952). Clark *et al*. (1978) have shown that these features can also be explained by crustal rebound after the Pleistocene and the increasing water load of the ocean.

A marked feature along the Japanese and Sakhalin coasts is the widespread occurrence of shore platforms (Takahashi, 1974). These are most

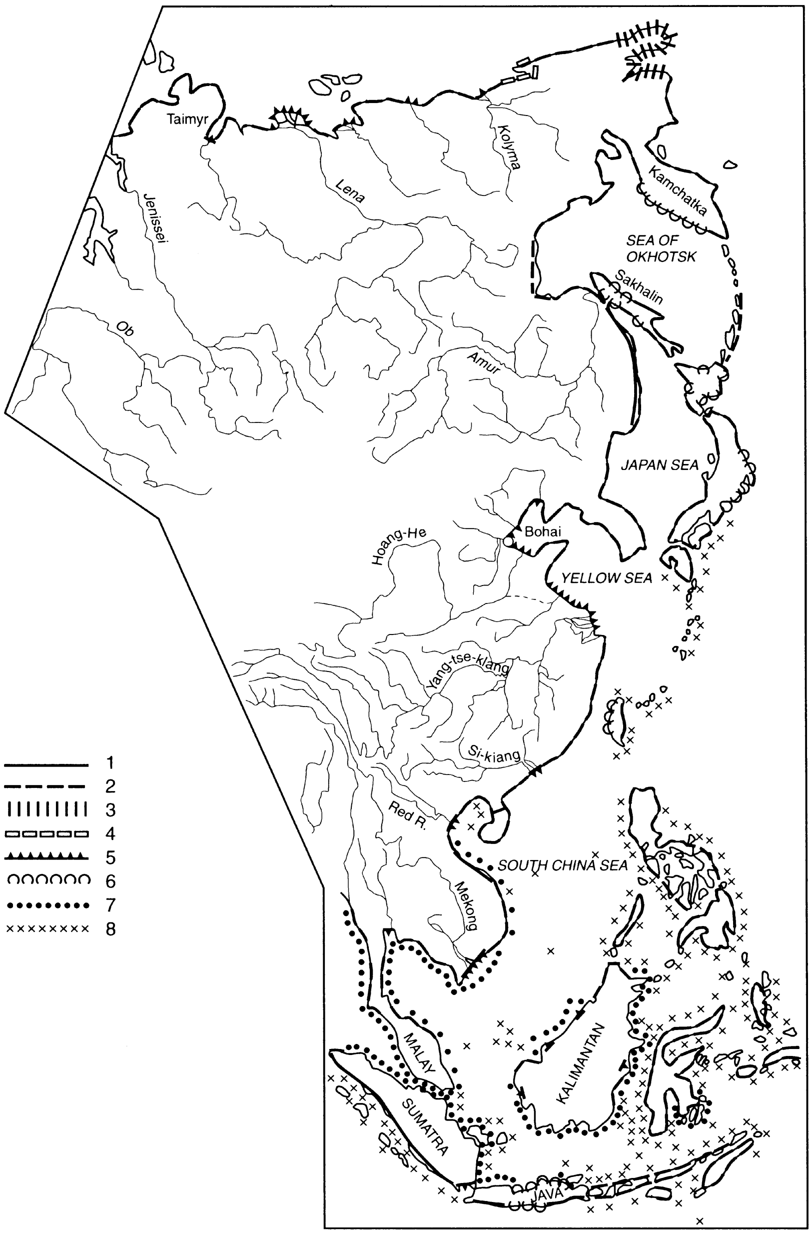

Figure A49 Coastal morphology of eastern Asia. (1) Comparatively straight coasts along mountain chains, sometimes with river deltas and local alluvial foreland; (2) Drowned older topography with an irregular coastline, somewhat altered by the sea; (3) Fjords; (4) Tableland coast Table and coast with cliffs; (5) Large river deltas; (6) Predominantly spits, barriers, mud flats, marshes; (7) Mangrove swamp; (8) Coral reefs.

conspicuous along the coasts of the Pacific and the East China Sea, less on the Sea of Japan coasts, and least along the Seto Inland Sea. Their maximum width varies from 530 m along the Pacific to 80 m on the Sea of Japan coasts, which roughly corresponds to the wave conditions on each coast. The average width is 30–80 m and the maximum length about 4 km; they occur on all types of rock, but tend to be wider on Neogene mudstones, sandstone, and tuff-breccia.

The East Asia mainland, Korea to Malaya

The mainland coast from Korea to the Malayan Peninsula is largely a drowned or ria-type coast, with abrasion at the headlands, accumulation (with sandy beaches, spits, and beach/ ridges) in the bays and, especially in China and southern Korea, numerous islands. Large estuaries and river deltas are present where major rivers reach the coast. In West and South Korea tidal flats have been formed in the bays and in the shallower parts between the islands (Guilcher, 1976), which have been partly reclaimed. Coastal terraces are present along the East Korea coast up to 100–150 m and along the West Korea coast up to 30–60 m, which reflects the emergence of the east coast and the submergence of the west coast. Also from the area around Hong Kong (Williams, 1971) coastal terraces and old beaches have been reported: they occur at +5 and +14 m (Berry, 1961) and are probably also present elsewhere. At higher levels, up to +70 m, benches are found, below present sea level flat surfaces can be distinguished down to −60 m. Especially the terraces at +5 and +14 m are thought to be caused by eustatic sea-level changes. Flat surfaces at +130 and +230 m are probably not of marine origin.

Around the Gulf of Bohai, between the Liaodong and Shandong peninsulas, the coast has been filled with recent alluvium from the Huang He (Yellow River), Luan He, Liao, and a number of smaller rivers. Long stretches of tidal marshland have been formed. Along the northwestern shore, however, up to 80 km of alluvial deposits were eroded again in historical times (von Wismann, 1940), probably because the Huang He then had a southerly course and no new sediment from that river reached the Gulf of Bohai at that time. The present situation dates from 1853, when the Huang He again took a northerly course.

Between 1448 and 1853 it had been reaching the sea south of the Shandong Peninsula after having joined the Huai He River. While at present the silt from the Huang He moves northward anticlockwise through the Gulf of Bohai, the silt flowing out of the southern mouth before 1853 was transported further south as far as the Yang-tse (Chang Jiang) River mouth, which was deflected southward. In 400 years the coastline in this area moved 36–62 km eastward.

South of the Yang-tse-Kiang (Chang Jiang) a ria coast ends at the delta of the Si-Kiang, while further south the coast is interrupted by the deltas of the Red River, the Mekong, the Chao Phraya, and other smaller rivers. Tidal flats of variable widths have been formed along Hangzhou Bay, Wenzhou Bay, and numerous smaller bays and estuaries. Salt-marshes along the upper parts of the flats have mostly been reclaimed. South of Hong Kong mangrove swamps are present and fringing coral reefs become increasingly numerous; in particular around the Gulf of Thailand extensive coastal barriers and sandy beaches have been formed. From Dong Hoi to Cape Varella in Vietnam the coast is formed by a 15–40 km wide belt of barrier complexes, lagoons, and sand dunes; from Cape Varella to Cape Padaran the coast is again a typical ria coast. Terraces have been found in Vietnam and Cambodia between +2 and +80 m (Carbonnel, 1964; Saurin, 1965). The terrace at +2 m and raised reefs, mollusks (oysters), and conglomerates at the same level have been found all along the coasts of Vietnam and Cambodia. Other terraces occur more regionally; the +4 m terrace only in Vietnam, the +15 and +25 m terraces in southern Vietnam and Cambodia, and the terrace at +80 m only near Cape Padaran.

Taiwan, Philippines

Compared to the mainland coast, Taiwan is very different. Situated in the tectonically active zone it has been slowly uplifted during the Quaternary. This uplifting continues at present, although there is some evidence for regional temporary subsidence. Eustatic sea-level changes are considered to have had little effect on the coast, since the changes in sea level have been more than balanced by the amount of uplift (Hsu, 1962). On the Pacific side, the coast is steep and erosion predominates (as also on the southwestern and northern coasts), but on the west coast, which is sheltered from the ocean swell and the tropical storms as well as from the strong northeastern monsoon, a flat, marshy coast is formed with tidal flats. Coral reefs are present on the Pacific side as well as round the Ryukyu Islands further north and along the Pacific coasts of Kyushu and Shikoku.

The Philippine coasts, situated like those of eastern Taiwan in the tectonically active zone, are comparatively steep but intersected by river outlets, broad valleys, and inlets with beaches, surrounded by coral reefs. Although the area has been drowned during the Holocene transgression, the islands have been rising during the Pleistocene and Holocene and there is evidence of differential uplift. Numerous and often extensive marine terraces are present; on Sabtan Island and on Luzon the highest are at +180 m, on Bataan at +275 m, and in northern Mindanao at +360 m (van Bemmelen, 1970), but no correlations have been made.

Malay Peninsula

The Malay Peninsula, together with the eastern part of Sumatra, western and central Kalimantan (Borneo), and the Sunda-Java Sea, belongs to the Sunda landmass, which has probably been tectonically stable since the middle Pleistocene. The presence of beach ridges several meters above present sea level has been interpreted as being the result of recent uplift, but can also be explained by crustal rebound after the Pleistocene and the increasing water load of the oceans (Clark *et al.*, 1978).

The east coast of Malaya is relatively smooth with shallow bays and few indentations. More than 80% of this coast is formed by sandy beaches interrupted by river outlets and small deltas; cliffs form about 10% of the coast (Nossin, 1965; Swan, 1968). Tidal swamps with mangrove are usually found landward of the beaches and sandbars. They are sheltered against the swell of the strong monsoon that comes from the northeast between October and April. During this period there is more erosion than accretion, especially between late October and January, when spring tides are at their highest. Accretion is widespread between February and September, when the tides are less effective and the wind blows mainly offshore. A minor period of erosion occurs from May to July when the spring tides reach secondary maxima.

The west coast of Malaya is for a large part covered with mangrove, which continues northward to the Irrawaddy delta and from there to the mouths of the Ganges. Locally, this mangrove belt is interrupted by cliffs, river outlets, and beaches. The islands around Singapore have been studied in detail by Swan (1971), who has drawn attention to the fact that in this sheltered, low-energy coast the coastal forms are very different from those supposed to be characteristic for such coasts in the humid tropics. Mangrove swamps, tidal flats, beaches, and fringing reefs, are present as well as cliffs, caves, shore platforms, and beach conglomerate (ironstone). This diversity is due to the intense and continuous chemical weathering, which makes possible subaerial and marine erosion by small waves, and to differences in rock type and exposure. Coastal sediment is produced through cliff erosion, which takes place along both sheltered and exposed parts of the coast.

Indonesia

In Indonesia, mangrove swamps are present along the coasts of Sumatra, northern Java, along most of Kalimantan (Borneo), along northern Borneo (Sarawak), and at the southern end of Sulawesi (Celebes). All these areas are relatively sheltered against the ocean swell. Cliffs and beaches are locally present (Wall, 1964), but although the rivers of Sumatra and Kalimantan carry large amounts of sediment to the sea, only the Kapuas and Pawan rivers, the Rajang and Baram rivers on the northern coast, and the Mahakam River in the east have built up sizeable deltas. Elsewhere, where sediment supply is abundant, broad alluvial lowlands have been formed. The coasts of Java are predominantly beaches interrupted by river outlets and deltas and locally by cliffs. However, along eastern Java, western Sumatra, and on most of the eastern Indonesian islands, the coasts are relatively steep. A few river deltas with associated swamps and alluvial foreland are present on the west coast of Sumatra and on the northeast coast of Java.

The main feature in western Indonesia is the large, drowned Sundaland (Molengraaff, 1921). Two large submarine valley systems, being the continuation of the present rivers in Sumatra and Kalimantan, are present on the continental shelf. During the Pleistocene periods of low sea level, one system drained Sumatra and east Kalimantan, discharging into the South China Sea. The other system, draining Java and south Kalimantan, discharged south of Makassar Strait. A divide crossed the Sunda Sea between Sumatra and Kalimantan across Billiton and the Karimata Islands. The Sundaland plain has been dissected at least twice during the Pleistocene as a consequence of the eustatic lowering of sea level (van Overeem, 1960). In the whole area, including Malaya, eustatic terraces are present from +50 to −90 m (Tjia, 1970).

On the former east coast of the Sundaland, a large barrier reef has been formed, stretching from Balikpapan on Kalimantan to the island of Sumbawa in the south. It is interrupted in many places and shows a large gap of about 100 km wide facing a deep embayment in the former Sundaland. The main river outlet was probably situated here. The reef began as a late Pleistocene fringing reef and has grown upward with the gradual rise in sea level. Locally, it reaches the sea surface as separate coral islands. Similar fringing reefs of smaller dimensions are present around Sulawesi and the smaller islands in eastern Indonesia, along the west coast of Sumatra (where they show gaps in front of the river deltas), and further north along the Nicobar and Andaman Islands. In the Sunda Sea, coral growth is restricted to a number of isolated areas away from muddy river outlets (Kuenen, 1933; Umbgrove, 1947). In eastern Indonesia, numerous atolls and barrier reefs have grown upward from gradually subsiding submarine ridges and platforms, rising abruptly and steeply from a depth of 1,000–2,000 m. The effects of winds and waves on the reefs are conspicuous, especially in eastern Indonesia, where the reefs grow more vigorously on the windward side. Sea currents cause erosion and may shape a whole group of reefs. Solution of coral occurs within the tidal range. On the former northern coast of the Sundaland no barrier reef has been formed. Here the former coast was flat and gradually merged into an extensive sandy and probably muddy shelf. The water in this area was presumably too turbid for coral reef growth. This is also the case along the south coast of Irian Jaya (New Guinea), where large alluvial plains have been formed, covered along the coast by mangrove.

ASIA, MIDDLE EAST, COASTAL ECOLOGY AND GEOMORPHOLOGY

Between the Bosphorus to the west and the Iran–Pakistan border to the east, the coasts of the Middle East may be divided into two different provinces, the Mediterranean one to the west and the Indian Ocean one to the east. The first province concerns the Aegean and Mediterranean coasts of Turkey on the one hand and the Levantine coast on the other hand. The second province includes three rather different sectors: the western coast of the Red Sea and the coasts of the Persian Gulf, two elongated and narrow inland seas, and the Indian Ocean coasts, comprising the south Arabian coast, the Gulf of Oman, and the Makran coasts. Each of these sectors presents its own particularities together with some common characteristics, whether in tectonics, climatology, ecology, or geomorphology (Figures A50–A58).

The coasts of Anatolia

Climate, vegetation, hydrology

Along the Aegean and Mediterranean coasts of Anatolia, the annual precipitation ranges from 400 mm in the plains, with a minimum in the sheltered areas like the Çukurova plain, to more than 1,000 mm on the hills and flanks of mountains, notably in the Lycian sector. In winter, the Aegean and Mediterranean coastal areas are by far milder than in central Anatolia, with mean January temperature higher than 10°C in sectors bordering the sea along the Mediterranean Sea and higher than 5°C on the lower slopes of the hills and mountains. But everywhere freezing may occur, especially in the Aegean area. Summers are very hot; mean August temperatures exceed 25°C and maximum absolute temperatures reach 40°C or more, particularly in the Cilician plain. Rainfall occurs in winter and the summer is dry for about six months. Vegetation is much more xerophytic than in the West Mediterranean province. The seaward slopes of the coastal mountain ridges are truly Mediterranean in vegetation and in climate. Along the Amanus Mountains, the evergreen maquis zone of *Quercus calliprinos* and *Pistacia palaestina* sometimes starts at sea level and extends to an altitude of about 700 m. In the Lycian–Cilician sector, the eu-Mediterranean belt is confined to a very narrow ribbon with the same plant association of the evergreen maquis. In the Aegean sector, the evergreen maquis mainly comprises the association *Pistacia lentiscus, Olea europaea*, and *Myrtus* (Zohary, 1973).

The ratio of precipitation/evaporation shows a deficit and the eastern Mediterranean Sea receives water coming from the Black Sea through the Bosphorus and Dardanelles Straits, the salinity in the Aegean Sea is notably lower than in the eastern Mediterranean; in August, it is less than 38‰ in the north, less than 39‰ in the south of the Aegean Sea, whereas it is more than 39‰ in the eastern Mediterranean along the Turkish and Levantine coasts. Marine currents are generally north–south in the Aegean Sea and east–west along the Mediterranean coast of Turkey. On the whole, sea water temperatures increase from the north to the south in the Aegean Sea and from the west to the east in the Mediterranean, rising for example in August from 25°C along the south–west coast of Anatolia to over 28°C along the Cilician coast.

Regional features

The Turkish Aegean coastline is very long (3,484 km) and indented. It presents a great variety of lithological units, with alternation of crystalline massifs and Mesozoic geosynclinal belts including mostly limestone, flysch, and ophiolitic formations. This area is tectonically controlled by a highly complex structure of east–west oriented active horsts and grabens. Peninsulas, islands, rocky cliffs, and a narrow continental shelf correspond to the horsts. In the grabens there are wide continental

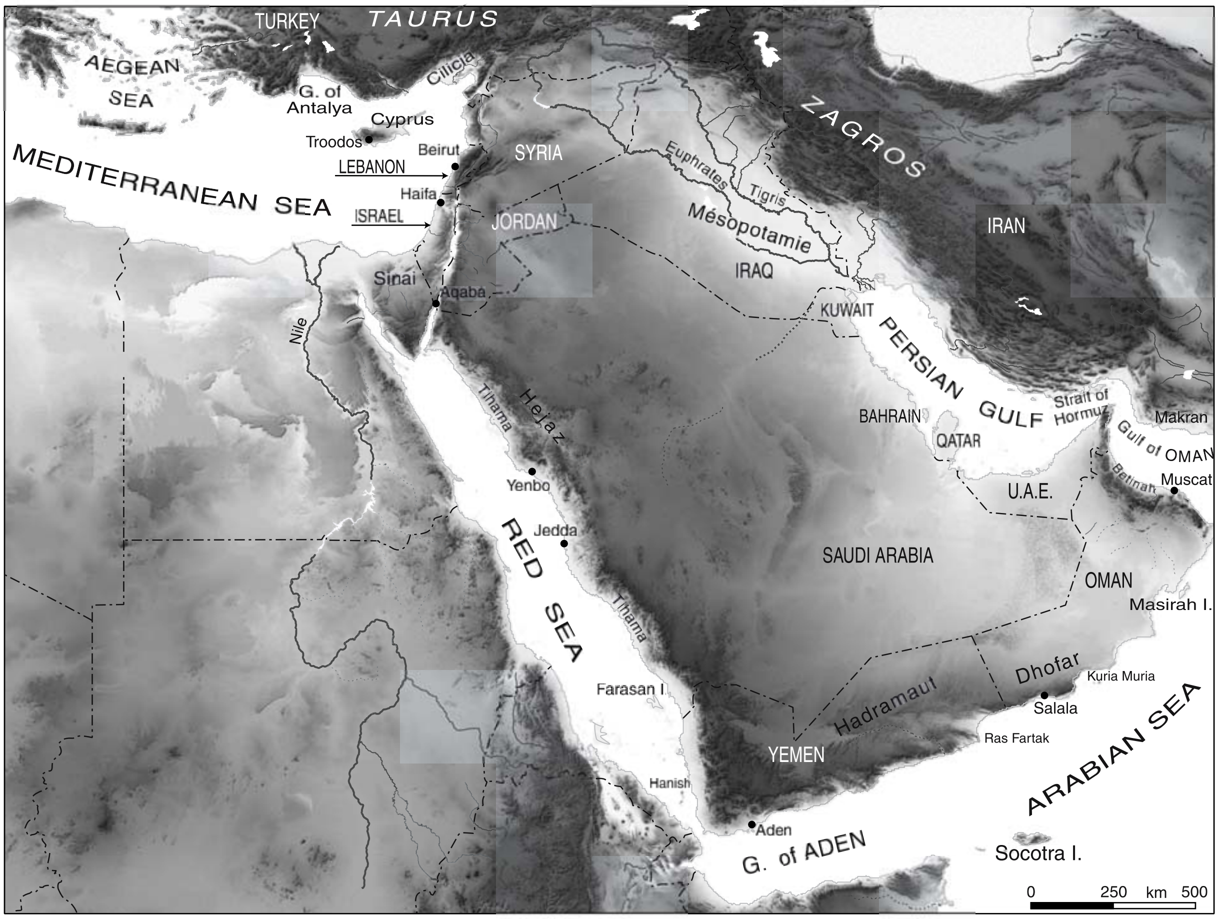

Figure A50 Location map.

shelves prolonging vast deltaic plains bordered with marshes, dunes, and sandy beaches. In the north, the Sea of Marmara, related to the greater Anatolian fault, is very deep (>1,300 m).

During the Middle Miocene severe tectonic phases occurred and grabens formed. These grabens were submerged by marine transgressions during the Quaternary, and during the glacial periods rivers deepened their courses. During the Holocene, when the sea-level rise had reached its present level about 6,000 years ago, major marine embayments occurred in several depressions where the main rivers ended; such as the Gediz, the Küçük Menderes, and the Büyük Menderez. Many important cities of the Hellenistic to Roman times were located on the immediate coastline and closely associated with the sea, such as Ephes, Priene, Milatus, or Heracleia; in the vicinity of Ancient Troy, the marine embayment protruded nearly 10 km south of the site. But, quickly, deltaic progradation and floodplain aggradation, caused by deforestation and severe erosion on the steep slopes of this mountainous country, markedly changed the landscape: the depressions were infilled with prograding river alluvium and deltas. These towns were separated from the sea; Ephes in the plain of the Küçük Menderes and Priene or Milatus in the Büyük Menderez basin, and the site of Troy is now about 6 km from the sea. Sometimes, for instance, in the Gediz Basin and the Izmir area, it seems that the evolution was more complex and mainly controlled by intense tectonics. The progradation was less marked where there is no major drainage system to provide sediment, for instance, in the south as in the Gökova Gulf. Now, progradation has largely halted mainly where the grabens widen rapidly into larger coastal embayments and modern deltas are wave dominated (Kraft *et al*., 1980; Erol, 1985; Aksu *et al*., 1987; Hakyemez *et al*., 1999; Kayan, 1999).

The Mediterranean coastline of Turkey (1,707 km) is more regular and rectilinear than the Aegean coast, because of its longitudinal structure. The coastline is subparallel to the Taurus Mountains consisting of Paleozoic to Tertiary folded formations where carbonate rocks outcrop largely, favoring numerous karstic features. West of Antalya, the Taurus Mountains, S–N oriented, rise sharply and steeply out of the sea with high cliffs and only very small deltaic coastal plains. From Antalya to Alanya, there is a major embayment with a wide coastal plain edged by extensive coastal dunes and sandy beaches with frequent beach-rock formations; the only exception are the travertine cliffs at Antalya. Marine Pleistocene terraces occur to the east of the Antalya Bay at heights from 5 m to 20–30 m or even higher. Here, as in the Hatay area, beaches and bio-erosional notches and benches are frequent, between +0.80 and +2.5 m, testifying to late Holocene uplifts (Pirazzoli, 1986; Kayan, 1994). East of Alanya, once more, the Taurus Mountains rise directly out of the sea with very steep flanks and cliffs in Paleozoic schists and Mesozoic limestones. Scattered sandy beaches exist at the mouth of the rivers but elsewhere the coastline is dominated by plunging cliffs or by pebble beaches at the foot of the cliffs. The main river is the Göksu, characterized by a small lobed delta plain. East of Göksu, between the SW–NE Taurus Mountains and the N–S Amanus mountains (or Nur Mountains), there is the large Çukurova plain (or Cilician plain) which is a progradational plain built by two big rivers, the Seyhan to the west and the Ceyhan to the east. The plain, formerly swampy or marshy, but now largely drained and dry, is edged by a series of broad Holocene accretion beaches. At the foot of the Amanus Mountains, the rectangular-shaped Gulf of Iskenderun is structurally controlled. At the very southern end of the coast of Turkey, the Orontes River crosses the Amanus Mountains in a narrow defile and ends in a small delta near the ancient harbor of Seleucia ad Orontes (Erol, 1985). Almost everywhere, the coastline is now receding owing to the taking of sediments on beaches and dunes, the setting up of dams, and slight raising of the sea level, and slabs of beach rock are more and more frequent on the beaches.

Cyprus Island lies south of Turkey. Its coastline, about 450 km long, is partly steep and rocky in the north (notably in the Karpos Peninsula) and in the SW (at the foot of Troodos massif) and partly beach-fringed, particularly in the southeast, alongside the Mesogea central plain, mainly between Limassol and Famagusta where there are some brackish lagoons.

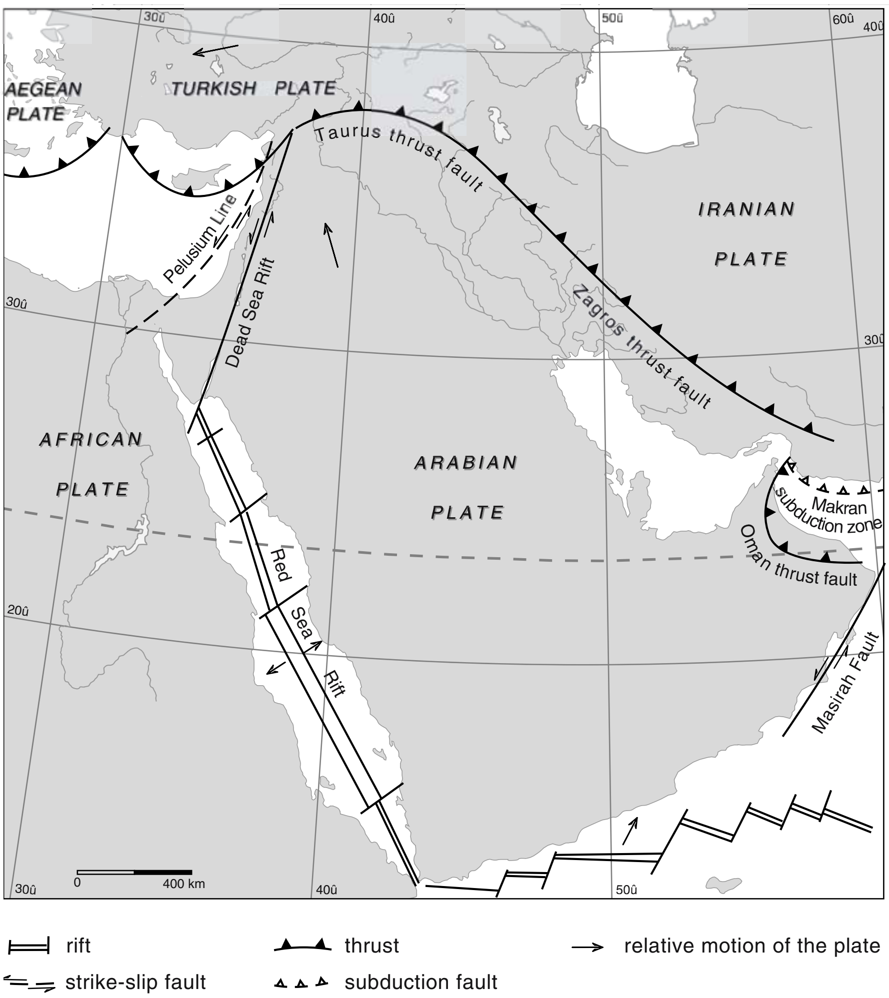

Figure A51 Tectonic map.

The Levantine coast

Climate and marine hydrology

The climate is clearly Mediterranean, with hot and dry summers, and rainy and mild winters and the winds mainly blowing from the west. Average rainfall decreases from the north (ca. 1,000 mm north of Latakia) to the south (313 mm at Gaza). Average air temperature along the coast usually ranges from 11°C to 14°C in January (with minima reaching the freezing point) and from 23°C to 26°C in August with absolute maximum temperatures over 45°C. Tidal range does not exceed 40 cm. There is an anticlockwise east Mediterranean current, which moves south–north along the Levantine coast. Longshore currents occur too, influenced by coastal morphology and wind direction, but the resultant shifting is to the north. All these currents carry the Nile sediments northward up to south Lebanon. Westerly and especially southwest winds are dominant. As the fetch is large, the coast undergoes strong wave action. In winter, storms are sometimes severe: in January 1968, with wind speeds of almost 150 km per hour, wave heights reached 7 m off the Beirut region.

The living world of the eastern coasts of the Mediterranean is impoverished and the littoral fauna and flora are poorly diversified in comparison to that of the western Mediterranean as a result of the extremely low biological productivity of the Levantine basin, mainly since the opening of the Suez Canal and the erection of the Upper Assouan Dam. Since the opening of the Suez Canal, over 300 migrant species have invaded the Mediterranean from the Red Sea at a faster and faster rate; 9 new species of fish arrived between 1902 and 1939, but 22 from 1965 to 1987. Among the "Lessepsian" crustaceans, decapods are particularly representative, such as *Myra fugax* or *Atergatis roseus*, and *Charybdis longicollis* represents up to 70‰ of the sandy–muddy bottoms. Among the Serpulids, 7 Lessepsian species have been identified, belonging to 3 genera, and 33 algae are possibly lessepsian (Por, 1982, 1990).

Coastal morphology

The rectilinear Levantine coast is open to the western winds and swells. The only noteworthy irregularities of the coast are such peninsulas as Ras el-Bassit in Syria, Ras el-Mina (near Tripoli), Ras Chekka, Ras Beirut, and Tyr in Lebanon, and Mount Carmel in Israel. Some of them (Tripoli or Tyr) are ancient rocky islands more or less recently connected to the mainland by a sandy bar (tombolo). Bays are generally small, the most important being the Akkar Bay, on the Syria–Lebanon frontier, and the Haifa Bay in Israel. Transverse faults, often east–west, account for the main features of the coastline. The north Levantine coast runs parallel to the folded coastal mountain range of Jabal Ansarieh in Syria and Mount Lebanon (culminating at 3,083 m) in Lebanon. The mountain range approaches very close to the Mediterranean Sea, mainly in Lebanon where, in the Jounieh Bay, for example, the altitude reaches 600 m less than 1 km from the sea as the crow flies. Nevertheless, high cliffs are uncommon, except in the Jabal Akra in the north of Syria, or at Ras Chekka or Ras Beirut in Lebanon. In the northern Levant, the continental shelf is narrow and broken by very deep and steep canyons, as in the Beirut Bay; in the south, the continental shelf gets wider and wider and its slope is very gentle. The coastal plain is discontinuous and narrow in the north Levant, widening in south Lebanon, between Saida and Tyr, and even more south of the Mount Carmel; getting wider and wider to the south, it reaches a width of 40 km near Gaza. On the other hand, north of Haifa, the coast is

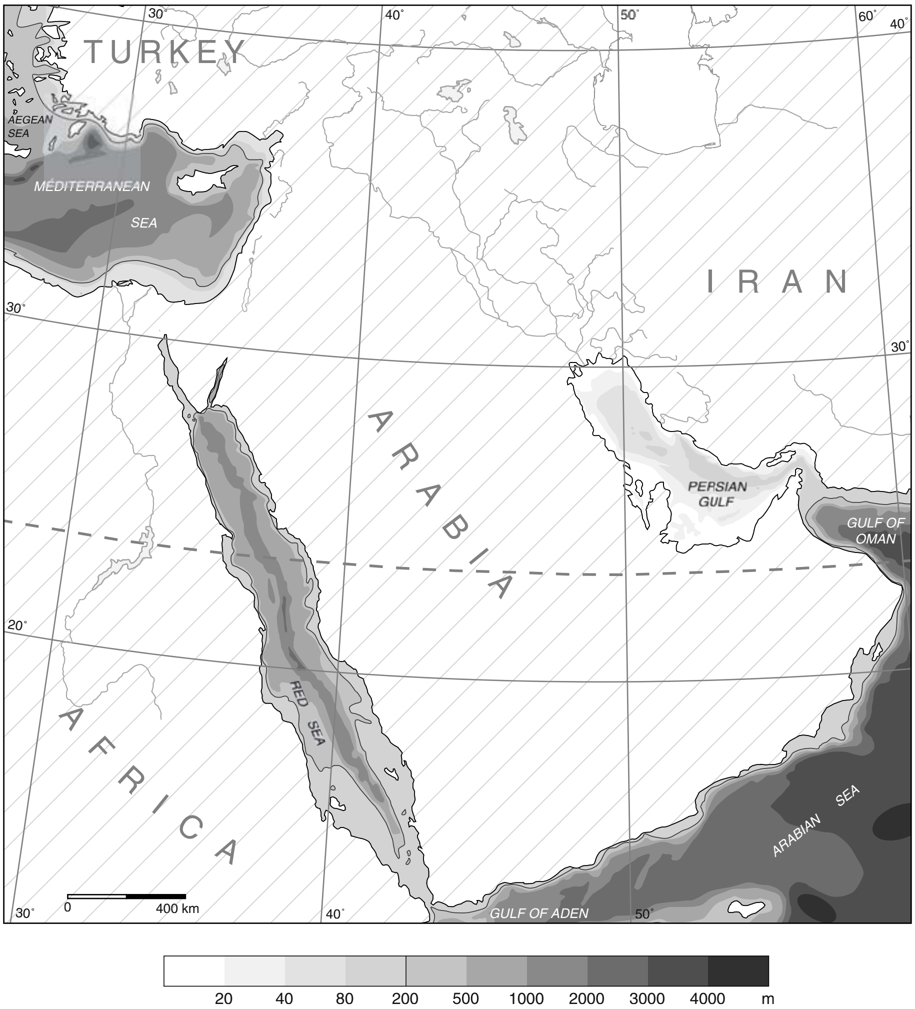

Figure A52 Bathymetry.

frequently rocky, in Cretaceous, Eocene, or Miocene limestones or in Pleistocene eolian or marine sandstones, with an indented outline and numerous creeks or coves.

Cliffs are generally one to some meters high and their base spreads out in a horizontal "trottoir" at mean high sea level. One to three meters wide on limestone, wider on sandstone, this trottoir has been cut into the rock, mainly by biochemical weathering, and is edged with a Vermetid biological construction (the sessil gastropods *Dendropoma petraeum* cemented by the calcareous red alga *Neogoniolithon notarisii* and perforated by Clionid boring sponges and rock-boring pelecypod *Lithophaga lithophaga*), forming an elevated rim buffeted by the fine weather swell. On the surface of the trottoir live *Vermetus triqueter*, a dense cover of *Mytilus galloprovincialis* and *Brachydontes* sp. The intertidal belt mainly shows two species of gastropods, *Patella caerulea* and *Monodonta turbinata*, and, in the upper mid-littoral belt, the barnacle *Chthamalus stellatus* (Safriel, 1974; Por, 1982). On limestone, the present day trottoir is frequently doubled by a fossil one, about +1 m m.s.l. and wider than the present one. This ancient trottoir has been interpreted as representing the occurrence of a rapid uplift movement during the early Byzantine period (Pirazzoli, 1986).

At the creek-heads there are pebble beaches fed by wadis, but the coastal plains are fringed with sandy dunes and beaches. In south Lebanon, the sands, light in color, are mainly of local origin and composed of broken calcium carbonate skeletons of pelecypods (mainly *Glycymeris violacescens*) and calcareous algae. Along the Sharon and Pleshet plains, in Israel, the sands are composed mostly of quartzose grains and heavy minerals mostly coming from the Nile delta. In the Beirut area, the quartzose sands originate in the lower Cretaceous sandstones which outcrop largely in the mountains nearby.

Ancient coastlines

Relicts of Pleistocene *kurkar* (dune calcarenite, called *ramleh* in Arabic) ridges form several parallel alignments in the coastal plain south of Mount Carmel, witnesses of several coastal dunes associated with transgressive coastlines; the waves sometimes attack the westernmost kurkar, cutting it into a cliff preceded by a wide rocky platform (Nir, 1982). The youngest one also occurs as small islands or islets off the coast of Palestine, Lebanon (at Sidon and near Tripoli), and Syria (Arados).

Syria, Lebanon, and Mount Carmel show fine examples of little deformed, but strongly uplifted Pleistocene coastlines up to 300 m above present sea level (Sanlaville, 1977), resembling wide horizontal flat platforms edged with indurated beach sediments, sometimes containing paleolithic artifacts. The last interglacial deposits, between 6 and 12 m, contain a rich Tyrrhenian fauna; at Naame, 15 km south of Beirut, 14 species living on the western coast of Africa but missing today on the Mediterranean coast, were found, such as *Strombus bubonius, Cantharus viverratus, Conus testudinarius, Arca afra, Cymatium costatum*, etc. (Fleisch *et al*., 1981). Holocene marine deposits are also frequent, indicating recent oscillations of the sea level or tectonic movements up to 2 m, but the aggradation beaches were often clearly in phase with fluviatile discharges controlled by climatic oscillations or anthropic factors (Sanlaville *et al*., 1997).

Erosion and pollution

Some decades ago, beach rock occurred here and there along the Levantine coast but it is now widespread all along the coast, in relation

Figure A53 Sea surface salinity (‰ in August).

to strong beach erosion which results in the disappearance of the beach sand and the exhumation of an ancient slightly consolidated buried beach, then strongly indurated when exhumed. Everywhere the coast is retreating, sometimes rapidly, and beach sediments and dune sands disappear quickly. This coast is also badly polluted and the landscapes are greatly altered by sea walls, breakwaters, harbors, and all sorts of concrete buildings. Because of the westerly swell, the presence of slabs of beach rock at the lower edge of beaches or the presence of deep and sharp lapiaz on the rocky coastal areas, and severe pollution, this coast is not as attractive as it was, despite good climatic conditions.

The Red Sea coast

Structure, climate, and marine hydrology

The Red Sea occupies a complex rift system between the African and Arabian plates, when separation occurred in the mid-Tertiary times. The Red Sea opened into the Indian Ocean in Miocene times and remained open into the Mediterranean until the early Quaternary. The beginning graben event reactivated erosion and due to the penetration of the sea, carbonates and evaporites were deposited, with coarse–clastic intercalations. With the closure of the Mediterranean connection and tectonic and eustatic changes affecting the Bab al Mandeb narrows, the Red Sea became isolated during the later Quaternary and, because of intense evaporation, greatly diminished in volume with a dramatic impact on shore-zone morphology and ecology.

Connection between the waters of the Red Sea and the Indian Ocean is hindered by a shallow submarine sill in the Bab el Mandeb narrows; the narrows are only 20 km wide and near the Hanish Island, the sill does not exceed −137 m. In the north, the Suez Canal established an artificial but very weak contact with the Mediterranean Sea. The climate of the area is hot and arid. In February, the temperature in the coastal plain (Tihama) varies from 12°C in the north to over 26°C in the south (23.5°C in Jeddah), and in August it is over 30°C (Jeddah, 32.4°C). The Tihama receives less than 50 mm of rain. North of Jeddah, the rainfall does not reach 100 mm in the mountains (occurring in winter and spring), but it is more important in the south: over 400 mm in the Asir and over 600 mm in Yemen (in summer and spring) where mountains are very high. But water is lost before reaching the sea, so the Red Sea does not receive freshwater, since evaporation is very high (more than 2 m per year). The shortage must be supplied by the Indian Ocean through the Bab al Mandeb, where three currents are superposed in summer and two in winter as a result of water density and seasonal winds. So the Red Sea is warm and very salty. Surface sea water temperature stands between 28°C and 31°C in the northern part in August (under 28°C in the Aqaba Gulf) and rises above 31°C in the southern part. In February, the surface sea water temperature rises from the north (less than 20°C in the Aqaba Gulf) to the south (26°C). Salinity is very high in summer, increasing regularly from the south (37‰) to the north (over 41‰ in the Gulf of Suez). Sea water temperature and transparency are very favorable to coral reefs and the mangal vegetation is well developed, dominated by *Avicennia marina*; along the southern Red Sea coast there is also found *Rhizophora mucronata, Bruguiera gymnorrhiza*, and *Ceriops tagal* (Glover, 1998). Winds are predominantly from the NW all over the Red Sea in summer; in winter, NW winds occur in the northern part of the Red Sea but SE winds blow in the southern part. The marine currents are oriented north–south in summer and south–north in winter. Tidal range is insignificant; 0.10 m in Jeddah, but atmospheric pressure and winds can bring about variations of the sea level up to 0.90 m, which is very dangerous for boats due to coral reefs.

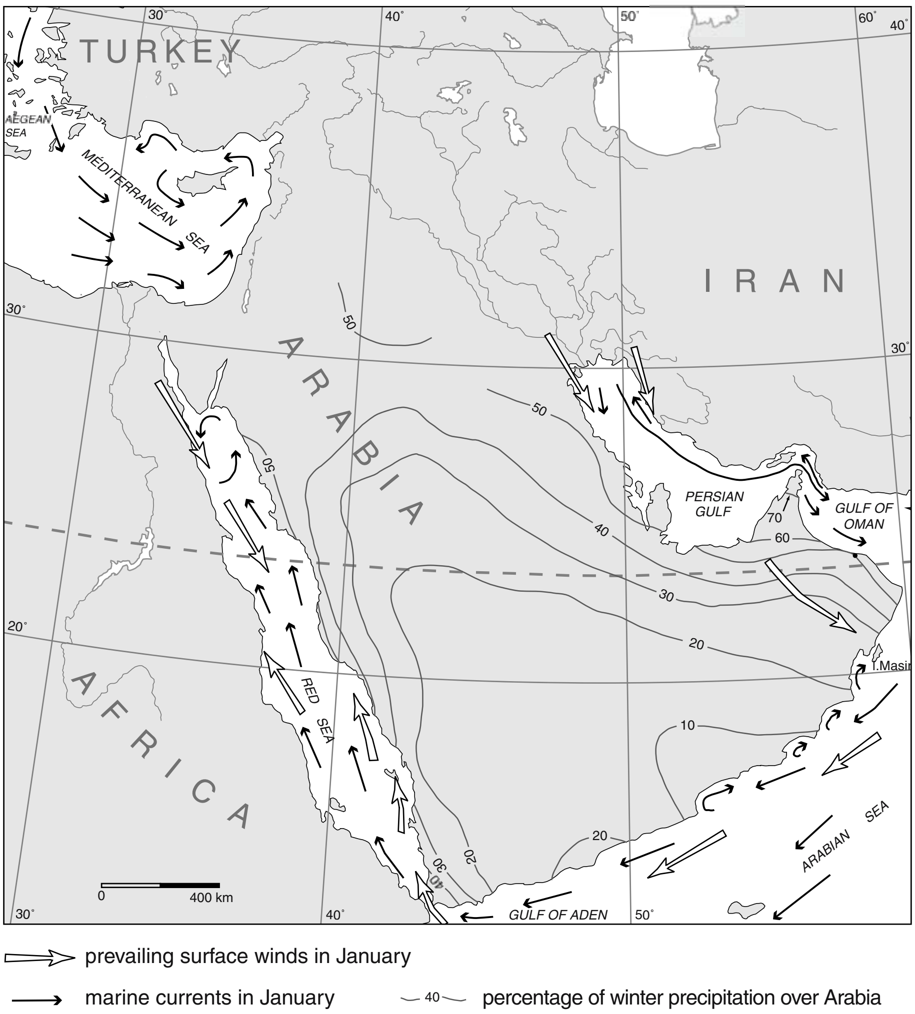

Figure A54 Winds and currents in January.

Coastal morphology

The landscape of the region is predominantly mountainous; the highest peaks are often in excess of 2,500 m, mainly in the south, in Asir or Yemen where mountains reach a height of over 3,000 m and up to 3,760 m at the Jabal Nabi Shuaib, in Yemen. In places, the strongly dissected mountains come right down to the sea. But generally a flat plain, 5–40 km wide, constitutes an almost 2,000 km long marginal corridor, called the Tihama, following the border of the Arabian Mountains. Plutonic, volcanic, and metamorphic rocks outcrop in the mountains. In the Tihama, the basement is generally hidden below Tertiary and Quaternary rocks. Tertiary sediments, which can reach a thickness of over 2,000 m, generally present a division into three series: Oligocene, Lower, and Middle Miocene limestones and conglomerates, Middle and Upper Miocene evaporites, and Upper Miocene–Pliocene limestones and clastic red series. Frequently, Tertiary rocks are exposed only at the edge of the basement and in a few places in the coastal plain where mainly Quaternary deposits outcrop, constituted of gravel terraces, extensive alluvial cones and uplifted coral reefs.

Coming out of the mountains, the alluvial surfaces fall relatively steeply to the coast. They can be recognized by their covering of pebbles and gravels with particularly dark desert varnish. Upstream, near the basement, a terrace consists of a thick sequence of coarse gravels and downtream mainly of fine sediments. There are generally several stepped alluvial terraces, the oldest characterized by coarse pebbles and a very dark patina, the youngest by a sandy to gravelly material and a lighter color. Relatively coarse windblown sands often occur in the upstream part of the coastal plain. Dating the fluvial terraces is rather difficult, but relative dating is sometimes possible. Between Umm Lajj and Yanbu, the basalts from the Jabal Nabah, K/Ar dated 1.4 ± 0.6 My, flowed into wadis that were already cut into the oldest terrace, which might be Lower Quaternary or Upper Pliocene and show evidence of vertical block movements; the formation of the middle terrace antidates the Umm Lajj basalts (0.4 ± 0.2 My). The age of the youngest gravel terrace can be estimated, due thanks to its direct connection to the 6–8 m marine terrace, which belongs to the last interglacial (Hötzl *et al.*, 1984).

Ancient coral reefs outcrop in the lower part of the coastal plain, in places slightly covered with gravels. The main reef body, very flat, is the 6–8 m marine terrace. Toward the sea, the main reef itself outcrops and, behind it, increasingly lagoonal facies. This ancient reef can be attributed to the last interglacial (isotopic stage 5e) and exhibits no real deformation. An older one, faulted, is probably 250 ky old (isotopic stage 7). A Holocene erosion step at 1–2 m above m.s.l., only a few meters wide, is carved into the edges of the 6–8 m reef, even on its landward side. The reef terraces form striking isolated erosional remnants and more or less broad table-like crests. Depressions and channels developed behind the reefs, which, subsequently, were sometimes occupied by bays (Sharm) when the sea level rose later. The best example is Sharm Yanbu with its narrow deep channel and its two branches representing the continuation of two wadi channels. The protective reef plate kept this crest from being eroded, while the loose material behind it was excavated. Such back-coast depressions recur repeatedly. These bays are the result of the last drop in sea level in the latest Pleistocene and the later increase in the Holocene. On the eastern edge of the reef crest, an inter-fingering of coral and beach formations with clastic continental sediments can often be seen. This interfingering points to the existence of a humid climate during the interglacial period. Carbon-14 dated remnants of trees indicate heavier-than-today precipitation during the so-called “Neolithic Pluvial.”

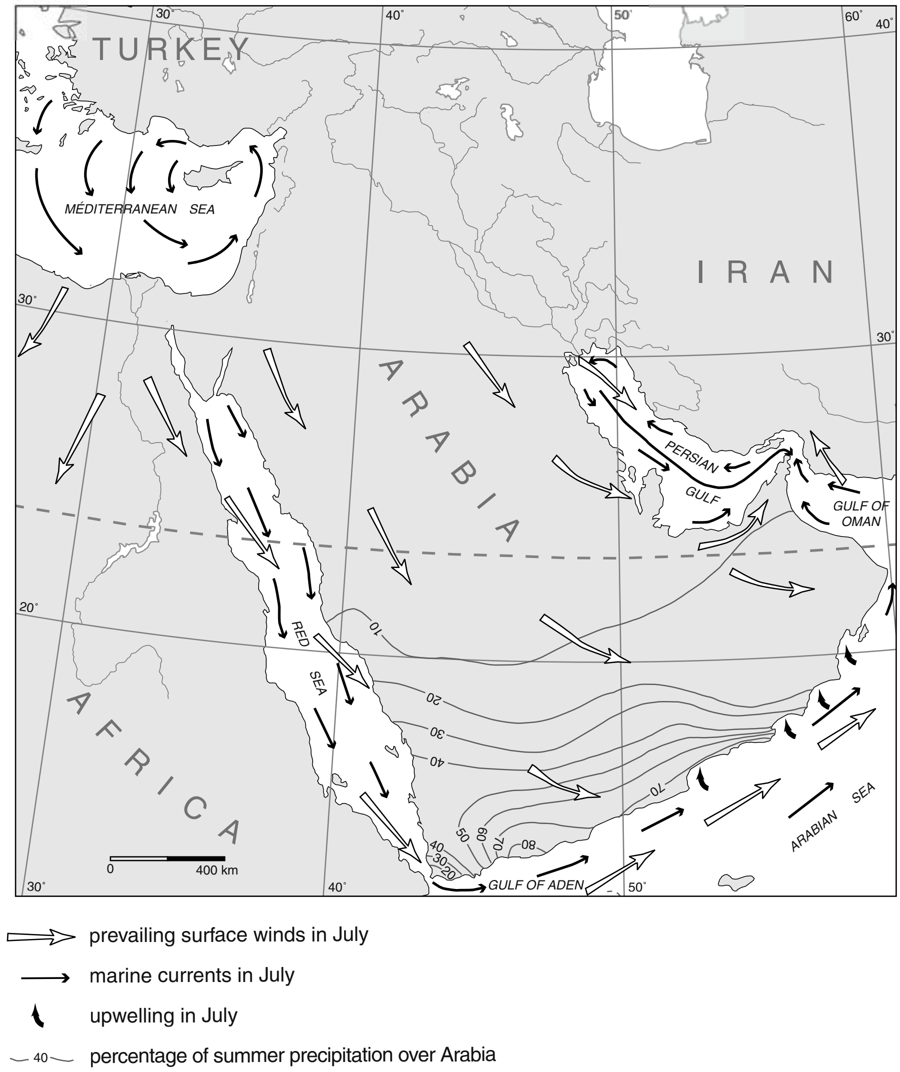

Figure A55 Winds and currents in July.

Coral reefs

Coral reefs are mainly of the fringing type; fringing reefs in a very nearshore position in front of steep cliffs, or fringing reefs with a lagoon within shallow water. They grow close to the mainland and are absent from wadi mouths. Barrier reefs and even atolls also occur, mainly in the central and southern part of the Red Sea. The outlines of the reef crest and the orientation of the foreslopes follow the tectonic pattern. Spectacular drop-offs are widespread and represent predominantly horst and graben structures parallel to the rift.

In the Aqaba Gulf, the fringing reefs exhibit a characteristic biozonation (Dullo and Montaggioni, 1998): (1) a local and poorly developed beach; (2) the back-reef zone, a sandy depression between the beach and the reef-flat, with a maximum width of 50 m and a depth of 1–2 m, the bottom sediment is colonized by scattered coral heads (*Stylophor*a, *Seriatopora, Platygyra, Millepora*), alcyonarian colonies (*Lithophyton, Cladiell*a, *Sinularia*) and seagrass beds (*Halophila, Halodule*); (3) the reef-flat zone, about 20 m wide, this is a dead coral pavement bordered by a 1 m rear-reef step. Coral communities are composed of small-sized colonies (*Stylophor*a, *Seriatopora, Acropora*) associated with hydrocorals (*Millepora*). The reef front forms a nearly vertical drop-off, 2–4 m high, with *Millepora* and branching red algae; (4) the outer slope zone, with loose sedimentary slopes (sandy talus and patches of *Halophila*) or coral-reef slopes, with their upper parts dominated by branching growth forms (*Stylophor*a, *Seriatopor*a, *Acropor*a, *Echinopora*). Along the coast of Arabia, the fringing reef constitutes an almost continuous belt and often has wide back-reef zones.

On the central and southern coast of Arabia, coral reefs also occur as offshore knoll reef platforms. In the vicinity of Jeddah, about 3 km west of the coastline, the offshore reef consists of a shallow platform covering an area of 800 km^2, bounded both shorewards and seawards by a vertical escarpment dropping rapidly to depths of 400–800 m, marking the edge of the Red Sea trough. The platform is occupied by scattered reefs separating sandy bottoms. The present reefs come from Holocene reefs settled on Pleistocene reef limestones. The coral community of the innermost part is dominated by *Stylophora pistillata*. Coralline algae are represented by massive branching and crustose forms (*Lithothamnium, Spongites*). The upper parts of the steeply reef flanks are settled by *Millopor*a.

In the southern part of the Red Sea, where the sea reaches its maximum width of 360 km, remarkably flat shoals (called *shab*) occur. The best example is the Farasan bank which extends from 16°N to 22°N. Lat. and reaches a width of up to 120 km. The sea is almost always less than 100 m deep and often only a few meters deep. The two main islands, which were very important for pearling at the beginning of the 20th century, are 60 km long and 8 km wide (al Kabir) and 35 km long and 10 km wide (Sajid). These islands are flat and low (under 20 m), except in a very few places where heights of up to 75 m are to be found, in domed eminences where gypsum and anhydrite outcrop as a result of halokinesis (Dabbagh *et al*., 1984).

Regional features

The Gulf of Aqaba is the continuation of the Red Sea rift, formed as a consequence of transform movements along the Aqaba–Levant structure. This narrow gulf slopes steeply to depths of over 1,800 m. In the north of the Red Sea, the coastline is very straight, free from larger indentations, with a trend of 140/150°, identical to that of the entire

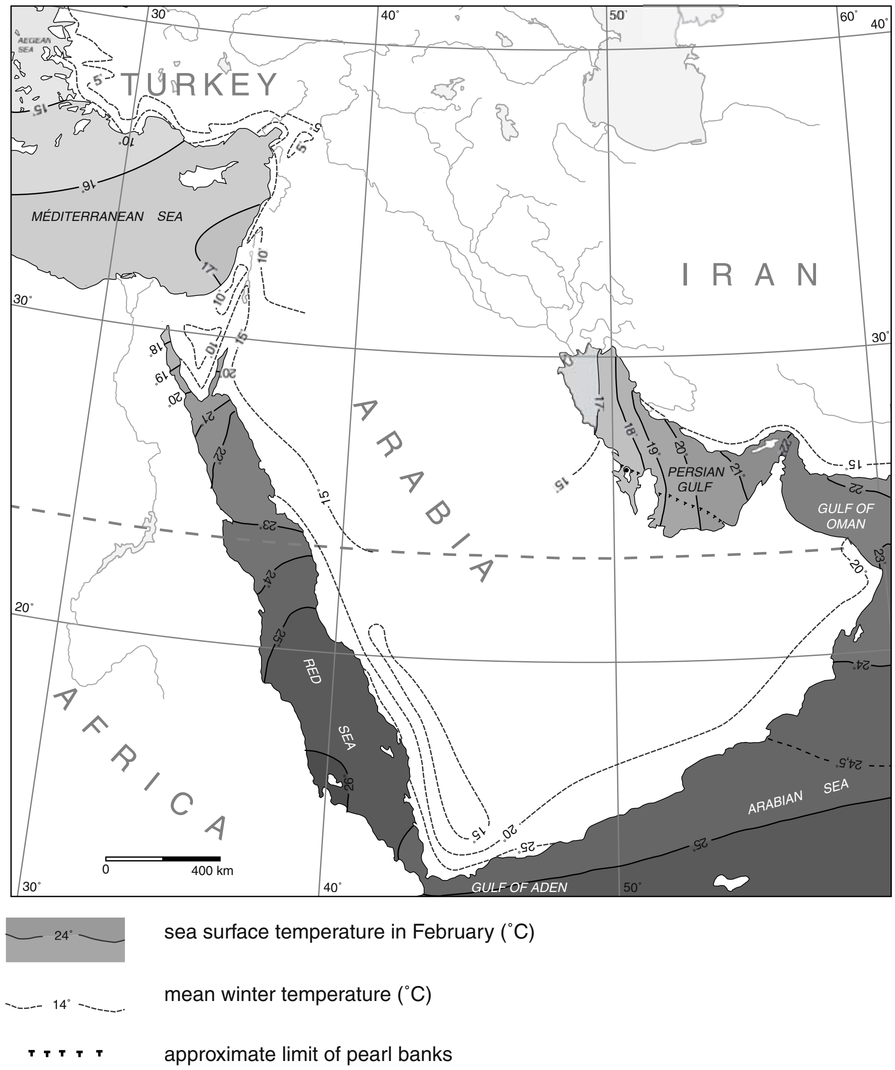

Figure A56 Mean winter temperatures.

graben. Sigmoid curves are typical of the central and southern parts of the Red Sea coast. The 200 m isobath shows significant deviations. It is seldom parallel to the coast, underwater ridges, and troughs repeatedly show the conjugated 70° course indicated by transform faults. The main wadis are generally related to young NE striking faults and block-faults.

The Wadi al Hamdh, with a catchment extending almost to al Madinah, is the most important drainage system in the Hejaz Mountains. Its load of sediment considerably contributed to the creation of a broad aggradation plain south of al Wajh. Even under the present arid conditions, its water, enriched with mud and rubble, regularly reaches the coastal plain, and sometimes the sea. A continuous reef belt has developed some 30 km away from the coast (Al-Sayari *et al.*, 1984).

Because of a wide break in the recent coral reef along the coast, Jeddah is one of the few places on the Red Sea coast where a large harbor could be located. Isobaths show an E–W channel from Wadi Fatimah into the Red Sea. The upper course of Wadi Fatimah extends into the massive basalt flows of the Harrat Rahat and the remaining catchment is made up mainly of Precambrian rocks. The middle course of Wadi Fatimah is to be considered as a fault-bounded graben. The presence of plutonic and metamorphic rocks limits the potential aquifers to the alluvions of the Wadi Fatimah which is an early source of water for the Jeddah city, as the ruins of a qanat(conduit) system show (Hacker *et al.*, 1984).

The plain of Jizan forms a narrow NW-oriented coastal strip. The strongly dissected Asir and Yemen high mountains overlook the whole area. At their base, parallel foothills, consisting of metamorphic schists or volcanic rocks reach heights of between 200 and 700 m. The plain itself averages about 40 km in width and is composed of alluvial deposits, except for some volcanic cones and the salt dome (diapir) of Jizan (Müller, 1984). Several important intermittent wadis flow across the plain, fed by the summer and spring rain falling in the mountains, but only their upper courses are perennial. Many volcanic intrusions, which occurred during the development of the Red Sea rift, are characteristic of the plain. Given the good state of preservation of some cinder cones, volcanic activity has continued up to recent geologic times. The coast is preceded by a reef over almost its entire length. Immediately adjacent to the coast is a sabkhah zone, some kilometers wide, consisting of silty, clayey sediments with high salt content. On its eastern border, this zone passes into the alluvial accumulation of the middle terrace (Purser and Bosence, 1998).

The Persian Gulf coast

Hydrology, climate, and structure

The Persian Gulf has an average depth of 35 m and a maximum depth of 100 m near its narrow entrance, the Strait of Hormuz, 60 km wide. Tidal range varies from 1 m at Dubai, 2.5 m at Bahrain, and 3.5 m at Kuwait to a maximum of 5 m in the Clarence Strait, between Qeshm Island and the mainland, and the tidal range averages ca. 1 m at Basra, 150 km upstream on the Shatt al Arab. Regional tidal currents are oriented approximately parallel to the axis of the Gulf. Tidal velocity may exceed 60 cm/s, their bidirectional movements favoring the development of spectacular oolitic tidal deltas (Purser and Seibold, 1973).

The considerable loss of water in the Gulf through evaporation is not compensated by precipitation and river inflow, the only notable inflow of fresh water coming from the Shatt al Arab, in fact mainly from the Karun (ca. 6,000 m^3/s). As a result, compensatory waters come from

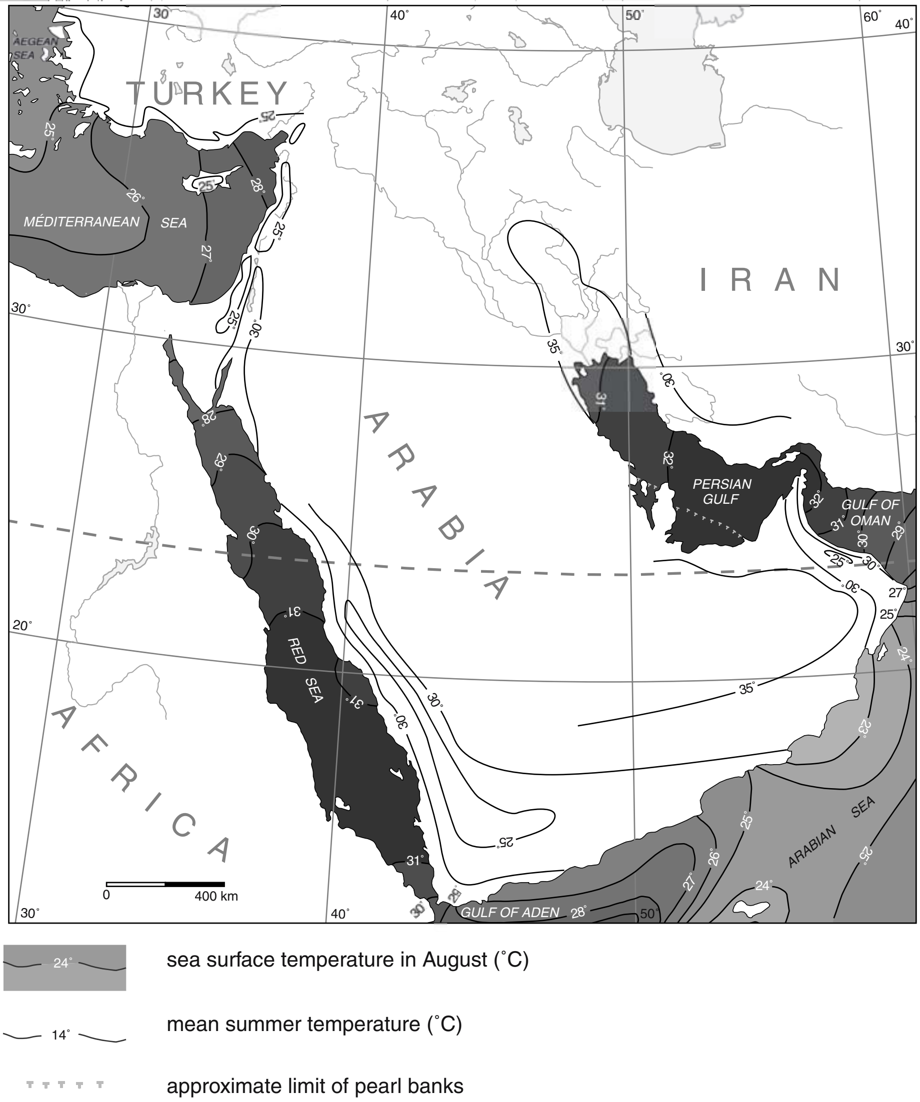

Figure A57 Mean summer temperatures.

the Arabian Sea, with surface current moving anticlockwise along the Iranian coast and coming down the Arabian coast, determining the distribution of salinity, temperatures, and nutrients. In summer, surface water attains temperatures over 32°C in the central part but very much higher in the Arabian lagoons. Temperatures in winter fall below 20°C in the northern part of the Gulf and even under 18°C north of Bahrain, where corals and mangrove cannot live (the absolute minimum is −5°C at Abadan). The range of variation in water temperature tends to increase away from the entrance of the Persian Gulf. The salinity of surface waters is high along the northern Iranian coast (39‰–40‰) but diminishes down to 30‰ west of the mouth of the Shatt al Arab, increasing then to the south along the Arabian coast (more than 38‰ east of Qatar and even 60‰ in the Gulf of Salwa).

The climate of the Persian Gulf area is hot and semiarid to arid. Mean monthly temperatures increase from 14°C at Kuwait to 18°C at Abu Dhabi in January and stand ca. 34°C in July all along the Arabian coast. Extreme temperatures are cool in winter and torrid in summer, the maximum absolute temperature reaches 49.2°C at Sharjah and 52°C at Abqaiq. Mean annual rainfall is less than 100 mm on the Arabian coast, slightly higher on the Lower Mesopotamian Plain and on the Iranian coast (ranging from 100 to 200 mm with a maximum of 230 mm at Bushire), rains occurring mainly in winter with a second peak in spring. The prevailing "Shamal" wind blows down the axis of the Gulf from the NW, then from the north to the south. Summer months are essentially calm, but during the winter the Shamal may be very strong. Mangrove stands are found at intervals along the Persian Gulf and *Avicennia* is the single species because it is the most resistant to low and high temperatures and to an intense evaporation resulting in high soil salinities. The northernmost site is in Bahrain and the greatest areas occur in the United Arab Emirates and in the Clarence Strait, in Iran, but the mangrove environment was richer and more extensive during the Middle Holocene and *Terebralia palustris*, frequent at that time, is now extinct (Glover, 1998).

The small but numerous streams draining the Zagros ranges are characterized by rough flash-floods and deliver a significant amount of terrigenous sediments. In contrast, the Arabian side of the basin is completely lacking in fluviatile influx so almost pure carbonate sediments predominate along the Arabian coastline. Oolitic sediments are forming both in exposed and sheltered environments and are particularly abundant in the southern part of the Gulf.

From the peak of the last glaciation until about 14,000 yr BP, the Gulf was free of marine influence. By 14,000 yr BP the Strait of Hormuz had opened up as a narrow waterway and by about 12,500 yr ago marine incursion into the central basin had started. The present coastline was reached shortly before 6,000 yr BP but the relative sea level then rose 1–2 m above its present level (Lambeck, 1996).

The difference in slope between the two flanks of the Gulf reflects the fundamentally different tectonic histories of Iran and Arabia. Its elongate axis separates two distinct geological provinces, the stable Arabian foreland and the unstable Iranian fold belt. The foundations of the modern Persian Gulf were largely laid in the Plio-Pleistocene Zagros orogeny.

The collision of the Arabian and Euro-Asian plates resulted in the formation both of a broad structural depression, about 2,000 km long, which extended from Syria to Hormuz and which eventually became an extensive sedimentary basin, and of the Zagros Mountains consisting in anticlines hugely folded with steeply dipping flanks, characterized by a

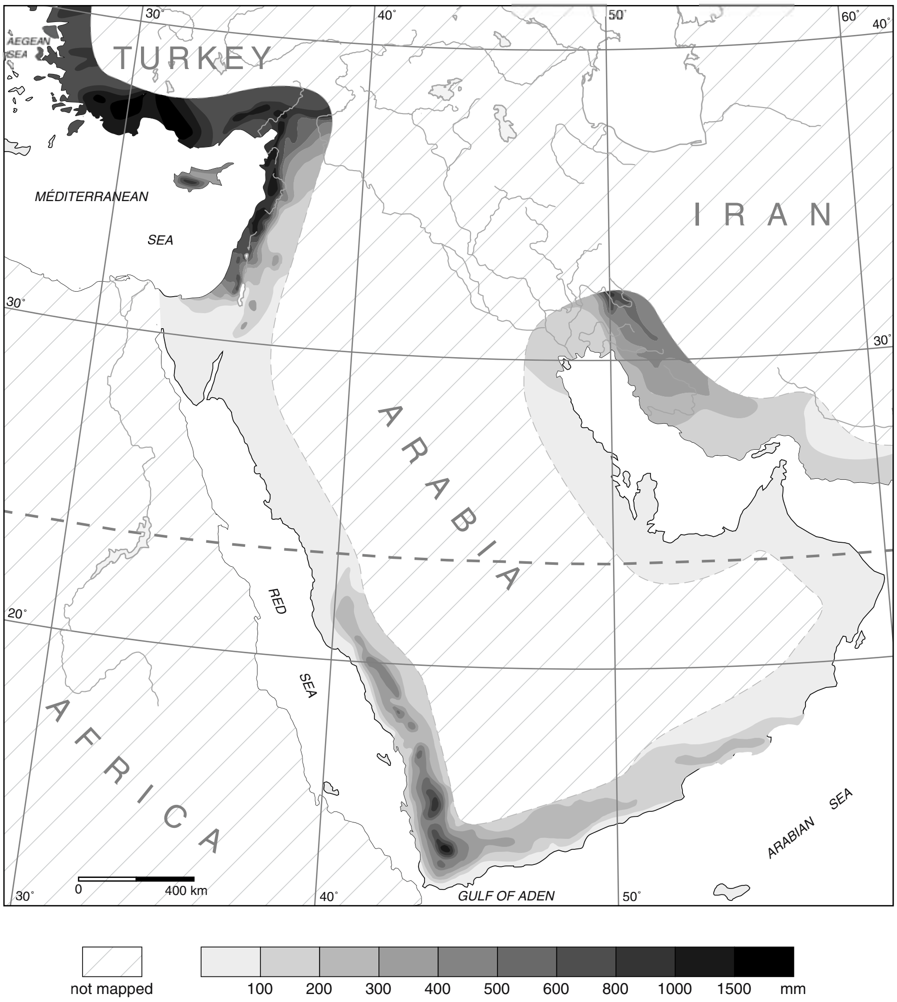

Figure A58 Mean annual precipitation in coastal areas.

NW–SE oriented belt, with mainly Late Cenozoic sedimentary formations in which clays, silts, and carbonates are predominant. The tectonic instability results in frequent earthquakes.

The low-lying Arabian coast and adjacent shallow seafloor are characterized by large, low-dipping anticlines with N–S or NE–SW trends, for example, in Bahrain and Qatar. In the Persian Gulf there are some 20 islands, as well as numerous submarine highs or shoals. Most of the islands and submarine shoals are clearly due to salt diapirism which, affecting the early Palaeozoic Hormuz salt series, was very active during the Plio-Pleistocene period and down to recent times (Kassler, 1973). The NW–SE Arabian coastline and the straight coastline from Abu Dhabi to Ras al-Khaimah may be partly controlled by faulting.

Regional features

The Shatt al Arab deltaic system. The extreme north of the Gulf corresponds with the deltaic system of the Shatt al Arab, the combined delta of the Euphrates, Tigris, and Karun. At the latitude of Basra, the two wide alluvial fans of Wadi Batin (Pleistocene) and Karun River (Holocene) restrict the width of the Mesopotamian plain, being responsible for the upstream development of extensive palustrine environments (Hammar Lake and marshes), where the Euphrates and Tigris deliver most of their water and suspended sediment. After loss of their suspended sediment in the marshes and shallow lakes, the clear waters are drained to the Shatt al Arab (Purser *et al*., 1982). In fact, much of the fluviatile waters and suspended sediment of the Shatt al Arab come from the Karun River. South of the two big alluvial fans, the Shatt al Arab forms a major deltaic system, dominated by strong tidal conditions, with large sebkhas flanking the waterways, wide tidal areas, sebkhas, marshes, and islands (such as the large Bubiyan Island). During the latter period of the flooding of the Gulf, in the mid-Holocene, much of these areas was likely to have been a shallow marine– lagoonal environment when sea level rose 1 or 2 m above its present level (Sanlaville, 1989, 2000).

The Arabian coast is low-lying, with only a slight relief corresponding to the broad gentle anticlines that trend N–S or NE–SW. South of the large Bay of Kuwait and down to the Gulf of Bahrain, the coast is low and almost rectilinear, with rocky promontories, wide sandy beaches, and extensive silted swamps. The sandy point of Ras Tanurah extends SSE for about 10 km. The Dammam Peninsula is related to an Eocene limestone anticline, as is Bahrain Island, rising to 122 m at Jabal Dukhan. The Gulf of Bahrain between Bahrain and the mainland is very shallow with extensive submerged spits and bars separated by long channels, while the Bahrain archipelago is surrounded by wide, partly coralline tidal flats, which are largely exposed at low tide. Near Bu Ashira, in Bahrain, a mangrove swamp is formed of thick but not very deep mud and small mangrove bushes where the fauna consists mostly of gastropods, especially of the Potamididae and Planaxidae families (Smythe, 1972). In the Qatar Peninsula, Eocene dolomite and limestone form massive and continuous outcrops forming cliffs separated from the sea by a strip of sebkhas, several kilometers wide. At the maximum of the Holocene transgression, the cliffs constituted an irregular coastline. After stabilization of the present sea level, fine sediment began to fill and regularize the embayments, creating hook-shaped spits at their southern ends and wide supratidal flats eventually formed on a complicated tidal channel system. Today, unusually strong easterly winds combine with high spring tides to flood the sebkhas as far inland as the ancient cliff. After a few weeks, evaporation of the flood water produces crusts of salt, gypsum, and dried algal mats which are progressively blown away (Shinn, 1973).

Most of the beaches are composed of carbonate sand and the bulk of this material is of biological origin, made up of small fragments of shells and corals. This beach complex includes subtidal and supratidal zones. On the eastern coast of Saudi Arabia, tidal flats occupy 30–40% in space of the numerous large or small bays along the coastline. They consist of mud and very fine sand deposited in bays and sheltered zones where wave energy is low and also of rock flats composed of mud, sands, and shell fragments cemented into beachrock known locally as *farush* (Basson *et al.*, 1977).

The mud flats generally consist of very fine, silty sediments which can be divided into several zones:

1. The marsh grass zone with plants such as *Phragmites communis, Aeluropus lagopoides, Bienertia cycloptera*.
2. The halophyte zone covered at high tide by only a few centimeters of water. It is the uppermost portion of the true intertidal region covered with *Arthrocnemon macrostachyum* and *Halocnemon strobilaceum*, with a far-stretching root system. In the mud surface there are sometimes to be seen the round holes of the crab *Cleistoma dotilliforme*.
3. The mangrove zone with *A. marina*, with trees 1 or 2 m high, with their characteristic pneumatophores.
4. The algal mat zone composed of cemented sediment with blue-green algae and diatoms. Microscopic animals live in this mat, including gastropods, ostracods, nematods, flatworms, copepods, and oligochaete worms.
5. The *Macrophtalmus* zone between the mangrove zone and the low-tide level. These *crabs (Macrophtalmus depressus* and *Macrophtalmus grandidieri*) live in a burrow in the mud.
6. The Cerithidae zone whose density can reach 2,100 individuals per square meter, with sometimes *Murex kuesterianus*.
7. Tidal creeks or drainage channels, dug by ebb tide, are a characteristic feature of the muddy tidal flats, with the presence of tide pools, about 2 or 3 m wide, 50 cm deep, and 10–30 m long, subject to great fluctuations of temperature and salinity. These tidal creeks are inhabited by a great variety of animals (shrimps, fishes, swimming crabs), which find there a shelter from the predators and rich food.
8. The sand flats frequently have a grayish color due to the presence of organic matter. At low tide, one can observe ripple marks produced by the ebbing water. Often, sands constitute a pellicular layer overlying the rock or a beach rock. The tidal channels are not strongly marked in that zone, where many crabs live, such as *Ocypode saratan, M. depressus, M. grandidieri Scopimera scabricauda*.
9. Rock flats also exist, for example, in the Gulf of Salwah, in bays where beach rock find exceptional conditions of formation. The *farush* consists of broken shells, sand, and mud cemented together. This type of environment presents very great biodiversity with polychaete worms, gastropods (*Thais* sp., *Monilea* sp., *Trochus* sp., *Littorina* sp.) pelecypods (*Pinctada* sp., *Isognomon* sp., *Anomia* sp., *Barabatia* sp.) and decapod Crustacea (*Alpheus* sp., *Pilumnus* sp., *Xantho* sp.), and also algae such as *Enteromorpha* sp., *Rhizoclonium kochianum, Achnanthes* sp.

Middle Holocene beach sediments are to be found 1 or 2 m above the present sea level, indicating a higher sea level than today. Pleistocene marine calcarenites are also known in that area where some paleo-wadis (W. Ar Rimah, W. As Sahba, and W. Ad Dawasir) have built gravel fans of enormous size.

The relatively linear character of the northern Arabian coast is modified by the Qatar Peninsula which strongly influences the marine currents and patterns of sedimentation on the SE side of the Persian Gulf. To the east of the Qatar Peninsula there is a broad, shallow area, 10–20 m deep, studded with numerous shoals and salt dome islands. An irregular bathymetric ridge, the *Great Pearl Bank Barrier*, extends eastwards from Qatar along the central part of the United Arab Emirates coast, whose coastline is characterized mainly by low, evaporitic, supratidal flats, which locally attain 10 km in width, and by storm beaches in more exposed settings.

The western and central parts of the Trucial coast are protected laterally by Qatar Peninsula and the Great Pearl Bank barrier. The coastline is characterized by a complex of islands and peninsulas. Each island is growing by accretion around a Pleistocene rock core. Accretion also occurs as tails of sediments, which locally form tombolos. The inter-island channels end seawards in spectacular oolite deltas. Small swamps, colonized by the black mangrove *A. marina* and other halophytic plants, have developed, favoring the deposition of carbonate muds. The shallowness of the lagoons, together with the protection provided by the coastal barrier complex has led to a very active intertidal flat accretion which has produced the wide sabkhah plain, approximately 5 km wide, during the last 4,000 years. The high salinity and temperature of the water, together with the extreme aridity, have led to the extensive development of dolomite and other evaporite minerals (mainly gypsum and anhydrite) within the supratidal sediments (Evans *et al.*, 1969; Purser and Evans, 1973). As the lagoons become completely filled, aeolian coastal sands may transgress over them.

The northern part of the coast is unprotected and direcly faces the entire length of the Gulf. It suffers from the effects of maximum wave fetch and a strong eastward longshore transport, which resulted in the development of storm beaches backed by coastal dunes mainly composed of skeletal carbonate sands, and the construction of major spit systems; between Sharjah and Ras al Khaimah, a series of subparallel spits has prograded the coastline some 5–10 km seaward, bringing vast lagoons into existence, the biggest being the Umm al Qowayn lagoon, which shelters vast mangroves. Further inland, the extensive quartzose dune fields of the Arabian desert extend up to the alluvial fans which skirt the Oman mountains. The NE section of the Trucial coast end in the cliffs and rocky shorelines of the Musandam Peninsula. They are mainly composed of limestone and are drained by a series of deeply incised wadis which terminate in spectacular alluvial fans, some of which reaching the coast.

The northern Persian Gulf coast is mountainous, with ridges up to 1500 m high formed by hugely folded, anticlines but the intensity of the folding diminishes markedly seawards where Pliocene folding produced regularly spaced elongate synclines and anticlines. In the south many anticlines are cut by salt diapirs. The chain of islands in the Gulf (Kharg, Shuaib, Qeshm, etc.) forms part of the Zagros foothill belt. The Zagros is seismically active, earthquakes are quite frequent and much detrital sediment is deposited in the form of alluvial fans delivered through short, ephemeral streams perpendicular to the main structural axis.

North of Bushehr, the coast is at first swampy, then low and sandy. South of Bushehr, the Iranian shores are essentially linear and rocky, the mountains rising abruptly above the sea, with narrow coastal plains associated with the estuaries of numerous small rivers flowing down the Zagros mountains. The coastal valleys yield evidence of two distinct fills separated by a phase of incision. According to artifacts, the deposition of the older ceased by 6,000 BC. The process of the younger began about 1,250 years ago. Most of the streams are now incising their channels (Vita-Finzi, 1978).

The Mehran River, oriented parallel to the Gulf, is situated along the axis of a syncline and has developed a big marine alluvial-fan delta, prograding into the Clarence Strait, between the mainland and Qeshm Island. Its very flat fan is dominated by silty and sandy deposits covered upstream by scattered vegetation of *Chenopodiaceae* and *Graminae*. Downstream there are mud banks with large desiccation polygons, the shores of the strait and of the smallest tidal creeks being populated by a dense belt of mangroves (*Avicennia*). The mud banks area, 15 km wide, includes a series of extensive, mostly bare tidal flats with a characteristic network of tidal channels (Baltzer and Purser, 1990).

The Persian Gulf area is the foremost producer and exporter of oil in the world and is now experiencing huge transformations. The landscapes have been strongly altered by the creation of harbors, channels, and artificial islands, the filling of lagoons and bays, and the construction of roads and towns. Oil pollution is a great danger and the equilibrium of the sandy shores is threatened.

The Arabian Sea coasts

Climate and hydrology

The coastline of the Arabian Sea, along the southern coast of Arabia, the Gulf of Oman and the Iranian Makran, is very hot and arid. Mean temperature in January is >20°C (22.8°C at Salalah and 25.6°C at Aden) and the maximum absolute temperature in August is >45°C (46.7°C at Mascate and 47.2°C at Masirah). Mean annual rainfall is <100 mm (38 mm at Aden, 94 mm at Masirah) and the rainfall variability is extremely high. Winter is the main rainfall period, except on the coast of Hadramaut and Dhofar where rainfall occurs mainly in summer. Precipitation over the coastal area of Salalah is usually in the form of a fine drizzle with daily totals seldom exceeding 5 mm but the presence of fog (on average 54 days per year) has a marked effect on vegetation growth.

As a whole, the Arabian Sea is very deep with a rather narrow continental shelf. Coral reefs exist intermittently where the continental shelf is wider. The tidal range is generally between 2 and 4 m. All during the year, the coast is buffeted by the heavy Indian Ocean swell. Winds and currents are parallel to the coastline in accordance with the monsoon circulation. The NE monsoon begins in October but is mainly characteristic between November and March, with a maximum in December and January. Winds are moderate and the sea propitious to navigation. The SW monsoon is longer and stronger. It begins in April and is very strong from June to September. Then the sea is very rough and navigation is dangerous so the fishers do not leave the harbors. Strong southwesterly winds blow along the southern coast of the Arabian Peninsula, forcing the ocean surface in a northeasterly direction and causing a compensatory upwelling of cold subsurface water. Along the Dhofar coast, between Ras Fartak and Masirah, sea surface temperature can be up to 5°C cooler than the ambient offshore values. These cold waters are rich in nutrients that trigger phytoplankton blooms and make for a great wealth of fish, 70% of the biological sediment is deposited during the summer monsoon months. Tropical storms and cyclones occur from time to time, almost entirely confined to May–June and October–November and cross the coast of Yemen and mainly Oman, generally between Salalah and Masirah, about once every three years. They occur more frequently along the Makran coast but are fewer in the Gulf of Oman. Well-developed mangrove stands are found at intervals along the Arabian Sea shore, mainly in the bays or lagoons.

Regional features

The southern coast of Arabia is more than 2,600 km long between the Bab el-Mandeb and Rass el-Hadd. It corresponds to a young rift border; its structure is very complex and the coast is often bordered with high mountains. Volcanic rocks outcrop here and there, particularly in the western part where they appear as islands and promontories, for instance in the Perim Island, at the entrance of the Red Sea, in the Aden district where extinct volcanoes are connected to the continent by tombolos, or in the Shuqra area. The Old Aden settled in a crater whose rim reaches the height of 551 m at the Jabal Shamsan. Narrow plains bordered by sandy beaches alternate with high rocky cliffs. At Ras Fartak, vertical cliffs reach up to 580 m high. About 450 km to the south, Socotra is a barren high (1,519 m) island of limestone and granite, 112 km long and 15 km wide with generally steep coasts and reef-fringed promontories. In eastern Dhofar, the Kurya Muria archipelago is edged with fringing reefs. The eastern part of the southern Arabian coast is low, sandy, and barren, notably in the Wahiba Sands area, in Oman. This coastal area belongs to the Sudanian vegetation region, well differentiated from the adjacent Sahara–Arabian region by hundreds of genera and thousands of species that are not to be found in the Holoarctis, especially different species of Acacia, mainly *Acacia tortilis, Capparis decidua, Calotropis procera, Panicum turgidum, Indigofera spinosa*, etc. (Zohary, 1973).

The Arabian coast of the Gulf of Oman, between Ras al-Hadd and the Strait of Hormuz, in the Musendam Peninsula, sweeps in an arc, some 650 km long, dominated by an isolated folded mountain range, the Jabal al-Hajar, whose highest point rises to 3,035 m. At either end of this range the mountains plunge straight into the sea and the coast is rocky and cliffy, with deep water inlets. In the center of the arc the mountains are separated from the sea by the great Batina Plain, some 280 km long and 20–30 km wide. The coast is sandy with a strip of sand dunes. Behind it, the piedmont plain is covered with silts, gravels, and conglomerate laid down in a now semi-fossilized drainage system. During the Quaternary, the deposition of wadi sediments occurred during the interglacial pluvials, whereas erosional processes predominated during the cooler aridials and numerous sea-level terraces were formed during the interglacials; traces of three coastlines dating from the last interglacial can be found and the Holocene sea level was higher than the present one (Hanns, 1998).

The Makran coast is part of an accretionary wedge of late Cretaceous to Holocene sediments which accumulated near an oceanic subduction margin, between two major strike-slip fault zone, the left-lateral Chaman fault zone to the east and, to the west, the right-lateral Zendan fault, which separates the simply folded Zagros Ranges from the turbidites and ophiolitic melanges of the Inner Makran.

The Makran ranges rise irregularly from the coastal plain in a series of ridges underlain by folded sedimentary rocks. Along the coast, outcrop mainly Pliocene thick, neritic, and monotonous sequences of calcareous mudstones (the so-called *Chatti mudstones* of Pakistan). They have been locally affected by gentle folding but the beds are often sufficiently undeformed to produce extensive and almost horizontal platforms. So, the coast is marked by a series of prominent headlands (Konarak, Chah Bahar, Gavater, etc.) separated by low areas. These rocky headlands rise as isolated flat-topped hills formed from marine sandstone, conglomerate, and coquina of the Ormara and Jiwani Plio-Pleistocene formations. The Konarak terrace, one of the best developed, is an 18 km long and 300–900 m wide platform. Most of the scientists who investigated this area were strongly interested in these platforms which exhibit spectacular stepped shore platforms and raised beaches (Page *et al*., 1979; Snead, 1993; Reyss *et al*., 1998). On Qeshm Island as many as 18 marine terraces were identified, up to 220 m in elevation, and as many as 19 levels, up to 246 m, near Chah Bahar. The lowest levels, less than 4 m high, were 14C dated as Holocene; for higher levels, up to 26 m in elevation. Uranium series analyses gave apparent ages between 100 and 140 ka BP, and therefore may be ascribed to oxygen-isotopic stage 5e (or 5c). These dates show that uplift rates did not exceed 0.2 mm/year during the late Quaternary, except in areas where salt domes exist, for example, on Qeshm Island where uplift rate was faster (6 mm/year). Deposits of the oldest levels are not suitable for dating because the shells and corals are very recrystallized. These marine terraces give evidence of the complex interrelationships of tectonism, coastal erosion and sedimentation, and eustatic sea-level changes (Reyss *et al*., 1998).

However, the main features of the coastal area could be the low-lying alluvial plains forming a coastal strip, 5 to more than 20 km wide, between the coastline and the mountains (Page *et al*., 1979). Several stepped terraces partly rocky and partly alluvial exist at the foot of the Makran ranges. The streams have eroded the siltstone and mudstone bedrock into low-lying pediments and built huge deltas. Locally, the plain is covered with sand dunes. Typical mud volcanoes outcrop as well in Makran as on the coastal plain of the Persian Gulf. In the coastal plain there are many shore deposits, series of prograding accretion beach ridges, isolating lagoons and marshes which shelter vast mangroves, before being filled by silt. In some places, ancient islands have been connected to the mainland by one or two spits which finally form a tombolo (Ras Tang, Konarak). So, the 19.3 km-long Gurdim terrace paralleling the coastline is connected with the coastal plain by a wide 12.8 km tombolo, displaying well-developed beach ridges. The Makran coast is unprotected and during the SW monsoon and especially in tropical storms and cyclones, the ocean and surf are extremely rough. Erosion continues to affect the headlands, but elsewhere progradation seems to have dominated along the flat sandy areas since the maximum of the postglacial transgression. Radiocarbon dates for shell samples collected in the central part of the tombolo of Konarak and elsewhere on the ancient beaches of the Makran coast gave ages between 4870 ± 100 yr BP and 6255 ± 320 yr BP (Page *et al*., 1979; Vita-Finzi, 1981). The same observations were made on beach deposits of the Pakistan Makran (Sanlaville *et al*., 1991). So, in Makran the coastline has been prograding since the Middle Holocene owing to both slight uplift and marine or alluvial sedimentation.

ASTEROID-IMPACT COASTS

A highly unusual category of general coastal morphology is created by asteroid impacts at some time in the geologic past. Asteroid impact creates a circular or ovoid crater beneath which is a brecciated zone that extends many thousand meters below the former surface of the Earth's crust. The eroded relics of these ancient craters have been called "*astroblemes*" (Dietz, 1961).

Three coastal areas in North America are believed to owe their morphology, at least in part, to asteroid impact. They are:

1. *Chesapeake Bay, and adjacent areas of Maryland and Virginia.* The coast is characterized by an unusual pattern of a drowned dendritic drainage system, that is to say, organized like the branches of a well-shaped tree. It is fed by the valleys of the Susquehanna, Potomac, and Rappahanock rivers. The asteroid or "bolide" struck 35.2 (+/−0.3) million years ago, in Late Eocene times in soft coastal plain and shelf sediments which to the impacting object, about 3–5 km in diameter and travelling at about 80,000 km/h, would have had the consistency of warm butter. Molten glass shards (cooled as tektites) were strewn over 9 million km^2. Penetrating about 600 m of youthful sediments it continued to a limited depth in the crystalline basement. The principal crater is about 85 km in diameter, and overlying (postimpact) sediments have slowly sagged into the depression and the surrounding area. In the center of this astrobleme, there is an inner depression with a peak in the center (just as in some other impact sites such as the Miocene Ries crater of Germany). A much larger area extending up to 90 km from the

principal crater rim is marked by a belt of radial fractures spreading out over much of the Salisbury Embayment. A polymictous debris plume reached NE, up the Atlantic coast at least 400 km. The subsurface structures have been proven by extensive seismic profiling and drilling (Poag, 1997). In the 35 Myr since the impact, the site has been the focus of differential compaction and subsidence (with eustatic revivals) that determines the general form of today's coastline. Another but much smaller asteroid fragment at the same time created the 25-km-wide Toms Canyon crater 140 km east of Atlantic City.

2. *Gulf of Mexico (Chicxulub crater)*. This impact occurred near the west side of the Yucatan peninsula of Mexico about 65.2 (+/−0.4) million years ago, generating a crater 180 km across. Its ejected debris has been traced to a semicircular rim extending in an arc through central Texas which suggests an incoming orbit heading NNW. This event was destined to become the Cretaceous/Tertiary boundary, marking a revolution involving major biotic extinctions, notably the dinosaurs, ammonites, and other classes (75% of all marine species). While the western and northern borders of the Gulf of Mexico had already developed as a broad arc in Mesozoic times, its southern border is marked by a meridional fault system that today truncates the western borders of Yucatan, a nearly horizontal platform of Miocene limestones. The impact theory, initiated by W. and L. Alvarez in the late 1970s (from evidence in Italy) triggered an intense interest that has been well reviewed by Marvin (1990) and expanded to events throughout the entire Phanerozoic (Rampino and Haggerty, 1996). It seems likely that anomalous patterns of coastlines worldwide should be explored for possible astrobleme ancestry.

3. *Hudson Bay*. The present form of this embayment is an epicontinental sea bounded particularly in the southeast by an extraordinary arcuate coast that coincides with an Archaean/ Proterozoic boundary injected by lopolithic sills of diabase. An ancient astrobleme is suggested by Dietz (1961).

ATLANTIC OCEAN ISLANDS, COASTAL ECOLOGY

While many islands lie in Atlantic waters, this entry will focus only on a few of the most significant to illustrate a variety of insular habitats from the Northern and Southern Hemispheres (Figure A59). Except for the Faeroe, Azores, Canaries, Bermudas, Ascension, Gough, and the islands of the Scotia Arc, relatively little is known about the coastal ecology of most of the islands scattered in the Atlantic. When available, data on the general biodiversity, the intertidal and subtidal zones, and the seasonal variation of the plankton will be presented, together with some aspects of the terrestrial ecology relevant to the coast and typical of islands.

The fauna and flora of most islands have several features that distinguish them from those of continents. Many of these are related to difficulties of dispersal. Organisms that can disperse well are more likely to be found on islands than those that cannot. Species of plants and animals on islands show equilibrium between new arrivals and local extinctions. Generally, the number of species is greater on large islands than small islands, varying in function of their isolation from other landmasses (Table A5). Thus, islands usually present an impoverished terrestrial and marine wildlife compared to equal areas of mainland (Williamson, 1981).

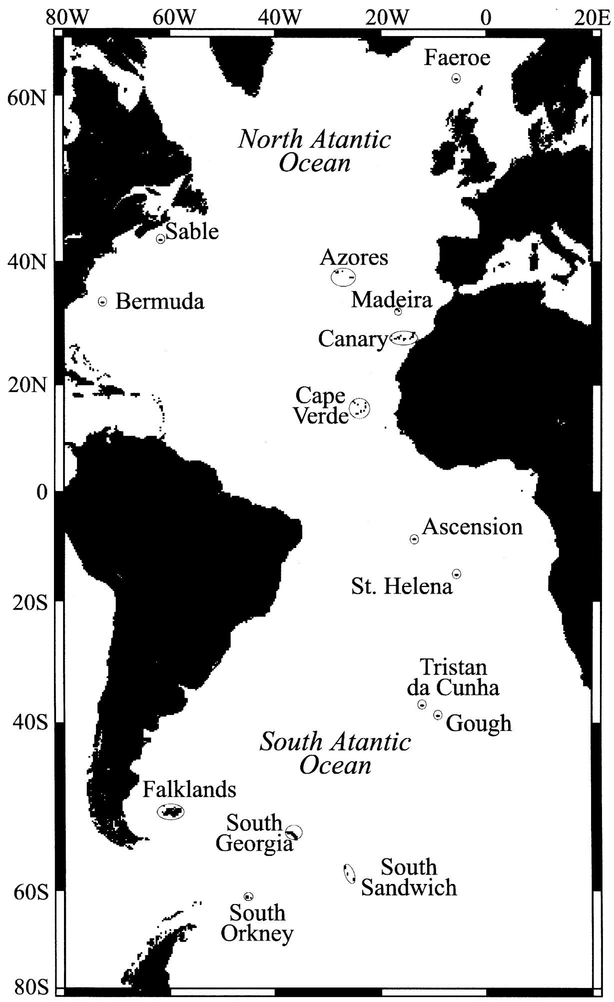

Figure A59 Map of the Atlantic Ocean locating the islands discussed in this entry.

Table A5 Isolation index of different islands or group of islands in the Atlantic Ocean (compiled from the United Nations Environment Programme)

Islands	Isolation index[a]
Bermuda	91
Azores	74–77
Madeira	66
Canary	12–41
St. Helena	113
Ascension	119
Tristan da Cunha	78
Gough	125
Falklands	59
South Georgia	113
South Sandwich	71–76
South Orkney	28–31

[a] The isolation index is the sum of the square roots of the distances to the nearest equivalent or larger island, the nearest island group or archipelago and the nearest continent. A range indicates the isolation variation among the different islands composing an archipelago or group of islands.

Faeroe (Denmark)

The Faeroe group comprises 1,398 km^2 of rugged and mountainous islands located just north of the United Kingdom, on the edge of the Rockall Rise. The coastline is indented, with fjord-like inlets, the marine life is abundant and the climate is mainly temperate oceanic.

As their situation in the transitional zone between the North Atlantic and the Arctic, the Faeroe Islands harbor a flora and fauna made up of both boreal and arctic species (Blindheim, 1989). The phytoplankton productivity of this area is considered to be one of the greatest in the world oceans. The blooms occur in March and consist mainly of diatoms (Braarud *et al.*, 1958). Compared to the spring bloom, the summer abundance of pelagic algae is rather poor, but more diverse (Blindheim, 1989). The zooplankton bloom begins around March–April, in conjunction with the phytoplanktonic bloom. The summer pelagic fauna is dominated by copepods such as *Calanus finmarchicus*, *Pseudocalanus minutus*, and also by the arrow worms *Sagitta elegans* and *Eukrohnia hamata*. The Euphausiacea represent another important component of the zooplankton. Common pelagic fish in the waters off Faeroe are herrings, Greenland halibuts, blue whittings, redfish, cods, and haddocks.

On the vertical slopes of the coast, from the lowest water spring tide mark, every centimeter of the subtidal benthic zone is covered in a profuse carpet of life. Kelp and other algae are gradually replaced by sea anemones and sponges in deeper water.

Marine birds like the puffin *Fatercula arctica* and marine mammals such as the pilot whale *Globicephala melaena* and the white-beaked dolphin *Lagenorhynchus albirostris* are abundant.

Sable (Canada)

Sable Island is located approximately 300 km southeast of the Canadian province of Nova-Scotia. The island itself is about 40 km long and 1 km wide, hence its temperate climate is markedly influenced by the sea. Ocean waters maintain winter air near freezing and keep summer temperatures below what would be considered room temperature. Fierce ocean currents sweep around the island causing the peculiar shifting of sand that constantly changes its contours. Between the dunes are numerous depressions usually filled with freshwater, and supporting a variety of aquatic plants and insects. A total of 179 species of terrestrial plants can be found on Sable Island. Along the coast, the moving sand is stabilized by the marram *Ammphila breviligulata*, the sandwort *Honckenya peploides*, and the beach pea *Lathyrus maritimus*.

Since all the shores of the island are sandy, benthic invertebrate diversity is low, although the sand dollar *Echinarachnius parma*, shrimp *Crangon septemspinosa*, and gastropod *Lunatia heros* are observed commonly. Among fish larvae, the pollock *Pollachius virens* and haddock *Melanogrammus aeglefinus* have been found around Sable Island. The American sand lace, smooth skate, yellowtail flounder, Atlantic cod, Atlantic mackerel, witch flounder, and spiny dogfish are also present.

Sable Island is the only known nesting place for the ipswich sparrow *Passerculus sandwichensis princeps*. Over 2,500 pairs of terns, mostly Arctic terns *Sterna paradisaea*, nest on the island along with over 500 pairs of black-backed gulls *Larus marinus* and 2,000 pairs of herring gulls *Larus argentatus*. A few sandpipers *Calidris* spp. and semipalmated plovers *Charadrius semipalmatus* also nest on the island and broods of black ducks *Anas rubripes* and red-breasted mergansers *Mergus sarrator* are produced near the ponds. During migration and after strong gales, nearly any species of bird in eastern North America may show up on Sable Island. About 300 Sable Island horses, introduced in 1738, are now living wild on the island. Sable Island also supports the largest breeding colonies of gray seals *Halichoerus grypus* and harbor seals *Phoca vitulina* in the western Atlantic Ocean. Harbor seals use Sable Island as a mating ground (Coltman *et al.*, 1999).

Not far from Sable Island is the Sable Gully, which is the largest marine canyon in eastern Canada, and is considered an important habitat for a wide diversity of marine life, including over 200 vulnerable northern bottlenose whales (*Hyperoodon ampullatus*).

Bermuda

The island group of Bermuda is located in the western central region of the North Atlantic oceanic gyre known as the Sargasso Sea, approximately 1,250 km southeast of New York City. Bermuda comprises about 130 islands and islets covering a land of just over 50 km^2. The climate is wet subtropical. These islands are characterized by tidal and nontidal ponds, rocky coasts, sandy beaches, and shallow marine bays. They harbor the most northerly mangroves in the world and the most northerly coral reefs in the Atlantic, including coral/algal and algal/vermetid reefs.

The ocean temperature of the surface waters off Bermuda varies seasonally between 18°C and 28°C. This island group can be considered a semi-tropical area where ocean conditions differ markedly from those encountered further south in the true tropics. In Bermuda, winter cooling and mixing of the surface layers occurs and a seasonal thermocline develops from late spring through fall (Morris *et al.*, 1977). The phytoplankton of the Sargasso Sea that surrounds Bermuda shows low concentrations, especially during spring and summer with about 3,000 cells L^{-1}. The density of phytoplankton reaches a maximum in fall and winter with 50,000 cells L^{-1}. In summer, the phytoplankton is mainly composed of coccolithophores, dinoflagellates, and diatoms. The main species, especially between late fall and spring, is the coccolithophore *Coccolithus huxleyi*. A spring bloom of diatoms, 200,000 cells L^{-1}, occurs around April. Dinoflagellates dominate in late summer concurrent with the lowest productivity of the year.

The zooplankton of the waters surrounding the Bermuda reef platform and of the inshore waters are distinct from the oceanic species. The larvae of numerous benthic invertebrates are a significant component of the reef and inshore zooplankton, which is 5 to 10 times more abundant than in the Sargasso Sea, fluctuating around 2,000 individuals m^{-3}. Maximum zooplankton abundance generally occurs after the phytoplanktonic bloom in late spring-summer and again in winter, following the spring and fall increases of phytoplankton. Both zooplankton peaks are of only short duration and are followed by rapid population declines. Copepods are the most abundant members of the inshore populations and dominate in summer and fall, representing about 70–95% of all species present. In winter, the appendicularian *Oikopleura graciloides* dominate and fish eggs are prevalent in spring. Copepods nauplii and gastropod veligers are abundant in spring and again in early winter. Though less abundant, medusae, cladocerans, decapod and fish larvae are also part of the zooplankton of Bermuda (Morris *et al.*, 1977).

The benthic habitats of Bermuda comprise rocky shores of the intertidal and subtidal areas, gullies, crevices and caves, muddy bottoms, mangroves, sandy-bottoms, and coral reefs. The coral reefs of Bermuda can further be divided into four different types: the ledge flat reef, the patch reefs, the coral knobs, and boiler reefs (Morris *et al.*, 1977). The muddy substrata, mainly located in shallow protected areas, are associated with mangroves but also occur in the deepest bassin depressions. The sublittoral zones around Bermuda, including the surroundings of coral reefs, are mostly sandy. Numerous algae and sea grasses cover the shallows and offer home or shelter to various invertebrates. Burrowing species are the most abundant group of invertebrates present.

The rocky shore, sublittoral, and coral reef habitats shelter the greatest number of species. Overall, 118 common species are known from the rocky-shore subtidal area, including several algae, cnidarians, mollusks, and echinoderms. The rocky intertidal zone harbors 82 common species, dominated by algae, mollusks, and crustaceans. Many of these species live in the lower fringe or directly in tide pools. In the coral reefs, there are about 79 common species, mainly corals, but also algae, sponges, mollusks, and crustaceans. Mangrove swamps sustain about 21 species, dominated by algae, shrubs, mollusks, crustaceans, and bryozoans (Morris *et al.*, 1977).

Macronesia

Macronesia encompasses the islands of Azores, Madeira, Canaries, and Cape Verde, which are located in the northeastern Atlantic.

The Azores consist of 10 Portuguese islands covering 2,244 km^2 and having a highly volcanic topography with many peaks and hollows (Bird, 1985). They lie about 1,500 km off the main coast of Europe and their climate is moist-moderate with abundant rainfall.

Currently, 274 species of algae are listed in the Azores, including 45 Chlorophyta, 52 Phaeophyta, and 177 Rhodophyta, among which are 10 endemic species. Although the Azores share algal biotopes with the Atlantic coast of mainland Europe, intertidal and subtidal seashores in the archipelago mostly lack the functionally important community of fucoids and laminarians widespread in the North Atlantic. Large brown algae such as *Fucus spiralis* are sporadic in the Azores, while *Laminaria ochroleuca* is known from only one location. Other large brown algae (*Cystoseira* spp., *Sargassum* spp.) occur in deep sheltered pools, lagoons, and some subtidal biotopes.

The intertidal areas of the Azores typically present three distinct zones. The highest band is dominated by littorinids (*Littorina striata*, *Melaraphe neritoides*). The upper boundary of the second zone is marked by the presence of barnacles *Chthamalus stellatus* and some small shoots of *Ulva rigida*, *Gelidium pusillum*, *Gelidium microdon, Ralfsia verrucosa*, and *Enteromorpha* spp. The third zone comprises an extensive area dominated by *G. pusillum* and *Centroceras capillacea*. In the adjacent subtidal area, the algal community changes along the depth gradient. *Ulva* spp., *Hypnea musciformis*, and *Asparagopsis armata* dominate the shallow depths. The 10 m depth community is characterized by the algae *Dictyota dichotoma*, *Halopteris* spp., and *Stypocaulon scoparia*, while *Zonaria tournefortii* is dominant at 30 m depth. With the exception of mollusks *Bittium* spp., that can be found everywhere, differences in the invertebrate fauna are also observed along the depth gradient. Sponges are an example of this: *Tethya aurantium*, *Halichondria panicea*, *Hymeniacidon sanguinea*, and *Timea unistellata* occur in the intertidal zone, whereas *Petrosia ficiformis*, *Erylus discophorus*, *Myxilla macrosigma*, and *Clathrina coriacea* are found between 10 and 15 m depth (Neto and Avila, 1999).

The southern oyster drill *Stramonita* (*Thais*) *haemastoma* preys intensively on the populations of *Mytilus edulis*, *Patella candei*, *Patella aspera*, *Crassostrea virginica*, *Ostrea equetris*, *Ischadium recuvrum*, *Balanus eburneus*, *Balanus amphitrite*, and *Chthamalus stellatus* which colonize the intertidal zone of the Azores. Sea urchins *Arbacia lixula* are also common on the rocky shores.

Over 175 species of mesopelagic fish are believed to occur around the Azores. The most widely spread families are included in the Stomiidae, Gonostomatidae, Sternoptychidae, and Paralepididae. The yellowmouth barracuda *Sphyraena viridensis* is a common pelagic coastal predator, mostly preying on juvenile horse mackerels *Trachurus picturatus*.

Large numbers of juvenile loggerhead sea turtles *Caretta caretta* thrive off the coast of the Azores. The sperm whale *Physeter macrocephalus* is the most common whale in Azorian waters. A total of 23 species of cetaceans have been observed, including the false killer whale *Pseudorca crassidens*, Risso dolphin *Grampus griseus*, bottlenose dolphin *Tursiops truncatus*, common dolphin *Delphinus delphis*, stripped dolphin *Stenella coeruleoalba* and spotted dolphin *Stenella frontalis*. *Balaneoptera acurostrata* and *Globicephala macrorhynchus* have also been recorded in winter and early spring.

The Portuguese archipelago of Madeira consists of one large and several small islands lying some 600 km off the coast of Morocco and representing a total land area of 810 km^2, mostly made up of extinct volcanoes. The climate is semi-arid subtropical. The slopes are steep, but well vegetated and terminated in high coastal cliffs. Beaches are mainly gravely, but beach borders are also found. The coastal marine fauna of Madeira is a mixture of species with Mediterranean affinities and distinctly tropical species that often reach their northern limit there (Wirtz, 1999).

Little is known of the precise marine ecology of this group. The sea urchin *Diadema antillarum* is an extensive herbivore that preys on algal bed. Thirty-eight species of fish are easily observed in the coastal waters of Madeira. The endangered Madeira soft-plumaged petrel *Pterodroma mollis madeira* occurs there, as well as the Mediterranean monk seal *Monachus monachus*, which breeds on the island. In fact, Madeira is one of the most important remaining localities for this species threatened with extinction.

The Canary group comprises 7,500 km^2 of dry islands spreading close to the coast of northwest Africa. These Spanish islands are mostly surrounded by sandy beaches and rocky shores and their climate is semi-arid subtropical.

In the Canary Islands, the chlorophyll concentrations range from 0.09 mg m^{-3} to 0.25 mg m^{-3}, with deep maxima between 75 and 100 m depth. The biomass in the shallower water corresponds to 2,000–28,000 cells L^{-1} near the coast (Ojeda, 1996). Some coastal lagoons are characterized by the conspicuous presence of Cyanophyta and Chlorophyta up to 10^5 cells ml^{-1}, thus imparting a green coloration to the water.

Primary productivity is high in the water off Canary Islands. The northern portion of the islands supports a high phytoplankton production where the Canary current collides with the coast. The biomass is not large but the turnover is pronounced. Bacteria associated with phytoplankton are abundant at the outer edge of the main phytoplankton concentration. Zooplankton accumulates in the marginal southern areas and is quite important in the upwelling area in the upper 50 m of the water column. The zooplankton community is generally composed of copepods, but mysidacea are usually important in all regions. Zooplankton also includes amphipods, ostracods, and mysids.

The sea urchin *Diadema antillarum* is commonly observed. Falcon *et al*. (1996) found 76 species of coastal fish around the Canary Islands, the most common being *Abudefduf luridus*, *Canthigaster rostrata*, *Chromis limbatus*, *Sparisoma cretense*, and *Thalassoma pavo*. Lorenzo (1995) indicated that many waders (*Charadrius alexandrinus*, *Calidris alba*, *Arenaria interpres*) were found in intertidal lava platforms and in supratidal lagoons of the Canary Islands.

St. Helena and Ascension (United Kingdom)

St. Helena is an isolated volcanic peak rising 4,400 m from the seafloor, slightly east of the mid-Atlantic ridge, about 1,900 km off the coast of Angola. It covers 125 km^2 as a deeply eroded volcanic cone. It has a dry subtropical climate. The bay on the south coast has a beach backed by calcareous dunes, which have been driven far inland by the southeast trade winds. The coastal areas are rugged and barren whereas the higher elevations in the center of the island present a lush vegetation (Bird, 1985).

St. Helena's isolated position in the South Atlantic has given rise to an unusual and remarkable land and marine flora and fauna. There are 60 species of flowering plants, of which 49 are endemic. Thirteen endemic species of ferns are present, almost all on the verge of extinction. Of 1,100 land invertebrates, 400 are unique to St. Helena. At least six unique land birds once occurred on St. Helena, only one, the wirebird *Charadrius sanctae helenae*, survives today. Also, modest seabird populations nest on isolated cliffs and rocks. The island is home to the largest species of earwig, *Labidura herculeana*. Endemic species of shrimps *Typhlatya rogersi* and *Procaris ascensionis* are present in rock pools. Ten shore fishes are found only around the island, and 16 more are found only here and at Ascension. The green turtle *Chelonia mydas*, and the hawksbill turtle *Eretomochelys imbricata* may breed along the coast of St. Helena.

Ascension is a 97 km^2 volcanic island isolated in the south Atlantic. The peak of a dormant volcano rises 3,000 m above the seafloor and a further 859 m above sea level to the summit of Green Mountain. The vegetation is sparse with scattered guano deposits and the island has a dry tropical climate. Imposing sea cliffs line the more exposed eastern coast (Bird, 1985). Beaches, intertidal rock pools, and rocky shores are mainly composed of bare rock, regularly covered by a layer of crustose coralline algae that has cemented all rubble into a uniform surface.

The general biodiversity of Ascension is not high, not only because of its isolation but also due to the absence of lagoons, estuaries, seagrass beds, mangroves, and coral reefs (Manning and Fenner, 1990). Price and John (1978) concluded that the primary facet presented by the intertidal and sublittoral fringe on Ascension was still that of stark bare rock, sometimes abutting or adjoining clean sand. Other factors such as strong tidal surge, supplemented by rollers, enormous waves that assault the island, influence the shore and shallow depth colonization. Finally, the blackfish *Melichthys niger* is another important factor regulating the presence of other species, as it deters colonization by grazing all surfaces that it can reach (Day, 1983), including the crustose algae described earlier. Stands of algae and colonies of sabellariid worms, barnacles, and solitary coral are limited to crevices, blowholes, and isolated tide pools where blackfish cannot penetrate (Manning and Fenner, 1990).

The sandy beaches of Ascension are high-energy areas made up of very coarse sand. Only digging crustaceans *Hippa testudinaria* have been found in the sand and crabs *Grapsus* spp. have been seen roaming over the open beaches at night. Isolated tide pools with rims of protective rock are often inhabited by dense beds of oysters *Saccostrea cucullata* (Manning and Fenner, 1990).

Much of Ascension's global conservation importance comes from the island's remoteness, which has produced one of the most remarkable island floras and faunas in the world. It is of world significance for its 11 species of breeding seabirds, especially the unique Ascension Island frigate bird *Fregata aquila*. There are six unique species of land plants, nine of marine fish and shellfish, and over twenty of land invertebrates.

Some 27 species of amphipods have been described in the pool habitats along the shore, and Manning and Fenner (1990) observed 74 species of decapods on Ascension. Of these, 41 occur in the western Atlantic, and most are common.

The echinoderm fauna of Ascension comprises 25 species, including brittle stars, sea cucumbers, sea urchins, and starfish. Eight of these species are amphi-Atlantic, one species is restricted to Ascension, three species are also known in the western Atlantic, four species are also found in eastern Atlantic, five species are circumtropical and four species are also found in St. Helena. These findings suggest that species dispersion by larvae is mediated by surface and subsurface transport of planktonic stages (Pawson, 1978).

About 81 species of shore fishes are known, including 11 endemic species. Ascension has one of the most important breeding populations of green turtle *C. mydas* in the world. The green turtles mate and lay their eggs on sandy beaches, whereas hawksbill turtles *E. imbricata* are less frequently seen along the shores.

Tristan da Cunha and Gough (United Kingdom)

Tristan da Cunha is a circular volcanic island of 103 km^2 rising 2,062 m above sea level. The island is bleak and barren, but zoned vegetation occurs above 1,350 m. It has a wet temperate climate and is surrounded by rocky shores.

Gough is a deeply dissected volcanic island located 350 km southeast of Tristan da Cunha. High cliffs with hanging valleys and waterfalls surround the surface area of 65 km^2. The luxuriant evergreen scrub forest thins out above the 300 m contour. The climate is a cool-temperate oceanic. The flora of Gough is typical of southern cold-temperate oceanic islands, with relatively low species diversity, and a large preponderance of ferns and cryptogams.

Both Tristan da Cunha and Gough are characterized by their isolation and high level of endemism near the shore. However, with increasing depth, the amount of faunal similarity increases between regions across the South Atlantic.

The marine area can be split into two distinct algal zones. From sea level to 5 m depth, algae consist mainly of bull kelp *Durvillea antarctica*, and beyond 20 m are dominated by *Laminaria pallida* and giant kelp *Macrocystis pyrifera*. Forty species of algae have been recorded, of which two species are endemic to Gough. Most littoral species found at Gough are widespread on other southern ocean islands, and 79 invertebrate species have been recorded. The absence of limpets and bivalves in the littoral and subtidal zones is noted. Sea urchins *Arbacia dufresnii* are abundant in the marine area, as are whelks *Argobuccinum* sp., chitons, starfishes, sea anemones, bryzoans, barnacles, slipper limpets, nudibranchs and sponges. Important marine species include the Tristan rock lobster *Jasus tristani* (from close inshore to 400 m depth around Gough), and octopi. Both are economically exploited by fishermen under close regulation. About 51 species of fish are known to occur in nearshore waters of Tristan da Cunha and Gough.

Gough has been described as a strong contender for the title of "most important seabird colony in the world," with 54 species recorded in total, of which 22 breed on the island and 20 are seabirds. About 48% of the world's population of northern rockhopper penguin *Eudyptes chrysocome moseleyi* breed at Gough. Atlantic petrel *Pterodroma incerta* is endemic to Gough and the Tristan group of islands. Gough also harbors a major colony of the great shearwater *Puffinus gravis* with up to three million pairs breeding on the island. The main southern ocean breeding sites of little shearwater *Puffinus assimilis* are Tristan da Cunha and Gough Island, with breeding pairs numbering several million. The wandering albatross *Diomedea exulans dabbenena* is virtually restricted to Gough, with up to 2,000 breeding pairs. The only survivors of southern giant petrel *Macronectes gigantous* also breed on Gough, with an estimated 100–150 pairs. Gough moorhen *Gallinula comeri* is found in fern bush vegetation areas, and estimates of population size vary from 300–500 pairs to 2,000–3,000 pairs. About 200 pairs of Gough finch *Rowettia goughensis* have been recorded, although recent estimates suggest that there may be 1,000 pairs. Other seabirds breed on these islands, such as the yellow-nosed albatross *Diomedea chlororhynchos chlororhynchos* and the great shearwater *P. gravis*. The penguin *Eudyptes crestata* is present on Tristan.

Subantarctic fur seals *Arctocephalus tropicalis* (200,000 individuals and increasing), and southern elephant seals *Mirounga leonina* (about 100 individuals) are the only two native breeding mammals. The former breed at beaches all round the island, whereas the latter are restricted to the island's sheltered east coast. Two other marine mammals are found in the area, namely the southern right whale *Eubalaena glacialis australis* and the dusky dolphin *Lagenorhynchus obscurus*. Reptiles, amphibians, freshwater fish, and native terrestrial mammals are absent, although the introduced house mouse *Mus musculus* is widespread and abundant.

Falklands (United Kingdom)

The Falklands include two main islands and several hundreds smaller islands and islets that cover about 12,000 km^2. The coastline is lengthy and highly indented with numerous rias at the mouths of winding valleys. The landscape is treeless, with tussocky grasses and extensive peat bog mantles (Bird, 1985). Some rocky coasts possess offshore kelp beds of *Macrocystis*. The climate is dry cool temperate.

The Falklands are exceptionally rich in marine life, including benthic and pelagic forms. Also, about 85% of the world population of the black-browed albatross (*Diomedea melanophris*), and the largest concentration of rockhopper penguins (*E. chrysocome*) are found on the islands. A total of 63 species of sea and land birds occur, including the night heron *Nycticorax nycticorax cyanocephalus*, ashy-headed goose *Chloephaga poliocephala*, kelp goose *Chloephaga hybrida malvinarum*, Garnot's ground tyrant *Muscisaxicola muscisaxicola macloviana*, and the common diving petrel *Pelecanoides urinatrix berard*. The penguins *Pygoscelis papua, E. crestata, Eudyptes chrysolophus*, and *Spheniscus magellanicus* are present on the Falklands. The islands are breeding grounds for sea lions (*Otaria flavescens*), elephant seals (*Mirounga leonoina*) and fur seals (*Arctocephalus gazella*). Fifteen species of whales and dolphins occur in the surrounding seas. Pelagic invertebrates such as the squid *Ilex argentinus* are abundant near the coast and can be considered the basic diet of birds and mammals.

Scotia Arc Islands (United Kingdom)

South Georgia, South Sandwich, and South Orkney Islands combined represent about 10,000 km^2 of land that peaks over 2,000 m. They are known as the islands of the Scotia Arc. Most of them rise steeply from the sea and are rugged and mountainous. Their coastlines are generally cliffed and rocky, with many inlets and some bay beaches.

South Georgia is a remote island located 1,330 km from any other land. It is largely barren and has steep, glacier-covered mountains. The climate is wet subpolar; it is variable, with mostly westerly winds throughout the year, interspersed with periods of calm; nearly all precipitation falls as snow. The South Georgia fauna is depauperated and consists mainly of direct developers. The intertidal fauna is of geologically recent origin. It is suggested that South Georgia shores stem from colonization by rafting from remote sources. There are abundant rocky shores with *Macrosystis* kelp offshore. Some 24 species of breeding seabirds and 26 visitors, 6 species of seals, and 10 endemic bottom dwelling fish are found around South Georgia. Penguins *Aptenodytes patagonicus*, *E. chrysolophus, Pygocelis antarctica* are present.

The South Sandwich Islands are of volcanic origin with some active volcanoes. They have a wet polar climate, and sparse vegetation of lower plants (lichens and mosses), richer around fumaroles with dense bryophyte communities. The penguins *A. patagonicus*, *E. chrysolophus, Pygocelis papua*, and *Pygocelis adeliae* are present.

The South Orkney Islands are located between the Antarctic Peninsula and South Georgia and they have a subpolar climate. The littoral zone is either lifeless or very poor. Scarce diatoms and a few species of chitons and gastropods are found along the littoral. At low tide, there are green and red algae in small rock pools, and amphipods and planarians under stones. At around 2 or 3 m depth, green and red algae appear with an increasing number of fauna including starfish, urchins, sponges, and ascidians. At around 8–10 m depth, new species of starfish appear and the general animal biomass increases with depth. At 30 m, ascidians, sea urchins, starfish, and brittle stars form vast colonies. The penguins *P. antarctica, P. papua* and *P. adeliae* are present around South Orkney.

Overall, the biota of the intertidal region is poor, even during summer, in the Scotia Arc Islands. Due to the rigorous conditions, most biota is confined to lower levels of the shore (Stephenson and Stephenson, 1972). The midlittoral zone that is most exposed to air is characterized by the presence of the *Porphyra* algae followed by *Ulothrix* and *Urospora* along the center of the zone. There are also algae in the tide pools and crevices. Limpets *Patinigera polaris* occur in crevices, whereas amphipods, nemertines, and flatworms are found clustered under stones and rocks. The tide pools of the midlittoral are home to many Antarctic species of algae such as *Leptosomia, Iridaea, Adenocytis* that can also extend their distribution to the infralittoral fringe area with *Desmarestia, Curdiea, Monostroma*, and *Plocamium*. The infralittoral fringe is characterized by numerous algae, mainly of the genera *Desmarestia* and *Ascosiera*. The huge *Phyllogigas grandifolius* dominates this area and its blades harbor a small fauna comprised, among others, of worms, sponges, hydroids, and mollusks (Stephenson and Stephenson, 1972).

There is no supralittoral fringe in many places, the mid-littoral fringe has a very restricted population but there is an increasing number of species in the infralittoral zone (Stephenson and Stephenson, 1972). Several animals such as sponges, alcyonarians, pycnogonids, amphipods, isopods, polychaetes, and nemertine worms are giant representative of their group (Knox, 1970).

The chlorophyll abundance in the surface waters shows a high degree of variability. The chlorophyll *a* in South Orkney fluctuates around 4 mg m^{-3} in summer. High pigment concentrations have been found especially between South Orkney and the South Sandwich Islands. The main species that compose the phytoplankton biomass are diatoms. *Chaetoceros neglectus, Chaetoceros dichaeta, Chaetoceros atlanticus, Nitzshia* sp., *Corethron criophilum* are the most common reaching densities around 10^5 cells L^{-1} (Zernova, 1970). The standing crop of zooplankton in the subantarctic represents 55 g m^{-3} between 0 and 50 m depth. Around South Georgia, the relationship between the density of phytoplankton and zooplankton is inverse (Knox, 1970). Copepods reach maximum densities at around 600 m depth, decreasing continuously toward the surface. The main species of zooplankton are *Euphausia superba, Euphausia frigida, Thysanoessa* spp., *Parathemisto* spp., and *Salpa fusiformis*. The main krill biomass is observed in areas of the island arc. The complicated underwater relief and coastline of this area leads to the formation of numerous gyres and local eddy currents trapping the krill (Makarov *et al*., 1970).

Krill has been found to be an important part of the diet of numerous fish living around the islands, including members of the families Rajidae, Paralepidae, Myctophidae, Scopelarchidae, Muraenolepidae, Gadidae, Moridae, Macruridae. The occurrence of various fish in the epipelagic waters of the Scotia Arc Islands, which are described by many authors as a highly productive krill zone, are also profitable to whales, seals, birds, and Antarctic fishes, but also to subantarctic and subtropical epipelagic species of the southern hemisphere. The crabeater, leopard, Ross and some other seals can be found in the Scotia Arc Islands.

ATLANTIC OCEAN ISLANDS, COASTAL GEOMORPHOLOGY

From south to north, the islands of the Atlantic covered here include the Scotia Arc (South Shetland, South Orkney, South Sandwich, and South Georgia), Bouvet, the Falklands, Tristan da Cunha and Gough, St. Helena and Ascension, Macronesia (Cape Verde, Canaries, Madiera, and Azores), Bermuda, Sable, Faeroes, and Jan Mayen (Figure A60). The Caribbean islands, Iceland, Great Britain, and Ireland are covered elsewhere.

Setting

With only a few exceptions such as Bermuda and Sable, it is clear from the spatial distribution of almost all of the other individual islands or island groups in the Atlantic Ocean that most owe both their location and coastal morphology to a turbulent tectonic and often volcanic past. The tectonic opening of the Atlantic Ocean is the key factor in this history. Commencing in the Late Jurassic some 140 million years ago and fully open some 65 million years ago (Hansom and Gordon, 1998), the Atlantic basin is characterized by the westward movement of both American plates and the eastward movement of the African and Eurasian plates. Basaltic magma upwelling into the crustal gap in the mid-ocean spreading center has over time produced a long submarine ridge composed of a series of fissure volcanoes known as the mid-Atlantic Ridge. In places the volume of upwelling magma has been sufficient to allow the construction of volcanoes that extend to the ocean surface and form the individual volcanic islands and island groups of Bouvet, Gough, Tristan da Cunha, St. Helena, Ascension, Macronesia, Kelard, and Jan Mayen. Elsewhere, where more than two plates and spreading directions are involved, this relatively simple mid-Atlantic geometry is more complex. For example, the development of the Scotia Arc in the South Atlantic was contingent on the opening of the Drake Passage and the eastward movement of several micro-plates along a progressively elongating arc. The boundaries of the Scotia Arc are marked in the south by the South Shetland and South Orkney Islands, in the north by South Georgia and in the east by the still-extending volcanic island arc of the South Sandwich Islands (Hansom and Gordon, 1998). As a result, the rocks of South Georgia, South Shetlands, and South Orkney are mainly composed of fragments of older rocks and intruded volcanics, most of which were created elsewhere and subsequently transported to their present sites. By contrast, 70% of the rocks of the South Sandwich Islands are recently extruded basalts (Baker, 1990).

This tectonic and volcanic past has also ensured that, with exception of parts of the Scotia Arc in the South Atlantic and Bermuda and Sable Island in the North Atlantic, almost all of the remaining mid-ocean islands are of volcanic origin (Bird, 1985a, b). Many remain as active volcanoes that rise from deep water and their coastlines are mainly characterized by steep cliffs cut into lava, ash or hyaloclastite. Since many of the volcanoes themselves are youthful, the coastlines are also young and in a state of continuing adjustment in response to marine activity and ongoing volcanic events. For example, Fogo, in the Cape Verdes, is an active stratovolcano with a symmetrical cone rising out of the ocean (Figure A61). Its slopes are composed mainly of subaerial lava flows, some of which are dated, and all of which end in marine cliffs, sometimes with small cliff-foot beaches composed of basalt boulders and gravels.

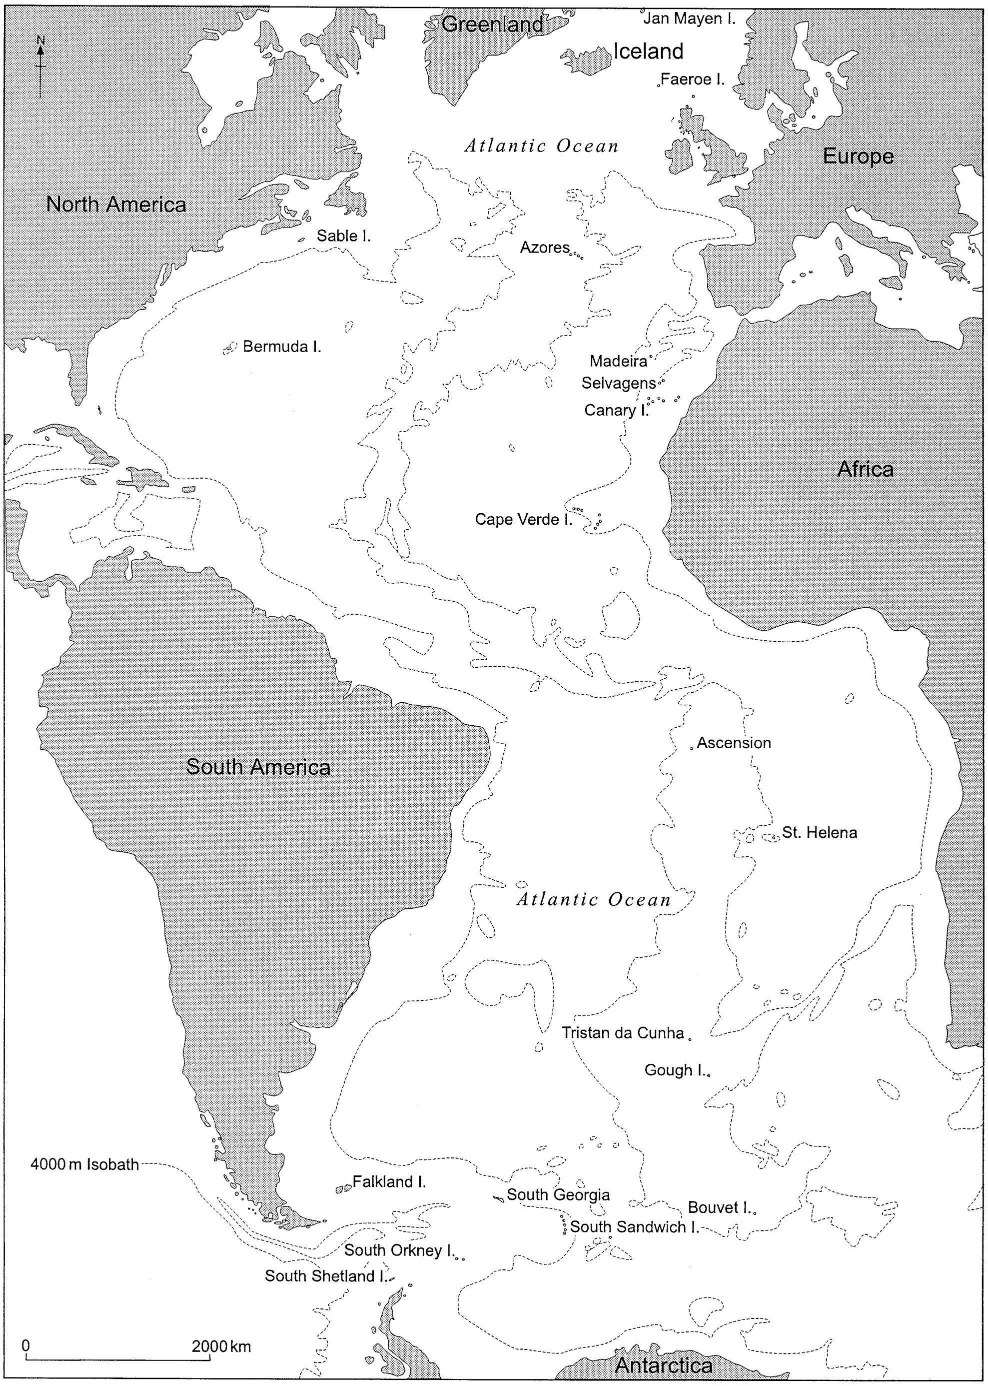

Figure A60 Location of the Atlantic Ocean Islands.

The Scotia Arc

Like most Antarctic coasts, the coasts of the Scotia Arc islands are mainly cliffed and rocky. Many of the cliffs are cut in glacier ice and beaches are regionally rare (Hansom and Gordon, 1998). Rapid cliff retreat rates of 1 cm a^{-1} have been calculated for the cliffs of Fildes Peninsula in the South Shetland Islands and are thought to be the result of efficient frost shattering (Hansom, 1983a). Since all of these coasts are affected by sea ice for up to eight months of the year, the more normal coastal processes associated with wave and tide operate intermittently and often in conjunction with floating ice fragments (Hansom and Kirk, 1989). This means that the relative order associated with wave processes is annually swept away and replaced by the bulldozing and grinding action of floating ice so that beach sediment is moved in a nonselective way to produce disorganized fabrics and landforms. In the South Shetland Islands much of the coast is either rock or ice-cliff, although some glacier termini rest on a low rocky platform at sea level. There are important exceptions, however, and significant beach development occurs on the peninsulas that protrude beyond the ice cover. The Fildes and Byers Peninsulas on King George Island and Livingston Island, respectively, are adorned with extensive emerged beach deposits, some of which connect offshore islets and skerries to the shore platforms of the main island (Figure A62). Prominent shore platforms occur at sea level and at altitudes of 3–8 m, 11–17 m, 28–50 m and 85–100 m above sea level and are cut into a variety of rock types (Hansom, 1983a). Although gravel beaches are found up to 200 m above sea level the most extensive are sited on the lower shore platforms at altitudes of 2.5–3 m, 5.50–6 m, 8–10.5 m, 12–13.5 m, and 16.5–18.5 m above sea level, as well as at present sea level (John and Sugden, 1971; Hansom, 1983a). Since the extensive sub-horizontal shore platforms that occur at present sea level in sheltered locations give way to steeper, ramp-like platforms in more exposed locations, Hansom (1983a) related their development to the interplay between the frequency of floating ice blocks that horizontally abrade the surface and wave activity that produces ramps. The upper part of the sub-horizontal platforms within sheltered bays is often adorned with an undulating layer of boulders that have been smoothed and compacted into extensive boulder pavements by the action of floating ice blocks (see Boulder Pavement) (Hansom, 1983b). Three of the islands, Penguin, Bridgeman, and Deception, are relatively new and active volcanoes and erosion of the friable rocks of the outer coast has produced cliffs of a variety of heights. The inner crater of Deception Island has been inundated by the sea and has several sand and gravel beaches that are frequented by penguins and tourists alike, in sharp contrast to the steep rocky outer coast.

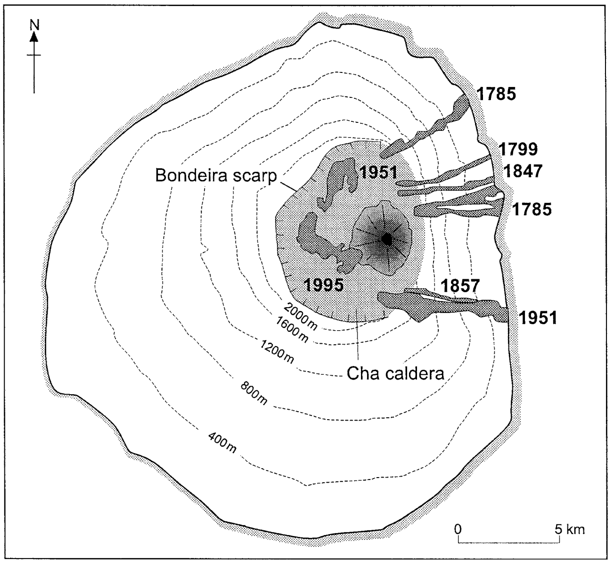

Figure A61 The island of Fogo, Cape Verde group is an active volcano and has a steep coast that is characteristic of many of the Mid-Atlantic Islands. 18–20th century lavaflows indicated as map.

Whereas the extensive beaches of parts of the South Shetland Islands allow for easy landing for both wildlife and boats, the coastline of the South Orkney Islands is more formidable. Three of the four largest islands, Coronation, Powell, and Laurie are dominated by large permanent ice caps spilling down steep rocky cliffs which plunge below sea level. A few bouldery beaches occur, for example, on Laurie Island. The remaining island, Signy is characterized by ancient schists and amphibolites that have been glacially scoured to produce a relatively low and rolling coastal plain with a rocky sloping shore albeit with only a few bouldery beaches. The coast of the South Sandwich Islands is as inhospitable as that of South Orkney, since only a small proportion of land is free of ice and there are few beaches or easy landing points. The South Sandwich group consists of a 400-km-long volcanic island arc caused by the subduction of the South Sandwich plate beneath the South American plate. Rising from an 8,428 m-deep ocean trench, the eleven main islands are all volcanoes made up of 60% lava and 40% tephra (Baker, 1990). The coastline is steep and cliffed but because many of the islands are still active volcanoes, erosion of softer tephras has produced a crenulate coastline with infrequent small bouldery beaches. All of the islands except Zavodovski are characterized by reefs and skerries and these are especially well-developed between smaller island clusters, such as in the extreme south at Thule, Cook and Bellingshausen islands. Low altitude bare coastal plains do occur on some islands, such as Zavodovski and Bellingshausen, but few scientists

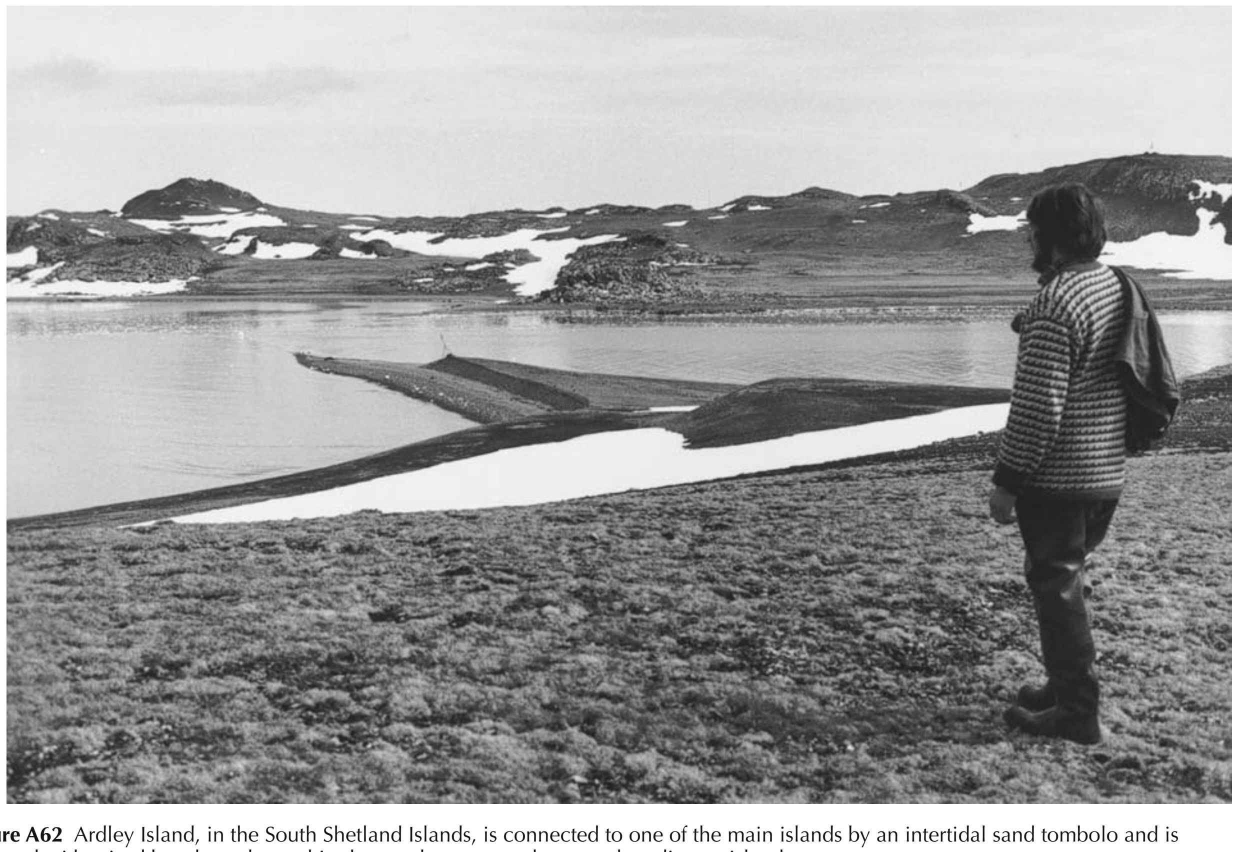

Figure A62 Ardley Island, in the South Shetland Islands, is connected to one of the main islands by an intertidal sand tombolo and is adorned with raised beaches whose altitudes are the same as those on the adjacent islands.

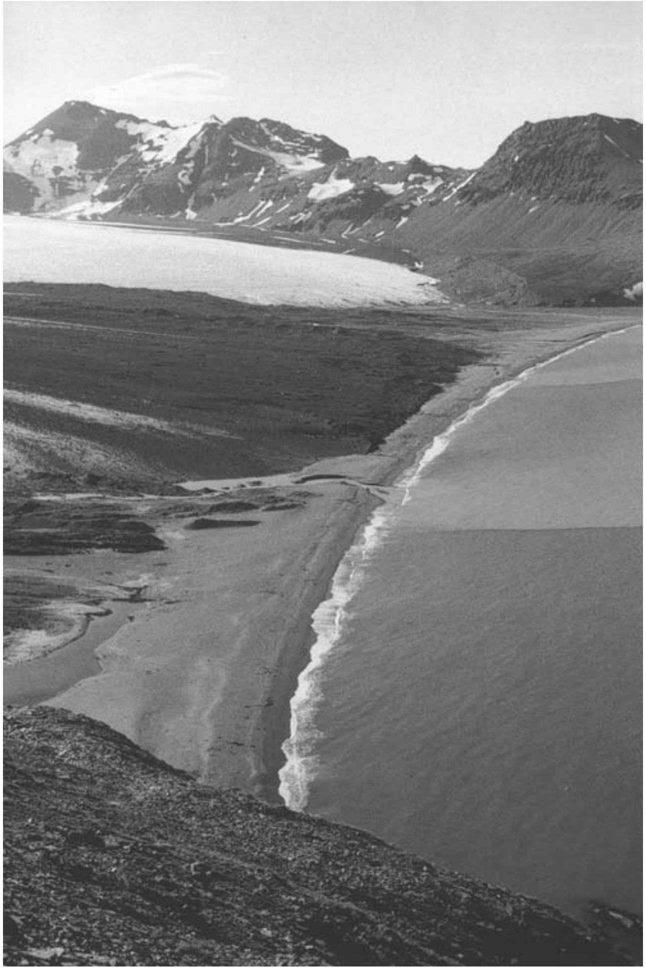

Figure A63 Saint Andrews Bay, South Georgia, is fed by glacigenic sediment and is characteristic of the extensive outwash beaches of the north coast of the island.

have investigated these islands and so, the nature of the plains is unknown. In the strong westerly ocean circulation of the Scotia Sea, pumice from South Sandwich is known to travel great distances. The pumice from a submarine eruption close to Zavodovski Island in March 1962 reached the beaches of New Zealand in late 1963, having been transported east within the Antarctic Circumpolar Current at 11–17 cm s^{-1} (Hansom and Gordon, 1998).

South Georgia on the northern limb of the Scotia Arc, is a 170-km-long and 40-km-wide sequence of volcaniclastic sediments folded into a mountain range that rises out of the Atlantic Ocean to heights of over 2,700 m. It is not volcanically active but is heavily glacierized and has all the characteristics of a glacially eroded coastal fold mountain range. Long ridge-like peninsulas separated by deep glacial troughs jut out into the sea. The south coast is more heavily glacierized than the north and is extremely rocky and dominated by steep cliffs cut in ice or rock. The few small cliff-foot gravel or sandy beaches that occur are swept by storm waves from the southwest and occasionally by storm surges (Hansom, 1981). On the north-facing coast, the glacier cover is more restricted and a significant amount of ice-free ground exists, particularly on the peninsulas. The peninsulas are flanked by high and steep cliffs but these often have narrow shore platforms at their base together with numerous offshore islets and skerries. Some fragments of emerged shore platforms are known to occur at altitudes of 2, 5, 6–7, and 20–50 m above sea level but a systematic study of distribution and altitude is lacking (Clapperton, 1971). The lower of the shore platforms are often adorned with emerged beaches at 2–4 m and 6–7.5 m above sea level (Clapperton *et al.*, 1978). Within the northern bays and fjords of South Georgia lie the most extensive beaches of the Antarctic region. Fed by numerous debris-laden glaciers and short glacifluvial streams, substantial areas of the sheltered inner fjord heads have become infilled by glacifluvial outwash plains fringed by extensive sand and gravel beaches (Hansom and Kirk, 1989). The largest of these outwash beaches occur at Salisbury Plain, Fortuna Bay, Cumberland Bay and St. Andrews Bay (Figure A63) (Gordon and Hansom, 1986). Some of the inner reaches of the fjords of South Georgia are affected by sufficiently large quantities of floating ice calved from adjacent glaciers to allow the development of intertidal boulder pavements similar to those produced by sea ice further south (Hansom, 1983b).

Falkland Islands

The coastline of the Falkland Islands, like the islands themselves, is low, flat, and reminiscent of the coastline of the Outer Hebrides of Scotland. Although hundreds of smaller islands exist, the main island group comprises West and East Falkland separated by Falkland Sound. The intricate and crenulate nature of the coastline is probably more related to the submergence and faulting of the underlying Devonian, Carboniferous, and Permian limestones and sandstones, rather than to the efficiency or otherwise of marine erosion and deposition. In spite of the majority of the coastline being rocky, steep and high cliffs are mainly absent except in the extreme west where 100–200 m cliffs occur at Beaver Island. Everywhere and especially within the broad embayments and inlets, there are innumerable small islets and skerries whose detailed morphology and outline appear to be structurally controlled. A notable feature of the rocky coastline is the abundance of dense stands of giant kelp in the nearshore. On the western flank of the fault that controls Falkland Sound, narrow coast-parallel outcrops of hard and softer rock have been eroded to produce an intricate series of small headlands composed of more resistant rock separated by small arcuate bays cut into less resistant beds. The result is an essentially linear coastline stretching the entire length of Falkland Sound, broken by regular and uniform bays where the outer rocks have been breached. The crenulate nature of the coastline and extensive areas of nearshore shallow water means that a wide range of sheltered locations exists for potential beach development. Streams, although abundant and rarely dry, do not appear to contribute significantly to beaches, since there is a lack of beach development adjacent to the mouths of the creeks and streams entering tidal waters. Beaches of sand and gravels tend to be located in either outer coast sites where ocean waves gain access or within inlets where more open aspects allow wind-generated local waves to produce beaches. The high proportion of shell-sand of the beaches points to an important biological input from nearshore shallow waters. Significant beach development on the outer coast occurs at Bull Point, Lively Island, and at Bertha's Beach where sandy spits and tombolos connect small islets to mainland East Falkland. Paloma Beach, Elephant Beach, and Concordia Beach in the north of East Falkland are all examples of large open coast sandy beaches where strong winds have resulted in blown sand spreads over inland areas. In West Falkland, large beaches occur within the inlet of Whitsand Bay. Unfortunately, as a result of indiscriminate mine-laying during the Falklands War, several of the beaches of East Falkland are now unsafe and access is restricted.

Bouvet, Gough, Tristan da Cunha, St. Helena and Ascension

Bouvet Island (Figure A60) stands at the southern end of the mid-Atlantic Ridge, the slopes of the central cone terminating on all sides in precipitous cliffs that descend abruptly to sea level. Probably a complex of volcanic cones, the island rises almost symmetrically to a flat ice-covered dome 935 m high. The ice covers the eastern side of the island where it reaches the sea in an ice cliff 122 m high. The north and west sides are free of ice but are much steeper. Between 1955 and 1958, a new 0.2 km^2 rock platform emerged at 25 m above sea level as a result of either eruption or rock falls associated with tremors (Stonehouse, 1972). Since little low-level ground was previously to be found around the coast of Bouvet, the new addition has become a prime-breeding site for penguins, petrels, and seals. Gough Island (Figure A60) lies 2,300 km to the east of the Cape of Good Hope, South Africa and is the eroded summit of a Tertiary volcano. Although the island is mountainous, rising to 910 m above sea level, the slopes are cut by deep gullies or gulches and the coastline is characterized by steep cliffs that appear to have undergone erosion to produce a variety of narrow boulder beaches at the foot of the cliffs. There are also numerous islets, stacks, and skerries that mostly lie within 100 m of the coast. Tristan da Cunha lies 350 km to the northwest of Gough. It is a circular island of 98 km^2 with four other small islands close by. The base of the central volcanic peak lies

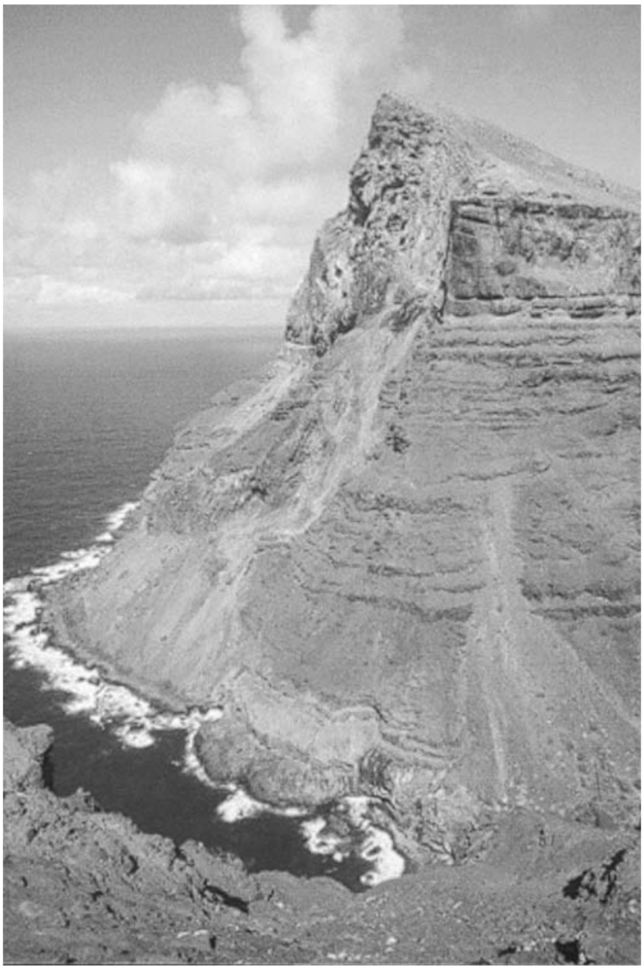

Figure A64 The steep cliffs of Saint Helena are capped by outcrops of trachyte at Great Stone Top on the south east coast. (Photo courtesy of Barry Weaver.)

3,700 m deep on the seabed and the summit rises to almost 2,100 m above sea level. The lower slopes are almost entirely lava and form high cliffs that surround the island. Emerged beaches, platforms, and caves occur at 5 m above sea level on Tristan but 12 m above sea level on the small adjacent islands, indicating differential tectonic uplift in the area (Bird, 1985b). In some places, small and inaccessible beaches occur, some of which are sandy. A small plateau at the foot of the main cliffs on the northwest side at Herald Point provides the site for Edinburgh, the only inhabited part of the island. The cliffs are lower along the Edinburgh coast, allowing access to the sea via small gullies. A narrow gravel beach has developed along this stretch of coast, fed by material eroded from the cliffs. In the months following the 1961 eruption at Big Point, on the updrift section of this coast, rapid recession of the cliff was noted (10 m in 8 weeks). This contributed to accretion of the downdrift gravel beaches which formed a spit enclosing a small lagoon (Bird, 1985b).

St. Helena (Figure A60) is 122 km^2 in area and lies in mid-ocean, 2,900 km from Brazil and 1,900 km from the west coast of Africa. Like Tristan and Gough, the coastline comprises high stepped and sometimes vertical cliffs cut by steep v-sided valleys. Emerged shore platforms stand at 4–6 m above sea level (Bird, 1985b) and the numerous offshore islets and skerries common on the south and west coast, such as at Egg Island and Cockburn Battery, are almost absent from the north and east coast. The highest cliffs occur at Flagstaff Bay in the north and at Man and Horse Cliffs in the southwest where they reach 580 m. The vertical steps in the coastal cliffs often correspond to differences in the composition of the outcropping of lava flows. At Great Stone Top, Turks Cap, and Prosperous Bay on the east coast, thick flows of trachyte form vertical faces, which cascade debris onto stone chutes below (Figure A64). Some of these extend into the sea to form fringing boulder beaches but nowhere on the outer coast are these well developed or extensive. Only in favored locations where the deep gulches reach the coast do small beaches, some of sand, occur, such as at Lemon Valley Bay. At Sandy Cove on the south coast, the sandy beach is backed by calcareous sand dunes. In mid-ocean some 1,300 km north of St. Helena lies Ascension Island, a Holocene stratovolcano with no known historic eruptions (Simkin and Siebert, 1994). Although more arid than St. Helena, the coasts of both islands are similarly high and surrounded by steep cliffs cut into volcanic lava. At Boatswain Bird islet, a natural arch has been eroded into a 98 m high monolithic stack of trachyte (Bird, 1985b). However, Ascension also has superb white sand beaches derived from shell and coral. Outside of the Caribbean area, the Atlantic Ocean is not noted for its corals although small structures are known from the coast of western Africa (Trenhaile, 1997). Although little seems to be known of the nature of the sediment supply to the Ascension beaches, the carbonates can only come from shells and coralline algae (such as *Lithothamnion*) growing in the narrow shallow water fringing the island. Erosion of adjacent rock shores and terrestrial sediment in-washed by infrequent rains probably account for the remainder of the beach sediment.

Macronesia

The island groups comprising Macronesia stretch lie in a long line that extends north between the coast of West Africa and the Portuguese coast (Figure A60). All of the island groups are volcanic in origin and many remain active volcanoes. Four main stratovolcanoes occur in the arid Cape Verde Islands, Fogo, Brava, Santo Antao, and San Vicente. Fogo is 2,829 m high yet only 24 km wide and so the steep seaward slopes end abruptly in retreating cliffs. The volcano has erupted 10 times between 1500 and 1995 each one sending long streams of lava down the flanks into the ocean and altering the coastal geometry. A similar picture characterizes the other islands of the group, each being surrounded by steep cliffs cut by deep gullies at the foot of which occur infrequent gravelly beaches. Emerged features have been noted at six levels up to 100 m above sea level. Some bays contain fringing algal reefs and in some locations boulders have been moved inland by wave activity by up to 200 m (Bird, 1985b). The Canary Islands comprise seven main islands, six of which host volcanoes. Some of these have erupted as recently as 1971. The coastline of the Canaries resembles that of the other mid-ocean volcanic islands in as much as the central volcanic spine of the islands falls steeply to a mainly rocky and cliff coast cut by deeply incised ravines. For example, in the northwest of Tenerife at Acantilado de Los Gigantes, sub-vertical cliffs reach 500 m. The occurrence of such cliffs has constrained some of the tourist-related expansion that many of the coastal towns and villages have undergone in recent years. Some cliffs have been formed in sediments brought down by torrents in the ravines. These deposits have since been tectonically uplifted together with the boulder beaches that once fronted them. The north coast of Gran Canaria has good examples of such cliffs, together with well-developed shore platforms a few meters above sea level. However, the volcanism of the Canaries has in places produced several long and low craggy volcanic peninsulas that have allowed beach development to occur. Fuertoventura, Lanzarote, Tenerife, and Gran Canaria all have sandy beaches some with extensive sand dunes. The long white sand beach at San Andres, on the southeast coast of Tenerife, has been artificially nourished with sand brought from the Sahara Desert. Between Maspalomas and Playa del Ingles, in the south of Gran Canaria, 328 ha of fine shell sand have accumulated at the mouth of the Fataga ravine to enclose a freshwater lagoon. On account of the relative aridity, most dunes in the Canaries are sparsely vegetated and the unfixed dunes at Maspalomas advance east towards the lighthouse at a meter per year. Some of the dunes have succumbed to tourist development, such as at Playa de las Canteras in the north of Gran Canaria. In the easternmost part of the islands, the supply of beach sediment from the nearshore and the inland ravines is augmented from a more exotic source. Fuertoventura and Lanzarote are affected by the summer *scirrocco*, a hot wind from the Sahara 90 km to the east, which carries large quantities of dust and desert sand to the islands. Locally known as the *kalima*, it turns the day into twilight and regularly covers surfaces with a thin layer of sediment. Over the centuries, this sediment has been an important source of sand for the beaches of the easternmost islands. In the south, Fuertoventura narrows at the Pared isthmus where sandy beaches extend eastward to connect the original island of Jandia to the main island by what is now a low and narrow peninsula. On the eastern shore, the sands of the 26 km-long Playa de Sotavento (Sp: leeward) are protected from the dominant westerly waves. On the western side, the Playas of Cafete, Pared and Barlovento (Sp: windward) are more exposed with strong currents and undertows. Nearby Lanzarote is a similarly dramatic landscape of lava fields and steep cliffs with intervening sand beaches, such as the sweeping Puerto del Carmen beach on the east coast. Accretion is common at many of the valley-mouth inlets.

Maderia comprises the main island itself, together with the smaller island of Porto Santo, the nearby Islas Desertas, together with the uninhabited Selvagens to the south. All of these islands are volcanic in origin but have not been active in the last 1.5 million years. As a result the, main volcanic core of Madeira, together with its plateau-like lateral subsidiary vents, has become eroded to produce deeply incised valleys and gorges running down to the sea. Between the mouths of the river valleys are high cliffs of vertical columns of basalt with layers of red and yellow tufa exposed in places. The 580 m plunging cliffs of Cabo Giroa, west of Funchal, are among Europe's highest, but high cliffs are found everywhere on the coast of Madiera. In the north, fragments of shore-platform occur as well as small islets and skerries, particularly near Faial. There are several well-developed stacks near Ponta do Sao Lourenco in the northeast. Small beaches of rounded gray basalt gravel occur at several places, particularly where river mouths occur. The only sandy beach is at Prainha, on the extreme east of the island where the sand is mainly basalt. Shell sand occurs on the low plateau area in the extreme east of the island. The nearby island of Porto Santo is 14 km long and 5 km wide, its generally low volcanic profile veneered by thin deposits of sand, calcareous sandstone and clay. The cliffs of the north coast reach 100 m but the south coast is dominated by an 8 km long white sand beach fronted by a shallow sandy-floored bay backed by low cliffs of cemented sands. Protected from the main force of southwesterly storms by Madeira, from the west by the small island of Baixo and from the north by its own cliffs, the south coast of Porto Santo is relatively sheltered. It appears to have been subject to sediment accumulation over a substantial period of time derived both from a combination of shell sand from shallow nearshore surfaces, aeolian sand blown west on the *scirrocco* from the Sahara to the east and from topsoil erosion caused by early deforestation. The Selvagens are composed of limestone capped by lava and ash and are cliffed to 100 m in the north but with a gentler beach-fringed coast in the south. Emerged beaches and dune calcarenites occur on Pleistocene marine terraces at 3 and 7 m above sea level (Bird, 1985b).

The most northerly of the islands of Macronesia, the nine islands of the Azores are a widely separated group of mountainous but fertile islands which share the steep nature of many of the mid-oceanic islands but also have long beaches and many fishing harbors. The coast of the largest island, Sao Miguel, is a microcosm of the Azores coastline. Where the coast is backed by higher volcanic peaks, it is characterized by steep cliffs fronted by patchy low shore platforms, offshore stacks and islets, such as at Mosteiros. Emerged beaches and platforms occur at various heights up to 60 m (Bird, 1985b). However, the highly indented coast also has short sandy beaches between cliff headlands. Where the hinterland is lower, longer sand beaches occur such as at Praia dos Moinhos and at Populo where small pine-clad sand dunes occur. Several coastal features of note occur on the other islands. Pico Island is 42 km long and dominated by a 2351 m cone-shaped stratovolcano of the same name. Various historical lava flows have extended the coastline and now have been eroded back to form low cliffs. In places sheltered from the dominant westerly waves, smaller volcanic forms survive on the coast, such as at Barca on the island of Graciosa where a volcanic cone has been sectioned by marine erosion to form bays fringed by crumbling cliffs of ash that cascade onto boulder beaches below. The 1957/58 eruption at Capelhino on Faial showered the adjacent coast in ash and contributed to accretion of the beach. At Porto Pim, also on Faial, a substantial sandy spit has developed (Bird, 1985a). Such is the power of the surf reaching the Azores that Pico has been chosen as the site of a pilot plant to produce energy from waves.

Faeroes and Jan Mayen

The rugged outer coast of the 16 main islands that comprise the Faeroes is the result of the deep incision of past glaciers into a thick pile of horizontally bedded flood basalts. These are slowly eroding, especially on the west and north coasts, due to constant exposure to high-energy westerly and northerly North Atlantic waves. The outer coast is dominated by high and sub-vertical cliffs that reach 820 m at Hestmuli in the north of the island of Kunoy. The rate of recession is unknown but is higher on the seaward facing slopes where cliffs have developed that tend to be steeper than immediately adjacent landward-facing glaciated slopes, such as at Tindholmur in the extreme west. The slopes of the inner coast are the sides of over-steepened glacial troughs that have been flooded by Holocene sea-level rise and are more subdued and better vegetated than the cliffs of the outer coast (Figure A65). Small skerries, islets, and stacks (Fr: drangur) are common as are deep clefts and geos (Fr: gjogvs) where dykes and faults have been differentially eroded into the horizontal basalts of the west coast. Small, often structurally controlled, ramped shore platforms are common around most of the coast but tend to be more fragmented and smaller on the more exposed west and south coast. More continuous and better-developed platforms occur near the entrances to the fjords, particularly in the east. For example, well-developed shore platforms occur on the east coast of Vidoy. There are very few beaches in the Faeroes and the ones that do occur are almost exclusively found at the sheltered fjord heads. In such locations, wave approach is unidirectional and the limited amounts of

Figure A65 Glacial troughs have been cut into horizontally bedded basalts and subsequently flooded by Holocene sea level rise to produce cliffs that are characteristic of the inner coast of the Faeroese fjords. The plunging cliffs of the Faeorese outer coast are everywhere exposed to high energy Atlantic waves.

sediment supplied by the small streams accumulates to produce small pocket beaches composed of black basalt sand (such as at Tjornuvik, Funningsfjordur, and Vidareidi) and occasionally backed by low sand dunes (such as at Sandur and Saksun).

The coastline of Jan Mayen is dominated by the volcanic bulk of Beerenberg, a 2,277 m stratovolcano that comprises the northern half of the 54-km-long island (Norsk Polarinstitutt, 1959). The coastline of Nord-Jan is steep and rugged, comprising 200–400-m-high cliffs eroded in ash, lava and tephra as well as into the ice walls of tidewater glaciers that spill down from the central crater. The coastline shows signs of recent advance as a result of lava tongues from eruptions in 1970 and 1985, which have extended into the ocean. These recent eruptions and flows are an extension of the mode of construction of the island over an estimated 700,000 years. Such additions to the coastline have resulted in the base of preexisting cliffs becoming buried by newer lavas and it is onto this platform that more recent glacier terminal moraines have been deposited, such as at Smithbreen in the northeast of the island (Kinsman and Sheard, 1962). At Kroksletta, near the northern cape, 4,000-year-old moraines that rest on top of an emerged shore platform and beach at 8–10 m above sea level have been buried by subsequent lava flows. The protruding seaward edge of the Kroksletta lava is now cliffed to a height of 5–13 m (Kinsman and Sheard, 1962). The south part of Jan Mayen is a hilly ridge of scoria craters and mounds and trachyte domes whose lower elevations and older age has produced a coastline of low gradient rocky platforms connected by gravelly beaches. In several places around the Sud-Jan coastline a prominent rock platform is present upon which is sited emerged beach gravels. This feature is particularly well developed on the north coast of Sud-Jan at Sorbukta, Engelsbukta, and Haugenstranda. Sediment supply to the central section coastline that joins Sud-Jan to Nord-Jan appears to be healthy both from erosion of the lava cliffs to the west and from shallow water sources: the 10 m depth contour lies about 0.7 km offshore. This has resulted in the construction of a substantial barrier beach enclosing a lagoon along an 11-km-long stretch of south-central coast at Lagunevollen, with a smaller barrier and lagoon at Stasjonsbukta on the north coast. The composition of these barrier beaches is not known but assumed to be composed of mixed sands and gravels transported from the west. Such a large beach complex is unusual for a small mid-oceanic island. However, the full impact of Atlantic westerly waves and swell at Sud-Jan is modified by a large circular submarine reef (probably an eroded volcanic cone), which reaches to within 11 m of the sea surface some 10 km south of Sud-Jan. Although the north coast is subject to variable amounts of sea ice for an average of four months, the south coast is mainly free of ice (Gloerson *et al.*, 1992). Elsewhere, the coastline of Sud-Jan is steep and rocky but the cliffs are not as high as in Nord-Jan and small gravelly cliff-foot beaches fed by rockfall and wave erosion of the adjacent lava occur.

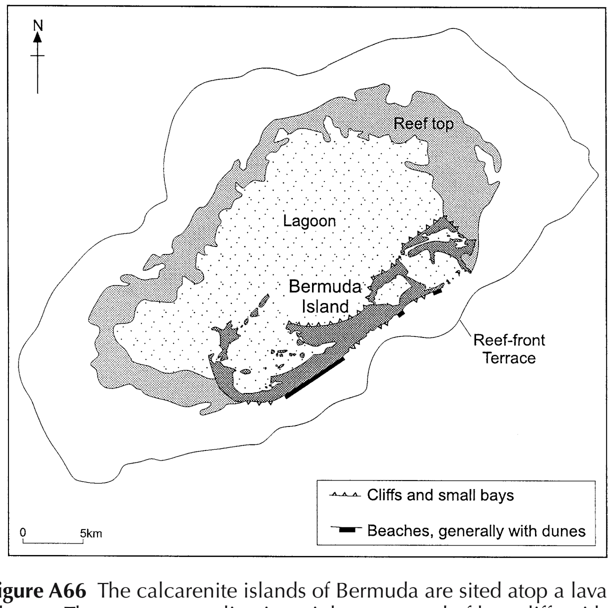

Figure A66 The calcarenite islands of Bermuda are sited atop a lava plateau. The present coastline is mainly composed of low cliffs with long beaches in the south (after Vacher, 1973).

Bermuda and Sable

With two notable exceptions, Bermuda and Sable, all of the Atlantic Ocean Islands have, or have had, a close and recent association with tectonic and volcanic activity. However, Bermuda, lying to the east of the Carolinas coast of the United States is a group of 150 limestone islands located about 1,000 km east of Cape Hatteras (Figure A60). The islands rest on the southern margin of a 650 km^2 platform that is presently submerged to depths of 20 m. However, boreholes at Bermuda have penetrated through a thin capping of calcarenites to meet lava at a variety of depths of 171, 43, 33, and 21–24 m (King, 1972). The platform of volcanic rocks is the site for the northernmost coral reefs in the North Atlantic. According to Vacher (1973) the present-day Bermuda platform consists of four geomorphological-ecological provinces: a reef-front terrace at 20 m depth; a main reef composed of 4 m deep coral-algal reefs everywhere except in the south where algal intergrowths occur; a 16 m deep lagoon in the north and the islands themselves forming a northeast trending chain near the southern edge of the platform (Figure A66). The exposed limestones of the islands are Pleistocene calcarenite, 90% of which is aoelian and the rest is beach and shallow water in origin (Vacher, 1973). The aeolianites were built from calcarenite produced mainly offshore and transported to the shore and so the inference is that during an earlier phase of submergence, the coastline was supplied by abundant reef-derived materials, which then led to beach and dune development before becoming lithified. This supply of reef-derived sediment to beaches and dunes continues today and progradation appears to be healthy (Bird, 1985a), but patchy. Nevertheless the present supply also appears to be more restricted than the former supply, since only on the island's south shore do extensive beaches backed by dune occur. These extensive sandy beaches are pink because of large numbers of fresh *Homotrema* clasts derived from the reefs 1 km from the shoreline (Mackenzie *et al.*, 1965). However, much of the modern south coast is cliff with only limited sources of offshore-derived sediment. Unlike during the earlier development of the calcarenites, the sediments of the lagoon now appear to play little part in beach supply. As a result, the islands' lagoon-facing shore is erosional with a line of cliffs and few pocket beaches (Vacher, 1973).

Sable Island (Figure A60), on the continental shelf to the east of Nova Scotia, Canada, is a low and wind-swept series of sandy islands famous for its sandy shoals and shipwrecks. The development of the Sable Island Bank, on which the islands sit, is related to the proximity of the continental shelf-break and the maximum ice positions of the Late Wisconsin and later readvances. These ice movements deposited a thick suite of glacigenic tills and superficial sandy material, that was subsequently subject to transgression, modification, and transport (King, 2001). The island has spectacular but desolate sandy beaches backed by sand dunes that reach up to 30 m high and cover 40% of the island's surface (Byrne and McCann, 1995). The intertidal zones of the long sandy beaches are characterized by prominent shoreface attached ridges with intervening depressions that reach up to 12 m deep (Dalrymple and Hoogendoorm, 1997). Strong alongshore currents cause eastward migration of these bars alongshore at rates of up to 50 m a^{-1} and at angles of up to 50° to the coastal orientation (Dalrymple and Hoogendoorm, 1997). The dunes of Sable consist of primary dunes that have developed *in situ* together with secondary dunes that have migrated across the island. The resultant coastal morphology represents a mix of both natural processes and anthropogenic disturbance. For example, the constantly changing coastal outline has resulted in the relocation of the lighthouse and is thought to be partly due to dune mobilization and reduced vegetation cover under the enhanced grazing pressure of introduced ponies (Owens and Bowen, 1977). Sable Island has undergone 14.5 km of eastward migration but, in spite of this, its 30 km^2 has been maintained over the past 200 years (Cameron, 1965). Sable Island thus seems to be subject to a regime of deposition that appears roughly balanced by an equivalent amount of erosion.

ATOLLS

Atolls are coral reefs found in the open ocean consisting of an annular rim surrounding a central lagoon. There is a general presumption that atolls have volcanic foundations and some 425 have been recognized around the world (Wiens, 1962; McLean and Woodroffe, 1994). However, because of similar superficial morphology many shallower water coral reefs have been termed "shelf atolls" (Ladd, 1977). In Indonesian waters 55 such reefs have been recognized though many will not have the volcanic foundations of the majority of atolls found in the Pacific and Indian Oceans.

The largest atoll is Kwajalein in the Marshall Islands ($120 \times 32\ km^2$) followed by Rangiroa in the Tuamotus ($79 \times 34\ km^2$), though many smaller atolls are only a few kilometers in diameter. In a sample of 99 atolls, Stoddart (1965) indicated a mean area of $272.5\ km^2$, and atolls worldwide are considered to have a total area of $115{,}000\ km^2$.

The contribution of atoll studies to marine geology

Ever since the historic scientific expedition of Charles Darwin in the *Beagle* (1832–36) atolls have captured the imagination of marine geologists and Darwin's synthesis of his ideas on the formation of coral reefs (1842) have stimulated 160 years of research. This stimulus has come from the facts that:

- reef-building corals grow in shallow (<100 m) water
- many atolls rise from depths of several thousand meters
- there is a similarity of morphology (annular rim and lagoon) wherever atolls are formed.

Darwin's hypothesis of atolls evolving from fringing reefs around a volcanic island via a barrier reef stage was the catalyst for subsequent mainstream investigations into glacio-eustatic sea-level change, vertical and horizontal tectonic movements, and the foundations and internal structure of oceanic atolls. Atoll investigations have subsequently played a major part in research into carbonate diagenesis, isostasy, continental drift, plate tectonics, and seafloor spreading. They have generally confirmed the remarkable insight of Darwin regarding the origin of atolls.

The internal structure and origin of atolls

Darwin recognized that resolution of the problem of atoll development required deep drilling and, after several aborted attempts, T. Edgeworth David of Sydney University in 1896–98 drilled the atoll of Funafuti to a depth of 339.7 m, all in shallow water coral, but so fragmented that those who opposed subsidence argued that the core passed through a detrital slope deposit. It was to be almost 50 years before drilling totally penetrated the coral of an atoll to the basaltic basement at a depth of more than 1,300 m on Enewetak atoll. Subsequent drilling, much of it associated with atomic tests, at Enewetak and Bikini atolls but also at Midway by the US Geological Survey, and at Muroroa and Fangataufa in French Polynesia, by the French, confirmed both the volcanic foundations of atolls and the depth of *in situ* coral far below the photic limits of both modern coral growth and growth at glacially lowered sea levels. Volcanic basement was determined at 1,283 and 1,408 m at Enewetak, 415 and 438 m on Mururoa (though seismic results show basalt as shallow as −170 m, Guille *et al.*, 1996), 153 and 503 m at Midway and 270–400 m at Fangataufa. These figures are typical of those from many other atolls, which have now been investigated by drilling or seismic survey.

While shallow water corals have been recognized to depths greater than 1,000 m, clearly confirming widespread subsidence, considerable lithification, cementation, and diagenesis has taken place in the lower sections of the atoll foundations, which have been determined as up to 30,000,000 years in age. Alteration of the carbonate rocks results from fluctuations of more than 100 m in sea level with vertical migration of phreatic water table favoring the transformation of the original aragonite of the biogenic structure to calcite. At depths greater than 500 m cold permeating sea water dissolves both aragonite and calcite leaving behind only low-Mg calcite. Dolomitization takes place within thick aquifers of mixed fresh and saline waters and is common in the lowest portions of the atoll foundations.

Like other reefs, atolls were most recently exposed during the last glaciation when karstic processes prevailed on the atoll surface, as in previous low sea-level phases, forming a clearly identifiable "solution unconformity" beneath Holocene reef material which is commonly only 10–20 m thick. Karstic features, including the saucer-like shape of atolls, have long been considered to be the major determinant of the gross morphology of atolls (e.g., see Purdy, 1974).

The internal structure and radiometric ages of basalts beneath atolls have been integral parts of the evidence to develop the ideas of plate tectonics and seafloor spreading (e.g., Scott and Rotondo, 1983; Guille *et al*., 1996). Volcanoes develop at oceanic "hot spots" from which they migrate through tectonic plate movement, acquiring coral reefs if they are in warm enough waters. Subsidence takes place due to both volcanic loading and cooling, and reefs and islands pass through the classic Darwinian sequence of fringing, barrier, and atoll formations producing linear chains along the direction of plate movement, such as the Hawaiian and Society Islands. If they are out of the zone of coral growth, subsidence continues and atolls become submerged as guyots, for example, the Emporer Seamounts to the northwest of the Hawaiian chain.

The surface morphology of atolls

The high energy situation of most atolls means that once they reached sea level after their last period of exposure, they have quickly developed strong zonational patterns. Reef slopes commonly display groove and spur structures, reef crests are surmounted by significant algal ridges and reef flats of about 500 m width are a conduit for sediments which form accumulating aprons of sand within the lagoon. Lagoons, with or without patch reefs are often of similar depth, within the range of 10–30 m with only a thick Holocene sediment veneer over the older Pleistocene foundations. Water circulation within the lagoons is complex, with wave setup raising swell side water levels and strong flow over the rim. Water escapes through leeward passes but in many instances a return bottom current back towards the swell side may be present.

Particularly on the swell and/or windward side of atolls, are linear islands termed "motus" separated by narrow passages or "hoa." The majority are constructed of coral gravel broken from the reef front and deposited a set distance back on the reef flat as the entraining waves lose their transportational capacity. Spectacular episodes of deposition have been described during hurricanes or tropical cyclones but these are not absolutely necessary for motu formation as equatorial atolls such as the Maldives, not experiencing strong, tropical revolving storms, also have significant island development. These islands may be only a metre or so above high tide and are regarded as the coastal landforms most susceptible to sea-level rise associated with global climate change.

AUSTRALIA, COASTAL ECOLOGY

Australia is a large island continent with over 61,700 km of coastline (including near by islands). The coastline stretches from the tropics (10°S) to cool temperate (44°S), north–south, encompassing 30° of longitude (113°E to 153°E), east–west. Australia's ocean territory is one of the largest marine jurisdictions in the world (16.1 million km^2) and extends from the tropical epicenter of global marine biodiversity to the Antarctic (Zann, 1995). Australia's continental inshore environment contains a major slice of the marine biodiversity of the Southern Hemisphere, including a large number of unique species (in the temperate south) and species threatened in neighboring regions (in the tropical north).

Several features distinguish Australian coastal environments from other coastal environments in the world: high climate variability; low runoff; and the influence of the El Niño–Southern Oscillation. Australia has the least runoff, the fewest rivers and the lowest rainfall of any inhabited continent. In addition, high evaporation rates and low continental relief (particularly along the southern coast) combine to markedly reduce the rate of runoff to oceans. Australia's high climate variability is partly associated with the effects of the El Niño–Southern Oscillation, which results in drought followed by heavy rains and flooding—particularly in the east (DEST, 1996). In southern areas, ecosystems are attuned to drought/flood cycles while in northern areas, ecosystems are attuned to wet/dry cycles.

Australia's unique geological and tectonic history have produced a highly diverse and distinctive marine biota. Over geological timescales, Australia's coastal environment and biota has evolved and been greatly influenced by geological, tectonic, and climatic stability, and along the southern coast, by geographical and climatic isolation (Poore, 1995). Australia has had a relatively stable climate due to the northward movement of the Australian tectonic plate (which has compensated for global cooling). The rate of change of relative sea level along the coastlines has been slow and largely controlled by changes in global sea level and eustatic processes, rather than localized tectonic movements. This has allowed the adaptation and migration of the marine biota. In addition, Australia's variable climate, range of coastal environments, and the low nutrient status of its coastal waters, have contributed significantly to the diversity and endemism of Australia's marine environments, particularly among some marine taxon (e.g., fish, mangroves, seagrasses, macroalgae, sponges). Low nutrient regimes generally promote biological diversity and coevolutionary strategies to rapidly harvest, utilize, and recycle limited nutrient resources.

The position, size, and shape of the Australian continent have also contributed to the high level of marine biodiversity. Australia straddles the Tropic of Capricorn, so over one-third of the continent is in the tropics with the remainder in the temperate latitudes. The large continental landmass of Australia (and extensive continental shelf) and the shape of the continent provide extensive east–west coasts, with few contiguous coasts in the world possessing such extensive east–west coastlines. Australia's northern coastline adjoins tropical water masses and the southern coastline (the longest in the Southern Hemisphere) adjoins the Southern Ocean, resulting in distinct tropical and temperate biotas. The El Niño–Southern Oscillation also has a major influence on water temperatures and marine life.

In southern Australia, endemism among the marine fauna and flora has been enhanced by the isolation of the coastal shelf biota from other southern continents (by ocean basins) since the Paleocene or Eocene and also, from a latitudinal temperate gradient to the north (Poore, 1995). Further, geological stability has allowed relatively undisturbed sequences, compared with many other parts of the world, and the survival of many ancient and relict species of Pangaean and Gondwanan origin, particularly for many invertebrate species (Durham, 1979; Fleming, 1979). The long east–west, ice-free, extent of the southern coastline (i.e., the longest stretch of south facing coastline in the Southern Hemisphere) has also contributed to the diversity among the temperate biota. Together, these factors have contributed to globally significant levels of biodiversity and endemism in the marine biota, particularly among the marine algae (Womersley, 1990; Phillips, 2001) and some invertebrate taxon (i.e., bryozoans, ascidians, sponges) (Edyvane, 1996). In addition, many of the marine species, which inhabit the temperate reefs of Australia, are characterized by short larval periods and localized dispersal. For these reasons, there is a great tendency for local and regional rarity and endemism in temperate waters, with species distributions characterized by small, isolated, localized populations.

Australia's "State of the Environment Report" (Commonwealth of Australia 2001) concluded that Australia's marine environments and habitats are generally in good condition, to the extent that this can be measured. Many of Australia's remote areas are assumed to be in good health because they are thought to face few pressures, but information is lacking to confirm this. Only a few areas, however, can be regarded as pristine, because pressures such as nutrient loading, pollution with persistent chemicals, and fishing, have affected nearly all parts of Australia's marine and estuarine ecosystems. Near many cities and other parts of the coastline the condition of some habitats (particularly seagrasses, saltmarshes, and mangroves), is poor. There is increasing concern at the state of estuaries, with assessments of declining water quality, threats to estuarine fisheries and other impacts in many areas. Most rivers, estuaries, and coastal waters near Australia's large population centers show signs of eutrophication. (Commonwealth of Australia 2001) Blooms of toxic marine algae, some species of which may have been introduced from other countries in ships' ballast waters, are periodic, serious problems in parts of southern Australia.

Physical setting

Oceanography

The waters surrounding Australia (and New Zealand) are linked to three of the large ocean basins of the Southern Hemisphere, the Pacific, the Indian, and Southern Oceans. The southwest Pacific Ocean, which borders the eastern margins of Australia, is dominated by the large anti-clockwise circulation of the South Pacific. The elements of this gyre consists of the western-flowing South Equatorial Current, which after crossing the tropical Pacific, deflects southwards to form the East Australian Current, and then turns eastward. South of Australia is the massive Antarctic Circumpolar Current or "West Wind drift". On the western margins of Australia, the Indian Ocean South Equatorial Current, driven by trade winds and westerlies, has a similar anti-clockwise circulation, flowing towards the east coast of Africa and merging with the Agulhas Current, the strongest western boundary current in the Southern Hemisphere. The subtropical convergence and the subpolar convergence zones isolate tropical and subtropical waters of Australasia from the nutrient-rich waters of the Southern Ocean, although some mixing of subantarctic waters does occur at depth in the south Tasman Sea (see Figure A67). For the most part, the southern coast faces the full force of the Southern Ocean and as such, experience some of the highest wave energies in Australia. The El Nino–Southern Oscillation (and El Nino/La Nina cycles) has a major influence on prevailing current systems around Australia, dramatically affecting water temperatures and marine life, including major pelagic fisheries.

Both sides of the island continent of Australia experience poleward-going warm currents, which act as conduits to bring tropical ocean waters with their entrained plants and animals to southern Australian waters. On the east is the East Australian Current (EAC) (a western boundary current) and on the west is the Leeuwin Current, which flows southward along the outer shelf to the southwest corner of the continent, and then runs eastward along the southern margin (Cresswell, 1991). The EAC flows south from the Coral Sea (Church, 1987) close to the continental slope, until central New South Wales (NSW) where it runs further offshore (Cresswell *et al.*, 1983). Once or twice a year the EAC turns into loops in the Tasman Sea off the NSW coast. These loops become detached from the current and form EAC eddies, warm disc-shaped water parcels having a diameter of 200–300 km, and extending 1,500–2,000 m into the ocean (Nilsson and Cresswell, 1981).

On the west coast of Australia, the Leeuwin Current is unique. Unlike other eastern boundary currents (such as the California, Benguela, and Peru Currents and the currents off North Africa), the Leeuwin Current flows southward (rather than equatorial) and is associated with warm water incursions and downwelling (rather than cold water and upwelling) (Cresswell and Golding, 1980; Bye, 1983). The Leeuwin Current is primarily driven by thermosteric effects associated with the flow of extremely warm waters from the Pacific to Indian oceans (via the Indonesian Archipelago). This strongly affects shelf circulation along the entire west coast (and to a lesser extent, south coast) and has profound effects on marine life and also, fisheries (i.e., Southern Bluefin tuna, western rock lobster, mackerel, Horse mackerel, Australian salmon, Australian herring) (Lenanton *et al.*, 1991). The

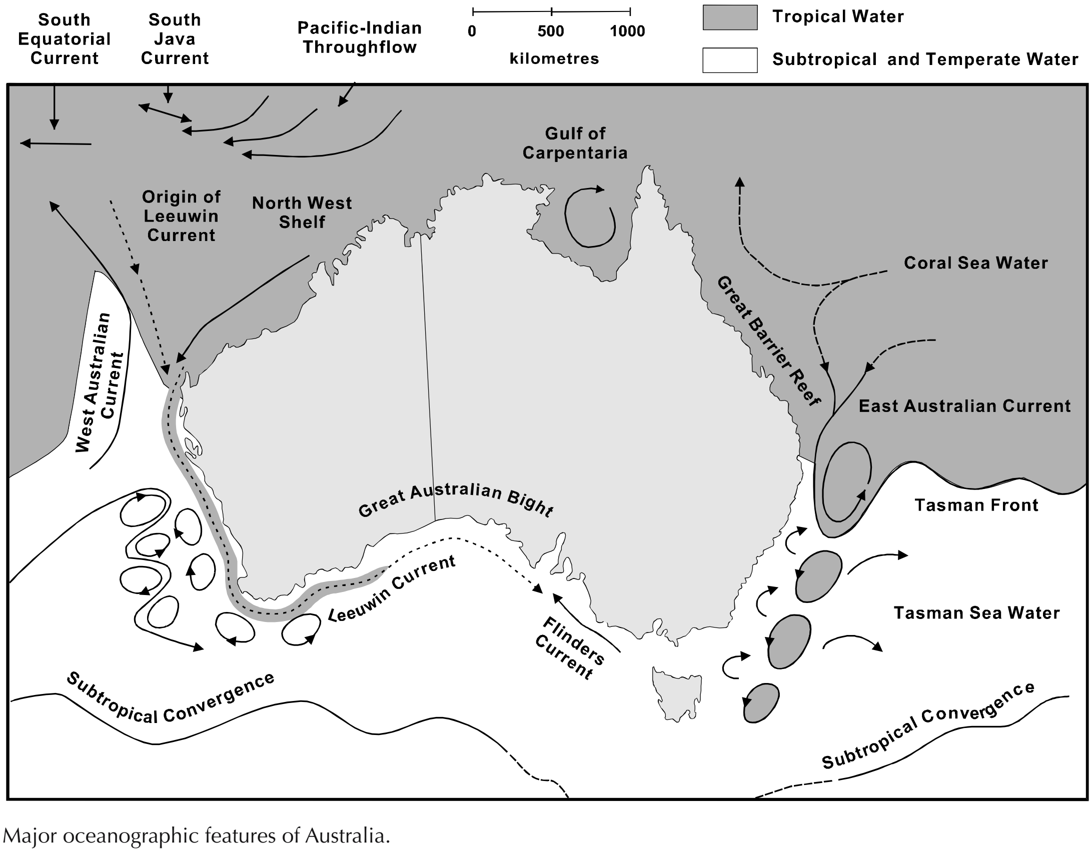

Figure A67 Major oceanographic features of Australia.

warm low-salinity waters of the Leeuwin Current are thought to be responsible for the distribution, migration, and patterns of dispersal of many pelagic marine organisms from the warm waters of the northwest of Australia to the southern seaboard. This is evidenced by a unique "tropical" or Indo-Pacific element, both in the demersal and pelagic fauna of the southern coast (Maxwell and Cresswell, 1981).

Wind-driven continental shelf waves have been identified as a primary source of current variability in practically all Australian continental shelf waters, such as the Great Barrier Reef (Cahill and Middleton, 1993), the New South Wales shelf, the Great Australian Bight (Provis and Lennon, 1981), Bass Strait (Middleton and Viera, 1991) and the North West Shelf (Webster, 1985). With topographic scales of several hundred kilometers the flows are strongly controlled by the coastline and somewhat insulated from the open ocean, and can be extremely complex (e.g. Gulf of Carpentaria, Bass Strait). Between November and May cyclones are a common feature of Australian tropical waters, and can generate strong currents and high mean sea levels, as well as high seas.

Isolation from open ocean waters allow some water masses of distinctive properties to form, particularly in embayments and gulfs. Inverse estuaries (i.e. estuaries which are more saline at the head, rather at the mouth of the estuary) are a characteristic feature of Australia's coasts, particularly in semi-arid regions, due to Australia's low rainfall and variable climate. In the upper reaches of Spencer Gulf and Gulf St. Vincent (in South Australia), low runoff coupled with high evaporation rates result in salinities exceeding 48 psu and 42 psu, respectively (Nunes and Lennon, 1986; de Silva Samarasinghe and Lennon, 1987). Similarly, the limited depth of Bass Strait (approximately 100 m), results in greater cooling of waters in winter (compared with the deeper adjacent ocean), and subsequent cascade down the continental slope into the Tasman Sea (Godfrey *et al*., 1980; Villanoy and Tomczak, 1991).

Nutrients

Australian coastal waters are generally low in nutrients (especially nitrate and phosphate), and hence, are low in phytoplankton and productivity. The oligotrophic nature of Australia's coastal waters is due to both, continental and oceanographic features. Oceanographic factors that contribute to the low nutrient status include: the isolation of Australia's coastal waters (i.e., Great Australian Bight) from rich subantarctic waters to the south; the lack of a nutrient-rich eastern boundary current (and associated upwelling) in the Indian Ocean (originating in high latitudes)—but rather, warm water, poleward currents that bring tropical, nutrient-depleted waters along the continent's east and west coasts (i.e., the East Australian Current and Leeuwin Current); the dominance of large areas by subtropical waters with limited nutrient reserves down to 100–200 m; and the lack of major sources of upwelling of nutrients along the Australian coastline. In addition, wind-induced upwellings, which give enhanced productivity to Equatorial Pacific and Equatorial Atlantic waters, are largely ineffective in the tropical waters of Australia, because of the confused array of closely positioned land masses and islands and their confined seas to the north. Several continental factors also contribute to general nutrient impoverishment. These include: the low nutrient status (particularly in phosphates) of the well-weathered, coastal-drained soils in many areas of Australia; low coastal relief or topography; and low run-off (due to the low and high variable rainfall in Australia).

Australia's marine and estuarine communities have evolved in a generally low ambient nutrient environment, but with in some places a highly variable, nutrient supply, due to the great variability in the climate—particularly the variability in runoff from the land. This may account for the apparent sensitivity and large-scale decline of some Australian biota (such as seagrasses) to nutrient enrichment of estuarine and coastal waters. Following European settlement, the catchments of Australian rivers are now, poorly vegetated, and low rates of infiltration of rainfall result. Thus, runoff from Australian rivers is more highly pulsed with long droughts interspersed with major flooding events. This flooding typically leads to turbidity and nutrient plumes into coastal waters.

Much of Australia's continental shelf and coastal marine environment lies within the tropics. At higher latitudes, water temperature, levels of wind mixing and inputs of light necessary for photosynthesis go through pronounced seasonal cycles (Harris *et al*., 1987, 1991; Clementson *et al*., 1989). Because of the annual winter replenishment of nutrients, temperate oceanic and continental shelf regions tend to support larger seasonal blooms of algae and greater production at higher trophic levels than do (non-upwelling) tropical ocean and shelf systems. However, there are no large seasonal blooms producing surpluses of organic matter. As a result, Australia lacks the large demersal fisheries that characterize Northern Hemisphere continental shelf systems. Lacking a well-defined seasonal cycle, biological variability in tropical ecosystems is more closely related to disturbance events and oceanographic processes such as upwelling, floods, tidal mixing, and cyclones.

Nutrient enrichment occurs in several isolated areas around Australia. These include persistent upwellings along much of Australia's eastern seaboard (along the New South Wales coast between Port Stephens and the Queensland border) and at sites along the southern coast of Victoria (Gippsland coast) and South Australia (southern Eyre Peninsula and between Port Macdonnell and Robe), bottom coastal enrichment off New South Wales, cyclonic eddies off eastern Tasmania (southwest Tasman Sea), convective overturn (off Tasmania), North West Shelf enrichment, and tidally induced enrichments of the Great Barrier Reef waters (Wenju *et al*., 1990; Furnas, 1995). Inshore southern habitats under the influence of localized nutrient-rich, cold water, seasonal upwellings, have resulted in very high levels of reef biodiversity (particularly among the macroalgae and invertebrates) and productivity. Off southern Eyre Peninsula, the region is also a key area of pilchard abundance (Ward *et al*., 1998) and one of the most important sites for seabirds and marine mammals in temperate Australia (Edyvane, 2000).

Continental shelf and shelf processes

Australia's continental shelf covers approximately 2 million km^2, an area equal to about 25% of the continent's land surface. It is shallow, generally less than 200 m in water depth, and in vertical profile is a smooth, flat surface, which dips gently seawards, with some parts rimmed by shelf edge barrier reef systems (e.g., the Great Barrier Reef shelf). In a global context, the depth of the shelf break (20–550 m water depth and defined as 200 m by international convention) and the width (2–1,500 km) exhibit a wide variability. The shelf break is located about 10 km offshore from Fraser Island (east coast) and North West Cape at Exmouth (west coast), but over 500 km distance offshore on the Arafura Shelf in the north.

The continental shelf is comprised of granitic crustal material—unlike the deep ocean bed which is underlain by basalt. During Pleistocene periods of lower relative sea levels, the shelf was exposed subaerially and the Australian mainland was "joined" by dry land to several of the adjacent large islands such as Tasmania and New Guinea. Such "land bridges" are considered to have facilitated the migration of animals and humans in the late Pleistocene "Ice Age". The shallow seas comprising the Sahul Shelf, Gulf of Carpentaria, Torres Strait, and Bass Strait were thus subjected to erosion and sedimentation by rivers and wind on several occasions during the past 150,000 years. The basins in Bass Strait, Bonaparte Gulf, and the Gulf of Carpentaria are considered to have been the sites of large fresh to brackish water lakes and lagoons during these periods of emergence.

Coastal sedimentation processes are dominated by: (1) swell waves and storm currents (80% of the world's continental shelves); (2) tidal currents (17%); or (3) intruding ocean currents (3%). Currents produced during storm events—either as tropical cyclones or temperate storms—dominate in the erosion and transportation of sediment over 82% of the Australian shelf surface area. Detrital and organic sediment (i.e. biogenic) sediment is generally dominant on the continental shelf, with carbonate content greatest in offshore sediments (Harris, 1995). In southern Australia, the inshore non-calcareous sediments are generally dominated by coarse-grained relict (i.e., sediment deposited in a previous low sea environment) or reworked quartz sand. In contrast, the inner shelf, non-calcareous sediments of tropical regions are commonly terrigenous silts and clays supplied by the large river systems of northern Australia (e.g., Great Barrier Reef region) (Belperio and Searle, 1988).

Sediments on Australia's southern continental shelf are arranged in zones parallel to the coast (reflecting the dominance of ocean swell and storm generated currents and long period swell waves) and represent some of the largest modern, cool-water, open shelf accumulations of carbonate sediments in the world (Connolly and von der Borch, 1967; Wass *et al*., 1970; Gostin *et al*., 1988; James and von der Borch, 1991). These include the Otway region of southeastern South Australia (i.e., Lacepede and Bonney Shelf) (James *et al*., 1992) and western Victoria (Otway Shelf) and Great Australian Bight (i.e., Eucla Platform) (James and Bone, 1992), the Rottnest Shelf, and the New South Wales Shelf (Davies, 1979). While hermatypic corals and the calcareous green alga

Halimeda characterize tropical shelf carbonate sediments (north of 24°S), bryozoa or "lace corals" and coralline algae dominate the cooler water sediments along the southern margins of Australia (south of 38°S) (Gostin *et al*., 1988).

The sediment loads supplied to the coastal zone by many rivers are trapped in estuaries, hence, little or no sediment may reach the deeper waters of the continental shelf (particularly along the southern shelf). River catchments in the seasonally wet northern parts of Australia generally have a higher sediment yield (on the order of 100–300 t/km^2/yr) than those in the south (on the order of 10–30 t/km^2/yr) (Harris, 1995). Export of continental terrigenous sediment to the wide southern shelf is low because of the low continental relief and lack of significant drainage to the sea, particularly in the Great Australian Bight (i.e., from southwestern Australia, to the mouth of Murray River in central South Australia). Within sheltered areas of low coastal relief, redistribution of coastal sediments result in shallow coastal embayments, dominated by tidal salt marshes, mangroves, and sea grass (e.g., Port Phillip Bay, Spencer Gulf, Gulf St. Vincent), while in exposed coastal areas of high wave energy (e.g., the Great Australian Bight), these reworked sediments supply sediment for extensive beach and dunal systems which dominate these regions (Gostin *et al*., 1988).

Tropical cyclones, associated with atmospheric low-pressure systems, are the cause of storm events in much of northern Australia. The sections of the Australian shelf most frequently affected by cyclones are the North West Shelf with up to 25 cyclones per decade and the Great Barrier Reef with up to 15 cyclones per decade. Tropical cyclones induce strong currents that erode and transport sediment over a wide area. Modeling studies on the North West Shelf (Hearn and Holloway, 1990) have shown that, under the influence of tropical cyclones, strong westward flowing coastal and inner shelf currents are established between the eye of the cyclone and the coast. Such cyclone-induced currents are clearly a significant factor affecting sediment movement on cyclone-dominated shelves, but they may also influence the long-term (net) sediment movement on some otherwise tidally dominated sections of the shelf.

Tidally dominated shelves occur generally where the mean spring tidal range measured along the coast exceeds 4 m (macrotidal). Around Australia, tidal ranges greater than 4 m occur along the northwestern coastline between Port Hedland and Darwin and reach a maximum range of about 9.2 m in King Sound. The southern Great Barrier Reef is also macrotidal, with a tidal range of 8.2 m in Broad Sound. Tidal currents are also an important sand-transporting agent in mesotidal (2–4 m tidal ranges) areas, such as Torres Strait, Moreton Bay (Queensland), and Bass Strait. Tidal currents are able to dominate sand transport in microtidal areas (tidal range less than 2 m) in restricted cases where coastal geometry affords shelter from ocean generated swell and wind-driven currents. Such is the case in many bays (e.g., Shark Bay), the approaches to some major ports (e.g., Port Phillip Bay) and in partly enclosed gulfs (e.g., Spencer Gulf, Gulf St. Vincent, and the Gulf of Carpentaria). Sediment transport and dispersal controlled by intrusive ocean currents affects only a little more than 1% of the Australian continental shelf. The only location where such currents are known to dominate sediment movement around Australia is the shelf offshore from Fraser Island, where the southward-flowing East Australian Current intrudes.

Coastal marine ecosystems and habitats

Marine ecosystems

The marine ecosystems of Australia has been the subject of several biogeographic studies and classifications in recent decades (Womersley and Edmonds, 1958; Womersley, 1959, 1981a,b, 1990; Bennett and Pope, 1960; Knox, 1963; Markina, 1976; Edgar, 1984). The biogeographical regions or provinces identified are traditionally regarded as coastal regions characterized by a relatively distinct and homogeneous flora and fauna, with only a small percentage of species common to adjacent regions, and usually differing in sea temperatures from adjacent provinces by more than 5°C. Many of these classifications have, until recently, been based on a knowledge of the distribution of intertidal biota (rather than on assessments of whole floras and faunas). Traditionally, the tropical and subtropical marine environments of Australia, i.e. >20°C, have been classified into three major biogeographical regions or provinces: the Damperian Province (from the Houtman Abrolhos, 28°50′S, off Western Australia, around northern Australia to Torres Strait); the Solanderian (or Banksian) Province (the mainland coast from Torres Strait, south to about 25°S in southern Queensland; and the Great Barrier Reef Province (comprising the Great Barrier Reef and associated islands) (see Figure A68). However, the widespread distribution of most pan-tropical Indo-Pacific algae suggests that the whole of the tropical Australian coast is probably best regarded as one province, with possibly subprovincial regions (Womersley, 1990).

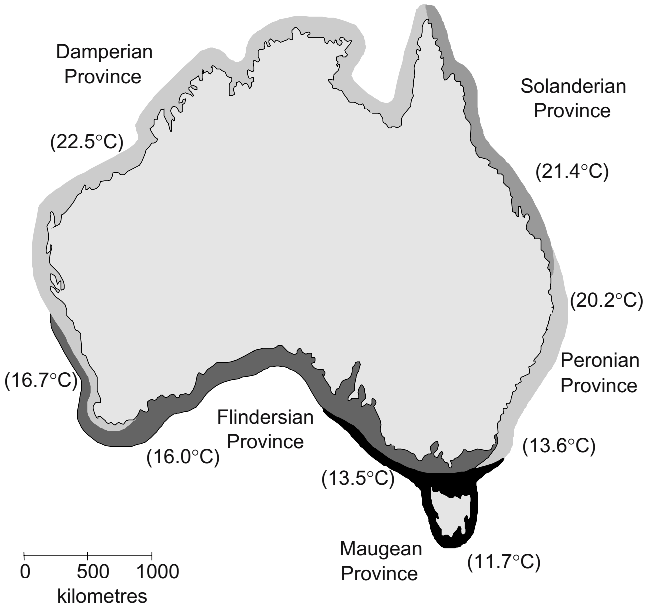

Figure A68 Marine biogeographical provinces of Australia, and average surface sea temperatures (from Edyvane, 1999; courtesy of SARDI).

The temperate marine environments of Australia have traditionally been classified into three provinces: the Flindersian Province, which encompasses the warm–cool temperate (i.e., 12–20°C) waters of southwest Western Australia, along the southern coast of Australia, to southern New South Wales, including the waters of South Australia, Victoria and Tasmania; the Maugean Province (or Subprovince of the Flindersian), which encompasses the cold temperate (i.e., 10–15°C) biota of Tasmania and Victoria and, to a lesser extent, South Australia (east of Robe) and New South Wales (south of Eden); and the Peronian Province, which encompasses the warm temperate (15–20°C) biota of the southern coast of Queensland, down the New South Wales coast to the Victorian border (Bennett and Pope, 1960; Knox, 1963; Womersley, 1981a,b; Edgar, 1984). The biota of Tasmania comprise elements of all three southern Australian marine biogeographic provinces (i.e., Peronian, Maugean, and Flindersian) (Edgar, 1984).

In recent years, biogeographic or regional ecosystem classifications have been developed for many coastal and nearshore marine environments around Australia (Muldoon, 1995). In several states, this has involved utilizing analytical multivariate procedures to classify patterns in nearshore ecosystem diversity. Many of these regionalizations have now been integrated as part of a national effort to develop an "*Interim Marine and Coastal Regionalisation of Australia*" (IMCRA) to assist in the development of a representative system of Marine Protected Areas (IMCRA, 1998). To-date, a total of two pelagic and nine demersal provinces (and biotones) are recognized for the continental shelf (out to the limit of the Australian EEZ), based on physical oceanography, seafloor topography and the distribution of pelagic and demersal fish (CSIRO, 1996a,b; IMCRA, 1998). At a finer scale, a total of 60 mesoscale bioregions have been identified for the nearshore marine environments of Australia, based on a wide range of physical and biological descriptors, such as climate, oceanography (water temperature, wave energy), tidal range, coastal geomorphology, and biology (habitats, marine mammals, endemic species) (IMCRA, 1998).

Coastal and marine habitats

The coastal habitats of Australia are largely influenced by the interplay of physical factors, particularly oceanography, climate, and coastal geology. As such the inshore environments of Australia range from low-energy muddy tidal deltas, which dominate the tropical north, to the swell-dominated rocky coasts and sandy shores of the temperate south. Muddy sediments dominate the tropical environments of Australia,

Table A6 Coastline and coastal types as a percentage of length of coastline around Australia. Percentages remaining from the total is coral reefs and estuary mouths (adapted from Fairweather and Quinn,1995)

	Coastline		Coast type				
State/territory	(km)	Percentage of total	Rock %	Sand %	Mud %	Mud/mangrove %	Total
Queensland	13,347	22.3	4	36	1	19	59
Northern Territory	10,953	18.3	9	40	6	48	97
Western Australia	20,781	34.8	19	49	2	19	87
South Australia	5,067	8.5	33	59	1	8	100
Victoria	2,512	4.2	26	64	7	9	99
Tasmania	4,882	8.2	29	68	2	2	99
New South Wales[a]	2,194	3.7	33	65	1	2	100
Total	59,736	100	18	47	2	19	84

Table A7 Coastal habitats around Australia (adapted from Galloway, 1982; Saenger, 1995; Kirkman, 1997; Edyvane, 1999)

	Coastal habitat		
State/territory	Mangrove (km^2)	Seagrass (km^2)	Number of estuaries
Queensland	4,602 (39.8%)	22,300[a] (40.1%)	307
Northern Territory	4,119 (35.6%)	900[b] (1.6%)	137
Western Australia	2,517 (21.8%)	22,000 (39.6%)	145
South Australia	211 (1.8%)	9,620 (17.3%)	15
Victoria	12 (0.1%)	100 (0.2%)	35
Tasmania	0	500 (0.9%)	63
New South Wales	99 (0.9%)	155 (0.3%)	81
Total	11,558	55,575	783

[a] Includes Torres Strait (18,000 km^2).
[b] Comprises Gulf of Carpentaria (900 km^2).

either under mangrove forests or as wide, near-flat shores on macrotidal coasts. While rocky shores are more widespread in temperate marine environments (particularly in the Great Australian Bight and Tasmania), occupying approximately 30% of the coastline (cf. approximately 11% in tropical areas), sandy beaches dominate the temperate coasts of Australia (see Table A6). While sandy beaches are common all around Australia, they occupy approximately 50–70% of the temperate coastline, particularly along the eastern and western coast of Australia—regions swept by Eastern Australian Current and the Leeuwin Current, respectively (Fairweather and Quinn, 1995). Coral reefs occupy 14% of Australia's coastal habitat and are essentially restricted to tropical regions.

Australian estuaries occur over a wide range of geological and climatic conditions and consequently display a great variety of form (Saenger, 1995). Australia has 783 major estuaries; 415 in the tropics, 170 in the subtropics, and 198 in temperate areas (Table A7). Estuaries are most common in the humid tropics. There are few estuaries on the long arid coastline in the southwest and west. In the semi-arid and arid regions of Australia, low rainfall and variable climate result in irregular freshwater inputs and prevalence of "inverse estuaries", that is estuaries that generally flow (and flood) only after local rains have fallen. Gulf St. Vincent and Spencer Gulf represent the largest temperate inverse estuaries in Australia, while Shark Bay and Exmouth Gulf (in Western Australia) are the largest tropical estuaries. Naturally rich in nutrients, estuaries are ecologically highly productive and are important habitats for adult marine fauna as well as critical nursery habitats for the juveniles of many species.

Coastal saltmarshes. Coastal saltmarshes in Australia are intertidal plant communities dominated by herbs and low shrubs, which are often associated with estuaries. Although there is a high degree of endemism at the species level in the saltmarsh flora of Australia, at generic and family level there is a strong similarity (in structure and composition) between Australian saltmarshes and those elsewhere in the Southern Hemisphere and also in the Northern Hemisphere (Adam, 1990). When viewed in a world context, Australian saltmarshes are not as distinctly "Australian" as are the various terrestrial communities of the continent (Adam, 1995).

Australia has 13,595 km^2 of coastal saltmarshes, with the most extensive areas occurring in the tropics (Bucher and Saenger, 1991). On the continental scale, there is a striking trend of increased species richness and community complexity with increasing latitude (Saenger *et al*., 1977; Specht, 1981; Adam, 1990). Saltmarshes in northern Australia, although extensive, are very species poor (frequently *S. virginicus*—dominated), with frequently less than 10 vascular plant species in their total flora. Compared to northern Australia, saltmarshes in southern Australia (i.e., Victoria and Tasmania), which cover much smaller areas, frequently support at least three times as many species (Adam, 1995). Not only is the flora of individual sites much greater at higher latitudes, but the regional saltmarsh flora is also much higher.

In northern Australia both mangrove and saltmarsh may be restricted to the lower, more frequently flooded intertidal zone while the upper intertidal takes the form of extensive hypersaline flats with only very sparse and localized vegetation. In southern Australia a biogeographic distinction can be drawn between saltmarshes on arid or seasonally arid (Mediterranean climate) coasts and those on temperate coasts with relatively high rainfall (Bridgewater, 1982; Adam, 1990). On drier coasts saltmarsh vegetation is characterized by a diversity of succulent, shrubby chenopods with a tendency to more open vegetation towards the upper tidal limit, while on wetter shores vegetation is denser with more grassland and sedgeland communities. Much of the primary production of saltmarshes is utilized in detrital pathways, which include microbially mediated decomposition, and take place either within salt marshes or in adjacent waters. The assumption of high productivity is linked with the "outwelling hypothesis", by which coastal wetlands act as a source of detritus and nutrients exported to offshore. Data on the linkages of saltmarshes to adjacent waters in Australia are lacking (Adam, 1995).

Saltmarshes provide habitat for numerous organisms of both terrestrial and marine origin. The most important fish habitats in intertidal wetlands are seagrasses and mangroves: Australian saltmarshes, unlike those overseas, generally have few permanent creeks and pans and so provide few fish habitats. Nevertheless, studies indicate that at least some saltmarshes may provide habitats utilized by fish (Morton *et al*., 1987; Connolly *et al*., 1997). Coastal wetlands are an important habitat for birds. The number of species breeding in saltmarshes is small, but the upper marsh vegetation provides nest sites for some species. A large part of the population of one of the rarest species in Australia, the orange-bellied parrot (*Neophema chrysogaster*), overwinters on saltmarshes in Victoria where it feeds on the seeds of chenopods. Migratory waders feed largely on invertebrates in intertidal sand and mudflats but saltmarshes may provide secure high tide roosts. Little is known about the utilization of saltmarsh by other faunal groups.

Mangrove forests. Australia has the third largest area of mangroves in the world (approximately 11,500 km^2) and some of the most diverse communities (Galloway, 1982). The mangrove flora of Australasia (the area including New Guinea, New Caledonia, Australia and

New Zealand) is one of the richest in the world, having approximately five times the species richness of all other regions excepting the neighboring region of Indo-Malesia (Duke, 1992). Generally, the greatest concentration of mangrove species in Australasia is found in southern New Guinea and northeastern Australia, where 45 taxa of mangrove plants are shared (Robertson and Alongi, 1995). The most recent review of mangrove species in Australia (Duke, 1992) recognized 39 taxa of mangrove plants belonging to 21 genera and 19 families. The taxa include at least four rare hybrids of more common species. Only one species, the newly discovered *Avicennia integra*, appears to be endemic to Australia. All other species are widely distributed on the island of New Guinea or in Southeast Asia.

Mangroves are generally associated with low energy, muddy coastlines, particularly tropical deltas. However, they can grow on a wide variety of substrates including sand, volcanic lava, or carbonate sediments (Chapman, 1976). Mangrove environments dominate the tropical coastal habitats of northern Australia, occupying approximately 11,228 km^2 (cf. 333 km^2 in southern temperate Australia) (see Table A7). Mangrove forests show their greatest development on humid, tropical coastlines where there are extensive intertidal zones (as found on low gradient or macrotidal coasts), and abundant fine-grained sediment, high rainfall and freshwater runoff from catchments. However, there are large local forests in the subtropics and as far south as Corner Inlet in Victoria at 38°S. The temperate marine environments of Australia are generally characterized by a lack of mud, tidal delta, and mangrove habitats, apart from large sheltered embayments (such as Port Phillip Bay, Spencer Gulf and Gulf St. Vincent). The largest areas of temperate mangrove forest occur in South Australia (approximately 332 km^2), largely within the sheltered gulfs of Spencer Gulf and Gulf St. Vincent (Galloway, 1982). Similarly, species richness in mangrove communities is greatest in the northeast humid tropics and there is a gradual decrease in the number of species with increase in latitude (Robertson and Alongi, 1995). Some estuarine systems on Cape York have up to 35 species of mangrove plants while to the south (Victoria and South Australia) only one species, *Avicennia marina*, occurs.

Variations in air temperature, rainfall, river runoff, sediment type (and deposition rate), tidal amplitude, and geomorphology along the Australian coast produce a variety of regional coastal settings for mangroves to grow (Robertson and Alongi, 1995). Mangrove communities vary from tall (up to 40 m), highly productive, closed canopy forests dominated by species of the Family Rhizophoraceae (particularly species of *Rhizophora* and *Bruguiera*) in the high rainfall, humid tropics of northeastern Queensland and the Kimberley coast of Western Australia—to the open woodlands of *A. marina*—which dominate the mangrove habitats at latitudes greater than 30°S. As conditions become more arid within the tropics (such as the Pilbara coast in Western Australia), water and salinity stress on mangroves increase in the intertidal zone and species richness decreases, and open canopy woodlands or short (1–5 m), and low productivity open shrublands develop (Semeniuk *et al.*, 1978).

Understanding of mangrove food webs in Australia currently only refers to tidally driven (non-estuarine) tropical mangrove forests (of north Queensland). These studies suggest that the carbon budget does not follow the classic overseas models of mangrove food chains—with high sediment bacterial biomass and production (sediment bacteria are a significant sink for carbon fixed by mangrove vegetation) greater than the sum of litter fall and dead wood turnover (Alongi, 1990). Meiofaunal and macrofaunal densities are low in mangrove forests, possible due to low food quality (i.e., very low nitrogen content) of mangrove detritus. Elements of the macrofauna, particularly decapod crustaceans (such as grapsid crabs of the subfamily Sesarminae), play major roles in food chains and nutrient transformations (i.e. retention of nutrient litter and hence, total tidal export of materials from forests) in intertidal tropical forests (Robertson, 1991). Little work has been done on other mangrove forest types and current models are unlikely to apply to the range of forest types in the different regions of Australia.

Mangrove ecosystems are important habitats for nekton. Fish species of the families Ambassidae, Clupeidae, Engraulididae, Gobiidae, and Leiognathidae are numerically dominant in mangrove waters, while species of Sparidae, Haemulidae, Lutjanidae, Carcharhinidae, Centropomidae, and Carangidae contribute significantly to the biomass of mangrove fish communities. Many of the dominant fish families occur in mangroves only as juveniles and recruitment from offshore waters is dependent on a number of factors, not least of which is the strength of the wet season and thus the prevailing inshore seawater salinities (Robertson and Duke, 1990). While recruitment factors are important, the variation in forest types and the availability of food and microhabitats are important factors in controlling spatial variation in fish densities and community structure (Robertson and Blaber, 1992).

There can be significant export of detritus from mangrove habitats to nearshore receiving waters. The importance of mangrove detritus in supporting higher consumers (such as fish and prawns) in estuarine and coastal areas of Australia has been confirmed. For instance, the zoea larvae of sesarmid and ocypodid crabs from mangrove forests are a major food source for juvenile fish in north Queensland estuaries. The juveniles of some penaeid prawns feed on mangrove detritus or on meiofauna that is mangrove dependent.

Some of Australia's most important single species commercial and recreational fisheries are directly linked to mangroves during at least part of their life cycles, such as the banana prawn (*Penaeus merguiensis*), bream (*Acanthopagrus australis* and *Acanthopagrus berda*), grunter (*Pomadasys kakaan*), barramundi and mangrove jack (*Lutjanus argentimaculatus*) (Robertson and Alongi, 1995). Other commercial fisheries have more indirect but equally important connections to mangroves. In the wet tropics of northeastern Australia, the seagrass meadows on which juvenile tiger prawns (*Penaeus esculentus*) depend often occur immediately seaward of mangrove forests (Robertson and Lee Long, 1991). Mangroves in Australia are also important nursery grounds for a variety of small non-commercial fish species, which are an important food source for carnivorous estuarine fishes such as barramundi and trevallies and jacks (Carangidae), and offshore billfish and mackerel.

As elsewhere in the world, mangroves play a major role in coastal protection in Australia. Mangroves in northern Australia are likely to play a major role in ameliorating the effects of cyclones and storm surges on nearby urban centers and low-lying agricultural lands. Mangrove forests are also major sites of trapping and stabilization of sediments derived from river catchments.

Seagrass beds. Seagrasses are productive, widespread, and ecologically significant features of Australia's tropical and temperate nearshore environments (Larkum *et al.*, 1989). Australia has the highest biodiversity of seagrasses in the world, the largest areas of temperate seagrass and one of the largest areas of tropical seagrass. Australian seagrasses are characterized by high speciation and also, endemism, especially in temperate regions. Australia has over 30 species of seagrass, which can be broadly categorized into tropical and temperate groups (Kuo and McComb 1989; Kirkman, 1997). On the basis of species composition and distribution a transition zone occurs at approximately 30°S (Moreton Bay) on the east coast and 25°S (Shark Bay) on the west coast (Larkum and den Hartog, 1989).

Of the 55,500 km^2 of seagrass meadows in Australia, the largest meadows occur in tropical Australia, in Torres Strait (17,500 km^2 or 31.5%) and Shark Bay (13,000 km^2 or 23.4%). Within temperate waters, seagrass meadows are largest and most diverse along the southern coast of Western Australia (9,000 km^2 or 16.2%) (Poiner and Peterken, 1995), and Spencer Gulf (5,520 km^2) and Gulf St. Vincent (2,440 km^2) in South Australia (Edyvane, 1999). In contrast, seagrass abundance (and diversity) is low in southeastern Australia, where the high-energy coastline restricts seagrass to estuaries and protected bays. For instance, seagrass occupies approximately 500 km^2 (or 0.9%) in coastal Tasmanian waters, 150 km^2 (or 0.3%) in the waters of New South Wales and 100 km^2 (or 0.2%) in Victoria waters (see Table A7).

Australia's seagrasses can be divided into those with temperate and those with tropical distributions, with Shark Bay on the west coast and Moreton Bay on the east coast located at the center of the overlap zones. Temperate species are distributed across the southern half of the continent, extending northwards on both the east and west coasts. These species have been studied most extensively, particularly the large genera *Amphibolis, Posidonia*, and *Zostera*, although species remain that have been little studied. The highest biomasses, and highest regional species diversity, occur in southwestern Australia, where seagrasses occur inside fringing coastal limestone reefs, or in semi-enclosed embayments. Large seagrass meadows are present in protected areas across the Great Australian Bight, and into South Australia and Tasmania. Along the New South Wales coastline, seagrasses are confined to estuaries such as Botany Bay, except for the large sheltered embayment of Jervis Bay (Kirkman, 1997).

In northern Australia, seagrass species possess tropical affinities, for example, *Thalassia* and *Cymodocea*. Tropical beds can be of high diversity, but generally possess lower biomasses than in temperate zones. While large areas of seagrasses occupy embayments such as Hervey Bay, Queensland, tropical seagrasses are generally confined to intertidal environments, or to deep water (Lee Long *et al.*, 1993). The genera *Halophila* and *Halodule* extend beyond the tropics into cooler waters. In the tropics these genera are heavily grazed by turtles and dugongs (Lanyon *et al.*, 1989). Grazing of tropical seagrasses by dugongs and sea turtles provides another unique aspect of tropical Australian seagrass meadows. Caribbean and Indo-Pacific seagrass meadows are characterized by the absence or depletion of macrograzers (i.e., manatees, sea turtles, dugongs), due to overfishing. Hence, tropical Australian seagrass meadows are probably more representative of the natural conditions in which tropical seagrasses evolved.

Seagrass growth is confined to estuaries and protected embayments in southeastern Australia, due to the high-energy coastline. Although a generalized north-to-south distribution pattern can be given, the distribution and dominance of the three sea grass genera (*Zostera, Halophila,* and *Posidonia*) is dictated by the occurrence and nature of those coastal features, which offer a suitable growth habitat for them.

Unlike temperate seagrass species, tropical seagrasses tend to occur in mixed-species stands. Thirteen species from seven genera are found across northern Australia. The region has a greater diversity of seagrass species and communities than elsewhere in the Indo-Pacific. Torres Strait supports one of the largest seagrass areas in Australia. A total of 17,500 km^2 of seagrass supporting habitat associated with 295 km of coastline or reef has been identified and mapped. The Gulf of Carpentaria, a shallow marine embayment, supports 906 km^2 of seagrass habitat along 671 km of coastline. The northwestern coast of Australia is the least well-known areas of northern Australia. Tropical seagrass meadows directly support dugong (*Dugong dugon*) and green sea turtles (*Chelonia mydas*) (Lanyon *et al*., 1989).

Seagrass communities are of considerable importance in the processes of coastal ecosystems because of their high rates of primary production and their ability to trap (and stabilize) coastal sediments and organic nutrients. Their importance to commercial and recreational fisheries is well documented (Cappo *et al*., 1998; Butler and Jernakoff, 1999). Additionally, seagrasses are important in substrate stabilization, supply and fixation of biogenic calcium carbonate, detrital food chains, nutrient cycling and as substrate for epibiota, and as critical habitats for many species (Larkum *et al*., 1989).

Rocky reefs. Rocky shores are the main hard substrata of headlands along the open coasts and sometimes within estuaries. Rocky reefs occur along the entire length of the Australian coastline, mostly within shallow ocean waters. However, they are more widespread in temperate marine environments (particularly in the Great Australian Bight and Tasmania), occupying approximately 30% of the coastline (cf. approximately 11% in tropical areas) (Table A6). Prominent areas of reef occur seaward of most headlands and rock platforms. Significant amounts of subtidal rocky reef are also found in deeper waters offshore, around islands, and in estuaries; among the latter, in drowned river valleys.

Species diversity is particularly high in temperate rocky reef habitats (Keough and Butler, 1995). The southern coastline has the world's highest diversity of red and brown algae (around 1,155 species), bryozoans (lace corals), crustaceans, and ascidians (sea squirts). Diverse assemblages of brown, red, and green macroalgae, along with sponges, ascidians and other sessile invertebrates enhance habitat complexity and provide many opportunities for specialization (e.g., Jones and Andrew, 1990; Lincoln Smith and Jones, 1995). Furthermore, the large macroalgae (such as kelp), that partially cover most rocky reefs, enhance overall species diversity by providing patches of shaded habitat favored by distinct assemblages of organisms (Kennelly, 1995).

The intertidal ecology of Australian rocky shores (particularly temperate coasts) has been relatively well described (Womersley and Edmonds, 1958; Womersley and King, 1990). In contrast, very few studies have been conducted on tropical rocky shores. Similarly, the subtidal hard substrata or reefs of Australia are little known. It has only been since the advent of SCUBA apparatus in the 1960s, that detailed subtidal reef studies have been conducted and these have largely been restricted to temperate reefs (e.g., Shepherd and Womersely, 1970, 1971, 1976, 1981; Shepherd and Sprigg, 1976; Shepherd, 1983; Edgar, 1984; Jones and Andrew, 1990; Underwood and Kennelly, 1990).

The ecology of subtidal temperate reefs in Australia is characterized by the structural dominance and diversity of large macroalgae and an abundance of sessile and mobile invertebrate assemblages (i.e., sponges, bryozoans, ascidians, hydroids, echinoderms, molluscs, crustaceans) (for recent views, see Underwood and Chapman, 1995; Keough and Butler, 1995). In the cold temperate waters of Australia (east of Robe, South Australia), shallow, wave-exposed nearshore reefs are dominated by large canopy-forming species of brown macroalgae, such as the Giant Kelp (*Macrocystis*), *Phyllospora comosa* and the just subtidal, Bull Kelp (*Durvillea potatorum*) (Womersley, 1981a,b; Womersley and King, 1990; Underwood and Kennelly, 1990; Underwood *et al*., 1991). In warm temperate waters (west of Robe), wave-exposed nearshore reefs are dominated by smaller (i.e., up to 2 m high), canopy-forming brown macroalgae, such as *Ecklonia radiata*, and fucoid algae (such as *Seirococcus axillaris, Scytothalia dorycarpa*, and species of *Cystophora* and *Sargassum*). In deeper waters, these large algae are replaced by smaller turfing red algae and sessile invertebrates (particularly sponges, bryozoans, ascidians, hydroids, and soft corals).

Urchins are important algal grazers on temperate reefs (Keough and Butler, 1995). Dominant genera on open coasts range from *Centrostephanus* and *Heliocidaris* in New South Wales, to *Heliocidaris* alone in South Australia, to a mixture of *Heliocidaris, Tripneustes*, and *Echinometra* in southwestern Western Australia. In the warm temperate waters of eastern Australia, heavy grazing by the common eastern Australian urchin (*Centrostephanus rodgersii*), typically results in distinct "urchin barrens" (Jones and Andrew, 1990). While this habitat (and urchin) has, until recently, been rare in southern Australia, it has become more common with the introduction (and increasing dominance) of *Centrostephanus* in southern waters over the past several decades. This is probably due to the increased southern penetration of the warm water, Eastern Australian Current along the eastern seaboard (due possibly to climate change), which has resulted in a significant increase in warm temperate components of the marine biota in southern Australia (Edgar, 1999).

Rocky reef provides refuge and feeding opportunities for a wide variety of fish and mobile invertebrates (Jones and Andrew, 1990; Lincoln Smith and Jones, 1995). Small fish and invertebrates can escape predators by hiding in cracks and crevices. Larger fish, along with octopus and cuttlefish appear to use rocky reef as cover from which they can ambush passing prey. Pelagic fish are also attracted to rocky reef areas by aggregations of small baitfish. Many species of invertebrates and algae live on or within rocky habitat and provide a diverse range of foods. Some fish along with abalone and sea urchins eat drift and/or attached algae associated with rocky reefs (Jones and Andrew, 1990). Many commercially and/or recreationally important fish and invertebrates depend on rocky reef habitat for some or all of their life (i.e., rock lobster, abalone). However, very little is known of the habitat linkages of these species, and their trophic interactions with other reefal organisms.

The species and size composition of fish communities using rocky reefs is likely to vary between (superficially) similar reefs, even within a relatively small area (e.g., a particular embayment, estuary or length of coastline), because of factors such as water quality, larval supply and proximity to other habitats such as sea grasses and mangroves (Bell *et al*., 1988; Hannan and Williams, 1998). Thus, many reefs are likely to have a degree of uniqueness in terms of their ecological function. Estuarine reefs, though relatively species-poor, are likely to represent an important "stepping stone" for larger juvenile fishes moving between nursery habitats (such as sea grass and mangroves) and habitats used by adults.

In areas of high wave exposure and localized, cold-water oceanic upwellings, very high levels of invertebrate and macroalgal diversity (i.e., 95–125 dominant species) occur on nearshore reefs, particularly for species of Rhodophyta (i.e., red algae) (Shepherd, 1981; Edyvane and Baker, 1996). Species of articulate and crustose coralline red algae are particularly prevalent in these mixed-red algal communities, and are known to form key microhabitats for the larvae of economically important invertebrates (such as the abalone, *Haliotis rubra*) (Shepherd and Turner, 1985). In areas of very high current or tidal movement, rocky reefs are dominated by suspension feeders (i.e., sponges, echinoderms, bryozoans), which form diverse sponge gardens, even in relatively shallow waters (<15 m).

Some macroalgal-dominated rocky reefs, by virtue of their latitude and/or offshore location, support distinct communities of tropical species. Diverse assemblages of reef-building corals along with associated tropical fish, algae, and invertebrates can be found as far south as the Solitary Islands (New South Wales) and Rottnest Island (Western Australia). Offshore islands are often host to tropical species well beyond their normal (inshore) ranges as they are often subject to warmer water temperatures than those experienced inshore (Kuiter, 1993), due to greater influence by the warm East Australian Current (Kailola *et al*.,1993).

Sandy shores. Sandy and soft-sediment shores and their biotic assemblages are unlike any other marine benthic habitat. In contrast to rocky shores, sandy and soft-sediment habitats are characterized by their three-dimensional nature (i.e., depth is an important variable); range of grain size, depth and chemistry of the sediments (which exerts a profound influence on the types of organisms living within it); large size range of organisms which include some that ingest the sediment matrix, as well as living on or within it; and the lack of large attached plants and dominance of microscopic primary producers (see review by Fairweather and Quinn, 1995). Importantly, soft-sediment habitats provide the contiguity of habitat with other types, such as sea grasses, mangroves, salt marsh and open ocean, which facilitates the movement of organisms among them—both between and within different stages of their life cycles.

As elsewhere in the world, unvegetated, soft-sediment shores remain one of the most under-researched marine benthic habitats in Australia (Fairweather, 1990; Fairweather and Quinn, 1995). In Australia soft-sediment research has been neglected in favor of studies on coral reefs, mangroves, rocky shores, and vegetated habitats within estuaries (Fairweather and Quinn, 1995). In a review of research papers published between 1980 and 1987, Fairweather (1990) reported that only 10% of the 729 papers examined dealt with sandy bottoms, and only 6% with muddy bottoms. This is despite the fact that sandy shores represent on average, approximately 47% (or 36–68%) of Australia's coastline, while muddy shores (particularly adjacent to mangrove forests) comprise approximately 21% (or 1–48%) of the coastline (Fairweather and Quinn, 1995).

Soft-sediment research studies in Australia are very limited and have largely been descriptive (i.e., species lists and zonation schemes) with a few quantitative or semi-quantitative studies (i.e., community descriptions linked to depth zonation), and include tidal flat studies (Rainer, 1981), subtidal soft-sediment studies on detailed examinations of spatial and temporal variation (Morrissey *et al.*, 1992a,b) and quantitative surveys of benthos in Port Phillip Bay (Poore and Rainer, 1979). Significantly, soft-sediment research in Australia has benefited considerably from foreign scientists who have established research programs in Australia, particularly on tidal flats in Western Australia (i.e., Black and Peterson, 1987; Peterson and Black, 1987) and sandy beaches in NSW and Western Australia (i.e., Dexter 1983a,b, 1984; MacLachlan and Hesp, 1984).

Due to the paucity of experimental studies, there are presently no cohesive theories about any aspect of the ecology of soft-sediment intertidal assemblages in Australia (Fairweather and Quinn, 1995). Similarly, understanding of trophic interactions on sandy beaches and hence the flow of energy in soft-sediment ecosystems, is limited.

Coral reefs. The central Indo-Pacific is the world's center of coral reef diversity, with at least 50% of the world's coral reefs, covering an area greater than 300,000 km^2. Australia has the largest area of coral reefs of any nation and the largest coral reef complex, the Great Barrier Reef (GBR). The GBR is the largest single coral reef in the world. There are also large areas of coral reefs in Torres Strait, the Coral Sea Territories and central and northern Western Australia. The Tasman Sea reefs (Elizabeth and Middleton Reefs and Lord Howe Island fringing reef) are the highest-latitude coral reefs in the world, thriving in conditions that are marginal for coral growth elsewhere. Australia's coral reefs form seven distinctive groups: high-latitude reefs of eastern Australia (Solitary Islands, Lord Howe Island, Elizabeth and Middleton Reefs), the GBR, reefs of the Coral Sea (e.g., Ashmore Reef, south to Cato and Wreck reefs), reefs of northern Australia and shallow, turbid waters of the eastern Arafura Sea, Cocos (Keeling) Atoll and Christmas Island, reefs of the Northwest Shelf, reefs of coastal Western Australia (e.g., Ningaloo and Houtman Abrolhos).

The central Indo-Pacific region of northern Australia and Southeast Asia supports by far the richest invertebrate fauna associated with coral reefs in the world (i.e., more than 100 coral genera and some 500 coral species, compared with only 25 genera in the Western Atlantic, and about 60 species from the Caribbean). Australia, because of its geographic position within the world's center of marine biodiversity, is critical to the conservation of corals because of the level of degradation in the region's equatorial reefs. Approximately 70% of all central Indo-Pacific coral reefs have been significantly degraded (Vernon, 1995). This degradation has occurred primarily through over-fishing (which has effectively removed the top of the food pyramid in most Southeast Asian and Japanese areas of reef), eutrophication and increased sedimentation (from urban outfall, deforestation, agricultural runoff and coastal development), and direct intrusive activities (principally through subsistence food gathering—particularly mining practices, shell collecting, and unregulated tourism).

The GBR is not the most diverse in terms of species (Indonesian and Philippine reefs have greater numbers of coral species) but it is extremely diverse in terms of reef types, habitats, and environmental regimes. This is because the GBR is large enough to extend from the low latitude tropics to subtropical zones, to have regions with very different climates (wind patterns and rainfall), tidal regimes, water qualities, bathymetry, island types, substrata, and even geological histories.

Specific threats to Australia's coral reefs include, elevated nutrients in the inner GBR, coral bleaching events, outbreaks of crown-of-thorns (*Acanthaster*) starfish in the outer central and northern GBR and Tasman reefs, damage from the passage of tropical cyclones and outbreaks of coral-eating *Drupella* snails in Ningaloo Reef, Western Australia. Coral reefs are well represented in marine protected areas in Australia. Australia's reefs are less affected by human activities than those in other countries, mainly due to low to moderate levels of use and their remoteness, but elevated nutrients and sediments resulting from inland soil erosion are a threat in non-arid regions.

Research on Australia's coral reefs has largely excluded inter-reefal regions (these comprise more than 90% of the area of the GBR and are heavily trawled for fish and prawns); has inadequately considered biology and processes at a total-systems level; has largely excluded the far northern GBR, the reefs of the Northern Territory and, most importantly, the reefs of Western Australia; and has failed to consider microbial processes (Veron, 1995). Research has also failed to adequately address the needs of long-term conservation, in particular, the effects of sediments and nutrients on reefs, the root cause of *Acanthaster* outbreaks, and the long-term effects of commercial and recreational fishing.

Evolution of marine biodiversity

Australia's coastal environments range from tropical to temperate latitudes and consequently, encompass a wide range of coastal habitats, such as coral reefs, algal reefs, seagrass beds, mangroves, saltmarshes and also, non-vegetated habitats (sandy beaches, mudflats). All major groups of marine organisms are represented, and many of the highly diverse groups and species are endemic—particularly in the southern temperate Australian waters. Australia has the world's largest areas and highest species diversity of tropical and temperate seagrasses, largest area of coral reefs, highest mangrove species diversity and third-largest area of mangroves (Zann, 1995).

The distribution patterns today are the result of contributions from two different early Tertiary biotas:

1. The pan-Pacific Tethyan biota and its successor, the Indo-West Pacific biota, have dominated the northern coasts of Australia since the beginning of the Tertiary and also contribute to temperate biotas, especially in the southwest. To the north, barriers to interchange of shelf and coastal biotas with Southeast Asia are only slight. There are, therefore, many widespread tropical elements in the northern Australian biota and a low percentage of endemicity. At its southern limit the Tethyan element is limited by the latitudinal temperature gradient.
2. The temperate Paleoaustral fauna has dominated southeastern Australian coasts also from the early Tertiary and is now the major element of the biota of the entire southern coast.

Australia's marine biological diversity, like that of the land, is notable for its high proportion of endemic species, particularly in southern Australia. While the marine flora and fauna of tropical Australia and the Indo-Pacific mixed some 20 million years ago (when the continental plates of Australia and South East Asia collided), the marine biota of southern temperate Australia has remained geologically and climatically isolated for over 65 million years—resulting in some of the highest levels of endemism in the world (Poore, 1995). In southern Australia about 80–90% of the species in most marine groups (e.g., fish, echinoderms, molluscs) are considered to be endemic (Poore, 1995) (see Table A8). In northern Australia, only about 10% of the species in most groups are endemic. Approximately 85% of fish species, 95% of molluscs, and 90% of echinoderms are endemic. In contrast, approximately 13%, 10%, and 13% of fish, mollusc and echinoderms, respectively, are endemic in the tropical regions of Australia (Wilson and Allen, 1987). The species in northern waters are mostly shared with the Indonesian archipelago, the epicenter of global marine biological diversity, but a region where many marine ecosystems are under threat.

Australia's southern marine platform, one of the largest in the world, is of considerable evolutionary significance. Due to its tectonic stability since the late Eocene (approximately 40 million years ago), sequences deposited have been little disturbed compared with many other parts of the world. As such, it provides a unique glimpse of the direct ancestral lineages for many invertebrate species found there today. These include the bivalve genus *Bassina* (family Veneridae), which has a continual fossil record from the Oligocene, and *Neotrigonia*, the only extant member of the family Trigoniidae, which was widespread and abundant in the Mesozoic (Durham, 1979; Fleming, 1979). Many of the endemic genera, such as the cowries *Notocypraaea* and the volutes *Ternivoluta*, have fossil lineages dating back to the early Tertiary and may be survivors from an ancient paleoaustral fauna. Other endemic genera, such as the cowries *Zoila*, the bivalves *Miltha* (family Lucinidae) and gastropods of

Table A8 Marine biodiversity in Australia (from Edyvane, 1999; courtesy of SARDI)

	Temperate		Tropical	
Taxon/group	Number of species	Degree of endemism	Number of species	Degree of endemism
Macroalgae	1,155	75% (red algae)	400	low
Sea grass	22	95%?	15	low
Fish	600	85%	1,900	13%
Echinoderms	220	~90%	high	13%
Asteroids	50	high	?	–
Crinoids	7	high	high	–
Ophiuroids	74	high	?	–
Echinoids	49	high	?	–
Holothurians	40	80%	?	–
Ascidians	210	73%	?	?
Mollusks	?	95%	?	10%
Cnidaria	–	–	–	–
Anthozoa	200	?	high	?
Hydrozoa	200	high	low	?
Scyphozoa	10	?	high	?
Sponges	~1,000	high	?	?
Bryozoa	~500	high	low	?
Pycnogonids	50	73%	low	?

the genus *Diastoma* (family Diastomatidae) are relicts of once widespread Tethyan groups that have become extinct elsewhere (Wilson and Allen, 1987).

Australia has a very long coastline (both latitudinally and longitudinally) but trends in species diversity are poorly documented. While saltmarshes, mangroves, fishes, corals, molluscs, echinoderms, and decapod crustaceans (crabs, hermit crabs, lobsters, shrimps, prawns) decrease in diversity from north to south, the same trends are not apparent in other marine taxa, that is macroalgae, seagrasses, sponges, bryozoans, nudibranchs, ascidians, and peracarid crustaceans (amphipods, isopods, and others) (Table A8). In marine amphipods (Barnard, 1991), the reverse is true. In isopod crustaceans a diversity gradient overall is not yet apparent but relative dominance of families certainly changes with latitude as it does in many other taxa. These biogeographic distributions have repercussions in functional ecology—for example, the taxonomic composition of crustacean scavenger guilds. Cypridinid ostracodes, cirolanid isopods, and lysianassoid amphipods play this role but last of these become relatively more important as one moves from tropical to temperate waters.

A noteworthy aspect of the temperate fauna is the occurrence in many genera of eastern and western species pairs that do not interbreed because of geographic isolation (allopatric species). Among the fish fauna there are some 18 of these pairs of sister species, including the wrasse, *Achoerodus viridis* (Eastern Blue Groper) and *Achoerodus gouldii* (Western Blue Groper), *Pelates octolineatus* (western species) and *Pelates sexlineatus* (eastern species) of the grunter family (Terapontidae), and *Vicentia* species (western species) and *Vicentia conspersa* (eastern species) of the cardinal fish family (Apogonidae) (Wilson and Allen, 1987). As a result, warm temperate fish faunas of the Pacific and Indian Oceans are distinct from each other. East–west species pairs have also been recorded in brachyuran crabs, mollusks, and asteroids in Bass Strait (Dartnall, 1974).

A number of Australia's marine species, although found elsewhere, find the greatest security in Australian waters. These include the green turtle (*C. mydas*), hawksbill turtle (*Eretmochelys imbricata*), and loggerhead turtle (*Caretta caretta*), now rare except in Australian waters (Marsh *et al*., 1995). The dugong (*D. dugon*), which is suffering from population decline in many parts of its range, is found in greater numbers in Australian waters than anywhere else in the world.

Trends in marine biota

The seas around Australia are globally significant in terms of many taxonomic groups. However, little is known of the status of most of the marine species. Scientific interest to date has largely centered on the higher vertebrates such as turtles, seabirds, seals, dugongs, and whales. Generally, microscopic organisms (algae, fungi, and bacteria), invertebrates and fish have been neglected. Many marine species remain undescribed and relatively little is known about most of the described species. The conservation status of very few invertebrate species is known. A number of species appear vulnerable because they are rare and have quite restricted habitats. An enormous taxonomic and monitoring effort would be required in Australia to describe all species and to determine their status. While regulations governing many of the fished species have long existed in Australia, marine fish conservation is a relatively new field and the conservation status of most species is poorly known.

Australia's marine phytoplankton includes representatives of all 13 algal classes, including diatoms (5,000 species) and dinoflagellates (2,000 species). The marine plant diversity of Australia is of global significance, particularly among the macroalgae of southern Australia, which represents one of the richest and most unique marine flora's in the world (Womersley, 1990; Huisman *et al*., 1998; Phillips, 2001). The richness of the temperate macroalgal flora (i.e., 1,155 species) is approximately 50–80% greater than for other comparable regions around the world, with an estimated 800 species and over 75% endemism recorded in the Rhodophyta (red algae) alone (Womersley, 1990). This is largely due to the length of the southerly facing rocky coastline (i.e., the longest, ice-free, temperate coastline in the world) and the long period of geological isolation (Edyvane, 1996). While other regions around the world, such as Japan and the Pacific North America, have recorded a higher number of macroalgal species (i.e., 1,452 and 1,254 species, respectively), the coastal waters of these regions encompass a wide range of climatic conditions, from arctic to tropical. Similarly, the level of temperate species biodiversity in macroalgae is approximately three times the level recorded in the tropical regions of Australia, where approximately 200–400 species of macroalgae have been described (Womersley, 1990).

The angiosperms (flowering plants) are also very well represented. Australia has 11 of the world's 12 genera of seagrasses and over half the total number of species (Larkum and den Hartog, 1989). Australia's waters also contain the highest level of species diversity and endemism for seagrasses in the world, with the greatest levels of speciation and endemism in temperate waters, where 22 species have been recorded (cf. 15 species in tropical waters) (Poiner and Peterken, 1995). Australia has 16 of the world's 20 families of mangroves and 40 of the world's 55 species of mangroves.

Among the marine fauna, Australia has one of the largest fish faunas in the world, due to the wide latitudinal range of Australian marine habitats, the presence of the Great Barrier Reef (the world's largest coral reef) and the radiation of a number of temperate fish families (Paxton *et al*., 1989). The warm East Australian Current and Leeuwin Current, flowing down the east and west coasts, respectively, also seasonally bring tropical species into more southerly latitudes. Australia has an estimated 4,000–4,500 species of fish, of which around 3,600 have been described. About a quarter of the species are endemic; most of these are found in southern Australia.

Diversity of several major marine taxa is highest in the tropical regions of Australia. This includes molluscs, echinoderms, and fish.

Among the molluscs, most families are represented in the Australian fauna and have more species in the north of the country than in the south. The level of endemicity in the north is low (about 10%) with most species distributed widely in the Indo-West Pacific region. In contrast, endemicity of the southern Australian fauna is about 95% and several endemic genera occur. Some endemic genera are relicts of the once widespread Tethyan fauna (as are the endemic families, Trigoniidae, Campanilidae, and Diastomatidae, each with a sole living representative). Other endemic genera are relicts of the ancient Paleoaustral fauna.

Echinoderms, with only a few hundred Australian species, repeat the biogeographic patterns of the fishes and molluscs with only 13% of species endemic in the tropical region and 90% in the temperate region. Many echinoderms have a long larval life which may explain why 22% of Tasmanian species occur also in New Zealand where they are transported by the West Wind Drift.

Among the fish fauna, approximately 3,400 species of marine fishes are pelagic or oceanic and wide-ranging in tropical and temperate seas (Paxton *et al.*, 1989). About three-quarters occur on the shelf and nearshore. The greatest number of species are in the tropics where approximately 120 families, 600 genera and more than half of the species (1,900) are found; and most of these are common to the Indo-West Pacific region. Although most species have pelagic eggs and larvae a moderate level of endemicity (13%) is maintained with the help of southerly flowing currents on both the east and west Australian coasts.

The fish fauna of temperate Australia comprises about 600 species of which 85% is endemic and 11% is shared with New Zealand (Wilson and Allen, 1987; Kuiter, 1993). Endemism at the genus level is about 38% (of an estimated 290 genera). One contribution to this high level of endemicity is radiation in a few families with low dispersability; viviparous clinids, brooding syngnathids, and nesting gobiescocids and gobiids. In some 8 families of fish that have more than 10 species, more than half of the total world species occur in Australian waters (e.g., Cheilodactylidae). The five marine fish families Brachio-nichthydae, Pataecidae, Enoplosidae, Gnathanacanthidae and Dinolestidae are endemic to Australia and a number of these families are monotypic. Several families of fish are noted for their explosive radiations in southern Australia. They include pipefishes and sea horses (Syngnathidae), leatherjackets (Monacanthidae), and anglerfishes (Antennariidae). The Australian pipefish fauna is regarded as uniquely diverse. Nearly 80% of the 47 genera in the Indo-Pacific region are found in Australia and 14 of these genera (38%) are endemic. Ten of these genera are monotypic (Wilson and Allen, 1987).

Australia also has an extremely rich chondrichthyan (shark, chimeras or ghost sharks, and rays) fish fauna. It is estimated that at least 296 species, comprising 166 sharks, 117 rays, and 13 chimeras, live in Australian waters. The richness of this fauna is apparent through comparisons with other areas: 182 species have been recorded from southern Africa; 174 from the Japanese Archipelago; and 130 from the eastern North Atlantic and Mediterranean Seas (Last and Stevens, 1994). More than half of the entire Chondrichthyan fauna, some 54%, is endemic to Australia. Of the shark fauna, 48% of the species are endemic, with most of the endemic species being found in tropical or warm temperate areas. More than half of the Australian chimeras appear to be regional endemics, and some 73% of Australian rays are endemic.

Among the reptiles, Australia has about 30 of the world's 50 species of sea snakes, around half of which are endemic (Marsh *et al*., 1995). The family of aipysurids live in coral reef waters and the family of hydrophiids live in inter-reefal waters of Australia's tropics. Six of the seven world's turtle species are found in Australian waters. One, the flatback turtle, is endemic. Breeding migrations may cover hundreds to thousands of kilometers and many turtles breeding in Australia may live around the island of Papua New Guinea, the southwestern Pacific Islands and Indonesia, making species management difficult. Turtles are slow to reach maturity and breed perhaps only five times in their lives, making them extremely vulnerable to overexploitation.

About 110 species of seabirds belonging to 12 families are found in Australia and its external territories. Of these, 76 species breed and spend their entire lives in the region. The remaining 34 species are regular or occasional visitors. Some 14 species or subspecies of Australia's seabirds (13% of the total) are considered to be threatened, largely because their colonies on oceanic islands are few in number and are vulnerable to harvesting and natural disasters. The wandering albatross on Macquarie Island, Abbot's booby on Christmas Island and the Australian subspecies of the little tern are classified as "Endangered" under IUCN criteria. Lord Howe's Kermadec petrel and white-bellied storm-petrel and Christmas Island's Christmas frigatebird are considered "Vulnerable."

In contrast to temperate biota, reef-building scleractinian corals are essentially tropical and their distribution is substantially different from that of echinoderms, molluscs, and fishes. The Australian fauna is a subset of Indo-West Pacific corals and is largely confined to the Great Barrier Reef and smaller reefs on the west coast (Vernon, 1995). There is not a gradual reduction in the number of species with increasing latitude but rather an abrupt depletion of species at the termination of the Great Barrier Reef and at the Houtman Abrolhos. Coral reefs do occur further south—for example, at Lord Howe Island and Solitary Islands—but the number of species is few. Few species of coral occur on the southern coast of Australia and reefs are not formed there.

The tropical dugong is the only fully herbivorous marine mammal and the only Sirenian (sea cow) to occur in Australia (Marsh *et al*., 1995). It is extinct or near extinct in most of its former range which extended from East Africa to South East Asia and the Western Pacific. Northern Australia has the last significant populations (estimated to be over 80,000) in the world. Large, long-lived mammals, dugongs become sexually mature at around 10 years and calve every 3–5 years, making them vulnerable to over-hunting. Major concerns are possible over-hunting of Torres Strait populations, mortalities in fish gillnets and shark nets and loss of sea grass habitat.

Three species of eared seals or pinnipeds breed in mainland Australian waters: the rare and endemic Australian sea lion (*Neophoca cinerea*), the Australian fur seal (*Arctocephalus pusillus doriferus*) and New Zealand fur seal (*Arctocephalus forsteri*) (Shaughnessy, 1999). The Australian populations of the New Zealand Fur Seal are limited in their distribution to southern Tasmania and the Great Australian Bight, and are found on the islands of Recherche Archipelago (WA), eastwards to Kangaroo Island (SA). The Australian Sea Lion is one Australia's most endangered marine mammals and one of the rarest and most endangered pinnipeds in the world and is endemic to Australia (Gales *et al*., 1994). Prior to seal-hunting, this species occurred along the whole of the southern coastline, but is now limited to the offshore islands of Western and South Australia, from the Houtman Abrolhos to the islands of Recherche Archipelago (WA), and from Nuyts Archipelago to Kangaroo Island (SA). Breeding populations of the Australian Fur Seal, which also breeds in South Australia, are confined to southeastern Australia, including Tasmania (Shaughnessy, 1999). Major human threats include entanglement in fishing nets and ocean litter, incidental killing, oil pollution, and disturbances by visitors.

Eight species of baleen whales and 35 species of toothed whales, porpoises, and dolphins are found in Australian waters, although none is endemic (Bannister *et al*., 1996). This is almost 60% of the world's total cetacean species. Australian breeding populations of southern right whales were seriously depleted by hunting as early as 1845. Their population has slowly increased from small remnants totaling a hundred or so, to between 500 and 800. Australian breeding populations of humpback whales were depleted by 1963. Numbers are recovering and there are now thought to be up to 4,000 breeding in Australian waters. Gillnets, shark nets set off bathing beaches, discarded fishing nets and ingestion of plastic litter are considered threats to cetaceans in Australian waters.

Marine and coastal research

While marine and coastal research in Australia is relatively young, Australia has gained preeminence in a number of research areas, including coral reef/tropical marine studies, marine geosciences, physical oceanography, fisheries research, coastal hydrodynamics and numerical modeling, and remote sensing techniques (DITAC, 1989; Zann, 1996). While some subjects and geographic areas are well known, there are serious gaps in knowledge and understanding of Australia's marine environment, particularly in relation to coastal and reef ecosystems, ocean/atmosphere processes, marine chemistry, chemical oceanography and importantly, baseline information on coastal and marine ecosystems, habitats and processes (to facilitate sustainable use).

Research on Australia's tropical marine environments and habitats (such as mangroves and coral reefs), particularly in the Great Barrier Reef region, is relatively advanced. This is largely due to the location and research missions of national marine research and management agencies (Fairweather and Quinn, 1995; Edyvane, 1996). In 1991, around 40% of marine research projects in Australia were undertaken in the tropics. Most research was undertaken in the Great Barrier Reef region (31% of total), followed by the New South Wales coast (16%), Bass Strait (12%), the southwest coast (5%) and the northwest (3%) (Zann, 1996).

Despite the high concentration of Australia's population (approximately 80% of the total population) in the coastal temperate areas of the continent, the habitats and biodiversity of temperate marine ecosystems (particularly subtidal habitats), have largely been under-researched and hence, are poorly documented and understood (Fairweather and Quinn, 1995). This has resulted in the lack of habitat conservation (and integrated management) in many areas of southern Australia, despite the high level of threats and the high level of biodiversity and endemism among a range of marine faunal and floral groups.

Temperate habitat studies in Australia have largely focused on isolated studies of intertidal rocky shores and estuaries and sea grass areas—habitats recognized as important in the management of nearshore fisheries (Fairweather and Quinn, 1995). Research on temperate rocky shores has principally focused on intertidal habitats or the biology of individual reef species or assemblages and particularly, population studies of commercially important species (Fairweather and Quinn, 1995). Regional habitat studies are generally rare and descriptions of macrofloral (or faunal) assemblages of subtidal habitats are geographically very patchy. For some regions (e.g., South Australia, Tasmania) detailed information is known based on isolated subtidal field surveys conducted in the 1970s and 1980s (i.e., Shepherd and Womersley, 1970, 1971, 1976, 1981; Shepherd and Sprigg, 1976; Shepherd, 1983; Edgar, 1984). It is only recently that studies involving broadscale coastal mapping and documentation of temperate subtidal communities, including, reef, sea grass, and soft-bottom communities, have commenced (Edyvane, 1999; Edgar *et al.*, 1997). Elsewhere (such as in the Great Australian Bight and offshore waters), there are almost no published inventories or maps on subtidal benthic habitats (Edyvane, 1996, 2000). This reductionist approach to the study of coastal nearshore ecosystems has principally hindered understanding of these ecosystems and the ecological linkages between reefal and non-reefal habitats (such as sea grass, mud, sandy coasts).

Habitat inventories are particularly required for rocky coasts and reefs and the continental shelf and large gulfs—the two habitats supporting the most valuable commercial fisheries (Cappo *et al.*, 1998). The need for a better understanding of habitat processes and dynamics was highlighted for all major habitat types—as testable paradigms about fisheries production exist only for temperate seagrass. Relative to their fisheries value, overall gaps in knowledge are particularly outstanding for the continental shelf (and slope), followed by rocky coasts, and reefs. Perhaps least studied in Australia are the nursery role and biological processes of sandy shores.

Much of the marine ecological research conducted in temperate Australia has focused on the study of ecological processes, particularly on rocky intertidal shores, rather than a description of the patterns of biodiversity and the distribution and abundance of marine assemblages. These studies have particularly focused on the role of intra- and interspecific competition and predation and their influence on the structure of rocky intertidal assemblages (Underwood and Kennelly, 1990), and also, patterns and variability in recruitment of marine invertebrates, both on small and large spatial scales (see review by Fairweather and Quinn, 1995; Keough and Butler, 1995).

Marine ecological research in Australia requires more effort into baseline mapping of marine biodiversity and the impacts of human use (at a range of temporal and spatial scales), long time-series datasets for trend analysis, and the modeling of coastal processes, and also a greater focus on the linkages between: catchment practices and effects on nearshore ecosystems; reefal habitats and non-reefal habitats; offshore and nearshore ecosystems; and the relationship between coastal physiography, physical processes and scaled patterns of biodiversity, that is ecosystem geography (Edyvane, 1996).

In recent years, a national audit of catchments, rivers and estuaries has been undertaken (Commonwealth of Australia, 2002). Several large, ecosystem-scale modeling studies of Australia's marine environments have also been undertaken, primarily for pollution management. These include Port Phillip Bay in Victoria (CSIRO, 1996), and Cockburn Sound and Albany Harbor (Simpson and Masini, 1990) in Western Australia, and the Huon River estuary in Tasmania, (CSIRO 2000) and Hervey Bay in Queensland (Tibbetts *et al.*, 1998, Dennison of Abal 1999). A major ecosystem study of the North West Shelf (in Western Australia) has been undertaken for tropical fisheries and multiple-use, ecosystem based management (NWSJES 2002).

Summary

Australia's marine environment extends from the coast to the boundary of it's 200 nautical mile exclusive economic zone and covers million square kilometers of seas (an area 16% larger than the land). As the world's largest island, Australia has wide range of coastal and marine environments, which stretch approximately 61,700 km, from the tropical northern regions to temperate southern latitudes. Along this extensive coastline occur a wide range of habitats and biological communities including rocky shores, sandy beaches, algal reefs, kelp forests, which dominate the temperate south, and coral reefs, estuaries, bays, seagrasses beds, mangrove forests and coastal salt marshes, which dominate the tropical north and also, the less understood mid-water, outer-shelf, and deepwater habitats. Australia's marine environments also include external territories in the Indian Ocean, South Pacific, Southern Ocean, and Antarctica.

The extent and diversity of Australia's marine and coastal environments has resulted in some of most diverse, unique and spectacular marine life in the world—supporting some of the greatest number of marine species in the world. For instance, Australia has the world's largest areas and highest species diversity of tropical and temperate seagrasses, the highest diversity of marine macroalgae, the largest area of coral reefs, the highest mangrove species diversity and global levels of biodiversity for a range of marine invertebrates (e.g., bryozoans, ascidians, nudibranchs) (Zann, 1995). Approximately 4,000 species of fish, 43 species of whales and dolphins, and 6 of the 7 world species of marine turtles are recorded from Australia.

All major groups of marine organisms are represented in Australian waters, and many of the highly diverse species are endemic or unique to Australia's waters. The nature of the temperate Australian marine biota, particularly the high level of endemism, is principally a result of the unique geological and tectonic history of Australia, particularly the long period of geological and climatic isolation. In temperate southern Australian waters, which have been geographically and climatically isolated for around 65 million years, most known species (i.e., 90–95%) are endemic or restricted to the area (Poore, 1995). In contrast, in the waters of tropical northern Australia, which are connected by currents to the Indian and Pacific Ocean tropics, most species (i.e., 85–90%), are shared with the Asia-Pacific region.

AUSTRALIA, COASTAL GEOMORPHOLOGY

The Australian coastline is about 20,000 km long (Figure A69), and has many long gently curving sandy beaches interspersed with sectors of cliffs and steep coast. The beaches on the western and southern coasts, from Broome in the northwest to Wilsons Promontory in Victoria and the western coasts of the Bass Strait islands and Tasmania are predominantly calcareous, whereas those of the eastern and northern coasts are generally quartzose, except in the vicinity of fringing coral reefs. Many of the beaches form the seaward margins of depositional sand barriers bearing multiple beach ridge or dune topography (Bird, 1973; Thom, 1984), and on the western and southern coasts the calcareous sands of the older (Pleistocene) dunes have been partially lithified by secondary carbonate precipitation to form dune calcarenites (calcareous aeolianites). These are extensive between Broome and Cape Leeuwin on the Western Australian coast, between Streaky Bay in South Australia and Cape Otway in Victoria, and locally around the shores of Bass Strait, including the west coasts of King Island and Flinders Island and the northwest coast of Tasmania. In places these Pleistocene dune calcarenites have been exposed to marine erosion and cut back to form cliffs and shore platforms (Figure A70).

Cliffs and rocky shores have also developed where older geological formations reach the coast: in Tertiary formations near Cape Cuvier, in granites and older shield formations between Cape Leeuwin and Albany, and in Tertiary formations at the head of the Great Australian Bight. Pre-Cambrian rocks reach the coast on the Eyre and Yorke peninsulas, on the Fleurieu Peninsula and on Kangaroo Island in South Australia. In Victoria there are cliffs cut in various formations, including Cenozoic basalts, Tertiary and Mesozoic sediments, Paleozoic rocks, and intruded granites. Tasmania has extensive rocky and steep coasts developed on pre-Carboniferous rocks and intruded granites, with Mesozoic formations, including Jurassic dolerites, on its southeastern coast. In New South Wales, there are cliffed and rocky headlands on Mesozoic and older rock formations, and in Queensland steep coasts, with limited cliffing, occur on similar formations inshore from the Great Barrier Reef (Figure A71). On the north coast of Australia cliffed and rocky sectors are extensive in Arnhemland and where the Kimberley Ranges reach the sea, both areas of Paleozoic and older rock formations.

In southwestern and southeastern Australia most of the rivers flow into estuarine lagoons with outlets constricted by sandy barrier formations. These lagoons show stages of infilling, largely by fluvial sediments, and some have been reclaimed by river deposition as broad swampy alluvial plains. In northern Australia, river mouths are less encumbered by coastal sand deposition and form estuarine gulfs and deltaic regions. The shores of estuaries, lagoons, and sheltered embayments are often bordered by marshes and swamps, which have advanced on to tidal sandflats or mudflats. The latter become more extensive on sectors of the northern coast where tide range is large.

Coralline reef formations are extensive off the northern half of Australia, particularly in the Great Barrier Reef off Queensland. Numerous outlying patch reefs and coastal fringing reefs occur off the

north and northwest coasts, around to Houtman Abrolhos off Western Australia (Fairbridge, 1967).

Variations in morphology around the Australian coast are related to geological, climatic, oceanic, and biological factors that vary regionally around the margins of the continent (Davies, 1980), taking account of changes in climate and sea level that have occurred on and around the Australian land mass (7.8 million km^2) and its bordering continental shelves (2.5 million km^2).

Geological factors

The western half of the Australian continent is a shield region dominated by Paleozoic and older formations that produce the hard, rocky coasts of the Kimberley region and southwest Western Australia. However, on much of the western coast these formations are obscured by Pleistocene dune calcarenites and associated Holocene dunes. On the Eyre Peninsula in South Australia the dune calcarenite mantle has been cut back by marine erosion to expose underlying harder Pre-Cambrian rocks, which become promontories as bordering cliffs in the less resistant dune calcarenites recede.

The eastern margin of Australia consists of folded Paleozoic rock formations with structural trends roughly parallel with the eastern coastline. These formations have been uplifted and dissected to form the Eastern Highlands, with a watershed varying from 20 to 400 km inland, and a succession of relatively small drainage basins feeding rivers that flow down to the Pacific coast. The structural pattern is complicated by the presence of sedimentary basins occupied by Mesozoic formations: the Sydney Basin, for example, contains the major sandstone formations prominent in cliffs along the New South Wales coast between Jervis Bay and Newcastle.

Between the Western Shield and the Eastern Highlands the continent is dominated by Cenozoic rocks, which occupy a number of basins, several of which extend to and beyond the present coastline. In eastern Victoria the Latrobe Valley syncline passes beneath a depression occupied by the Gippsland Lakes region, where complex sand barriers of Pleistocene and Holocene age are fringed by the Ninety Mile Beach. In western Victoria Tertiary rocks dip gently off the uplifted Mesozoic formations of the Otway Ranges and pass beneath an extensive volcanic province, locally active into the early Holocene: the sequence is clearly displayed in cliff sections westward from Cape Otway to Discovery Bay. Bass Strait is underlain by another sedimentary basin, and on a smaller scale Port Phillip and Western Port Bays in Victoria occupy fault-bounded sunklands (Bird, 1993). Western Tasmania is dominated by Lower Paleozoic rock formations, but in the southeast these are overlain by Mesozoic rocks in an area where Cenozoic faulting has influenced the evolution of ridges and valleys now partly drowned as rias.

In South Australia, a sedimentary basin underlies the Lower Murray valley, and the river flows across Tertiary formations to enter coastal lagoons (Lakes Albert and Alexandrina) behind the Pleistocene dune calcarenite barriers of Encounter Bay. At the head of the Great Australian Bight the Eucla Basin contains Tertiary formations that outcrop on a long stretch of even-crested cliffs bordering the riverless Nullarbor Plain. Similar cliffed formations mark the Carnarvon Basin at Cape Cuvier, but the Tertiary rocks in the Canning Basin, in northwest Australia, vanish beneath the Great Sandy Desert and the dune calcarenites of the Eighty Mile Beach, and the Joseph Bonaparte Gulf Basin is largely a shelf structure. The Carpentaria Basin runs northward under the Gulf of Carpentaria, a graben with Cenozoic formations declining from the western side of Cape York Peninsula, and the much smaller Laura Basin occupies the hinterland of Princess Charlotte Bay on the eastern side.

Despite the existence of these several Cenozoic basins Australia has been generally a rather stable continent, and there are extensive planation surfaces, Cenozoic and older, that show little tectonic deformation, In consequence the continent is notably flat and low-lying, with 80% of the land area below the 500 m contour. Many of the rivers (e.g., the Murray) have low channel gradients as they approach the sea, and carry mainly fine-grained sediments (silt and clay) to their mouths. Steeper gradients exists in rivers draining the Pacific slopes of the Eastern Highlands, and some of these carry sand and gravel in the loads delivered to the sea. Fluvial sediment yields are also influenced by outcrop lithology and past as well as present weathering regimes. Most of the granite outcrops in the Eastern Highlands have been deeply weathered, and rivers draining them derive quartz-rich sands; weathered basalt supply silt and clay, and river gravels are produced by the disintegration of Paleozoic metasediments. On the coast marine erosion has generally removed weathered mantles, so that the granites, for example, usually protrude as rocky headlands, as at Wilsons Promontory in Victoria.

Figure A72 The River Don, in north Queensland, carries sand and gravel down to the coast, where it is spread along the shore by wave action (photo: E.C.F. Bird, Copyright-Geostudies).

Although, the general picture is one of prolonged stability in Australia, marginal neotectonic activity has been recorded locally, especially in Victoria, and the possibility that slight coastal warping has continued into Holocene times cannot be ruled out.

Climatic factors

The prevailing aridity of the interior and much of western and southern Australia has resulted in few rivers draining to the coast: those few flow intermittently, with occasional brief episodes of flooding. In the southwest of Western Australia and the southeast of South Australia winter rainfall nourishes seasonal runoff, but Australia's largest river system, the Murray-Darling, draining a catchment of about a million square kilometers, has only a limited discharge at its mouth compared with those of similar scale in more humid regions. In consequence of hinterland aridity, terrigenous sediment supply to the coasts of much of western and southern Australia has been meager, and coastal deposition nourished primarily from seafloor sources is dominated by carbonate sands of biogenic origin. The presence of such material in shelf sediments is a further consequence of the lack of terrigenous supply, hinterland aridity having evidently prevailed also during Pleistocene phases of lowered sea level.

By contrast, the Eastern Highlands have a higher and more regular rainfall, and the steeper catchments draining to the Pacific coast nourish river systems that have delivered a more substantial terrigenous sediment supply. Coastal sediments are dominated by quartzose sands, some of which are supplied directly by such rivers as the Shoalhaven, the Hunter, the Burdekin, and the Don (Figure A72), particularly during episodes of flooding. Much of the sand deposited in beaches and barriers along the Victorian and New South Wales coasts has, however, been swept in from the seafloor during successive marine transgressions in Pleistocene and Holocene times by the reworking of shelf deposits of quartzose sand derived partly from fluvial supply during low sea-level phases and partly from weathered rock outcrops now submerged. The contrast between the carbonate sands and dune calcarenites of southern and western Australia and the quartzose sands of the southeastern and eastern coast is thus related to a contrast in shelf sedimentation, due in turn to a contrast in hinterland topography and climate through Quaternary times.

Along the Queensland coast terrigenous sediment supplied by rivers includes quartzose sands and lithic gravels derived from relatively steep catchments as well as muddy sediment derived from tropical weathering mantles on catchment outcrops. In addition, coastal sedimentation is locally complicated by the presence of fringing and nearshore reefs built by corals and associated organisms in tropical waters. Reef clastics derived from these are added to adjacent beaches, but despite the proximity of a rich coralline province the beaches of Queensland are generally poor in carbonates (Bird, 1978).

In Northern Australia, summer rainfall (some from occasional cyclones) results in substantial runoff from river systems, but catchments are generally larger and less steep than those of the east coast, and fluvial loads are dominated by fine-grained sediment derived from prolonged weathering of surface outcrops, sandy yields being limited and localized. Muddy sedimentation is extensive on the shores of the Gulf of Carpentaria and in northern embayments and inlets, particularly around Van Diemen Gulf, Joseph Bonaparte Gulf, and King Sound, each of which receives major inputs of river water and sediment.

Other features related to climate include the nature and rate of rock weathering in the shore zone, most active under humid tropical conditions in northern Australia, and the vigor of wind action, which is much stronger on temperate coasts than in the humid tropical north, a contrast that helps to explain the more extensive development and greater mobility of coastal dunes in western, southern, and southeastern Australia (Figure A73) than in the north and northeast. Davies (1980) elucidated such contrasts as these within a climatically based sector classification, clockwise around the continent, from warm temperate humid (Fraser Island to Portland), warm temperate arid (Portland to North West Cape), tropical arid (North West Cape to Broome), and tropical humid (Broome to Fraser Island) coastal sectors.

Oceanic factors

Swell generated by storms in the Southern Ocean moves in to the western, southern, and southeastern coasts of Australia, and its refracted patterns are effective in shaping the long, curved outlines typical of sandy beaches. In New South Wales, for example, refraction of the

Figure A73 Parabolic dunes spilling inland from the sandy beach on the coast of Encounter Bay, South Australia (photo: E.C.F. Bird, Copyright-Geostudies).

dominant southeasterly swell is responsible for the asymmetrically curved outlines of beaches between bedrock headlands (Chapman *et al*., 1982).

In the southern half of Australia coasts are frequently exposed to storm wave action generated in coastal waters as cyclonic depressions move through from west to east. With relatively deep water close inshore, these are typically high wave energy coasts with bold cliffs and headlands and smooth depositional outlines. Extensive sand deposition has constricted the valley mouth inlets formed by marine submergence during the Late Quaternary marine transgression and formed estuarine thresholds of inwashed sand at their entrances (Roy, 1984).

On the east coast north of Fraser Island ocean swell is interrupted by reef structures, and in the lee of the Great Barrier Reef it is largely excluded from coastal waters (Hopley, 1982). Within these waters the prevailing southeasterly winds generate only moderate wave energy, and consequently the coast has but limited sectors of cliffing, poor development of shore platforms and irregular depositional outlines, with many spits, cuspate forelands and some protruding deltas, notably the Burdekin; sectors of mudflat and mangrove swamp occur on shores in the lee of headlands and islands. Sandy barriers and dune systems have been deposited on a much smaller scale than on the oceanic coasts, and take the form of beach-ridge plains, often built as cheniers on emergent mudflats. River mouths are less encumbered by sand deposition, and coastal lagoons do not occur north of Fraser Island. In the absence of ocean swell, shoreward drifting of sea floor sand has made only a limited contribution to coastal sedimentation on the Queensland coast.

On the north coast of Australia swell from the Indian Ocean is attenuated by the exceptionally broad continental shelf, and its effects are further diminished by the large tide ranges. In the Timor and Arafura Seas and within the Gulf of Carpentaria local wind action produces generally low to moderate wave energy on bordering coasts. Steep sectors show little cliffing and retain the intricate outlines of submerged landscapes of fluvial dissection, while depositional sectors are typically irregular and varied in detail. Storm surges accompanying tropical cyclones accomplish rapid short-term changes, and may be responsible for the emplacement of sandy cheniers on coastal plains, for example, on the depositional lowland south of Van Diemen Gulf and on the low-lying coasts of the Gulf of Carpentaria, where surges of up to 7 m have been reported.

Although, Pacific tsunamis have generated only minor surges on the Australian coast in the past two centuries it is possible that they occurred at earlier stages on a larger scale, and may have shaped some apparently emerged features (Bryant *et al*., 1996).

The broad patterns of longshore drifting on the Australian coast are northward and eastward from Cape Leeuwin and northward along the east coast, but where coastal outlines are adjusted to the dominant swell patterns little net drifting occurs (Davies, 1980).

In addition to variations in wave energy there are marked contrasts in tide range around the Australian coast (Figure A69). In the southern part of the continent, from North West Cape around to Fraser Island, mean spring tide ranges are generally microtidal (<2 m), rising to mesotidal (2–4 m) in Spencer Gulf and Gulf St. Vincent in South Australia and in Western Port Bay and Corner Inlet in Victoria. In southwestern Australia the spring tide range is less than 0.5 m, and it can be difficult to detect tidal oscillations because wind stress and barometric pressure variations raise and lower the sea surface by larger amounts. On the Queensland coast and in the southeastern part of the Gulf of Carpentaria tide ranges are typically mesotidal, but the northwestern coast between Port Hedland and Darwin is macrotidal (>4 m), with a maximum of 10.5 m in Collier Bay, near Yampi Sound.

Where tide range is, small wave energy is concentrated within a narrow vertical range, and where it is large, wave energy is more dispersed. Thus, the tidal variation emphasizes the contrast between high wave energy conditions in the southern part of Australia and low wave energy conditions along the northern coast. Large tide ranges also generate strong ebb and flow currents, which impede the deposition of wave-shaped structures, such as spits and barriers, and lead to the formation of wide funnel-shaped estuaries, such as that of the Fitzroy, opening into King Sound. Broad sandflats and mudflats are exposed at low tide and, with diminished and intermittent wave action above mid-tide level, salt marshes and mangrove swamps become more extensive than on microtidal coasts, where the small tide range compresses the biological zonations.

Figure A74 Mangroves advancing seaward on the coast of Cairns Bay, north Queensland. An outer zone of *Avicennia* is backed by *Rhizophora* and then a varied mangrove community (photo: E.C.F. Bird, Copyright-Geostudies).

Figure A75 The intertidal zone in King Sound, Western Australia, has branching tidal creeks fringed by mangroves, desiccated sandy mudflats, and a serrated high tide shoreline where desert dune ridges and swales have been submerged by the sea (photo: E.C.F. Bird, Copyright-Geostudies).

Biological factors

The effects of organisms on coastal processes are limited by their geographical range, conditioned mainly by climatic and oceanic factors. Reef-building corals live in Australian coastal waters from Houtman Abrolhos in the west around to the Capricorn Group at the southern end of the Great Barrier Reef. They are most prolific off the northeast coast, while off the northwest they give place to bryozoan and oyster banks and off the west coast the reefs are submerged dune calcarenite ridges with only a veneer of corals (Fairbridge, 1967).

Mangroves extend as far south as Corner Inlet (38°51′45″S) adjacent to Wilsons Promontory in Victoria. In the humid tropical sector of northeast Queensland there are up to 27 mangrove species in wide swamps backed by rain forest vegetation (Figure A74), but in drier sectors there are fewer species and the seaward mangrove fringe is backed by salt marshes and hypersaline mudflats. The effects of mangroves on sedimentation vary from one species to another, but the white mangrove (*Avicennia marina*), the most widespread of the Australian mangrove species and the only one extending as far south as Victoria, has a pneumatophore network that acts as a sediment filter and is consequently an agent of land-building alongside estuaries and embayments sheltered from strong wave action (Bird, 1993). Introduced *Spartina anglica* has re-shaped the intertidal profiles of Andersons Inlet, a Victorian estuary, and the Tamar estuary in Tasmania, by developing a depositional marshland terrace, but it does not grow in warmer environments farther north.

Shelly beaches (as distinct from beaches of shelf-derived biogenic carbonate sand) are confined to coastal sectors where shell-bearing organisms live abundantly, notably on rocky shores and reefs and within estuaries and lagoons. These are extensive towards the heads of the South Australian Gulfs and on the western shores of Port Phillip Bay, where their dominance reflects the local absence of other types of beach material on a coast formed by the marginal submergence of a basaltic plain (Bird, 1993).

Inherited features

Australian coastal landforms include various features inherited from past phases of contrasted environments. Some of these are related to changes of sea level during Quaternary times: the submergence of valley mouths and the shoreward drifting of sand from the sea floor to form beaches, barriers, and coastal dunes have already been noted. In addition, there are coastal features formed during past phases of higher sea level, some of which have persisted from Pleistocene times while others may be refered to a higher Holocene sea-level episode.

Figure A76 Cliffs cut in soft Miocene limestone on the Port Campbell coast in Victoria, with some of the outlying stacks known as the Twelve Apostles (photo: E.C.F. Bird, Copyright-Geostudies).

These features include emerged shore platforms, some with associated fossil beach deposits backed by former cliffs now degraded to bluffs; emerged coralline reefs; emerged sandy thresholds near the mouths of estuaries and lagoons; and beach ridge and barrier features standing higher, in relation to sea level, than they did at the time of their formation.

The interpretation of some of these features has been questioned. It is necessary to distinguish between emerged shelly beaches and the shelly aboriginal kitchen middens frequently encountered above high-tide level, and to be sure that apparently emerged features were not formed when storm surges or tsumanis carried wave action briefly to higher levels. Coastal features that have undoubtedly emerged may be the outcome of tectonic uplift of the land margin, a fall in sea level, or some combination of the two. Emerged features dating from Pleistocene times often show evidence of dissection by fluvial incision or wind scour extending below present sea level during the last phase of lowered sea level, as on the inner barrier of the Gippsland Lakes (Bird, 1993), whereas emerged features of Holocene age do not show such dissection.

On parts of the Australian coast the landforms bear the imprint of weathering under past phases of climate that were warmer, cooler, wetter, or drier than at present. These include lateritic weathering profiles in cliff exposures of Tertiary rock in Victoria, inherited from a Pliocene phase of warmer and wetter climate, and the presence of periglacial deposits on cliffs in southernmost Tasmania, inherited from a Pleistocene phase of colder climate. On the east coast of the Cape York Peninsula near Cape Flattery extensive systems of elongated parabolic dunes, now largely covered by scrub and forest, originated under drier and perhaps windier conditions in the past. Patterns of coastal rock weathering northward and southward of the wettest sector of humid tropical coast in northeast Queensland indicate that the warm and wet environment has been at times more extensive than it is now. The high parabolic dunes on Fraser Island must also have formed under different conditions in the past, for they now carry a cover of rain forest. It is possible that sand mobilization here was also partly related to phases of rising sea level, when vegetated dunes deposited during earlier phases of stable or falling sea level were trimmed back by marine erosion and exposed to the effects of onshore wind action.

The shores of King Sound include narrow sandy peninsula ridges and intervening corridor embayments that are features inherited from an arid landscape of sand ridges and swales that has been partly submerged by the Late Quaternary marine transgression (Figure A75).

Shore platforms

Shore platforms on the Australian coast show a variety of forms, some sloping seaward, others almost horizontal. Some are related to coastal structures, especially where they coincide with exhumed bedding planes on resistant strata, but many transgress shore structures. Seaward sloping platforms are essentially abrasion ramps, but subhorizontal platforms have been influenced by shore weathering processes which have tended to flatten and maintain platforms originally cut by abrasion. Subhorizontal platforms are well developed at about high-tide level on cliffed coasts cut in basalt and fine-grained sedimentary formations, such as sandstones and shales, which are subject to disintegration by wetting and drying processes (and possibly also by salt crystallization) down to a level of saturation by sea water. These are well developed on sandstones and mudstones on the New South Wales coast south of Sydney.

On dune calcarenite coasts similar platforms have developed at a lower level, equivalent to the level attained by fringing reefs built upward by corals. Their flatness is evidently the outcome of solution processes effective down to the level at which precipitation of carbonates becomes dominant, indurating the platform surface, a process that has been demonstrated on the Nepean Peninsula in Victoria (Figure A70). Where waves are supplied with sand or gravel derived from cliff erosion, fluvial outflow or sea floor sources, abrasion becomes more effective, and the subhorizontal benches give place to platforms that slope seaward.

Modern dynamics

Erosion is predominant on Australian beaches, even on the shores of barriers and beach-ridge plains that prograded earlier in Holocene times, and most beaches are backed by cliffed dunes. Exceptions are found on growing sectors of spits and cuspate forelands, on deltas still receiving fluvial sediment (notably in northern Australia), and on sectors where beach sand has accumulated alongside protruding structures, such as harbor breakwaters. There are also some sectors, notably on the western coast of Western Australia, in Streaky Bay in South Australia, off northwest Tasmania and near Corner Inlet in Victoria where sand is still moving in from nearshore shoals to maintain or prograde beaches (Sanderson *et al*., 1998).

The prevalence of beach erosion could be due to a slight rise in sea level in recent decades or to increased storminess in coastal waters, but the most likely explanation is a general reduction in the supply of sand from the sea floor, which had previously nourished beach and barrier progradation. Other factors have contributed locally, such as the reduction of fluvial sand supply following dam construction in the Barron and Burdekin Rivers in North Queensland and the diminution of sand supply where the longshore sand supply has been intercepted by breakwaters, as at Sandringham on the coast of Port Phillip Bay (Bird, 1996).

Cliffed coasts have continued to recede, especially on sectors where soft rock formations confront stormy seas, as on the Tertiary sands and clays of the Port Campbell district in Victoria (Figure A76). Minor progradation has been detected on some mangrove-fringed coasts, as in Cairns Bay, Queensland, and on salt marshes, particularly where *Spartina* grass has been introduced. Elsewhere there is evidence of reduction of mangrove and salt marsh fringes, as in Western Port Bay, Victoria, where there has been drainage of swampland and construction of boat harbors.

Human impacts

Coastal morphology in Australia has been modified in various ways by human activities, particularly in the vicinity of urban centers, where ports have been constructed, seawalls built to halt coastline recession, cliffs stabilized and groins inserted in an attempt to retain a beach fringe. A substantial part of the formerly cliffed northeast coast of Port Phillip Bay, on Melbourne's Bayside, now consists of artificial bluffs lined by such structures, and depletion of the natural beach fringe has been offset by artificial beach nourishment. Similar works have been introduced to the Adelaide coast, where the beach is now maintained by periodic renourishment using sand dredged from a prograded beach alongside a breakwater at the Outer Harbor.

Many coastal dune areas show evidence of vegetation loss and initiation or acceleration of blowouts as a consequence of clearing, burning, trampling, or vehicle damage to the dune vegetation. Attempts have been made to restore stability by fencing dune areas and planting vegetation, including the introduced European marram grass, *Ammophila arenaria*. Such activities as beach nourishment and dune stabilization mark a trend toward management of coastal morphology in Australia, with the aims of conserving many natural systems and their biota and providing recreational opportunities in the coastal environment.

BARRIER ISLANDS

Definition and occurrence

Barrier islands are elongate, shore-parallel accumulations of unconsolidated sediment (primarily sand), some parts of which are supratidal, that are separated from the mainland by bays, lagoons, or wetland complexes. They are most abundant along the coastlines of the trailing edges of continental plates and of epicontinental seas and lakes (e.g., Caspian and Black Seas). They do not occur on coasts with tidal ranges greater than around 4 m, because their primary mechanism wave action is not focused long enough at a single level during the tidal cycle to form the island and the strong tidal currents associated with such large tides transport the available sand to offshore regions. Barrier islands do occur, primarily as spit forms, on leading edge and glaciated coasts, but they are a minority coastline type in those areas.

Barrier islands are the dominant coastline type along the Atlantic and Gulf coasts of the United States, most of them having been formed within the last 4,000–5,000 years during a near stillstand of sea level.

Barrier islands on depositional coasts

Depositional, coastal plain shorelines typically have barrier islands located between major river deltas and estuaries. Two types of barrier islands may be present, those that consistently migrate landward (retrograding) and those that build seaward (prograding). The island type depends upon the ratio of relative sea-level change to sediment supply. Diminished or low sediment supply and/or rapid sea-level rise promotes the development of retrograding barrier islands and *vice versa* for prograding barrier islands.

Retrograding barrier islands are composed of coalescing washover fans and terraces that are overtopped at high tides, usually several times a year (Figure B1). Stratigraphically, a relatively thin wedge of sand and shell of the washover terrace overlies backbarrier sediments, which are typically composed of muddy sediments deposited in the lagoons or wetlands behind the islands. These islands are impractical sites for human development because of their constant landward migration.

Prograding barrier islands are composed of multiple beach ridges. Many have a drumstick configuration because of selective sand accumulation on the updrift end of the island (the direction sand comes from). The most notable changes on prograding islands occur when the adjacent tidal inlets migrate or when the inlets expand dramatically during hurricane storm surges.

Stratigraphically, prograding barrier islands are composed of sand 8–10 m thick (thickness depends upon wave size), which has prograded over offshore muds (Figure B1). When human development occurs on these islands, buildings are usually secure from all but the most extreme hurricanes, if they have been set back an adequate distance from the front-line dunes and tidal inlets. But that security will vanish if a major rise in sea level occurs (Hayes, 1996).

The morphology of prograding barrier islands is controlled by a combination of wave and tidal forces (Hayes, 1979; Davis, 1994a). Under *wave-dominated* conditions, which most commonly occur in microtidal areas (tidal range $\leq$2 m; Davies, 1964), the barriers are long, typically tens of kilometers, with widely spaced inlets that have large flood-tidal deltas and small ebb-tidal deltas. Washover fans are common and the islands are flanked on the landward side by bays and/or lagoons (Figure B2). Barrier islands along *mixed-energy* coasts (Hayes, 1979), which typically occur in mesotidal areas (tidal range = 2–4 m), are stunted and short (usually $<$10 km) with abundant tidal inlets that contain large ebb-tidal deltas and small to nonexistent flood-tidal deltas. These islands are flanked on the landward side by complex tidal channels, tidal flats, and wetlands (Figure B3). Barrier islands do not occur on *tide-dominated* coasts.

Origin of barrier islands

Barrier islands are thought to most commonly originate in one of the three possible ways: (1) by spit elongation (Fisher, 1967); (2) retreating transgressive barrier islands (Swift, 1975); and (3) a process termed *transgressive–regressive interfluve hypothesis* by Hayes (1994). In many parts of the world, it is clear that the source of sand for the existing barrier islands originated from an updrift headland, and as a spit extended away from the headland it was cut into segments during storms, creating tidal inlets that eventually attained permanence. Swift (1975) stated that barrier islands originated at a lower stand of sea level and migrated over the drowning coastal plain as sea level rose during the early Holocene. The "primary barrier" of Pierce and Colquhoun (1970), the nucleus for many prograding barrier islands, no doubt originated in this way. According to the transgressive–regressive interfluve hypothesis, as sea level rose, the transgressive barrier eventually perched on the topographic high of an interfluve located between major alluvial valleys that were carved during the last Pleistocene lowstand (Figure B4). Once sea level stabilized around 4500 years BP, prograding barrier islands developed in areas with adequate sediment supply. As the island grew, beach ridges prograded away from the interfluve, with major tidal inlets forming at both ends of the island over the antecedent lowstand valleys (Moslow, 1980). This mechanism explains the origin of many of the major prograding barrier islands along the coast of the southeastern United States.

Barrier islands on leading edge and glaciated coasts

The somewhat rare barrier islands on the leading edge, west coast of the United States are, for the most part, relatively short spits that have built

away from rocky headlands or river mouths. River discharge controls the shape of the spit during high discharge, and waves control it during low discharge (Dingler and Clifton, 1994; Smith, *et al.*, 1999).

Although occurring in a wide variety of types, which were classified into six major categories by Fitzgerald and Van Heteren (1999), barrier islands make up <25% of the glaciated coastline of New England. Most of these islands originate as spits, which are transformed into a variety of forms by tidal and wave action. Antecedent topography and geology also play important roles in shaping the morphology of the barrier islands along this complex coastline.

BARRIER

A barrier (coastal barrier) is an elongated coastal ridge of deposited sediment built-up by wave action above high tide level offshore or across the mouths of inlets or embayments. It is usually backed by a lagoon or swamp, which separates it from the mainland or from earlier barriers. A barrier, thus defined, is distinct from a bar, which is submerged at least at high tide (Shepard, 1952), and from reefs of biogenic origin (see Coral Reefs). Most barriers consist of sand, but some contain gravel as well as sand, and others consist entirely of gravel (shingle): see Gravel Barriers. Chesil Beach, on the south coast of England, is a well-known shingle barrier, and similar features are seen on the southeast coast of Iceland, and on the east and south coasts of South Island, New Zealand. Commonly the gravel has been derived from glacial or periglacial deposits, as on the north coast of Alaska and the southern shores of the Baltic Sea.

Barriers are said to occupy about 13% of the world's coastline (Leontyev and Nikiforov, 1965). They are most extensive on the Gulf and Atlantic coasts of North America and the ocean coasts of Australia, South Africa, and eastern South America, but they also occur on a smaller scale elsewhere, notably in Sri Lanka and New Zealand. Some barriers are transgressive, migrating landward across lagoon and swamp deposits; others remain in position, or are widened seaward by progradation, usually indicated by successively formed beach or dune ridges. Transgressive barriers occur where sediment is washed or blown over into backing lagoons or swamps, particularly during storms. Low sectors of a barrier through which storm waves or surges flow are called swashways, and sediment swept over a barrier through these is deposited as a washover fan on the inner shore.

On some coasts there are multiple barriers, the inner and older barriers being of Pleistocene age bordered (and overlain) by outer and younger barriers of Holocene age. Thus the Gippsland Lakes in southeastern Australia are enclosed by an Inner Barrier and an Outer Barrier (the Ninety Mile Beach), separated by lagoons and swamps, and with relics of an earlier, Prior Barrier that predates the enclosure of the existing Lakes (Bird, 1973). In this case, barriers have developed seaward of earlier marine coastlines, but evidence of preceding exposure to the open sea is not always present, particularly in lagoons where the enclosing barriers have been transgressing landward during a phase of rising sea level, as on the Siberian coast (Zenkovich, 1967).

The term barrier beach indicates a single, narrow elongated ridge (usually less than 200 m wide) built parallel to the coast, without surmounting dunes. A barrier island is bordered by transverse gaps (tidal inlets, lagoon entrances, river outlets), which may be migratory and subject to closure; it usually bears beach ridges, dunes and associated swamps, and minor lagoons, and may incorporate recurves (Schwartz, 1973). Examples include Scolt Head Island on the east coast of England, and several along the Atlantic coast of the United States. A barrier with many interruptions becomes a barrier island chain. A barrier attached to the mainland at one end can be termed a barrier spit, as on the coast north of the Columbia River in Washington State (where Long Beach is a barrier spit partly enclosing Willapa Bay); one built across the mouth of an embayment a bay (baymouth) barrier. There are also mid-bay barriers and bay-head barriers, defined by their position.

In general, barriers are found on coasts where the tide range is small (as on the southern Baltic coast), and become chains of barrier islands where currents produced by larger tides maintain transverse gaps (as on the Danish, German, and Dutch North Sea coasts).

Barriers can form in various ways (Schwartz, 1971), multiple causality being related to the nature and supply of sediment, the transverse profile of the coast, tide range, wave conditions, and relative sea-level change. Some barriers may have formed by the emergence of nearshore swash bars as sea-level fell (e.g., Knotten, on the Danish island of Laesø), but many developed during and after the Late Quaternary marine transgression by submergence of pre-existing sand ridges and the shoreward drifting of sea floor sediment. Of these, some are still transgressive (as on parts of the Atlantic coast of the United States) while others have become anchored, and widened by progradation (as on parts of the southeast Australian coast). Growth and landward transgression of barriers has been demonstrated in recent years on parts of the coast of the Caspian Sea, which has risen about 2 m since 1977 (Kaplin and Selivanov, 1995).

Barrier spits may show features indicative of longshore growth, such as former recurved terminations on the landward side (as on Orfordness in England or the Langue de Barbarie in West Africa), but others have been built and widened by wave-deposited sediment from the sea floor (as on Clatsop Spit in Oregon), and many result from combinations of onshore and longshore sediment drifting.

The shaping of barriers can be traced with reference to patterns of beach and dune ridges indicating stages in their growth, and from their stratigraphy, which may indicate phases of upward growth, landward movement, and seaward progradation, as in Van Straaten's (1965) classic study of barriers on the Netherlands coast and Thom's (1984) study of sand barriers in eastern Australia. Barriers of unconsolidated sand are readily re-shaped by wave and wind action, but where barrier sediments have become lithified (e.g., the Pleistocene dune calcarenites in Australia and elsewhere) they are more durable, and may show cliffing (as in the inner barriers of the Coorong in South Australia). Some barriers incorporate segments of pre-existing terrain, such as the glacial moraines on Long Island in New York, Walney Island in northwest England and Sylt on the German North Sea coast.

BARRIERS, GRAVEL—See GRAVEL BARRIERS

BARS

Sedimentary ridges, both symmetric and asymmetric, and generally larger than bedforms that characterize the upper shoreface of coastal zones dominated by waves are called *wave-formed bars*. They were recognized as early as 1845 on the marine coasts of Europe (Elie de Beaumont), by 1851 in the Great Lakes of North America (Desor), and subsequently on marine and lacustrine coasts worldwide (see Schwartz, 1982, pp. 135–139). However, confusion still surrounds this term because of its use for ridges with a wide range of size, morphology, location, and orientation relative to the shoreline. Also, the term *bar* has been used in a variety of environments, from subaerial to those dominated by tidal currents or river currents. Furthermore, the present understanding of the origin(s) and dynamics of *wave-formed bars* is still incomplete.

Shepard (1950) called shore-parallel ridges and troughs *longshore bars* and *troughs*, equating them with the terms *ball* and *low* of Evans (1940), and associated them with plunging breakers. He emphasized the *seasonality* of such bars on the west coast of the United States, and subsequently terms such as *winter* and *summer, storm* and *normal*, and *storm* and *swell* have been applied to denote the presence or absence of bars. Although a correlation between profile form and storm waves or season may exist in some localities (e.g., Inman *et al*., 1993), it is not universal. Both *barred* and *non-barred* profiles occur at times in some areas, while in others only one profile type may persist throughout the year. There is usually a distinct *relaxation time* between the forcing conditions and bar adjustment; thus in the short-term, bars are generally in a transient state. In the longer term (years to decades), wave-formed bars represent the *equilibrium morphology* for many coastal environments.

Bar morphology

Wave-formed bars are most clearly identified as near-symmetrical or asymmetrical undulations in the upper shoreface profile (Figure B5). They occur intertidally and subtidally, and may range in number from one to more than thirty, this number often varying through time. Short and Aagaard (1993) introduced a bar parameter, $B^* = x_s/gT^2 \tan\beta$, to

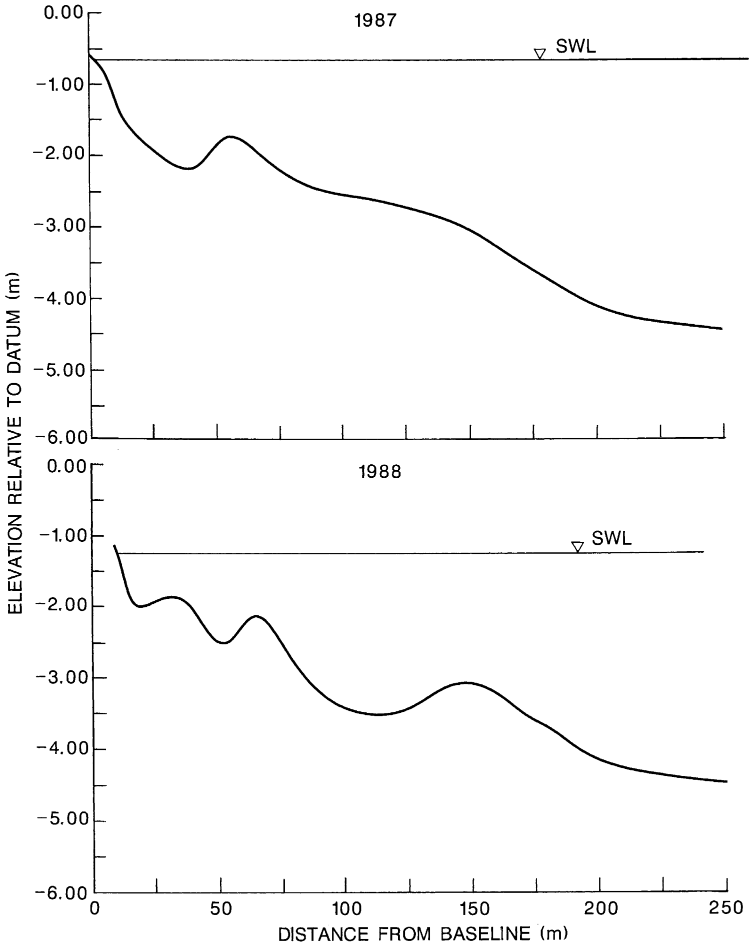

Figure B5 Typical barred profiles from a sandy nearshore environment in the Canadian Great Lakes. The profiles were surveyed in successive years along the same transect. Note the differing number and position of the wave-formed bars at the same location, even though the mean beach slope is the same.

identify the number of bars on a linear sloping shoreface (tan β) terminating at a constant depth at a distance offshore, x_s. When $B^* < 20$, the profile is non-barred, for $B^* = 20$–50, 1 bar occurs; for $B^* = 50$–100, 2 bars, for $B^* = 100$–400, 3 bars; and for $B^* > 400$ there are 4 bars. Crest heights above the adjacent trough can range from less than a decimeter (Carter, 1978) to more than 4.75 m (Greenwood and Mittler, 1979). In plan view, they form continuous or compartmentalized, linear, sinuous, or crescentic patterns, and range from shore-parallel to shore-normal in orientation, often producing periodic or *rhythmic* topography both alongshore and cross-shore. The morphometry of bars has been studied by Greenwood and Davidson-Arnott (1975), Hands (1976), and Reussink *et al.* (2000) in order to define the equilibrium form and dynamics induced by a specific set of environmental constraints.

Bar classification

A *universal* classification of *wave-formed bars* does not yet exist, and indeed it may never be possible to define perfectly mutually exclusive classes. A simple descriptive classification based on morphology and the associated environmental constraints is illustrated in Table B1 (Greenwood and Davidson-Arnott, 1979). The group names are those in common use, and the definitive paper describing each type is cited. Other classifications are based on the concept that bars are part of a temporal sequence of beach profile evolution and that they are scaled to that of the controlling wave process. The morphological sequence is controlled by incident wave energy (high and low frequency) and was identified either through aerial photographs or more recently through video-imagery (e.g., Short, 1979; Lippmann and Holman, 1990; see Figure B6). Many coastal environments do not experience such sequential behavior.

Ridge and runnel topography (*Type I*) is found on low-angle, macro- to meso-tidal foreshore slopes dominated by surf action and foreshore drainage during the tidal cycle. Although low in amplitude these bars are usually stable in form and position or migrate only slowly. In contrast, the *cusp-* or *bar-type sand waves* (*Type II*) are extremely dynamic, often destroyed during storms and regenerated as the storm wanes and smaller amplitude, longer period waves propagate shoreward. These bars result from surf bores and swash action near the toe of the swash slope (an alternative name is *swash* bar). Furthermore, they may develop from *Type VI* bars as they migrate relatively rapidly both alongshore and onshore, and in the latter case may *weld* to the foreshore (Davis *et al.*, 1972; Aagaard *et al.*, 1998). Note that there is confusion with respect to the term *ridge and runnel* as used in northwest Europe and North America (Orford and Wright, 1978; Orme and Orme, 1988). Here, the term *ridge and runnel* is restricted to its initial definition by King and Williams (1949); the forms described by Hayes and subsequent workers (Hayes and Boothroyd, 1969) are classified here as *Type II* bars.

Type III multiple parallel bars (e.g., Nilsson, 1973; Exon, 1975) and *Type IV transverse bars* (e.g., Niedoroda and Tanner, 1970; Carter, 1978; Dolan and Dean, 1985) tend to be limited to low-angle shorefaces and small to moderate wave heights, coupled with limited water level shifts. However, they have been identified on more energetic shorelines (Konicki and Holman, 2000).

The number of bars increases with decreasing beach slope (Davidson-Arnott, 1988). The height and spacing of the multiple bars increases in the offshore direction, and bar form is near symmetrical in contrast to the *Type II* group. Transverse bars run normal or obliquely to the shoreline and can range in length from 3 m up to 4 km, with heights from less than 0.05 m up to 2 m and alongshore spacing of the

Table B1 Bar morphologies and environmental constraints

			Morphology					Environmental constraints			
Class	Name	Definitive description	Size (m)	Planform	Profile	Number seaward	Location	Wave energy	Breaking processes	Tidal range	Slope

order of 10^0–10^2 m (Carter, 1978; Gelfenbaum and Brooks, 1997). The larger forms may migrate alongshore at rates up to 8 m a^{-1}. Usually, transverse bars are anchored to the shoreline (indeed they appear as an extension of a shoreline protuberance), but Konicki and Holman (2000) recorded the unusual case of transverse bars running offshore from a *Type VI* bar.

The division of *nearshore bars* into two groups is based upon size, stability, and the controlling waveform. *Type V bars* are associated with large plunging breakers, which produce narrow, low amplitude ridges on relatively steep slopes: they lack a well-defined asymmetry and are essentially unstable modifications of non-barred nearshore profiles. *Type VI bars*, in contrast, are relatively large configurations formed seaward of the low water level. Where there is more than one bar, the distance offshore, depth-of-water over the crest, and bar height all usually increase offshore in a regular manner, although in some cases the height decreases after some offshore distance (Lippmann *et al.*, 1993; Ruessink and Kroon, 1994). The volume of sediment in each bar form usually increases consistently offshore. *Type VI* bars may be three-dimensional, sinuous-to-crescentic, and the alongshore length scales may range from 10^2 to 10^3 m (Greenwood and Davidson-Arnott, 1975; Bowman and Goldsmith, 1983). Where more than one bar is rhythmic, the alongshore wavelength decreases shoreward.

Bar genesis

The boundary conditions necessary for bar formation depend upon the longer term evolution of the coast, which dictates the nature of the bed materials (grain mineralogy, size, sorting, etc.), the bathymetric setting (slope, exposure, etc.), and the geographic location (wave climate, tidal regime, etc.). Local forcing conditions for bars have been studied both theoretically and empirically, and by experiments in the laboratory and the field (see van Rijn 1998). In general, barred profiles are associated with large values of both wave steepness and wave height-to-grain size ratios, and are associated with the final stages of shoaling and dissipation of wave energy through breaking, and the complex hydrodynamics, which accompany these processes (Wright *et al.*, 1979). Furthermore, the size of wave-formed bars induces a very strong feedback to the shoaling and breaking process. Although cause and effect are far from clear, it is evident that equilibrium bar profiles can exist only where the time-averaged sediment transport (suspended and bedload) is zero everywhere on that profile.

A large number of specific hypotheses have been proposed for bar formation over the last 50 years and all involve mechanisms for convergence of sediment transport; these hypotheses were primarily related to *Type V and VI* bars and fall into three major groups:

(1) *break point hypotheses* relate bars directly to wave breaking and result from: (i) a seaward transport of sediment entrained by roller or helical vortices under plunging or spilling breakers, respectively (Miller, 1976; Zhang, 1994; Figure B7); (ii) convergence of sediment at the breakpoint through onshore transport associated with increasing asymmetry and skewness of the high-frequency incident waves and offshore transport through set up induced undertow (Dally and Dean, 1984; Dally, 1987; Thornton *et al.*, 1996). However, Sallenger and Howd (1989) concluded that bars are not necessarily coupled to the breakpoint, but can grow and migrate, while within the inner surf zone, landward to the point of initial breaking.

(2) *infragravity wave hypotheses* propose that low frequency waves generated within the surf zone (surf beat) or offshore and reflected produce a convergent pattern of drift velocities, which interact with the large incident short wave oscillatory velocities to induce a range of bar forms from two- to three-dimensional crescentic forms (e.g., Bowen and Inman, 1971; Short 1975; Bowen 1980; Holman and Bowen, 1982; Bowen and Huntley, 1984). These waves can be standing or progressive and can be produced in a number of different ways as a result of energy dissipation during breaking and are frequently related to amplitude modulation of the incident wave field (*groupiness*; Roelvink and Broker, 1993; Reussink, 1998). Alternating scour and deposition by mass

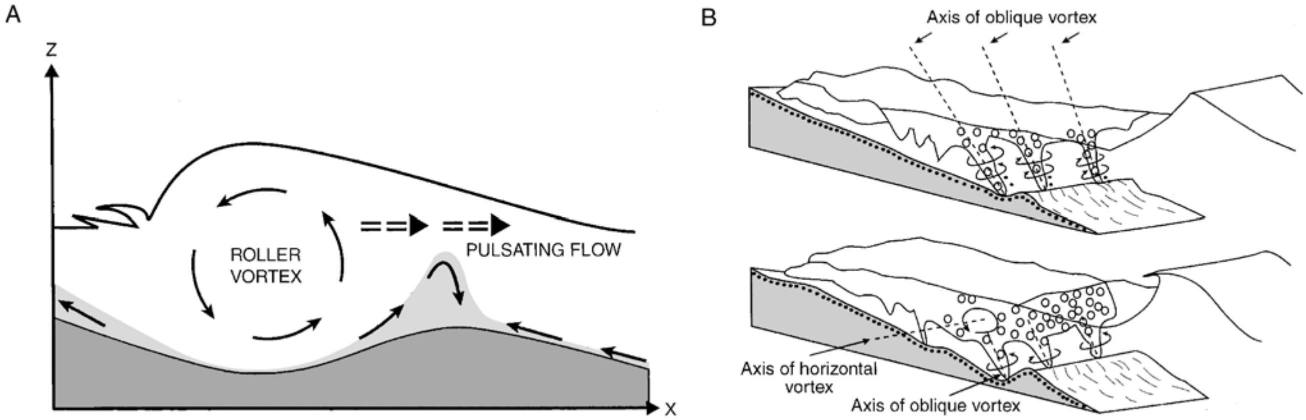

Figure B7 Bar formation by breaking waves: (A) trough scouring by a roller vortex under plunging breakers and offshore sediment transport converging with sediment driven onshore by shoaling waves (modified after Miller, 1976); (B) trough scouring by oblique vortices generated under spilling breakers (modified after Zhang, 1994).

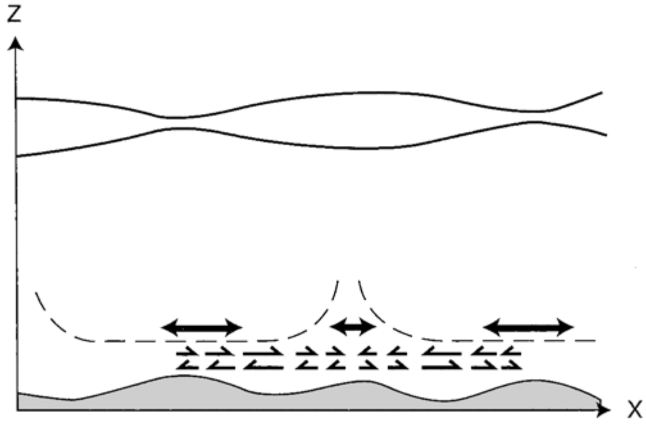

Figure B8 Bar formation as a result of mass transport in the boundary layer of a strongly reflected incident wave. The surface wave envelope is shown as well as the circulation within the bottom boundary layer. Bed load will converge at nodes of the surface elevation and suspended load at antinodes. Note: the boundary layer flow is indicated by single-headed arrows; the mean flow is indicated by double-headed arrows.

transport velocities in the bottom boundary layer generated by standing waves, resulting from the interaction of reflected and incident waves, was shown to occur in the laboratory by Carter *et al.* (1973; Figure B8). The boundary layer was actually segregated. At the bed, drift velocities converge at nodes, while at some distance above the drift velocities converge at antinodes. Under large waves when bars are most active, suspension transport is dominant and therefore sediment will converge and bars will form at the antinodal position of standing waves (e.g., Bowen, 1980). Reflection of waves in the infragravity range was clearly demonstrated by Suhayda (1974) and shown to relate to bar forms by Short (1975) and Katoh (1984). Sediment moves to null positions in the drift velocity field of low-frequency standing (Figure B9(A)) or progressive edge waves (Figure B9(B)), which are periodic both alongshore and offshore. Recent field measurements have clearly shown the importance of group-bound long waves to suspended sediment transport in barred surf zones (e.g., Osborne and Greenwood, 1992), but isolating the drift velocities associated with these secondary waves is difficult. This second-order drift velocity hypothesis requires one dominant wave frequency, which is not common (see Bauer and Greenwood, 1990 for an exception). However, there are a number of suggestions to overcome this inadequacy of the edge wave hypothesis. Aagaard (1990) has argued for the excitation of cutoff mode edge waves (limited by the beach slope) and selection of the dominant mode as that mode which is closest to the wave group period. A phase coupling between the primary orbital motion of a partially standing long wave and groupy short waves was also proposed by O'Hare (1994) to avoid this requirement of narrow bandedness in the infragravity spectrum. Other mechanisms producing a limited number of edge wave frequencies and modes are topographic control (Kirby *et al.*, 1981; Bryan and Bowen, 1996) and interaction of edge waves and the longshore current (Howd *et al.*, 1992). O'Hare and Huntley (1994) propose a leaky wave origin for an inner surf zone bar, which is relatively insensitive to the group period, incident wave height, and the width of the infragravity spectrum.

(3) *self-organization hypotheses* propose that processes associated with the complex, nonlinear feedback between the sand bed and the hydrodynamics give rise to a range of topographic forms. For example, alongshore and offshore sediment movement was proposed under meandering or cellular nearshore circulations produced by (i) instability of longshore flows (Figure B10; Barcilon and Lau, 1973; Hino, 1974; Falques, 1991; Damgaard Christiansen *et al.*, 1994); (ii) coupling between morphodynamic instability and mean flows (Deigaard *et al.*, 1999; Vittorio *et al.*, 1999; Falques *et al.*, 2000); and (iii) Bragg scattering from periodic topography (Heathershaw and Davies, 1985; O'Hare and Davies, 1993; Rey *et al.*, 1995; Yu and Mei, 2000). These mechanisms cannot produce bars directly, but require some initial perturbation of the profile. However, it has been shown that some bar characteristics are not well predicted by these models (e.g., the cross-shore/ alongshore spacing—see Konicki and Holman, 2000). The nonlinear action between shoaling waves and the bed (Boczar-Karakiewicz and Davidson-Arnott, 1987) was also proposed as a mechanism for generating periodic patterns of sediment transport which matched the spacing and general shape of multi-barred shorelines.

The horizontal roller vortex mechanism is most applicable to single *Type V* bars of the US west coast, and justifies the early correlation of bar formation with wave steepness. Multibarred profiles reflect either multiple breakpoints (Dally, 1980; Davidson-Arnott, 1981) or bar formation by distinct differences in wave energy; for example, an outer bar may be produced under storm waves and an inner bar by less energetic conditions (King and Williams, 1949). Water level shifts and coincident shifts in breaker location could also produce a multiple barred system. Oblique, helical vortices were produced under spilling rather than plunging breakers in the laboratory and could account for both single and multiple barred profiles (Zhang, 1994). However, the mass transport velocities under reflected standing waves would perhaps best explain the formation of *Type III* multiple parallel bars; simple reflection of the incident waves could not be the cause, since the length scales of the bars would require much longer periods. The theoretical convergence patterns of drift velocities under standing edge waves provide strong support for their role in forming crescentic *Type VI* bars. Progressive edge waves may be responsible for linear bars of the same group (Huntley, 1980). Further, the edge wave periods necessary to produce the length scales found in nature is of the same order as the well-known *surf beat*. However, the generation of these trapped modes of oscillation still remains ill-defined, even though field observations of low-frequency peaks in the nearshore energy spectrum have been made on barred coasts and related to the presence of edge waves (Huntley, 1980; Bauer and Greenwood, 1990).

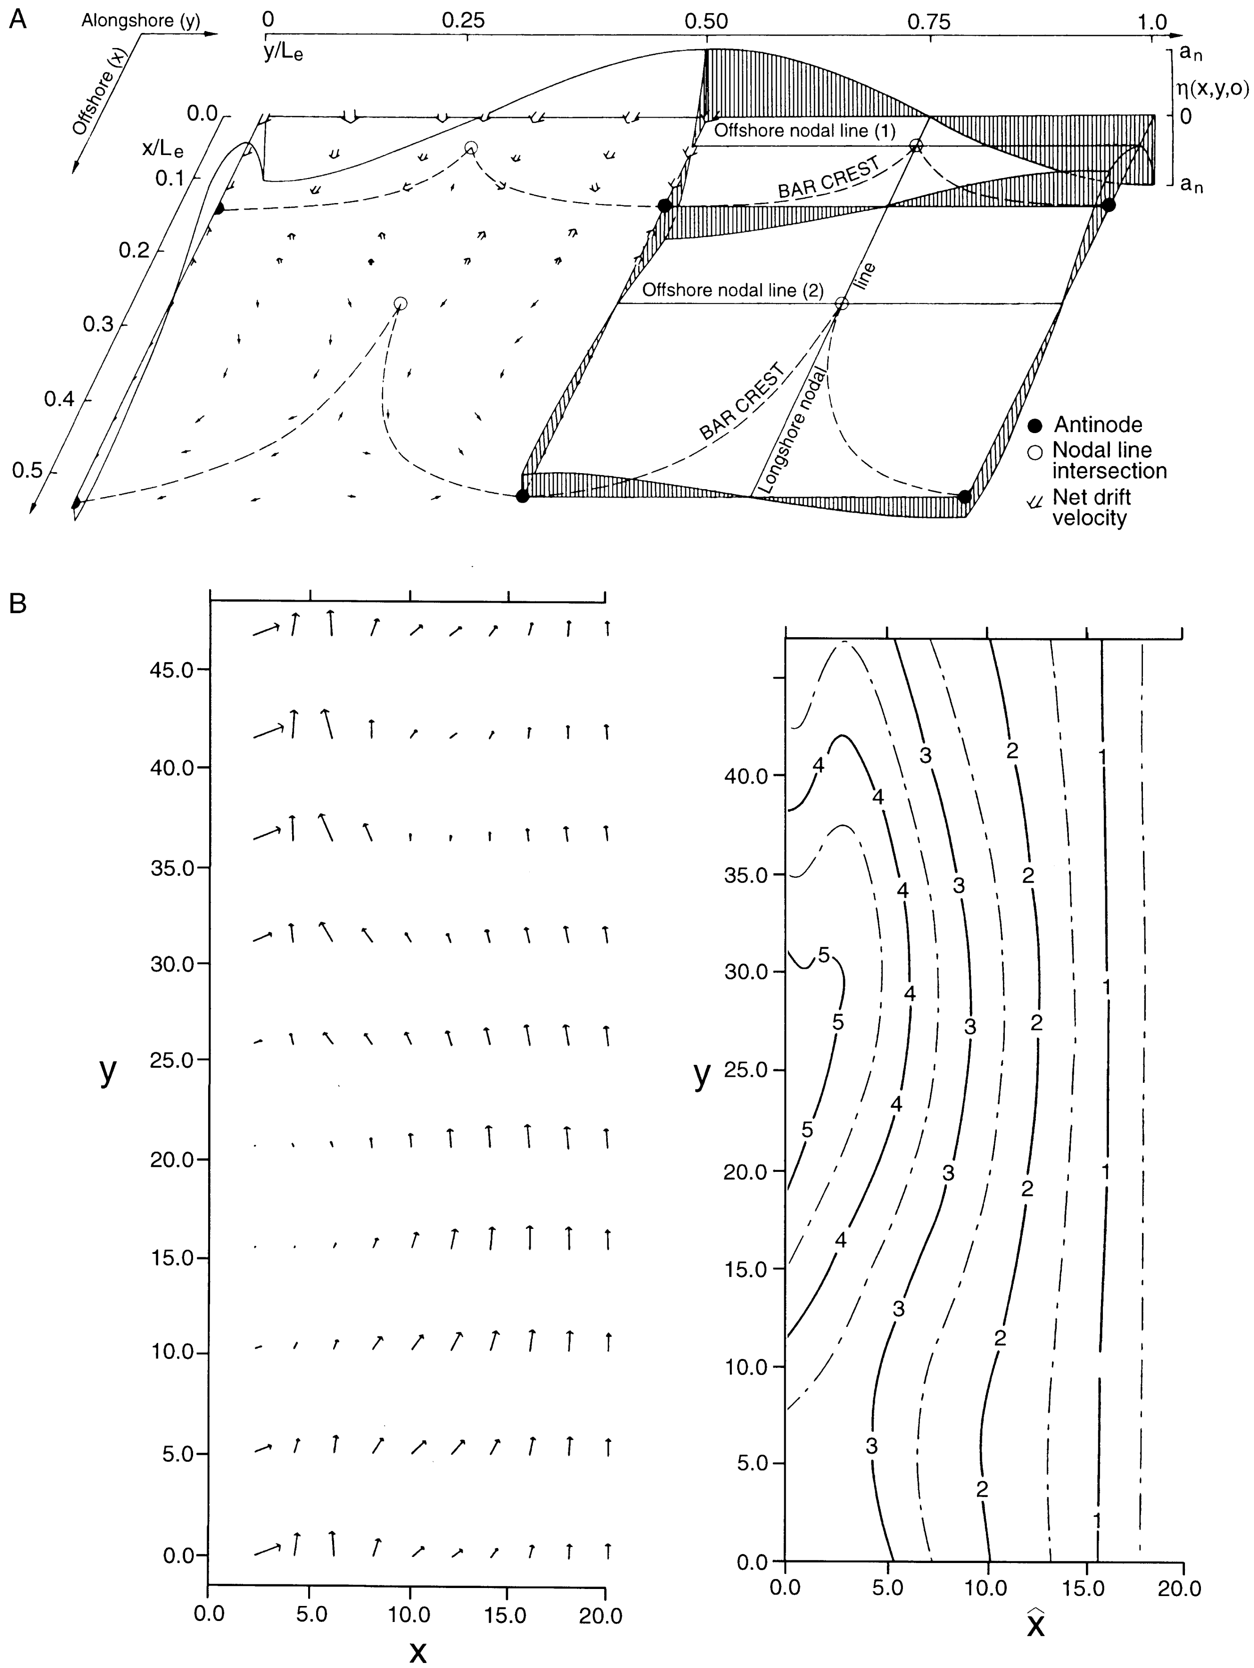

Figure B9 Bar formation by infragravity waves: (A) net drift velocities associated with standing edge waves and the creation of crescentic bars (modified after van Beek, 1974). (B) dimensionless drift velocities and equilibrium nearshore bathymetry associated with the propagation of two edge wave modes (1 and 2) of the same frequency in the same direction (modified after Holman and Bowen, 1982). Note: *y* represents the alongshore direction and *x* the across-shore direction.

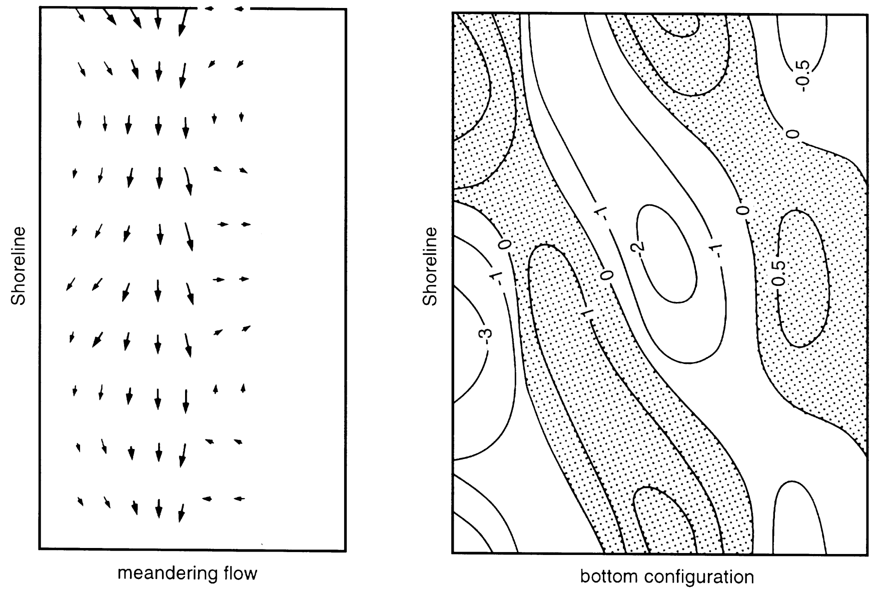

Figure B10 Bar formation due to hydrodynamic instability between longshore currents and the sand bed (modified after Hino, 1974). Note the meandering nature of the longshore flow and the sinuous bar topography that is produced.

Barred topography has long been associated with the occurrence of cellular nearshore circulations (Shepard *et al.*, 1941), and Hino (1974) proposed that an instability of the fluid sediment interface would generate variations in sediment transport resulting in sinuous or crescentic undulations of the surf-zone bed (Figure B9). Certainly the role of rip-cell circulation in bar dynamics has been well documented for *bar-* and *cusp-type sand waves* (Bowen and Inman, 1969; Davis and Fox, 1972; Sonu, 1973; Greenwood and Davidson-Arnott, 1975; Wright and Short, 1984), for *transverse bars* (Niedoroda, 1973), and for *Type VI* bars, both crescentic and straight (Greenwood and Davidson-Arnott, 1979). However, it is also possible that the regularity in nearshore circulations is in fact controlled by the presence of edge waves (Holman and Bowen, 1982). Whichever mechanism initiates bars, there will be feedback between the topography and the hydrodynamics, perhaps giving rise to some "hybrid" model of formation (Holman and Sallenger, 1993).

Bar morphodynamics

In general, the smaller the *wave-formed bar* the more dynamic it is, as there is less sediment involved in morphological changes (Sunamura and Takeda, 1984). However, there is considerable variability in morphodynamic behavior, depending upon bar type, the general environmental constraints, and indeed the antecedent state of the bar (i.e., whether or not it is close to its equilibrium position). Bars also tend to migrate at lower rates as the tidal range increases, since at some stage the bars are being exposed subaerially and remain static at this time. Bar dynamics have generally been related to behavior under specific storm events. However, the magnitude, frequency, and sequencing (*chronology*) of such events may be important in the nearshore, which as a nonlinear dynamical system, is extremely sensitive to feedback processes (see Moller and Southgate, 1997; Southgate and Moller, 2000; see Elgar, 2001 for an alternative view). There now exist at least two long time series of morphological change: (1) thirty years of annual profiling along 100 km of the Dutch coast (Ruessink and Kroon, 1994); (2) sixteen years of bathy metry recorded at Duck, NC (Plant *et al.*, 1999). Extensive measurements of the cross-shore location, and alongshore bar shape, are now being made successfully on a near continual basis at a number of locations worldwide using video-imagery (e.g., Lippmann and Holman, 1990; van Enckvort and Ruessink, 2001).

Type I bars are relatively stable in general, although landward migration rates of ~10 m per month have been recorded. Under low energy conditions the ridges have been observed to be: (1) destroyed by storms and regenerated in the post-storm period (Mulrennan, 1992); and (2) formed by storms (Hale and McCann, 1982). *Type II* bars have been shown to migrate at relatively rapid rates, both onshore and alongshore, and *Type III* bars migrate also at a relatively rapid rate. *Type II, IV*, and *VI* bars have been shown to occur as part of a temporal sequence of beach evolution by Wright *et al.*, (1979), Wright and Short (1984), Sunamura (1988), and Lippmann and Holman (1990). This sequence ranges from fully dissipative (barred profile) to fully reflective (non-barred profile) wave conditions, and therefore, is related to the surf similarity parameter ($\varepsilon = a_b\omega^2/g \tan^2\beta$; where a_b = breaker amplitude, ω = incident radian wave frequency, g = the gravitational constant, β = beach slope). In the Australian Model, the two-dimensional shore-parallel longshore bar and trough occurs at the fully dissipative beach stage, the rhythmic bar and beach at an intermediate stage, and the non-barred profile occurs at the fully reflective stage. In regions where a more limited range of waves exist, the beach may simply change between one or two stages, and where the environmental constraints are more restrictive still, then the bars may assume only one characteristic morphology. Further refinement of the stage model used the *Dean Parameter* ($\Omega = H_b/\omega_s T$; where H_b = breaker height in meters; ω_s = sediment fall velocity in meters per second; T = wave period in seconds). Barred profiles occurred when $\Omega > 0.85$ and non-barred profiles occurred when $\Omega < 0.85$ (Wright *et al.*, 1985). Sunamura (1988) used the dimensionless parameter $K^* = H_b^2/gT^2d$, where g is the gravitational constant and d is the grain size, to classify sequences dependent upon erosional or accretional beach stages. Erosion is characterized by $K^* \geq 20$ and is associated with offshore bar migration, slope decreases, and a dissipative state; while $5 \leq K^* \leq 20$ indicates onshore migration and beach accretion. Yet, a further parameter was introduced by Kraus and Larson (1988) to separate barred and non-barred profiles, $P = gH_o^2/\omega_s^3 T$, where H_o = offshore wave height. A value of 9,000 separates barred (greater values) from non-barred profiles (Dalrymple, 1992).

Type VI nearshore bars have been found to migrate onshore, offshore, and alongshore, with offshore rates reaching 2.5 m h^{-1} during storms and erosion/accretion rates of 0.05 m h^{-1} (Sallenger *et al.*, 1985; Aagaard and Greenwood, 1995). Onshore migration rates are generally smaller, but may still reach 1 m h^{-1}. When the *Type VI* bars are three-dimensional, they may migrate alongshore at rates up to 10 m per month (Greenwood and Davidson-Arnott, 1975). Ruessink *et al.* (2000) examined the relative rates of across-shore and alongshore migration using complex empirical orthogonal functions applied to profile data. The alongshore migration rate ranged up to 150 m per day and was strongly related to the alongshore component of the offshore wave energy flux. Short-term variability in bar crest position was shown to be due to changes in the quasi-regular topography, and not to alongshore uniform on–offshore migration. While offshore migration under storms has been clearly related to hydrodynamic forcing, especially the setup-driven undertow (Gallagher *et al.*, 1998) or mean currents modulated by infragravity waves (Aagaard and Greenwood, 1995), the onshore migration of Type VI bars is poorly known. Generally the motion is attributed to skewed fluid velocities and accelerations (Elgar *et al.*, 2001).

On the Dutch coast a multiple bar *Type VI* system exhibited characteristics of a feedback-dominated system, producing cyclic changes over either 4 or 15–18 years (Wijnberg and Terwindt, 1995). Plant and Holman (1997) showed that bars on the east coast of the United States exhibited unpredictable behavior in relation to wave height changes and yet still moved through a sequential pattern of form changes. This paradoxical behavior they related to feedback effects. The forcing for these transitions is as controversial as bar genesis, since direct hydrodynamic forcing has been proposed as well as a self-organization mechanism.

Little work has been done specifically upon bar decay, other than the welding process associated with *Type II* bars (e.g., Davis *et al*., 1972; Aagaard *et al*., 1998). However, the one major exception is the study of the multiple bar system along the Dutch coast. Here, the bar system shifts progressively offshore over time and the outermost bar decays. This has been attributed to the action of highly asymmetric, nonbreaking waves (Larson and Kraus, 1992; Reussink and Kroon, 1994; Wijnberg, 1997). Plant *et al*. (2001) suggest that a morphologic feedback mechanism can lead to bar decay. As bars move onshore under nonbreaking conditions they are also reduced in height; thus they move further away from wave breaking, allowing further bar decay. This has been observed at Duck, NC (Lippmann *et al*., 1993).

Predictive models of bar genesis and dynamics

Because of the relatively poor knowledge of long-term bar behavior and the inadequacy of local sediment transport models for the complex nearshore environment, predictive models for the genesis and dynamics of wave-formed bars are still far from complete. In general models proposed are either (1) process-based models (e.g., Bowen, 1980), or (2) behavior-based models (de Vriend *et al*., 1993). The latter range from: (1) highly parameterized models to predict summer–winter (bar–berm) profiles (e.g., Aubrey, 1979) or sequential bar evolution (Wright and Short, 1984; Sunamura, 1988) to (2) statistically based models for predicting bar dynamics (Aubrey *et al*., 1980) to (3) morphological models to simulate large-scale beach changes (e.g., Cowell *et al*., 1995).

BAY BEACHES

The length of shore in bays, sounds, lagoons, and estuaries (here termed bays) greatly exceeds the length of ocean shore in many countries. Beaches are common in these bays, but they are often so small and isolated that they escape attention, except in populated locations. The definition of bay in relation to the open coast is somewhat subjective, and bays such as Monterey Bay, California may have wave-energy levels that are among the highest in the world. This discussion is confined to low-energy beaches that occur in mostly enclosed bays where the fetch distances for local wave generation are generally less than 50 km. The principal factors affecting the morphodynamics of these beaches are locally generated waves and wave-induced currents, but wind-induced and tidal currents play a role in morphologic change. Fluvial processes may become dominant at estuarine shores in narrow basins or tributaries. At the low end of the wave-energy continuum, other terms, such as stream bank, intertidal marsh margin, or bay bottom may be more appropriate than beach.

Shore processes

Waves generated by local winds in bays have low heights (usually mean heights <0.2 m and storm wave heights <1.0 m) and short periods (2.0–4.5 s) (Nordstrom, 1992). Ocean waves entering bays play a limited role in beach change where shores do not face ocean entrances (Jackson, 1995). Tidal range affects the vertical distribution of wave energy over the profile, determining the width of the beach and the duration that waves break at any elevation. Bay beaches are usually characterized by a steep upper foreshore with a broad, flat fronting terrace. On tidal beaches, spilling waves break in a broad surf zone across the gently sloping terrace at low tide, but the energy in the waves is low. At high tide, waves reach the upper foreshore with little loss of energy and usually break as plunging waves.

Longshore currents are predominantly generated by the breaking of local wind-waves but refracted ocean waves, tidal flows, and wind drift are locally important and may result in flows bayward of the breaking waves that are opposite flows generated by local wind-waves. Tidal currents are important near channels, projecting headlands, and constrictions in the bay, and they may be the dominant agent of sediment transport on the terrace bayward of the foreshore. Ice forms faster and has a greater influence on mid- and high-latitude bay beaches than on ocean beaches because bay waters are colder in winter, shallower, and less saline; ice lasts longer because low wave energies are slow to remove it. Ship and boat wakes are higher on bay beaches than on ocean beaches because vessels can pass close to the shore, but the average energy in the wakes is usually only a small percentage of the average energy of wind waves in all but the smallest bays.

Water level changes can be locally induced by winds blowing across the bay or they can be induced by flow of water through inlets from surges generated on the open coast. Winds can increase water levels on the downwind side of the bay while lowering water levels on the upwind side, but a large opening to the sea on the downwind side of the bay can result in lower water levels downwind.

Beach and shore characteristics

Beaches comprise a large proportion of the shore in many bays (Nordstrom and Roman, 1996). Important examples include Delaware Bay (Jackson, 1995), Chesapeake Bay (Rosen, 1980; Ward *et al.*, 1989), Puget Sound (Downing, 1983; Terich, 1987). Beaches in smaller bays, with limited availability of sand and gravel may be small, highly localized, or confined to ocean entrances. Many beaches have been created in urbanized estuaries where none would occur naturally because wave energies are too low. These artificial beaches are often wider than natural beaches in undeveloped areas. Some new beaches are accidental by-products of landfill operations; some are created intentionally as new beach recreation areas (Nordstrom, 1992).

Bay beaches may be unvegetated or partially vegetated and composed of sand, gravel, or shell. Surface sediments are often coarser on bay beaches than on ocean beaches with a similar source. Lag gravel is common on the beach surface, formed from particles exhumed by swash or by preferential elimination of fines by low-energy waves. Individual pebbles move readily over the sand surface, and swash excursions create bands of gravel on the upper foreshore.

The depth of mobilization of sediments on the upper foreshore is shallow (e.g., <0.2 m under storm conditions), and the active beach may be only a thin veneer of unconsolidated material overlying an immobile layer of coarse sediments, clay, peat, or a shore platform. Mobilization of sediments on the low tide terrace by waves may occur only to depths of 10–30 mm, and biological activity may play a greater role than wave processes in altering the characteristics of the surface and subsurface (Nordstrom, 1992).

Vegetation plays a greater role in influencing morphologic change on bay beaches than on ocean beaches because of greater abundance of vegetation in bays and the reduced ability of the low-energy waves to move it. Vegetation helps bind bottom sediment and attenuate wave energies; vegetation flotsam in the breaker and surf zones alters the wave and current characteristics and the likelihood of entrainment of beach sediment; vegetation litter in the wrack line forms barriers to waves, currents, and swash uprush.

Bay shorelines are often composed of numerous isolated beaches with different orientations. They have high variability in morphology and rate of erosion over small areas resulting from local differences in fetch, wind direction, stratigraphy, inherited topography, resistant outcrops on the foreshore, variations in submergence rates, and amounts of sediment in eroding formations (Phillips, 1986; Rosen, 1980). Beach compartments are isolated into longshore drift cells defined by deep coves or headlands formed by resistant rock, marsh, or human structures.

The net rate of longshore transport on estuarine beaches varies with orientation, fetch distance, and size of each drift cell and ranges from tens of cubic meters to tens of thousands of cubic meters (Wallace, 1988). Although rates of transport are low, the magnitude of erosion can be high because the quantities of sediment in transport represent a sizable fraction of the total unconsolidated sediment in the active beach. Many bay shores are eroding at greater rates than nearby ocean shores.

Beach change

The upper foreshores of most bay beaches are modally reflective. Conspicuous cyclic morphologic change is confined to the immediate vicinity of the foreshore. Sediment removed from the upper foreshore during high-wave-energy events is deposited on the lower foreshore with a change to a concave upward profile shape. Sediments moved farther offshore onto the terrace form only a thin veneer over the surface instead of forming the break point bar that is prominent on many ocean beaches. Landward and bayward displacement of the entire foreshore profile may also occur while the profile slope is maintained. This parallel-slope retreat and advance is common when sediment exchange is due primarily to longshore transport and is most pronounced near the ends of drift compartments (Nordstrom, 1992).

Resource values of bay beaches

The fronting terrace of a low-energy bay beach has a relatively stable substrate that allows macroscopic plants and fauna to thrive. The upper foreshore is more energetic and may have less species diversity and abundance. Infauna and macroalgae provide prey to juveniles of commercially valuable fish, and the intertidal area provides habitat for recreationally important clams and numerous species of epifauna and infauna. The upper foreshore may be an important spawning area for horseshoe crabs. Fish and invertebrates are prey for foraging birds, especially in the regularly exposed intertidal zone. Wrack from plant litter is inhabited by numerous amphipods and insects. The swash zone and dry upper foreshore are also foraging areas for birds, including upland species.

Bay beaches are not as intensively used for recreation as ocean beaches, but they have important complementary values. They provide convenient surfaces for launching and landing boats and boards for wind surfing. They are favored by parents with children because they provide a safer environment than on the ocean. Many bay beaches are underutilized for recreation because of the unclean appearance of the beaches or lack of awareness of their existence or unique attributes, but ease of access causes bay beaches close to urban areas to have relatively high rates of use.

Shore protection and management

Erosion control strategies for bay beaches may differ from strategies for ocean beaches because of differences in the scale of erosional forces and in the value of resources. Protection programs are facilitated because beach segments are small, isolated drift cells, often under jurisdiction of only one management agency and because small-scale, low-cost protection may be utilized. Low wave energies and gentle offshore gradients make construction of fixed offshore engineering works more practical than on high-energy beaches. Shore-parallel walls are often successful because they can withstand direct attack of local waves; they take up minimal space on the beach and adjacent upland; and they limit the loss of biological resources on the fronting terrace or bay bottom. Projects funded by national or state/ provincial governments are often not economically feasible, resulting in a fragmented approach to protection by individual property owners. Simple engineering principles are often ignored in constructing small-scale protection structures, including lack of filter cloth or weep holes in bulkheads, failure to build structures deep enough to prevent toe scour or high enough to prevent overtopping, weak fastenings, and failure to use adequate sized armor stones or perform maintenance. As a result, there is much evidence of structural failure. Beach fill is increasingly used for protection or recreation, but fill can cover benthic habitat and eliminate shallow-water areas for aquatic plants. Bayside nourishment projects can be inexpensive because only small quantities of fill are required. Fill materials brought in from outside the region may retain their exotic appearance because of limited mixing by low-energy waves.

There has been considerable federal and state intervention in decisions on developing bay shores, especially in productive estuaries, but this intervention is rarely conducted to maintain beach resources. Alternative human uses such as transportation, industrial developments, residences, and boating are compatible with a coastal location according to most policies, and actions to enhance these uses may eliminate beaches. The number and value of bay beaches can be enhanced by implementing beach nourishment operations, altering vegetation, constructing appropriate protection structures, acquiring key sites for public use, and enhancing access. The ease of constructing and maintaining bay beaches and the paucity of quality recreation space in many urban areas make creation of new beaches as surrogates for ocean beaches an attractive option.

BEACH AND NEARSHORE INSTRUMENTATION

Instrumentation in studies of the coast generally, and of the beach and nearshore zone in particular is designed to measure attributes of form and changes in the form (bed) over time, including bedforms; fluid processes related to waves, water level and currents in the water and wind on the beach; and sediment concentration and mass transport rate in the water and on the beach. These measurements may be made at a variety of temporal scales ranging from fractions of a second to months and years and spatial scales ranging from a few square millimeters to hundreds of square kilometers. Some attributes are measured individually, but much of the focus today, and over the past three decades, has been on measurements of morphodynamics, in which the objective is to measure fluid and sediment transport processes and the resulting change in morphology at a temporal scale of minutes to days and occasionally months. Much activity is focused on sandy and to a lesser extent muddy coasts and much of the instrumentation described here is devoted to these, but some work also takes place on the erosion of cohesive clay and bedrock coasts. The highly dynamic nature of the nearshore and swash zone in particular poses many problems for the design of instruments for measuring fluid and sediment transport processes. In addition to the need for very rugged instruments and supports for mounting them, there are difficulties posed by the lack of access to much of the nearshore during storm conditions, and by the presence of bubbles and organic matter in the water column. Ultimately, the instrumentation is designed and deployed to measure particular properties and processes of the beach and nearshore zones, and therefore, this review is organized by the measurement objective rather than particular instrument types.

Measurement of form and changes in form (erosion and deposition)

Erosion of cohesive and bedrock coasts

Where the coastline is developed in bedrock, till, and cohesive muds the focus of attention is usually on the measurement of rates of erosion in relation to the strength attributes of the material and the erosional or forcing processes (Sunamura, 1992). On a small scale, erosion by weathering and abrasion of rock coasts generally takes place so slowly that measurements are made at point locations on a timescale of months to years. The micro erosion meter originally used to measure solution of limestone was adapted for use on intertidal shore platforms (Trudgill *et al*., 1981). It consists of a pointer attached to a micrometer gauge on a mount that can be placed on pins drilled into the rock platform. The mount swivels to allow measurement to be taken at several points around the station so that an average value can be obtained. Measurements are commonly taken at intervals of months or years because of the relatively slow rate of downcutting (Kirk, 1977; Viles and Trudgill, 1984). A cruder version of the instrument has been adapted for measurements of erodability of tills and clays underwater (Askin and Davidson-Arnott, 1981; Davidson-Arnott and Langham, 2000). Because the erosion rates are typically up to several centimeters per year, measurements can be made on a weekly to monthly basis.

Measurements of the erodability of fine-grained cohesive muds commonly found in a variety of marine and estuarine environments, have commonly been made with a variety of benthic flumes—essentially inverted channels of various configurations which can be deployed either on the exposed tidal flat or underwater (Amos *et al*., 1992; Maa *et al*., 1993; Houwing, 1999). Water is circulated through the channel at increasing speeds until the shear on the bed induces erosion and the erosion rate is measured either directly, or indirectly by measurement of suspended sediment concentrations. Recent experiments have also been made with the Cohesive Strength Meter, an automated device which employs a carefully regulated vertical jet of water and monitors the rate of erosion with respect to the impact force (Tolhurst *et al*., 1999).

Erosion and deposition of sediments

While large-scale changes in form can be measured by a variety of techniques described below, these techniques are usually carried out at finite intervals of days, weeks, or months. Measurement of changes in the bed at particular locations on the timescale of dynamic measurements of fluid flow and sediment transport, typically on the order of minutes to hours, has proved to be surprisingly difficult to do in shallow water. One major problem in the nearshore during storms on sandy coasts is the difficulty of distinguishing the bed from the material immediately above it, which is being transported as bed load or suspended load close to the bed. Techniques for measuring changes in elevation at points in the nearshore range from simple erosion rods to optical and acoustical instruments.

Simple measurements of change in bed elevation and the total depth of activation can be made with rods emplaced along a profile or on a grid which are surveyed before and after a storm (Greenwood *et al*., 1979). The rods can be emplaced by wading and diving. The maximum scour depth can be resolved by placing a washer on the sand surface and then measuring the depth of burial following the storm. Results from a grid of these can be used to measure volume change in the nearshore (Greenwood and Mittler, 1984). Similarly, thin rods can be used on the subaerial beach to measure erosion by wind and thus provide a comparison volume to measurements of sand transport or deposition. Other approaches involving this simple technology in coastal applications include the use of a bedframe device to measure rates of sediment deposition in foredunes (Davidson-Arnott and Law, 1990, 1996) and the use of Surface Elevation Tablet (SET) stations in measuring net change in saltmarshes (Cahoon *et al*., 2000). Recently, automated devices which act in a similar fashion have been developed. One approach uses a vertical array of photocells spaced at a small increment, usually on the order of 1 cm, with the bed being distinguished by either a change in the voltage output or a circuit which can detect where the break is between exposed and buried cells (e.g., Lawler, 1992). An alternative method uses the difference in conductivity between sediments and seawater to distinguish the bed level (Ridd, 1992). The value of these instruments is that they are relatively low cost and therefore provide the potential for deployment of sufficient sensors to give reasonable spatial coverage across the surf zone.

It should be possible to detect the bed using a small echo sounder mounted on a support above the bed, though this has proved notoriously difficult when there are large amounts of sediment moving over the bed and in suspension. One adaptation of this approach is to mount the transducer on a frame with a sealed stepper motor that permits it to traverse a section of the bed, thus permitting determination of two-dimensional bedform properties and migration rates (Greenwood *et al*., 1993). Transducers and miniature versions of sidescan sonar have been used more successfully in deeper water where sediment concentrations are much lower. Recent developments in acoustic doppler technology give a much better definition of the bed. Several versions of acoustic doppler velocity profilers (ADCPs) are available which enable the speed of currents to be detected at incremental distances from the sensor. When pointed downward, these are able to distinguish the bed more precisely than simple sonar devices, because the doppler shift is absent from sediments that are not moving (see section below on Sediment concentration, mass transport rate, and deposition for information relating to the ADCP). Small, relatively cheap acoustic sounders are available for use in air and can be used on the beach to measure changes in elevation of the bed or the water surface in wells installed to measure the water table. These devices can also be mounted on tracks to give a profile of changes in elevation during a transport event and the dimensions of any bedforms that develop.

Measurement of form and form change

Measurement of the dune, beach, and nearshore form on a scale of meters to kilometers has traditionally been done using standard survey and hydrographic techniques. Surveys out to the limit of wading have been carried out with levels and theodolites, and the use of a total station incorporating an electronic distance measurement (EDM) unit and electronic data storage is now standard. These permit rapid surveys over a range of elevations and the output is readily incorporated into a wide range of contouring and geographic information system (GIS) software packages which can produce digital elevation models and permit easy extraction of volume change through repetitive surveys (see Figure B11). In shallow water, depth has traditionally been determined using standard echo sounders mounted on a boat (Gorman *et al*., 1998). Digital recording has now replaced the standard paper trace and positional data can be recorded simultaneously using a global positioning system (GPS). Towed arrays or acoustic multibeam transducers can be used to give simultaneous mapping of a wide swath, including information on large bedforms (Morang *et al*., 1997). Better definition of the seafloor and three-dimensional bedform features can be attained with sidescan sonar, which utilizes a towed transducer that emits a signal at right angles to the tow direction and records returns from a swath either side of the transducer (Morang *et al*., 1997).

The use of GPS which integrates signals from three or more satellites to determine location and elevation for a variety of surveying tasks, is now becoming standard in measuring beach form and change as it is in so many other fields. Simple systems can give positional accuracy of a few meters and elevation to about 10 m. Much greater accuracy can be obtained through the use of differential systems, which simultaneously capture the signal from the satellites and from a land-based station whose position and elevation is known precisely (see Figure B11). Moderate priced differential systems make use of Coast Guard beacons, which are set up along the coast for navigational purposes. These can give positional accuracy of ± 2–3 cm and vertical resolution of about double that, though the accuracy decreases with distance from the beacon. More expensive differential systems use a base station set up over a known position and a rover station for the actual survey. The systems can be used to measure the height and position of particular points but they can also be put in a backpack or on a vehicle allowing continuous recording of a traverse. This permits the mapping of linear features such as the waterline, thalweg of tidal creeks, bar crest, and top and bottom of cliffs, thus permitting much better delineation of these features and permitting more accurate delineation of change through repetitive surveys.

A major problem for morphodynamic experiments in the nearshore and surf zone is to obtain measurements of form change during intense storm events. While measurements of sediment transport and nearshore water motion can be obtained throughout an event, most measurements of form change have been obtained through standard surveys carried out during low wave conditions before and after the event. Some data during storms can be obtained from jetties and from specially constructed platforms that span the surf zone. However, some specialized equipment makes data collection during quite high wave conditions possible. These include various sled devices, which can have either a mast with a prism for measurement by a total station or a GPS station to enable position and elevation to be determined. The sleds may be towed by boat beyond the surf zone and winched onshore or a pulley system may be attached to an anchor seaward of the surf zone, enabling the sled to be pulled offshore without recourse to a boat. One highly specialized instrument is the CRAB used extensively at the CERC facility at Duck, North Carolina to carry out a variety of tasks in the water, including surveys in waves up to 3 m (e.g., Plant *et al*., 1999).

Production of topographic maps from stereo pairs of aerial photographs has been a standard procedure for five decades but photo rectification and automated contouring have required expensive equipment and are rarely used for small-scale beach studies. However, new developments in video technology and digital photogrammetry are making remote measurements of form change much more practical. Video technology has been applied for more than a decade to measure waves and swash run-up (see below) but it has also been applied to measurement of the position of nearshore bars through time exposure of wave breaking (Konicki and Holman, 2000; Ruessink *et al*., 2000; Alport *et al*., 2001). The intensity of wave breaking is captured by creating time exposure images over a period on the order of 10 min and the resultant smooth white bands outline the zones of wave breaking on shallow bar crests and at the beach. Video cameras can also be used to monitor changes in dynamic features such as tidal inlets and associated ebb and flood tidal deltas (Morris *et al*., 2001).

The use of digital images from still and video cameras to produce digital elevation models (DEMs) through a variety of computer software packages is of especial interest in mapping coastline changes and changes in the morphology of the beach and foredune area (Chandler, 1999). The technique makes use of overlapping pairs of photographs produced either in the traditional way through the movement of a camera installed in a plane, helicopter, or a land-based vehicle, or through the use of images taken from two fixed positions. In the case of aerial photography or moving vehicles, the position of each digital image can be linked to real time positional data provided by DGPS. Where fixed cameras are used on the beach, control points whose position and

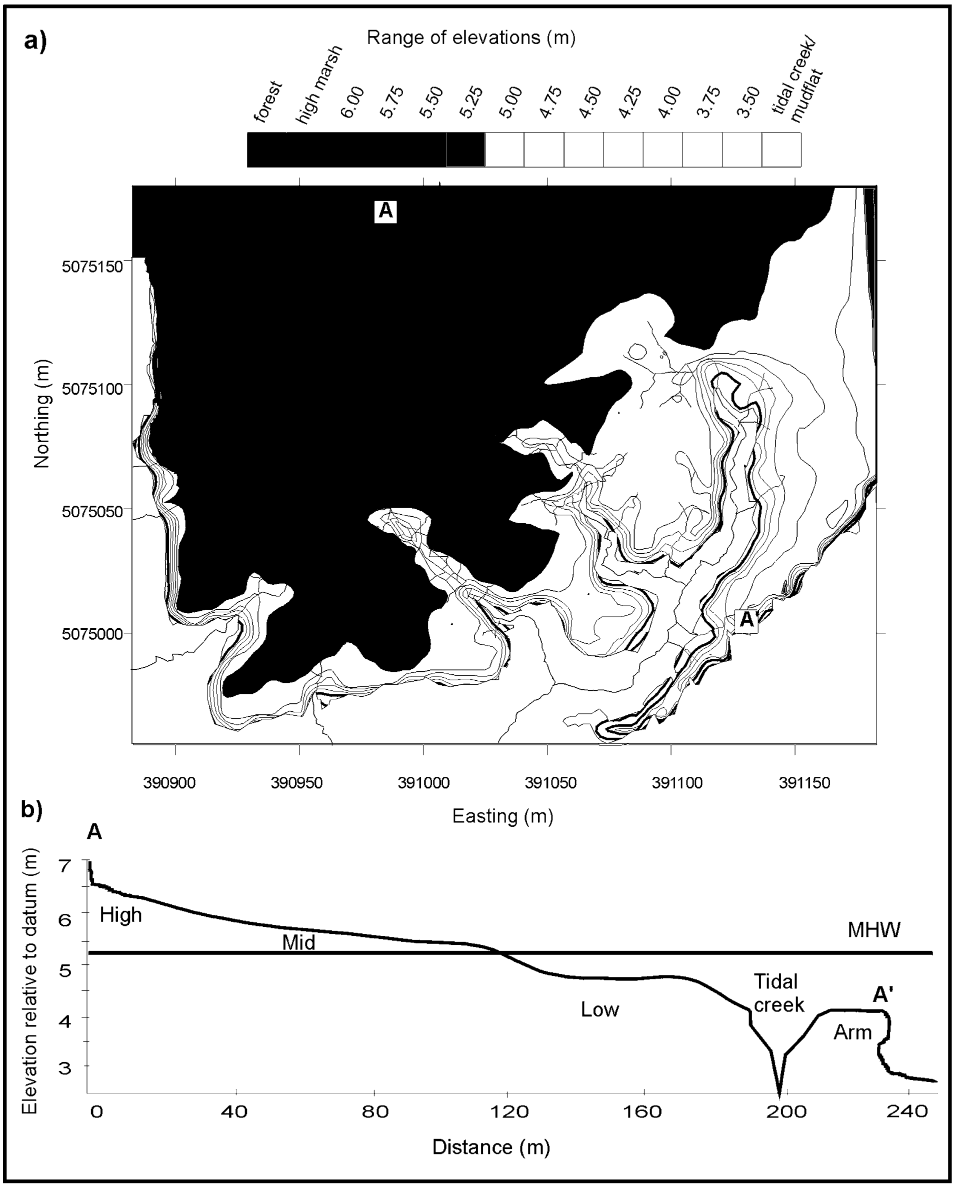

Figure B11 Digital elevation model of a saltmarsh and tidal creeks, Bay of Fundy, Canada, produced from measurements made with a total station and with a DGPS system.

elevation have been surveyed precisely are used to aid in rectification (Hancock and Willgoose, 2001). The advantage of these automated photogrammetric systems is that they can provide a very large number of data points for construction of the DEMs and much of the processing can be automated, thus allowing the evolution of topography over days, weeks, or months to be captured.

On a larger scale, the development of light detection and ranging (LIDAR) technology combined with DGPS permits topographic mapping of both the land surface and the nearshore bed to depths of 10–15 m (Irish and White, 1998; Sallenger *et al.*, 2001). The technology makes use of a laser transmitter/receiver, which transmits laser pulses toward the surface and records the traveling time of the reflected pulse. The pulse is reflected from the land surface and, over water, the return from the bottom can also be detected down to depths that depend on the degree of absorption, scattering, and refraction in the water; these in turn depend on sun angle and intensity and on the degree of turbidity in the water. The system can be deployed in a helicopter or fixed wing aircraft. Apart from the unique ability to map both the land and shallow nearshore, the technique offers a relatively low-cost method for determining topographic changes due to major storms and hurricanes (Sallenger *et al.*, 2001), and for surveying changes in areas such as salt marshes and tidal mud flats which are difficult to access with standard surveying approaches.

Winds, waves, water levels, and currents

Much of the focus in field studies of the beach and nearshore zone is on measuring the morphodynamics of sandy coasts, and to a lesser extent that of muddy coasts. These experiments require measurement of fluid and sediment dynamics over a range of timescales from fractions of a second to hours, days, and months and over spatial scales ranging from a few centimeters to hundreds of meters. Until recently, different instrumentation has been required to measure the fluid dynamics from that measuring sediment dynamics. Over the past three decades, mechanical devices for measuring fluid dynamics have been increasingly replaced by solid-state electronics involving the application of a range of direct and remote technologies. Because of the broad range of forcing variables and the spatial scales involved in determination of sediment transport, a wide range and large number of instruments is typically employed. Instrumentation typically involves measurement of wind speed and direction (both for aeolian transport on the beach and for the dynamics of the water surface), water surface elevation, wave form and direction, and water motion.

Wind speed and direction

Wind speed and direction have traditionally been measured by some form of mechanical cup or propellor-type anemometer and resistance

Figure B12 Array of cup anemometers and wind vanes mounted on towers to measure wind flow over the beach foreshore at Innisfree Beach, Ireland. Two versions of integrating sediment traps are seen on the left—the smaller traps are cylindrical traps after Leatherman (1978) and the other traps are wedge traps (Nickling and McKenna-Neuman, 1997).

wind vane mounted on a mast above the water or land surface. These give good resolution of the horizontal wind velocity at a particular elevation. Typically, in studies of aeolian transport on the beach several vertical arrays of anemometers will be deployed in order to obtain measurements of internal boundary layer development and to estimate the bed shear velocity u_* (Greely *et al.*, 1996; see Figure B12). The vertical flow can be obtained with systems of three propellor type anemometers or with two mounted at 45° angles as in the K-Gill anemometer (Atakturk and Katsaros, 1989). Sonic anemometers now offer the ability to measure fluid motion in all three dimensions, though their size is still large enough to make measurements close the bed (and thus the saltation layer) difficult. Recent modification of the Irwin sensor, a vertical pitot tube that can be mounted flush with the bed (Irwin, 1980), offers the ability to obtain direct measurements of wind stress near the bed with little disturbance to the flow.

Mean water level

Measurements of water surface elevation are collected routinely to measure changes due to tides, storm surge, and wave set-up and set-down across the breaker and surf zones. Traditional mechanical floats have now been replaced by optical and acoustic sensors installed in stilling wells. Most studies of surf zone dynamics have made use of mean values of the surface elevation measured from wave staffs or pressure transducers, though the accuracy of these measurements is on the order of +/− several centimeters. More precise measurements that can be used for investigating detailed mechanisms of nearshore circulation can be obtained through the use of manometer tubes deployed into the surf zone from the shore (Nielsen and Dunn, 1998).

Waves

Field measurements of waves in the inner nearshore and surf zones can be obtained by some form of surface piercing wave staff, which has the advantage of providing a direct measure of the wave form. These systems make use of the conduction of electricity by water, particularly seawater, and record either the change in electrical resistance or capacitance of the system as water rises and falls over a length of uninsulated cable which is part of an electrical circuit (Ribe and Russin, 1974; Timpy and Ludwick, 1985). The change in resistance or capacitance can be conditioned to produce a variation in an output signal which may be a DC current or a frequency. The sensor itself may be fixed to a support jetted into the sand in the nearshore (see Figure B13) or attached to some physical structure such as a jetty or platform. The advantage of the surface staff is that it provides a direct measure of the water surface form and they have been used extensively in many studies, particularly in fetch limited areas where installation can be accomplished during calm conditions (Davidson-Arnott and Randall, 1984; Greenwood and Sherman, 1984).

The disadvantage of wave staffs is that they are subject to high wave forces when deployed in shallow water and they have largely been replaced with some form of pressure transducer housed in a watertight case. These can be deployed some distance below the surface, or on the bed and they are often colocated with other sensors such as electromagnetic current meters and nepelometers (see below). They sense the change in pressure associated with the passage of individual waves. The pressure variation with depth can be predicted from wave theory and thus it is possible to develop a transform function that will relate the recorded variations in pressure to the surface wave form (Lee and Wang, 1984). Since there is usually a spectrum of frequencies present in the pressure transducer record, the transform should be performed for all of the frequencies present. This is not a trivial task, though it can be done routinely in a data analysis program. There is some loss of information on the true form of the surface wave as well as the loss of the higher frequencies with increasing depth of deployment, but this is offset in studies in and close to the breaker and surf zones by the ease of deployment and the reduced exposure to breaking wave forces.

The water surface can also be measured remotely using a video camera to measure the change in surface elevation against a graduated pole or screen. This gives a good measure of the wave form without interference and it enables determination of whether the wave is broken or not. The record can be digitized manually or a computer software algorithm can be used to extract the position of the surface automatically. Video cameras have also been used extensively to extract data on run-up frequencies on the beach (Holman and Sallenger, 1985). Recent developments in LIDAR technology may also permit application to measuring waves (Irish *et al.*, 2001).

Individual wave staffs or pressure transducers provide a picture of the variations in water surface elevation through time—that is, they give

Figure B13 Resistance wave staffs (left) deployed over an intertidal ridge and runnel, Nova Scotia, Canada. A grid of depth of disturbance rods is deployed across the bar (center) and frames supporting OBS and electromagnetic current meters can be seen in the far right.

information on wave height and period but not on the direction of travel. This requires either the deployment of several instruments in an array, which permits determination of the wave direction through a comparison of travel time between various sensors (Bodge and Dean, 1984; Howell, 1992), or the measurement of both the horizontal and vertical components of water motion using a pressure transducer and bidirectional electromagnetic current meter or an acoustic doppler current meter (see following section).

Because of the rapid oscillatory motion associated with wave action in shallow water, mechanical current meters are generally not useful in studies of fluid processes in the inner nearshore and surf zone, though miniature-ducted impellor current meters have proved useful in some locations (Wright *et al*., 1982; Masselink and Hegge, 1995). Measurements of hydrodynamics in the nearshore and surf zone were revolutionized in the 1970s by the development of electromagnetic current meters (EMCMs) and they have been used extensively in almost all field experiments as well as in the laboratory (Huntley and Bowen, 1975; Cushing, 1976). Examples of their use can be found in numerous experiments including the Nearshore Sediment Transport Study (NSTS, Seymour, 1989), the Canadian Coastal Sediment Study ($C^2 S^2$; Willis, 1987) and in the various experiments carried out at the CERC at Duck, North Carolina (Birkemeier *et al*., 1997). The current meters produce a fluctuating magnetic field around the sensor head and measure the voltage generated by fluid flow in the field using Farraday's law. Typically, the instruments have four sensors mounted orthogonally so as to detect flow along two orthogonal axes. The current meter is usually mounted so as to detect horizontal flow, but it is possible to mount it with one axis vertically. The sensors have a fast response time, permitting sampling at frequencies >5 Hz and are able to detect very small mean flows in a highly fluctuating environment (see Figure B14). The majority of EMCMs used in the field have been made by Marsh-McBirney Inc. of Maryland, USA. Large models have a 10.5 cm diameter head and the small ones, which have been used extensively in the surf zone have a 4 cm head. These current meters have been evaluated extensively (Aubrey and Trowbridge, 1985, 1988; Guza, 1988) and their widespread use allows for ease of comparison between different studies. While EMCMs are now being replaced by various forms of acoustical instrument, they are still useful in the breaker and surf zone because of their smaller sensitivity to the presence of air bubbles.

In the past decade, various forms of acoustical doppler instruments have been developed which have been used in laboratory and field experiments. Essentially, they emit an acoustic signal which is reflected by fine material in the water column from a focal point and received by orthogonally mounted transducers. The relative motion in each axis is then determined by the doppler shift of the signal. The acoustic doppler velocimeter (ADV) is the simplest of the instruments and measures velocity at a single point on the order of a few centimeters from the emitting transducer.

Sediment concentration, mass transport rate, and deposition

Obtaining measurements of sediment transport is the third key element in morphodynamic experiments in the coastal zone. There are a large number of instruments available and a variety of approaches have been taken, but much work remains to be done to obtain reliable measurements over a reasonable spatial and temporal scale (White, 1998). Estimates of net longshore transport over periods of weeks, months, or years at a location can be obtained from measurements of the amount trapped at a total barrier, either over a short period at a purpose-built groin (Wang and Kraus, 1999) or at a large jetty. A number of studies have also used fluorescent or radioactive tracers for measurement of longshore sediment transport or of transport pathways within the surf zone. However, the focus here is on instrumentation for instantaneous measurement of the transport rate either directly, or indirectly through the combination of measurements of sediment concentration and net water motion. Direct measurement techniques include various traps and acoustic doppler instruments that measure concentration and velocity simultaneously through some portion of the water column. Indirect techniques for measuring concentration include optical and conductivity devices.

Figure B14 Electromagnetic current meter (left) and three OBS probes mounted on a "goalpost" in the intertidal zone, Skallingen, Denmark. Electronics for the current meter are installed in the waterproof housing secured to a pole jetted into the sand to the left of the goalpost. A profile line of large depth of disturbance rods is visible at the right.

Traps and pumps

A number of devices have been used in attempts to trap sediment suspended in the water column of the net transport in the swash or surf zone, but the oscillatory motion associated with wave action makes this task much more difficult than, for example, under unidirectional flow in a river. Pump samplers have been used with varying degrees of success and various bottles for capturing the suspended sediment load. These all require considerable effort and the logistical difficulties coupled with doubts as to the accuracy of the sampling process have limited their further use. Recently, arrays of streamer traps consisting of long bags of fine mesh fixed to a rigid rectangular inlet have been used to measure transport where there is a net current present. These traps are able to capture large amounts of sediment, but it is still not clear that they can provide reliable estimates of the net transport or that they provide accurate results over a range of conditions.

Optical devices

Optical devices emit light and give a measure of the sediment concentration in the water column at a point either through the degree of attenuation of the light beam or through the amount of light reflected from particles in suspension. They therefore do not provide a direct measure of sediment transport and thus must be collocated with a device such as an EMCM which measures the fluid flow. The light transmitted is generally in a narrow wave band in the infrared range in order to minimize the effects of natural light in the water.

Transmissometers measure the degree of attenuation of the light over a fixed distance separating the emitter from the receiver. They tend to be relatively bulky instruments best suited for work some distance seaward of the breaker zone in depths greater than 10 m where suspended sediment concentrations are relatively low. A Sea Tech transmissometer with a 5 cm path length was developed for use in shallow water (Huntley, 1983) but the much smaller probes associated with instruments measuring reflected light proved more suitable for the inner nearshore and surf zones.

Much of our understanding of the dynamics of suspended sediment transport in the nearshore over the past three decades has come from the use of the optical backscatterance sensor (OBS) originally developed at the University of Washington (Downing *et al*., 1981) and now produced commercially by D & A instruments. The OBS is a miniature nephelometer which measures the backscatterance of light by sediments suspended in the fluid. It utilizes a narrow infrared beam which has the advantage of minimizing interference by sunlight and confining the sampling volume to a short distance from the probe. The sensor is compact (2.1 cm diameter) with transmitter and receiver mounted next to each other at the end of the probe, thus minimizing flow interference and enabling sensors to be mounted in close proximity to other probes or to electromagnetic current meters with which they are often collocated (see Figures B14, B15(a)). The OBS probe is very rugged, enabling it to be deployed in areas of strong currents and breaking wave impacts, and it is clearly superior to other nephelometers for work in the nearshore marine environment (Greenwood *et al*., 1990). They are designed to measure suspended sediment concentrations in areas where concentrations may be high and/or may vary rapidly over short time periods (i.e., on the order of 0.25 Hz). They have been used in a wide range of marine environments, including the shoreface and continental shelf (Wright *et al*., 1991; Kineke and Sternberg, 1992), the breaker and surf zones (Black and Rosenberg, 1994), and estuaries (Kineke *et al*., 1991).

Provided they are not deployed too close to the bed (interference with the bed itself) or too close to the surface (effects of ambient light) both transmissometers and OBS probes work well. They are linear over a wide range of grain sizes from clay to sand and there has been extensive testing and calibration of both types of instruments in the laboratory and field (Downing and Beach, 1989; Osborne *et al*., 1993; Greenwood and Jagger, 1995; Bunt *et al*., 1999; Sutherland *et al*., 2000). However, they perform best with a narrow range of grain size and calibration, where there is a wide range of grain size they are subject to considerable error (Bunt *et al*., 1999).

Routine field calibration of the instruments is difficult and laboratory calibration requires quite complex facilities and involves the difficulties of obtaining representative samples of suspended sediment to be returned to the lab for testing. Recent testing of a laser *in situ* scattering and transmissometry (LISST) instrument produced by Sequoia Scientific (Traykovski *et al*., 1999; Gartner *et al*., 2001; Mikkelsen and Pejrup, 2001) offers the potential to measure the complete particle size distribution and concentration simultaneously. Initially, this may offer a means of calibrating cheaper, less bulky sensors but further developments may lead to smaller versions which could be deployed close to the bed.

Acoustic Doppler velocity profilers

Acoustical instruments offer the possibility of measuring both particle concentration and velocity simultaneously and over some appreciable portion of the water column, and thus providing a direct measure of the transport rate. Acoustic Doppler velocity profilers (ADVP) use the same basic technology as the ADV described above. However, they measure the return signal in very small increments of time, thus allowing the determination of velocity and concentration in discrete "bins." They can be used from a boat with position fixed by DGPS and can thus give a complete picture of flow over bedforms in estuaries and tidal channels (Best *et al*., 2001).

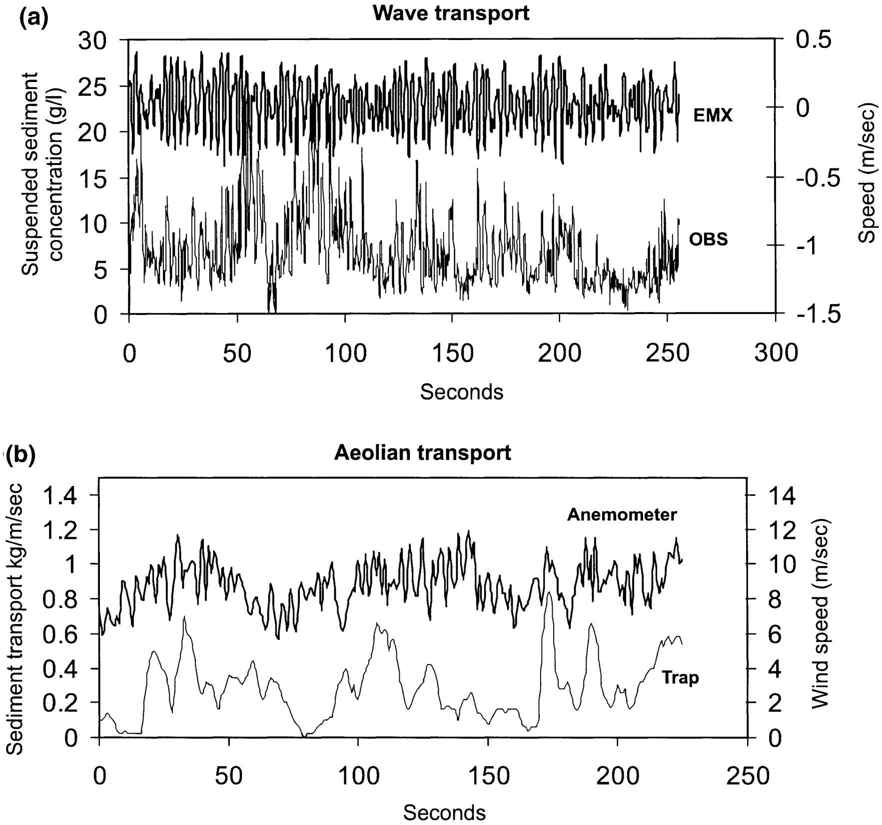

Figure B15 Comparison of flow and sediment transport in the nearshore and on the beach. (a) On-offshore flow speed measured with an electromagnetic current meter and suspended sediment concentration measured with an OBS probe at an elevation of 0.15 m above the bed on the crest of an intertidal sand bar (see Figure B13). The instruments were sampled at 4 Hz. (b) Horizontal wind speed measured with a cup anemometer and sediment transport rate measured with a wedge trap fitted with an electronic balance. The instruments were sampled at 1 Hz and smoothed with a 5 s running mean.

Aeolian sand transport

The design of field instrumentation for measuring sand transport by wind has tended to lag behind that available for measuring transport in the water. Sediment transport from the beach over a period of days or weeks can be measured indirectly by measuring accumulation in vegetated sand dunes by profiling or by the use of a bedframe device (Davidson-Arnott and Law, 1990, 1996).

Most direct measurements of sediment transport have been made with simple vertical traps which are oriented into the wind and which allow the sand captured to collect in the base. The sediment collected over a period of time is weighed to give an average transport rate for the collection period. A major problem is to design the trap so that it is isokinetic, otherwise sand in transport is diverted away from the trap opening by the pressure buildup. Simple vertical traps, which have been used widely may have an efficiency <30%. Wedge-shaped traps have improved aerodynamics and are likely much closer to isokinetic (Nickling and McKenna-Neuman, 1997—see Figure B12). However, these traps are more sensitive to changes in wind direction and will undersample when the wind angle exceeds 5°; thus they can only be used for periods of 15–30 min without attention. A variety of other trap designs are available (Goossen *et al.*, 2000) but all have a number of problems with accuracy.

Horizontal traps offer the opportunity to sample all of the transport load and provide a means for calibrating vertical traps. They require a large pit several meters across and again will integrate total transport over periods of tens of minutes to hours (Greely *et al.*, 1996). Use of a wet horizontal trap can reduce some of the logistics (Wang and Kraus, 1999) because the trap need only be a few centimeters deep.

A number of trap designs are now being used to obtain measurements of the instantaneous mass transport rate, thus permitting comparison of the transport rate with measurements of the wind flow. The trap design of Nickling and McKenna-Neuman has been modified to incorporate a continuous weighing electronic balance (Mckenna-Neuman *et al.*, 2000; see Figure B15(b)). Bauer and Namikas (1998) used the same trap but designed a combination tipping bucket and strain gage to weigh the sand collected over long time periods. The design of Jackson (1996) uses a similar weighing mechanism to that used by Bauer and Namikas, but the trap itself is a circular collection funnel that is mounted flush with the surface. This avoids the problem of isokinetic sampling associated with vertical traps and has the advantage of omni directional collection. However, it measures flux to the surface rather than the total transport rate.

Impact measurement

The drawbacks of trap designs and the need for high speed, continuous sampling of the transport rate have led to the development of several instruments that measure the impact of saltating grains and then attempt to calibrate this to the transport rate. The saltiphone (Arens, 1996) uses a microphone to record impacts and the intensity is then recorded as a voltage signal. While this gives a measure of the relative transport rate, it has proved difficult to calibrate and is sensitive to variations in grain size. The SENSIT (Stockton and Gillette, 1990) responds to the impact of saltating grains on a piezoelectric crystal and counts the number of impacts per second. It has also proved difficult to calibrate to give a measure of the mass transport rate and seems to offer only a relative measure of the grains in saltation. Because of the small sampling area a vertical array of the sensors must be deployed in order to measure the total mass transport rate.

BEACH CUSPS—See RHYTHMIC PATTERNS

BEACH DRAIN

Introduction

For over half a century, reporters have suggested a link between the elevation of beach groundwater and erosional or accretional trends of the beach face. Beach dewatering (the artificial lowering of the water table within beaches by a system of drains and pumps) is suggested by its proponents as a practical alternative to more traditional methods of coast-stabilization. Within the last 15–20 years several tests have been installed, and to date seven to eight commercial dewatering systems have operated. The following is a review of the origins and development of the dewatering concept from early work on beach face permeability and beach groundwater dynamics, to recent field and laboratory studies that have explicitly examined the effect of artificial groundwater manipulation on beach face accretion and erosion.

The origin of the beach drain

The beach drain (Figure B16) is not a new concept, but was revived in the last 20 years due to commercial interests (Turner and Leatherman, 1997).

The origins of the beach drain concept can be traced back 50 years to early work in two parallel fields of coastal research: the role of beach face permeability in controlling erosion or accretion (e.g., Bagnold, 1940); and the tidal dynamics of beach groundwater (e.g., Grant, 1948). The installation within the last 10 years of prototype beach dewatering systems in Europe (Vesterby, 1994) and the United States (Lenz, 1994) signified the transition of the beach dewatering concept from the hypothetical to the practical. The potential use of beach drain technology is beginning to be noted within the mainstream coastal engineering community (e.g., Abbott and Price, 1994, pp. 334–336), and in the last five years a limited number of journal articles (e.g., Weisman *et al.*, 1995; Li *et al.*, 1995) and more frequent papers presented at the coastal engineering conferences (e.g., Davis and Hanslow, 1991; Ogden and Weisman, 1991; Davis *et al.*, 1992, 1993; Oh and Dean, 1994) have served to raise the awareness of the beach dewatering concept. However, if beach dewatering technology is to meet the promise that its proponents claim, the answers to a number of fundamental questions must be addressed.

Counter to the impression that may be gained from publications and other materials produced by commercial players in the beach dewatering industry, the underlying physical mechanisms that may contribute to the success of the beach drain concept are *not* yet fully elucidated.

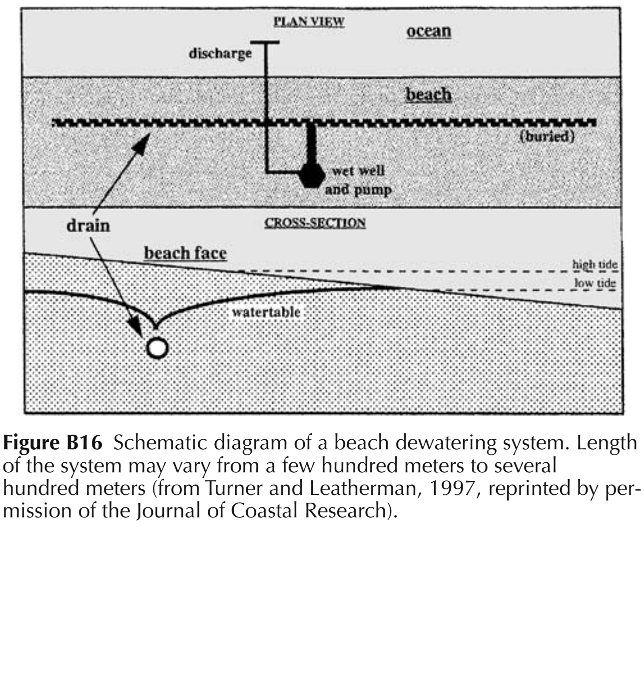

Figure B16 Schematic diagram of a beach dewatering system. Length of the system may vary from a few hundred meters to several hundred meters (from Turner and Leatherman, 1997, reprinted by permission of the Journal of Coastal Research).

Dewatering is a well-established practice in the excavation industry, but the inclusion of a highly dynamic land–ocean boundary where sediment motion is a function of both static inter-granular forces, and surf and swash zone hydrodynamics, makes the description of transport mechanisms across a dewatered beach face unique. On the more practical side to many coastal scientists and engineers, the field evidence from operating dewatered sites remains inconclusive. A comprehensive and independent assessment of the mid-to-long-term operation of a prototype installation is yet to be reported in the scientific literature, and until such a study is completed it is unlikely that the prevailing mood of healthy skepticism (e.g., Bruun, 1989) will be either validated or changed.

History and development

Bagnold's seminal laboratory investigations (Emery and Foster, 1948) undertook the first published study describing the dynamics of the water table in sandy beaches. They referred to prior unpublished work of Zinn (1942).

Several laboratory and field tests are described by Turner and Leatherman (1997) including Bagnold (1940), and Emery and Foster (1948). Ogden and Weisman (1991) undertook two-dimensional (2-D) tests using irregular waves ranging from erosive to accretive and concluded that for the range of conditions tested, the beach drain had no significant effect on the rate of erosion or accretion at the still water line, but did promote berm development and hence overall beach face steepening. A more recent study by the same researchers (Weisman *et al.*, 1995) examined the effectiveness of beach dewatering under the influence of the tides, and concluded that water table lowering maintains its effectiveness in promoting berm growth and beach face steepening for both tidal and nontidal cases. Heaton (1992) undertook a series of single and multiple wave experiments, and quantified a general trend that increasing water table elevation resulted in an increasing volume of sediment eroded from the beach face. Oh and Dean (1994) reported a set of three experiments where the water table was alternatively elevated, lowered, and equal to mean sea level, and concluded that an elevated water table resulted in the overall destabilization and erosion of previously marginally stable regions of the beach face. A simple seepage model (Oh and Dean, 1994) demonstrated that outflow across the beach face may act to reduce the effective weight (and hence stability) of surficial sediment.

Considerable activity has taken place in Australia. Davis *et al.* (1992, 1993) made field tests and found that for fair conditions the drain increases beach stability while storm conditions had the opposite effects. Nielsen (1990, 1992) did considerable testing including the infiltration effects on sediment mobility under recorded stabilizing as well as destabilizing forces and their relation to fluidization. Nielson's latest (2001) is an attempt to determine infiltration on effects on sediment mobility. Many field tests are described by Turner and Leatherman (1997) providing results or conclusions from each separate test programs.

First full-scale test—Thorsminde, Denmark

A test site at Hirtshals was not considered a success by the Danish Geotechnical Institute and was subsequently dismantled, but the results from the Hirtshals West site were deemed encouraging, and it was decided to undertake the first large-scale test of the dewatering concept at Thorsminde on the west coast of Denmark. Hansen (1986) provides details of the beach and installation, which are summarized to varying degrees by Ovesen and Schuldt (1992) and Vesterby (1991, 1994). The test site is located on the exposed North Sea coast, where the shoreline fluctuated seasonally by ±15 m with a reported average erosion rate of 2–4 m/year.

The conclusion after year of operation was:

1. The usual seasonal fluctuation in shoreline position was halted and net recession ceased.
2. The southern drained region prograded seaward approximately 10 m and stabilized at a distance of 20–25 m in front of the drain line, while the northern drained region, after an initial period of recession, also stabilized at a distance of 20–25 m in front of the drain.
3. End effects appeared to extend the effective drain length by 100–200 m, particularly on the southern down-drift side of the dewatering system.

Continued tests with independent observers were not very successful. The report by the Coastal Directorate (Bruun, 1989) has the following conclusion:

1. Under mild wave conditions the coastal drain system stabilizes beach profiles and provides a wider, higher high-tide beach. The coastal drain system is useful under certain specific conditions as described.
2. The coastal drain does not stop beach or dune erosion during storms. It is in no way a substitute for artificial nourishment. Its effectiveness on an eroding shore will decrease with time.

First installation in the USA—Sailfish Point, Florida

In 1988, Coastal Stabilization, Inc. (a subsidiary to Moretrench American Corporation) installed a 180 m-long-beach dewatering system at Sailfish Point, near the southern end of Hutchinson Island, on the Atlantic coast of Florida, USA. The beach is composed of fine-grained, well-sorted sand; the most notable feature along this otherwise open Atlantic coast is the natural coastline protection provided by a rock reef located approximately 100–150 m offshore. It has been suggested that despite the presence of the reef, between 1972 and 1986 recession of the high-tide shoreline exceeded 2 m/year. It is important to note that this erosional trend is reported to have reversed and become accretionary prior to the installation of the beach drains in 1988 (Terchunian, 1989; Dean, 1989).

The dewatering system installed at Sailfish Point (referred to as "Stabeach" by Coastal Stabilization, Inc.) consisted of a 0.3–0.5 m diameter PVC pipe buried at an elevation of approximately −2.5 m, providing a collection drain for numerous 1.5 m long horizontal well points attached at approximately 3 m intervals along its length. Collected water traveled via a suction pipe to a pumping station located landward of the dune line (Lenz, 1994). An independent report prepared for Coastal Stabilization, Inc., by Dean (1989) after 11 months of monitoring concluded that it was not possible to separate natural beach changes from those induced by the dewatering system; but a second report by the same author (Dean, 1990) after approximately 20 months of operation provided the first independent evidence that the dewatering system was having a positive effect on the beach. From a straightforward analysis of time series of sand volumes and the position of the high-tide shoreline, Dean concluded that, while it remained difficult to separate natural beach changes and those caused by water table lowering:

1. The dewatering system appeared to have resulted in local moderate accretion, in contrast to a general erosional trend to the north and a relatively small accretionary trend to the south.
2. The system appeared to result in a considerably more stable high-tide shoreline relative to both control segments north and south.

Recent installations

Some beach drains have been installed in the United Kingdom, United States, and Denmark. The results, however, were generally nonconclusive (Turner and Leatherman, 1997).

Conclusions

This brief report provides an overview of the history and current status of beach dewatering as a potential practical alternative to more traditional methods of coastal stabilization. The specific findings are as follows:

1. A link between the elevation of coastal groundwater and erosion or accretion trends at the shore has been reported in the coastal literature for over 50 years. The origins of this work can be traced to parallel but initially unrelated strands of beach research in the 1940s that were simultaneously providing new insight into the role of swash infiltration in determining erosion and accretion at the beach face, and the dynamics of beach groundwater in controlling the saturation characteristics of the foreshore.

2. In the mid-1970s, the first laboratory investigations were reported that examined the artificial lowering of beach groundwater as a method to promote shore accretion and stability, and the results proved encouraging. By the late 1970s the results of the first field investigation of this approach were reported, but the results of this work were less conclusive.

3. Commercial interest in beach dewatering as a practical alternative to more traditional methods of shore stabilization was initiated in the early 1980s as the result of an unrelated engineering project on the Danish coast. The decreasing efficiency of a buried seawater filtration system was observed to correspond to the rapid build up of sediment in front of intake pipes.

4. A full-scale test of the dewatering concept on the open North Sea coast of Denmark was undertaken during the period 1985–91. Initial results proved encouraging, and for the first two and half years of the system's operation published data suggest that, relative to untreated control sites, the dewatered beach stabilized and showed a positive trend of shore accretion. During the ensuing four years, the published

monitoring results were less conclusive, and it was interpreted that the beach drain was having no discernible positive effect on enhancing net beach width. Relative to the eroding control sections of beach, it was tentatively concluded that the dewatering system reduced the rate at which the coastline was eroding.

New dewatering sites should at present be regarded as experimental, rather than a proven solution to erosion management. The main problem with the drain is that it does not produce sand. It only takes some sand away from adjoining beaches. Compared to artificial nourishment the drain is uneconomical. Coastal researchers must investigate further both the dynamics of coastal groundwater determining the time-varying saturation characteristics of the beach face; and the modification of sediment transport mechanisms at the beach face induced by groundwater infiltration and seepage. Only when a physical understanding of these processes is gained, will the mechanisms determining the success or failure of the dewatering concept be understood (Turner and Leatherman, 1997).

BEACH EROSION

Introduction

Beaches are loose accumulations of sand, gravel, or a mixture of the two that bound an estimated 30% of the world's coasts (Bird, 1996). Because they consist of more or less loosely packed noncohesive sediments, beaches act as buffers that absorb, reflect, and dissipate energy delivered to the shore by waves. By doing so, they shelter areas behind the beach, especially during storms, from wave attack and flooding. Such back-beach zones may be cliffs, dunes, or low-lying marshes and lagoons. On many coasts of the world, the beaches and these associated back-beach environments have been taken up by development (Nordstrom, 1994). A lot of this development has occurred over the last three to four decades, thriving on the worldwide growth in domestic and international tourism, and largely favored by the diversification of beach recreational activities. The boom in coastal development, especially on low-lying sandy coasts, has been matched by an increasing awareness that the beaches that form the foundations of prosperity of many communities are eroding in many places. An estimated more than 70% of the world's beaches are now eroding (Bird, 1996). Lack of foresight in construction and development planning has, in many cases, led to massive and irreversible urbanization of the coast that renders many communities vulnerable to the insidious effects of beach erosion. Erosion impairs the capacity of a beach to act as a buffer against storms. This means that beach erosion may have serious negative repercussions for low-lying island states, for shorefront communities, and for beach-based leisure activities on which depend many jobs and from which many coastal communities draw income.

Beach studies started mainly in connection with military activities, notably during the preparation of the World War II landings on the French coast. Since then, they have increased dramatically, especially over the last three decades, as beach erosion has become a critical issue in coastal zone management in many countries. Evaluating the implications of beach erosion necessitates a clear definition of what beach erosion is and how it is measured, notwithstanding the fact that the physical processes involved in the dynamics of erosion are still not well understood.

Perception of beach erosion and measurement of erosion rates

Proper coastal management requires a clear definition of beach erosion and accurate quantification of erosion rates. Although beach erosion has received great attention from coastal scientists, government agencies, local authorities, and beachfront owners, its perception and exact definition are controversial issues, mainly as a result of the diverse interests of the different parties involved in beaches and/or their management (Esteves and Finkl, 1998). This statement, made in reference to beaches in Florida, holds true for beaches in many developed countries. Beach erosion is a process whereby a beach loses its sediment, resulting in a depletion of its sediment budget. This process occurs where the beach can no longer balance energy produced by waves and by water piling up against it, leading to net sediment loss and lowering and retreat of the beach. Basically therefore, beach erosion may be viewed as resulting from an imbalance between, on the one hand, the energy inputs and, on the other, the resistance of the beach bed and sediment liable to be mobilized by the fluid forces. The erosion process itself is thus a way of eventually reestablishing balance through dissipation of energy. However, this is a scientific and objective view of beach erosion. Perception of the problem generally tends to be associated with developed shores in urban areas mainly where sandy beaches are important to the economy (Finkl and Esteves, 1998). As these authors have shown for the beaches of Florida, which account for about 25% of the total sandy shores in the United States, this bias of the erosion perception is shown in discrepancies in the delimitation of both erosion problem areas (EPA) and critically eroded areas (CEA) among different surveys. There are no common standards for objectively classifying beach erosion. Each party perceives beach erosion in its own way. Furthermore, beach erosion is not commonly perceived as a problem on undeveloped shores. In an effort at objective standardization, Esteves and Finkl (1998) and Finkl and Esteves (1998) propose a useful, comprehensive beach erosion classificatory scheme covering developed and undeveloped coasts.

There are also no common standards for quantifying rates of beach change (Moore, 2000) and for determining high-tide shoreline position (Galgano *et al*., 1998; Morton and Speed, 1998; Douglas and Crowell, 2000). Beach erosion is generally quantified through some statistical treatment of retreat rates and volumetric losses (e.g., Leatherman, 1983). The input data comes either from field surveys that have gained in accuracy with the advent of electronic stations and differential global positioning systems (GPS), or from numerically rectified aerial photographs, maps, and land-use documents. Other new methods include digital video imagery near ground level or from low-flying aircraft, and airborne scanning laser altimetry or light detection and ranging (LIDAR) (Mason *et al*., 2000; see also entry on *Mapping Beaches and Coastal Terrain*). Beach erosion rates and volumetric losses may also be estimated from the depletion of beach nourishment material where such nourishment is regularly carried out (e.g., Finkl, 1996, see entry on *Beach Nourishment*).

Rates of beach erosion may range from a net moderate loss of less than a meter a year to several meters following just one storm event. Such rates may also vary alongshore, decreasing from a maximum in "hot spots" or high-tide shoreline areas subject to the most severe perturbations, to "cold spots" where the effects of such perturbations are no longer felt and the high-tide shoreline is stable. Extreme rates of beach retreat in isolated "hot spots" along the southeast barrier-island coast of the United States approach 4 m yr^{-1}, causing substantial loss of land and oceanfront property (Finkl, 1993). Reliable determination of rates of beach retreat is important in coastal planning, especially as regards construction setbacks.

Beach erosion processes within the profile

The beach is a three-dimensional (3-D) sediment body that extends alongshore from the upper limits of wave run-up to the outer limits of wave action, the so-called closure depth, in the nearshore zone. However, while the upper limits may be relatively easy to identify using geomorphic features (Morton and Speed, 1998), the offshore limits are not, for obvious reasons. Beach erosion may be a short-term (order of hours to seasons) process that reflects adjustment to wave energy changes, or a longer-term (order of years) one that reflects an increasingly deficient beach sediment budget (Figure B17). On sandy beaches, short-term changes involving erosion are commonly part of a so-called morphodynamic cycle of adjustment of the beach profile to seasonal or nonseasonal changes in wave energy (Short, 1999). Seasonal changes commonly correspond to the classic winter profile flattened by storms and the summer profile that accretes under fair weather conditions. Beach profile adjustment generally leads to better absorption of the nearshore and incident wave energy, leading over a more or less long period of time (hours to months), to an equilibrium situation and shoreline stability. The period of adjustment depends on the wave energy inputs, the beach morphology, and the sediment volume. Rapid beach recovery is quite common, but recovery may sometimes take several years following major storms (Morton *et al*., 1994; Galgano *et al*., 1998). Sandy beach morphology and sediment volume are intricately related, defining profiles that are either short, steep, and reflective, commonly associated with coarse sediment, or wide, flat, and dissipative, commonly with fine sand (see entries on *Reflective Beaches* and *Dissipative Beaches*). In the former, much of the sand is locked up in the intertidal beach, forming especially a voluminous subaerial beach sometimes comprising an upper beach terrace called a berm. In the latter, much of the sand is stored in shallow intertidal to subtidal bars. High-energy waves impinging on steep reflective sandy beaches result in the fastest response times, resulting in erosion of the upper beach and berm, and seaward removal of the sand to form barred dissipative beaches. In such situations, erosion of the upper beach is therefore compensated by accumulation on the lower beach, without there being necessarily a net loss of sediment. However, coastal managers are sensitive to changes in subaerial beach volume, so that such short-term upper beach and berm erosion, especially where severe, may raise anxiety.

Beaches characterized dominantly by gravel differ in their behavior. Such coarse-grained beaches have generally steep, narrow reflective profiles that are commonly inert and unresponsive, to a certain degree, to increases in wave energy. This is either a result of the spatial organization of the constituent clasts and/or because of the capacity of these coarse-grained beaches to absorb wave energy through high percolation rates (Carter, 1988; Forbes *et al*., 1995; Orford *et al*., 1996). Macrotidal beaches, found in areas with large tidal ranges (>4 m at spring tides), also commonly show slow or moderate response to high-energy events, compared to their more common microtidal counterparts, because of their wide, dissipative profiles and the rapidity of migration of the wave domains that goes with the important tidal excursion.

On any sandy or gravelly beach profile, short-term morphodynamic changes may be embedded in longer-term changes involving net sediments gains or losses, the latter being synonymous with overall beach erosion throughout the profile. Whatever its origins, a net loss of beach sediment results in durable changes in beach morphology as the beach seeks to adjust to this situation of sediment deficit. Durable erosion generally results in a permanently scarped beach profile exhibiting an upper beach scarp (Figure B18). In some cases, erosion can lead

Figure B17 The erosion and retreat of a gravel beach in Picardy, France, has left a World War II blockhouse stranded on the beach.

Figure B18 Durable beach erosion is commonly manifested by an upper beach scarp. The erosion here, which threatens coastal settlements and has led to inland relocations of several villages and an international highway, has occurred downdrift of the port of Cotonou in Benin, West Africa on a coast subject to strong longshore drift.

to the total disappearance of a beach. The sediment lost accumulates elsewhere, either further alongshore, in other beaches, in estuarine and lagoonal sinks, or in offshore sinks.

In spite of a considerable amount of beach research over the past three decades, the sediment transport processes operating on beaches and involved in beach erosion are still poorly known (Butt and Russell, 2000; also see entries on *Beach Processes* and *Surf Zone Processes*). "Normal" waves and wave shoaling processes in the nearshore zone lead to net shoreward flows that may result in sediment drifting alongshore or from offshore working its way toward the beach. In essentially reflective beach systems, these shoreward flows are balanced by gravity-driven seaward return flows down the beach face. The net sediment budget of the beach would then depend on its ability to diminish the seaward return flow volume through processes such as infiltration and grain size and bedform adaptations to flow strength. These processes depend on beach slope and grain size, both interrelated, and on the water table on the beach. Low, dry season water tables on microtidal beaches composed of medium to coarse sand in West Africa favor exceptionally steep beach slopes (up to 18°) that result from berm buildup through sand deposition by swash infiltration. Higher rainy season water tables have the opposite effect of encouraging little infiltration, thus favoring sediment transport down the beach. Erosion processes on the more complicated dissipative beaches depend on the complex interplay of various modes of fluid motion near the beach (Komar, 1998). These include incident gravity waves, infragravity or low-frequency waves generated by transfer of energy from the former, alternations of high and low waves or wave groupiness, wave-induced currents, tidal currents, currents due to wind forcing, wave–current interactions, and patterns of energy concentration related to the way these various fluid forces interact with the morphology. On a few of the world's coasts subject to strong, sustained winds, eolian processes may also contribute in removing sand from the beach.

Gravel beaches show specific behavioral modes because of their coarse grain sizes. The dynamics of these beaches are fully discussed elsewhere (Forbes *et al*., 1995; Orford *et al*., 1996; see entry on *Gravel Barriers*). On sandy beaches subject to episodic high-energy erosive events, a variety of related meteorological and hydrodynamic factors combine to enhance beach stripping. These are setup of the water level close to the beach, due to waves, onshore wind forcing, and sometimes the direct exposure of the beach to the low pressure system that generates the storm waves, and durable saturation of the beach face through both rainfalls that commonly accompany stormy weather and enhanced swash run-up. Water pileup on the seaward-sloping beach must be balanced by seaward return flows, or in low-lying sand barrier systems, by overwash. In these high-energy events, liquefaction and removal of the beach sand may be accompanied by deposition of these sediments in offshore areas where the energy of seaward flows peters out or is balanced by shoreward-directed energy. The beach profile retreat is also a short-term mechanism of creating accommodation space for the temporary water pileup. The sediment transported seaward may initially travel via major rip current pathways generated by incident and infragravity waves. Sand may flow alongshore from these pathways, because of the commonly oblique incidence of waves and wind setup, feeding strong longshore currents. Subsequently, as larger waves and strong winds lead to more pileup of water on the beach, the seaward return flows may no longer be simply canalized in rip channels and mass balancing seaward flows may occur, resulting in generalized beach stripping and offshore sediment loss. The intensity of beach erosion depends on various factors such as the wave energy level, the antecedent beach morphology, orientation of winds relative to the coast, their strength, beach grain size, tidal range and tidal state, and the duration of high-energy conditions.

Longshore manifestations of beach erosion

A beach may comprise one or several sediment cells with bounding limits to longshore drift. Swash and drift-aligned beaches (see entry on *Drift and Swash Alignment*), respectively, designate beaches associated with weak and strong rates of longshore drift (Davies, 1980). In many cases of beach erosion, the process is a subtle, insidious one that does not require the high-energy events described above (although these may spectacularly enhance erosion rates) other than seasonal increases in wave energy to which the beach is generally well adapted. This is particularly the case on coasts subject to strong longshore drift rates on which depend the overall stability of the beach. Erosion functions essentially where major engineering structures block the sediment load drifting alongshore. Continuity of sediment transport downdrift by the longshore current is assured by beach erosion. The strongest drift rates, sometimes exceeding 1 million $m^3 a^{-1}$ of sand or gravel, are found where large swell waves impinge with marked obliquity on long, open beaches, as on the Gulf of Guinea coast in West Africa, in New Zealand, and the Kerala coast of India.

The longshore manifestations of beach erosion have received attention in the literature, both in terms of the plan shape of freestanding beaches (as opposed to short, headland-bound bay beaches) and of the effects of major engineering structures. The plan shape of freestanding beaches may change rapidly in response to sediment depletion. These changes basically reflect sediment cell divisions (Carter, 1988) that may also involve switches from drift to swash alignment, in an attempt by the beach to adjust to sediment deficit by diminishing longshore transport. Examples have been described from both sandy (e.g., Anthony, 1991) and gravelly beaches (e.g., Forbes *et al*., 1995; Orford *et al*., 1996; Anthony and Dolique, 2001). The large-scale changes in beach plan shape are also accompanied by beach textural and profile reorganizations. Downdrift of jetties, a major cause of beach erosion (see next section), the high-tide shoreline morphology in plan commonly defines a log-spiral curve (see entry on *Headland Bay Beach*) or a half-heart bay (Silvester and Hsu, 1993) that may extend several kilometers. This shape illustrates the more severe retreat that affects the beach just downdrift of such structures. Continuity of sediment transport by the longshore current after the jetty is assured by sometimes rapid and significant beach erosion. Erosion diminishes downdrift of this "hot spot" as the longshore current becomes increasingly charged with sediment, leading to a more linear high-tide shoreline. At some distance downdrift, erosion becomes nil and the high-tide shoreline may even show advance from the accumulation of sediment eroded from the beach updrift. These longshore changes are sometimes manifested by a fast "erosion front" and a slow "erosion front" separated by a salient, or "bump," that may exacerbate erosion downdrift (Bruun, 1995). The existence of such two fronts along any eroding beach probably reflects two sediment cells on either side of a central downdrift accumulation terminus fed by beach erosion within the more updrift cell. The accumulation "bump," or salient, influences wave incidence angles in such a way as to minimize drift and capture sediment, thus aggravating erosion within the following longshore cell, as examples from gravel barrier beaches have shown (e.g., Orford *et al*., 1996; Anthony and Dolique, 2001). According to Bruun (1995), the distance of downdrift migration of erosion fronts on the Atlantic shoreline of Florida is of the order of 30–40 km, the fronts migrating essentially from inlet to inlet. This distance is similar to that downdrift of the seaport of Lomé, in West Africa (Anthony and Blivi, 1999).

On some beaches, especially headland-bound bay beaches, it is not uncommon for seasonal or longer-term changes in the predominant direction of wave approach to induce changes in longshore drift. This process results in "beach rotation" (Short, 1999), which is the periodic lateral movement of sand towards alternating ends of the embayed beach. It results in erosion at one end of the beach, while the other accretes. In rare cases, beach rotation is due to short- to medium-term (order of a few years) changes in nearshore bathymetry that affect wave refraction and dissipation patterns. The massive mud banks delivered by the Amazon river to the muddy coast of South America migrate westward toward the Orinoco delta, inducing changes in incident wave energy levels by strongly modulating wave refraction and diffraction patterns. These generate lateral movement of sand in embayed beaches between bedrock headlands in Cayenne, French Guiana, resulting in alternations in erosion (Figure B19) and accretion over time, without net sediment loss (other than through illicit sand extraction). Similar effects on beaches elsewhere may be generated by changing sand bank configurations offshore, as in the case of the sandy beaches of northern France bounding the English Channel and the southern North Sea.

The causes of beach erosion

The sediment that accumulates on the shore to form a beach may come from various sources. Any poorly consolidated material on which waves and currents impinge may be a source. Such material may be an initial coastal and nearshore deposit of diverse origin such as glacial till or fluvial sediments, or may be delivered to the shore through landslides or by volcanoes. These sources are usually cut into coastal cliffs and underwater slopes that recede as they deliver sediments to the shore for beach construction. Dunes may also deliver sand to the beach but the beach and dunes, especially those immediately bounding the beach, should be considered as an interrelated system with sand interchanges. Some infilled estuaries and many sand- or gravel-rich deltas also supply sediment to beaches, especially at times of high river discharge.

Any natural or human action that affects the supply capacity of a given source and the cross-shore and longshore sediment transport processes on beaches may result in erosion. In many cases, especially on long open beaches, several factors, whose specific roles are difficult to

Figure B19 An example of a beach in Cayenne, French Guiana, affected by periodic rotation due to mudbanks migrating alongshore. The erosion presently affecting this end of the beach (concomitant with accretion at the opposite end) has been aggravated by illicit sand extraction. Note the massive rock protection on the upper beach.

Figure B20 Beach accumulation and erosion, respectively, updrift and downdrift of a jetty in Upper Normandy, France. Erosion on this coast has been exacerbated by the stabilization of cliffs that hitherto supplied flint clasts to the beaches.

disentangle, may jointly cause beach erosion. The most readily discernible causes of beach erosion are where identified human actions and activities perturb the beach sediment budget and the morphodynamic functioning of the beach. This cause of beach erosion dramatically developed in the 20th century with the multiplication of dams across rivers and large-scale urbanization of the coastal zone worldwide. On many coasts of the world, the construction of dams has, over the long run, led to coastal sediment starvation and beach erosion. The effects of artificial structures on the shore (see *Shore Protection Structures*), and especially beaches, have received considerable attention in the literature (Walker, 1988; Silvester and Hsu, 1993; Bird, 1996; Charlier and De Meyer, 1998). One important cause of beach erosion worldwide is the construction of jetties and ports (Figure B20). In many coastal communities, as along the eastern United States, the lagoons behind barrier islands are important economic waterways whose inlets need to be deepened by dredging and kept open permanently by groins and breakwaters. These impede the longshore drift of sand that is vital in nourishing beaches downdrift. Esteves and Finkl (1998) estimate that 90% of beach erosion in southeast Florida has been caused by human action, mostly the construction of deepened inlets with protective jetties. Deepwater ports constructed on open beach coasts subject to strong longshore drift have similar negative effects, as in the Bight of Benin in West Africa (Anthony and Blivi, 1999). Here, national seaports in Togo, Benin, and Nigeria have resulted in dramatic beach erosion downdrift of the port breakwaters, and in equally spectacular beach accretion updrift. The continual beach erosion on this coast (Figure B18) has led to successive inland relocations of coastal communities and of the major international highway linking the three countries, at great cost to their already beleaguered economies.

Another source of perturbation of beach sediment budgets and a cause of beach erosion is coastal urbanization, which involves the development of urban fronts with high-rise condominiums and hotels on the upper beach. Some of the best examples include the US Atlantic and Gulf coasts (Nordstrom, 1994; Esteves and Finkl, 1998), and the Mediterranean rivieras (Anthony, 1997). In many cases, related dune systems have been flattened or severely degraded, and this has had a dramatic effect on beach stability. Dunes tend to be overlooked as the "savings account" of the shore while the beaches act basically as a "checking account." The dunes store important volumes of sand that help in balancing the beach budget. In the past, uncontrolled shorefront urbanization has commonly entailed narrowing of many beaches, diminishing in time their wave-energy buffering capacity, and leading to beach erosion (Figure B21). Beachfront urbanization also often requires defense structures, notably walls and revetments emplaced on the upper beach. Depending on their design, these structures may act as static barriers that reflect wave energy offshore, thus aggravating beach erosion, although some doubt has been recently cast on this negative effect of sea walls (Kraus and McDougal, 1996). In the past, urbanization and the development of road and rail networks has sometimes involved the direct quarrying of sand or gravel from beaches with fragile sediment budgets. This practice is still frequent in developing countries that lack awareness of the environmental consequences of such beach sediment depletion.

To stabilize already eroding beaches, groins are sometimes built across the beach with the aim of trapping sediment drifting past. Breakwaters are also sometimes built off the beach to dissipate some of the wave energy that erodes the beach. In playing an efficient role sometimes in alleviating beach erosion, these structures may be instrumental in simply transferring the erosion problem further downdrift, often to the detriment of another community. It is not uncommon to see groin fields sprouting downdrift, increasing in numbers as the problem goes from one community to the next. The gravel barrier beach in Upper Normandy (Figure B20) and Picardy, France, is a clear illustration of this downdrift "march" of erosion and of the attendant groin field. In Picardy, a groin field emplaced to stabilize an eroding gravel beach grew from 6 groins in 1976 to 96 groins in 2000 over a distance of 10 km (Anthony and Dolique, 2001). The initial erosion of this beach started with the construction of several jetties updrift in the 19th and 20th centuries, and was aggravated by the artificial consolidation and stabilization of several sectors of cliffs that hitherto liberated gravel flint clasts to the beach longshore drift cell (Figure B20). This practice of cliff stabilization has, in some cases like this one, led to beach sediment starvation and erosion.

Natural sediment depletion is considered as a major cause of worldwide beach erosion (Bird, 1996). On many of the world's coasts, especially in areas where sea level over the past 5–6,000 years has been relatively stable, the sand forming the beaches was derived from sediments on the inner continental shelf. These drowned nearshore deposits have been reworked by waves and driven onshore to form successive beach ridges and dunes sometimes several kilometers wide, as along large stretches of the Australian, West African, and Brazilian coasts.

This process, called progradation, has stopped in most areas as the nearshore sediment supply has petered out. The beaches bounding these prograded coasts are sensitive to any long-term changes in wave energy, resulting, for instance, from greater storminess or sea-level rise. Although exhaustion of nearshore sediment stocks is commonly invoked as a cause of beach erosion, it is hard to substantiate because of the lack of records of long-term beach and nearshore profile changes.

Beaches, as mentioned earlier, may show short-term changes in profile in response to storms and fair weather conditions. Apart from the various causes of sediment depletion evoked above, changes in the state of the sea also lead to durable beach erosion. These changes include greater storminess, short-term variations in sea level related to major changes in sea surface temperatures such as, those associated with El Nino events, and secular sea-level rise, commonly imputed to global warming. Changes in offshore wave energy are due to storms, such as the northeasters in the eastern United States, and cyclones, or may reflect more subtle increases in wave energy due to greater storminess and sea-level rise. Exceptional waves generated by submarine landslides or earthquakes may also lead to significant beach erosion. These events generate destructive high-energy waves that remove the beach sediments offshore. The seaward return flows may lead to losses of sand beyond the offshore limits of the beach profile, such that the sand cannot be returned to the beach during the following fair-weather wave conditions. On beaches bounding low-lying coasts, permanent losses of sediment may also occur inland as waves wash over the shore. Greater storminess implies more frequent episodes of higher incident wave energy often accompanied by strong wind setup of water level inshore. Many beaches do not have the available sediment stocks to adapt to such increases in wave power and to the currents resulting from wind and wave forcing. Sea-level rise, either on a short-term basis, due to short-term events such as El Nino, or of a secular nature due to global warming, would similarly favor wave energy impingement higher up the beach face (see entry on *Sea-Level Rise, Effect*). New sediment commonly does not move in from alongshore to balance the increase in wave energy, and the beach erodes as its sediment stocks are transferred seaward. Depending on the wave energy regime and the rate of sea-level rise, such sediment may be permanently trapped offshore as the base of wave action moves upward through sea-level rise. This pattern of beach erosion resulting from sea-level rise has been extensively debated in terms of what has become known as the Bruun rule (e.g., SCOR Working Group, 1991; Thieler *et al*., 2000).

Managing beach erosion

Good beach management requires both accurate bookkeeping on rates and patterns of beach change and implementation of the right strategies in the face of erosion. Beaches are a multiresource asset in many ways, involving huge sums of money in developed economies, both in terms of revenue and for design and implementation of management policies. As a result, the number of parties involved in beach management may be considerable, ranging from state legislators and engineering bodies, through recreational and tourist agencies, to scientists, beachfront home owners individually or as associations, and environmental and ecological pressure groups. Beaches are, as such, objects of conflicting interests. In many developed economies, beach erosion has become the fundamental coastal zone management problem, and a national issue in several countries bordered by long stretches of densely developed low-lying shores, such as the Netherlands and the United States. It has also become a cause of major concern for low-lying island states subject to sea-level rise (Leatherman, 1997). In the face of beach erosion, the management options are very few indeed. These include the determination of development setback lines in order to accommodate future erosion without endangering constructions. In the absence of precise determination of beach erosion rates, this strategy may fail, as on the Bight of Benin coast in West Africa (Figure B18). A second strategy is that of letting erosion take its course, generally in undeveloped areas where the process does not constitute a hazard. A third strategy is that of fighting beach erosion at all cost, especially where vital national, economic, or military interests are at stake. The finest example of such a policy is that of the Netherlands (Hillen and Roelse, 1995). On some developed shores such as parts of south Florida, the value of beach real estate and the revenue from beaches are such that the high-tide shoreline position has to be maintained, generally through the implementation of costly solutions such as efficient bypassing of inlets (see entry on *Bypassing at Littoral Drift Barriers*) and, especially, regular beach nourishment (Finkl, 1996). These are often, and increasingly, the only efficient ways of restoring the beach sediment volume. These "soft engineering" techniques have been discussed in numerous papers in scientific journals, especially the *Journal of Coastal Research* and *Shore and Beach*, as well as in regular newspaper commentaries in many countries. A specific comment needs to be made here on engineering practice in managing beach erosion. In many countries, including the United States, beach erosion has been managed using various assumed empirical relationships. Some of these relationships have been reviewed recently by Thieler *et al*. (2000) who draw attention to their oversimplified assumptions relative to the complex reality of beaches. In Europe, engineering practice in some countries, notably the Netherlands, has treated coastal management within a geomorphic systems approach, rather than simply in terms of deterministic engineering models. While the dependence on engineering models is still well entrenched in France, the tendency in Britain has shifted in recent years toward considering beach and, more generally, shore erosion management, in terms of a geomorphic systems approach (Hooke, 1999) that integrates local experience (Brunsden and Moore, 1999). The complexity of beach erosion and the large number of parties involved in its management should call for a sensible and balanced mix of science with a systems approach, engineering expertise, past and present experiences, and the specificities of the local context in which erosion occurs.

Many developed countries are today faced with minor to critical beach erosion problems, largely because of lack of foresight in coastal development patterns. While they may have the resources to combat beach erosion, the same is not true for developing countries which cannot divert much needed money toward beach management, often considered as a "low priority" area. These countries are increasingly subject to the pressures of an often rapid pace of economic development, and of beach-based tourist activities, while facing the threats of sea-level rise from global warming. It is perhaps reassuring that because of the still moderate level of coastal development in many of these countries, they have the opportunity of avoiding the mistakes made in the past by the developed countries by planning such development in a way as to ensure sustenance of the beach resource. This opportunity can be seized through active transfer of knowledge from the developed to the developing countries.

BEACH FEATURES

Limits and formation of beach features

When discussing the types of features that can be observed along a beach, it is important to first consider the boundaries in the coastal zone that define the limits of a beach. In everyday usage and in the scientific literature, there are some differences in defining these limits, primarily with regard to the seaward limit. Recreational beach users will often consider the beach to extend no farther seaward than the shoreline, and thus limit the beach to an entirely emergent feature, having a width that varies with changing water level. Scientific usage typically extends the beach out to the maximum limit of low water regardless of the water level at any particular time. In some scientific usage, such as in the discussion of coastal sediment dynamics, the seaward limit of the beach may be considered to extend out to the breaker zone (Figure B22) well beyond the low-water shoreline. The most useful definition, and the one used here, is that the beach refers to the zone containing unconsolidated material that extends from the limit of ordinary low-water (or mean low-tide level) on its seaward side to the limit of influence by storm waves on its landward side (Figure B22) (Hunt and Groves, 1965; Baker *et al.*, 1966; Coastal Engineering Research Center, 1984).

Based on morphology, the beach is divisible into two zones. The *backshore* is the more landward and higher part of the beach and is typically a near-horizontal to gently landward-sloping surface. The backshore is not affected by the run-up of waves except during storm events, and so this is the typically dry part of the beach. The landward limit of the beach, which is the limit of influence of storm waves, generally is marked by a change in material, a change in morphology, or a change to a zone of permanent vegetation. Examples of such a landward limit include dunes, cliffs or bluffs, or even engineered structures such as bulkheads or revetments. The *foreshore*, also called the *beachface*, is the more seaward part of the beach. The foreshore has an overall seaward slope, but may include one or more ridges and troughs on its lower slope. Because the foreshore extends to the limit of ordinary low-water, at times of high-water the lower part of the foreshore is submerged.

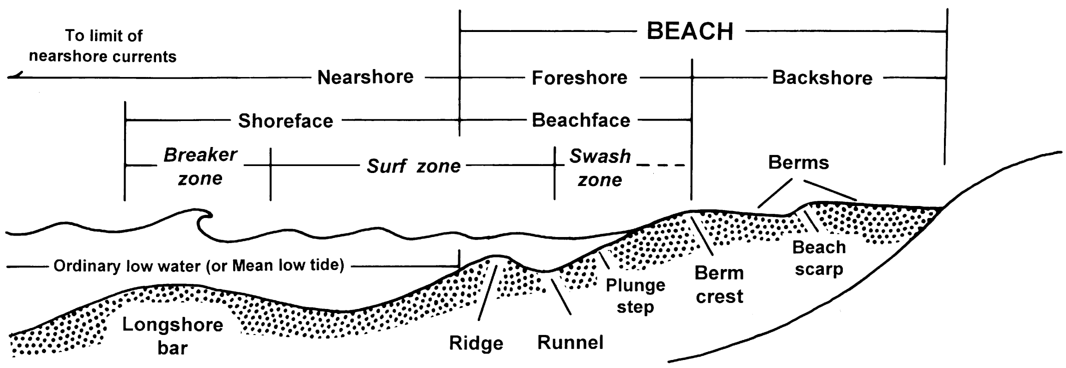

Figure B22 Generalized beach and nearshore profile showing names of major beach features and zones.

Critical in the definition of a beach is the presence of unconsolidated materials. These unconsolidated materials are what make a beach, and it is the erosion, transport, and deposition of these materials that results in beach features. Worldwide, the most common beach material is sand-size sediments composed of mineral, shell, or rock fragments. Coarser beach materials include gravel, cobbles, shingle, and even boulders. The beach will be made from whatever is locally available for the waves to rework. Along shores impacted by commercial or industrial activity, it is not uncommon to find beaches composed in part or completely of bricks, broken concrete, demolition debris, or any other material that may have been dumped along the shore and subjected to movement and redistribution by wave action.

The types of features that may occur along and across a beach vary in time, scale, and relative position. The primary agent in forming beach features is wave action (Davis, 1985). Other important agents are the rise and fall of water level, currents, wind, and ice in settings where coastal ice can form. Some beach features can form and persist indefinitely with minimal change in shape or location, but these are the exception. Because the beach is a dynamic setting, most beach features are ephemeral. Once formed, most beach features will only persist until new wave, water level, current, or wind conditions destroy them and replace them with new features.

Beach slope

Beach slope, which refers to the slope of the foreshore or beachface, deserves special mention as a beach feature because it is one of the characteristics used to distinguish different beaches. Slope is a dynamic feature that changes with changes in wave conditions as well as the gain or loss of different sediment sizes on the beach face. In general, the slope angle, measured relative to a horizontal plane, increases as the grain size increases; thus beaches composed of material such as pebbles or cobbles will tend to have a steeper beach face than ones made of sand. This slope difference relates to the greater permeability of the larger materials (Bagnold, 1940; Bascom, 1951; King, 1972). The wave run-up (or swash) can percolate downward through the interstitial spaces of the larger materials, and this minimizes the erosional influence of the run-back (or backwash). Storm conditions will flatten the beach slope as beach sediment is eroded and transported seaward. In the calmer wave conditions following the storm, beach slope recovers to a steeper slope as material is accreted to the beach.

Major beach features

Major beach features are here defined as those having large topographic expression or large areal extent. One of the beach features that can have the largest vertical expression on a beach is a *beach scarp*. Beach scarps are erosional features that occur when the slope of the beachface is lowered during storm events, and the beachface migrates landward by cutting into the backshore. The result is a near-vertical slope along the limit of this erosion (Figure B23). The height of a beach scarp may be just a few centimeters or a meter or more depending on the degree of wave action and the type of beach material. Beach scarps are commonly observed in areas where a new supply of sediment (i.e., beach nourishment) has recently been applied in an effort to replenish and build up the beach and wave action has cut into this nourishment and redistributed the sediment in the process of reestablishing an equilibrium beach profile.

Figure B23 Beach scarp resulting from recent storm erosion along a sand beach on the Illinois shore of Lake Michigan at Illinois Beach State Park. (photo by Michael Chrzastowski, Illinois State Geological Survey.)

One of the reasons that beach scarps are prominent beach features is that these near-vertical erosional features are cut into a near-horizontal area of the upper beach. This upper beach, in many cases, is a broad, near-horizontal to gently landward-sloping area called a *beach berm*, or simply a *berm* (Figure B22). Berms are depositional features formed from the wave-induced onshore accumulation of sediment. Local coastal conditions may preclude formation of a berm along some beach segments, while other beach segments may have two or more berms at different elevations. When more than one berm occurs, the lower berm(s) (sometimes called the *ordinary berm*) is a result of average or more typical waves, and the higher berm(s) (sometimes called the *storm berm*) is a result of the less frequent larger waves. A beach scarp may exist between two berms having different elevations. The seaward margin of the berm is typically defined by a rather abrupt change in slope from the near horizontal surface of the berm to the inclined surface of the beachface. The line defined by this change in slope is called the *berm crest* or *berm edge*. The berm crest is the distinguishing beach feature that divides the beach into the foreshore and backshore zones (Figure B22).

When low-water occurs, large-scale beach features are exposed that formed underwater and have a morphology influenced by waves, water-level changes, and associated currents. *Ridges and runnels* are the most common of these features. Ridges are elongate low mounds of beach material that are parallel or subparallel to the shore; runnels are the low areas or troughs that occur between the ridges and on the landward side of the shoremost ridge. A single ridge–runnel set may occur with the runnel on the landward side of the ridge or, if the lower foreshore is a broad, low-slope area, multiple sets of ridges and runnels may extend across this area. Such multiple sets of ridges and runnels form a washboard or corrugated topography across the lower beachface that contrasts with the smoother surface across the upper beachface. Another term for these features is "*ball*" referring to the ridge, and "*low*" referring to the runnel. The term "trough" is also sometimes applied to the runnel.

Ridges and runnels, when present in multiple sets, are one example of the types of repetitive patterns that can be observed in beach features. Another major beach feature with a repetitive nature is the *beach cusp*. Beach cusps are low mounds of beach material, separated by crescent-shaped troughs, occurring in a series along the shore. Yet another repetitive feature, and one of potentially large vertical scale, is the *beach ridge*. Beach ridges are depositional features, formed by the mounding of beach material by wave action, usually during storm events. Beach ridges are formed in the backshore zone, in some places at the most landward limit of wave influence, and they can extend as a nearly continuous linear feature for many kilometers along the shore. Wind transport may contribute sand to the tops of these ridges and form superimposed dunes (i.e., dune ridges). A single beach ridge may develop, persist for some time, and then be destroyed by renewed storm action. Sequential beach ridges may form through a series of depositional events and, with time, the juxtaposition of these ridges will contribute to the progradation of the coast.

A major beach feature common to barrier island beaches is the *washover fan*. During storm events, elevated water levels and large wave run-up can combine to transport large volumes of beach material across the beach to be deposited in broad, lobate accumulations on the landward margin of the beach. These deposits, called *washover fans*, essentially extend the landward limit of the beach and play an important role in the landward and upward migration of the beach during conditions of rising sea level (Kraft and Chrzastowski, 1985). On barrier island beaches, the formation of washover fans results in the burial of back-barrier marshes and filling along the barrier margin of lagoons.

Coasts that are subject to seasonal ice formation, such as the Great Lakes coasts of North America, can have various beach features that are related to the presence of coastal ice. A hummocky topography may develop along the upper foreshore as a result of sediment pushed into ridges and mounds by wave-thrusted ice. Shallow depressions may also develop across the upper foreshore where wave run-up may remove thin slabs of ice-cemented sand. Once an ice complex forms along the shore, a hummocky topography may develop in the lower foreshore by the action of grounded ice and the scour and fill by waves and currents around the edges of the ice. On the outer edge of the ice, an erosional trough may develop caused by the downward deflection of wave energy as waves impact the ice face. This trough can be a half-meter deep and 2–3 m wide (Barnes *et al*., 1994). The trough location will shift toward or away from shore as the ice margin shifts in these directions. These troughs and all other ice-related beach features are relatively short-lived. Once the ice conditions cease, any ice-induced modifications to the beach morphology are quickly eliminated by ice-free wave conditions.

Minor beach features

Minor beach features are defined here as those with minimal topographic expression or small areal extent. Although limited in height and area, some of these beach features can be visually prominent because of contrast in color, texture, or materials compared to the surrounding beach. Prime examples of such prominent, small-scale beach features are the *tidemark* which is the high-water mark left by tidal water, and *swash marks* formed along the landward limit of wave swash on the beach face. The tide mark is generally a nearly continuous wavy line defined by an accumulation of driftwood, seaweed, and other floatable debris collectively called *flotsam*, left on the beach by the previous highest tide level. Swash marks are a series of superimposed scalloped or fan-shaped patterns defined by fine sand, mica flakes, or bits of seaweed deposited along the most landward reach of the swash. Swash marks are beach features that are in a nearly continuous state of formation and destruction with each new swash event. So too are *backwash patterns* which are diagonal patterns formed on the beach by the dispersion of backwash flowing around small obstacles such as a shell or pebble. A falling tide or the lowering of water level after a storm can contribute to the formation of *rill marks* which are small, erosional furrows or channels across the beachface caused by the seaward flow of water as the water table in the beach lowers and water percolates out onto the beachface in a spring-like manner. *Air holes* may also occur on the beachface as water percolates and forces air from the pore spaces up to the surface.

Near the ridge and runnel on the lower foreshore slope, a subtle linear feature may occur called the *step* or *plunge step*. This is a subtle decline in the foreshore profile that is caused by the final plunge of waves before running up the beachface. The plunge step is best developed in settings of low tidal range and steep foreshore slope (Davis, 1985).

Because one or more of the berms of a beach are elevated above the influence of the swash, fine sand across these berms is typically dry and can be influenced by wind action. Although the berms are located on the beach, features can develop here that are common to dunes and desert settings. Sand ripples may develop, small dunes may form in wind shadows such as behind logs or other driftwood, and wind deflation areas may occur where the fine sand has been removed to lower the surface and leave a concentration of coarser particles similar to a desert pavement.

BEACH NOURISHMENT

Introduction

Beaches occur where there is sufficient sediment for wave deposition above water level along lakes, open ocean coasts, embayments, and estuaries. Beach nourishment most commonly takes place along marine beaches, which are among the most dynamic environments on earth. On a global scale, estimates of marine sandy beaches (see entry on *Sandy Coasts*) range from about 34% (170,000 km) (Hardisty, 1990) to 40% of the world's coastline (Bird, 1996). Beaches form essentially 100% of the coast of The Netherlands, 60% in Australia, and 33% in the United States (Short, 1999). Comprising a significant proportion of the world's coastline, beaches are important considerations for coastal recreation and storm protection, while others are used for residential, commercial, and industrial purposes. Although they serve as natural barriers to storm surge (*q.v.*) and waves (*q.v.*), today about 75% of the world's beaches are subject to erosion (Bird, 1985). In the United States, the percentage of eroded beachfront is somewhat greater than the world average and is estimated by some coastal researchers to approach 90% (e.g., Leatherman, 1988). During the last century, many erosion-control techniques were developed to mitigate the unwanted impacts of erosional events, especially those associated with accelerated rates of erosion in the vicinity of groins, seawalls, or jetties along developed shores. Traditionally, coastal armoring structures such as seawalls, breakwaters, and groins were relied upon to reduce wave energy approaching the shore or to catch sediment moving across or along the shore, and thus provide protection from coastline retreat. Engineering works, however, provide only partial protection and in some cases actually exacerbate the problem they were designed to cure. During the last century, beach nourishment was recognized as an environmentally friendly method of shore protection, especially along the coasts of the western world. Today, artificial beach nourishment is the method of choice for shore protection along many developed coasts with eroding beaches (Figure B24).

Despite the fact that beach nourishment has been used in many hundreds of locations under a wide variety of environmental conditions (e.g., Psuty and Moreira, 1990; Silvester and Hsu, 1993), and frequently integrated with hard structures as part of strategic shore protection efforts, there is much debate about whether the procedure is the best solution to problems of coastline retreat. Although there are many arguments against beach nourishment, artificial supply of beach-sand remains the most practical method of protecting against coastal flooding from storm surges, for advancing the shoreline seaward, and for widening recreational beaches.

Definitions, terminology, and concepts

The term *beach nourishment* came into general use after the first renourishment project in the United States at Coney Island in 1922 (Dornhelm, 1995). In engineering parlance, the terms *beach (re)nourishment*, *beach replenishment*, and *beach restoration* are often used more or less interchangeably in reference to the artificial (mechanical) placement of sand along an eroded stretch of coast where only a small beach, or no beach, previously existed. There are, however, subtle connotations in the application of each term. Sediments that accumulate along the shore in the form of beaches are naturally derived from a variety of sources such as fluvial transport in rivers to deposition of sediments in deltas, from preexisting sediments on the offshore seabed, from chemical precipitates (e.g., oolites on carbonate banks in tropical and subtropical environments), or from organisms living along the shore (e.g., shells and exoskeletons from marine organisms). When the natural sediment supply is interrupted, beaches become sediment-starved and the shoreline retreats landward due to volume loss. Efforts to artificially maintain beaches that are deprived of natural sediment supply thus attempt to proxy nature and (re)nourish the beach by mechanical placement of sand. The beach sediment is thus *replenished* by artificial means. *Beach restoration* implies an attempt to restore the beach to some desired previous condition. A nourished or *constructed beach*

A

Figure B24 a.

could be placed along a previously beach-less shore, whereas a restored beach is revitalized by the mechanical placement of sediment.

Beach nourishment projects involve placement of sand on beaches to form a *designed structure* so that an appropriate level of protection from storms is achieved. The placement of sand is commonly by methods such as dredging sand from borrow areas on the seafloor (e.g., Finkl *et al*., 1997), bypassing sand around deepwater inlets or other obstructions (e.g., groins) along the coast that interrupt the littoral drift, or overland delivery of sand from inland quarries to the coast. Although pumping of sand from offshore is the most widespread method of application, due to the large volumes of sediment that are required for most projects, other developments feature placement of sand by trucking or barging from quarries or construction sites, as well as removal of sand from dunes, or relocation of sediment on the berm via *beach scraping* (e.g., Bird, 1990; Healy *et al*., 1990; McLellan, 1990; Verhagen, 1996). It is now known, however, that removal of sand from dunes is not an appropriate option for sand supply because dune and beach sediment budgets are inextricably interlinked (Psuty, 1988). Although most beach nourishment projects deal with sand-sized particles on low to moderate energy coasts, shore protection efforts are also undertaken in very high-energy environments where gravel beaches are featured (e.g., Zenkovich and Schwartz, 1987; Peshkov, 1993).

Beach nourishment, which entails the construction of new beaches where none existed before or restoration of degraded beaches, usually takes place on developed shores. Along undeveloped shores, beaches provide natural habitat (e.g., nesting grounds for sea turtles and shorebirds) but on developed shores beaches additionally protect coastal infrastructure from storms and are important recreational sites for a globally expanding tourist industry. When beaches are degraded by decreased width and lowering of berms (see entry on *Beach Features*), many communities choose to replace lost sediment by pumping beach-quality sand from offshore to selected renourishment sites onshore.

Arising from reviews of replenishment activities in the United States, a new terminology was developed to describe the ruggedness or persistence of sand placed along the shore to form artificial beaches. Beach durability defines how well the beach performed under a variety of conditions. The definition *of beach durability* by Leonard *et al*. (1990a) states that "... the time between placement and loss of at least 50% of

B

Figure B24 b.

the fill volume ...” represents the half-life of a beachfill. The identification of *profile evolution*, performance of the beachfill after placement, is an important consideration of durability and longevity.

Historical background to the deployment of beach nourishment for shore protection

The beach at Coney Island, New York, was the first to benefit from a concerted effort at beach nourishment when, in 1922, more than $1 \times 10^6\ m^3$ of material were dredged from New York Harbor and transported to Coney Island (Hall, 1953; Dornhelm, 1995). Based on the apparent success of this new shore-protection measure, there soon followed a number of other projects along eroding shores elsewhere in New York and along coastlines in New Jersey and southern California. As in the case of Coney Island, beachfills in these early artificial renourishment projects were dredged from sediments in harbors and ship channels. In 1939, Waikiki Beach, Hawaii, was artificially nourished as a recreational beach.

Some other early beach nourishment projects included efforts in Africa and Europe. The construction of jetties for the Durban, South Africa, harbor entrance in 1850 initiated erosion of an adjacent downdrift beach. Groins were built along the shore but they did not stop the aggressive beach erosion. Based on the recommendations of a Belgian engineer, additional long, low groins, in combination with sand bypassing, were added. This was the first attempt at *beach stabilization* using renourishment techniques in South Africa (Swart, 1996). Around 1850, seawalls and groins were deployed along the North Sea coast of Norderney in an effort to stabilize this eroding German barrier island. Although these engineering structures prevented dune erosion, they did not stop the loss of sediments from the beach. In an attempt to alleviate problems associated with coastline retreat due to beach erosion, the first large-scale beach nourishment project in Europe was initiated on Norderney in 1951. By 1989 the beach had been renourished an additional six times (Kunz, 1993).

Beach nourishment projects have been carried out in many other counties including Australia, Belgium, Brazil, Cuba, Denmark, France, Great Britain, Japan, New Zealand, Portugal, Russia (see discussion in

C

Figure B24 c. Beach renourishment on the Gulf Coast of western Florida. (A) Renourishment on Longboat Key, west-central Florida coast near Sarasota showing an eroded beach partly protected by rock revetments and seawalls. In the central foreground there is no beach at high tide. Placement of beachfill is advancing from north to south, as shown in the top of the photo. (B) The restored beach, now 100 m wide, provides a degree of protection from storm surge while providing a much enlarged recreational beach area. (C) Small coastal suction, cutterhead dredger obtaining sand from an offshore borrow near Captiva Key, southwestern Florida. Beach-quality sand is pumped ashore in a slurry via a floating pipeline. About 75% of the renourished beaches on the Florida west coast have a half-life longer than 5 years (Dixon and Pilkey, 1991) (photos: Courtesy of Coastal Planning and Engineering, Inc., Boca Raton, FL).

Walker and Finkl, 2002). Even though the basic goal of beach nourishment is to elevate the beach and advance the shoreline in order to realize all of the consequent benefits of multiple use but especially increased storm protection, the techniques of sand transfer to the shore and design parameters differ among national approaches. In the United States, the State of Florida has a long and distinguished record of beach nourishment along the southeast coast that involves such notable achievements as: (1) the first sand bypassing weir jetty in the world (Hillsboro Inlet, Broward County), (2) the longest continuously operating fixed sand bypass plant (South Lake Worth Inlet, Palm Beach County) in the world, (3) longest half-life of any renourished beach in the United States (Miami Beach, Miami-Dade County), and (4) the first successful groin-aragonite beachfill project in the United States (Fischer Island, Miami-Dade County) (Finkl, 1993; Balsillie, 1996).

Needs for beach nourishment

Although beach erosion (see entry on *Erosion Processes*) is common along most coastlines, it is often difficult to recognize in the field unless there are obvious indications of sediment removal. The development of beach scarps in the berm, dune breaches with overwash, presence of tree stumps or marsh muds on the beachface, and location or damage of buildings precariously close to uprush levels are all signs that beaches are moving landward due to sediment loss. Young *et al*. (1996) describe these features as *geoindicators* that are helpful for evaluating coastline change along beaches. Such indications of beach erosion are important parameters for estimating the sensitivity and extent of the beach-erosion problem and remediation. The removal of beach materials is by wave action, tidal or littoral currents, or wind. Ranges of countermeasures provide protection from beach erosion, foremost among them during the last quarter of the 20th century, being *artificial nourishment* (i.e., the mechanical placement of sand on the beach).

Beach protection measures are necessary because beaches are important natural resources that support multipurpose activities. When well maintained, beaches provide storm surge protection, flood control, recreational activities, and habitat for numerous species of plants and animals (Wiegel, 1988). Lack of proper coastal maintenance may allow beach erosion to reduce dunes and other natural upland protection, increase loss of natural habitats, degrade a major source of tourist revenue, and shrink the overall economy (Strong, 1994; Finkl, 1996). Beaches thus need to be protected because they reduce vulnerability to coastal development in high-velocity areas (see entry on *Global Vulnerability Analysis*).

Although beaches provide a measure of protection to the shore from damage by coastal storms and hurricanes (typhoons and tropical cyclones), their effectiveness as natural barriers against surge flooding depends on their size and shape and on the duration and severity of storms. Beaches are also highly valued as recreational resources that contribute to the economic well-being of many coastal regions in the world. The trend of increasing beachfront development since World War II has resulted in the replacement of dune systems with buildings. This practice has increased exposure of buildings to damage from natural forces (Figure B25), especially high-energy secular events. The presence of buildings close to an eroding coastline enhances the reduction in beach width because the stabilized shore cannot move landward as it would under natural conditions (see entry on *Human Impact on Coasts*). Fixation of the coastline by construction in turn adversely impacts both natural storm protection and recreational quality of affected beaches (NRC, 1995).

The deterioration or degradation of beaches is regarded as undesirable because beaches provide natural protection from storms and have economic value. The unwanted effects of beach erosion commonly place life and property at risk, usually from flooding, and decrease a community's ability to maintain a viable tourist-based economy. Commercial and residential development on upland areas behind beaches and in close proximity to eroding beachfronts are mainly jeopardized by decreasing (eroding) beach widths (e.g., Wiegel, 1988, 1994). Increased potential for economic loss and safety concerns for human life thus drive desires to remediate beach erosion by artificially replacing sand that is lost to erosion.

In addition to the use of beach nourishment for combating coastal erosion, the procedure has been advocated because it: (1) tends to be less expensive and easier to construct than hard structures, (2) is aesthetically desirable, "user friendly" (e.g., Nelson, 1993) and "environmentally green" (Finkl and Kerwin, 1997), (3) provides a source of sand for wind-created or artificially created dunes which add to the protection of inshore areas (e.g., Psuty, 1988; Malherbe and LaHousse, 1998), (4) utilizes "waste products" from dredging or construction projects (e.g., Hillyer *et al*., 1997), (5) contributes to the littoral sediment budget and may benefit down-drift locations (e.g., Lin *et al*., 1996), (6) capitalizes on natural processes (e.g., Charlier and De Meyer, 2000) and thus is more acceptable to society, and (7) restores habitat for biota (e.g., Finkl, 1993; Verhagen, 1996).

Causes of beach erosion

Artificial beach nourishment became necessary only when beachfronts were developed for recreational, urban, industrial, and military uses. It is often difficult to understand at once the causes of shore erosion because they can be natural or introduced by human activity along the shore. When induced or accelerated by engineering structures the process is sometimes referred to as *structural erosion* (Pilarczyk, 1990). Beach erosion is influenced by numerous factors such as uplift (e.g., neotectonism) or subsidence (e.g., groundwater withdrawal, compaction of sediments) of the land surface, change in climate patterns (especially storm frequency, deviation of prevailing wind direction), interruption of sediment supply to the coast, eustatic fluctuations of the sea surface, blockage of littoral drift, and construction on the coast. An increase in relative sea level (i.e., drowning of the coast and landward retreat of coastlines) is, however, often cited as the primary geophysical cause of beach erosion (e.g., Leatherman, 1988; Douglas *et al*., 2000) but many other factors are involved. Construction of dams on major exorheic rivers withholds delivery of sediment to the coast. In the case of the Mississippi River, the sediment load today is about half what it was in pre-dam construction days. Further, sediments that bypass a dam are usually fine-grained and therefore more likely to be carried out to sea and lost to coastal accumulation. Dredging of deep inlets, navigational entrances (see entry on *Tidal Inlets; Navigation Structures*), and the construction of shore protection structures such as jetties are other

Figure B25 Example of an overdeveloped coastal segment along Balneário Camboriú Beach (Santa Catarina State, southern Brazil), where construction of condominiums and tourist facilities restricts the natural dune–beach interaction with phases of seasonal storminess. During perigean spring tides, and storm surges resulting from the passage of atmospheric cyclonic fronts, the beach is under water and the beachfront road and adjacent shops are flooded. Periodic beach replenishment is required to widen the dry-beach width and add height to the berm. Without beach nourishment, developed coastal segments such as this one lose socioeconomic amenities associated with a wide recreational beach and become increasingly vulnerable to flooding.

interrelated factors that contribute to the degradation of natural beach systems. This list is by no means comprehensive and yet it must be concluded that the causes of beach erosion are manifestly complicated and often interrelated.

Although a range of natural processes contributes to the landward retreat of coastlines, urban development along the shore necessitates placement of sand on eroding beaches in an effort to protect infrastructure. The essence of the problem is not the dynamic adjustment of coastlines to fluctuating ambient conditions but construction too close to the water. Most coastline development is deliberate for reasons of access, proximity, or aesthetics. Whatever the initial impetus for developing coastlines, the result has been an expensive exercise in what is usually nationally funded coastal protection. Coastline retreat in Australia, for example, is not as problematical as it is in the United States because the Commonwealth government established Crown lands along most of the coast keeping urban development some distance inland. In other countries such as The Netherlands where land has been reclaimed from the sea, large dikes and other engineering structures (see Walker, 1988) such as dunes and renourished beaches are part of efforts to hold back the sea. Although these areas have multipurpose uses (e.g., storm protection, conservation, recreation, water catchment), they are not open to intensive urban uses (Pilarczyk, 1990).

Coastal development often includes the dredging of ports and harbors and the navigational channels that serve them. Jetties that provide protection from waves in the channel are used to stabilize the geographic migration or orientation of many entrances. Jetties and deep inlets, as well as other shore protection structures such as groins, interrupt the natural littoral drift by impounding sediment or causing it to be jetted offshore beyond the longshore sediment transport system. It is now widely recognized that the interruption of sediment transport along the shore by artificial structures causes downdrift shores to become sediment-starved, which in turn results in shore erosion and retreat of the coastline (Figure B26). Large littoral drift blockers (e.g., deep navigational entrances, groin fields) can initiate downdrift erosion that propagates for several tens of kilometers (Bruun, 1995). In a study of 1,238 km of Florida coastline, distributed among 25 coastal counties and covering about 95% of the state's beaches, Finkl and Esteves (1998) concluded that littoral drift blockers on Florida's Atlantic and Gulf coasts accounted for 72% of the statewide beach erosion. Along the southeastern coast where there are numerous stabilized inlets, and the volume of sediment transported in the littoral drift is relatively small (e.g., $<50{,}000$–$100{,}000\ m^3\,a^{-1}$), littoral drift blockers appear to cause about 90% of the beach erosion. Most of the beach erosion here is thus anthropogenically induced and is, at least theoretically, quite preventable from a technical point of view. In practice, however, remediation of the beach erosion problem is politically recalcitrant.

The causes of beach erosion are complicated interacting processes and it is emphasized that beach nourishment only treats erosional symptoms and does not eliminate the causes. Beachfills are sacrificial in the sense that they are not permanent solutions to the beach erosion problem; they thus provide only temporary protection and it is anticipated that replenishment will be repetitive.

Design of beach nourishment projects

Beach nourishment projects are designed to: (1) increase dune and berm dimensions (i.e., height, length, and width), (2) advance the coastline

Figure B26 Hillsboro Inlet, Broward County, southeast Florida. Erosion of the downdrift coast, seen in the coastal offset (photo center), was caused by stabilization of this inlet by jetties. Subsequent construction of a weir jetty on the updrift side of the inlet permitted sand to overwash into an interior sand trap on the landward side of the jetty. A floating dredge sucks the sand from the trap and pumps it to the downdrift side of the inlet via a submerged pipeline. Dredging is mostly conducted during storms when sediment is overwashed through the weir because the trap quickly fills with sediment. If the sand trap is not cleared as it fills, excess sediment spills into the navigation channel where it becomes a hazard to boaters. This sand bypassing arrangement moves 100% of the estimated net littoral drift to the downdrift beach which is thus maintained in a healthy state.

seaward, (3) reduce storm damage from flooding and wave action, and (4) widen the recreational beach area. Beach nourishment projects are complicated technical procedures that require careful preparation for successful execution of site-specific engineering design (Finkl and Walker, 2002). The scale of mechanical sediment supply is quite variable, ranging from large enterprises that involve federal and local partnerships where sometimes tens of millions of cubic meters of sand are involved to small-beach restorations that may require less than 50,000 m^3 of sand. Equipment for obtaining, transporting, and placement of sand on the beach varies with the scale of the project. Large projects require robust equipment that can handle large volumes under high-energy conditions for open ocean dredging (Figure B27). Placement of sand on small, protected beaches (e.g., pocket beaches, embayed shores) (see also entry on *Bay Beaches*) can often be achieved with small dredges during fair weather conditions (Figure B28). In either case, sediment is often redistributed along the shore by front-end loaders, graders, and tractors to achieve the design profile (see also Figures B24 and B30).

Emergency repair of *erosional hot spots* (localized coastal segments where there is increased erosion and rapid shoreline retreat that dramatically exceeds background rates of erosion, as described by Finkl and Kerwin, 1997) that develop during storms may require only a few thousand cubic meters of sediment until more thorough corrective action can be initiated. Beach nourishment the world over is based on the application of natural sediments, mostly beach-quality sands derived from offshore dredging. Many developed nations now recycle glass products and volumes of recycled glass cullet are increasing yearly. The State of Florida, for example, annually produces in excess of 130,000 tonnes of surplus glass cullet that could be made available for beach nourishment (Finkl and Kerwin, 1997). Glass cullet, a chemically inert form of silica, can be graded (mechanically ground) to desired colors and grain sizes to perfectly match native beach sands. For small projects, costs per cubic meter of placed cullet are usually less than beachfill sands.

The design process specifies the quantity, configuration, and timing of sediment distribution along a specific coastal segment to emulate natural storm protection or recreational area, or both. The design must consider rates of long-term (background) erosion as well as temporal impacts of storms and wave climate to adequately address variables associated with the quantity, quality, and placement of beachfill along the shore. As a general rule, sediment comprising the nourished beach is anticipated to erode at least as fast as the background rate of the pre-nourished coastline. It is usually observed in practice that sediment volume loss rates and coastline retreat for artificial beaches are significantly greater than historical rates for the natural beach (e.g., Dean, 2000), even when differences in grain size and sorting are taken into account (e.g., Ashley *et al*., 1987). Although an allowance for continued erosion of beachfill is part of the design assessment, the purpose of beachfill design is to maximize the longevity of artificial beaches. The designs can only be optimized by changing the morphological configuration of the beachfill or by the choice of the fill material. The grain-size of borrow material was traditionally considered to be the most important factor for optimizing beachfill. Studies by Eitner (1996), however, indicate that grain-size has little effect on beachfill longevity because grain-size influences the critical threshold stress to a lesser extent than does the grain

Figure B27 Large ocean-going dredge operating off the coast of southeast Florida. The *Illinois*, owned and operated by the Great Lakes Dock and Dredge Company (Oak Brook, IL, USA), is one of the largest suction cutterhead dredges in the United States. The 98-m long dredge, which digs to a nominal depth of 32 m, has a 760 mm discharge diameter and can pump sand 7,635 m without booster pumps. With total installed power of 8,400 kW, and 1,400 kW cutter power coupled with 662,000 L fuel capacity, the *Illinois* is ideal for working offshore for long periods in rough weather conditions. The dredge is not self-propelled and must be moved to projects by tugboats. When on site, the dredge has a large swing radius using a system of anchors and cables to maneuver within about a 300 m range without resetting the anchors. This dredge can work in swell up to 2 m high and usually operates 24 h a day when possible. Beach-quality sand from the borrow area is pumped in a pipeline to the beach. Because the dredge might operate up to 2 km offshore, the pipeline is floated on the surface near the dredge for ease of maneuverability and submerged near the shore for safety of boaters and beach users.

A

B

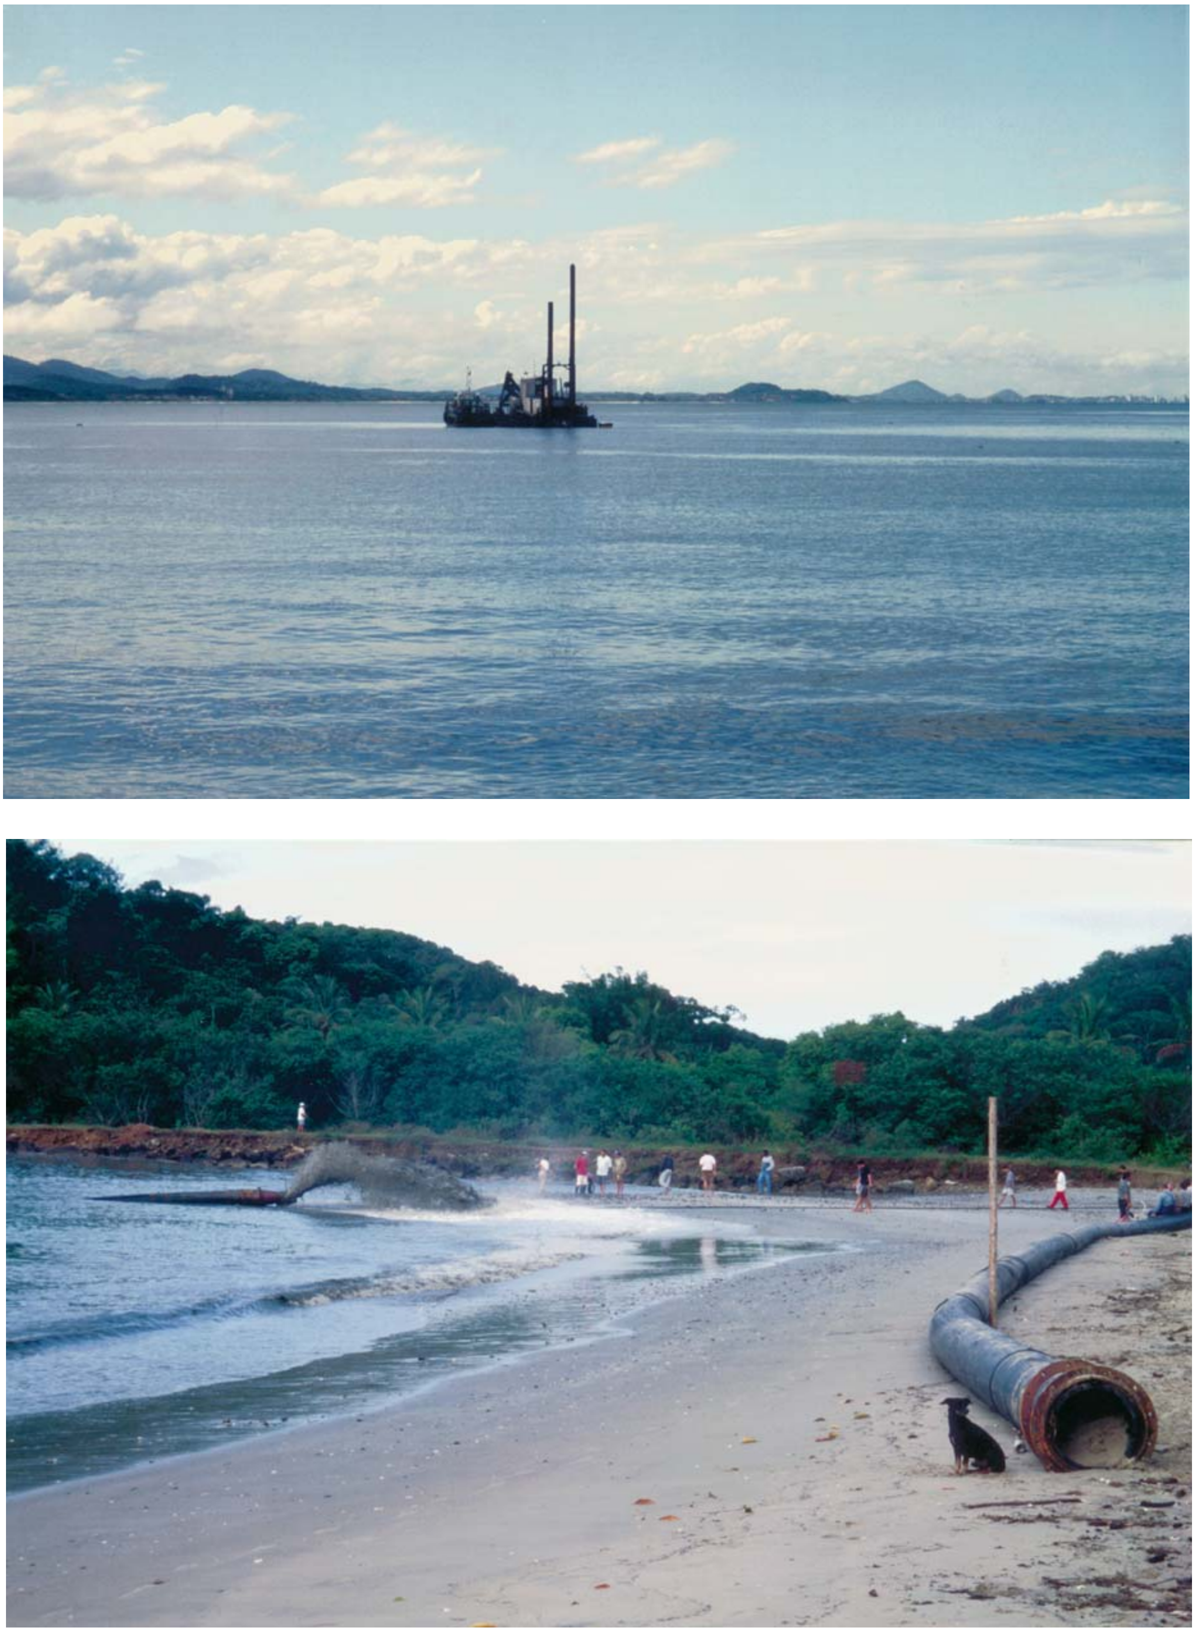

Figure B28 Small-scale beach renourishment at Alegre Beach, Santa Catarina, Brazil. Local erosion of a beach on the downdrift side of an inlet required sand renourishment for shore protection, recreation, and marine fisheries (beach launching sites for local fisherman). (A) The small coastal dredge pumps sand from the seabed offshore to the beach via a submerged pipeline. (B) Sediment is pumped up onto the upper beach-face in a slurry, as shown in the subaerial plume in the photo center. Extra pipe is stored on the berm for future use as the dredge moves about in the offshore borrow area.

density. Only a coarser material such as gravel, which also has a significantly higher critical threshold stress, may effectively extend beachfill longevity. In general, however, most researchers agree that coarser grain sizes produce steeper, more stable, and longer-lived fills (e.g., Bruun, 1990; Pilkey, 1990; Smith, 1990; Dean, 1991). Controversy does, however, surround the kinds of methods used to estimate erosion rates. Houston (1990), for example, emphasizes that designer extrapolations or predictions of replenished beach life of one to several decades is not advisable because beach conditions are too variable and especially vulnerable to cycles of storminess.

There are various methods of *beach nourishment design* that are complimentary in the overall process of optimizing *project performance*. Potential designs are initially evaluated at a preliminary level in which the anticipated project performance is predicted using simple and relatively inexpensive methods. After the performance characteristics are compared with project objectives, the design is refined until the performance predictions confirm an optimal design. For sites without complex boundaries (i.e., straight beaches without terminal groins, inlets, or headlands), prediction tools correctly estimate the time required for renourishment to within approximately 30% of actual project performance (NRC, 1995). Subsequent to establishing the preliminary design, more sophisticated predictive methods are used to optimize the design. This bimodal approach checks preliminary and advanced methods of design, facilitates a rapid and efficient convergence to final design, and provides a clear perspective of how well the design parameters fit project requirements. If the predicted volumetric losses, based on preliminary and advanced methods, differ by more than 50%, the essential elements of the design procedure are reviewed and revised, where necessary.

The design beach

The *design profile* is the shore-normal cross section that an *equilibrated beach* is anticipated to assume. The best estimate of this profile is obtained by the seaward transfer of the natural beach profile by the amount of beach widening that is required (USACE, 1992). Estimates of beachfill volumes are generally increased if the borrow material is finer grained than the native sand. The *construction profile* is the cross section that the contractor is required to achieve. Because the constructed beach, which contains design fill and the advanced-fill volumes, is often steeper than the design cross section due to construction limitations, it is also usually significantly wider than the design profile. Wave action adjusts the construction cross section to a flatter dynamically equilibrated slope within the first few months to a year after placement of the beachfill (cf. Figure B31). Because the dynamically adjusted profile contains *design and advanced fills*, it is wider than the design width during the *nourishment interval* (the time elapsed between nourishment episodes). At the time of renourishment, the design and equilibrium profile are theoretically equal (NRC, 1995).

Mechanical deposition of sediment along a beach nourishment site, during initial construction or renourishment, may not correspond to the natural profile of the beach at the time of placement (Figure B29). In the United States, use of a construction profile rather than a natural profile is the normal placement practice. It is customary for nourishment designs in the United States to establish uniform beach width along a project's length. It is also standard practice to provide sufficient sand to nourish the entire profile from the dune to the depth of significant sand removal, the so-called *depth of closure* (DoC). The DoC is a term used by engineers to define the *depth of active sediment* movement on the seabed (see also entry on *Depth of Closure*). Other terms that are related to this critical concept include profile pinch-off depth, critical depth, depth of active profile, maximum depth of beach erosion, seaward limit of nearshore eroding wave processes, and seaward limit of constructive wave processes. The DoC in beachfill design is defined as "The depth of closure for a given or characteristic time interval is the most landward depth seaward of which there is no significant change in bottom elevation and no significant net sediment transport between the nearshore and the offshore" (Kraus *et al*., 1998). This definition applies to the open coast where nearshore waves and wave-induced currents are

Figure B29 Emergency beach renourishment at Gravatá Beach, Santa Catarina, Brazil. A coastal highway and commercial infrastructure was threatened by beach erosion during a strong southeaster that brought heavy surf conditions to the coast during the Southern Hemisphere winter of 1999. Removal of the beach by wave and current action, undermined part of the coastal highway interrupting coastal access. Although of finer grain size than the native beach sand, emergency fill was trucked to the site for immediate shore protection.

the dominant sediment-transporting mechanisms. The definition of the DoC infers or stipulates that: (1) the landward water depth at which no sediment change occurs can be reliably identified, (2) there is an estimate of no significant change in bottom elevation and no significant net cross-shore sediment transport, (3) a time frame is related to the renourishment interval or design life of the project, and (4) at the DoC cross-shore transport processes are effectively decoupled from transport processes occurring farther offshore.

Estimates of fill requirements are based on the geometric transfer of the active cross-shore profile seaward by the design amount. If the beachfill grain size matches the native sand and there are no rock outcrops, seawalls, or groins, the design profile (shore-normal cross section) at each alongshore range marker (permanent locations of cross-shore survey sites are typically spaced every 330 m along Atlantic and Gulf coast beaches in Florida) should ideally match the dynamically stable shape of the native beach profile. Cross sections may be more closely spaced in beach nourishment project areas for better engineering control. Enough sediment is included in the design to nourish the entire profile (Hanson and Lillycrop, 1988).

The total sediment volume is independent of the cross-shore profile because the shape of *the renourished profile* is parallel and similar to the existing natural profile. Extra fill is required, however, in front of seawalls in order to achieve the proposed berm elevation. After these seawall volumes are calculated, estimates of nourishment fill volumes are based on seaward translocation of the entire profile. It is emphasized that sand is usually needed along the entire profile, both above and below the water because the beach, by definition, retains subaerial (berm) and submarine (beachface) sections. Placement of the required extra fill volume in front of seawalls typically moves the high-tide shoreline farther seaward than adjoining non-seawall segments. This design requirement, however, causes alongshore gradients in littoral drift that tend to become erosional hot spots. An alternative to providing the additional seawall volumes is to build narrower berms in front of seawalls. Narrower berms are advantageous because they reduce littoral drift gradients that are set up by overly wide sections of nourished beaches in front of seawalls. Similar levels of storm protection (for uplands) are provided by narrower berms when they are backed by seawalls compared to wider berms without them. In many instances, however, beach nourishment in front of seawalls can become problematic, especially where coastline retreat extends landward along coastal segments adjacent to the seawall and where there is deep wave scour in front of the wall (see discussions in Kraus and Pilkey, 1988).

Coastal engineers attempting to predict beach washout and profile response seaward of seawalls often employ beach and dune recession models. Commonly used approaches include EDUNE (Kriebel, 1986), SBEACH (Larson and Kraus, 1990), and GENESIS (Hanson, 1989; Hanson and Kraus, 1989). The numerical models predict the evolution of the cross-shore beach profile toward the so-called equilibrium storm profile (NRC, 1995). Both models are based on principles related to the disparity between actual and equilibrium (theoretical) wave-energy dissipation per unit volume of water within the surf zone. For convenience of calculations, the models assume that sand eroded from the upper beach deposits offshore, with no loss or gain of material to the profile. It is well-known, however, that beach sediment is often transported offshore and is lost from the littoral drift system (e.g., Pilarczyk, 1990). Estimates of storm surge used in coastline recession models, and for calculating run up, are based on USACE (1984, 1986, 1989) engineering manuals. Storm-surge frequencies and extents of coastal flooding are also deployed by the Federal Emergency Management Agency (FEMA) and the National Oceanographic and Atmospheric Administration (NOAA). Storm hydrographs are thus obtained from FEMA, NOAA, and universities to generate probabilities of storm-induced shoreline recession. Wave statistics can be obtained from wave gage records, published summaries of observations, or wave hindcast estimates such as the Wave Information Study (USACE, 1989). Other methods such as the Empirical Simulation Technique (EST) (Borgman *et al.*, 1992) develop joint probability relationships between various multiple parameters contained in historical data records. Using historical storm records as input, the EST statistically develops a much larger storm-response database while maintaining statistical similarities to original data and it is thus possible to achieve estimates of storm-induced beach recession (Howard and Creed, 2000).

Protocols for overfill on design beaches

Beachfill is usually dispersed out of the nourishment area (i.e., away from the replenished or artificial beach) to adjacent shores or deeper water. The process leading to a decrease in beachfill volume is referred to as "loss," although this sand still temporarily contributes to the stability of the shore in general, but not at the original location. From the point of view of sediment transport, the sand is not "lost" because it is partly retained in the littoral system. From the perspective of the beach manager, however, migration of sediment away from the beachfill represents a tangible decrease of dry beach area.

Erosion of nourished beaches feature two distinct components: (1) the linear regression of the volume of sand in the coastal profile and (2) additional erosion arising from the newly nourished shoreline which becomes more exposed (lying more seaward) than adjacent shore up- and downdrift (Verhagen, 1996). Sediment losses alongshore as well as adjustment or equilibration of the constructed cross-shore profile are responsible for the so-called "additional erosion." In cases where the volume loss associated with the coastal erosion is large compared to the quantity of the beachfill and where the previous rate of erosion is known, a multiplier is used to compensate for all sand loss. Verhagen (1996) suggests a value of 40% extra fill. The presence of structures such as seawalls, due to their interaction with coastal processes, may also require additional fill.

The term *advanced fill* refers to the eroded part of the beach profile before nourishment becomes necessary. The volume and areal distribution of advanced fill is estimated from analysis of the historical rate of erosion and shoreline change. The potential impact of *project fill* on coastal processes is an additional consideration that is taken in account. Procedures used to make these estimates include the historical coastline change method (USACE, 1991) or numerical methods (Hanson and Kraus, 1989). The *historical shoreline change method* assumes that the nourished beach will erode at the same rate as the prenourished beach. This method is commonly employed by beach designers (based on survey results) but can yield a significant underestimate of nourishment requirements (NRC, 1995).

Most long-term erosion (as opposed to episodic storm erosion or development of erosional hot spots) of a nourished beach is initiated by increased gradients of littoral drift along the project length. Major littoral drift gradients affecting the stability of nourished beaches are the preexisting background (regional) rates or historical erosion of the prenourished shore and stresses associated with the high-tide shoreline salient that was advanced seaward by the project fill. These perturbations of normal coastal processes are the cause of *end losses* and *spreading* of the fill. All of these littoral drift gradients interact with the nourished beach causing a progressive loss of fill. Exclusive consideration of the background erosion rate neglects end (and spreading) losses, which causes an underestimate of nourishment volume and overestimate of project life. Although losses from the project due to spreading cause accretion on adjacent beaches, they must be included in the advanced-fill design in order to achieve performance objectives (NRC, 1995).

Nourishment profiles

Models of beachfill placement depend on renourishment design schemes that are selected by considering static and dynamic peculiarities of the site, fill requirements, temporal and spatial distribution of natural habitats, and costs. Some of the more common approaches include: (1) placing all of the sand in a dune behind the active beach, (2) using the nourished sand to build a wider and higher berm above mean water level, (3) distributing fill material over the entire beach profile (above and below water), or (4) placing sand offshore in an artificial bar (NRC, 1995). The approach taken partly depends on the location of the source material and the method of delivery to the beach. If the borrow site is a quarry on land and the sand is transported by trucks to the beach (cf. Figure B28), placement on the berm or in a dune is generally most economical. If the material is pumped shoreward from offshore ocean-going dredges (cf. Figure B26), it is usually more practical to place the sand directly on the beach, in the nearshore zone, or to build an artificial bar. If pumped onshore in a sand-water slurry, the sand is subsequently redistributed by grader or bulldozer across the shore to form a more natural beach profile (Figure B30).

The use of large dunes (i.e., man-made dikes) fronted by renourished beaches as an effective coastal protection measure has long been recognized in The Netherlands (Verhagen, 1990; Watson and Finkl, 1990). These constructed dune–beach systems are designed to withstand the 1-in-10,000-year condition of wave intensity and storm surge flooding. This extreme level of protection is justified because entire cities lie behind the coastal defenses.

Bruun (1988) advocates nourishing the entire beach profile, which he terms *profile nourishment*. The main advantage of this approach is that the sand is placed in approximately the same configuration as the existing profile, so that drastic initial adjustments are mostly avoided, especially

Figure B30 Restoration of Captiva Beach in 1996 on Sanibel Island, southwestern Florida, showing beach-quality sand pumped from offshore via a submerged pipeline to the shore. The sand–water slurry debauches from the pipe end (lower center foreground) to form an alluvial fan that builds up along the shore. Shell hunters often congregate about the proximal part of the sediment fan hoping to find collector's specimens. Shore birds search the distal portions of the fan for crustaceans brought up from the seafloor in the offshore borrow area. Road graders and bulldozers redistribute the pumped sediment into the beachfill design shape that often incorporates overfill that will be sacrificed to the littoral system as the beach equilibrates to the ambient wave climate. The beachfill is sometimes initially somewhat darker than the native beach sand, as shown here, due to a small percentage of organic content. Organic matter in the fill bleaches out within a few weeks and the native-colored sands imperceptibly grade into the fill material. Pipe extensions lie at the foot of the foredunes (photo, lower right) and mark the approximate position of the back berm (photo: Courtesy of Coastal Planning and Engineering, Inc., Boca Raton, FL).

the rapid erosion of the nourished berm. When wave action undermines the newly constructed berm, a beach scarp frequently forms along the length of the project fill. These scarps can pose hazards to beachgoers trying to gain access to the water from the berm (Figure B31). In some cases, foot traffic across the scarp tramples the steep slope to a flatter one that cuts into the beachfill. These cuts or beach tracks can provide ingressive pathways for surge and run-up which in turn can accelerate erosion of the project fill volume.

Artificial nourishment of eroded beaches can be indirectly achieved by placing dredged sand in the offshore zone (McLellan, 1990). Dredged material is deposited in shallow water, typically using a split-hull barge either as a mound or shaped as a long liner ridge that simulates a shore-parallel sand bar. It is anticipated that the sand deposited in the offshore mound or artificial bar will migrate onto the beach. Prior to welding onto the beachface, the bar causes waves to break farther offshore, a process that reduces the wave energy on the beach in the lee of the bar. The disposal depth of the offshore nourishment should be shallower than the seaward boundary of active sediment transport (as defined by normal to moderately elevated energy conditions) so that sediment quickly moves onto the subaerial beach.

Mechanical bypass systems

Shore protection structures (*q.v.*) or other coastal construction works can interrupt littoral drift flow patterns and trap sediment near structures, within navigational entrances to port and harbors, and in flood- or ebb-tidal deltas. Sediment trapping by littoral drift blockers causes downdrift beach erosion (e.g., Finkl, 1993; Bruun, 1995). In order to mitigate the downdrift effects of sand starvation along the coast, it is necessary to move sand around barriers in order to supply beaches with sediment. Due to losses of sediment offshore (see previous discussion), the quantity needed for downdrift beach nourishment may be greater than the trapped sediment volume. Some bypassing systems that are geared for normal use may be overwhelmed during large storms while others function best during or immediately after storms when sediment is brought to the *sand trap* (a dredge pit that collects sediment).

Fixed bypassing systems generally are less effective and more expensive to run than mobile floating systems (Bruun, 1993). Most bypassing plants work at less than 50% efficiency, and some at 30%, which means that less than half of the drift is bypassed to the downdrift beaches. The combination of periodic beach replenishment and innovative bypassing techniques is an option that can restore longshore sediment transport and greatly reduce beach erosion (Bruun, 1996). Suggested new alternatives include mobilization of the bypass intakes on rails or cranes, implementation of jet pumps, or seabed fluidizers (Bruun and Willekes, 1992).

Several different kinds of mechanical bypassing systems are used effectively in a variety of coastal settings: (1) mobile dredges in the harbor and or entrance (e.g., Santa Cruz, CA), (2) movable dredge in the lee of a detached breakwater that forms an updrift sand trap (e.g., Channel Islands and Port Hueneme, CA), (3) floating dredge within an entrance using a weir jetty on the updrift side (e.g., Hillsboro Inlet, FL; Boca Raton, FL; Masonboro Inlet, NC; Perdido Pass, AL), (4) fixed pump with dredge mounted on a movable boom (Lake Worth Entrance, FL; South Lake Worth Inlet, FL), (5) jet pumps (eductor) mounted on a movable crane, with main water supply and booster pumps in a fixed building (e.g., Indian River Inlet, Delaware) (NRC, 1995). These, and other installations, and their operational performances are described in engineering and design manuals (e.g., USACE, 1991) which provide guidance for the design and evaluation of sand bypassing systems.

Veneer beachfills

Veneer fills are beach-quality sands that are placed over a relatively large volume of material that is generally not suitable for beach nourishment. The unsatisfactory materials, which may be either grossly coarser or finer

Figure B31 Example of a large beach-replenishment project involving more than 6 million m^3 of sand that was pumped from offshore in southeast Florida near Port Everglades (Fort Lauderdale). As shown in the photo, the beachfill has been eroded back to the native sand beach (left) and the built beach is perched about 2 m above the eroded beach. The beach scarp that developed during erosion of the fill was graded by dragging a heavy I-beam across the sand. The more gradual slope facilitated access to the water by reducing the hazardous vertical face of the scarp.

than normal beach sand, remain as an underlayer beneath the thin surface sand veneer. Veneer beachfills are thus used in situations where beach-quality sand is not available in sufficient quantities to economically undertake a nourishment project. The usual reason for placing a veneer fill is based in economics where the cost is prohibitive if a cross section is totally built of beach-quality sand. Veneer fills are of two basic types: (1) fills where the underlying materials are coarser than typical beach sands (e.g., boulders, coral, rocks) and (2) fills where the underlying materials are finer than typical beach sands (e.g., silts or silty sands where the median grain size is much smaller than native sand). In the United States, veneer beachfills have been used in Corpus Christi, TX; Key West, FL; and Grand Isle, LA (NRC, 1995). A fundamental design problem associated with veneer fills involves selection of a veneer that is thick-enough, so that it will not erode away and expose the underlayer during storms or before scheduled replenishment. Although variable, depending on the local conditions, the thickness of the veneer must provide a sedimentary envelope that incorporates profile variations without compromise.

Pros and cons

In the United States, there are two schools of thought regarding beach nourishment; the larger group favors artificial placement of sand on eroding beaches as part of shore protection measures while the other smaller group discourages the practice on the grounds of environmental, economic, sociological, or political grounds. A recent study by the US National Research Council (NRC) examined the diversity of viewpoints about the success or failure of nourishment projects (Table B2). It was concluded that the factors involved include a large number of interest groups who have different "... viewpoints, objectives, needs, and ideas ..." (NRC, 1995, p. 41).

In the 1980s and early 1990s, there was much debate about the pros and cons of beach nourishment with many illuminating facts coming from both sides of the issue (Pilkey, 1990). As persuasive as many arguments were, the end result was that federal support for new beach nourishment was largely withdrawn when the US Congress removed the USACE from many new projects by reducing or eliminating funding (e.g., Finkl, 1996). If beach renourishment is to continue as a shore-protection measure in the United States, local funds will have to support the practice along many stretches of the coast.

Proponents of beach nourishment favor continuance of the engineering practice for many reasons, the most important of which feature shore protection (mainly flood control against storm surge) and economic value in terms of income from recreational use. The arguments for beach nourishment are legion and include those factors already indicated as part of the needs for shore protection.

Antagonistic to views of beach nourishment are concepts that focus on environmental impacts of offshore dredging (e.g., Nelson, 1993), especially near sensitive environments such as coral reefs and sea-grass beds, and placement of sand along the shore which buries meiofauna and infauna, or which may adversely impact rare species such as sabellariid worm reefs. Divergent opinions also focus on expenditures of public funds for coastal segments that do not provide public access to the beach or interpretations of coastal management practices that call for retreat from the coast. Other issues that are sometimes raised concern beachfill performance (i.e., durability, longevity, half-lives of replenishments) which is keyed into the design life of renourished beaches (e.g., Houston, 1991; Davis *et al.*, 1993; Farrell, 1995). The USACE, for example, often estimated and advertised life spans of a decade or so for many proposed projects. Studies subsequently found that, on average, the life spans of renourished beaches were usually less than anticipated. Durabilities of renourished Atlantic beaches, for example, were found to have a half-life of about 4–5 years. (Pilkey and Clayton, 1989). The percentage of renourished beaches lasting more than 5 years along Atlantic coastal barriers averaged about 65% while those on Gulf and Pacific coasts, respectively, averaged about 75% and 65% (Leonard *et al.*, 1990b; Dixon and Pilkey, 1991; Trembanis and Pilkey, 1998).

Conclusions

Among the different approaches to beach nourishment the world over, are various techniques that essentially boil down to methods of placing suitable sediment along the shore to: (1) maintain an existing but eroding beach, (2) create a new beach where none existed before, or (3) to improve a seriously degraded former beach. No matter the actual method of beach nourishment design that involved acquisition of suitable sediment and placement along the shore, this soft engineering approach to erosion mitigation must be regarded as a temporary solution to a chronic problem. In spite of the fact that in the United States, for example, there has been more than a half-century of experience, beach nourishment remains a procedure with unclear universal application. Experience has shown that there are no simple rules that work everywhere because it is now widely appreciated that local site characteristics must be important criteria in successful design. Peculiarities of local conditions related to bathymetry, sediment grain size or shape and composition, exposure and orientation of the beach to prevailing and storm wind patterns, wave climate, and para- and diabathic sediment

Table B2 Evaluation of beach nourishment projects, based on objectives, interpretation of criteria for success, and various measures of performance (modified from NRC, 1995)

Objective	Criteria for success	Measures of performance
Create, improve, or maintain a recreational beach	A viable recreational asset (acceptable dry-beach width and carrying capacity) during the tourist season	Periodic surveys of beach width using quantitative techniques. Assessment of beach visits and carrying capacity via such methods as aerial photography
Protect coastal infrastructure from wave attack and flooding by storm surge	Sufficient sand, gravel, or cobbles remaining in a configuration that blocks or dissipates wave energy and surge. Hard structures may be included in the solution	Evaluation of structural flooding damage following storms that do not exceed the project design
Maintain an intact dune seawall system	No overtopping during a storm that does not exceed the design water level and wave height limits	Verification of stabilized shore line position
Create, restore, or maintain beach habitat	Episodic erosional extremes do not exceed the design profile. Structures, if allowed, remain intact. Postfill erosion rates comparable to historical values	Profile surveys showing that the sedimentary volume and configuration meet or exceed the design profile
Protect the environment	Sediment volume, areal extent, and condition plus vegetation of the back beach or dune meeting environmental needs	Observation and survey of habitat characteristics and conditions
Avoid long-term ecological changes in affected habitats	Return to pre-nourishment (native beach) conditions within an acceptable time frame	Periodic monitoring of faunal assemblages of critical concern

flux pathways can all affect shore erosion and beach stability. Intricacies of shore processes and their interactions with engineering works such as jetties, dredged channels, groins, and breakwaters, for example, can exacerbate natural shore erosion. Fortunately, it is now realized that many shore protection structures are themselves the main causes of accelerated beach erosion. In southeast Florida, for example, stabilized navigational entrances (i.e., jettied tidal inlets) are responsible for about 90% of the beach erosion problem (e.g., Finkl and Esteves, 1998). As formidable as this figure may seem, it is now evident that improved sediment bypassing at littoral drift blockers, as described by Bruun (1995), can significantly enhance beach nourishment efforts by prolonging what are relatively short life spans of placed sediments. Using a combination weir jetty, interior sand trap, and floating suction cutterhead dredge, the Hillsboro Inlet in Broward County (southeast Atlantic coast of Florida), is able to annually bypass 100% of the estimated net littoral drift (Finkl, 1993). Thus, in many instances, improved sand bypassing at inlets can maintain sediment transport alongshore to supply downdrift beaches with incremental sand.

Shore protection via beach nourishment comes, however, with a high price tag but there often are few options that are practical. Retreat from the shore in highly developed coastal infrastructures is not possible nor is a passive approach where structures or facilities are threatened by beach erosion or coastal flooding. The Dutch, for example, have taken an aggressive approach by actually reclaiming land from the seabed by diking and poldering (see Walker, 1988). Elsewhere, most of the world's developed shores thus face the promise of attempting to maintain present coastlines via beach nourishment.

Even though beach nourishment is the shore protection measure of choice for many coastal managers, the future of the procedure in the short-term (less than 50 years beyond today) may seem bright but in the long term (more than 100 years from today) the prognosis would be poor. If the natural rise in mean sea level (see entry on *Sea-Level Rise*) continues to be exacerbated by human action to the point that relative sea level continues to increase, many coastal areas will experience inability to locate suitable beachfill materials in sufficient quantity to support artificial nourishment. As beachfill materials become scarcer due to increased demands, project costs will escalate, but cost/benefit ratios will probably be favorably maintained because of higher property values per length of coastal segment. Further, if the general rise in eustatic sea level accelerates as some researchers predict, renourished and constructed beaches will be no match for increased vulnerabilities from erosion and storm surges. The problem is, unfortunately, growing as more and more stretches of shore are developed.

Recommendations to improve performance (i.e., life span, durability of beach nourishment projects) include mapping of the shore zone (both subaerial and submarine features) to better understand the topographic features and sediment transport pathways that are related to coastal stability in the local area. Post-project monitoring is another important step that can help assimilate factors that are related to the degradation of beachfill project life. For now, beach nourishment projects meet the needs of many coastal communities that require protection of beaches.

BEACH PROCESSES

The continuous changes taking place in the coastal zone constitute *beach processes*. A *beach* is one part of the *coastal zone*, which is the transitional area between terrestrial and marine environments. The coastal zone comprises the beach; an underwater region that extends seaward to the depth where waves no longer effect the sea bottom; and inland to features such as *sea cliffs*, *dune fields*, and *estuaries* (*q.v.*). Beach studies focus on understanding spatial and temporal changes in alongshore and cross-shore geomorphic features of the beach (*Beach Features: q.v.*) and in the size and composition of beach sediment. Over time, the coastal zone changes in character in response to changes in wave climate and other physical processes.

Comprehensive knowledge of beach processes is crucial to society because the majority of the world's coastlines are eroding (Thornton *et al.*, 2000). Moreover, *sea-level rise* (*q.v.*) from *global warming* could accelerate coastal land loss, resulting in an increasing rate of loss of coastal habitat and structures. Coastal land loss has a large negative societal impact because approximately two-thirds of the world's population lives adjacent to the ocean or large inland bodies of water. In the United States, more than half of the population lives within 50 miles of the shore, while about 85% of the sandy shore is eroding from a combination of damming of rivers, inlet improvements, sand mining in the coastal zone, sea-level rise, and large storms (*q.v.*). Understanding the processes that cause land loss on sandy coasts is particularly important because beaches are a popular recreational area; are essential to commerce; and protect coastal cliffs, dunes, and structures.

Beaches continually change in response to changes in wave conditions. The changes occur over both short- and long-terms, reflecting both subtle changes associated with daily or weekly variations in tidal level or wave climate and gross changes associated with seasonal variations in wave climate. Beaches usually shift back and forth between a wide, built-up berm with a barless nearshore zone and a small-to-absent berm with one or more well-developed bars in the nearshore. These fluctuations often occur on top of an equilibrium profile that exhibits no net long-term change.

Textbooks that discuss beaches, the coastal zone, and the processes that affect them include Johnson (1919), Guilcher (1958), Shepard (1963), Shepard and Wanless (1971), Bascom (1980), Komar (1983, 1998), Bird (1984), Carter (1988), Carter and Woodroffe (1994), and van Rijn (1998). A report by Thorton *et al.*, (2000) summarizes the state of coastal processes research as of 1999.

Beaches

Many classifications exist to describe different types of coast. Van Rijn's (1998) classification consists of mud, sand, gravel/ shingle, and rocky coasts. In this classification, approximately 10% of the coasts are mud and 15% are terrigenous sand and carbonate sand coasts. Because of their large societal importance, most studies of coastal change have been conducted on sand coasts, which typically are wave-dominated environments (*q.v.*).

The beach is the most prominent visual feature of sand coasts. It is the area of unconsolidated material that extends landward from the low-water line to the place where there is a definite change in material or physiographic form (e.g., a cliff or dune), or to the line of permanent vegetation (*Coastal Boundaries: q.v.*). Beach material can be any combination of sand (grain size = 0.0,625–2 mm), granules (2–4 mm), pebbles (4–64 mm), cobbles (64–256 mm), and boulders (>256 mm) (*Sediment Classification: q.v.*). The grain size on most beaches is in the sand range.

Grain size and composition

In temperate climates, beaches typically consist of quartz and feldspar grains derived from the weathering of terrestrial rocks. Commonly, denser minerals (*heavy minerals*) that are specific to also occur in small percentages. On volcanic islands, the sand frequently includes lava fragments and associated minerals. Worldwide, many beaches have a calcium carbonate fraction from the breakup of shells, concentrations of foraminiferans, and nearby coral reefs (*q.v.*). For example, on the island of Hawaii, beach sand can be black, green, or white. The black sand comes from the erosion of lava beds and decomposition of hot lava flowing into the ocean; the green sand comes from the mineral olivine, which crystallizes when magma cools; and the white sand consists of calcium carbonate. Although calcium carbonate beaches are usually associated with the tropics, beaches in other climes also can have a large shell fraction.

Because the heavy-mineral fraction in beach sand is indicative of the provenance of that sand, heavy minerals can be used to trace the movement of sand along the beach. For example, Trask (1952) showed that the sand reaching the harbor at Santa Barbara, CA comes from the area around Morro Bay, CA, more than 160 km up coast. He established this by using the mineral augite as a tracer. Along the stretch of coast between the two cities, augite occurs in all beach sands, but the only source area is in the vicinity of Morro Bay. The concentration of augite decreases between Morro Bay and Santa Barbara as non-augite sources (e.g., local streams and cliffs) add to the sand moving along the coast.

Beach profile

Figure B32 shows a typical shore-normal cross section, or *profile*, of the coastal zone. The coastal zone can be divided into four major subzones: *backshore*, *foreshore*, *inshore*, and *offshore*. The locations of the beach subzones depend on whether the beach has accreted or eroded (*Beach Erosion: q.v.*). The offshore and inshore are seaward of the low-water line. The former is a relatively flat part of the profile seaward of the breaker zone. The latter includes the breaker and surf zones (*q.v.*). The foreshore is the sloping portion of the profile (typically 2–10°) and encompasses the normal intertidal part of the beach. On an eroding beach, the foreshore could cover the entire beach. The *beach face* is the upper portion of the foreshore that is normally exposed to wave *uprush*; it is often synonymous with the foreshore. On an accreting beach, the *berm crest* is the transitional area between the foreshore and backshore; often it is a striking feature several meters above low water, especially on cobble and boulder beaches (Guilcher, 1958). The backshore extends landward from the berm crest to the edge of the beach; the nearly horizontal part is the *berm*, which forms from the deposition of lower-foreshore sediment that is transported over the berm crest. There can be more than one berm on a backshore. A nearly vertical escarpment (*scarp*) caused by erosion of an earlier berm crest can separate berms on multi-berm beaches.

The loss of beach sand usually corresponds to a gain of sand in the nearshore, and *vice versa*. Beach sand also can be lost to sanddunes, estuaries, and submarme canyons Human activities can result in both beach loss and gain. *Pocket beaches* can be an exception where the sand often shifts alongshore with changes in wave climate. Visually, the result is a shift in the profile of the beach in both the horizontal and vertical. Although such changes are commonly associated with winter

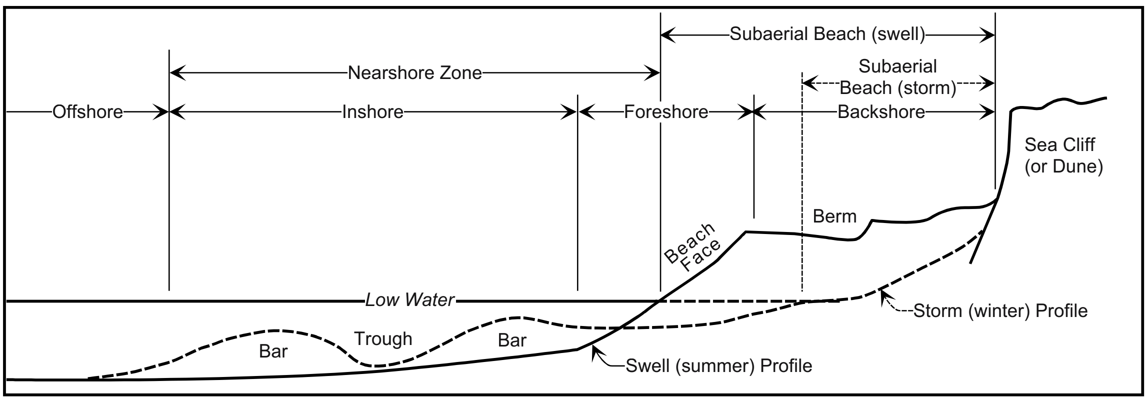

Figure B32 Terminology for the coastal zone along a shore-normal profile.

(erosion) and summer (accretion), in reality they occur any time of year in response to stormy and fair weather. *Storm waves* erode the berm and shift the shoreline (defined as the high-water line or wet–dry boundary) landward. *Swell waves* build up the berm and shift the shoreline seaward.

For sandy beaches, Wiegel (1964) developed a relationship between median grain size, slope of the beach face, and wave climate using data from many US beaches. Grain size and beach slope were measured at mean tide level where the correlation was best (Bascom, 1951). The relationship shows that that the slope depends on two factors—grain size and wave exposure (Figure B33). For any given wave climate, slope increases with increasing grain size. Correspondingly for a given grain size, the smaller the waves, the steeper the beach face. Thus, a beach face becomes flatter when eroding (larger, storm waves) and steeper when accreting (smaller, swell waves).

Beach processes

A complete understanding of beach change requires an understanding of the processes active throughout the coastal zone. Accordingly, beach processes is a subset of *coastal processes*, or *coastal morphodynamics* (morpho-: form, structure; dynamics: motivating or driving forces). Thus, coastal processes involve investigations of the interactions of coastal-zone features and hydrologic, meteorologic, and fluvial forces by means of sediment transport (*q.v.*). Coastal geomorphology and fluid dynamics couple at a continuum of temporal and spatial scales such that the fluid dynamics produces sediment transport, which produces geomorphic change. Progressive modification of the geomorphic features in turn alters boundary conditions for the fluid dynamics, which evolve to produce further changes in sediment-transport patterns and consequently the geomorphic features (Cowell and Thom, 1994).

Coastal processes happen over a wide range of spatial and temporal scales; the upper limits are generally set at 10 km and 1 yr, respectively. For example, the properties of waves entering the coastal zone from deep water and interacting with the nearshore profile determine the overall characteristics of nearshore waves and flows. However, small-scale processes control the turbulent dissipation of breaking waves, bottom boundary layer, and bedform processes that determine the local sediment flux. Cross- and longshore variations in waves, currents, and bottom slope cause spatial gradients in sediment fluxes resulting in changes due to erosion or accretion. Traditionally, the study of coastal processes has been restricted to small and intermediate scales (Thornton *et al.*, 2000); making it but one of several influences on the coastal zone (Figure B34).

The rate of response of geomorphic features to the fluid dynamics depends on scale; larger features take relatively longer to change (temporal scale in Figure B35). Hence, equilibrium is almost instantaneous for small-scale processes, and quasi-equilibrium becomes more noticeable as the geomorphic scale increases. For example, bedform scale and forcing history link the rate of transition between bedform types inside and just outside of the surf zone. Under large waves, significant changes in small-scale bedforms can occur within a single wave cycle, but changes in large-scale bedforms can exhibit significant hysteresis.

Wind, waves, tides, storms, and stream discharge are important driving forces in the coastal zone. Streams transport sediment from the

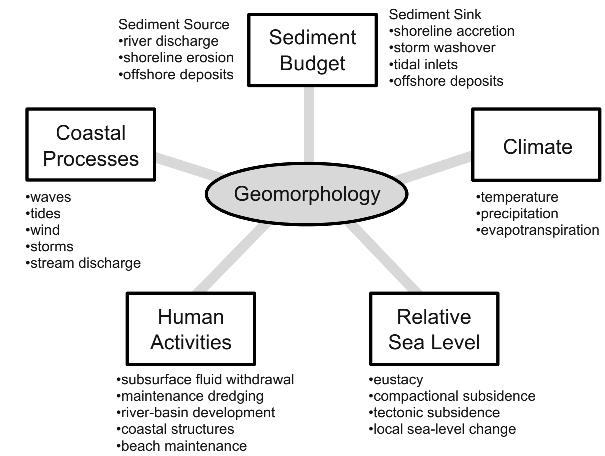

Figure B34 Processes that influence the geomorphology of the coastal zone (Thornton *et al.*, 2000).

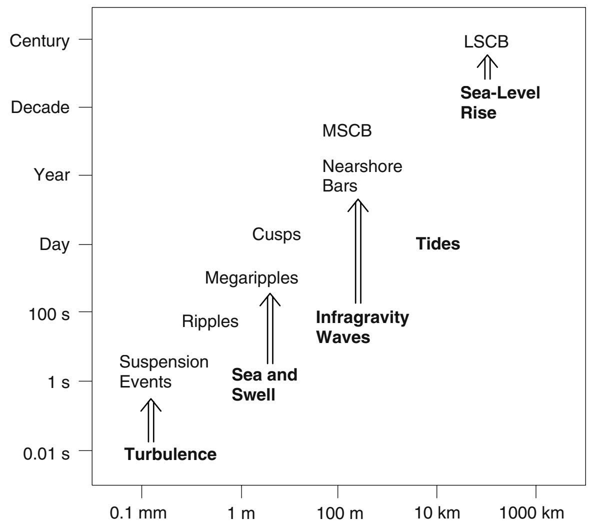

Figure B35 Temporal and spatial scales for coastal processes (Ruessink, 1998). Fluid forces are boldfaced.

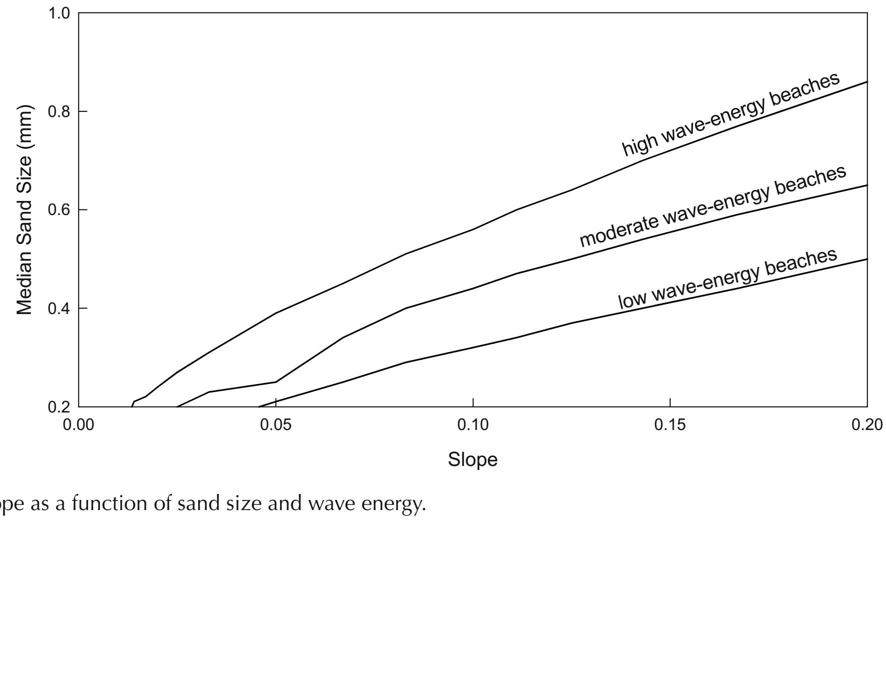

Figure B33 Beach slope as a function of sand size and wave energy.

hinterland to the coastal zone for the other forces to distribute. Wind directly transports beach sand and generates waves (*Meteorological Effects: q.v.*). Waves produce currents that transport sand cross-shore and longshore. Tides play a supporting role by exposing different parts of the beach face to waves and currents. Storms produce strong wind, waves, and elevated sea level, which can cause extensive coastal erosion; movement of sand to the nearshore or across barrier islands (*q.v.*) and spits (*q.v.*); and coastal flooding, as well as intensifying small- and intermediate-scale processes.

Waves are the major source of energy driving beach change in the nearshore. As a wave approaches the coast, it reaches a water depth where it begins to interact with the bottom (*shoal*). That depth occurs when the ratio of water depth to deep-water wavelength is less than 0.5, which is commonly in the depth range of 10–20 m. *Wave base* is the term Bradley (1958) gave to the depth at which normal wave erosion begins (also see Dietz, 1963). *Depth of Closure* (*q.v.*) is the maximum depth of extreme bottom changes; it is a function of the nearshore storm-wave height exceeded 12 h per year and the associated wave period (Hallermeier, 1981). Shoreward, a wave undergoes a systematic transformation (*shoaling*) where wavelength (L) decreases and height (H) increases (H/L is the wave *steepness*). When the ratio of the wave height to water depth reaches 0.73–1.03 (Galvin, 1972), the wave breaks, producing a beachward flow (*bore*). The result is an upward (*run-up*) and downward (*backwash*) flow of water on the beach face (the *swash zone*). If run-up reaches the back of the beach, it can erode cliffs, dunes, and structures.

Sand transport begins soon after waves begin to shoal. Transport volume and velocity increase shoreward in proportion to increasing intensity of the wave-bottom interaction. Whether there is beach erosion or beach accretion depends on wave height and period. Storms raise sea level by piling up water against the coast (*storm surge*) (*q.v.*), and greatly increase wave height and steepness (*storm* waves). Such waves tend to produce beach face erosion with the sediment being moved to the nearshore. Lower, less-steep waves (*swell* waves) produce accretion by moving nearshore sand onto the beach face. Storm and swell waves can occur any time of the year, although the former are more common in the winter and the latter in the summer. Consequently, the belief that erosion is a winter phenomenon (season of storm waves) and accretion a summer phenomenon (season of swell waves) is not completely correct. Basically, the wave climate continuously varies, and the beach face never reaches an equilibrium state where the volume of sand moving up the beach face equals that moving down.

Breaking waves create a circulation system where the water driven shoreward across the surf zone returns to the offshore via a strong, narrow flow called a *rip current* (Figure B36) whose spacing ranges from tens to hundreds of meters. Velocities in rip currents are often strong enough to carry sediment and swimmers bathers alongshore through the breakers; in those cases, a distinct watercolor demarcates the rip current. Often the velocity is too strong to swim against, so people caught in a rip current must swim parallel to shore to escape.

If a wave enters the coastal zone at an angle to the bathymetric contours, its crest bends to align with those contours (*refraction*). If the wave breaks at an angle to the beach, a longshore current develops. Because sand grains move with the flow, longshore sediment transport (*q.v.*) occurs (*littoral drift*). Because the sand grains are subject to both run-up and littoral drift, they follow a zigzag path along the beach face.

Geomorphic features

Based on the temporal and spatial scales of sediment transport and geomorphic change, the coastal zone can be divided into two cross-shore subzones—the upper and middle shoreface—and three longshore subzones—micro, meso, and macro cell. In the upper shoreface, breaking waves and bores generate active sand transport and rapid geomorphic response. In the middle shoreface, slow sand transport rates result in slow geomorphic change. Micro cells include smaller geomorphic features such as ripples and small beach-face features that change in times of a day or less. Meso cells include geomorphic features such as sand bars (*q.v.*), beach profiles, and beach cusps that change in a year or less. Macro cells extend kilometers and include large coastal geomorphic features (Figure B35).

Micro-scale beach features

When waves begin to shoal, there is a back-and-forth water motion at the seafloor with onshore and offshore excursions being equal. The sediment moves the same way, and symmetric *oscillation ripples* form normal to the direction of wave advance. Nearer to shore, the water motion at the seafloor becomes asymmetric because the onshore component of the wave orbits is larger than the offshore one. These *current ripples* have a gentle seaward facing slope and a steep onshore one. Near the breaker zone and in much of surf zone, the bed is flat because of intense water motion. However, current ripples can form in the seaward flowing *rip currents*.

At the upper swash limit, deposition of debris forms scalloped, marginal lines known as *swash marks*. Backwash flowing around small obstacles form seaward opening "V"s, and in some cases, rhombic patterns develop as a result of the minor currents generated in the backwash. Seepage of interstitial water down the foreshore slope at low tide cuts miniature channels termed *rill marks*.

Meso- and macro-scale beach features

Generally, sediment eroded from the foreshore and transported offshore forms one or more longshore bas with a trough shoreward of each one. The bars can extend alongshore for kilometers except for breaks caused by rip currents. Studies by Evans (1940), Keulegan (1948), King and Williams (1949), and Shepard (1950) concluded that there is a strong relationship between the bars and breaking waves. Keulegan, who studied bars formed in a laboratory wave channel, found that wave height and steepness govern the bar position. An increase in wave height moves the bar seaward (deeper water). Holding the wave height constant and reducing the wave period moves the bar shoreward. Starting with a smooth profile, the bar initially forms just shoreward of the breaker position. As it grows, both the bar and breakers migrate landward. When the bar is fully developed, it modifies energy transfer in the surf

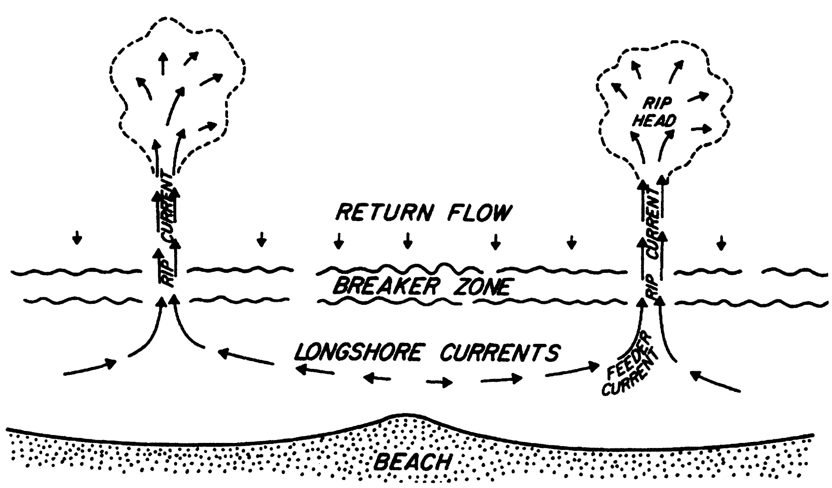

Figure B36 The nearshore circulation cell. Breaking waves create a circulation system where the water-driven shoreward across the surf zone travels alongshore (*longshore current*) and returns to the offshore via a strong, narrow flow (*rip current*) (after Komar, 1998).

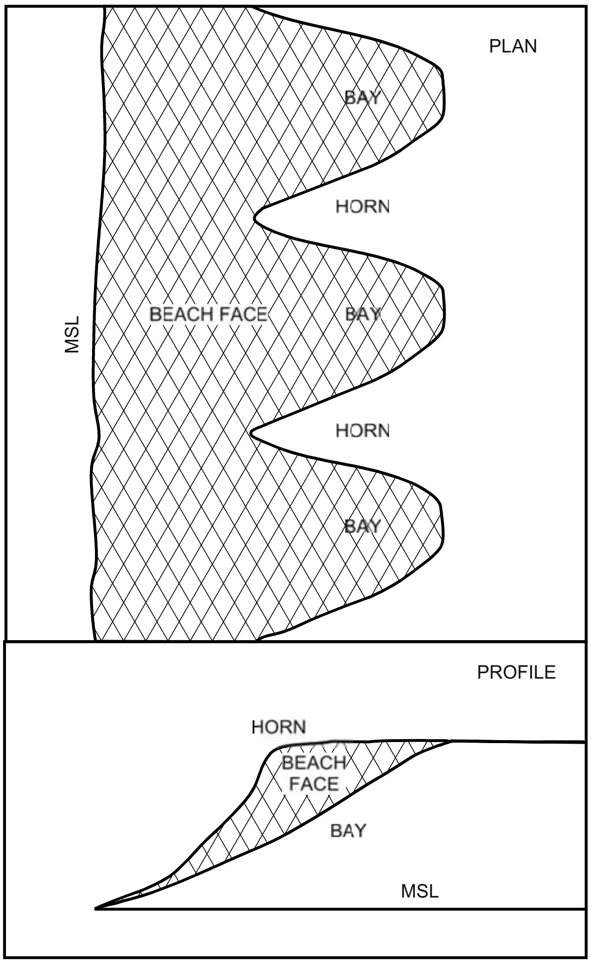

Figure B37 Plan and profile views of a cuspate beach.

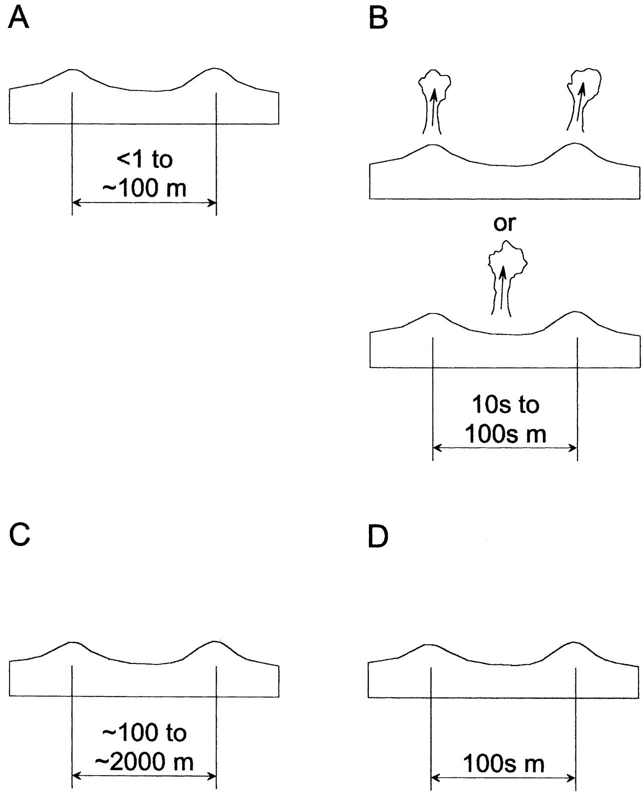

Figure B38 Classification of rhythmic shoreline forms: (A) reflective beach cusps; (B) rip current embayment cusps; (C) crescentic bay cusps; (D) transverse and oblique bars (after Komar, 1998).

zone by reducing the amount of energy that the breaking waves can impart to the waves that reform in the surf zone. Shepard (1950) found that there can be no bar and trough for short-period storm waves because there is not a well-defined breaker zone.

Beaches can be two- or three-dimensional based on the linearity of the berm and beach face. On two-dimensional beaches, the berm crest and foreshore contours are straight and parallel. On three-dimensional beaches, the berm crest and foreshore have rhythmic, crescentic features (*Beach Cusps: q.v.*) that vary greatly in height and length. All cusps are characterized by seaward facing ridges or *horns* separated by *embayments* or *bays* (Figure B37). Attempts to classify these features by size (e.g., Dolan and Ferm, 1968; Dolan *et al*., 1974) have been unsuccessful because there is a large overlap in sizes of cusps formed by different mechanisms. Komar (1983) developed a classification scheme with four types of cusps whose origins can be attributed to different processes of waves and currents within the nearshore (Figure B38). These are reflective beach cusps, rip current embayment-cusp systems, crescentic bar-cusp systems, and transverse and oblique bars (see Figure B38 for wavelengths).

There has been much disagreement as to the origin of reflective beach cusps. One recent theory is that *edge waves*, waves trapped at the shore with net motion in the longshore direction and decreasing amplitude offshore (Holman, 1983), play a role in the formation of beach cusps. In a laboratory wave tank, Guza and Inman (1975) found that beach cusps developed in response to edge waves. In the field, Huntley and Bowen (1978) observed the formation of cusps in the presence of edge waves. Werner and Fink (1993) proposed that beach cusps form through strong, positive feedback between wave run-up and beachface topography.

A rip current embayment-cusp system develops when rip currents erode the beach face creating embayments. The cusps are midway between the embayments (Bowen and Inman, 1969). The cusps correspond to positions of zero longshore sediment transport produced by waves combining with the feeder currents that flow alongshore toward the rip currents (Figure B36). In some cases, rip current erosion can be so extensive that the embayments cut across the beach, exposing foredunes and cliffs to wave attack (Komar and Rea, 1976; Komar and McDougal, 1988). Beach sediment can be deposited in the lee of a rip current so that the cusps correspond to the rip locations. This appears to occur most commonly on steep beaches under relatively low wave conditions (Komar, 1971).

Crescentic bars are rhythmic lunate features with uniform spacing primarily found underwater, commonly on long straight beaches (Shepard, 1952; Hom-ma and Sonu, 1963). They appear to be confined to regions of small- to medium-tidal range (Bowen and Inman, 1971) and form best where the beach slope is low. The generally accepted mechanism for their formation is by edge waves in the infragravity range (Bowen and Inman, 1971).

Transverse and oblique sandbars are nearshore features that do not parallel the beach, and they are welded to the beach face. There are various explanations for their formation that include the rotation of rip-current segmented bars (Sonu, 1972), processes akin to the migration of river bars or the development of river meanders (Bruun, 1954; Sonu, 1969; Dolan, 1971), and the superposition of edge waves (Holman and Bowen, 1982).

Beach change

Beach cycles

Various cycles affect the beach, depending essentially on changes in wave steepness and effective sea level. In regions of tidal action, the swash–backwash zone and breaker zone shift landward and seaward with the flood and ebb tide. The range of the tides and the slope of the foreshore determine the distance over which the shift takes place. With other parameters remaining constant, breaker height will be greater at high than at low tide. At high tide, the prevailing waves approach less hindered over the relatively deeper water of the nearshore, whereas at low tide, approaching waves are modified by the shoaler depths of the gently sloping nearshore bottom. Under this changing regime, scour may be slightly increased at high tide.

At approximately 7.5-day intervals, the tidal range changes from minimum (neap) to maximum (spring). The change from neap to spring tides can produce upper-foreshore erosion with lower-foreshore and nearshore deposition (LaFond, 1938; Inman and Filloux, 1960). LaFond and Rao (1954) postulate the cumulative result of higher effective sea level, higher waves, and a time lag in recovery during the low spring tide cause the redistribution of sand. The opposite sand movement can occur during neap tides.

Effects of beach erosion

Erosion strips sediment from the beach face and moves it to the nearshore or redistributes it alongshore. When enough sand is removed, there is no longer a high, wide beach, and waves can attack coastal features such as cliffs, dunes, and anthropogenic structures. In some places, storms transport beach sand across spits and barrier islands and deposit the sand in adjacent lagoons. If the sand returned to the beach is less than the volume eroded, the beach narrows, and if possible, the shoreline shifts landward.

Shoreline retreat is a natural process that is of little or no concern in unpopulated areas. However, in populated areas, shoreline retreat is a major issue. Several years can pass between storms severe enough to cause significant damage to a stretch of coast. Consequently, many people build or buy homes and other facilities on the coast with the idea that the adjacent beach is permanent. Later they watch storm waves remove the beach sand and directly attack their property or the coastal cliffs and dunes that protect them. Then, affected communities quickly want to know how to save their beaches and protect their homes and facilities. Although beaches usually rebuild after storms, a beach does not always return to its pre-storm position, and the community must take remedial measures to reverse long-term shoreline retreat.

Because storm waves threaten coastal facilities when fronting beaches lack sand, post-storm beach accretion is essential to minimize economic loss in the coastal zone. In areas where there is insufficient beach to protect coastal structures, there are several procedures to prevent or mitigate shoreline retreat. Traditionally, these procedures require building a protective structure (*q.v.*) on the beach or at the landward edge of the backshore. These include *seawalls*, *revetments*, *groins*, and *breakwaters*. While these structures often protect the property behind them, the fronting beach typically does not return because increased water turbulence at the structure prevents sand deposition during swell conditions (see Dean, 1999 for examples). The result is a section of coast with no beach, and if longshore sand transport is not properly taken into account, the shoreline downdrift of a structure also can lose its sand and retreat. Furthermore, structures often fail if improperly designed, allowing coastal retreat to resume.

Beach nourishment (*q.v.*) is another technique used to prevent shoreline retreat by augmenting the native beach sand with sand imported from other areas. Although beach nourishment creates wide beaches, this technique may not provide a long-term solution to beach loss especially where erosion rates are high or there is a persistent problem. A major problem is that the cost of importing sand can be high, especially since the sand should be similar in character to the native sand and because more sand is frequently needed after a storm season. When this technique is successful, there will be a year-around beach for public use and shoreline protection.

Other techniques include relocating coastal structures to allow for shoreline retreat and defining setback lines for coastal development. Shoreline retreat permits nature to take its course, but often is infeasible in populated areas. Setback lines, which are based on historical shoreline retreat rates, need to be implemented before coastal development begins.

Sediment budget and littoral cell

The budget of littoral sediments is simply an application of the principle of conservation of mass to the littoral sediments—the time rate of change of sand within the system depends upon the rate at which sand enters the system versus the rate at which it leaves. An analysis, therefore, involves evaluations of the relative importance of various sediment sources and losses to the nearshore zone, and a comparison of the net gain or loss with the observed rate of beach erosion or accretion.

The budget of littoral sediment involves making assessments of the sedimentary contributions (credits) and losses (debits) and equating these to the net gain or loss (balance of sediments) in a given sedimentary compartment or littoral cell (Bowen and Inman, 1966; Komar, 1996). The balance of sediments between the credits and debits should be approximately equivalent to the local beach erosion or accretion.

Table B3 The budget of littoral sediments

Credit	Debit
Longshore transport into the area	Longshore transport out of the area
River transport	Wind transport away from the beach
Sea cliff erosion	Offshore transport
Biogenous deposition	Solution and abrasion
Hydrogenous deposition	Mining
Wind transport onto beach	
Beach nourishment	

Table B3 summarizes the possible credits and debits of sand for a littoral sedimentary budget, while some of the more important components are diagrammed in Figure B39. In general, the longshore movement of sand into a littoral compartment, river transport, and sea-cliff erosion provide the major natural credits; longshore movement out of the compartment, offshore transport (especially through submarine canyons), transport into estuaries, and wind transport shoreward to form sand dunes are the major debits. Included in Table B3 are the major human-induced credits and debits, including beach nourishment, which is increasingly used to rebuild lost beaches, and mining (*q.v.*), which directly removes sediment from the nearshore.

Research techniques

More is known about the geomorphology of the coastal zone than about the processes that modify the geomorphology. For example, it has only been during the past decade that the coupling between waves, circulation, and changes in nearshore bathymetry has begun to be observed and modeled. In addition, research is now focusing on fluid velocities and particle flux profiles in the bottom boundary layer and in the surface boundary layer under breaking waves. Studies of velocity and sediment concentration measurements in the swash zone are moving forward with the development of new instruments.

At present, it is not possible to forecast the effect of an upcoming storm season on a section of coast. However, it is possible to ascertain both the ultimate storm profile and the rate at which a beach returns to its original profile or shifts to a new equilibrium profile. The principle method for obtaining quantitative data on beach change is to repeatedly survey a beach. Comparing the resulting profiles will give erosion and accretion rates for the time encompassed by the surveys.

Geomorphology

Various surveying techniques are available to determine the geomorphic character of the coastal zone. Offshore, a boat-mounted depth sounder can be used to measure the bottom profile (*Bathymetric Surveys: q.v.*), and a side-scan sonar can be used to collect oblique views of the bottom. Both of these techniques are limited to depths where boats can safely operate, which does not include the breaker and surf zones. Furthermore, their accuracy is limited because of boat movement by waves and currents.

Vehicles have been developed to measure beach profiles across the nearshore. These include remotely controlled tractors (Seymour *et al.*, 1978; Dally *et al.*, 1994), sleds (Sallenger *et al.*, 1983), and an 11-m high motorized tripod that can drive across the beach and into the nearshore (Birkemeier and Mason, 1978). MacMahan (2001) mounted an echosounder and a *global positioning system* (GPS) (*q.v.*) unit onto a waverider to profile from deep water through the surf zone.

Surveying with a rod and transit is the most common method used to obtain beach profiles. Techniques range from the "Emery Board" procedure that uses two wooden rods separated by a rope, to sophisticated instruments that use light beams to measure the distance to a prism. The vertical accuracy of the latter instruments can be less to than 1 cm. With all these instruments, however, a closely spaced grid of points can be difficult to achieve except in small beach areas. When a beach is two-dimensional, a single cross-shore survey is sufficient to characterize it, but a beach with cusps and other three-dimensional features requires multiple cross-shore and, in some cases, alongshore surveys. With temporal surveys along a fixed shore-normal line, the existence of cusps can cause errors in comparing beach volume and beach-face location. At present, kinematic GPS units mounted on survey rods and various kinds of vehicles are being used to rapidly survey large sections of beach (Kaminsky *et al.*, 1998).

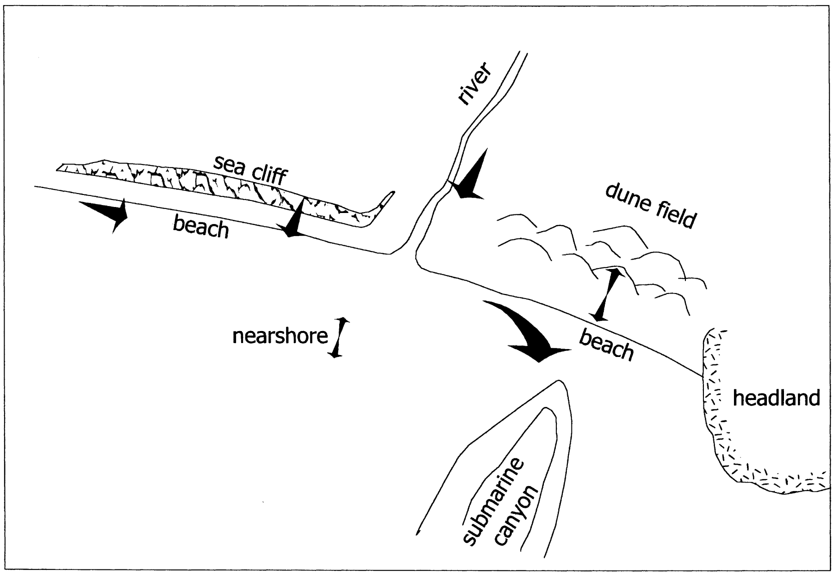

Figure B39 Principle constituents of a littoral zone sediment budget in a natural setting. Size of arrows is a rough indication of relative importance, though they can vary for a given situation. Not shown are anthropogenic impacts such as sand mining (after Komar, 1998).

Remote sensing techniques can be used to study large sections of the subaerial part of the coastal zone. Some of the techniques also can be used to look at geomorphic features in the nearshore. Air photos provide a qualitative look at the geomorphology, and quantitative measurements are possible with images that can be orthorectified. Such images are especially useful for measuring cliff retreat. Plant and Holman (1997) measured intertidal beach shape using a combination of time exposures and differential GPS. Lippmann and Holman (1989) investigated the locations and forms of offshore bars by taking several-minute time exposures from a camera mounted high above the beach and looking longshore. Recently, LIDAR (light detection and ranging) (*q.v.*), an airborne scanning instrument, has been used to map the subaerial part of the coastal zone (Brock *et al.*, 1999) and shallow parts of the nearshore (Irish and Lillycrop, 1999). These instruments are capable of rapidly estimating elevations to within a couple of centimeters approximately every 3 m^2 over regional scales.

Physical processes

Many instruments are available to measure water and sediment motion at all scales throughout the coastal zone. Many of them are sturdy enough to withstand the forces generated in the breaker and surf zones. Pressure sensors and bidirectional current meters have a sampling rate fast enough to measure water depth and wave-generated currents, respectively. Optical sensors measure sediment concentration. Sonic devices measure rapid changes in bottom elevation and, in some cases, the height of sediment suspension.

Future research in coastal processes

The goal of future research in coastal processes includes developing predictive models for:

- bedload and suspended sediment transport under combined wave and current forcing;
- turbulent wave/current boundary layers over 3-D small-scale morphology;
- effects of moving sediment on boundary layer;
- contribution to sediment transport by bedform migration;
- effects of grain-size distribution on sediment transport (Thornton *et al.*, 2000).

Morphology and its variability are important end products of predictive models. However, because sediment transport is not well understood, prediction of morphological change is inadequate at all scales. For example, at smaller scales, ripples and megaripples are observed to be ubiquitous, but have not been incorporated into models even though their effect on the flow field (as roughness elements) and sediment transport may be significant. Complex patterns in long-term, large-scale morphology have also been observed. However, models for morphology change have predictive skill only over the short term, whereas long-term, large-scale predictions are not yet possible. Research issues include:

- predicting morphology across the spectrum of length scales;
- free versus forced large-scale morphology models;
- understanding feedback between morphology and the flow field;
- coupling between length scales.

BEACH PROFILE

The beach profile is one the most studied features of coastal morphology. The shape of the beach profile determines the vulnerability of the coast to storms, the extent of usable beach for habitat and recreation, and the legal boundary distinguishing public and private ownership of land (Shalowitz, 1962, 1964; Anders and Byrnes, 1991). The first modern studies of the beach profile were motivated to understand its shape and variability in support of amphibious operations during World War II, when personnel and supply boats had to cross the beach profile from offshore to the dry beach (Bascom, 1980).

Beach profile terminology

The term "beach profile" refers to a cross-sectional trace of the beach perpendicular to the high-tide shoreline and extends from the backshore cliff or dune to the inner continental shelf or a location where waves and currents do not transport sediment to and from the beach. The profile shape is variable, depending on the time of year within the annual beach cycle and, also, the elapsed time after a storm. Waves, water level, and sediment grain size are the main controlling factors of beach profile shape.

Terminology associated with the beach profile is shown in Figure B40. The backshore runs from the seaward-most dune or the cliff to the land and water intersection. One or more berms may appear on a beach, depending on seasonal changes in water level. Berms are flat areas created during times of accretionary wave conditions, typically during summer. The beach intersects the water at the foreshore, and the foreshore is typically a plane slope that extends over a water level range from low tide to high tide. During a storm, a vertical step or scarp may form on the berm. The inshore covers the surf zone from the seaward end of the foreshore to past the seaward-most longshore sand bar, joining to the offshore. Several bars and associated troughs may appear on the beach profile.

Approximations of beach profile shape

As a first approximation, it is often possible to represent the profile of a gravel, pebble, or sandy beach (Here, the profile is assumed to have an unlimited supply of sand and that no "hard bottom" is present such as limestone reefs, coral reefs, and other non-erodable (hard) substances.) by a straight line of constant slope as,

$$h = x \tan \beta, \qquad \text{(Eq. 1)}$$

where h is the still-water depth, x the distance from shoreline, and $\tan \beta$ is the beach slope. This expression, defining a "plane beach" or planar beach slope has convenience for making simple calculations. Typically, however, the foreshore is the only area of the beach profile well represented by a straight line.

A more realistic representative profile shape was introduced by Bruun (1954) and studied extensively by Dean (1977, 1991). This profile is called the "equilibrium" or "x to the two-thirds profile" and is given as,

$$h = Ax^{2/3}, \qquad \text{(Eq. 2)}$$

where A is the shape parameter and will be discussed below. For water with temperature of about 20°C and typical sand sizes with sediment fall speed varying between about 1 and 10 cm s^{-1}, Kriebel *et al.* (1991) found that A could be related to fall speed w by,

$$A = 2.25\left(\frac{w^2}{g}\right)^{1/3}, \qquad \text{(Eq. 3)}$$

where g is the acceleration due to gravity. Moore (1982) was the first to study the functional dependence of A and found it to be an increasing function of the median grain size d_{50} for a wide range of materials. The empirical curve can be approximated by,

$$\begin{aligned} A &= 0.41(d_{50})^{0.94}, & d_{50} &< 0.4 \\ A &= 0.23(d_{50})^{0.32}, & 0.4 &\le d_{50} \le 10 \\ A &= 0.23(d_{50})^{0.28}, & 10 &\le d_{50} \le 40 \\ A &= 0.46(d_{50})^{0.11}, & 40 &\le d_{50} \end{aligned} \qquad \text{(Eq. 4)}$$

for which d_{50} is expressed in millimeters. The equilibrium profile can encompass a large range in grain size, as seen by the values in equation 4. Because the shape parameter A increases with increasing sediment grain size or fall speed, finer-grained beaches have gentle slopes and coarser-grained beaches are steeper, in accord with observations (Bascom, 1980).

Bars and troughs

Bars and troughs, also called longshore bars and longshore troughs, are the major perturbations from the equilibrium profile. Typically, areas with small tide range possess the most prominent bars because the wave breaker line remains in one position longer. Multiple-barred beaches are common on the Great Lakes, bays, and the Gulf of Mexico coast of the United States, for example, where the tide range is small. Some of these bars are formed by various predominant waves, such as typical waves and storm waves. Likewise, if the wave conditions occupy a relatively narrow range of height and period, such as on the north shore of Long Island, New York (facing the Long Island Sound), bars tend to be more prominent as compared to bars on the south shore of Long Island, because the Atlantic Ocean has a much more variable wave climate and smears out such bottom features.

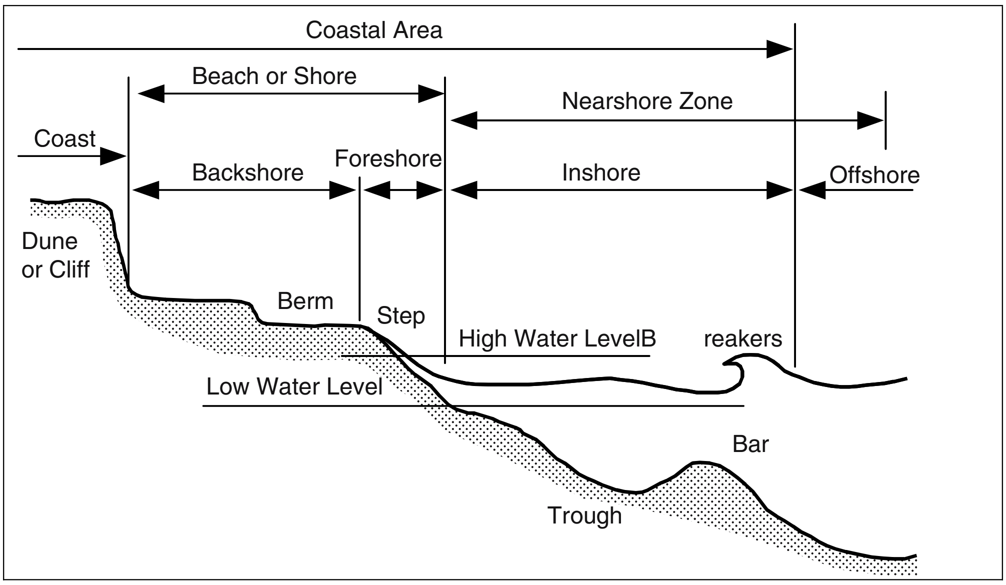

Figure B40 Terminology associated with the beach profile.

Larson and Kraus (1989) analyzed large-scale laboratory data for breaking waves and sandy beach beaches and found that the depth over the crest of a bar h_c was related to the breaking wave height H_b as

$$h_c = 0.66\ H_b. \qquad \text{(Eq. 5)}$$

Conversely, if the depth over the crest of a well-established bar is measured, the breaking wave height that created the bar may be inferred from equation 5 to be $H_b = 1.5\ h_c$.

The beach profile at North Padre Island, TX, located along the Gulf of Mexico, was surveyed in the mid-1970s in one of the earliest applications of a sea sled, and then again in the mid-1990s with a sled, assuring high accuracy (see Profiling, Beach). Figure B41 plots a time series of surveys made at the same location on the beach. In both eras, profile elevation was referenced to mean sea level (MSL) at a local ocean tide gauge. Although the beach may have advanced or receded during the two decades, the shape of the profile can be compared because of the common vertical datum.

Figure B41 indicates that one to three (occasionally four) bars can appear on the profile at North Padre Island. It can be estimated through equation 5 that these bars are related to different classes of waves as outer bar—severe storm waves; middle bar—typical storm waves; and inner bar—waves under normal Gulf of Mexico conditions. In Figure B42, the average of 18 beach profile surveys taken alongshore at North Padre Island in 1996 is plotted together with the equilibrium ($x^{2/3}$) profile, equation 2, determined by the median grain size in the surf zone (0.18 mm). Sediment sampling performed during the surveys demonstrated a decrease in grain size with distance offshore, and such a decrease in size of surficial sediments is typical along the beach profile, with the coarsest material located at the beach face and bars, and the finer material located offshore. Coarse material is also found at the landward sides of longshore bars, because the finer material is transported away from this hydrodynamically energetic area.

Seasonal characteristics of the beach profile

During winter and the occurrence of seasonal storms (periodic northeasters, tropical storms, hurricanes), waves and cross-shore currents remove material from the beach and deposit it in bars far offshore. Large volumes, for example, 30–100 $m^3\ m^{-1}$ width of beach, can be removed from the beach berm and dune in a single large storm. Whether a beach will erode or accrete and the bar move onshore or offshore can be estimated with a dimensionless parameter called the Dean number formed as $N = H/wT$, where H is the wave height in deeper water, w is the beach sediment fall speed, and T is the wave period. For $N > 3.2$, erosion is

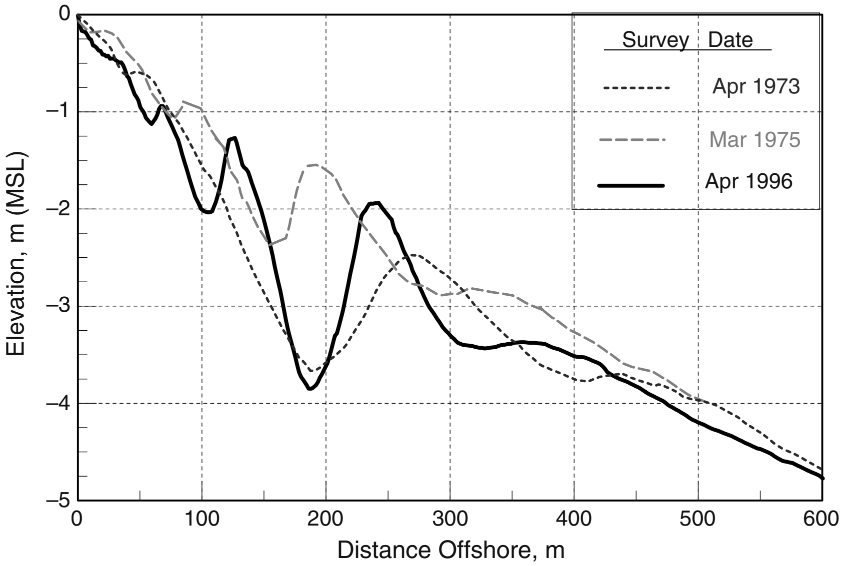

Figure B41 Beach profile surveys taken by sled two decades apart, North Padre Island, TX.

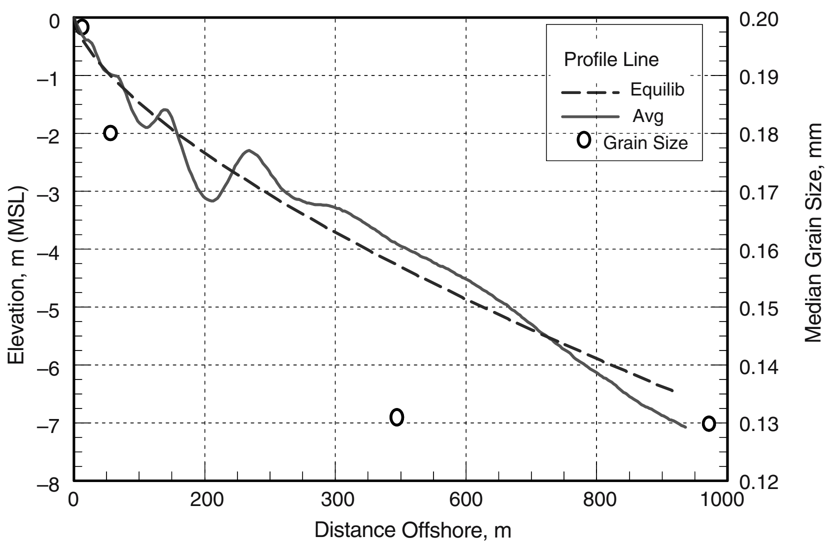

Figure B42 Average beach profile and equilibrium profile, North Padre Island, TX, 1996.

probable, whereas for $N < 3.2$, accretion is probable (Kraus *et al.*, 1991). Large values of the Dean number tend to occur during storms, when wave heights are large, and small values tend to occur in the summer, when wave heights are small or after storms, when the wave period of the swell waves becomes long. During the following milder accretionary waves of summer, material gradually moves onshore and returns to the beach, deflating the bar(s) and building the berm. Wind-blown sand then gradually rebuilds the dunes.

Sometimes, storms can be so severe that the beach does not recover on the timescale of human lifetime or engineering projects. Such is probably the case on the south shore of Long Island for the "Great New England Hurricane" of September 1938, which weakened the barrier islands and caused many breachings or cutting of temporary inlets. Sand taken offshore by such strong storms lies is such deep water that summer or "recovery" waves cannot readily transport it back to the beach.

The seasonal averages of a large number of surveys made on the same cross-shore transect (Line 62) are plotted in Figure B43. The surveys were made at the US Army Corps of Engineers' Field Research Facility (FRF), in Duck, NC, located on the "Outer Banks" barrier island chain. The profile is surveyed every two weeks as routine monitoring or more frequently for specific research goals by means of a large motorized tripod, estimated to have a vertical accuracy of ± 2 cm. The National Geodetic Vertical Datum (NGVD) is close to MSL at the FRF. Bars are absent from the plots because the average is taken over a large number of surveys. Sand moves offshore in winter (arbitrarily defined as the interval January to March) and returns in summer (June–August). A broad hump in the winter average at about 2–4 m depth indicates the presence of storm bars during that season. During summer months, the steep profile in shallower water created by the winter waves is gradually replenished and becomes shallower.

One property of the beach profile observed in Figure B43 is that the spring (April–June) and fall (October–December) average profiles almost plot on top of one another, and in between the two terminal states of summer and winter (Larson and Kraus, 1994). The regularity in profile response to waves indicates that the processes should be predictable with relatively simple techniques. Although not shown, the average of all profiles corresponds well with the equilibrium profile with a median grain size of 0.2 mm.

The seasonal response of the profile is shown in another way in Figure B44, which plots the average change in depth irrespective of sign (absolute value) as a function of average depth for the winter and summer profiles. The change in depth is less in summer than in winter, which is intuitively reasonable because waves are smaller in summer. The average maximum depth change occurs in winter, near the shoreline, and is

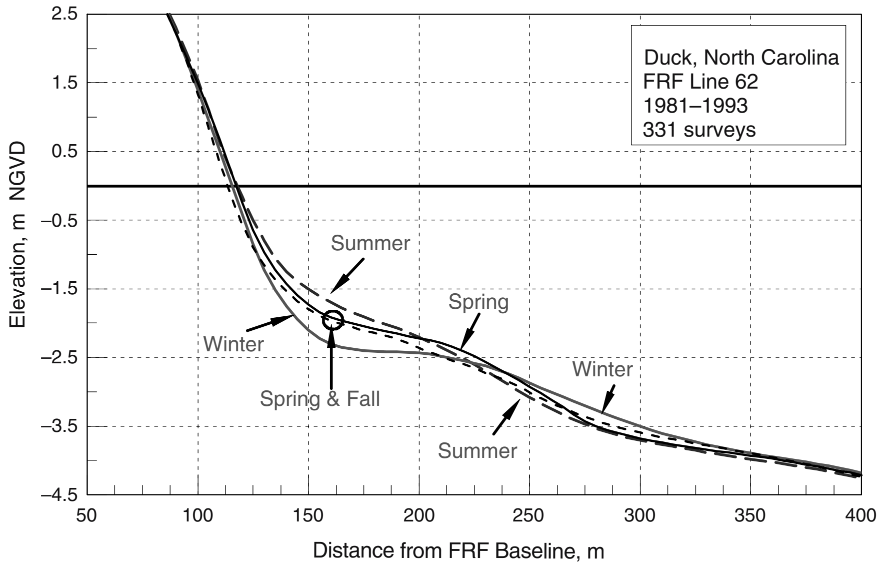

Figure B43 Average seasonal profiles, Duck, NC.

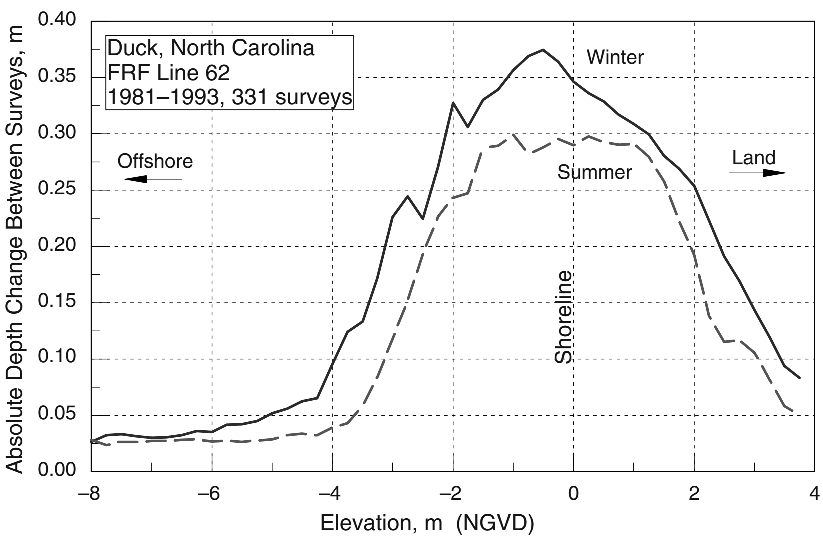

Figure B44 Average absolute depth change for summer and winter surveys, Duck, NC.

about 0.5 m (1.5 ft). The location where the profile changes little through time, delineating the area where sediment in the offshore is no longer exchanged with the beach, is called of the depth of closure (Kraus *et al.*, 1999). Knowledge of how much the profile elevation changes is required for modeling coastal processes, for designing beach fills, for placing pipes, outfalls, and cables, across the surf zone, and for placement of instruments so that they do not become buried.

BEACH RATING—See RATING BEACHES

BEACH RIDGES

Definitions

Johnson (1919) defined beach ridges as depositional features constructed by waves at successive shore positions. Reineck and Singh (1975) characterized beach ridges as having been formed at high-tide level of "rather coarse sediment" and related to storms or exceptionally high water stages. Bates and Jackson (1980) designated beach ridges as low mounds of beach and beach-and-dune material, heaped up by waves over the backshore beyond the present limit of storm waves or ordinary tides, but there is a risk of confusing wave-deposited and wind-deposited ridges. Referring to relict strandplain dunes as beach ridges, Carter (1986) used the term very broadly to cover "all large constructional forms of the upper beach, capable of preservation," applying it also to landward-shifting offshore bars, already welded swash bars, and prograded berm ridges.

Davis *et al*. (1972), Fraser and Hester (1977), Carter (1986, 1988) and others referred to onshore-migrating swash bars and/or to the stranded end products as "beach ridges." For some time after welding to the shore, the prograding sandy berm ridges may continue to be impacted by daily beach processes. Most North American and Australian authors considered stabilized onshore beach ridges as either of predominantly wave-built or of wave and wind-constructed, composite origin (e.g., Price, 1982). Hesp (1984, 1985), Mason (1990), and Mason *et al*. (1997), thus distinguishing between low profile "smooth, terrestrial," squat berm ridges and steep dune ridges that often overlie and bury them.

Beach ridge presently is defined as a relict shore ridge that is more or less parallel with the coastline and with other landward-adjacent ridges. It is built by wave swash (a berm ridge) that may be surmounted by wind-deposited sediment (a foredune). Once such a ridge becomes isolated from daily active beach processes by coastal progradation, which may lead to the construction of one or more new ridges to seaward, it becomes a beach ridge. On wide eolian backshore plains, shore-parallel dune ridges may also form behind active foredunes. Regardless of their dimensions, shapes, and origin, active beach/shore ridges impacted and modified almost daily by shore processes are excluded from the designation.

Associated landforms

A berm was originally defined as a narrow, scarp-backed, and wave-cut horizontal surface in the beach foreshore (e.g., Komar, 1976). Subsequently, it came to mean a wedge-shaped ridge, between an upper foreshore slope and a landward-inclined berm top surface (King, 1972). Its base is the horizontal plan that intersects the foreshore slope at the level of the backshore plain. Hine (1979) defined a berm as a shore-parallel linear body of triangular cross section with a horizontal to slightly landward-dipping surface (berm top) and a steeper seaward-dipping slope (beach face). Berms are short-lived and frequently reforming landforms, often absent from a beach.

Swash currents deposit sediment that builds the landward-sloping high-tidal berm above the level of the adjacent backshore. The ephemeral high-tidal sand berms are of aggradational origin, with secondary indications of erosional scarping. Increased onshore winds during falling tides briefly stabilize the water level. Intermediate-level berms with vertical scarplets may form during these stillstands.

Berm ridges, occasionally sizable and more permanent than berm surfaces are wave-built intertidal-supratidal landforms. The lithosomes are composed of intertidal and high tidal (swash-overwash) deposit, bounded by the backshore plane and the berm surface along its foreshore margin (Figure B45). After becoming isolated by progradation from the daily effects of beach processes, these inactive landforms attain the status of wave-constructed beach ridges. Formed on mainland or island beaches or on shore-parallel sand spits, berm ridges are bracketed between the foreshore and the landward (or lagoonward) margin of the backshore. On the landward side they may follow the shoreline of an elongated lagoon or beach pond ("cat's eye pond"; Coastal Research Group, 1969), enclosed by a sand spit (Figure B46). Shore-parallel inter-ridge swales bracket each ridge. Sets of prograding berm ridges form on beaches of limited sand supply. Short *et al*. (1989) reported on a nearly exclusively swash-built beach ridge plain in Australia, and in Egypt, Goodfriend and Stanley (1999) described a shelly sandridge plain, composed of 20–30 cm high, wave-built ridges without eolian cover.

Several authors have regarded high-tidal sand berms as incipient (wave-built) beach ridges during the Australian "berm debate" (Davies, 1957; Bird, 1960; Hails, 1969). Later, Bird and Jones (1988) proposed that if a berm survived a 15-day tidal cycle, it becomes a beach ridge. Berms have also been credited with providing a foundation for the development of embryonic foredunes that develop into full-sized ones (Davies, 1957; Bird and Jones, 1988). However, foredunes often form along the seaward margin of the backshore plain as well. The presence of berms, often absent from beaches, especially from dissipative and high-energy beaches (e.g., Short, 1984), is not an indispensable precondition for foredune development (Hesp, 1984, 1985).

Berm formation by wave action on the Tabasco shore of the Gulf of Mexico has been attributed to alternating "cut-and-fill" cycles of erosion and aggradation (Psuty, 1966). This berm-shaping process,

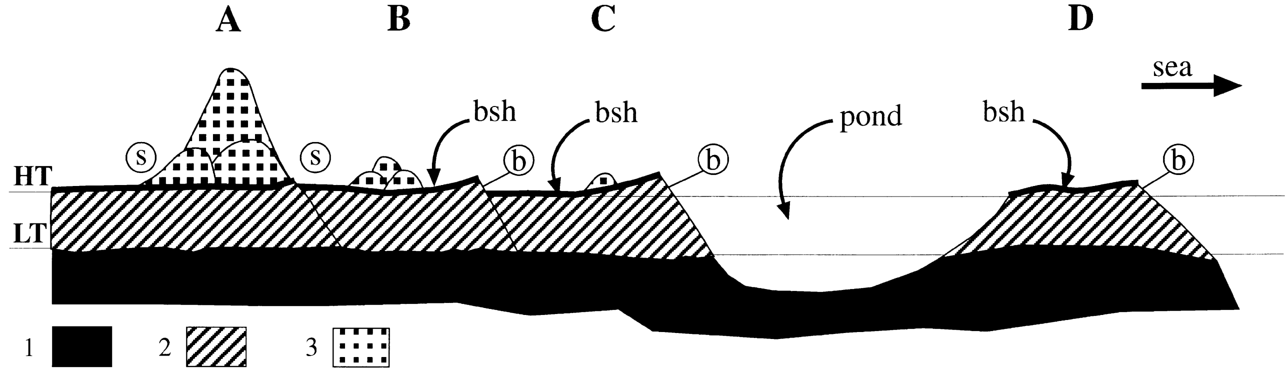

Figure B45 Beach ridge-associated depositional facies and landforms on a prograding strandplain. Depositional facies: (1) subtidal; (2) wave-built, intertidal-to-supra-high tidal; (3) eolian. Landforms: b, berm; bsh, backshore plain; s, swale; A, foredune; B, accreting embryonic dunes on backshore plain in the early foreshore stage; C, single embryonic dune on berm ridge (backshore-berm) surface; pond: spit-growth-enclosed beach pond; D, pond-isolated berm ridge (intertidal-supratidal sand spit interval), without embryonic dunes. HT, high-tide level; LT, low-tide level. (Otvos, 2000) Reprinted with permission from Elsevier Science.

however, appears to be a localized and ephemeral phenomenon without bearing on long-term strandplain development. The adjacent, 20-km wide Tabasco strandplain, for example, has been receiving abundant eolian sand supply and represents a foredune ridge plain, underlain by backshore and berm ridge deposits.

Truncation lines that separate mainland and island beach ridge sets

Where beach ridge progradation has been abruptly terminated by shore erosion, then followed by renewed beach growth, there are cross-cutting truncation lines that separate generations of beach ridges in mainland and island barriers of Quaternary age. This process was historically documented on several Mississippi coast strandplain islands (Otvos, 1981). The St. Joseph Bay-area barrier spit and small mainland strandplains in NW Florida provide good illustrations (Figure B47).

Gravel-boulder ("storm") ridges. Storm-associated high tides and waves build gravel ramparts as high as 6 m (Clapperton, 1990). Gravel-boulder ridges, associated with storm surges therefore rise well over their associated sea (lake) levels. Coarse clastic sediments, including shelly material resist backwash erosion and become stranded on these shore ridges. Permanent shingle emplacement at superelevated tide levels is aided by backwash percolation into the permeable gravelly substrate (Carter, 1988). For a given still-water level, the height of wave-built ridges built during winter storms may vary by as much as 2–2.6 m (Adams and Wesnousky, 1998). These "storm" ridges are common on glaciated and bedrock shores; also on tectonically or isostatically raised marine and lacustrine terraces. Examples abound in Canada's Maritime Provinces, New England, and on high Pacific shores between Alaska and Mexico.

Coarse clastic beach ridges or bedrock terrace veneers accompany raised strandlines of pluvial and glacial lakes in the North American interior basins (Fulton, 1989; Morrison, 1991). Coarse clastic sediments were delivered by high-gradient streams, alluvial fans, mass wasting, occasionally even fluvioglacial processes. Adjacent bedrock areas that served as sediment sources have undergone intensive physical weathering under periglacial and cold-temperate conditions. Pluvial Lake Bonneville and its successor, early stage Great Salt Lake in Utah and Nevada; as well as Lake Lahontan in Nevada and California provide the best examples (Morrison, 1965, 1991; Currey, 1980; Adams and Wesnousky, 1998, 1999). Gravel-boulder ridges, deposited on wave-cut bedrock terraces form discontinuous tabular and tabular cross-stratified bodies, several meters thick (Adams and Wesnousky, 1998). Playa beach ridges that contain carbonate nodules, include paleosols and incorporate secondarily calcreted and gypsum-creted grit in the arid Lake Eyre basin, Australia, one of the world's largest internally drained regions (Nanson *et al*., 1998).

Bouldery-gravelly coarse clastic sediments that often dominate ice-dammed glacial lake shorelines along the fluctuating glacial margin in North America have originated from reworked moraine till, fluvioglacial delta, periglacial colluvium, and in particular ice-contact (esker, kame, outwash delta) deposits. Major examples include relict shore features on glacial Lakes Agassiz, Algonquin, and Ojibway (Fulton, 1989, pp. 144–145, 257, 343, 362–364). Due to sand scarcity, the short life span of a given strandline, and erosive wave regimes, instead of regular beach ridges gravelly-bouldery shore zone lags frequently veneer wave-cut lake terrace surfaces.

Sediment types and ridge forms of sandy beach ridges. Depending on the wide range of wave and current conditions and source sediments on a given marine or lake shore sector, the upper beach deposits (intertidal–supratidal intervals) may be represented by fine-to-coarse, even gravelly sands in the berm ridges. Whereas, sorting tends to be good in uniformly sandy beaches, it becomes moderately sorted when coarser clastic fractions are also included (e.g., Thompson, 1992). Chappell and Grindrod (1984) described a rare transition between sandy ridges of a regular beach ridge plain and a small adjacent chenier plain, composed of shell-rich ridges. Reflecting the low relief and gentle seaward and landward slopes of the berm ridges, basinward-dipping parallel laminae and low-angle (3–5°) cross lamination tend to characterize the upper foreshore slope.

Subhorizontal or gently landward-dipping laminations occur on the landward beach ridge surfaces. The highly variable beach ridge dimensions, the height above still water level and slope angles depend on wave conditions, local tidal, or lake level ranges, including wind-induced rise in sea and lake-levels along given shore sectors.

"Pebble-armored ridges." Pebble sheets plastered onto sand dunes during storms were designated as gravelly ramp barriers (Orford and Carter, 1982; Mason, 1990). The hydraulic ratios and shapes of shell bioclasts result in higher transport and dispersal rates than with regard to larger, denser silicate rock clasts. Whereas, gravel/boulder ridges accumulate during direct storms, their impact tends to flatten and disperse already existing ridges, composed of sand and lighter, platy shell clasts (Greensmith and Tucker, 1969; Rhodes, 1982, p. 217). Higher-energy events enable accumulation even of bioclastic rudites (Woodroffe *et al*., 1983; Meldahl, 1993).

Beach ridges, strandplain versus terrace development

Strandplain formation may be a continuous process with grain-by-grain addition of sand to the widening foreshore. Continuous progradation of the neap berm at mid-to-high level results in a gently undulating, almost level beach plain. On mesotidal foreshores where neap high tide remains below the highest foreshore levels, continuously accreting neap berms are uninterrupted by inter-berm swales (Hine, 1979, Figure 17(A)). Increased sand supply along the low-microtidal Gulf of Mexico beaches leads to steady outbuilding of the foreshore, accompanied by consequent progradation of narrow, closely spaced beach ridges. Discontinuous beach ridge progradation involved either the stranding or remolding of landward-migrated mesotidal swash bars on the foreshore (Hine, 1979; Carter, 1986) or spit growth from and downdrift reattachment (Figure B46) to the beach in microtidal settings (Otvos, 1981). Both processes isolate elongated ponds. Fronted seaward (lakeward) by newly formed active foredunes, and slowly filled by eolian and washover sands, such ponds may gradually become wide supratidal inter-ridge swales (Figure B46).

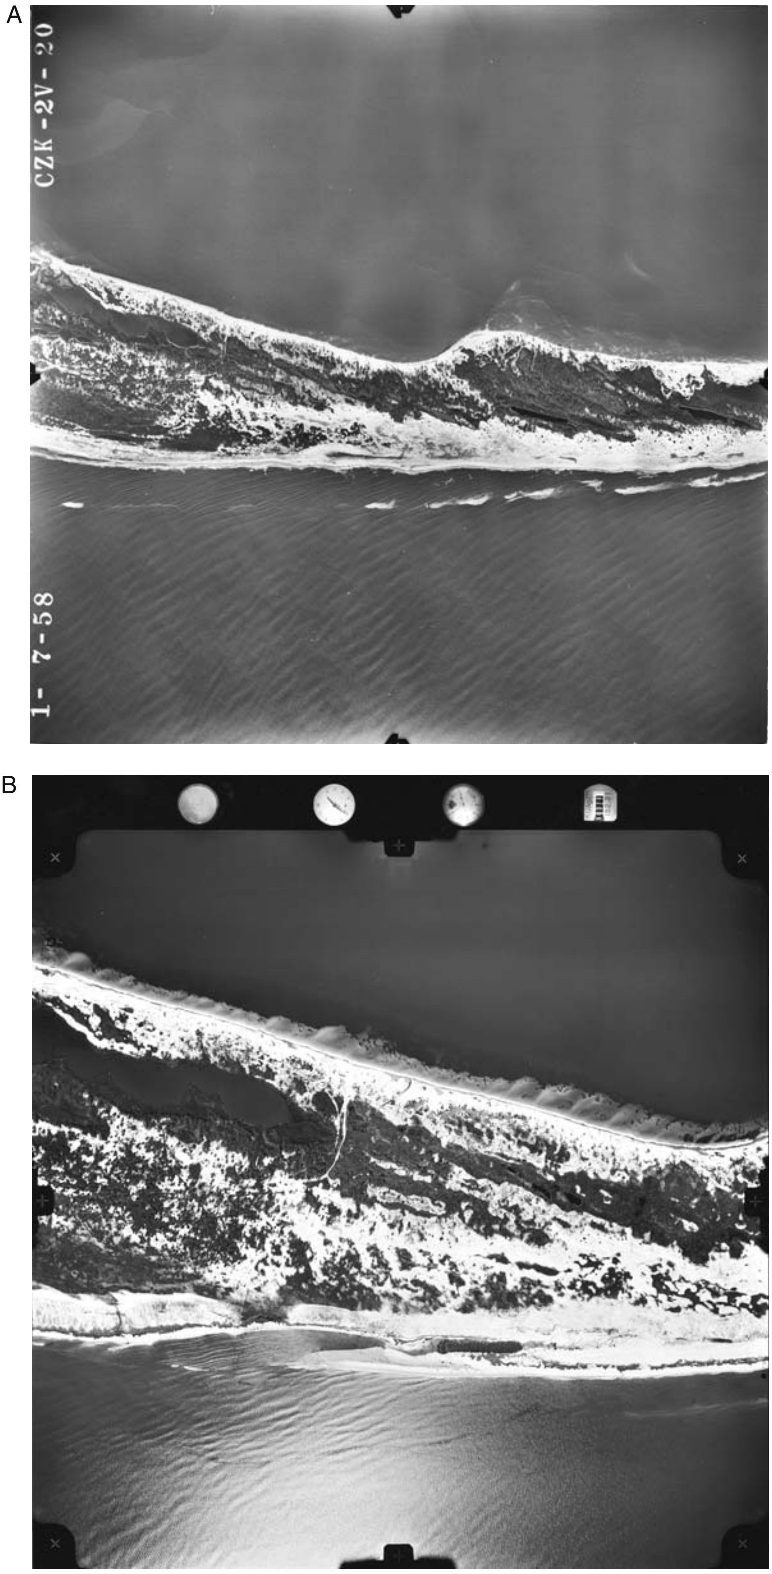

Figure B46 Prograding strandplain, southeastern Horn Island, MS. (A) Inter-swale ponds between old beach ridge sets in wooded interior. Elongated shore-parallel ponds of different orientation isolated from Gulf of Mexico (south) by barren narrow strip of backshore and berm ridges (USDA aerial photo, January, 1958. Width of image: 4.56 km). (B) Eleven years later: western half of previous image. Shore-parallel westward spit and spit-platform growth about to form new cat's eye pond (bottom). Already isolated beach pond to east. Eroding (white) and forested (dark) old interior beach ridge sets, with swale ponds in the island interior (USCGS aerial photo, October, 1969. Width of image: 2.3 km).

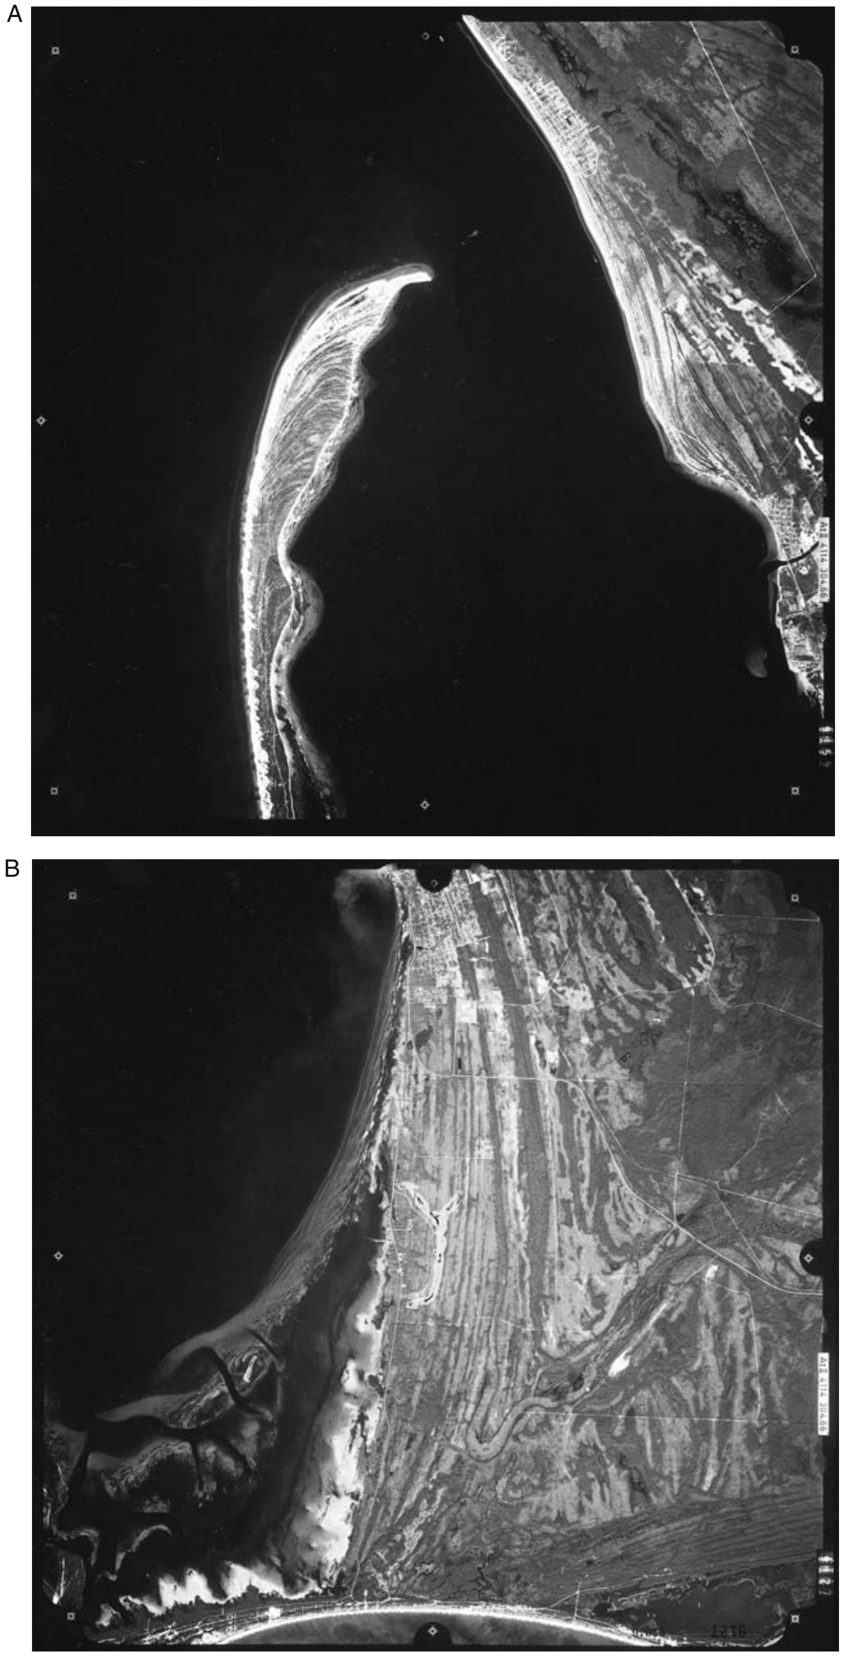

Figure B47 (A) Generations of narrow Late Holocene strandplain fans, northern St. Joseph Bay, NW Florida. Left: north tip of St. Joseph Peninsula (barrier spit). Right: small Holocene Palm Point mainland strandplain. Upper right corner: wide Late Pleistocene (Sangamon) beach ridges and partially filled swales represent erosion-impacted strandplain sectors. (B) St. Joseph Bay, NW Florida. Quaternary strandplains. Wide beach ridges of N–W-trending Late Pleistocene (Sangamon) strandplain (center field of photo) again contrast with narrow, crisply outlined Late Holocene strandplain ridges (lower right corner) (USGS aerial photo, October, 1978. Width of image: ca. 15 km). (Otvos, in press).

A comparison of Late Pleistocene strandplain ridges with the sharply outlined, narrow Late Holocene beach ridges illustrates the fact that prolonged infilling and erosional modification of Pleistocene strandplain ridges result in more subdued, more gently sloping beach ridges, separated by wider swales (Figure B47).

Instead of strandplains, gently undulating, nearly level eolian sand terraces form when sand supply and beach progradation does not keep pace with rapidly growing and sand-trapping beach vegetation. Beach progradation and/or eolian sand supply rates under these conditions are relatively low (e.g., Ruz and Allard, 1994).

Rates of beach ridge development

Depending on ridge dimensions, sediment supply rates, hydrodynamic and vegetative conditions, beach ridge development may proceed slowly or quickly. Thus, Nanson *et al.* (1998) report on a beach ridge along an Australian playa lake that during a high lake stage, formed in less than one year. Development rates in a number of other calculated examples from worldwide locations ranged between 1.8 and 3.3 yr/ridge, at other sites the rates were as low as 30–150 yr/ ridge (in: Otvos, 2000, pp. 90–91).

Beach ridges as ancient sea/lake levels markers

Former sea (lake) levels may be identified when a hortizontal interface is recognizable between the wave-built foreshore and the overlying eolian lithosome in a given ridge. This was the case in Lake Michigan strandplain ridges (Fraser and Hester, 1977; Thompson, 1992) where low-angle sand and gravel cross beds and trough-cross-bedded lacustrine sands of wave-built origin underlie land snail-bearing, cross-bedded, in part massive, structureless dune sands. On pure sand beaches that lack granule and pebble clasts due to the very short transport distance from the immediately adjacent source of sediment, distinctions between wave- and wind-deposited lithosomes often are difficult or impossible to make on granulometric grounds alone.

At times of superelevated lake and sea levels, associated with storm-related temporary rise of the water levels wave-built sandy, shelly, or gravelly beach ridges may aggrade significantly above normal high-tide levels (e.g., Mason, 1990; Mason and Jordan, 1993). Precise reconstruction of former sea levels from beach ridges therefore may be problematical.

Similar to beach ridge summits, coarse clasts are useful markers of reference surfaces to document postdepositional tectonic and isostatic changes, including vertical displacement, tilting, and warping of the land surface. In their absence, wave-cut bedrock terraces and lag clast-veneered strandlines may also serve this purpose. Strandline stairsteps were documented on isostatically uplifted marine and glacial lake shores in subarctic North America and Scandinavia (e.g., Hudson Bay, Tyrell Sea; Fulton, 1989). Flights of raised beaches characterize former pluvial/playa lake shores in western North America, Australia, and other presently arid and semiarid regions. Bounding surfaces of lower foreshore Lepidopthalmus (formerly, Callianassa) ghost shrimp-burrowed barrier ridge deposits and correlative adjacent lagoonal-saltmarsh surfaces in six Late Pliocene-Pleistocene coastal terrace sequences were similarly utilized on the Georgia-northeast Florida seaboard (Hoyt, 1969).

BEACH SAFETY—See LIFESAVING AND BEACH SAFETY

BEACH SEDIMENT CHARACTERISTICS

Beach sediments are derived from a wide variety of sources, including cliff erosion, rivers, glaciers, volcanoes, coral reefs, sea shells, the Holocene rise in sea level, and the cannibalization of ancient coastal deposits. The nature of the source and the type and intensity of the erosional, transportational, and depositional processes in a coastal region determine the type of material that makes up a beach. In turn, the characteristics of the sediments strongly influence beach morphology and the processes that operate on it (Trenhaile, 1997).

Grain size

The grain size of pebbles and other large clastic material can be measured with callipers, and sieves are used for sand and other coarse beach sediments. A number of techniques are used to determine the size of finer sediments including Coulter Counters, pipettes, hydrometers, optical settling instruments, and electron microscopes. The grain size can be expressed using the Wentworth scale, which is based on classes that are separated by factors of two, so that each is twice the size of the one below. A $\log_2$ transform can be used to provide integers for each of the Wentworth class limits:

$$D_\phi = -\log_2 (D_{\mathrm{mm}})$$

where D_ϕ is the grain diameter in phi units (ϕ) and D_{mm} is the corresponding diameter in millimeters (Table B4). Unfortunately, the term "grain diameter" can refer to several different things (Sleath, 1984):

(1) the mesh size of the sieve through which the grains are just able to pass;
(2) the diameter of a sphere of the same volume;
(3) the length of the long, short, or intermediate axes of the grain, or some combination of these lengths; or
(4) the diameter of a smooth sphere of the same density and settling velocity as the grains.

Table B4 Sediment grain size classification

Type	ϕ units	Wentworth (mm)
Boulder	>-8	>256
Cobble	-8 to -6	256–64
Pebble	-6 to -2	64–4
Granule	-2 to -1	4–2
Sand		
Very coarse sand	-1 to 0	2–1
Coarse sand	0–1	1–0.5
Medium sand	1–2	0.5–0.25
Fine sand	2–3	0.25–0.125
Very fine sand	3–4	0.125–0.0625
Silt		
Coarse silt	4–5	0.0625–0.0312
Medium silt	5–6	0.0312–0.0156
Fine silt	6–7	0.0156–0.0078
Very fine silt	7–8	0.0078–0.0039
Clay		
Coarse clay	8–9	0.0039–0.00195
Medium clay	9–10	0.00195–0.00098

The weight-percentages of the sediment can be plotted against the diameter in phi units in the form of histograms or frequency curves. Grain-size distributions are most frequently represented, however, by plotting the grain size data on a probability, cumulative percentage ordinate, and the phi scale on an arithmetic abscissa. The percentiles on the cumulative size distribution can be used to estimate the mean, standard deviation, and other simple descriptive statistical measures, although the calculations can also be made by computer. For comparative purposes, sediment samples can be represented by the mean or median grain size, or by the size of the grain that is coarser than some percentage of the sample.

There have been many attempts to identify the transportational processes and the depositional origin of sediments based on their sediment-size distributions. The grain-size distributions of beach sediments often consist of three straight-line segments, rather than the single straight line of a normal distribution plotted on a Gaussian probability axis. The three segments have been variously interpreted as representing: coarse bed load, fine suspended load, and intermediate-sized grains that move in intermittent suspension; the effect of packing controls on a grain matrix, the larger grains being a lag deposit, with the finest grains resting in the spaces between grains of median size; and different laminae in the beach, representing several depositional episodes. A further possible explanation is that the segmentation of grain-size distributions on log-normal cumulative probability paper may reflect the use of an inappropriate probability model. The log-normal model poorly represents the extremes of natural grain-size distributions, which may conform much better to a hyperbolic probability function (Trenhaile, 1997). Some workers believe that the four parameters of a logarithmic hyperbolic distribution are more sensitive to sedimentary environments and dynamics than the statistical moments of the normal probability function, but others have found that there is little difference (Sutherland and Lee, 1994). Grain sizes may also be fitted to a skew log-Laplace model, a limiting form of the log-hyperbolic distribution which is essentially described by two straight lines, and is defined by three parameters (Fieller *et al*., 1984).

Grain shape

The shape of beach grains can be expressed in various ways. The roundness of a grain, which refers to the smoothness of its surface, has been defined as the ratio of the radius of curvature at its corners to the radius of curvature of the largest inscribed circle. Grain sphericity describes the degree to which its shape approaches that of a sphere with three equal orthogonal axes. The shape of a grain can range from spherical, to plate, to rod-like forms, according to the relationship between the three axes, which can be depicted in the form of a ternary diagram. Grain shape can be measured and defined using a variety of indices. They include the E shape factor (ESF):

$$\mathrm{ESF} = D_s\left[\frac{D_s^2 + D_i^2 + D_l^2}{3}\right]^{-0.5}$$

and the Corey shape factor (CSF):

$$\mathrm{CSF} = \frac{D_s}{(D_i D_l)^{0.5}}$$

where D_l, D_s, and D_i are the long, short, and intermediate axes of the grain, respectively.

The shape of coarse clasts can be determined fairly easily by direct measurement, but this is usually impossible or too time-consuming for sand and other small grains. Therefore, the roundness and sphericity of sand grains has often been estimated by visual comparison with a set of standard grain images of known roundness, although Fourier analysis is increasingly being used (Powers, 1953; Thomas *et al*., 1995). Winkelmolen's (1971) "rollability" index, the time taken for a grain to roll down the inside of a revolving, slightly inclined cylinder, is easier to measure than other shape parameters, and the shape distribution factors, obtained by plotting grain rollability against grain size, may be more characteristic and indicative of the mode of origin of coastal sediments.

Grain density

The density of a grain is determined by its mineralogy (Table B5). In temperate regions, most beach sediment originated from the granitic rocks of continents, and they largely consist of quartz and, to a much lesser extent, feldspar grains, but carbonates may dominate in the tropics, especially where there are coral reefs. The sediments in pocket beaches enclosed between prominent headlands, and in beaches derived from other restricted source areas, however, can be strongly influenced by the mineralogy of the local geological outcrops, or by the accumulation of shelly carbonate material. Beaches can consist almost entirely of heavy minerals in volcanic areas, and the usually small amounts of heavy minerals in continental beach sediments, such as magnetite, hornblende, and garnet, help to identify the source rocks, their relative importance, and the direction of longshore transport.

Bulk density and packing

Bulk density reflects the way the grains are arranged or packed together. Spherical grains of uniform size can be packed in four ways. The centers of grains in unstable cubic packing describe the corners of a cube, whereas a tetragonal arrangement is formed by moving the upper layer of grains so that they occupy the hollows between the grains below. With orthorhombic packing, the centers of the lower layer of grains form a diamond pattern, with the centers of the grains in the upper layer directly above. A rhombohedral arrangement is created by moving the upper layer of grains into the hollows created by the lower layer. The porosity of the sediments is 48%, 30%, 40%, and 26% with cubic, tetragonal, orthorhombic, and rhombohedral packing of spherical grains, respectively.

The shape of the grains exerts an important influence on the bulk properties of a sediment, including its packing geometry, stability, porosity, and permeability. Small cavities are created in a deposit by shell fragments and other flat, flaky, or plate-like particles, which greatly increase its porosity. Differences in the size of the grains also affect packing density and porosity. Smaller grains occupy the spaces between larger grains, increasing the packing density and decreasing the porosity. Grains that are less than about one-seventh the size of the larger grains can pass down through the voids between the larger grains. Packing is also influenced by deposition rates. Cubic arrangements develop when there are high depositional rates and grain collisions, and rhombohedral packing, when slow deposition allows grains to settle into their optimum positions. Grains settling onto the bed with high fall velocities jostle and vibrate the underlying layers, increasing the packing density and reducing the porosity. Suspended grains settling out in still water are also less densely packed that those that are deposited by waves and currents.

Table B5 The mean density of some minerals found in beach sands

Mineral	Density (kg m^{-3})
Aragonite	2,930
Augite	3,400
Calcite	2,710
Foraminifera shells	1,500
Garnet	3,950
Hornblende	3,200
Magnetite	5,200
Microcline	2,560
Muscovite	2,850
Orthoclase	2,550
Plagioclase	2,690
Quartz	2,650
Rutile	4,400
Zircon	4,600

Grain sorting

Grains are sorted or separated according to their shape, size, and density (Table B6). Beach sediments are generally better sorted than river sediments, but less well than dunes. Beach grain-size distributions are occasionally positively skewed, but the skew is generally negative. Although the presence of a tail of coarse grains has been attributed to the removal of fine grains, or the addition of coarse clasts or shells, skewness can also arise from a single sedimentary event, and it is not necessarily symptomatic of the mixing of two or more sediment populations (McLaren, 1981).

Cross-shore and longshore changes in beach sediment characteristics can result from mechanical and chemical breakdown, differential transport of grains according to their size, longshore variations in wave energy, the addition or loss of sediment, or the mixing of two or more distinct sediment populations. Sorting occurs through selection, breaking, and mixing (Carter, 1988). Rejection and acceptance phenomena play an important role in the selection process, and in perpetuating sorted grain distributions on beaches. Rejection accelerates the transport of coarse grains over finer grains, whereas shielding impedes the movement of fine grains over coarser grains. Grains moving over material of similar size have a high probability of being assimilated or accepted by the underlying material.

Erosion of a source material produces a lag deposit that is coarser, better sorted, and more positively skewed than the original sediment. If all the transported sediment is deposited, the deposit will be finer, better sorted, and more negatively skewed than the source. If the transported sediment is only selectively deposited, the deposit will be better sorted and more positively skewed than the source. The deposit will be finer than the source if only material finer than the mean size of the source is eroded, but it may be coarser if sediment larger than the mean size is removed from the original deposit (McLaren, 1981).

The mean grain size of beach sediments depends on the characteristics of the source and the nature of the sedimentary processes. Mean grain size varies according to differences in wave energy along beaches and on the exposed and sheltered sides of islands, and it also changes through time as gently sloping, storm-eroded beaches recover to their steeper, fully accreted states. In the cross-shore direction, the coarsest sediments are generally found on a beach at the plunge point of the breaking waves, and the grains tend to become finer seawards and

Table B6 Factors controlling sediment sorting (Steidtmann, 1982; with permission of Blackwell Science)

Rate of sediment accumulation
- Slow—allows reworking of grains
- Rapid—allows little or no reworking of grains
- None—scour

- Density

landwards of this point. There are often coarser sediments on the upper part of the beach, however, which could either have been stranded over the berm crest by large swash events, or it could be a deflation lag deposit, resulting from the aolian removal of finer grains to form dunes. It is not known whether larger or smaller grains move most easily alongshore, and therefore whether examples of beach sediments becoming coarser downdrift represent anomalous or normal situations. In any case, whereas there is often longshore grading on beaches in essentially closed embayments, it is generally lacking or poorly developed where there are large amounts of sediment moving alongshore, or where active sediment throughput does not allow enough time for it to develop (Carter, 1988). The degree of grain-size sorting normal to the beach is also a contentious issue. Some workers have found that the poorest sorting occurs in the breaker and surf zones and the best in the swash zone, whereas others have found that the degree of sorting declines on either side of the breaker zone.

Beach sediments are also sorted according to grain density, and particularly to the abundance and mineralogy of the heavy mineral component. Small heavy mineral grains occupy the spaces between the larger and less dense quartz and feldspar grains, shielding them from the flow so that they are less easily entrained. The lighter quartz grains are transported alongshore more rapidly than the heavy minerals, even when both types of grains have the same settling velocity—presumably because the smaller size of the heavy mineral grains inhibits entrainment during each brief suspension episode. Selective longshore transport of quartz grains may therefore result in heavy minerals becoming concentrated in erosive lag deposits.

There are often concentrations of heavy minerals on beaches in the form of bands or streaks near the high tide or upper swash zones, in the troughs of ripples, or where there are shells, coarse clasts, or other flow obstructions. The upper swash zone may consist of dark layers of fine, heavy mineral grains grading upwards into light colored layers of coarser, quartz–feldspar grains. The alternating layers are between about 1 and 25 mm in thickness, and they typically extend along the beach for a few tens of meters (Clifton, 1969). The formation of swash laminae has been attributed to shear sorting in the downrush, which causes the coarser grains to migrate upwards into the zone of lower shear, while the finer and heavier grains move downwards, into the zone of maximum shear at the bed. An alternate explanation is that the smaller particles tend to fall into the spaces between the larger grains, thereby displacing coarser grains toward the surface.

Heavy mineral concentrations in the cross-shore direction have either been attributed to wave asymmetry, the heavy minerals being carried onshore by high current velocities, but not by the weaker offshore flows, or to beach erosion and offshore transport of the quartz–feldspar grains. There may be poor separation under vigorous wave conditions, however, and the heavy and light minerals can be entrained and transported together.

There has been little research on the effect of sand grain shape on longshore and cross-shore sorting patterns. The proportion of angular grains increases in the direction of longshore transport between Delaware and Chesapeake Bays, possible because their lower settling velocities allow them to remain in suspension longer, so that they are carried further and at higher rates than more rounded grains. On Long Island, however, grains become rounder with longshore transport. In a laboratory and field study, grains of similar size and mineralogy (quartz) were differentially transported and sorted within the swash zone, with the more rounded grains being deposited near the top of the uprush (Trenhaile *et al*., 1996).

BEACH STRATIGRAPHY

A beach is the boundary between the land and water bodies such as oceans and lakes that develops on wave-dominated coasts. It is defined as a shore consisting mainly of unconsolidated materials extending from the low-water line to where marked changes in physiographic form and/or materials are observed or to the permanent vegetation line. The zone between the low-water and high-water levels, which has a concave topography and slopes gradually seaward, is known as the foreshore or beach face. The area landward from the crest of the most seaward berm of a beach is called the backshore.

The slope gradient of the beach face varies according to material, particularly the grain size, and wave intensity (Carter, 1988; Hardisty, 1990). In general, beaches consisting of coarse-grained materials and high-energy beaches have steeper slopes. Waves and currents continuously change the slope gradient and materials of beaches, resulting in the formation of characteristic sediment facies (Harms *et al*., 1975; McCubbin, 1981).

Succession of coastal sediments

At accumulating or progradational beaches, the succession of coastal sediments consists of lower shoreface, upper shoreface, foreshore, backshore, and dunes in ascending order. This is a typical succession on a wave- or storm-dominated sandy coast. The shoreface, located in the nearshore zone, has a concave topography formed by waves. The upper shoreface, also called the inshore, is a zone with bar and trough topography constantly influenced by waves and wave-induced currents. The migration of bars landward or seaward and rip currents result in the tabular cross-stratification and trough cross-stratification that characterize the upper shoreface sediments. Two-dimensional (2-D) and three-dimensional (3-D) wave ripple structures are also commonly found. These sedimentary facies reflect mostly fair-weather wave conditions. The upper shoreface sediments overlie the lower shoreface sediments, which are characterized by swaley cross-stratification (SCS) or hummocky cross-stratification (HCS). HCS is characterized by low-angle ($<15°$) erosional lower set boundaries with subparallel and undulatory laminae that systematically thicken laterally and by scattered lamina-dip directions (Harms *et al*., 1975). SCS is amalgamated HCS with abundant swaley erosional features. These sedimentary structures are thought to be formed by the oscillatory currents of storm waves with offshore-directed currents. During storms, beaches are eroded and longshore bars migrate seaward. Strong oscillatory currents caused by storm waves agitate sea-bottom sediments at the shoreface. Some of the sediments are transported offshore by bottom currents caused by coastal set-up and gravity currents. Oscillatory currents related to calming storm waves produce HCS/SCS in the shoreface to inner shelf region overlain by wave ripple lamination. HCS/SCS is found only in sediments of coarse silt to fine sand. Because lower shoreface sediments are mainly deposited during storms, there is a sharp boundary formed by bar migration between upper and lower

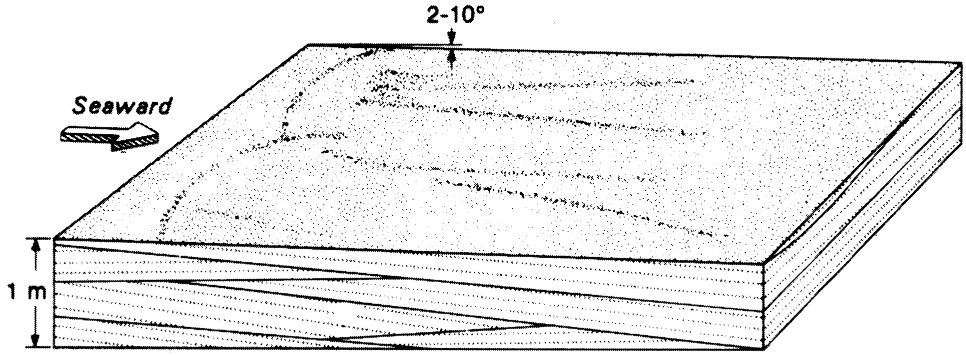

Figure B48 Swash cross-stratification. Stratification and set boundaries are formed parallel to changing slope of beachface and dip generally seaward (after McCubbin, 1981).

shoreface sediments. The lower shoreface topography depends on inner-shelf topography. Because typical shoreface topography can form only on a gentle/flat basal surface, no clear shoreface topography can form in the steep shelf regions of active plate margins. Thus, sometimes only the upper shoreface is referred to as the shoreface.

The uppermost part of the upper shoreface sediments is a step zone sediment characterized by slightly coarser materials, which are overlain by foreshore sediments. The foreshore sediments are characterized by gently seaward-dipping (2–10°) parallel lamination and wedge-shaped set boundaries. This structure is called swash cross-stratification or wedge-shaped cross-stratification (Figure B48). The essential characteristics of this stratification are 1–30 cm-thick bedsets, low-angle dips of laminae and set contacts, an average dip direction toward the sea or lake, mostly erosional set contacts, and laminae lying parallel to set contacts.

Backshore sediments overlie foreshore sediments with a gradual contact and are characterized by low-angle landward-dipping parallel lamination, current ripples, plant remains such as rootlets, and heavy mineral concentrations. Light minerals are removed by winds and form eolian coastal dunes behind the backshore. Heavy mineral concentrations are also a characteristic feature of erosional beaches, where they are residuals of the eroded beach sediments.

The coastal succession and sedimentary facies reflect the intensity of current velocity under fair-weather and storm conditions and seaward-decreasing energy conditions. Under fair-weather conditions, from the foreshore to the upper and lower shoreface, the bedforms (sedimentary structures) found are upper plane beds (parallel lamination), 3-D and 2-D subaqueous dunes (trough and tabular cross-bedding), and 3-D and 2-D ripples (ripple lamination), respectively. On the other hand, under storm conditions, beaches are eroded and the lower shoreface resembles an upper flow regime resulting in the formation of HCS. Ripples are formed in shelf regions.

Foreshore sediments

There are three hierarchies of foreshore sediments: lamination, tide-controlled structures, and storm wave/current-controlled structures.

Foreshore sediments are characterized by parallel lamination formed by the combined processes of wave swash (uprush) and backwash. Each lamina shows reverse grading from fine to coarse with thicknesses of a few millimeters to 2 cm related to each swash and backwash event as a result of either downward filtering of fine particles, or Bagnoldian dispersive pressure resulting from shear between the grains in the flow (Clifton, 1969; Allen, 1984). The fabric of the foreshore sediments shows elongated grains that orient themselves normal to the shoreline, and both landward-imbricated and seaward-imbricated grains are reported. However, these imbricated structures are influenced by the combination of waves and tides.

Reversals of the imbrication dip are thought to result from a predominance of swash transport during the flood stage and backwash transport during the ebb stage. The tidal pattern also influences the depositional thickness of the foreshore sediments. The thick layers are deposited during cycles of higher tidal range, and the thin layers are deposited during cycles of smaller tidal range (Yokokawa and Masuda, 1991). Grain size is also influenced by tides. Water-level changes by tides cause the breaker zone of waves and swash/backwash to shift. Allen (1984) showed that coarser sediments are deposited during flood stages, and finer sediments are deposited during ebb stages.

Storm waves and storm-induced currents have an erosional impact on beaches. During subsequent waning and fair-weather conditions, beaches recover as a result of sediment accretion by waves. This cycle results in an upward-fining succession from a basal erosional surface with coarse-grained materials to finer sandy materials. The coarse deposits formed under high wave energy just after the storm show a remarkable dominance of seaward-dipping imbrication, independent of tidal cycles (Yokokawa and Masuda, 1991). By regarding major erosional surfaces in beach sediments as sequence boundaries according to the sequence stratigraphic model, the depositional zone of foreshore sediments and their stacking pattern can be analyzed. A bedset with a thickness of tens of centimeters bounded by major erosional surfaces is regarded as a depositional sequence, and a lamina set with a thickness of several centimeters to ca. 20 cm is regarded as a parasequence. The depositional pattern of lamina sets shows a landward shift of the depositional zone (onlap) in the lower part of the bedset and a seaward shift of the depositional zone (downlap/progradation) in the upper part. Moreover, bedsets also form a higher order sequence (Masuda *et al.*, 1995).

Changes in waves from seasonal changes in wind direction and wave strength and type produce seasonal beaches. For example, high, strong waves may create high-level beaches with coarse sediments and a steep beachface, or occasionally erosional beaches with residual coarse sediments and heavy minerals, at the high-water level in winter; and calm waves may make gentle, accretional beaches in summer, depending on the location of the beach.

Beaches are distributed not only along wave-dominated coasts but also along tide-dominated coasts influenced by waves. In general, tide-dominated coasts have muddy or sandy tidal flats in the intertidal zone. However, waves create narrow beaches in the upper part of the intertidal zone, occasionally with beach ridges landward from the beach. A typical example is the coast of the Mekong River delta, which is a meso-tidal coast with waves. Beaches and well-developed beach ridges are found in the upper part of the intertidal zone to the supratidal zone (Ta *et al.*, 2002).

BEACH USE AND BEHAVIORS

Introduction

Beaches comprise only 9% of the total conterminous coastline in the United States (Ozmore, 1976). Unfortunately, while no national census of beach visits exists, several studies rank beach recreation as one of the most popular outdoor recreational activities in the United States. It is, therefore, surprising that so little research has been undertaken that addresses the socioeconomic aspects of these activities. This anomaly is particularly noticeable when contrasting the volume of physical and biological research undertaken dealing with beaches and the nearshore environment. Historically, beach recreational activities have centered on the following three activities: bathing, shore-based fishing, and beachcombing. During the past 20 years, many new activities have emerged, several of which use beaches primarily as a staging area. Such activities include surfing, windsurfing, boogie boarding, and a host of shallow-water boating activities including kayaking, canoeing, personal water crafts (PWC), and surfboarding. Many of these activities are incompatible with the more traditional uses of the beach, resulting in user conflicts. Some of these have been managed through the introduction of local, state, and federal legislation, while others have been adjudicated in the courts. Finally, the absolute increase in the number of users of beaches, as well as the diversity of activities occurring, have resulted in a growing demand for both access and accessibility to the nation's beaches.

This entry begins with a historical overview of beach uses, followed by a discussion of three related concerns: increased beach density; the demands this has placed on beach access and accessibility; and how this problem has been addressed. The entry concludes with a discussion about the increasing threat to beachgoers from pollutants in coastal waters.

Overview of beach uses and the factors affecting beach activities

It is likely that beach recreation owes its origin to the perceived value of beaches as healthy environments capable of relieving serious medical conditions (Goodhead and Johnson, 1996). In Britain, during the early part of the 1800s, many people visited beaches with the belief that immersion in, and the drinking of, seawater was healthy and would result in the relief of a number of physical ailments (Meyer-Arendt, 1986). Half a century later, these activities had evolved into resorts generally located within a day's travel of major European and North American cities. Newport, and to a lesser extent Narragansett, Rhode Island, became well-known resorts in New England and were connected by rail to both Boston and New York. In England, Brighton served the same function. More recently, the Hamptons on Long Island have become important beach destinations point for the wealthy. However, nearly all of the research dealing with the early history of beach recreation is descriptive.

One of the few examples where geographers have sought to move from purely descriptive studies to nomothetic research can be found in the extensive writings of Meyer-Arendt, who built on the early work of British geographers with an interest in beach recreation. These studies centered on the concomitant urbanization of coastal areas. Meyer-Arendt studied a number of beach resorts along the northeast Gulf coast, and, based on these efforts, developed the Coastal Resort Morphology Mode (Meyer-Arendt, 1986). This is a spatiotemporal, five-stage recreational land use model. The initial stage is characterized by easy beach access that has attracted limited residential developments, which, in turn, support a small recreational business district (RBD). Toward the end of this first stage, increased day visitation takes place. This second phase is referred to as the "Take Off" stage and is characterized by increased recreational development, extending outward from the RBD. Most of this development is along the coastline on both sides of the RBD. Sometimes a recreational fishing pier is constructed, usually at the foot of the RBD. The third phase is dominated by further development and urban expansion. True central business district (CBD) land uses characterize the area immediately surrounding the RBD. Residential developments continue to expand outward, and most of the early structures located closest to the CBD undergo rapid demolition or conversion to more up-scale recreational developments. Most of the structures still cater to a seasonal clientele, but with a small core of year-round residents. If the resort is located on a barrier beach, developments will have reached the bay-shore. As a result, much of the wetlands located there will have been destroyed by canalization, or filled in, resulting in significant environmental impacts. The fourth stage is consolidating the developments characterized in the previous stage, except that condominium developments now cater to those who no longer can afford to buy (let alone build) single-family homes. The final phase is characterized by complete saturation, where lower income residents and those on fixed incomes are forced to sell out, in part because of high property values and property taxes. Dolan and his co-workers analyzed the rise and decline of religious sea camps during the 19th century, only vestiges of which exist today.

Following the end of World War II, beach visitation became one of the most popular outdoor recreational activities that cut across all socioeconomic groups, although significant social and ethnic discrimination was still in evidence. Furthermore, the popularity of beach visitation continued to increase in concert with a general population migration from inland to coastal areas (Kimmelman *et al*., 1974). Perhaps a contributing factor to the popularity of beach recreation related to the low cost associated with bathing, where transportation often represented the only cost of engaging in the activity. During this period, the predominant activities were bathing, sunning, and socializing, attractions that are as popular today as they were then. The only difference is that today many beachgoers are experiencing significant competition due to other outdoor recreational activities that utilize the beach as a staging area for other water-based activities. These include shore-based fishing and the launching of a variety of light vessels that can be trailered or car-topped, including kayaks, canoes, surf and sailboards, and PWCs.

For many beachgoers, the beach represents a place on which a host of activities can be undertaken, including bathing, sunbathing, ball playing, and socializing. While some degree of specialization appears to take place on certain beaches, most beach visitors tend to participate in several different activities during a day-on-the-beach.

Most early studies concerned with beach uses sought to describe and classify beach users and beaches based on perceived preferences. Several of these studies emerged from the Chicago School of Geography; under the direction of Gilbert White (1973) and his students, where the resource users' perceptions of the environment were seen as the primary factors influencing behavior. The initial research thrust dealt with perceived flooding risks, but these studies soon expanded to include all kinds of perceived environmental factors influencing behavior, including those affecting beach visitation. Few studies have analyzed the activities and social interactions occurring on the beach (Gerlach, 1987). Examples of these include Hecock who concluded that beachgoers were attracted to certain beaches based on their physical characteristics (Hecock, 1966). This study suggested that younger beachgoers preferred beaches with a stronger wave environment where bodysurfing could be undertaken. Conversely, families with small children preferred beaches where the wave environment was more gentle and where the beach slope was less steep, allowing children to play safely in the shallows (Jubenville, 1976).

One area that most coastal recreational planners and resource managers have addressed concerns the number of beach visitors that a given beach can accommodate. While no overall accepted standard exists on the number a given site can accommodate before the perceived value of a visit begins to decline, some efforts were made to address this issue nationally. The Outdoor Recreational Resources Review Commission suggested that 2,000 bathers could be accommodated per one mile of beach (Rockefeller, 1962). One problem with this measure is that no distinction is being made on the basis of the width of the beach. Jackson (1972), citing a California study, suggested that each bather in lakes required a minimum of 50 square feet of water. Other factors play a role in the decision-making process leading to a person, family, or group deciding to visit a given beach. In a study conducted in the New York–New Jersey Metropolitan area, West (1973) found that access and especially accessibility were considered more important factors compared to water quality.

By far, most of the social studies conducted on beaches have dealt with density and crowding (Boots, 1979). In this context, several authors identified "crowding" as a factor influencing beach use (Sowman, 1987). De Ruyck *et al*. (1987) identified two types of densities, one of which defined overall density as a number of visitors per unit area. He also defined "patch densities," a term he referred to as "social carrying capacity" on three beaches in South Africa. These researchers found that density tolerance was influenced by the size of the beach (the smaller the beach, the greater the willingness to accept more people (greater densities). He also found that "crowd attracting beach activities," such as impromptu ball games and other sports events, resulted in higher crowding tolerance by the visitors.

In an unrelated study, West (1974) also found that beachgoers' perception of beach density varied depending upon the respondent's residence. Those beach visitors living in urban areas were willing to tolerate greater beach crowding compared with those living in suburban areas.

Beach access and accessibility

Access and accessibility are terms often used interchangeably, however, in this entry access refers to the ability to move from an existing "right-of-way," such as a road or public parking lot, to a public beach. Accessibility refers to the obstacles that a beach visitor may encounter in traveling from his or her home to the beach. Such obstacles may include a lack of parking facilities, high entry fees, or in an urban context, a lack of public transportation to the beach.

Physical access to the shore is governed by two sets of law, one related to common law, the other by legislation. The common law principles concerning beach use originate from old Roman Law, which held that beach resources (seaweed, fish, and shellfish) were held by the sovereign, who then allowed the citizens to fish and collect seaweed from the shore. This principle was adopted in Britain during the Roman reign and eventually transferred to North America during the Colonial Period where, following independence, the concept of the "sovereign" was replaced with the general public. This meant that the government held the submerged lands seaward of the mean high water line (MHWL) in trust for the general public. In most US states, the legal definition of the public domain is seaward of the MHWL (Anon, 1988). The MHWL, in turn, is defined on the basis of the location of the average high-tide shoreline during a full metonic cycle.

A legislative approach to increasing public access was initially implied in the Coastal Zone Management Act (1972), and in the subsequent amendments. The 1986 amendments were identified as an area of special interest. Most coastal states have made some efforts to increase public access to the nation's beaches, although accomplishments vary widely. One of the aims of California's and Oregon's, and to a lesser extent Washington State's Coastal Management Program has been to increase physical access at certain intervals along their respective coastlines. Along California's rural coast, the aim is to provide coastal access every three miles. This goal is comparable to those formulated in Oregon and Washington. The objective of providing access to the shore at regular intervals has been more problematic along the Eastern Seaboard, in large part because of much higher population densities, less land in public ownership, and overall higher land prices. Together these factors have made eminent domain acquisition much more difficult and costly. Some states have attempted to increase coastal access using the principle of perfecting public right-of-ways. Rhode Island has undertaken a statewide search to identify existing and abandoned right-of-ways, largely through legal research. This effort has significantly increased public access to the state's coastal areas.

The absence of physical access to the beach is only one of the many constraints that a potential beach visitor is likely to encounter. Lack of accessibility may at times be a greater hindrance to visiting the beach. Such factors may be deliberate attempts by local cities and towns to limit or outright prohibit out-of-town visitors on local beaches. In other instances, impeded accessibility is unintentional or unavoidable (Heatwole and West, 1980).

Limiting or prohibiting beach access to out-of-town citizens on facilities owned and operated by local municipalities may vary from outright prohibition to charging unreasonably high entry or parking fees. Many of these instances have been adjudicated in the courts, which have generally ruled that where higher entrance fees have been levied against nonresidents, such fees may be permitted as long as the increased fees cover the additional costs resulting from accommodating the increased number of nonresidents. The courts have generally assumed that a portion of a resident's property tax is designated to the operation of recreational facilities, including beaches, and that opening such beaches to nonresidents often means increased expenditures to insure the health and welfare of the visitors. This may mean higher costs to cover the costs of additional guards, beach patrols, cleanups, and other services. The courts have generally felt that such additional expenditures could be recovered by charging the nonresidents a higher fee compared with those levied on residents (Neptune v Burrough of the City of Avon, 1972).

The popularity of beaches and beach uses has increased significantly during the latter part of the 20th century, a development that is likely to increase for the foreseeable future. This increased demand has raised two concerns: use conflict and water quality declines.

Conflict resolution

As mentioned in the introduction, many additional beach uses now exist. Some of these are incompatible with traditional recreational beach activities. Examples include shore-based fishing, various boating activities, including water skiing, use of personal water crafts and surfing. Most of these conflicts have been dealt with on the local level, while a few have been adjudicated in a court of law. Of the management procedures that have been introduced on the local level, zoning procedures are probably the most common. Zoning, as it was first conceptualized in New York City in 1916 (Haar, 1977), was originally intended to control building height. Zoning maps later followed with zoning ordinances specifying restricted or prohibited uses.

Recreational applications of zoning have been attempted both on land and on the water in an attempt to reduce conflicts between and among different recreational pursuits. On the water, zoning has been used by a number of municipalities to segregate swimmers and bathers from boaters—especially powerboaters, surfers, and PWCs. Two versions of zoning have been used: permanent zones and space/time zoning ordinances. In the case of permanent zones, a protected activity (e.g., swimming or bathing) is protected from all other activities by prohibiting those from entering the designated area. A less common practice is sometimes referred to as time zoning. In this instance, the competing uses are assigned different periods when each activity can take place, thereby eliminating any conflicts between competing uses. If a given beach is sought by both swimmers and surfers, the beach may be restricted to one user group while the other use may be permitted during different periods. A coastal municipality may allow surfers access to the beach during the early morning and again in the late afternoon. Swimmers and bathers may have exclusive use of the beach and adjacent nearshore during the period from mid-morning to late afternoon.

The same procedures may be utilized on land in areas where users compete for the same area. Sunbathing and shore-based fishing are both legitimate recreational activities that sometimes may compete for the same stretch of beach area. Shore-based fishing may be restricted to the early morning and late afternoon, while sunbathing may be permitted from mid-morning to late afternoon.

Environmental impacts on beach use

Socioeconomic factors are not the only variables influencing beach recreation quantitatively as well as qualitatively. There are at least two additional variables that increasingly have played a role in this nation's beach recreational activities. One concerns the increased outbreaks of algal blooms, in particular, those classified as harmful. The other concerns the impact that beach activities may have on endangered species and the restrictions imposed on beach visitors to protect threatened and endangered biological resources.

Algal blooms have occurred along the nation's coasts at least since the Spanish first settled Florida. However, there is growing evidence that these incidents are increasing quantitatively and qualitatively. The number of harmful algal bloom (HAB) incidents have increased significantly in recent years as have the impacts on marine life, swimmers, bathers, and people handling fish and shellfish affected by these incidents. While the cause for these events has not yet been determined, there is growing evidence that land-based pollution is partially responsible (Anon, 2000). The effects of HAB events range from the discoloration of large patches of waters to fish kills, die-offs of manatees in Florida, and possibly the deaths of small marine mammals in the United States, Scandinavia, and the Mediterranean. So-called "red tide" incidents in Florida, have significantly affected swimmers and bathers. Toxins released from these HABs can also become airborne, resulting in respiratory irritation, coughing, and sneezing by people who are not even in direct contact with the affected waters (Luttenberg, 2001).

The second factor that has influenced swimming and bathing in recent years is the potential conflict between the Endangered Species Act and all types of beach recreational activities. During the 1980s and 1990s, large stretches of barrier beaches on Cape Cod were closed to fishing, overland vehicular traffic, and bathing in an effort to protect the Piping Plover nests and fledglings from being trampled. In 1988, it was estimated that only 20 pairs of piping plovers were nesting within the Cape Cod National Seashore (Lopez, 1998). Largely because of the severe restrictions placed on beach traffic (both pedestrian and vehicular), a substantial increase in nesting pairs has been noted throughout the seashore (Lopez, 1998). These accomplishments, however, have not been made without impacts on beach recreation in general, shore-based fishing or bathing. Within the Cape Cod National Seashore, less than 10 miles of the Atlantic shore are now open to ORV traffic during the nesting season (from March through July). Similar restrictions have been imposed on bathing and beachcombing in piping plover nesting areas.

Conclusions

Beaching and bathing continue to be two of the most popular outdoor recreational activities both here and abroad, yet with few exceptions, not many studies have addressed the behavior and motivation of the beach-going public. Studies conducted on or adjacent to beaches generally fall into two groups. The first has sought to analyze the reaction of the beach visiting public to deteriorating water quality. The second group of studies has concentrated on infrastructure changes that have taken place in the areas immediately inland from many popular bathing beaches. While these studies are important both socially and economically, it is suggested that many additional findings would enhance our understanding of the factors motivating the beach visitor and the management of beaches. Answers that are needed include studies dealing with crowding and density tolerances and better understanding of beach preferences by different user groups. Are some beaches attracting certain population groups simply because they are more accessible, or because the amenities found on the beach attract specific user groups interested in participating in activities (e.g., surfing) that may not be readily available on all beaches? The role of physical access is still an issue in many communities, notwithstanding that access along the shore is recognized by most states as a public right, Public beaches constitute less than 10% of all the beaches in the United States. This increasingly scarce resource may be better managed if we had a better understanding of the factors that attract and detract the public to certain beaches.

BEACHROCK

Formation and distribution of beachrock

Beachrock is defined by Scoffin and Stoddart (1987, p. 401) as "the consolidated deposit that results from lithification by calcium carbonate of sediment in the intertidal and spray zones of mainly tropical coasts." Beachrock units form under a thin cover of sediment and generally overlie unconsolidated sand, although they may rest on any type of foundation. Maximum rates of subsurface beachrock cementation are thought to occur in the area of the beach that experiences the most wetting *and* drying—below the foreshore in the area of water table excursion between the neap low and high tide levels (Amieux *et al*., 1989; Higgins, 1994). Figure B49 shows a beachrock formation displaying typical attributes.

There are a number of theories regarding the process of beach sand cementation. Different mechanisms of cementation appear to be responsible at different localities. The primary mechanisms proposed for the origin of beachrock cements are as follows:

(1) physicochemical precipitation of high-Mg calcite and aragonite from seawater as a result of high temperatures, $CaCO_3$

Figure B49 Multiple unit beachrock exposure at barrio Rio Grande de Aguada, Puerto Rico. The sculpted morphology, development of a nearly vertical landward edge, and dark staining of outer surface by cyanobacteria indicate that this beachrock has experienced extended exposure. Landward relief and imbricate morphology of beachrock units define shore-parallel runnels that impound seawater (photo: R. Turner).

supersaturation, and/or evaporation (Ginsburg, 1953; Stoddart and Cann, 1965);

(2) physicochemical precipitation of low-Mg calcite and aragonite by mixing of meteoric and fresh groundwater with seawater (Schmalz, 1971);
(3) physicochemical precipitation of high-Mg calcite and aragonite by degassing of CO_2 from beach sediment pore water (Thorstensen *et al*., 1972; Hanor, 1978); and
(4) precipitation of micritic calcium carbonate as a byproduct of microbiological activity (Taylor and Illing, 1969; Krumbein, 1979; Strasser *et al*., 1989; Molenaar and Venmans, 1993; Bernier *et al*., 1997).

Although most beachrock cement morphologies suggest an inorganic origin, physicochemical mechanisms operating alone do not adequately account for the discontinuous distribution of beachrock formations. As Kaye (1959, p. 73) put it, "the problem hinges more on an adequate explanation for the absence of beachrock from many beaches than on its presence in others." The discontinuity of beach cementation, along with the complex assemblage of cement types found in adjacent samples of beachrock led Taylor and Illing (1971) to propose that the microenvironment exerts a greater influence on the cementation process than does the macroenvironment.

Several beachrock researchers concur with this assessment and support the theory that *initial* cementation in beach sands is controlled by the distribution and metabolic activity of bacteria because: (1) dark, organic-rich micritic rims have been identified around cemented grains in most petrographic studies of beachrock (Krumbein, 1979; Beier, 1985); (2) microbially mediated precipitation of carbonates has been repeatedly demonstrated in both marine and terrestrial environments (Buczynski and Chafetz, 1993); and (3) bacterial populations are particularly large and productive in the intertidal zone of water table fluctuation where beach lithification occurs. Once biologically mediated cryptocrystalline cements are established as nucleation sites, larger crystals precipitated via physicochemical processes can grow and bridge the sediment grains.

Rates of beachrock formation are undoubtedly variable but are generally believed to be quite rapid, on the scale of months to years (Frankel, 1968). For example, Hopley (1986) reported that beachrock formed within six months on Magnetic Island near Townsville, Australia, while Moresby (1835) wrote that Indian Ocean natives made an annual harvest of beachrock for building stone and within a year they had a new lithified crop.

Several Pleistocene and older beachrock formations have been identified. However, the dynamic nature of sandy coastlines and a historically fluctuating sea level necessitate that most occurrences of *intertidal* beachrock are less than 2,000 years old. This is commonly supported by the incorporation of modern man-made artifacts in beachrock formations rather than by ^{14}C dates, as beachrock is poorly suited for radiocarbon dating.

The majority of recent beachrock is formed on beaches in the same regions that favor coral reef formation. This is generally below 25° latitude where there is a well-defined dry season and "the temperature of ground water at a depth of about 76 cm in beaches remains above 21°C for at least 8 months of the year" (Russell, 1971, p. 2343). However, beachrock can also form at higher latitudes. For example, beachrock exposures are common throughout the Mediterranean and have been reported along portions of the coasts of Norway, Denmark, Poland, Japan, New Zealand, South Africa, the Black Sea, and the northern Gulf of Mexico. Beachrock formations have also been reported on lakeshores in Pennsylvania, Michigan, Africa, New Zealand, southeast Australia, and the Sinai Peninsula.

Subaerially exposed beachrock units constitute only a small proportion of the cemented sediments in the intertidal zone. For example, Emery and Cox (1956) found beachrock *exposures* on only 24% of the predominantly calcareous beaches of Oahu, Kauai, and Maui, whereas jet-probing conducted by Moberly (1968, p. 32) revealed that "exposed or covered beachrock appears to be present at all calcareous beaches in the state" of Hawaii. In the event of continued sea-level rise and human activities that exacerbate coastal erosion, much more beachrock will be exhumed.

Morphology of beachrock formations

Beachrock formations typically consist of multiple units, representing multiple episodes of cementation and exposure. Beachrock that forms below the foreshore has an upper surface slope that tends to mimic that of the seaward dipping (4–10°) internal beach bedding. However, beach sand cementation has also been found to occur below the berm and foredune of a beach (Russell, 1971; Hopley and MacKay, 1978). Those authors found that the beachrock forming below the backshore had a nearly horizontal upper surface that corresponded to the groundwater table and truncated the original beach bedding.

Most intertidal beachrock formations are detached from subaerial and subtidal cemented sediments. Beachrock is laterally discontinuous as well, usually exposed for only short distances before disappearing under loose sand or ending entirely. It is likely that the formation and preservation of beachrock on a given section of beach is negatively correlated to alongshore increase in wave energy and frequency of beach erosion.

The reported thickness of beachrock formations ranges from a few centimeters up to 5 m, with approximately 2 m being most common. Variations in degree of cementation within a beachrock unit can be controlled by variability in porosity, permeability, and composition of different sand layers (Molenaar and Venmans, 1993). Generally, precipitation of cements is most rapid near the top of a beachrock unit. Accordingly, young beachrock units are better cemented at the top and noticeably less so near the base. This attribute makes them more susceptible to scour at their base upon exposure, commonly resulting in undercutting and slumping. It is this undercutting that fosters the development of nearly vertical landward edges on beachrock units. In areas where a chronic deficit in sand supply or erosive conditions have exhumed the seaward edge of a beachrock formation, it is frequently observed to be steep as well.

Long-term exposure of beachrock will radically change the ecology of a sandy shoreline by providing a hard substrate that can support an increased diversity of animal and plant life. The reader is referred to the papers of McLean (1974), Jones and Goodbody (1984), and Miller and Mason (1994) to learn more about the ecology and biophysical modification of intertidal beachrock exposures.

Beachrock and coastal evolution

Although beachrock, as defined, forms in the intertidal zone, it does not always remain there. On prograding coasts, a series of beachrock units may form at depth, leaving older units stranded well behind the active beach. On retreating coasts, outcrops of beachrock may be evident offshore where they may serve as a hard substrate for coralgal reef growth. If the strike of the beach changes over time, then the strike of the beachrock units will reflect that change.

Armed with the knowledge that beachrock is formed in the intertidal zone, many geologists have related beachrock outcrops to changes in sea level for particular coasts. Semeniuk and Searle (1987) demonstrated that beachrock formation can keep pace with slow shore recession, resulting in a wide, continuous band of beachrock, but that rapid shore recessions (or periods of high wave energy and foreshore instability) are represented by gaps (unconsolidated sediment) in a sequence of beachrock units. Assuming a nearly constant rate of sea-level rise, these gaps may indicate that beachrock can temporarily stabilize the position of the shore under erosive conditions until sea level has risen enough to cause the shore to jump back (Cooper, 1991). Many other researchers have asserted that beachrock outcrops will protect a beach from erosion, as well as control the plan configuration of a coastline.

Research by Turner (1999) has demonstrated that the influence beachrock has on beach processes will largely depend on the extent and morphology of the exposure, both of which evolve over time. Cumulative exposure and erosion of a beachrock formation over a period of years to decades can foster a gradual increase in the landward and seaward relief of the beachrock units and the development of shore-parallel runnels and shore-perpendicular breaches in the beachrock. The high seaward relief of such a beachrock unit effectively attenuates incident wave energy and retards onshore sediment transport. The high landward relief of the beachrock unit can act as the seaward wall of a runnel that blocks offshore return of backwash and forces impounded seawater and entrained sand to flow laterally on the foreshore to low spots and shore-normal breaches in the beachrock formation. Beachrock breaches and runnels are erosionally enlarged over time, locally increasing onshore inputs of wave energy and longshore sediment transport rates on the foreshore.

On a beach on Puerto Rico's west coast, beach width and volume were found to be least stable where the seaward beachrock unit was breached and most stable away from the breaches behind high relief beachrock. Sections of foreshore most protected by a high relief beachrock ridge exhibited the lowest volumes of subaerial sand storage, unusually narrow beach widths, and the slowest beach erosion recovery rates. In short, a beach with a high relief intertidal beachrock exposure is more likely to be sediment deficient and out of synch with the wave regime. This puts the backshore of a beachrock beach at risk of catastrophic retreat following the development of a breach in the beachrock or in the event of a high energy wave event coupled with a storm surge or spring high tide.

Conclusions

The transformation of sandy beaches to rocky beachrock beaches is increasingly common in the tropics and subtropics. Where beachrock is exposed by erosion, it acts as a natural breakwater or revetment, decelerating further shoreline and backshore retreat. However, it also tends to retard beach buildup and is poorly suited to recreational use, both major issues in the tropics where tourism is often the primary source of income. The potential for beachrock to significantly alter the evolution of a coast justifies additional research on its influence on beach processes. In particular, the characteristics and effects of beachrock on dissipative beaches have received little attention and are likely to be significantly different than those observed on more reflective beaches.

Despite many petrographic investigations of beachrock cements, the processes responsible for beachrock formation are still poorly understood. Given the likelihood of cement diagenesis in the beach environment, there is a need to pursue other research methods. For example, the subsurface formation of beachrock should be tracked on a variety of beaches over an extended period. The processes affecting beach sand cementation should also be examined under controlled conditions in a laboratory setting. Preliminary experiments conducted by Turner (1995) indicate that the addition of dissolved nitrate or organic carbon to beach sand microcosms stimulates bacterial growth and the precipitation of intergranular calcium carbonate. This leads to the question as to whether coastal discharges of groundwater contaminated with fertilizers or human wastes are increasing the rate and geographic range of beachrock formation.

BEAUFORT WIND SCALE

The Beaufort scale of wind velocity relates wind speed to the physical appearance of the sea surface by considering such factors as apparent wave height and the prominence of breakers, whitecaps, foam and spray. It is the oldest method of judging wind force. Originally devised by Admiral Sir Francis Beaufort of the British Navy in 1805 to simplify the signaling of wind and weather conditions between sailing vessels, it has since been repeatedly modified to make it more relevant to modern navigation. Table B7 gives an updated modern version of the Beaufort scale, adapted from British Admiralty (1952), Thomson (1981), and US Army Coastal Engineering Research Center (1984). Meyers *et al*. (1969) presented an elaborate version of the wind scale based on British Admiralty (1952), McEwen and Lewis (1953), and Pierson *et al*. (1953). Wind speed measured at 11 m (36 feet) above sea surface is usually applied to use the scale. The wave heights are approximate and represent fully arisen sea state. As with any subjective judgment method, the Beaufort Scale is far from perfect. Similar subjective scales have been proposed to assess tornado and hurricane damages. The Fujita scale (F-scale) was proposed in 1951 by Tetsuya Fujita for rating the severity of tornadoes as a measure of the damage. The Saffir–Simpson scale is used for rating the severity of damages by a hurricane.

BIOCONSTRUCTION

The term, *bioconstruction*, usually refers to a bioconstructed limestone that has been built-up by colonial and sediment-binding organisms including algae, corals, bryozoans, and stromatoporoids. The term, bioconstructed limestone, was introduced by Carozzi and Zadnick (1959) in their study of the Silurian Wabash reef in southern Indiana. The word, bioconstructed, was used to distinguish the limestones and dolomites which were found in a reef from the dolomitic calcarinites preserved in the reef flanks and the dolomitic shales in the country rock (Carozzi and Zadnick, 1959). The term, bioconstruction, was next applied to Devonian stromatoporoid reefs in the Beaverhill Lake Formation, Upper Devonian, Alberta Canada (Carozzi, 1961).

European use of the word bioconstruction

The word, *bioconstruction*, was widely accepted and used in European geologic journals, but has not appeared in any North American journals since 1961. The European use of the term, *bioconstruction*, includes what the North American geologists would refer to as reefs, bioherms, and biostromes. Based on living coral reefs, Ladd (1944) defined a reef as a rigid, wave-resistant framework constructed by large skeletal organisms. A broader definition of a reef as "a discrete carbonate structure formed by in-situ organic components that develops topographic relief upon the seafloor" has been proposed by Wood (1999, p. 5). Cumings (1930) defined a bioherm as a mound-like, dome-like, lens-like, or reef-like mass of rock built-up by sedentary organisms (such as corals, algae, foraminifera, mollusks, gastropods, and stromatoporoids), composed almost exclusively of their calcareous remains and enclosed or surrounded by rock of different lithology. A biostrome is defined as a distinctively bedded and widely extensive lenticular, blanket-like mass of rock built by and composed mainly of the remains of sedentary organisms and not swelling into a mound-like or lens-like form; an organic layer, such as a bed of shells, crinoids, or corals, or a modern reef in the course of formation, or even a coal seam (Cumings, 1930).

Types of bioconstructions

Examples of several different types of bioconstructions, which would fall into the categories of reef, bioherms, and biostromes, are included to show how the term bioconstruction is used in the European literature. In Spain, rugose corals and calcareous algae bioconstructions are also called biostromes (Rodrigues and Sanchez, 1994). In Jurassic and Cretaceous strata in Germany, Rehfeld (1996) describes different forms of sponge bioconstructions which comprise bioherms, biostromes, and sponge meadows. The wave resistant calcisponge and algal reefs of the Capitan reef facies, partially wave resistant reef mounds and non-wave resistant skeletal mounds in the Guadalupe Mountains of New Mexico, are described as Permian bioconstructions (Noe, 1996). Therefore, bioconstruction is a general term for limestone and dolomite deposits formed by colonial and sediment binding organisms which include reefs, bioherms, and biostromes.

Table B7 Beaufort wind scale

Beaufort No.	Name	Wind speed knot	m/s	Effect of wind at sea surface	Significant wave height (m)	Effect of wind on land
0	Calm	<1	0.0–0.2	Like a mirror	0	Still, smoke rises vertically
1	Light air	1–3	0.3–1.5	Ripples form with the appearance of scales, but without foam crests	0.1–0.2	Smoke drifts, vanes remain motionless
2	Light breeze	4–6	1.6–3.3	Small wavelets, crests appear glossy but no breaking	0.3–0.5	Leaves rustle, vanes move, wind can be felt on face
3	Gentle breeze	7–10	3.4–5.4	Larger wavelets begin to break, some scattered white horses	0.6–1.0	Constant movement of leaves and small twigs, flags begin to stream
4	Moderate breeze	11–16	5.5–7.9	Small waves predominant but fairly frequent white horses	1.5	Dust and loose paper are lifted, thin branches move
5	Fresh breeze	17–21	8.0–10.7	Moderate waves, distinctly elongated, many white horses, chance of spray	2.0	Small trees in leaf begin to sway
6	Strong breeze	22–27	10.8–13.8	Long waves with extensive white foam, breaking crests, spray likely	3.5	Large branches move, power lines whistle, stop lights sway, umbrellas difficult to control
7	Moderate gale	28–33	13.9–17.1	Sea heaps up and white foam from breaking waves begins to be blown in streaks, spindrift begins to be seen	5.0	Entire trees sway, some resistance to walkers, car feels force of wind
8	Fresh gale	34–40	17.2–20.7	Moderately high waves of greater lengths, edges of crests break into spindrift, foam is blown into well-marked streaks	7.5	Twigs break off trees, difficult walking against wind
9	Strong gale	41–47	20.8–24.4	High waves, rolling sea, dense streaks of foam, spray may affect visibility	9.5	Roof tiles lifted off, windows may be blown in, trees may topple
10	Whole gale	48–55	24.5–28.4	Very high waves with long overhanging crests, foam in great patches blown in dense white streaks downwind, heavy rolling sea causes ships to slam, visibility reduced by spray, sea surface takes on whitish appearance	12.0	Trees uprooted considerable structural damage to some buildings
11	Storm	56–66	28.5–32.7	Exceptionally high waves, sea covered with long white patches of foam blown downwind, wave crests blown into froth everywhere, visibility impeded by spray	15.0	Widespread damage, extensive flooding in low lying areas if wind is directed onshore
12	Hurricane	>66	>32.7	Air filled with foam and spray, sea completely white, visibility seriously impaired	>15.0	Severe structural damage to buildings, widespread devastation and flooding

Conclusions

Bioconstruction is distinctly a European term for a limestone which has been built-up by colonial and sediment binding organisms such as algae, corals, bryozoans, and stromatoporoids. It combines what North American geologists would refer to as reefs, bioherms, and biostromes.

BIOENGINEERED SHORE PROTECTION

In an effort to arrest shore erosion at many coastal locations and to provide protection to marinas and harbors, it may be necessary to construct structures in high wave energy zones. Current practice involves utilization of structures constructed using large armor stones, concrete and steel walls, and a variety of other "hard" engineering techniques. Quite often, these structures do not add to the aesthetic and recreational attributes of a site and may impact significantly on the local environment. Integration of bioengineered components into the design of breakwaters and shore protection systems can be utilized, in certain cases, to enhance the project by providing better biological habitat and ancillary water quality improvement. Thus the goal of a project changes to include not only the stabilization of the eroding area or the provision of "quiet" waters, but to increase the quantity and quality of habitat available to fish and waterfowl communities, while providing an effective and aesthetic control of natural environment.

Background

In both the engineered and natural environment, the flow of water often causes erosion. The causes must be understood before the problem can be addressed. In the coastal zone, the flow of water results from wave action, the associated runup and backwash, wave breaking, alongshore currents, and the natural flow of water along side and overtop of the high-tide shoreline. In addition to the interaction of the high-tide shoreline or lakeward structure with water, a considerable amount of animal and human activity create additional stresses on the high-tide shoreline. Bioengineering methods of shore protection offer a practical solution that can also create an aesthetically pleasing and environmentally beneficial "buffer zone." Bioengineering, in this context, is the utilization of vegetation, either by itself or in combination with other defense mechanisms, depending upon the local environment. The other defense mechanisms may include the use of rock lining, offshore islands, wave screens, and submerged shoals that limit the wave energy reaching a site. Quite often, these defense structures can be designed to provide significant enhancement to the environment, particularly in providing suitable fish habitat for spawning, feeding, and hiding from predators.

The value of vegetation for protecting the soil depends on the combined effects of roots, stems, and foliage. Roots and rhizomes reinforce the soil. Immersed foliage elements absorb and dissipate energy and may cause sufficient interference with the flow to prevent scour. In a sediment-laden environment, they may also promote deposition.

A coastline requiring protection can be considered as two separate areas and thus habitat enhancement can be geared toward two communities; the high energy nearshore environment and the onshore environment, which can be suitably modified to ensure low wave energy levels. Enhancement of the nearshore zone can include construction of rock revetments as reef habitat, inclusion of submerged offshore structures to reduce wave energy levels reaching the shore and primary wave defense structures which provide habitat enhancement potential by the nature of their design (Figure B50). Selection of stone and design of its placement is developed in a manner to provide a reef like habitat beyond minimum stone placement required for the minimal shore

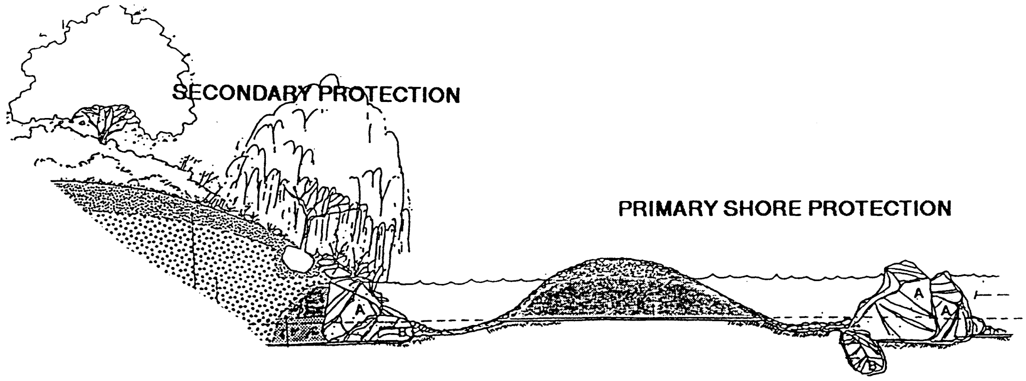

Figure B50 Utilization of shoals.

stabilization. The effectiveness of both natural and artificial reef like habitats as fish community habitats has been well documented. Proper design and installation of rock will provide protective cover and feeding areas and will supply the needs for small aquatic and benthic organisms by providing protection from the high energy wave action and from larger predators.

Low wave energy areas can be created behind a primary defense such as an offshore rock structure or wave screen, or through the creation of lagoons behind stable control structures (Figure B51). The development of constructed wetland pockets and areas for other shallow water plants can occur in these lagoons. This can be promoted by the establishment of "biological" riprap in the form of brush and woody plant debris. These materials will provide a setting that will foster the accumulation of shore plants from wind blown seed banks. As the brush decomposes, it provides a limited release of nutrients to the developing plant community and is eventually replaced by living plants. The establishment of new habitat will provide the opportunity for colonization by wetland plant and animal species that require quiescent waters. Transient use of the habitats by a variety of aquatic and migratory waterfowl is an additional potential for these environments.

Goals and objectives

The designer is encouraged to consult specialists in the fields of coastal hydraulics, fisheries, geomorphology, biology, landscape architecture, or any field that could make the project a success. The design of bioengineered breakwaters and shore protection that functions environmentally requires a multidisciplined approach. Usually, no individual has all the expertise required to ensure successful implementation.

The following geomorphologic, hydraulic, and biological changes may occur as a result of modification of the shore, which would occur from the creation of a marina or harbor, or from local erosion protection schemes:

- Loss or elimination of aquatic vegetation
- Loss or elimination of backshore vegetation
- Removal of specific nearshore bathymetrical features
- Modified substrate conditions
- Modified hydrodynamic, flow, sediment, and water quality regimes
- Changes in nutrient conditions and reductions in food organisms
- Aesthetic degradation
- Reductions in habitat diversity and environmental stability
- Increased water temperatures.

The shore is a dynamic system where impacts are difficult to predict. Engineered structures, when properly designed and constructed, can provide both species and habitat diversity and thereby mitigate potential adverse changes. However, the goals and objectives of the shore protection design must be correctly identified early in the design process. The designer must be aware of the design goals and objectives to correctly identify, size, and locate the various functional elements within the system. Biodiversity within and adjacent to the shore is interrelated with the quality in updrift and downdrift areas. Changes to any one of these components may adversely impact on others.

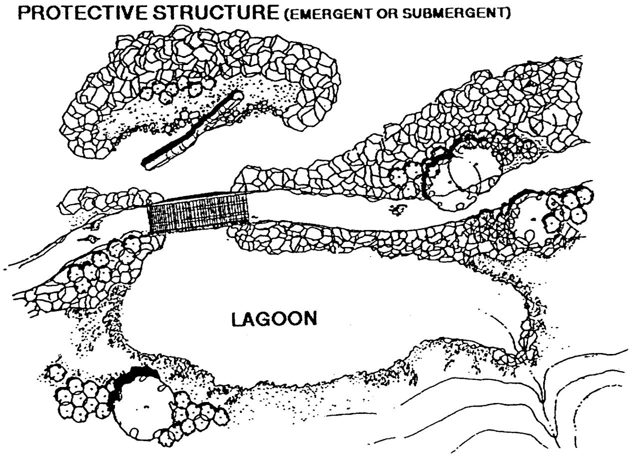

Figure B51 Development of a lagoon cell.

Habitat requirements

Aquatic life generally requires a habit that contains the following:

1. Sufficient water depth and volume for each life stage.
2. Adequate water quality with preferred ranges of temperature, dissolved oxygen, PH, etc.
3. A variety of continuous hydrodynamic conditions varying from deep water to shallow water for breeding and cover. Also flow conditions that sort bed load materials to provide a good environment for bottom dwelling organisms are advantageous.
4. Adequate cover to provide shade, concealment, and orientation.
5. Adequate food to maintain metabolic processes, growth, and reproduction.

Shore improvements should be designed for the individual fish species. Specific requirements for reproduction, juvenile rearing, and adult rearing with regard to feeding location, concealment from predators and competitors, and sanctuary from flow extremes and ice formation varies between species. Loss of the natural bathymetric features, which are utilized by particular species as a result of implementation of shore protection, could eliminate many of the requirements necessary to sustain significant biodiversity along the nearshore area. In addition, removal of existing shore vegetation, in either the emergent of submergent zones would significantly reduce or eliminate the potential to sustain a fish population.

Utilizing vegetation

In certain low wave energy environments, vegetation may be used by itself to provide suitable protection to an eroding shore. Reeds and

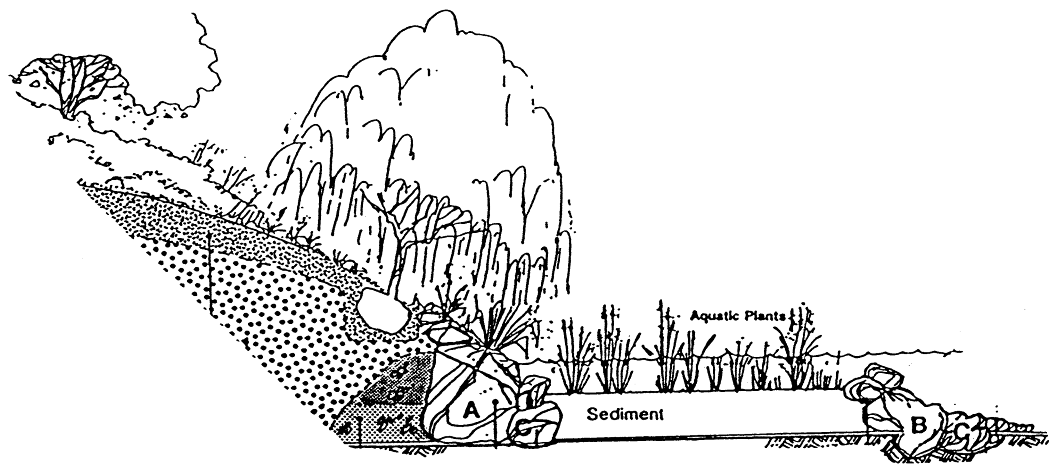

Figure B52 Emergent vegetation used in conjunction with stone.

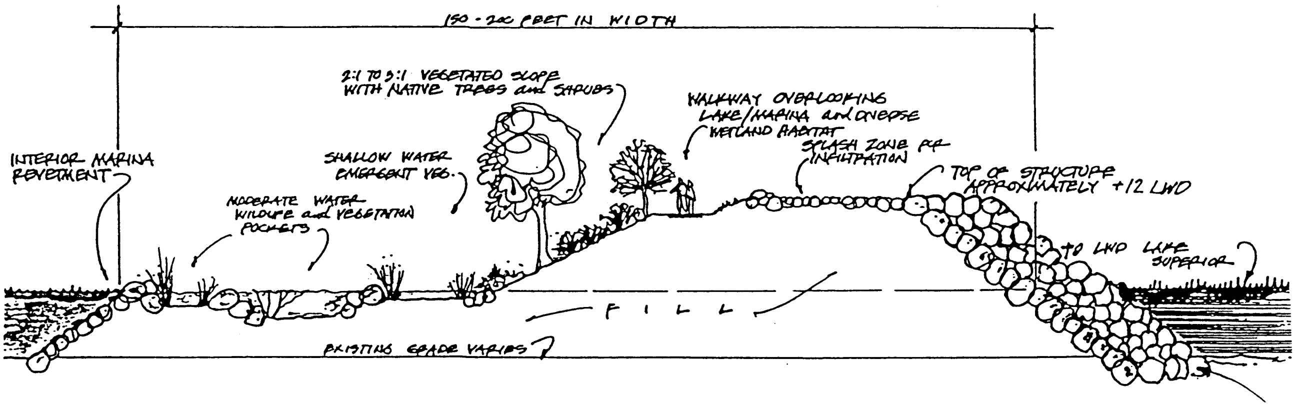

Figure B53 Control structure/lagoon.

other marginal plants can form an effective buffer zone by absorbing wave energy and restricting the alongshore flow velocity adjacent to the shore. They therefore have a protective value. Specific functions that they can perform include:

1. Absorbing and dissipating wave-wash energy.
2. Interference and protection of the shoreline bank from the flow.
3. Reinforcement of the surface soil through the root mat and prevention of scour of the bank material.
4. Sediment accumulation brought about by the dense plant stems.

Marginal plants require very wet ground and generally will not survive in water that is more than 0.5 m deep for long period of time. They flourish in conditions of low flow velocity and their integrity is weakened by wave action in excess of 0.5–0.75 m. Different species offer different levels of protection with regard to wave energy dissipation. For incident wave conditions under 0.5 m, reed beds having a width of 2–2.5 m may dissipate 60–80% of the incoming wave energy. In areas with higher levels of wave energy, riprap and geotextiles may be used in conjunction with vegetation to provide effective bank protection (Figure B52). In areas of high incident wave energy, an area of low wave energy can be created behind a primary defense such as an offshore rock structure or wave screen, or through the creation of lagoons behind stable control structures (Figure B53), as described above.

Natural methods of protection generally have low capital cost in comparison with conventional engineering methods. However, they may well have higher recurrent cost due to regular inspection, trimming and cutting, and repair. In areas where a combination of conventional and bioengineered structures are required, recent experience at several sites on the Great Lakes has established that these techniques may cost 20–30% more than conventional techniques alone.

Possible disadvantages are that natural protection schemes take time to mature and to become fully effective. Depending on the type, natural protection may take several growing seasons to reach the desired standard of protection.

Bioengineering differs from other conventional forms of engineering in two key respects, which strongly influence the design approach:

1. Bioengineering involves considerable practical experience and judgment, as opposed to the application of quantitative design theory or rules.
2. Careful management is required not only in the establishment of vegetation, but also in its aftercare over the initial growing seasons.

Use of vegetation requires the following points to be considered

The principal plant groups that can be used are aquatic plants, grasses, shrubs, and trees. Selection is based on consideration of the different roles to be performed by the vegetation, taking into account the physical and chemical properties of the soil, the climatic conditions, and the soil/water regime under which the plant must survive. Vegetation establishment may take several growing seasons and is a seasonal activity that must be managed and maintained. The engineer must prepare and agree to specific management objectives and a management program with the owner/client. This is in order to ensure that the vegetation is maintained in a fit condition to perform its intended roles.

Zones and horizons of natural protection

With natural methods of protection, and particularly methods involving the use of live material, the effectiveness of different materials is strongly dependent on their location in relation both to the dominant external water level and to the subsoil soil/water regime. To achieve effective protection using natural materials, the designer will almost inevitably need to use different methods of protection in different zones and horizons of the shore (Coppin and Richards, 1989).

Use of reeds

The emergent and marginal types of aquatic plants, such as the common reed, bulrush, and great pond sedge, are frequently used for interference and protection purposes to form a protective margin along the shore at the waterline. They also encourage siltation by absorbing current flow energy, and thus reducing the sediment-carrying capacity of the flow. Reeds can be easily weakened by erosion and loosening of the soil around the rhizomes due to wave energy. It is therefore necessary to protect the zone containing roots from high-velocity flow or significant wave attack. Provided this is done, the stems and leaves will protect the shore bank above.

Uses of shrubs and trees

A limited range of trees are water-tolerant and can be used in bioengineering structures for bank protection in both the aquatic and damp zones. The willow, alder, and black poplar are the principal water-tolerant species. In particular, a dense root structure is able to provide some protection as well as substantial reinforcement effect to enhance the stability of the shore both above and below the mean water level. The willow and poplar are particularly useful for bioengineering because they can be propagated from cut limbs. The cut limbs can be placed such that secondary root growth develops and shoots sprout from dormant buds. Trees, which are not water-tolerant, do not have any major direct function in shore stabilization, although they may provide shade to control the growth of aquatic life as discussed earlier.

Use of grasses

Grass is used very extensively in bank protection in the zones above the high water level. Grass roots cannot tolerate prolonged submergence periods. A wide variety of grass species and mixtures therefore are appropriate to satisfy the functional, environmental, and management requirements for a protection scheme. The principal functions which grass fulfills are those of interference, protection, root reinforcement, and soil restraint. The surface root structure forms a composite soil/root mat, which enhances the erosion resistance of the bare subsoil,

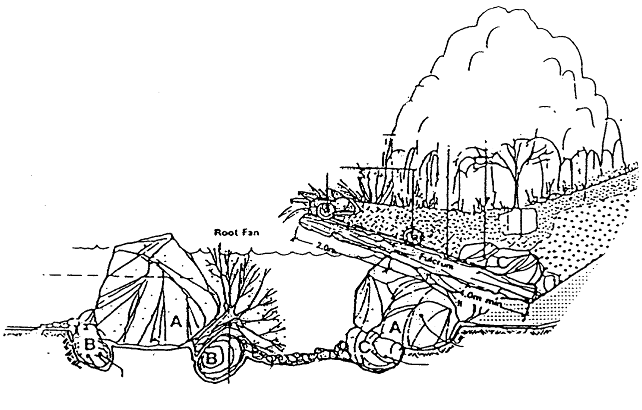

Figure B54 Timber (CANTILEVER) to provide habitat and shade.

and which is anchored into the subsoil by deeper roots. The engineering function of grass may be augmented by the use of geotextile or cellular concrete reinforcement to form composite protection. With both types of reinforcement, the visual effect of grass is retained. Erosion of grass cover by wave runup generally occurs by the scouring of soil from around the roots of a plant, thereby weakening its anchorage until the plant itself is removed by the drag of the flowing water. The effectiveness of grass protection can also be seriously reduced by any localized patches of bare soil or poor grass cover.

The rate of growth of different grasses varies considerably. Complete grass cover should normally be achieved by the middle of the first growing season while full protective strength of the sward is reached during the second season. Provision should be made for aftercare including mowing, fertilizing, and weed control.

Use of timber and woody material

A variety of timber and other dead woody materials can be used in the shore protection scheme usually fulfilling reinforcement, protection, and sometimes drainage functions (see Figure B54). Natural hardwoods will retain their integrity for 5–10 years if built into the bottom of a bank below the water level. Out of the water they can last longer but the worst environment for timber is the alternately wet and dry zone around mean water level.

Monitoring

As part of the project design for the shore stabilization enhancements, a monitoring program is required. The purpose of the monitoring program is to measure the success and applicability of the enhancement methods to other shore projects.

Baseline habitat conditions should be assessed by observation and characterization of existing conditions. A plant survey and macroinvertebrate sampling of the nearshore benthic environment and a terrestrial plant survey should be performed to document existing plant and animal populations. Incidental observations of birds should be made as part of fieldwork. Sampling of nearshore fish populations should be coordinated with local regulatory agencies. Post-construction monitoring of the establishment of biological communities should be completed to evaluate the success of a particular scheme.

Conclusions

Shore protection enhancements similar to those described in this entry have been successfully implemented at numerous sites on the Great Lakes, most notably in Canada at Red Rock Marina, Lake Superior; Thunder Bay Harbor, Lake Superior; Kingston, Lake Ontario; and various reaches of the St. Lawrence Seaway, and at Bender Park, Lake Michigan; Silver Bay, Lake Superior; and in Louisiana (Gulf of Mexico) in the United States. The range of design wave conditions range from 0.75 to 4.5 m at these various sites. Many other projects are in the process of implementation.

Utilization of bioengineered shore protection, in concert with virtually transparent offshore protection (submerged breakwaters, wave screens, etc.) can provide for significant levels of protection while maintaining the natural beauty of an area, and, in most circumstances, providing significant opportunities for habitat enhancement and increased biodiversity.

BIOEROSION

In his study of the erosion of steep cliffs around Huntington Sound in Bermuda by excavating sponges, Neumann (1966) defined the term bioerosion as the removal of consolidated material or lithic substrate by direct action of organisms. Soon after the term, bioerosion, was introduced, geologists and biologists described many different types of bioeroding organisms including algae, bacteria, foraminifera, sponges, bryozoa, annelid worms, barnacles, gastropods, bivalves, echinoderms, fish, and mammals. The process of bioerosion was also reported from many different marine and non-marine environments ranging from mountain slopes to the tops of deep sea knolls, and from rocky intertidal zones and coral reefs to the flanks of continental shelves. Bioerosion has also been reported from climatic zones extending from tropical and subtropical to the subarctic and arctic. Several different types of experiments have been devised for studying the rates of bioerosion by different types of organisms and in different environments. Although bioerosion was first recorded for living sponges in the intertidal zone, evidence for bioerosion was also found in the ancient rocks extending back at least to the Silurian.

Bioeroding organisms

Several different types of microbial borers have been described from modern environments and ancient rocks. Microbial borers including cyanobacteria and chlorophytes were found in modern reef environments at depths between 0 and 230 m, and boring hetertrophs are present between 100 and 300 m (Vogel *et al*., 1996). Evidence for boring algae (cyanophyta) has been preserved in Silurian bivalves and may be responsible for the silicification of their shells (Liljedahl, 1986). Twenty species of foraminifera, ranging age from Jurassic (Callovian) to Recent, are known to make cavities in hard substrates (Venec, 1996). The bioeroding foraminifera were found in turbulent, warm, shallow-water environments.

A wide variety of living and fossil invertebrates have been identified as bioeroders. Several species of boring sponges have been reported from reef areas in Bermuda (Neumann, 1966) and Grand Cayman Island in the British West Indies (Acker and Risk, 1985), and on a deep sea knoll at depths of 1,600 to 1,800 m (Boerboom, 1996). The bioeroding mollusks include chitons, gastropods, and bivalves. *Chiton pelliserpentis* removed hardened mudrock during feeding at Mudrock Bay in Kaikoura, New Zealand (Horn, 1984). The spawn of the gastropod, Nerita, settled on the sea bottom and eroded carbonate rocks at Cathedral Point in Costa Rica (Fischer, 1980). The bivalve genus *Lithophaga* was an active chemical borer in reefs from the Carboniferous through the Eocene (Krumm, 1992). Rock-boring echinoids excavated large cavities in reefs in the South Florida keys (Kues and Siemers, 1974) and on Enewetak Atoll in the Marshall Islands (Russo, 1980). The rock-boring barnacle, *Lithotyra*, eroded the rock face while grazing in the intertidal zone (Ahr and Stanton, 1973). The polychaete annelid, *Eunice*, burrowed into the carbonate rocks along the shore of the Gulf of California.

Vertebrates including fish and mammals play an important role in bioerosion on reefs and mountain slopes. Parrotfish have been observed feeding on coral in reef environments and their rates of bioerosion were measured (Frydl and Stearn, 1978). Recolonization experiments on coral reef communities near Aquaba on the Red Sea demonstrated that herbivorous fish were a major factor in structuring coral reef communities (van Treeck *et al*., 1996). In the Pyrenees of Spain, the indirect effect of digging by small mammals was considered more significant than the direct detachment of soil cover (Martines and Pardo, 1990).

Rates of bioerosion

Several different field experiments have been used to estimate the rates of bioerosion by different organisms and in different environments. On the carbonate coastline of Bermuda, experiments show that the sponge *Cliona lampa* is capable of removing 6–7 kg of material from 1 sq. m of carbonate substrata in 100 days, corresponding to an erosion rate of calcarenite of more than 1 cm per year (Neumann, 1966). In Kaikoura, New Zealand, *Chiton pelliserpentis* removed mudrock from the surface at a rate of 47.3 g/sq. m on the high shore and 173 g/sq. m on the low shore (Horn, 1984). This was equivalent to about 2% of total on the high shore and 5.5% on the low shore. On Moorea reef barrier flat in French Polynesia, bioerosion rates for echinoids was estimated at 4.5 kg/sq. m per year and for scarid fish at 1.7 kg/sq. m per year (Peyrot *et al*., 1996).

Environments of bioerosion

Although most examples of bioerosion have been studied from tropical reefs and intertidal zones, bioerosion also has been reported from high-latitude environments, the outer continental shelf and deep-sea knolls. Algae borings were found in gastropod shells and echinoderm tests in the high-latitude, low-energy environments in the firths of Clyde and Lorne, Scotland (Akpan and Farrow, 1985). Boring sponges were dredged up from Newfoundland from depths of approximately 1,600–1,800 m on top of Orphan Knoll, 550 km northeast of Saint John's (Boerboom, 1996). Evidence for bioerosion was also found in the clastic sediments on the outer continental shelf around the Hudson Canyon off the eastern coast of the United States (Twichell *et al*., 1984). A workshop on bioerosion convened by Bromley (1999) has reviewed several different aspects of bioerosion ranging from the style of bioerosion in Late Jurassic reefs to the role of bioerosion in carbonate budgets in Indo-Pacific reefs.

Conclusions

Bioerosion by microorganisms, invertebrates, and vertebrates is widespread throughout many different carbonate environments from the early Paleozoic to the Recent. Bioeroding organisms have been reported from mountain slopes to deep-sea knolls, from the rocky intertidal zone to coral reefs and from the tropics to the arctic circle. The rates of bioerosion vary from a few grams per square meter to several kilograms per square meter depending on the organisms involved and the depositional environments.

BIOGEOMORPHOLOGY

Biogeomorphology is a discipline that combines ecology and geomorphology. Geomorphology is the study of landforms and their formation. Ecology is the study of the relationships between biota and their environment. The environment is defined as factors that affect biota. These factors can be abiotic (physical, chemical), biotic (other organisms), or anthropogenic (humans). Abiotic geomorphological processes may affect biota and biota may in turn affect geomorphological processes. The interaction between both defines the discipline of biogeomorphology. *Biogeomorphology is the study of the interaction between geomorphological processes and biota*.

Essential concepts

The term biogeomorphology was first used in the 1980s (Viles, 1988), although earlier studies have been conducted that were focused on biogeomorphology without using this term. Biogeomorphology is studied in terrestrial as well as in aquatic systems. In coastal systems biogeomorphological interactions are clearly demonstrated in the shallow, productive waters, and in various sedimentary environments. Examples of biogeomorphological interrelationships include sand dune development, tidal flats, salt marshes, mangrove systems, and coral reefs.

Relevant geomorphological factors in coastal systems are bathymetry, bed composition (rock, gravel, sand, silt), and the transport of sediment. It also includes factors that drive morphological processes, such as water flow and wave energy. The biota involved in coastal biogeomorphology include plants and animals, ranging from very small (algae) to very large (whales).

The geomorphological influence on biota is in its most direct form the influence on habitats (living environments) of flora and fauna. The coastal morphology and geomorphological processes define the gradients between high and low, between wet and dry, and between sedimentation and erosion. These gradients and the processes that cause them are determinative for gradients in grain size of the sediment, nutrient levels, organic matter levels, and moisture. Plants and animals are tuned to specific conditions and will therefore be abundant in specific locations.

The biological influence on geomorphological processes is the influence of biota to create, maintain, or transform their own geomorphological surroundings. This is demonstrated by the influence of vegetation on the hydraulic resistance, erodability and sedimentation, or by the influence of fauna on sediment characteristics through bioturbation and biostabilization.

In some cases morphological processes are dominant over biological processes and therefore the biota have to adjust to their environment. In other cases biological processes are dominant. The most interesting are those cases where there is a mutual interaction that leads to feedback coupling of processes. When looking for these cases, it is important to examine the temporal and spatial scales of the mutually interacting processes. Biogeomorphological interrelationships can be found in several coastal environments, for both hard and soft substrates.

Biogeomorphology for hard substrates

On rocky shores and coral reefs a typical community of organisms thrives that affects the erosion rates of its substrate. Influenced by abiotic factors such as wave energy, splash water, inundation frequency and -period, depth, desiccation and substrate type, a clear zonation can be found of various cyanobacteria, (macro-)algae, fungi, lichens, molluscs, sponges, worms, sea urchins, fish, etc. Some of these organisms dwell on the surface of the substrate, while others live within the substrate. Their effect on erosion of the substrate is divided in "biological corrosion," processes that modify the substrate but provides no erosion product, and "biological abrasion" (see *Bioerosion*), processes that do generate an erosion product. Grazing, burrowing and boring on or in the substrate carries out biological abrasion, and is most significantly found in coral reef systems.

Biogeomorphology for soft substrates

In soft coastal systems, the interrelationships between geomorphological factors and biota can mainly be noticed for benthic fauna and flora. The presence of benthic species is affected by hydraulic and morphologic conditions, such as depth, current velocity, salinity, and grain size. The effect of soft substrate communities on geomorphology is divided into biostabilization and biodestabilization. Biostabilization leads to an increase in soil resistance, preventing erosion, while biodestabilization leads to an increased erodability.

Biostabilization by plants

On tidal flats, small algae (diatoms) are capable of affecting the geomorphology. These diatoms can form extensive algal mats and excrete EPS mucus, which is a sticky substance made of polysaccharides that glues the sediment together and therefore protects the sediment against erosion. Sea grass is dependent on clear water, it needs sunlight to grow. A sea grass meadow slows down the current velocity near the bed and therefore sand and silt will not resuspend in the water, which otherwise would lead to turbid water. Furthermore, their root system binds the substrate. Ultimately, deposition of suspended sediment is encouraged in a sea grass meadow, which leads to the supply of organic material with nutrients, needed for growth.

Seaweeds are also capable of adjusting their physical environment by damping down wave energy; and salt marshes also play an important role in stabilizing sediments. Salt marsh vegetation makes fine sediment settle down resulting in a continuous heightening of the marsh. The higher the marsh gets, the more vegetation can grow and the better the marsh is protected against erosion. Other stabilizing effects result from cementation of beachrock by cyanobacteria and stromatolite formation by algae.

Biostabilization by animals

Some macrozoobenthos can actively catch sediment particles from the water column and bring them to the bed. The presence of a mussel bank, for example, will alter the bed in different ways. Mussels slow down the water flow and they protect the bed against erosion. Mussels also actively catch small particles from the water column by filterfeeding and subsequently excrete these as pseudofeces. This results in a change in the soil composition to finer sediments.

Animal tube fields are also believed to stabilize the sediment, because there is a clear accumulation of fine particles and organic matter between the tubes. The tube itself may affect small-scale turbulence and therefore have a stabilizing effect, however, a great deal may be attributed to the community of microorganisms between the tubes that excrete mucus. Other stabilizing effects result from large banks of dead shells and mucus binding by meio- and macrofauna.

Biodestabilization

Benthic fauna may destabilize the substrate by their digging and feeding activities (bioturbation). The constant mixing and recycling of sediment in the top centimeters of the bed results in a characteristic vertical particle-size profile. The selective uptake and excretion of preferred particle sizes results in sorting and pelletizing sediments. Together with the digging of burrows and the constant movement within the substrate, these activities lead to the generation of a surface micro-relief that has a higher hydraulic roughness and is more prone to erosion. Furthermore, bioturbation also affects the sediment water content, porosity, and sediment cohesion.

Scale interactions in biogeomorphology

Different physical and biological processes can have dynamic interactions when they operate on the same spatial and temporal scales. Processes that act on a very small scale may appear as noise in the interactions with processes on larger scales. Their effect can be accounted for by proper averaging procedures (e.g., for turbulence). Processes that act on a large-scale may be treated as slowly varying or even constant boundary conditions when studying their effects on processes on smaller scales (e.g., sea-level rise due to climate change). Techniques for scale interactions are reasonably well established in geomorphology (De Vriend, 1991) and are based on scale linkage via sediment transport. In biology, however, population and community dynamics give rise to spatial and temporal structures that are not easily linked. In recent years, the importance of scale has been increasingly recognized (Legendre *et al*., 1997) as an essential aspect of understanding the biotic and abiotic processes that affect the biogeomorphology of coastal systems.

BIOHERMS AND BIOSTROMES

History

Originally coined by Cumings (1932), the word bioherm along with its brother term biostrome have been widely used in reef literature, but their proper stratigraphic definition is often misunderstood.

In the original meaning (Chevalier, 1961) a bioherm was defined as a mound or lens-shaped organic build-up, edified by the skeletons of various organisms and lying unconformably inside a stratigraphic series of different lithology. Conversely, a biostrome was a flat, layered reef structure, wide or narrow in shape and causing no stratigraphic disturbance inside its sedimentary environment.

Discussion

Both words "bioherm" and "biostrome" were obviously coined for fossil build-ups, whose stratigraphic position in the sedimentary sequence can be studied; and they were also commonly used for the description of living or subfossil structures, whether the sedimentary environment of the latter is accessible or not to study.

Definitions vary according to authors: In the Encyclopaedia Britannica a bioherm is defined as an "ancient organic reef of moundlike form built by a variety of marine invertebrates ... (and coralline algae). A structure built by similar organisms that is bedded but not moundlike is called a biostrome."

Many geologists, however, extend these definitions to gravity deposited mounds or layers of skeletal remains, such as shells or broken coral, including reworked or transported material, as illustrated by Roger Suthren in his on-line lectures in Sedimentology, a second year Geology module at Oxford Brookes University: "Bioherms: (are) mound or lens-shaped (biological build-ups). Some are in-place organic structures (reefs), others are banks of loose, transported carbonate sediment consisting largely of shells or skeletons. Biostromes: (are) laterally extensive beds, sheets or ribbons of carbonate material. Some have grown in-place (reefs); others consist of transported shells and skeletons."

For Battistini *et al*. (1975) a bioherm is a: "lens shaped organic reef ... embedded *in situ* inside sedimentary layers of different lithological nature ... it may be surrounded by a peripheral talus of biodetrital sediments," whereas a biostrome is a "layered, bank like organic reef of variable extension, creating no discontinuity inside the embedding sedimentary layers."

There is, therefore, no general agreement upon a complete definition taking into account at one and the same time such different characters as: age, stratigraphic conformity or unconformity, along with the autochtonous or allochtonous nature of deposited organisms.

Furthermore, many authors (notably among biologists and geographers) tend to use "bioherm" as a general term not only for major biological build-ups such as extensive algal rims or coral reefs (e.g., see Adey and Burke, 1976) but also for small-scale organic build-ups, for which the word "biostrome" would better fit. Bosence and Pedley, who had first used "bioherm" in a preliminary publication (1979) dealing with Miocene layers of calcareous algae in Malta, appropriately dropped it for "biostrome" in their final paper (1982).

It is, therefore, difficult for an actualist (whether geologist or not) to find criteria sufficiently precise and reliable to distinguish between the alternate notions of bioherm and biostrome. For example, an algal rim growing on the outer edge of a coral reef is indeed a bioherm, or a part of a bioherm since it takes an active part in the sedimentary processes of the latter, but the same kind of formation thinly coating a limestone or a volcanic shore, or on a vertical cliff, without altering sedimentation should be called a biostrome even if both formations are in continuity with one another.

Further difficulty lies in the fact that, for actualists, detrital accumulations of dead shells and broken skeletal material (generally mud-supported) are considered as something very different from a true build-up or reef, since the latter is fundamentally made of an *in situ* developed formation, resulting in boundstone or framestone lithologies *sensu* Bathurst (1971).

Conclusions

Unless bio-accumulated detrital mounds and layers are taken out of the definition of bioherms and biostromes (a revision that only geologists can decide), and the status of small-scale build-ups is settled, the use of the latter words should preferably be restricted to the stratigraphic study of the fossil formations for which they were first coined (their associated detrital facies, and other types of detrital formations being included or not). Students of living reefs are conversely encouraged to prefer more general terms (such as "biological build-up," "reef-like structure," or "biogenic construction") instead.

BLACK AND CASPIAN SEAS, COASTAL ECOLOGY AND GEOMORPHOLOGY

Coastal zone of the Black Sea

The coasts of the Black Sea are rather uniform and slightly embayed. The Crimea is the only large peninsula protruding offshore. The wide opened bays facing the sea (Odesskii, Kalamitskii, Tendrovskii, Karkynitskii, Yarylgachskii, Burgasskii) as well as the above mentioned Crimean Peninsula are located in the northern part of the region. The southern, eastern, and western coasts are smooth and uniform with small bays. The total extent of the coastline exceeds 4,000 km (Figure B55).

Zenkovich (1958, 1959) contributed much to the study of the Black Sea coasts. In the two-volume monograph, he described coasts of the former Soviet Union and analyzed dynamics and morphology of certain regions. Diverse coastal areas were described by investigators from different countries (Nevesskii, 1967; Shuiskii, 1974; Simeonova, 1976; Kiknadze, 1977; Zenkovich and Schwartz, 1987; Shuiskii and Schwartz, 1988; Kaplin *et al*., 1991, 1993). The American Society of Civil Engineers has recently published a collection of articles concerning the Black Sea coasts (Kos'yan, 1993).

The environmental problems of the coasts have been discussed in many publications. The most complete summaries were given in the monographs of Sapozhnikov (1992) and Kuksa (1994).

Large-scale investigations were carried out in the frame of the international INEP program "Black Sea Environmental Program." Due to these activities about 2,000 analytical maps of the Black Sea natural environment were compiled, among them the map of the main sources

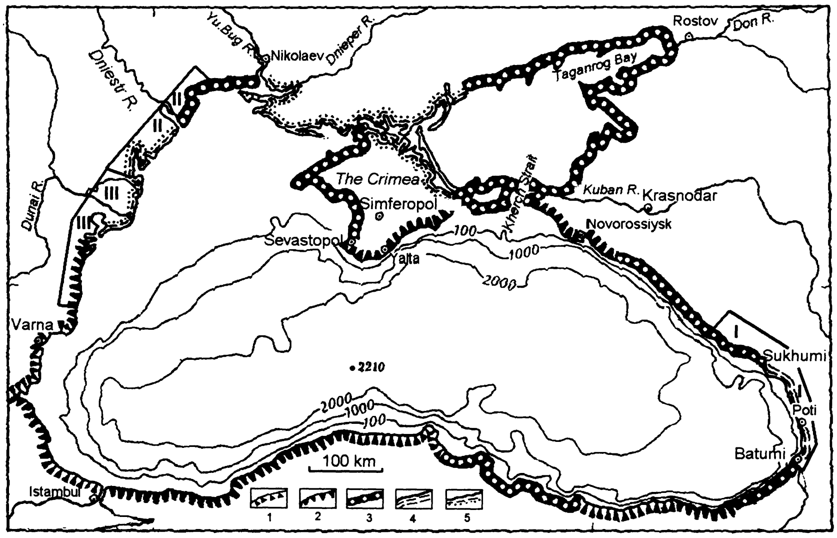

Figure B55 Types of coasts of the Black Sea and the Sea of Azov. 1, straight faulted; 2, erosional bight; 3, graded erosional and depositional; 4, graded depositional; 5, liman and lagoon, erosional and depositional. Key study areas are shown by numbers (I–III).

of pollution in the nearshore zone with subsequent entry to the geoecological information system (Berlyant *et al.*, 1999). The Geographic Information System (GIS) was processed at the Geographical Faculty of the Moscow State University. The users of this GIS may receive not only maps, but also the tables with the data on the amount of pollutants and other information concerning the sources of pollution and natural reserves of the Black Sea. A compact-disc "Black Sea GIS" was published by INOPS/ENVP in 1998.

Environmental problems of the coast

Two main problems could be outlined among the environmental problems of the coasts: (1) influence of the rising sea level upon coastal processes and intensification of erosion related to it; (2) increasing anthropogenic impact.

Anthropogenic impact is mainly manifested by water pollution. Water contamination by pesticides leading to degradation of bottom vegetation was revealed in shallow bays (Kuksa, 1994). It is the result of disposal of freshwater from irrigation systems of Southern Ukraine. Water pollution caused a 3-fold decrease in the phytoplankton biomass in the nearshore zone and a 1.5-fold decrease in the zooplankton and zoobenthos biomass. Considerable pollution of the sea and especially its nearshore zone is determined by the influx of freshwater from the largest river of the region—the Danube. Its influence is noticed along the coasts of Ukraine, Romania, Bulgaria, and even Turkey. The Danube discharges enormous amount of oil-products, heavy metals, pesticides, and other pollutants. Pollutants are mainly accumulated in bottom sediments and biota. For instance, water plants of the Danube coast contain 0.007–0.020 mg/kg of mercury.

The concentration of pollutants discharged by the Danube decreases eastward (near Odessa and Sevastopol) and southward (in Romania and Bulgaria). Other rivers, the Dnieper, Inguri, Rioni, Chorokh and others, contribute much to the contamination of the nearshore waters.

Due to pollution of nearshore waters the role of biogenic sediments (mainly shells) in coastal dynamics decreases. At the end of the 1940s shelly sediments constituted 40–50% of coastal accumulative forms on the northwestern coast (Zenkovich, 1982), while in the 1980s its contribution was less than 10% (Shuiskii, 1974).

Another important ecological factor of anthropogenic origin is the influence of economic activity on the sediment budget in the coastal zone. Regulation of the rivers causes a sharp decrease in the solid river runoff and, hence, less sediments are supplied to beaches. Mass removal of sediments (sand, pebbles, gravel) directly from beaches, quarries, the nearshore zone, and river mouths considerably damaged the coastal zone. In the Caucasian coastal region this process started at the end of the last century when beach sediments were taken for construction of railroads. Mass sediment removal continued in the 1950s–1960s, when ports and other economic objects were built. During 1945–55, 100 million m^3 of beach pebbles were removed from the Tuapse-Adler coast (Kiknadze, 1977). As a result of this action, many beaches of the Caucasian coast became one-half smaller during two or three decades. This caused intensive coastal erosion. Of the 312-km-long Georgian coastline, 220 km were subjected to coastal erosion due to its retreat at a rate of 1–3 m/year. Active coastal erosion manifested by beach destruction was also recorded in the Crimea (Zenkovich, 1982).

During the last few decades many countries have been taking efforts to protect their shores. However, many hydrotechnical constructions such as seawalls, groins, breakwaters, and others have intensified an adverse effect of the sea on the coast. Construction of artificial beaches appeared to be the most effective method. During 1981–86 in Georgia, about 8 million m^3 of sediment was taken from subaerial quarries that facilitated creating artificial beaches with a total area of about 60 ha. As a result, a recreation zone was formed and the problem of shore protection in Georgia was practically solved (Kiknadze, 1977; Zenkovich and Schwartz, 1987). Creation of artificial beaches or additional sediment supply to existing natural ones was undertaken in other regions as well (Odessa, Crimea, Bulgaria).

Coastal geomorphology

In general, erosional coasts predominate along the Black Sea. Elevated mountainous coasts predominate in the eastern and southern parts of the Black Sea. This is a zone of young Alpine orogenesis. Graded and erosional accumulative coasts are typical of the western and northern parts of the sea. Geologically this zone is dominated by hard blocks protruding from the ancient Russian platform and remains of the Baikalian orogenesis. In the Eastern Black Sea erosional processes are especially active due to an extremely narrow continental shelf which sometimes nearly coincides with the coastline as in the Caucasus. Thus, the submarine slope has steep gradients allowing large storm waves to attack the coast.

Slopes of the Great Caucasian Ridge form the largest part of the Caucasian coast, since the axis of the ridge is subparallel to the coastline. This is the reason why cliffy coasts up to 200 m high prevail between Anapa and Sukhumi. The cliffs are cut in the steeply sloping flysch beds and its ridges are noticed in the submarine bench. In the southern part of the Caucasian coast, the Batumi region, foothills of the Little Caucasian Ridge reach the shore. The Colchis Lowland lies between the Great and Little Caucasian Ridges. It follows the large Alpine flexure. The lowland is swamped and its flanks are only slightly higher than the sea level. The lowland experiences a prolonged tectonic submergence. Many rivers flowing from the slopes of both ridges drain onto the Colchis Lowland. Despite this, sandy coasts do not migrate seaward. The heads of submarine canyons are located close to the mouths of the large rivers such as the Inguri, Rioni, Supsa, and others. The alluvial material is removed to the canyons instead of being accumulated on the beaches. Moreover, in many places the shores of the Colchis Lowland are eroded (up to 3 m/year).

The presence of large promontories near Adler, Pitsunda, Sukhumi, Burup-Talii are typical of the Caucasian coast. They are located near

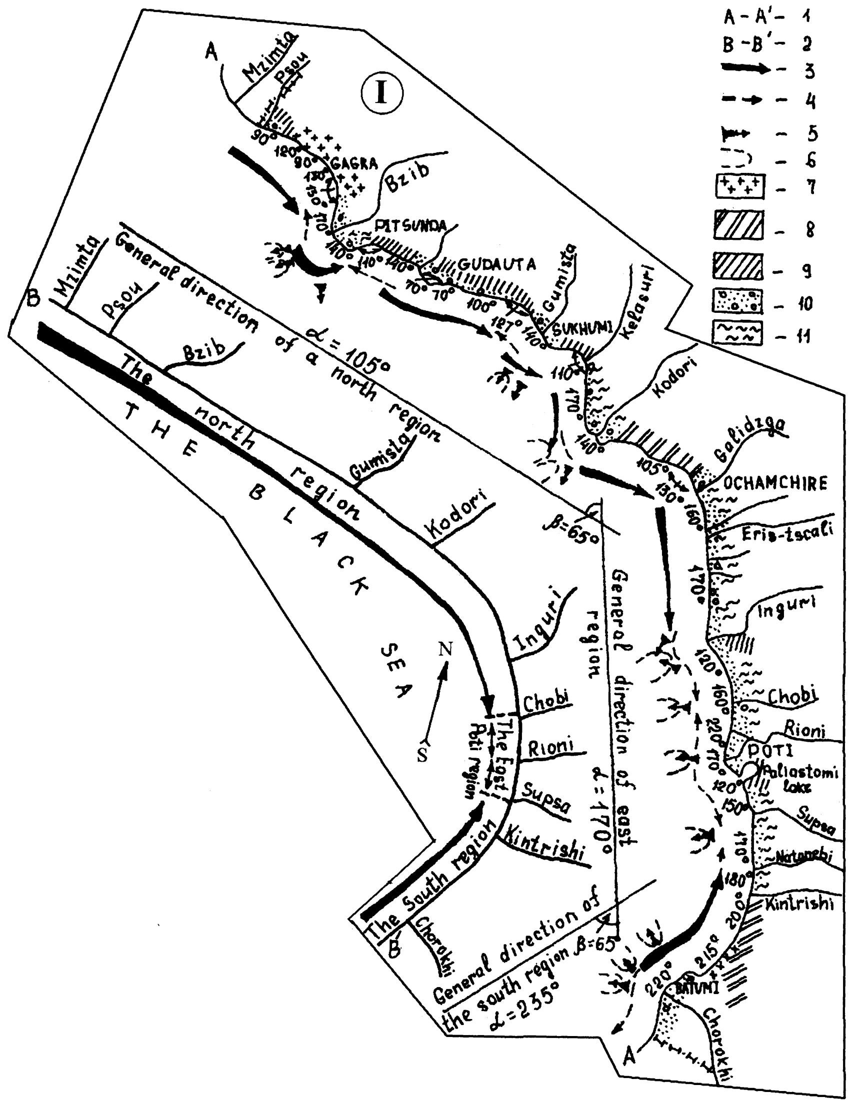

Figure B56 Schematic map of morpho- and litho-dynamics of the Black Sea coast in Georgia (after Kos'yan, 1993). 1, modern coastline; 2, coastline during the period of the drop in sea-level rise 6–5 ka; 3, longshore sediment streams, their direction and relative actual capacity; 4, direction of migration and transport of finer sediment; 5, partial loss of sediments at considerable depths; 6, canyon heads and steep falls; 7, cliffed rocks with erosional relief; 8, semi-cliffed rocks (conglomerates, marl, schists, etc.) with erosional relief; 9, related rocks (marine and lagoonal clays) with plain relief; 10, loose deposits (pebbles, gravel, sands of terraces, dunes and beaches); 11, bog and lacustrine deposits.

the river mouths and consist of the Holocene alluvium (Figure B56). These promontories protrude far offshore and overlie a significant portion of the continental shelf. No other large accumulative landforms are present on the Caucasian coast. The beaches are associated either with numerous river mouths or places of longshore sediment drift discharge. They are mainly composed of gravel and pebbles.

As shown above, accumulative forms are subjected to active erosion. Its intensification is caused by natural reasons: sea-level rise at a rate of 1–2 mm/year and decrease in river discharge due to regulation of rivers and removal of beach sediments. Heads of submarine canyons contribute to coastal dynamics since part of the material transported by alongshore drift is accumulated there. For example, the Akula submarine canyon near Pitsunda accumulates about 80 thousand m^3 of sediments per year (Kiknadze, 1977; Kos'yan, 1993).

Within the Georgian coastal zone alongshore drift is directed to the southeast (Figure B56). Each sediment stream represents a dynamic system with its own source of sediment supply and areas of sediment loss (submarine canyons and steep slopes) or final discharge. The capacity of alongshore sediment streams ranges from 3–15 to 150–220 thousand m^3/year. A small alongshore sediment stream is directed to the north from the Chorokh river mouth to the Colchis Lowland.

High erosional shores are typical of the mountainous coasts of the Crimea. They are subjected to active erosion since they are affected by severe winds (and waves) blowing from the southwest and southeast. Shore destruction is accelerated by landslides occurring in clays. Sometimes the landslides have an area of hundreds of square meters. For instance, the town of Alupka is located on six large landslides and its stability is conditioned by several factors. Of these are influence of underground and surface waters, abrasion, load of buildings and other construction.

Many shores of the Southern Crimea are formed by the slopes of ancient volcanoes (Karadag region) and tectonic faults. Outcrops of volcanic rocks and limestones form capes separated by shores represented by soft shales, clays, and sandstones. Ria-coasts occur near Sevastopol and Balaklava.

Beaches of the Southern Crimea are formed of pebbles, because finer sediments (more than 0.03) are transported down the steep submarine slopes. Removal of pebbles for building purposes caused the disappearance of beaches. However, some of them have been recently restored.

Many shores of the Southern Crimea are artificially protected. Dynamic interaction between different regions is weak due to the absence of large rivers supplying sufficient amounts of alluvial sediments to the coastal zone. Thus, local shore protection is successful and has no negative influence on adjacent coasts. Different, usually complex, engineering structures are used that protect coasts from both landslides and abrasion. Of these are embankments with seawalls, traverses, breakwaters, groins with artificial sediment filling between them, etc. (Zenkovich, 1982; Kos'yan, 1993).

Steep coasts of the Southern Black Sea are formed by densely forested northern slopes of the high Eastern and Western Pontus mountains stretching subparallel to the coastline. The mountains gradually lower westward and near the Bosphorus Strait their height does not exceed 300 m. Erosional and denudation coasts with steep rocky cliffs are widespread in Turkey. Only in separated small bays do the sandy-pebbly "pocket" beaches occur. Areas of sediment accumulation are associated with mouths of such large rivers as the Kizil-Irmak, Sakarja, and Eshil-Irmak. These rivers form rather large deltas prograding far offshore and nearly reaching the edge of the narrow continental shelf. Violent storms produced by severe northwesterly winds deflect the pathways of alluvium to the east thus forming flanked barriers (Kos'yan, 1993).

The largest curves of the Turkish coast correspond to the lowland peninsulas of Bafri and Djiva, related to river deltas and the mountainous Injeburun Peninsula.

Western and northwestern coasts of the Black Sea are rather low with hilly plains of different origin (alluvial, marine, and alluvial–marine) facing the sea. The delta of the Danube, the largest river of Western Europe, is located here. It has a complicated structure. Besides common channel bars there are a series of cheniers (local name "grindu") marking the stages of delta progradation. The river mainly discharges through its northern Kiliiskii channel. Thus, the southern part of the delta is smaller and is being slightly eroded. Active utilization of the Danube water for irrigation by five countries reinforces erosion of the southern part of the delta. There are numerous water reservoirs in the delta: lakes-limans (northern part), complexes of lakes and lagoons (southern part), lakes (inner part). From the north the delta is bounded by the Budzhak plateau, and from the southwest by the lake–lagoon complex of Rozelm-Synop. Abundance of warm water and high fertility of soils favor plant and animal life.

Coasts to the northeast from the delta are represented by plains and low plateaus. The only exception is the anticline of the Tarkhankut Peninsula. Its steep slopes are mainly composed of easily eroded loesses and clays. The rate of erosion ranges from 7 to 20 m/year (Shuiskii, 1974).

These erosional coasts alternate with lagoons and limans. Limans represent the lower parts of river valleys that have been flooded during the Holocene transgression. Most of them are separated from the sea by sandy–shelly accumulative forms (spits or baymouth barriers). Specific environmental conditions exist in limans since their waters are warmer and less salty. As a result, productivity of waters is higher.

A considerable part of the coast is subjected to landslides. Both landslides and coastal abrasion destroy valuable territories of the Ukrainian steppes. At present, the accumulative forms in the mouths of limans are eroding. They are composed of sand layers overlying lagoonal clays, thus giving evidence for migration of the accumulative forms toward the lagoons (Shuiskii and Schwartz, 1988).

Two opposite longshore drifts exist in the region stretching to the northeast from the Danube River to Odessa (Figure B57).

Jagged coasts are characteristic of the region to the east from Odessa including the western Crimea. Adjacent lowlands experience relative submergence at a maximal rate of 30 cm/ 100 years as recorded in the inner part of the Karkinit Bay. Large accumulative forms are the most interesting elements of the coastal relief, that is, the Kinburn spit and the system of the Tendra-Dyarylgach spits related to it.

The Kinburn spit and Odessa shoal (to the west of it) originated in the place of the Dnieper and South Bug deltas junction. Under the

Holocene sea-level rise deltaic sediments were reworked and a system of subaerial and submarine sand bars was formed. Dunes and salt lakes located on the Kinburn spit are parallel to the coastline.

The Tendra and Yarylgach spits represent a joined accumulative form that continues to grow. However, landward migration also takes place. As a result, the central part of the accumulative form became attached to the continental shore, and its distal end formed two separate spits.

The eastern part of the Crimean Peninsula, together with the Taman Peninsula, form a single coastal region divided into two parts by the Kerch' Strait. The territory is covered by limans and lagoons associated with the ancient and modern delta of the Kuban' River. However, erosional shores are dominant. The coastline represents a series of arcs where clays of Maikopian age intercalate with solid rocks of Neogene age that form headlands.

Along the Kerch'–Taman' coast relics of the ancient accumulative forms and lagoonal silts were reported that allowed for reconstructing the Holocene history of the coastal area.

The western coast of the Black Sea lies in Romania and Bulgaria. The Romanian coast is subdivided into two parts. Its western part corresponds to the Danube delta that equals 78% of the delta surface. As mentioned above this part of the delta is now eroding at the rate of up to 7 m/year (Kos'yan, 1993).

Southward from the delta the coast is graded. It is composed of loesses, clays, and limestones of Neogene and Pleistocene age. A considerable part of the southern Romanian coast (51 km of the total 101 km) is abraded and consists of active cliffs 2–40 m high. The rate of abrasion averages 1–2 m/year, sometimes reaching 7 m/year. Maximal rates are characteristic for cliffs composed of loesses and clays. Capes are usually formed of Neogene limestones. Submarine benches are typical of the Romanian erosional coasts. Their width sometimes reach 1,100 m (Figure B58).

Coastal accumulative forms are represented by sandy beaches resting against cliffs and, near the river mouths, and by barrier forms separating lakes and lagoons. Sintghiol is the largest sandy barrier. Sedimentary material is supplied to the sea by the Danube delta and active cliffs.

The Romanian coast is actively used for recreation. To protect the coast from destruction certain efforts have been taken: construction of seawalls, cobble filling, etc.

The coasts of Bulgaria are mainly erosional. In southern Bulgaria erosional forms are restricted to the small bays of the zone of Alpine orogenesis. Cliffs of eight different types are distinguished in this area: from 15 to 20 m high cliffs with even surfaces composed of uniform loess and clayey deposits to high cliffs (up to 60–90 m) with uneven surfaces and a series of landslide steps on the slopes. Such cliffs are widespread in the region between Kavarna and Balchik and Kranevo-Zlaty Pyaski. Earthquakes facilitate landslides thus considerably accelerating retreat of the coast. The average rates of erosion vary from 0.005 to 1 m/year. Maximal rates reach 30 m/year. The estimated amount of material released due to abrasion of cliffs is 1,344,100 m^3/year.

Material produced by coastal abrasion and alluvium forms the beaches that occupy 28% of the Bulgarian coast (Simeonova, 1976). Some of the beaches, like that at Varna, prograde at a rate of 0.75 m/year. Similar process operate near the mouth of the Kamchiya River and in the region of the popular resorts of Albena and Zlaty Pyaski. However, most of the accumulative coasts retreat. For instance, between Cherny Nos Peninsula and the Albena resort the rate of retreat is 0.12–0.63 m/year. Generally the rate of retreat grows in the northward direction. Erosion often results from the negative influence of human activities and underestimation of the role of coastal processes. To protect coasts from erosion Bulgarian engineers fill up tetrapods with stones and construct dams separating the bays from the sea and straighten the coastline.

The coasts are also protected by groins (often short and without any filling between them), seawalls and other less effective structures. The most effective means, such as creation of artificial beaches, are not implemented in Bulgaria.

Sea-level oscillations played an important role in the recent evolution of the Black Sea coasts. From the available data it follows that during the 20th century sea level was steadily rising at the average rate of 2.1 ± 1.3 mm/year (Nikonov *et al.*, 1997). This estimation is based on the data collected at 70 points on the Russian, Ukrainian, Georgian, and Bulgarian coasts. The values exceed the average rate of the global sea-level rise, probably due to tectonic submergence of the Black Sea depression. Different estimations of the sea-level oscillations could be definitely attributed to different tectonic movements. The highest rates of sea-level rise were recorded in the Colchis Lowland, while the lowest ones were in the northeastern Black Sea.

Thus, it might be concluded that submergence of the coasts has been the main trend in their recent evolution. This process leads to abrasion of the cliffed coasts and erosion of the accumulative ones. However, under predicted conditions of more rapid sea-level rise, erosion will be intensified and many of the unique accumulative forms will be destroyed. First of all this affects the accumulative forms of the limans in the northwestern coastal area (Tendra, Binburn, Yagyrlach spits). Their destruction may have a severe impact on the ecology of limans that are the zones of extremely high bioproductivity. Sea-level rise will accelerate destruction of the Holocene accumulative forms on the Georgian and Turkish coasts. In this connection, all countries of the region must plan enhancing protective activities and carry out a long-term policy of coastal management.

Coastal zone of the Caspian Sea

The coasts of the Caspian Sea display a great variety of natural environments being located in different landscape zones. Recently, the problems associated with the rapid rise of its sea level have generated particular interest, especially in the context of the expected accelerated rise of the global sea level (Dolotov and Kaplin, 1996).

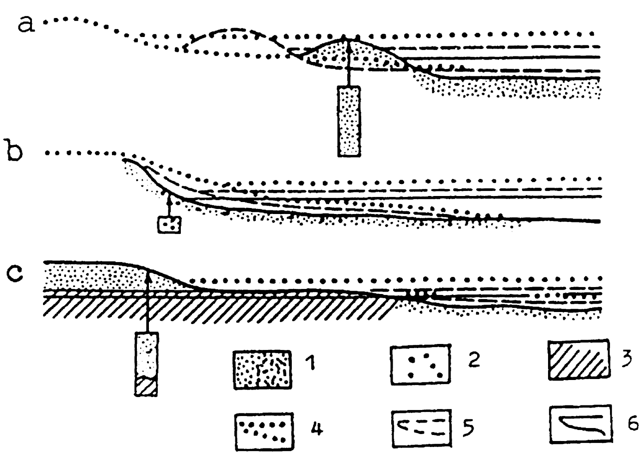

Figure B59 Processes of relief formation and sediment accumulation in shallow-water neashore zone under sea-level fall (after Dolotov, 1996). a, continuous sediment accumulation; b, erosion of external edges of accumulative coasts; c, preservation of sandy accumulative body; 1, sand; 2, pebble; 3, bedrock; 4, 5 and 6, successive positions of sea level.

The history of investigations on the Caspian Sea coasts was discussed in detail in the monograph of Leont'ev and Khalilov (1965). Further generalization was given in the monograph written by Leont'ev with co-authors (Leont'ev *et al.*, 1977). Present environmental problems of this area were outlined in the monographs of Kuksa (1994) and Zonn (1999).

Environmental problems of the Caspian Sea coastal zone arise from active economic development of not only the Caspian Sea itself, but its drainage area and adjacent territories (Kaplin and Ignatov, 1997). This region is distinguished by repeated sea-level changes, both seasonal and multi-annual. That is why the Caspian Sea is a natural laboratory for studying evolution of coasts under different sea-level oscillations.

In the modern historical period a rapid sea-level fall (of nearly 1.7 m) occurred from 1929 until the early 1940s. Dynamic changes in the coastal zone mainly depended upon the rate of sea-level fall (or decrease in depth in the nearshore zone) and the amount of sediments in the coastal area (Dolotov, 1961).

On the shallow-water sand coasts that are typical of the Caspian Sea the relief-forming processes are controlled by sediment budget, gradient of the coast, and configuration of the coastline under sea-level fall going on at different rates. Three types of the coasts with different patterns of relief changes have been identified.

Continuous accumulation of sediments and progradation of coasts (Figure B59(a)) takes place in case sufficient amounts of sediments are supplied to the coastal zone from adjacent land and shores (positive sediment budget over prolonged time period). If a positive sediment budget is replaced by a negative one progradation of the coast changes to landward retreat of the coastline (Figure B59(b)) (irregular sediment supply). Under insufficient sediment supply erosion is replaced by preservation of sandy accumulative bodies that occurs when direct wave attacks over the former coastline have ceased (Figure B59(c)).

Under sea-level fall the evolution of the Caspian Sea coasts went on in the following manner: continuous accumulation of sediments, emergence of the seafloor, and continuous seaward advance of the coastline. The area of coasts enlarged, and economic activity occupied new territories where settlements, roads, oil- and gas-pipelines, and resorts were constructed (Dolotov, 1996). Taking into consideration the predicted future sea-level fall the Soviet Government decided to create a vast recreation zone in the coastal regions of Dagestan and Azerbaidzhan (Molchanova, 1989). The Caspian coast offers several advantages over the Caucasian coast of the Black Sea. Sandy beaches are wider and longer here, solar radiation is more active and the number of sunny days in summer is higher (Veliev *et al.*, 1987). Part of these constructions has already been built.

In 1978, an unexpected and sharp sea-level rise occurred. The average rate of sea-level rise was 14–15 cm/year, but in some years it was as high as 30 cm/year and even more. The direct influence of the sea-level rise was flooding of coastal lowlands and acceleration of coastal erosion. The indirect impact included the rise of groundwater, swamping of the coastal area, salinization of soils, and expansion of surge areas. Environmental conditions of both the nearshore shallow zone and adjacent land sharply changed. Sea-level rise favored erosional processes and general landward migration of the coastline.

At the same time, contrary to the general trend of sea-level rise, in some patches of the western coast accumulation of sediments went on and the coastline migrated seaward. This happens, when sediment input exceeds the amount of unconsolidated sediments flooded by the advancing sea. These coastal regions are of special interest since they give a unique opportunity for future economic development (primarily recreation) even under the ongoing sea-level rise.

Generally, the character of relief changes under sea-level rise depends upon the rate of this rise, relief-forming environmental processes (hydrodynamics), and sediment balance. Coastal morphology determines the character and rate of the natural catastrophic processes together with their impact on economy and population (Dolotov, 1996).

Coastal geomorphology

Based on differences in relief, the Caspian Sea coast is subdivided into four regions (Leont'ev *et al.*, 1977).

The western coast receives about 50% of the total solid river runoff, while the material produced by abrasion is considerably less abundant. As a result of a positive sediment balance coastal erosion is suppressed. Under dominant northwesterly and southeasterly winds longshore drift streams are formed that smooth the coast and create accumulative forms.

River runoff is practically absent in the eastern regions. Active erosion in the recent past has not produced sufficient amounts of sedimentary material, since the cliffs are mainly composed of clays and limestones. Biogenic and chemogenic sedimentation went on slowly. As a whole, the coast is more embayed than in the west. In places where the coastline remains relatively straight over long distances, prevailing waves that are transversal to the coast form large accumulative barriers.

The northern coast is distinguished by extreme shallowness. Southeasterly and northerly winds predominate here. Abundant fine-grained alluvial material supplied by rivers is transported in the form of suspension. Winds and on- and offshore currents form the coasts characterized by frequent and significant displacement of the coastline.

Southern coasts are represented (Voropaev *et al.*, 1998) by coastal lowlands ranging in width from 1 (in the central part) to 60 km (near the large deltas of the Sefidrud and Gyurgyan Rivers). More than 40 small rivers discharge into the Caspian Sea in this region. During the past 50 years, solid river runoff was considerably reduced due to construction of reservoirs on all the large rivers. Granulometric composition of the beaches changes from gravel–pebble (western Mazenderan) to sand (Gilidzhan, central Mazenderan), and silt (eastern Mazenderan).

Several types of accumulative coasts occur in the Caspian Sea: lagoonal shores, coasts with terraces and other accumulative forms, erosional and deltaic shores, mudflats, coastal lowlands formed by onshore winds and waves (Figure B60).

Deltaic coasts occupy considerable parts of the coast—these are the deltas of the Volga and the Ural in the north, Terek and Sulak in the northwest, and Kura in the southwest. Even, quite recently, these rivers discharged considerable amounts of sediments into the sea thus supporting progradation of deltas. This process intensified during sea-level falls. In the northern Caspian Sea, where the Volga and Ural deltas are located, coasts have retreated seaward by dozens and hundreds of kilometers since 1929. In the late 1950s and 1960s large-scale hydroengineering projects were launched. This caused dramatic decrease in river discharge of such rivers as the Kura, Terek, and Sulak. The rise of the Caspian Sea level caused erosion of deltas. Coastal lowlands of the Northern Caspian region became inundated, and the previously accumulated coastal landforms were destroyed.

Large portions of the Caspian Sea coasts are flat. They were formed in course of regression that took place from the 1930s to the 1970s. Mudflats occur in the northern Caspian region, around Kirov Bay in southern Azerbaidzhan, in the region surrounding Krasnovodsk Bay and to the south from it. During regression aggradation of the northwestern coasts of the sea proceeded at a rate of 60–100 m/year, in the Kizlyar Bay it was faster and reached 150–200 m/year, and northward of it-even 700–800 m/year. In the Kirov Bay wind-induced mudflats were up to 1.5 km wide (Kaplin, 1997). The sea-level fall resulted in considerable advance of land in the eastern coastal regions. For instance, southward from the Cheleken Peninsula the average rate of land advance during the period from 1929 to 1957 was 34–36 m/year (Leont'ev *et al.*, 1977). Naturally, shallow bays of the northern coast were dried up.

The change from regressive to transgressive regime has dramatically affected the drained shores with mudflats. Gentle gradients (close to 0.0001) of submarine slopes caused passive flooding of the coasts.

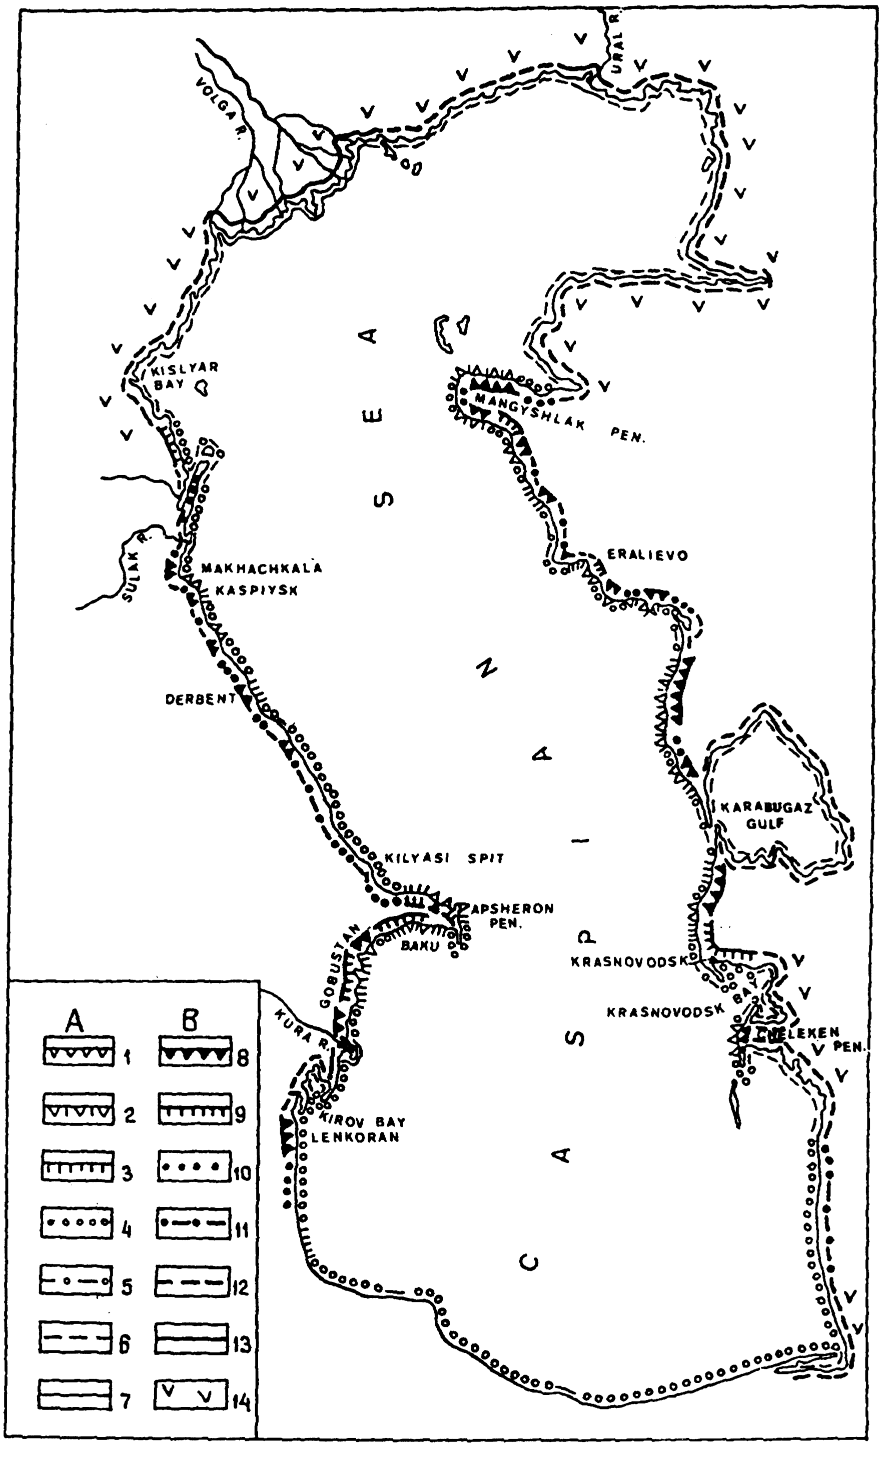

Figure B60 Types of the Caspian Sea coasts (after Ignatov *et al.*, 1993).
A, regressive stage (prior to 1977). 1, erosional shore; 2, erosional shore with passive cliff; 3, erosional–accumulative shore; 4, progradingbeach; 5, accumulative lagoonal shore; 6, mudflats formed by wind-induced surges; 7, deltaic coast. B, transgressive stage (after 1978). 8, erosional shore; 9, erosional–accumulative shore; 10, prograding beach; 11, accumulative lagoonal shore; 12, mud flats; 13, deltaic coast; 14, areas affected by transgressive flooding.

Sea-level rise resulted not only in submergence of land, but rise of the groundwater table and, hence, salinization of groundwater and swamping of the adjacent lowlands. The Kirov Bay was filled with water again. In the vicinity of the Kilyazinskaya spit (northern Azerbaidzhan), a flat coastal terrace that formed in 1940 due to sea-level fall has been partly flooded and swamped. Considerable parts of coastal lowlands in the northern near Caspian region on both sides of the Volga River have been flooded. Accumulation of sediments went on in such bays as the Komsomolets, Kaidak, Mertvyi Kultuk, Bol'shoi Sor in the Bugaz Peninsula, and in depressions between Baer knolls that are widespread in the northern and northeastern Caspian lowlands. Wind-induced surges up to 1.5–2 m high caused passive flooding of this vast area. These phenomena resulted from a longshore drift and caused episodic abrasion of the coasts and erosion of the seafloor, producing furrows and ridge-and-runnel erosional forms. Wind-induced currents re-suspended sands and silts previously accumulated on the seafloor. Suspended material was removed by currents and precipitates near the shoreline to form saltings (mudflats).

Sea-level rise changes accumulative coasts as well. As mentioned above, accumulation that took place during the regressive stage affected nearly the entire coastline, but the pattern was somewhat different. As sea level was falling, cliffs became passive, longshore drift ceased, and spits were eroded, especially at their base. We can exemplify the Kura and Agrakhan spits on the western shore, the accumulative form of Cape Rakushechnyi, Kenderli, and Krasnovodsk spits on the eastern one. With the drop in sea level, the middle and lower parts of submarine slope became eroded. The produced clastic material is gradually transported upward the slope and accumulated near the shore. Intensive landward transportation of sediments inhibited the longshore drift.

Due to the sea-level rise former cliffs became active again and abrasion intensified. Transgression changed the profile of submarine slopes, especially their upper parts. These changes are accompanied by erosion of the frontal part of accumulative forms or creation of bars near the water edge that later turn into beach barriers separating the sea from lagoons. Many lagoonal shores were formed in Dagestan and northern Azerbaidzhan, where gradients of the submarine slope equal 0.005. The present sea-level rise is responsible for accumulation of beach barriers separating lagoons. The beach barriers are overlapping lagoons thus giving an impression that the coastline retreats. However, lagoons keep expanding despite the landward migration of beach barriers since flooding of drained territories and the rise of the groundwater table favor further expansion and deepening of lagoons.

The coasts of Dagestan and Northern Azerbaidzhan, with steeper gradients (up to 0.01), have shore-attached bars formed of coquina. These bars have an asymmetrical profile giving evidence of their landward migration towards young terraces behind them. No lagoons are formed because the coasts are steep and lie above sea level.

Finally, slopes with gradients exceeding 0.01 are subjected to active erosion of both Holocene and recent accumulative forms. This trend leads to significant landward retreat of the coastline (Kaplin, 1997). Evolution of such coasts follows the well known "Bruun's rule" (Bruun, 1962).

The transgression has also affected erosional coasts. The latter are typical of the Eastern (Mangyshlak Peninsula, regions northward from the Kara-Bogaz-Gol Bay, Cheleken Peninsula) and, partially, Western (Dagestan, Lenkoran', Apsheron Peninsula) Caspian Sea. The share of erosional shores on the Dagestan coast increased from 10% to 40%, on the Azerbaidzhan coast—from 20% to 55%, Kazakhstan—from 8% to 13%, and Turkmenistan—from 7% to 22%. Until recently, some places on the Dagestan coast have been protected from erosion by offshore submarine ridges composed of limestone. Benches and ridges have been flooded by the transgression, during storms (especially surges) waves reach the cliffs. If the cliffs used to be protected by accumulative terraces, clastic material has been actively reworked; part of it being transported into the longshore drift and the rest removed down the submarine slope. In general, the above-water parts of the slopes were more actively abraded by sea waves, and the coastline rapidly migrated landward. In some parts of the Dagestan and Lenkoran', the rate of the process reached 20–25 m/year.

Therefore, the recent rise of the Caspian Sea level has significantly modified the dynamics of all identified coastal types. Evolution of the coasts subjected to relative submergence depends upon the gradient of the submarine slope (Kaplin, 1997). Different ways in evolution of accumulative coasts under the sea-level rise (Figure B61) have been discussed in several publications on the Caspian Sea (Kaplin, 1989, 1990; Ignatov *et al.*, 1992, 1993). The coastal dynamics of the Caspian Sea display a certain discrepancy between transgressive and regressive regimes on the one hand, and cycles of the coastal evolution on the other hand. A regressive regime usually corresponds to the cycle of accumulation. However, erosion of coastal accumulative forms started in the 1960s when sea level was still falling. Certainly, one of the reasons why erosion became active is economic activity, such as construction of barrages and irrigation networks that reduced the solid river runoff and led to the deficiency of sediments in the coastal zone. On the other hand, it is natural that an erosional cycle succeeds the accumulative one. The reason is that both a drop in the sea level and its rise under transgression are associated with reformation of the submarine slope and with its erosional cutback. Yet, during regression the zone of the shore slope erosion shifts seaward, not landward, involving parts of the outer slope where benthonic material is of a finer grain size. With time the deposits of fractions that can be transported up the slope and that can built the accretion forms are depleted. Although the rates of the Caspian coastal processes are much higher than of those in the world ocean, these processes are essentially similar. Therefore, research into the Caspian Sea coastal dynamics has importance beyond its regional significance. It may be of great use for simulating the formative laws applying to the coastal dynamics of the world ocean, particularly as the ocean level is rising and is likely to keep rising in the future as a result of global warming (Kaplin, 1997).

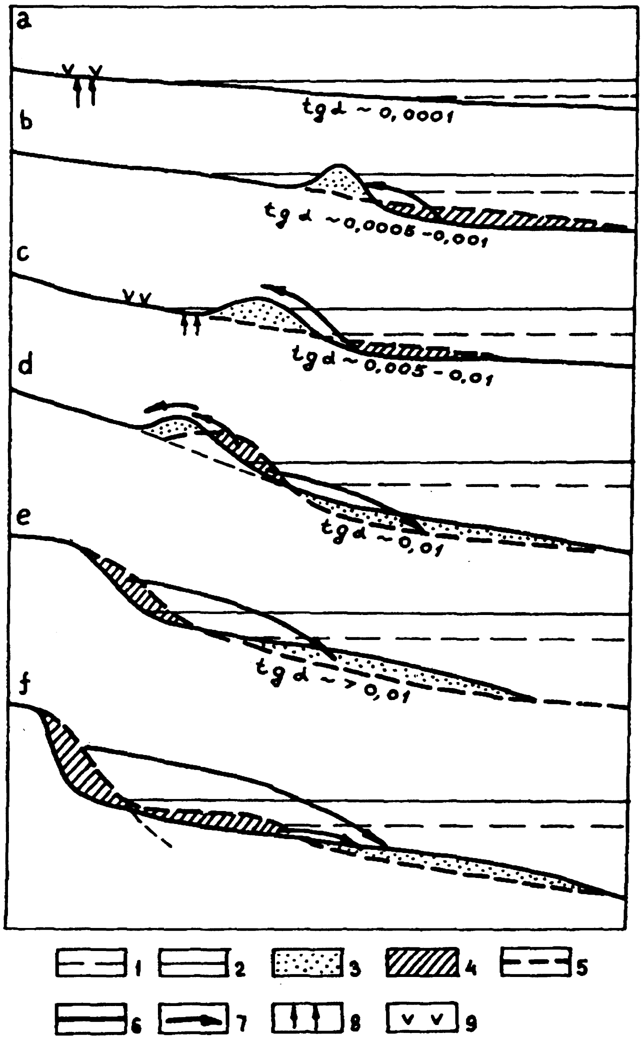

Figure B61 Schematic representation of the Caspian Sea transgressive coasts in function of the offshore gradient (after Kaplin, 1989).

Environmental problems of the coasts

The present environmental conditions of the Caspian Sea are determined by the effect of rising sea level and increasing anthropogenic impact (Kaplin, 1997).

Considerable sea-level rise has already adversely affected the economy of the coastal states of the Caspian region including the Russian Federation that occupies its northwestern part—the Dagestan, Kalmykia, and Astrakhan' region. Many industrial and habitable buildings, recreational structures and other objects are now in the zone of flooding or in the zone of subsoil water penetration (Dolotov, 1996).

The rising sea level poses threats as follows: flooding and underflooding of coastal areas earlier occupied by communication facilities, livestock farms, grazing lands, fish hatcheries, piers, fish spawning grounds, wildlife and nesting bird habitats. It also prevents cattle from accessing fertile pastures. Incursions of seawaters into areas occupied by human settlements or farms generally lacking treatment facilities resulted in capture and retransportation of technogenic products, municipal effluents and wastes toward the Caspian Sea increasing the supply of pollutants. Flooding causes malfunctioning of irrigation channels and transverse drains in the irrigated areas. Intensive shore erosion has caused losses of considerable land areas.

Special environmental problem is the underflooding of running and suspended wells in the oil and gas fields and subsequent propagation of oil products. Since oil production has or had been carried out over many decades it is evident that significant amounts of oil have been accumulating in the soil, finding their way into, and heavily polluting the sea. The oil film formed over large areas, dramatically reducing water evaporation and affecting the Caspian water balance (Kaplin, 1997).

Starting up of the first turn of the Astrakhan' gas-condensate complex together with exploitation of oil and gas-deposits present a potential threat to existence of unique ecosystem of the river mouths in the Northern Caspian region (Kuksa, 1994). Development of shelf oil and gas fields by the Caspian states strongly affects natural processes by pollution of water and bottom sediments, destruction of plant cover, and considerable reduction of fish resources (Kurbatova, 1994).

In course of the Caspian sea-level rise some of the productive oil and gas fields on the coast will be flooded. The flooded area will also include prospective sites for deep exploratory well-drilling.

The major sources of pollution of the Caspian Sea water consist of: river (surface) runoff; untreated effluents discharged from enterprises, farms, or human settlements in coastal areas or in the river mouths; navigation accidents and technical processes in industries operating directly in the Caspian water area; surface washout during surges; and flooding of producing oil and gas fields, industrial sites, agricultural lands, and human settlements.

River runoff is the largest source of pollutants to the Caspian Sea accounting for 90% or even more of the total influx of pollutant. It is attributed to the fact that the Volga, Ural, Kura, and Terek rivers receive polluted effluents from various industrial facilities and farms along their entire courses. Concentration of various pollutants in river water at river mouths exceeds the maximum permissible levels, frequently by a very wide margin (up to 10-fold or more).

It should be noted that pollutants transport with river runoff is a rather constant process, varying only slightly in different years. The most important consequences are as follows: large amounts of pollutants carried to the sea by rivers under the influence of hydrometeorological factors (wind, currents, waves) penetrate the entire water column and bottom sediments, that later act as the sources of secondary pollution of seawater. Self-purification processes are unable to neutralize the water continuously impacted by chemical inputs. Environmental conditions in river deltas are seriously threatened, mainly in deltas and river mouth beaches. The latter represent the most valuable natural water complexes that act as the principal fish spawning and foraging grounds as well as waterfowl nesting places and rest areas.

The second important source of pollutants transported to the sea are effluents discharged from enterprises, farms, or human settlements situated directly on the coast. An extremely adverse effect on the marine environment is produced by sudden discharge of pollutants resulting from accidents at enterprises of treatment facilities as well as various failures of sewage systems (Kaplin, 1997). All maritime cities, first of all, Astrakhan', Baku, Makhachkala, Turkmenbashi, are sources of pollution that drop to the sea sewage waters (Zonn, 1999).

The third major source of seawater contamination are accidents (oil and oil products spills) occurring during navigation and exploitation of offshore oil- and gas-fields, as well as, owing to the sea-level rise, flooded coastal oil fields. Accidental spills of oil and oil products are a source of significant damage to marine ecosystems, because concentration of pollutants may be extremely high exceeding the permissible level by hundreds or by even thousands of times.

Biological resources and fish reserves are affected as early as at the stage of seismic exploration of oil and gas fields. Special damage was caused by blasting operations that were responsible for the large-scale mortality of sturgeons. During drilling operations on the continental shelf, a special threat is posed by sustained discharges of liquid and solid wastes that are associated with the drilling process. Environmental consequences in the areas of offshore oil- and gas-field development are observable 5–12 km away from the drilling site and are manifested as high levels of oil pollution of water, bottom sediments, aquatic and benthic fauna and flora, and reduced species diversity of benthic communities and degradation of their structure (Kaplin, 1997).

The sea receives water wastes from many sources. From 2 to 5 tons of heavy metals, 60,000–200,000 tons of petroleum products, and more than 5 million tons of organic pollutants are dumped into deltas every year. The sediments are, therefore, contaminated by heavy metals, especially lead and cadmium, and their concentrations exceed many times those of the natural background. The composition of organic matter within the limits of deltas and their flood-plains causes deterioration of the oxygen regime and leads to hydrogen sulfide pollution of the beaches.

The flooding and associated contamination of land initiates specific biogeochemical processes whereby anaerobic gas generation is stimulated. The waters then become contaminated by metal compounds, heavy hydrocarbons, carbon dioxide, and nitrogen compounds, as well as bituminous substances and aromatic (benzene) polycyclic hydrocarbons. Generation of hydrogen sulfide poses the greatest danger (Kaplin, 1995).

Transformations of ecosystems in all rivers of the Caspian Sea basin occurred due to hydraulic engineering and hydro-energetic projects, exploration of oil- and gas-fields, oil-chemical production, irrigation of nearshore territories, and increase of industrial and domestic water supply (Zonn, 1999).

BOGS

Terminology

The term bog is used to describe certain forms of wet terrestrial vegetation. Unfortunately, in common with the words employed for many other categories of wetland, there are variations and inconsistencies in usage, regionally (particularly within Europe) as well as globally. Bog has been broadly defined so as to encompass all types of peat forming vegetation (see entry on *Peat*) or narrowly defined to denote only plant communities which are dependent upon precipitation and dust for supplies of water and nutrients. The term peatland is more appropriate for the former. The latter "ombrotrophic" condition may be an absolute state, however, this is by no means always the case and it is perhaps not surprisingly, therefore, that such communities have floristic affinities with other wetland vegetation types. Consequently, recent authors (Wheeler and Proctor, 2000) have preferred to use the term bog to describe a type of vegetation, that is, one which is usually dominated by either (or a combination of) sphagna (mosses), ericoids (dwarf shrubs), or Cyperaceae (sedges). Bogs are characteristically base-poor (with a pH < 5.0) and generally, though not exclusively, occur over a substratum of peat. Rather than peatland, an additional term, mire is preferred here to describe all forms of wet terrestrial vegetation. Bogs frequently grade into base-rich mires, which in Europe are referred to as fens. Fens may be herbaceous or wooded (fen carr in Europe), for which in the United States the terms marsh and swamp are, respectively, commonly used.

Classification and distribution

Mire vegetation is strongly influenced by hydrology and topography and hydro-topographical relationships have been widely used in mire classification schemes. Fundamental is the division made between the ombrotrophic (atmospheric) and minerotrophic (via surface runoff or percolating groundwater) supply of water and nutrients. Waterlogged peat can accumulate above the groundwater level (to a maximum depth of about 10 m) leading to the formation of raised mires. Such mires are entirely ombrotrophic and therefore base-poor, supporting only bog vegetation. Other mires are to some extent influenced by a mixture of ombrotrophic and minerotrophic sources, local scale variations in which are expressed through hydrochemical and floristic gradients. Such mires are by no means always base-rich and bog vegetation will occur either where the soils of the catchment are poor in soluble minerals (minerotrophic bogs) or where precipitation/evaporation ratios are particularly high. The latter situation is not uncommon along the Atlantic seaboards of North America and northwestern Europe. Here extensive, primarily ombrogenous, "blanket" bogs can cover the landscape spreading over relatively steep slopes and descending down to sea level.

On a regional and continental scale, the geographic distribution of mire types reflects the climatic regime. The limit of ombrogenous bog development in southeastern Labrador, for example, coincides with the 1,100 mm precipitation isopleth (Foster and Glaser, 1986). Globally mires are more widely distributed at high and low latitudes and at high altitude. Nevertheless, extensive lowland mires, such as the Everglades, occur even in the subtropics and tropics where in coastal districts they merge into brackish marshes and mangrove swamps. Regional and continental level reviews of bog and related vegetation types can be found in Gore (1983).

A variety of mire types are found in coastal situations (see entry on *Wetlands*). Some North American and northwestern European sites show complete spatial gradations from salt marsh, through fen and minerotrophic bog to raised bog. Similar temporal gradations can be reconstructed from peats deposited within coastal sedimentary sequences. Species composition in coastal mires is likely to be additionally influenced by the input of sodium and chloride via salt-spray, brackish groundwater, or as a result of flooding episodes.

Origins and development

Mire communities can develop from waterbodies (a process referred to as hydroseral succession) or over formerly dry surfaces. Both circumstances apply in coastal situations where vegetation changes in stratigraphic sequences are frequently used to infer waterlevel movements resulting from fluctuations in relative sea level. However, it should be noted that any environmental process influencing waterlevel elevation or nutrient status is capable of producing vegetation change. Such change can also result from internal (termed autogenic) processes, most obviously through the accumulation of sediment. Therefore, while the growth of mire over a dry surface indicates rising waterlevels, mires can develop over marine/brackish sediments as a result of falling, stable, or even slowly rising waterlevels (if exceeded by the rate of sediment accumulation).

Vegetation sequences and the processes influencing the development of coastal mires are reviewed in Waller *et al*. (1999) with particular reference to stratigraphic information collected from the Romney Marsh depositional complex in southeastern England. *Alnus glutinosa* (alder) dominated fen carr (swamp) vegetation developed, above salt marsh clays, and prevailed at sites close to the upland edge and in neighboring river valleys, from ca. 6000 to 2400 yr BP. This community appears to have been sustained both by inflowing base-rich water and rising relative sea-level (preventing vertical isolation from groundwater). At sites immediately behind a coastal barrier peat formation began later. Here salt marsh clays are followed by a sequence of herbaceous fen, minerogenic bog, and ombrotrophic bog. Bog development appears to have required both vertical and spatial isolation from base-rich water sources. The former was induced by a decline in the rate of relative sea-level rise and by climate change. An additional factor appears to be the mobility of the peat matrix. Peat formed from herbaceous vegetation is more mobile than woody peat and acidiphilous vegetation developing on such surfaces is therefore less likely to be flooded with base-rich water. Spatial isolation seems to have been achieved by the extensive landward accumulation of peat and the presence of the barrier. The importance of the latter is demonstrated by the widespread occurrence of bog in back-barrier environments in the Low Countries during the Holocene epoch. Having achieved independence from groundwater the ombrotrophic vegetation of Romney Marsh was able to continue growing for a further 1000 C14 years after other mire types within the depositional complex were subject to renewed marine inundation.

Paleoenvironmental reconstructions using bog sediments

Sediments derived from bog, in common with other organic deposits, comprise an important paleoecological archive. Preserved plant material (seeds, pollen, and vegetative remains) and faunal remains such as Rhizopods (testate amoebae) and Coleoptera (beetles) can be used to elucidate *in situ* environmental changes and in some cases changes occurring in adjacent habitats. Analysis of the pollen preserved in organic sediments has proved a particularly powerful tool for understanding long-term vegetation trends. Mires may also contain archaeological artifacts (see entry on *Archaeology*) and in northwestern Europe a number of exceptionally well-preserved human remains, referred to as Bog bodies, have been recovered. Ombrotrophic bogs, being dependent upon precipitation for their growth, have additionally been an important source of information on climate change during the Holocene epoch. In particular, stratigraphic changes from darker more decomposed peat to lighter fresh *Sphagnum* peat have been taken to indicate periods of faster peat growth and therefore wetter climatic conditions. Changes in bog stratigraphy at many locations across northwestern Europe (including coastal locations) indicate such a climate shift occurred around 2650 yr BP (van Geel *et al.*, 1996). Unfortunately, changes in bog stratigraphy are not always synchronous between, or even within, bogs. Growth rates vary not only geographically but also in response to local hydrological features.

Organic sediments derived from coastal situations are commonly employed in reconstructions of former sea level as they can be radiocarbon dated and certain plant communities can be related to a specific ("reference") waterlevel range (see entries on *Peat* and *Sea-Level Indicators, Biological in Depositional Sequences*). The latter is clearly not the case with sediments derived from ombrotrophic bog. Given the difficulties distinguishing between ombrotrophic and minerotrophic bogs on the basis of floristic composition, and the gradations possible between these conditions, organic sediments derived from acidophilious vegetation should be avoided when collecting material for this purpose.

Human exploitation

Mires are exploited as a source of peat for fuel and horticulture and, following drainage, for cultivation. Ombrotrophic sediments are best suited for the former purpose, minerogenic for the latter. The extensive exploitation of peat for fuel can be traced back to the medieval period in northwestern Europe. For example, large quantities were removed from a series of valleys on the edge of the coast of Norfolk in eastern England. Subsequent flooding created a series of shallow lakes referred to as Broads. Peat continues to be a major energy resource in a number of countries (Russia, Ireland). Reclamation of the lowland mire complexes in Europe occurred from the 17th century onwards through the construction of effective drainage channels subsequently aided by pumping (see entry on *Reclamation*). Such activities result in the lowering of the land surface both as a result of sediment compaction (the loss of interstitial fluid) and erosion (as the surface organic sediments decompose). At Holme Fen, in Eastern England, where *Sphagnum* is an important peat constituent, the ground surface fell by 3.87 m between 1848 and 1978 (Hutchinson, 1980). The large-scale exploitation of bogs has increasingly led to calls for their conservation. Along with other forms of wetland they are included within the RAMSAR Convention (see entry on *Wetlands*).

BOULDER BARRICADES

Definition, distribution and historical development

Boulder barricades are elongate rows of boulders that flank the coastline, separated from the shore by an intertidal flat (Figure B62). They are the result of ice transport and therefore are found only in Arctic and sub-Arctic regions. They are formed by the grounding of boulder-laden ice rafts in nearshore zones during spring ice break-up.

In North America, boulder barricades have been reported in Labrador (Daly, 1902; Rosen, 1979, 1980); Hudson Strait, east Foxe Basin, Baffin Island (Bird, 1964); and the St. Lawrence River (Brochu, 1961; Dionne, 1972). In other areas they have been reported in the Baltic Sea and Fennoscandia (Lyell, 1854; Tanner, 1939). Lфken (1962) utilized uplifted boulder barricades in northern Labrador as an accurate sea-level indicator to delineate the Holocene regression. While Tanner (1939) observed a decrease in barricade development corresponding to a reduction in tide range from 1.3 to 0 m in Labrador, the features do occur in other nontidal (i.e., Baltic Sea) areas.

Lyell (1854) first recognized boulder barricades as an ice-deposited landform. Daly (1902) introduced the term, but believed that they were an accumulation of boulders at the seaward limit of wave backwash, with ice playing a secondary role. Tanner (1939) concluded that the features were the result of boulder-laden ice cakes piling up against a fixed shore icefoot. Conversely, Brochu (1961) hypothesized that intertidal ice-cakes were moved seaward during ice breakup, pushing boulders to the low water line.

Boulder barricade formation

Monitoring of coastal ice in central Labrador during both winter and spring breakup are the basis for a model for the entrainment of boulders into ice and the transportation during spring breakup. In tidal regions, such as Labrador, intertidal ice freezes downward with increased freezing at each high tide. Boulders are frozen in the ice and become lifted from the intertidal bottom. Observations on a broad intertidal flat indicate that more boulders are lifted from the upper intertidal zone, so apparently the less-frequent lifting of the ice during spring tides was more effective at encasing boulders than the diurnal lifting from the lower intertidal zone. High melting rates occur from the ice surface in the late winter, so the continued freeze-down and surface-melt result in the transportation of boulders up through the ice.

Figure B62 Boulder barricade in Makkovik Bay, Labrador.

Figure B63 A boulder adrift on an ice cake, Makkovik Bay, Labrador.

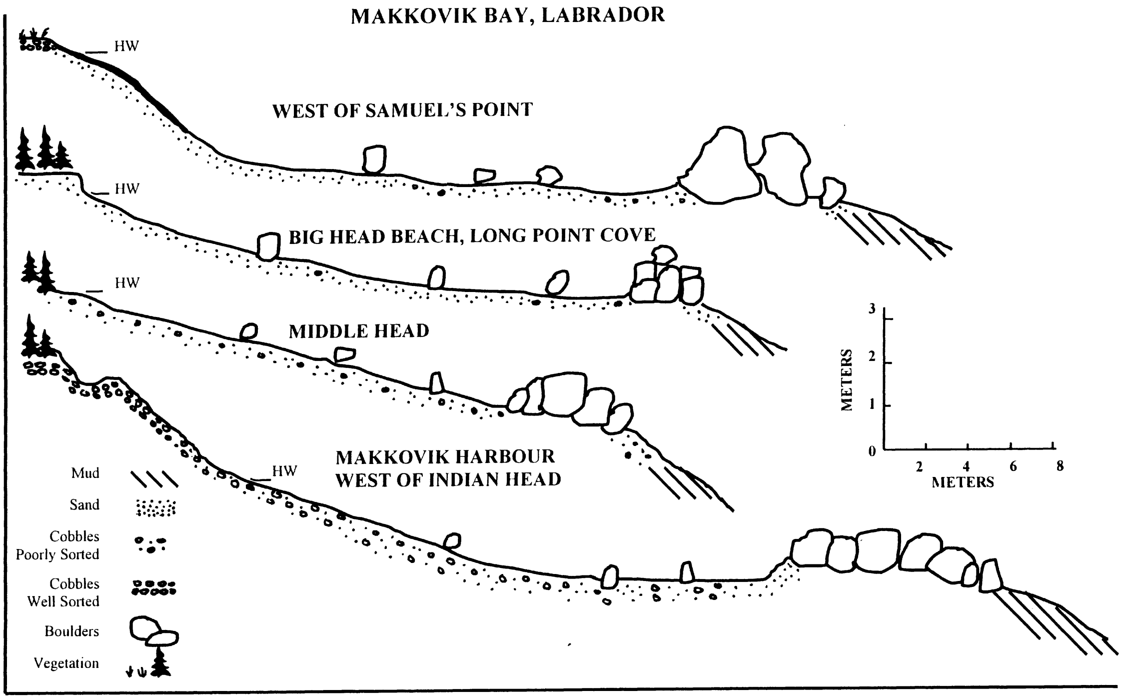

Figure B64 Nearshore profiles at selected sites in Makkovik Bay, Labrador. Random boulders are common in the intertidal zone, while most accumulate as a boulder barricade landward of a steep drop off to deeper water (from Rosen, 1982, with permission of Kluwer Academic Publishers).

In the Baltic Sea off Tallinn, Estonia, which is nearly non-tidal, the infrequent lifting of ice for freeze-down and encasement, and floating for spring transportation may be due to meteorological tides that are a major cause of sea-level fluctuations in the region (Maurice Schwartz, personal communication).

In spring when the snow cover has melted, boulders have been observed sitting on intertidal ice pans (Figure B63). The intertidal zone breaks up before offshore areas because of numerous tidal cracks and the decreased albedo of the mud-laden nearshore ice. Shore leads up to 1 km wide serve as thoroughfares for these wind-transported ice rafts. The boulders may be randomly deposited in the nearshore as *boulder flats*, as commonly occurs on the deltaic flats at the heads of embayments. However, in central Labrador many of the intertidal zones consist of uplifted marine clays with the top surface planed-off by contemporary wave and ice processes. This results in a slope-break near the low water line (Figure B64). Since the ice thickness is comparable to the tide range, there is a high probability for ice-rafts to ground at this position. Accumulation of boulders over successive seasons results in an intermittent barricade, which further serves to trap ice rafts during breakup. Landward of the slope break/boulder barricade position, random boulders, or boulder flats are also common.

At Tallinn, Estonia, the boulder barricades form in a similar setting. In this area, the nearshore is a rock-cut bench and the barricades accumulate at the seaward limit of this bench. (M. Schwartz, personal communication). Conversely, in the St. Lawrence Estuary, there is a range of nearshore boulder forms, including boulder flats, mounds, ridges, and pavements (Dionne, 1972), which corresponds with no evidence of a nearshore slope break.

Summary

Boulder barricades are the result of grounding of boulder-laden ice rafts in the nearshore zone during spring ice breakup. Wind and tides are the major transport mechanisms. The requisite conditions for the formation of boulder barricades are: a rocky coastal setting, sufficient winter ice, and water-level fluctuations to entrain boulders in ice rafts; a distinct slope break in the nearshore zone. Without the third condition, boulders will be desposited as boulder flats.

Boulder barricades are distinctly different from *boulder ramparts* and *ice-push ridges*, which are common on coastal and lake shorelines in that they are located seaward of the strandline, rather along the water line, due to the conditions discussed above.

BOULDER BEACHES

Strictly speaking a boulder beach is one where the mean clast size meets the formal definition of "boulder" in the terms of the Wentworth grade scale, that is with a mean particle dia-meter of >256 mm (−8 *phi*) (Wentworth, 1922). However, the term is also sometimes used in a general sense to describe beaches where the sediment is a mixture of boulders and large cobbles.

Boulder beaches are found in high wave-energy environments where clasts of these large dimensions are released directly by erosion of bedrock, or where material is delivered to the shore zone by slope movements such as rockfall. In both cases sediment size is a function of joint spacing. Preformed boulders may also be supplied by erosion of Quaternary deposits such as glacial till, and by infrequent high-magnitude river floods.

While a considerable body of literature exists on gravel beaches, (usually concerned with pebbles and small cobbles), beaches of large cobbles and boulders have been neglected. This is partly because morphological response times are too long for consideration in the normal time-frame of academic field programs, and also because very large clasts are difficult to characterize. Some publications purporting to be general overviews of coarse sediments completely disregard boulders. Others set arbitrary upper limits to their area of interest in that, even where boulders form part of the beach sediment, sampling, experimental work, and subsequent analyses are confined to, at maximum, the cobble sizes. Most workers are reasonably precise about the lower size limit of the sediment studied, but the upper limit often remains vague: this may be partly due to the prevalent use of the *phi* scale, which becomes increasingly generalized in the coarser sizes. Terminology is often imprecise, for example, the description "gravel" is commonplace, although it covers all clasts coarser than 2 mm diameter (-1 *phi*), and so does not distinguish among pebbles, cobbles, and boulders.

Sedimentology

The few studies that have been carried out on boulder beaches have tended to look at details rather than broad patterns of sedimentation and morphology, for example, Bartrum (1947), Shelley (1968), and Hills (1970). The neglect of large clast beaches has led to attempts to apply sedimentation models derived from studies of pebble and cobble beaches to the boulder beach environment. Doubts concerning the validity of such extrapolations were fully confirmed by a comprehensive study of boulder beaches by H.L. Oak along the coast of New South Wales in Australia (Oak, 1984). Oak proposed that boulder beaches demonstrate certain unique sedimentary characteristics that distinguish them as fundamentally different from pebble and cobble beaches. Hence, relationships established in the many studies of gravel beaches are often inapplicable.

The dominant characteristics of boulder beaches listed by Oak are:

1. A high wave-energy environment, competent to move large clasts.
2. Upbeach fining of sediment.
3. Abundant breakage of sediment.
4. Positively skewed size distributions.
5. Upbeach decrease in roundness.
6. No shape zonation.
7. No sphericity grading.
8. Low foreshore slopes, decreasing as particle size increases.

Of these characteristics numbers 2–4 and 6–8 contrast strongly with the known sedimentary characteristics of pebble and cobble beaches.

Sediment size

Mean clast size is the most significant parameter determining the sedimentary character and behavior of a boulder beach. The pattern of general upbeach coarsening typical of smaller grade gravels is a function of two interlinked processes: (1) storm swash can carry most of the range of available clast sizes upslope, and (2) backwash is competent to carry a major part of this range at least some distance seawards. Neither of these is true of a boulder beach, and so clast size is the primary determinant of movement. Clast size decreases upbeach because the dominant boulders are so large that they can only be moved by traction as bedload, and even then perhaps only in very infrequent intense storms. Only the sub-population derived from breakage of the larger clasts can be suspended. As wave uprush moves up the beach face, permeability reduces its volume, and gravity effects and turbulence reduce its velocity so quickly, that only increasingly finer material can be transported. Backwash effects are negligible, so the smaller clasts, including breakage products, remain where swash deposits them. Waves can move the larger boulders to the trim line at the base of the beach, but cannot move them any distance upslope.

As high-energy marine processes act on predominantly boulder-sized sediment winnowing of the fines produces a sediment assemblage dominated by a relatively small number of well-sorted large clasts, with a very minor subordinate population of smaller fragments, most of which have survived in the high-energy area only because of entrapment. The distinctive positively skewed size distribution of a boulder beach is attributed to the presence among the beach sediments of this tail of fines derived as breakage products of the dominant boulder population. Since large clasts resist continuous movement, spasmodic breakage during storms is the dominant size-reducing process (Bluck, 1969; Matthews, 1983). Abrasion is limited to the effects of passive sandblasting or the small movements of *in situ* abrasion, both of which are largely confined to a limited area at the base of the beach. In contrast, on pebble/cobble beaches breakage is minimal and most size reduction is achieved by attrition. The very fine products of this process will be removed in suspension, unlike pebble-sized breakage products, which may be retained on the beach.

Sediment shape

Shape sorting (and the related characteristic of sphericity sorting) is poorly developed on a boulder beach. This forms a contrast with the characteristic shape zoning of a pebble beach, which results from selective clast transportation in which backwash plays an important role. On a boulder beach the sedimentation process is fundamentally different because the morphology is purely swash-formed. Selective shape sorting becomes increasingly ineffective where clasts are large and where wave conditions are turbulent. On a high-energy boulder beach shape sorting is insignificant because shape is only a dominant influence when entrainment forces are at critical thresholds for selective transport. When forces are not marginal, mass rather than shape, is the dominant control on net up- and down-beach transport potential.

Shape-controlled sorting processes are inoperative because, (1) even when storm waves are competent the prevailing bedload transport mechanism is basically insensitive to clast shape, and size will remain the dominant factor, (2) the large clast sizes and the high porosity of the beach means that backwash does not have the energy potential to create shape sorting, and (3) the rugosity of the beach surface militates against the gravity-induced downslope movements of pebble grades, which are instead trapped in the voids between boulders. Only storm swash leaves its fingerprint and as a result the only primary structure imprinted on a boulder beach is swash-controlled upbeach fining. Size, therefore, exercises not only an initial control on upbeach sorting, but it is also the terminal control. As mean clast size decreases the size control typical of boulder sedimentation gradually gives way to the shape control associated with pebble and cobble sedimentation.

Sediment roundness

Beach boulders are typically smoothed and rounded. On high-energy coasts clast transport, given free movement conditions, is very rapid. This casts considerable doubt on whether the angular, rough-textured blocks produced by wave quarrying and rockfall could possibly acquire such a degree of rounding and smoothing on a short (both spatially and temporally) unimpeded journey from source to boulder beach. Active and passive abrasion and rounding processes continue to take place in the beach environment, but their effects are largely confined to the base of the beach. Clasts at higher elevations on the beach face may have been emplaced by one high-magnitude storm. Marine influences will rarely reach these elevations, and only slow weathering processes can contribute to further rounding. It is doubtful whether the sum of these beach-face processes can entirely account for the evolution of clast shapes from an initially angular form controlled by geology, to the rounded, marine form characteristic of boulder beaches. It seems more likely that the majority of boulder beach clasts have spent some time in the intensely turbulent and abrasive hydrodynamic environment represented by traps such as potholes, gullies, and channels. Eventually a storm liberates the clasts to continue their journey to the beach.

Roundness is most pronounced toward the base of a boulder beach because the large clasts in this area experience marine action over longer time periods, and also because angular breakage products will be transported upbeach by wave action. Rounding cannot be taken as evidence of clast movements within the beach deposit, as rounded profiles can be attributed to pre-emplacement history (see above), and can also be created and maintained by *in situ* processes such as breakage, mutual attrition, and "water load abrasion". The large well-sorted clasts found in the high-energy zone near the seaward margin of the beach characteristically demonstrate rounded, flattened ellipsoidal profiles. The remarkable stability of the lower part of a boulder beach in the face of high-energy wave action is probably due to a combination of large clast size, imbrication caused by strong unidirectional flows, and a variety of other fitting and interlocking processes acting on the beach fabric (Shelley, 1968; Hills, 1970; Bishop and Hughes, 1989).

With distance upbeach angularity tends to increase, especially in the finer grades with more compact and platy shapes. This is a general comment, as the size- rather than shape-controlled swash transport mechanism will occasionally carry clasts exhibiting the full range of roundness well up the beach face. The major reason for the upbeach increase in angularity is the influence of breakage during infrequent storms. The products of breakage will remain as a component of the beach sediments because at higher positions on the beach face wave action that might winnow small-grade material is infrequent, backwash is ineffective, and the only agency acting to increase roundness is the relatively slow process of spheroidal weathering. On the boulders near the landward margin of the larger beaches, surface soundness deteriorates as weathering processes produce a rougher texture, and lichen colonization is common. In a general sense it is probably valid to consider the development of weathering rinds and lichen cover as indices of decreasing marine influence and movement. However, recent rockfall blocks on any part of the beach face carry a weathering/lichen signature from a subaerial environment, not a beach environment.

Sediment orientation

On gravel beaches pebbles transported as bedload generally tend to be oriented with the long axis parallel to the shore, that is; transverse to the direction of swash movement. Such preferred orientation patterns are weakly developed on boulder beaches because a high velocity turbulent flow on a coarse bed leads to decreased regularity in orientation patterns. Clast collisions can change orientations, disturbing or perhaps even completely obscuring the pattern imprinted by the transport process. Clasts can also be oriented by the prevalent waves without undergoing net transport. Thus, while a bedload transport mechanism does generate preferred orientations, the generally weak development of this characteristic on boulder beaches is probably due to the interplay of high-energy wave action with the particularly rough surface of the beach deposit.

Beach profile

On all types of beaches relationships involving slope are regarded as particularly significant because slope is usually considered the primary index of morphological response to wave action. There have been so few published studies on boulder beaches that discussion on their profiles must be tentative.

The most notable feature of the typical boulder beach profile is a lack of variation over time. Even during relatively severe storms changes involve only individual clasts, with the beach slope itself remaining unchanged. Some boulder beaches exhibit obvious concave upwards profiles. In detail, many have one basically rectilinear main facet extending down to mean high-water mark or below, with overall concavity produced by narrow and rudimentary low angle facets in the intertidal area. The beach profile can be conceptualized as providing a "fingerprint" of the resultant of earlier swash/backwash interaction. On boulder beaches backwash is minimal so beach material is pushed shorewards to rest at an angle controlled by the balance of gravity and the dominant swash forces. For this reason, coarse beaches are more likely to be concave upwards than fine beaches.

On boulder beaches mean beach slope decreases as mean size increases. This characteristic appears to be in direct conflict with one of the basic tenets of coastal studies, that is, that coarser sediments produce steeper slopes, partly because the angle of rest is higher, but mainly because high percolation reduces backwash, which would tend to draw down material and lessen the slope. Shepard (1963) published a table in which the predicted average beach face slope for clasts in the 64–256 mm size range (-6 to -8 *phi*) was 24°. However, the slopes of boulder beaches are considerably below this predicted value, an illustration of the dangers inherent in extrapolating from work on finer grade material. Most studies of boulder beaches record slopes in the range 6°–14° with the mean lying around 12°.

Oak (1984) formulated an explanation for the finding that the slopes of boulder beaches are gentler than predicted. On all beaches of whatever mean sediment size, storms produce an equilibrium profile that is flatter than the pre-storm profile. The accepted principle that a beach must adjust to wave energy by flattening its profile holds true then, even for boulder-sized clasts. Beach angle does indeed increase with clast size, but only if waves can move all sediment. In practice only high-energy storm waves are competent to move large clasts, so the profile of a boulder beach is in fact a "lag" storm profile, adjusted to and formed by storm waves. On sand and pebble beaches lag times are short, and in the days after a storm infill will steepen the beach face. However, this does not happen on a boulder beach, as normal wave action cannot bring about a steep fairweather profile, so the beach typically exhibits a relatively low-angle storm profile. Therefore, the relatively gentle slope of a boulder beach, with its concave upwards profile, can be considered indicative of high swash velocities and minimum sediment storage, that is, a storm profile. The persistence of the profile simply reflects the fact that competent storms are infrequent.

BOULDER PAVEMENTS

Striated boulder pavements can form either on intertidal surfaces in areas affected by floating ice (Martini, 1981; Hansom, 1983, 1986) or at the base of glaciers or on grounded ice sheets (A.G.I., 1974; Boulton, 1978; Visser and Hall, 1984). Pavements have also been described from fluvial environments (Mackay and Mackay, 1977). Their distinctive nature also allows them to be used in the sedimentary record to assist in the reconstruction of past ice-affected environments (Eyles, 1988). Pavements deposited subglacially are argued to be the result of accretion of boulders around an obstacle and to carry striations that are largely unidirectional. Although there are no detailed descriptions of such pavements forming in present glacial environments, they have also been described from the top surface of Quaternary deposits as well as buried within such deposits (Hansom, 1983; Eyles, 1988). Pavements formed on present cold-climate intertidal surfaces are thought to be the result of abrasion and bulldozing of boulder-lag surfaces by floating ice and small icebergs (Martini, 1981; Hansom, 1983, 1986, Gilbert *et al.*, 1984; Forbes and Taylor, 1994). The striations that the boulder surfaces carry are then controlled by the direction of movement of blocks of floating ice together with the rotational striations imparted when such blocks become stranded. Prerequisites for the development of intertidal boulder pavements are held by Hansom (1983) to be: (1) a boulder source; (2) frequent onshore movement of floating ice; and (3) a low-gradient intertidal zone. Given such conditions, the degree of development of the pavement seems to be controlled by the frequency of onshore ice movement, because the best formed pavements occur in areas subject to the highest frequencies of freely moving ice rather than areas that remain frozen for substantial parts of the year.

Figure B65 A well-developed boulder pavement in the South Shetland Islands, Antarctica. The polygonal depressions are caused by tidally grounded ice blocks which smooth and striate the boulders.

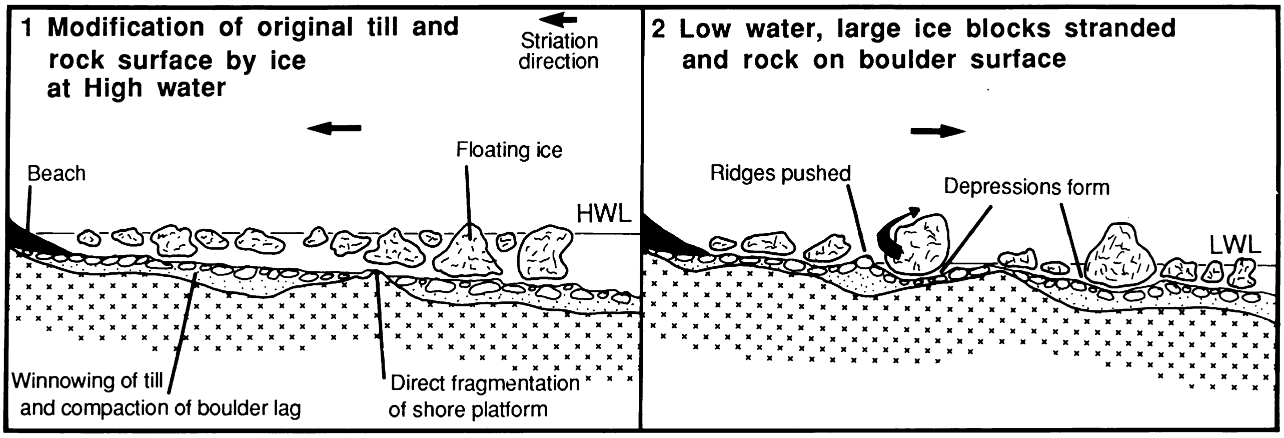

Figure B66 A model showing the development of a boulder pavement at the extremes of the tidal cycle. Progressive stranding of ice blocks causes compaction, polishing, and striation of the boulders as well as forming depressions in the pavement surface.

Marine boulder pavements are composed of smoothed boulders, often of up to 1 m in diameter, that are tightly packed together in the intertidal zone, the pavement surface appearing as a smooth, highly polished, and striated mosaic. The pavement surface is often interrupted by outcropping bedrock together with shore-normal furrows and polygonal depressions that can be up to 5 m across (Figure B65). In the South Shetland Islands (see *Atlantic Ocean Islands*) they have been described as comprising a single layer of boulders underlain by a layer of clay containing locally derived lithologies, whereas in South Georgia, pavements are underlain by glacial till into which the boulders have been packed (Hansom, 1983). The main processes involved in pavement development are summarized in Figure B66. Floating ice blocks coming ashore onto a low gradient boulder-strewn shore bulldoze and pack loose boulders in the zone of grounding, initially in the upper intertidal but increasingly at the seaward edge. Some boulders may come from direct fragmentation of rock outcrops of any underlying shore platform that may exist and some may come from ice-rafted exotics. Polishing of the boulder surface is achieved by rock-shod floating ice abrading and striating the surface of the boulders (Hansom, 1983). The orientations of the striations also inform the development processes of the surface polygonal depressions since the spread of striations on boulder ridges parallel to the shore can only be achieved by partially stranded ice blocks rotating on the pavement surface (Figure B66).

In the Antarctic, boulder pavements are found in varying degrees of development across 10° of latitude from South Georgia to the Antarctic Peninsula and in Victoria Land, pavements of tightly packed and smoothed boulders locally veneer the shallow subtidal shore platforms of the Adare and Hallett Peninsulas (Hansom and Kirk, 1989). The distribution and development of the Antarctic pavements show clear relationships between the frequency of floating ice grounding and wave processes. Where the frequency of ice grounding is high then the pavements are well developed. In the South Shetlands, the probability of floating ice and the percentage of ice concentration are both high. This limits the wave processes that destroy the pavement surface while ensuring frequent ice smoothing and packing. The result is a morphogenetic environment with a mix of ice/wave processes that is optimal for pavement development. Moving south away from this optimal ice/wave zone the incidence of grounding ice is reduced and so in the Antarctic Peninsula, wave processes are negligible, the incidence of fast ice is high and the frequency of ice grounding is low. Pavements here are poorly developed and embryonic. On the open coasts of South Georgia, well to the north of the optimal ice/wave zone, wave processes dominate, the frequency of grounding ice is low and so pavements are again poorly developed. However, within the sheltered inner fjords of South Georgia, wave processes are restricted, the frequency of floating ice is higher on account of glaciers calving into tidewater and, as a result, the boulder pavements are better developed (Hansom and Kirk, 1989). In the fjords of Vestfirdir in Iceland, similar forms also exist but are poorly developed as a result of the juxtaposition of a very limited ice-climate and a very low energy wave environment (Hansom, 1986).

Martini (1981) suggests that the incidence of boulder pavements can be taken as a reliable indicator of intertidal ice action. Thus, the occurrence of emerged pavements at 5, 9, 12.5, and 17 m above sea level in the South Shetland Islands is convincing evidence of unchanged morphogenetic conditions in the area at least since the uppermost of the pavements was formed some 9000 years BP (Hansom, 1983). Eyles (1988) uses boulder pavements in a similar way to reconstruct fluctuations in ice environments in the Gulf of Alaska during the early Pleistocene.

BYPASSING AT LITTORAL DRIFT BARRIERS

Definition

A littoral drift barrier is an obstacle against the littoral drift or migration of material along the shore. Such barriers may be natural, for example, major headlands on the shore, or man-made such as jetties, breakwaters, or dredged channels, which established a hindrance for the normal drift of material along the shore.

Natural barriers may be responsible for major changes in the natural uninterrupted shore. The California saw-toothed headland shore is a large example of that. Bypassing is transportation of materials across the barrier, breaking the barrier-effect.

Bypassing by nature

Bypassing is the way that material, after a short interruption caused by an inlet, channel, jetty, or other kind of littoral barrier, is given back to the normal littoral drift zone a distance downdrift from the littoral barriers. If nature did not bypass sand across inlets, passes, and channels on seashores, many *marine forelands* including barriers, spits, and entire peninsulas would not exist. A typical example of this is Florida, which was built of sand washed down by rivers and streams from the Appalachian highland, and carried southward, for final deposition in the huge barrier and ridge systems.

Bar bypassing—limited tidal action

Figure B67 shows a barrier with an inlet. Littoral drift material passes along the barrier. At the downdrift end, it continues on its way across the inlet on a submerged bar, the extent and depth of which depends on the amount and character of the material which bypasses and the intensity of wave and current action. By increasing amounts of littoral material, the bar area increases and depth decreases.

In most cases, migration of tidal channels takes place in the direction of the littoral drift. Sand is transported over the bar under the influence

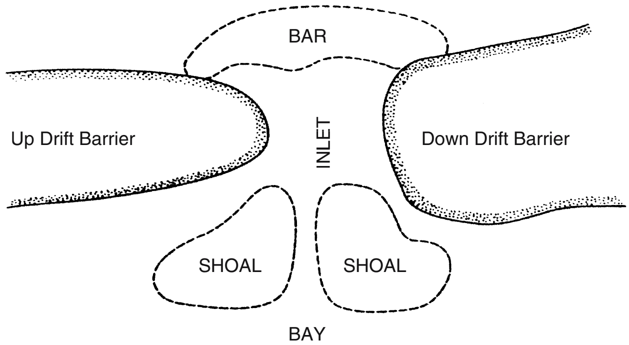

Figure B67 Coastal inlet with predominant bar bypassing (from Bruun, 1990). (Reproduced by permission. From Port Engineering V2 4E copyright (c) 1990, Gulf Publishing Company, Houston, Texas, 800-231-6275. All rights reserved.)

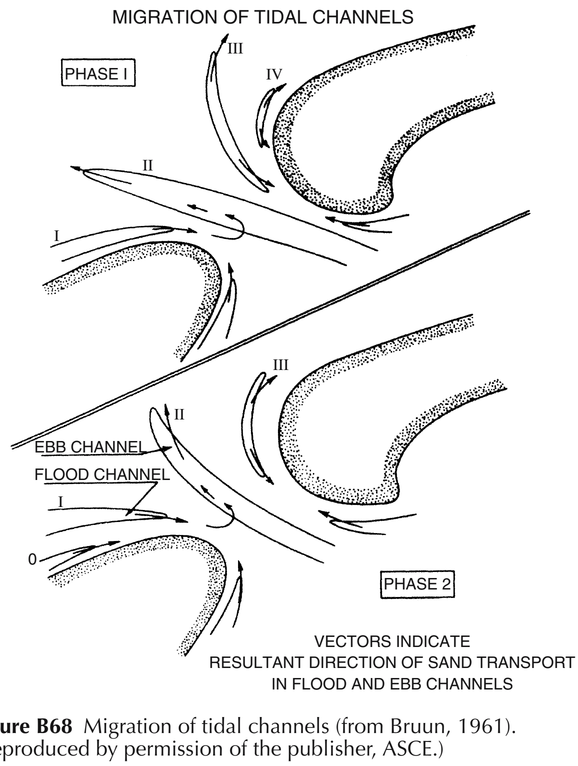

Figure B68 Migration of tidal channels (from Bruun, 1961). (Reproduced by permission of the publisher, ASCE.)

of waves and deposited on the updrift bank of the channels, thus forcing the shifting.

In the vicinity of tidal inlets, the generally strong tidal currents in the inlet change the littoral drift pattern entirely. Along the uninterrupted coastline, wave action is generally the predominant cause for the transportation of material. In the vicinity of tidal inlets, however, transport of material takes place under the combined effect of waves and tidal currents.

In tidal rivers, estuaries and inlets, tidal channels can usually be identified as either *flood* or *ebb* channels. Flood channels carry predominantly flood flow, causing a resultant sand transport in a bayward direction; they usually have a shoal at the end. Ebb channels carry predominantly ebb flow and have resultant material transport seaward and a bar or shoal at the end (Figure B67).

Principles involved in bypassing by tidal flow action—unimproved inlets

In general, sand transfer by tidal flow takes place in two different ways, namely by migration of channels and bars and by transport of sand by tidal flow in the channel. Tidal channels in inlets, particularly those running between the gorge and the ocean, are subject to migration. This means that they change location continuously, moving from one side of the inlet to the other. In Figure B68, this principle is demonstrated by Phases 1 and 2 of a tidal channel system. Channels in Phase1 are numbered, I, II, III, and IV. In Phase 2 the locations of these channels have changed compared with Phase 1, and a new channel, 0, has developed. In this example, the channels move from left to right, and bars or shoals between the channels move in the same direction with the result that a bar occasionally joins the downdrift coast.

One may distinguish between inlets that are mainly bar-bypassers (Figure B67) and inlets that are rather tidal flow bypassers by considering the ratio between tidal prism during spring tide (Ωm^3) and the total amount of material carried to the inlet entrance by the littoral drift (M_{tot} in cubic meters per year). A great many cases were analyzed and showed that inlets with $\Omega/M_{tot} < 50$ were mainly bar-bypassers, while inlets with $\Omega/M_{tot} > 150$ were mainly tidal flow bypassers. Inlets with $50 < M_{tot} < 150$ combined the two modes. Inlets or harbors without or with only little tidal prism have only one bypassing style-man-made bypassing or dredging.

Man-made littoral drift barriers

Human intervention of coastal processes started when they erected shore-perpendicular or parallel breakwaters for protecting ports against waves and sediments and groins for coastal protection on open littoral drift shores. This type of construction began in the 19th century in the Mediterranean and on the shores of the British Isles (Bruun, 1990). The problem of man-induced erosion was magnified when the Dutch invented dredging in an effort to provide greater channel depths for navigation. It was by hard and very expensive experience that they learned that when they put something out in the sea, "something is going to happen." Commonly, shoaling occurs on one side and erosion on the other side of an obstruction. In most instances, this probably came as a surprise and often initiated "desperate efforts" in order to maintain depths at an entrance (e.g., by extending updrift breakwaters or jetties or by dredging operations with available equipment or by both). This provided only a temporary relief for navigation and usually the greater the efforts to maintain depths, the more severe the erosion on the downdrift side.

The first technical counter-measures were the construction of groins and/or seawalls. While both mitigated the nearshore or onshore erosion problem, they also aggravated the downdrift erosion. Not until the late 1930s was it realized that the only practical solution to the problem was the elimination of the barrier effect. This was done by establishing sand bypassing whereby material is pumped or trucked across the barrier to the downdrift beaches.

The need for bypassing was supported by legislation such as the Florida law (1987), which reads as follows (Section 161.142, Declaration of Public Policy Relating to Improved Navigation inlets):

"(1) All construction and maintenance dredging of beach-quality sand should be placed on the downdrift beaches; or, if placed elsewhere, an equivalent quality and quantity of sand from an alternate location should be placed on the downdrift beaches.

(2) On an average annual basis, a quantity of sand should be placed on the downdrift beaches equal to the natural net annual longshore sediment transport."

Quantitative considerations

The quantitative aspect of longshore drift blocking by barriers is very simple. If the barrier causes the loss of a certain quantity of material

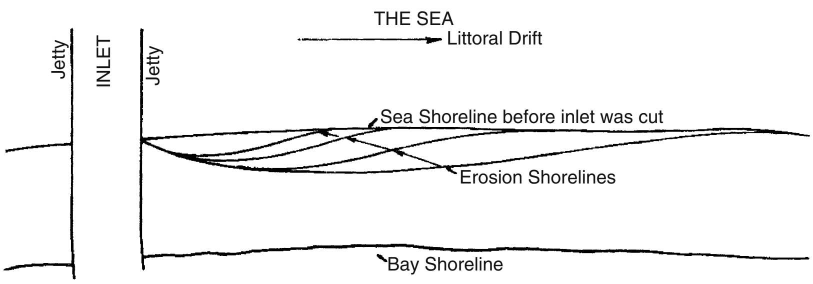

Figure B69 Shoreline development downdrift of the Fort Pierce Inlet, Florida, schematics (from Bruun, 1990). (Reproduced by permission. From Port Engineering V2 4E copyright (c) 1990, Gulf Publishing Company, Houston, Texas, 800-231-6275. All rights reserved.)

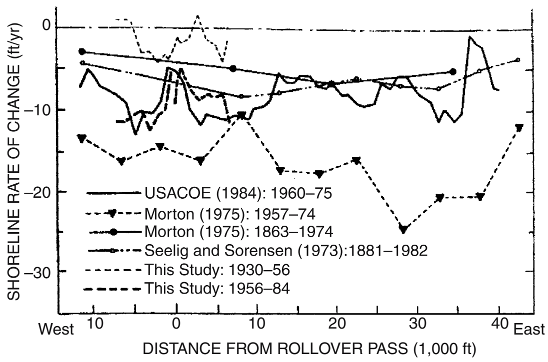

Figure B71 Comparison of shoreline rates of change near Rollover Pass, Texas (from Bruun, 1995, reprinted by permission of the Journal of Coastal Research).

which was "locked up" by the barrier, this quantity is unavailable to downdrift beaches, which consequently will suffer erosion of that magnitude. The more difficult question is: how is erosion, due to loss of sand, distributed downdrift as a function of time.

Coastal geomorphological considerations

Three parameters are important in this context: the length of the adversely affected shore, the cross-sectional retreat of the erosion cut and the rate of expansion of erosion, and its dis-tribution downdrift as functions of time. Length and cross-sectional evolution of the erosion cut give the geometric development as a function of time. The corresponding development in the offshore bottom follows the same general pattern, but there is usually a material change in the configuration of the offshore profiles, which tends to flatten in the downdrift areas (Bruun, 1990, chapters 7 and 8). Figure B69 shows a typical longshore shoreline development trend, Figure B70 (Bruun, 1990) shows the offshore development as well.

The dominant sediment bypassing mechanism at a tidal inlet affects the extent and magnitude of the downdrift high-tide shoreline response. The updrift coastline response to the introduction of a jetty is fairly localized and little dependent upon the sediment bypassing mechanisms active at the tidal inlet. Tidal inlets which are predominantly tidal-flow bypassers have more severe, downdrift effects on high-tide shoreline response than tidal inlets which bypass sediment through bar bypassing. Tidal inlets which are combined tidal flow and bar bypassers have relatively constant downdrift effects (magnitude and rate of change) through time. Significantly deepening the channel through the bar can alter the dominant sediment bypassing mechanism.

Bodge (1992, 1999), Rosati and Ebersole (1996), and Bruun (1995) made efforts to quantify the response of adjacent shores by tidal inlets. Rosati and Krauss (1999) have continued these efforts. Bodges (1999) paper is universally applicable. Bruun (1995) gives about 20 examples of which two are mentioned below.

The literature only mentions few examples where the downdrift long distance development was recorded as function of time to obtain a rate. Examples in the literature include Fields *et al*. (1989) and Bodge (1993, 1999). Theoretical approaches are available, but they concentrate on immediate downdrift reactions. Although admittedly, the effects continue to expand downdrift "infinitely" as indicated by Pelnard-Considere (1956).

Obviously, the migration rate of the downdrift erosion depends upon the quantitative magnitude of the *barrier effect*, for example, the loss of material to inlet shoals. A large loss will expand faster than a small loss.

"Beach/Inlet Processes and Management", Special Issue No. 18, of the *Journal of Coastal Research* (1993, A.J. Mehta, Editor) has a great number of examples on the influence of coastal inlets on the littoral drift system. The short distance effect of the inlet on the downdrift erosion is shown in several figures, but the development downdrift is cut short by only examining the development for a limited distance downdrift.

Rollover Pass, Texas

Conditions at Rollover Pass on the Texas Gulf, 31 km northeast of the Galveston Inlet, are described by Bales and Holley (1989) and by Bruun (1995). The pass is a man-made artificially stabilized inlet on the Bolivar Peninsula. Improvements of the pass were completed in 1959. Figure B71 compares shoreline rates of change near Rollover Pass. Referring to the period 1957–74 in the figure, it may be seen that the downdrift effect extended at least 40,000 ft. or 13 km and probably more. Based on 1957–74, one arrives at a migration rate of erosion of 13/17 = 0.8 km/year. The rate is 0.9 km/year if 1959, the completion year for the improvements, is used.

Ocean City Inlet, Maryland

Shoreline evolution on either side of the inlet is dealt with by Leatherman (1984). Historical shoreline changes on the downdrift side of the inlet on Assateague Island are shown in Figure B72. Construction of the Ocean City Inlet jetties, in combination with a net southerly longshore littoral drift, has resulted in severe erosion along north Assateague Island. It appears that none of the 120,000 m^3 of sand that annually flows south along this coastal sector reaches Assateague Island. Since the jetties, built 1934–35 are filled to capacity (1984), the material is largely moving offshore to build a huge ebb tidal delta that is detectable from space through analysis of Landsat imagery. A comparison of the 1942 and 1962 coastlines clearly shows the trend since the

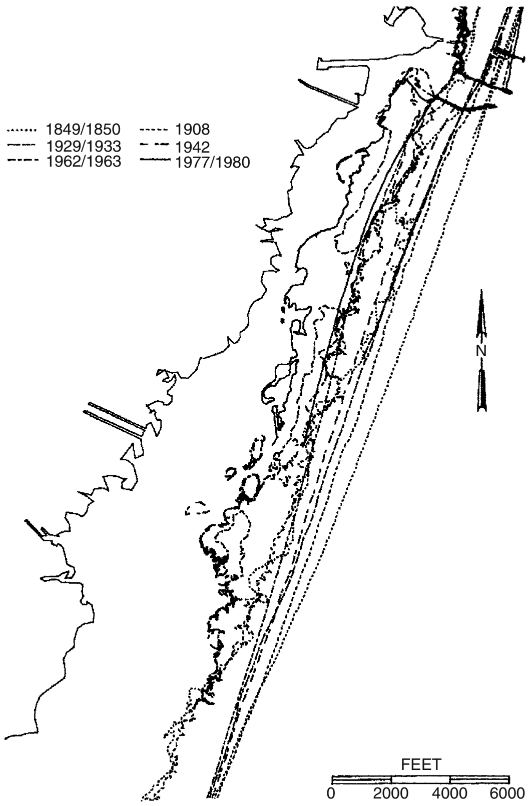

Figure B72 Barrier Island migration showing landward displacement of both Ocean and Bay high tide shorelines of Assateague Island (1850–1980). The Barrier Island maintained its width, 120–210 m, with this rapid translocation. The mainland bayshore has remained essentially stable (from Bruun, 1995, reprinted by permission of the Journal of Coastal Reasearch).

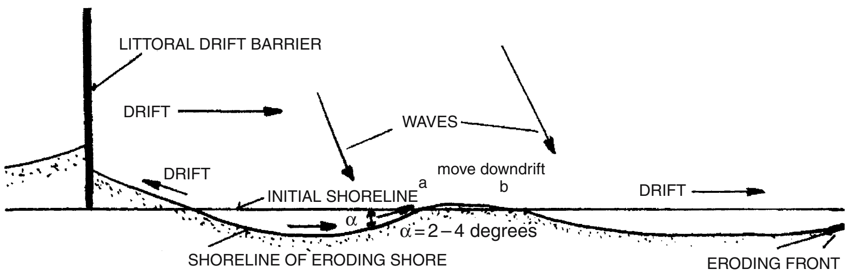

Figure B73 Schematics. The development of downdrift erosion at littoral drift barrier (from Bruun 1995, reprinted by permission of the Journal of Coastal Research).

jetty construction. The arc of erosion south of the inlet is clearly evident when considering historical changes 1950–80 in Figure B72. The historical high-tide shoreline's high-tide changes tend to converge further downdrift. This artificially induced erosion continues to impinge further downdrift through time.

Figure B72 does not extend far enough downdrift to indicate the front of the jetty-induced erosion. By a slight extrapolation, it was found that it is most likely that in 1962 it had reached 10 km south. That is, a front movement of 10 km/20 years— 0.5 km/year.

This was further confirmed by Rosati and Ebersole's (1996) quantitative research, which demonstrated that the downdrift erosion extended at least 14 km downshore (Bruun, 1995, 2000).

The zero or slow down area

The peculiar "zero-area" which sometimes appears downdrift at a rather short distance from the barrier (Figure B73) is a coastal geomorphological feature which *does not necessarily indicate the extreme limit of leeside erosion*. Obviously, the high-tide shoreline has to resume its initial direction following its change of direction on the downdrift side of the barrier. This can only be accomplished by an S-curve, which in turn develops a kind of a "corner" at point "a" as seen in Figure B73. This makes the local following section of the shore resemble "a groin" with some (minor) stabilizing effects updrift, but at the same time aggravating the large-scale erosion downdrift caused by the littoral drift barrier. A consequence of that is that the bump is most developed when the drift is very predominant and less visible for a more neutral situation.

Conclusion

The downdrift high-tide shoreline development at a littoral drift barrier may in some cases, but not always, be described by a short (local) as well as a long distance effect which both move downdrift at various rates; the long distance movement being two to three times faster than the short distance, or about ~0.5 km/ year versus ~1–1.5 km/year. These figures may be subject to considerable variances depending upon wave intensities, barrier morphologies and littoral drift magnitudes as well as upon the relative predominance of the drift. The short distance effect is a coastal geomorphological feature, the long distance a materials deficit feature. Quantitative research is making progress (Bodge, 1999; Rosati and Kraus, 1999).

Bypassing technologies

Figure B74 (Bruun, 1990) is a review of bypassing plants and principles distinguishing between non-scouring and scouring conditions (tidal entrances). Bypassing may be undertaken by bypassing plants or by bypassing arrangements.

The most simple examples of bypassing are found at breakwaters, single or double, perpendicular or parallel to shore provided with dredged entrance channels for navigation (Tables 9–16 of Bruun, 1990, is a comprehensive overview of bypassing plants and arrangements). Table B8 summarizes the situation as of 1990 (Bruun, 1990).

The main difference between bypassing at harbors and at tidal entrances lies in the action of the tidal currents. It may therefore be said that while in the case of harbors, bypassing arrangements may be

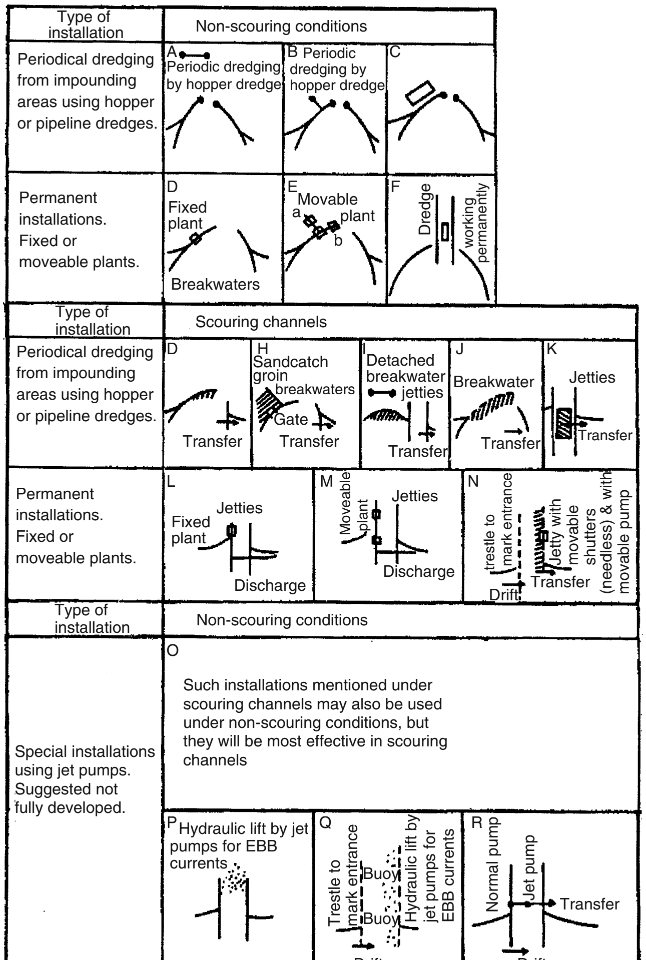

Figure B74 Various principles of bypassing (from Bruun, 1990).

designed solely on wave mechanics principles, the design at tidal inlets also includes current mechanics.

At Paradeep, State of Orissa, Bay of Bengal, India, a large movable plant which included a 750 hp pump producing 500 t sand/h was installed on a 370-m steel trestle running perpendicular to the updrift breakwater, in the middle sixties (Figure B74(E)). The specifications required that the dredge pump combined with a booster pump should be capable of handling this quantity of slurry through an 46 cm reducing to 41 cm pipeline about 2,200 m long. The plant was supposed to work fairly regularly throughout the year in most weather conditions. The trap capacity, however, proved to be too small to handle the strong deposits during the monsoon and sand bypasses the trap when it is filled, some of it in suspension even before it is filled. The result is that it has become necessary also to operate a hydraulic pipeline dredge in the entrance to remove the sand, which escaped the trap. It is probably rather doubtful that more fixed plants, although proposed or under discussion, will be built as the most recent experiences are not very promising. The 191,000 m^3/yr plant at Palm Beach Inlet in Florida, Figure B75, has not been satisfactory either and has seldom operated at the planned full capacity. It is going to be replaced by a more effective arrangement.

Future development of bypassing

The most reliable or effective trap arrangement is undoubtedly the detached breakwater built offshore on the updrift side (Figures B74(A), (I) and Figure B76). But it is an expensive solution requiring a large offshore area, a usually rather expensive breakwater and an effective suction dredge of a seagoing, therefore also expensive, type plus a rather long and therefore also costly pipeline, possibly with one or more booster stations to push the material all the way to the downdrift side beaches.

Generally, it may be said that developments that are taking place favor the most flexible arrangement of traps to be dredged by floating equipment, which bypass the material across the littoral drift barrier. The success of such arrangements, however, depends partly upon the correct placement of the trap from a sedimentation as well as a practical viewpoint in regard to transfer of material and partly upon the equipment available for transfer and the economics involved.

Trap arrangements at or on the updrift side of a sand catch breakwater like Figures B74(B), (C), (H), however, leave the dredging equipment somewhat exposed to wave action. The submerged weir (Figure B74(J)) was introduced to alleviate this drawback but it has not been fully satisfactory in all cases. While the Hillsboro Inlet, Florida, the "old timer" in the group, must be classified as a success, the arrangement at the Masonboro Inlet, North Carolina and the arrangement at East Pass, Florida, have experienced some difficulties due to weir operation.

The Hillsboro Inlet

The Hillsboro Inlet in southeast Florida, is a natural inlet to the Atlantic Ocean, connecting the Atlantic Intracoastal Waterway to the ocean. It provides free access for commercial and recreational boats, and storm water drainage for a large interior land area.

There was about a 1.2 m depth over a rock bar at the entrance in its natural condition. The inlet channel was improved in the 1960s by an excellent design developed at the University of Florida, confirmed by a hydraulic model study. The channel was cut to a depth of 3 m. A 61 m jetty on the north side for the predominant littoral drift and a 122 m jetty on the south side, were constructed.

The north side jetty has a natural weir (low section) for material transfer across the jetty, and a sand deposit basin (trap) inside for storage of material. The stored material is later transferred by a hydraulic dredge to beaches south of the inlet.

A worn-out dredge was replaced in 1983 by a 41 cm dredge reduced to 30 cm. The year-round dredging operation is very successful due to the weir design. The channel is able to be kept at an operating depth of 2.4 m 92,000 $\pm$ 15,000 m^3 of beach quality material is bypassed each year, essentially all the littoral drift sand deposited in the inlet basin and channel.

When sand is dredged promptly from the channel after a storm, less material is lost to the ocean by ebb tides or deposited in the interior channel by flood tides. The beach south of the inlet has accreted yearly and has not had to be renourished since 1983. It appears to be reaching equilibrium. A planned project will increase the outer channel depth to 6 m, improve the geo-metry of the entrance, increase the material captured for bypassing, and improve navigation safety and drainage.

Alternative bypassing systems using jet-pumps

Jet pumps submerged in the entrance for transfer by normal pumping power (Figure B74(R)) may also prove a useful procedure but it only covers a rather local area, although its influence may be expanded for some distance to either side by several pumps and pipelines (Boyce and Polvi, 1972).

The application of jet pumps to stir up material, Figures B74(P), (Q), (Bruun, 1990) using ebb currents as the main flushing or carrying agent, may prove to be a very practical arrangement, but it only helps to carry the material away from a certain local area like agitation dredging and does not transfer the material.

A jet pump system was built at the Nerang River entrance in Queensland, Australia, as described by Bruun (1990). It is based on an updrift array of jet pumps. The pumps have a large capacity, but there are problems with clogging of the pumps by debris.

Use of submerged pumps combined with fluidization

Weisman *et al.* (1982) describe improvement of channel and bypassing stabilities by perforated hydraulic pressure pipes placed below the bottom. A few examples are mentioned here.

Case one, inlet with a dredged, otherwise unprotected channel

It may be improved by lift pipes placed across the bar, at the same time improving bypassing by combined wave and (ebb) current action. A trap may also be placed in the channel to accumulate materials carried to the trap by ebb as well as by flood currents. This trap has a "lift system" in the middle that may be emptied whenever needed, for example, by a fluidization pump.

Case two, inlet entrance improved by special geometry jetties for channel stability and bypassing

Lift pipes are used to obtain optimum stability of the channel across an entrance bar or shoal (almost standard). This also improves bypassing by combined ebb currents and wave action. Channel stability is further improved by a trap in the channel operated continually for lift during ebb flows, so that the channel always stays clear. The trap may be emptied intermittently for transfer, by fluidization. Outside the updrift jetty a large trap is established for continuous transfer of material carried to the trap by littoral currents and onshore bottom creep due to wave action. This transfer may also be undertaken by fluidization using the same pump as for the bar lift.

Advantages of using hydraulic lift for channel stability

The advantages of using hydraulic lifts to increase flushing abilities are well demonstrated in nature by the influence of wave action in "opening up" a cross section. It may also be observed at places where nature delivers—free of charge—the hydraulic pressure. Some natural tidal inlets placed are accordingly all over the world. The lift may be operated according to needs and particularly during and after heavy storms. The lift is able to direct the sediment transport oceanward. Such a lift system may be used in connection with a submerged pump like the Punaise which is an underwater pump of Dutch origin. It has the shape of a thumb-tack. The pointed part digs itself down in the bottom by hydraulic pressure pumps. The fluidized material is carried from the cone-shaped pit through pipeline to the discharge area. The Punaise has been tested in the Netherlands and is being tested in the United States by the US Army Corps of Engineers.

The Punaise

The shape of the dredge gave it the name "The Punaise" (Dutch word for thumb-tack). The first "PinPoint" dredge, Punaise PN250, was commissioned in 1990, the second dredge Punaise PN400 was commissioned in late 1993.

The Punaise works on a very simple principle. A pump and suction pipe are connected to ballast tanks and then the entire structure is submerged to come to rest in the bottom where dredging is to be carried out.

The link to a small shore-based control unit and energy supply is provided by cables and hoses while a pipeline is used to transport the dredged material. The submerged pump excavates by hydraulic erosion. It creates an unstable slope upon which sediment flows to the suction intake. The unique support system makes use of the suction pipe that is embedded into the bottom to a level below the dredging depth (1–3 m) thus providing both horizontal and vertical stability.

Conclusion

1. Fixed bypassing plants will be replaced by more flexible plants. For major projects large floating plants like the trailing hopper dredger which discharges downdrift is common.
2. For medium size projects bypassing most likely will be by proper size, but smaller, hopper, or pipeline dredgers.
3. For projects of more modest size bypassing will be by shallow water hopper dredgers in some cases combined with underwater pumps and fluidized on arrangements (Visser and Bruun, 1997).

CAPPING OF CONTAMINATED COASTAL AREAS

The rapid and under-regulated development of industries in the past has left major contamination problems in several coastal and estuarine areas. Such contamination from historical chemical releases (industrial discharges, storm sewers, wastewater, landfill runoff, and leachate) severely impairs the ecological and recreational functions of the estuary/ocean. The discharged contaminants typically adhere to the fine sediments and settle in low-energy zones, which are conducive to deposition. Once settled, such sediments can exert significant oxygen demand, reduce benthic diversity, and result in poor water quality.

Contaminated sediment removal can be expensive because a high degree of efficiency and reliability is required in such operations. Capping is an attractive, nonintrusive and cost-effective method of remediating contaminated sediments in rivers and harbors, where draft restriction is not a major concern. The same physicochemical properties and hydraulic conditions that favored the initial adsorption to and deposition of the contaminated sediments typically favor successful containment by capping. Since capping is an *in situ* technique, it can often be accomplished at approximately 20–30% of the cost of a remedial dredging project.

Cap definition and considerations

Capping involves the controlled placement of clean sediment (usually sand) over the contaminated sediments in order to isolate them from the environment. The cap thickness is a function of several factors including desired breakthrough time, bioturbation, and contaminant flux. At high-energy sites, the cap is often armored by a layer of stones. Where the size of the armor significantly exceeds that of the base material, a layer of intermediate size stones (filter layer) is provided to prevent hydraulic washout of the base material. Another special case is the use of a geotextile layer on top of the native sediment layer to provide added bearing capacity and load distribution, especially when the sediments are very soft and the cap is multi-layered.

To ensure sufficient protectiveness and isolation of the contaminants, the cap should withstand the worst design case physical and chemical events at the site. Major physical destabilizing forces include extreme water flows, storm waves, and tidal currents. Molecular diffusion, ground water-induced advection, hydrodynamic dispersion, and pore water flux due to consolidation are the major chemical destabilizing forces. A base sand isolation layer provides protection from chemical events and an armor/filter layer (usually riprap and gravel/cobbles) provides protection from physical forces. Bioturbation (sediment processing by benthic organisms) is another major destabilizing force causing mixing of the water/sediment interface, thereby releasing contaminants to the water column. Therefore, the design thickness of the cap should account for physical and chemical isolation, as well as bioturbation. Since the likelihood and type of organisms that may colonize the cap would vary from site to site, a site-specific survey of benthic organisms is often required. This could also be estimated by chemical and isotopic analysis of thinly sectioned sediment cores for sediment mixing depths.

The success of a capping operation depends on the proper selection of construction techniques for the cap and armor materials. Mathematical modeling of cap performance using design equations is frequently used since: (1) it can evaluate the effectiveness of the cap as a chemical barrier for various design parameters, and (2) it can quantify potential contaminant release rates to assess long-term effectiveness of the cap. A brief review of the cap design criteria and guidance for the selection of cap construction equipment are presented here.

Design criteria

Special factors of interest to cap design/evaluation include cap behavior during placement, settlement of the cap, and native sediments following placement, potential contaminant release mechanisms, and stability of the cap in the long term (Mohan, 2000). Design considerations for an underwater cap can be classified into the following six categories (Palermo, 1991; Zeeman, 1993; Mohan, 2000):

Site investigations: A good field database is an essential starting point for an effective cap design. Investigations should include evaluation of water depth, currents, wave forces, flow velocities, extreme events (storms, floods), ice effects and forces, soil and foundation properties (strength, consistency, compressibility, and permeability), contaminant types and levels, and water column/biota contamination data.

Cap area: The cap should ideally cover the entire horizontal extent of the contaminated sediments. Mapping the horizontal distribution of the contaminants is essential to identifying this parameter. In special cases where sediment contamination is vast and widely distributed spatially within the waterbody, the extent of the cap should be determined based on human health exposure risks and isolation of the bulk of the contaminant mass to the food chain.

Cap movement during placement: Underwater caps may be placed using several techniques such as surface placement from barges, clamshell, or pipelines, placement using spreader boxes, tremie pipes, and underwater placement using clamshells. Several mechanisms are of interest as the cap is being placed. One of the main concerns during placement of the cap is the movement of the slug (velocity and properties) as it reaches the ocean or river bed. Theoretical considerations should include impact velocity of the sand, thickness and horizontal dispersion of the sand slug, and required number of lifts for obtaining the design thickness.

Table C1 Comparison of cap construction techniques (Mohan, 1997, Proceedings Coastal Zone '97)

Equipment	Water depth	Material	Accuracy	Resuspension	Mixing	Cost
Barge discharge	Deep	Sand	Medium	Medium	Low	Low
Submerged discharge	Both[a]	All[b]	High	Low	Low	Medium
Skip box	Shallow	All[b]	High	Low	Low	Medium
Conveyor belts	Deep	Sand/rock	Medium	Medium	Medium	Medium
Dry/wet pumping	Both[a]	Sand/silt/clay	Medium	Low	Low	Low
Surface/underwater clamshell	Both[a]	Sand/rock	Medium	High	High	Medium
Modified dredges	Deep	Sand/rock	Medium	Medium	Medium	High
Thin-layer disposal	Deep	Sand	High	Medium	Low	Medium

[a] Deep and shallow water application.
[b] Material types (sand, silt, clay, and rock).

Geotechnical stability: Construction of a sand cap over soft native sediments may cause stability concerns due to the increased stresses in those layers. The primary stability concern during cap placement is the potential for the sediments to fail under the increased stresses, and to form "mudwaves" which could be trapped in subsequent layers of sand cap material. This concern is particularly valid since contaminated sediments typically have very high water contents and low shear strengths, resulting from the lack of sediment consolidation. Cap stability analysis involves consideration of three major factors: (1) settlement of the cap and foundation material, (2) bearing capacity of the cap, and (3) slope stability of the cap.

Chemical stability: Chemical analysis is one of the major design elements since it defines the effectiveness of the cap in containing (and isolating) the contaminants from the water column. There are four major mechanisms that could potentially release contaminants through the cap system: (1) diffusion, in the absence of groundwater flow, (2) advection and dispersion, if groundwater flow through the cap is present, (3) release of pore water due to sediment compression, and (4) erosion of contaminated sediments due to pore water release during sediment compression.

Physical stability: An underwater cap must be designed for a specific level of protection. This implies that the cap/armor should be able to withstand the impact forces resulting from a certain return period event (typically the 100-year event). An armor layer is provided when necessary to protect the sand isolation layer from being eroded away due to hydraulic and environmental forces. In general, bottom velocities exceeding about 0.3 m/s (1 fps) can initiate sediment erosion. Considerations include protection from river flow, wave action, propeller wash forces, ice loads, and forces resulting from pore water release mechanisms.

Hydraulic filtering: The cap/armor should also be designed to withstand the impacts of the hydraulic filtering forces. There are two ways of providing this protection: (1) by installing a separate filter layer between the armor and cap layers, and (2) by installing a "graded" armor layer (i.e., with a wider grain size range) above the cap layer.

Construction techniques

Table C1 lists the factors influencing the selection of cap construction equipment based on site- and material-specific properties.

Summary

Since the early 1980s, several pilot-scale and full-scale projects have been conducted to field-test the effectiveness of capping under a variety of site conditions (Strugis and Gunnison, 1985; Palermo, 1991; Wang *et al.*, 1991; Fredette *et al.*, 1992; Zeeman, 1993; Averett and Francingues, 1994; Nelson *et al.*, 1994; Hull *et al.*, 1998; Laboyrie and Flach, 1998; Lillycrop and Clausner, 1998; Shaw *et al.*, 1998; and Mohan *et al.*, 1999). These studies have established the validity of the environmental isolation provided by the capping process, thereby making capping a viable tool to be screened during coastal clean-up projects. Note that a final decision on the preferred remedy for a specific site should be based on technical, environmental, and economic analysis of the various alternatives (capping, dredging/capping, dredging/disposal, and no action) for the site.

CARBONATE SANDY BEACHES

Introduction

Carbonate beaches have a significant proportion of the sediment fabric of biogenic origin, and carbonate in composition. Carbonate beaches are therefore wave deposited accumulations of sediment (sand to boulder in size) deposited on shores where a nearshore supply of biogenic debris is available. The carbonate detritus can originate in a range of environments and from a number of sources including coral and algal reef debris, mixed skeletal material including broken shells, foraminifera, bryozoa, gastropods and ostracods, some terrestrial animals, and ooids.

In the tropics, they are associated with three separate environments. They are most commonly found adjacent to/or nearby coralline-algae reefs. They also occur in lee of tropical intertidal sand and mud flats where shells are winnowed to form shelly beach ridges–cheniers; and they may occur adjacent to carbonate banks in shallow tropical seas. In temperate regions, there are three separate sources of carbonate material. They are found adjacent to carbonate encrusted rocky shores and reefs. Temperate sea grass meadows along lower energy shores supply molluscs and other debris to sand flats and lower energy beaches; and are most extensive adjacent to some high-energy carbonate-producing, temperate continental shelves. Carbonate-dominated beaches also tend to exist in areas with the above conditions, where there is insufficient material of terrigenous origin to significantly dilute the carbonate proportion, particularly in arid regions.

An additional characteristic of many carbonate beaches is the post-depositional modification (diagenesis) of the sediment to form beach calcarenite (beachrock) in warm tropical waters, and aeolian calcarenite (dunerock) in more arid tropical to temperate environments. Once formed, the lithified sediments can have a dramatic impact on the nature and future evolution of the coastal system, particularly when the beach and/or dunerock is exposed to wave-wind processes. Even beaches with little carbonate may experience similar diagenetic processes particularly in warm tropical waters. Given this an additional definition of carbonate beaches are those whose processes and morphology are significantly impacted by the presence of carbonate grains and cements, particularly the formation of beach and dune calcarenite.

This entry will briefly examine the location of carbonate beaches, the major sources of carbonate sands, and the impact of the carbonate sands on beach morphodynamics.

Location

Carbonate beaches exist in tropical and temperate locations, including some in relatively high latitudes. The main prerequisite for a carbonate beach is a source of carbonate-producing detritus, and a mechanism to erode and/or transport it to the shore. Bird and Schwartz (1985) recorded 32 tropical and 14 temperate countries where carbonate beaches and beach and/or dune calcarenite have been recorded. Scholle *et al.* (1983) also provide a list of locations and references and where carbonate beach and dune systems have been recorded, while Robbins and Magoon (2001) is a more recent overview of primarily tropical carbonate beach systems.

Table C2 provides a summary of major beach carbonate sources and materials in tropical and temperate regions. The table and even the locations recorded in Bird and Schwartz is by no means exhaustive, as sediment characteristics are only available in the literature from a small minority of the world's beaches. This overview is based on the published data and locations at present. Future work will no doubt expand the range and perhaps types of carbonate beaches.

Table C2 Location, sources, and form of carbonate beach systems

	Source	Material	Beach morphology
Tropical			
Open coast	coral-algae reefs	coral-algae fragments	reflective
Deltaic coasts	tidal sand/ mud flats	molluscs	cheniers, beach ridges
Shallow tropical seas	carbonate banks	ooids, skeletal, peloidal, pellets, aggregate sands	beach ridges
Temperate			
rocky coast	encrusting organisms	rocky shore biota	variable
low energy	sea grass meadows, tidal sand flats	molluscs, red algae foraminifera, bivalve fragments,	reflective/sand flats
high energy	inner shelf	molluscs, red algae, encrusting bryozoans, echinoids	low to high energy + dune calcarenite

Tropical locations and sources

Tropical carbonate beaches generally occur between 25°N and S in association with three major carbonate-producing environments: coralline-algal reefs, tidal flats, and carbonate banks.

Coral reefs

Tropical carbonate beaches are predominantly located in association with coralline-algae reef systems, particularly fringing reefs, which lie in close proximity to the shore, and all beaches associated with atolls and cays, where the eroded reef debris is the sole source of material. Tropical reef beaches include windward boulder ramparts formed in lee of exposed high-energy reefs, sand and coral cays formed on coral islands, and atolls and mainland beaches composed of sand through boulder debris (Scoffin and Stoddart, 1983). Richmond (2001) provides an overview of tropical Pacific island carbonate beach systems including sediment sources, rates of supply, and physiographic settings.

Presence of an offshore reef is insufficient to guarantee carbonate beaches, as there must also be a mechanism to erode and transport the carbonate detritus from the reef to the shoreline. The world's longest reef system, the 2,000 km long Great Barrier Reef, lies between 20 and 200 km from the Australian coast. Most of the carbonate detritus is deposited tens of kilometers offshore close to the source reefs and does not reach the shore. The mainland coast is therefore dominated by terrigenous sediments, low in carbonate (<20%). Only scattered fringing reefs in the northern reef system actively supply carbonate sediments to the adjacent mainland beaches forming carbonate rich beaches (70–90 %) (Short, 2001).

Tidal flats

Tidal sand and mud flats are extensive in tropical regions in association with river mouth deltas and protected embayments. These surfaces and adjacent subtidal sediments provide a habitat for a range of organisms, particularly molluscs. When exposed to episodic wave erosion and reworking the coarse carbonate detritus, together with any coarse terrigenous material, is eroded and reworked shoreward and deposited as shelly beach ridges, on sand flats, and cheniers, on mud flats (e.g., see Rhodes, 1982).

Carbonate banks

Carbonate banks occur in shallow tropical seas and are arranged perpendicular to shore as tidal-bar belts or shore parallel as marine sand belts. They may be composed of ooids, and/or mixtures of skeletal, peloidal, pellets and aggregate sands. Low tidal deltas and barrier islands surrounded by low-energy carbonate beaches can form in association with the banks. They have been recorded in south Florida and the Bahamas, and in Western Australia's Shark Bay (Scholle *et al.*, 1983).

Temperate locations and sources

Temperate carbonate beaches occur outside the tropics in a range of temperate environments, from cool humid climates in Scotland and Ireland, to Mediterranean climates in Greece and the Black Sea, but are most commonly associated with arid to semiarid temperate coasts in North and South Africa and southern and western Australia. The three major sources of temperate carbonate sands are rocky shores, temperate sea grass meadows, and shelf biota.

Rocky shores

Rocky shores play host to a range of encrusting carbonate organisms (Calhoun and Field, 2001) whose death assemblages can be reworked onshore usually into carbonate enriched embayed or pocket beaches, with source headlands to either side and rock reefs offshore. Knuuti and Knuuti (2001) report on a Maine Beach (43°N) composed of 80% carbonate material consisting of barnacles, echinoids, mussels, and other material. Higher latitude carbonate beaches and dunes have also been reported in Ireland and Scotland (54 and 59°N) (Scholle *et al*., 1983).

Sea grass meadows-sand flats

Sea grass meadows of *Posidonia* and *Zostera* provide a habitat for a range of molluscs, together with red algae, foraminifera and bivalve fragments, as well as sea grass roots and detritus. This material is reworked shoreward to build intertidal sand flats backed by low-energy shelly beach ridges. Such systems occur commonly in the southern Australian gulfs and Great Australian Bight (Short *et al*., 1989), and throughout Shark Bay on the central west coast.

Shelf biota

Temperate continental shelves across southern and western Australia, around South Africa and along the western and north African and southern and eastern Mediterranean coast contribute carbonate detritus to the most extensive temperate carbonate beach and dune systems. On the southern Australian shelf Boreen *et al*. (1993) describe a shallow (30–70 m) inner shelf containing a range of hard-bodied organisms particularly molluscs, red algae, encrusting bryozoans, echinoids and soft kelps, and sponges. The shelf is dominated by high-energy wave action, which erodes and transports carbonate detritus shoreward. Along the south and western Australian coast it contributes to a 9,000 km coastal system containing 3,000 beaches occupying 70% of the coast, with regional beach systems composed of between 58% and 80% carbonate, and individual beaches reaching 100% carbonate (Short, 2001) (Figure C1).

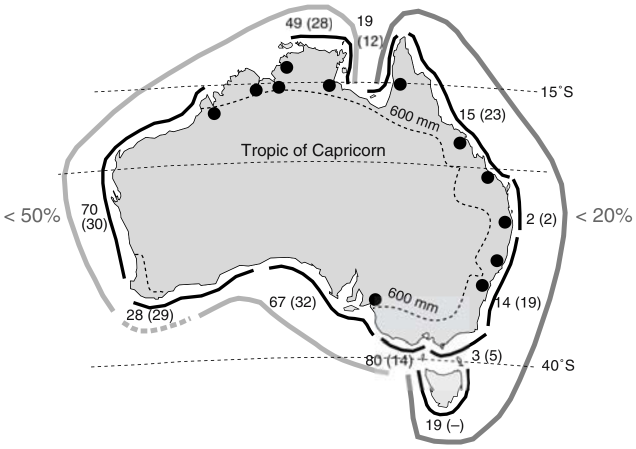

Figure C1 Australian carbonate beach sands. Numbers indicate mean regional percentage of carbonate beach sand, with standard deviation in brackets. Note the dominance of carbonate sands across the southern and western coast derived from continental shelf biota, and in low-energy areas, from sea grass meadows, while in the northwest fringing reefs are a major source. Dots indicate major river systems and 600 mm isohyet delineates Australia's humid fringe (from Short, 2001, with permission of the ASCE).

Beach systems

The beach systems associated with carbonate beaches, behave similar to quartz beaches, and are dependent on the sediment and wave–tide characteristics. They may be composed of boulders through fine sand, may range from wave to tide dominated, and from reflective to dissipative. Their sediment characteristics and grain size is largely related to the sources and level of wave energy. Boulder coral ramparts and cays are associated with windward reef systems (Scoffin and Stoddart, 1983). Most tropical carbonate beaches tend to be of low energy and composed of coarser sands and gravel including those in lee of reefs and sand–mud flats, the latter may also contain a high proportion of whole and shell fragments, a consequence of which is their description also as "shell ridges."

Temperate beaches can also range from coarse to fine. Coarser sands and some gravel are usually associated with the lower energy beach ridges form in lee of sea grass meadows and their low-energy nearshore and/or intertidal sand flats. Shell Beach in Shark Bay, Western Australia, a very low-energy system formed in lee of shallow sand banks and sea grass meadows consists of 100% shells (Figure C2). Local carbonate enrichment of energetic beaches by *Donax* species (commonly known as cockles, coquina, pippis) derived from adjacent foreshore habitats occurs through tropical and temperate locations.

The finest and best-sorted carbonate sediments are associated with shelf-derived carbonates on high-energy coasts. The erosion, transport, and energetic deposition process leads to a diminution of the source material into some of the finest (<0.1 mm), well to very well sorted, beach material. While there has been a limited amount of work in the sources of such material (e.g., Boreen *et al*., 1993; James *et al*., 1999) there is no published work in the actual sources (and age) of the beach sands. This is an area of considerable scope, particularly as it would provide information on the rates of contemporary carbonate sediment supply.

Diagenesis

A characteristic of carbonate beaches in all locations is the post-depositional modification of the carbonate fabric through geochemical processes, which commences soon after deposition. This is manifested as the commonly termed beachrock and dunerock. Beachrock, or more correctly beach calcarenite, refers to the precipitation from seawater of carbonate cements in the intertidal zone of tropical beaches, leading to the cementation of the intertidal beach zone. The beach and swash zone is an ideal environment for the precipitation of marine cements. Groundwater supersaturated with $CaCO_3$ is pumped by both wave and tidal activity through the usually coarse, highly porous, permeable sediments. The cement is derived from precipitation from the seaward matrix, and not from solution of the *in situ* sand grains. Cements are typically aragonite or high Mg-calcite (10–14%). Cements precipitated from freshwater contain low Mg-calcite (5%). As a consequence the rock normally has extremely well-preserved structures and is typically exposed as tabular, seaward sloping slabs of beachrock (Figure C3).

Figure C2 Detail (left) and view (right) of Shell Beach, Shark Bay, Western Australia, which is composed of 100% molluscs derived from adjacent sea grass meadows (A.D. Short).

Figure C3 Beachrock detail showing well preserved, cemented beach laminations, Maceio, Brazil (left); and tabular, seaward dipping beachrock, Heron Island, Queensland (A.D. Short).

Figure C4 Beachrock rich in coquina shells, backed by eroded rock forming a beachrock breccia, Marineland, South Carolina (A.D. Short).

This process needs only a few years to decades to occur, though most would have occurred during the late Holocene.

Beachrock formation requires that sediments remain close to the surface and shoreline, the source of wave and tidal pumping. For this reason, they occur on stationary rather than prograding shores.

Once the beachrock is formed it may remain buried and have little impact on contemporary beach processes. However, as the unconsolidated beach narrows the underlying beachrock will influence swash permeability and the groundwater table, leading to a super-elevation of the groundwater and exit point, both of which will enhance beach erosion.

When the rock is exposed at the shore it behaves as an impermeable sloping seawall (Figure C3), which will decrease permeability, enhance erosion and retard sediment deposition and beach recovery. The rock itself may be eroded as tabular boulders, which are deposited to the lee as a boulder breccia (Figure C4).

If the beachrock becomes stranded off the shore, as a shore-parallel or curvilinear reef, it will act as an attached or detached shore-parallel breakwater, with usually discontinuous form longshore. This affects wave breaking, attenuation, and refraction. Wave breaking on the reef may result in zero ocean wave energy in lee of the reef, either permanently and/or at low tide (Figure C5). Wave attenuation over lower reef sections and/or at high tide will reduce waves in lee of the reef; while wave refraction over and or around detached reefs will redirect the wave train. The impact of the above is first to decrease breaker wave energy at the shore, and second to realign the backing sedimentary shore parallel to the refracted wave crests. As a consequence, shores in lee of beach rock reefs have lower energy beach systems and are more crenulate (Figure C5).

In temperate and some more arid-tropical locations, longer term pedogenic process in carbonate rich beach and dune deposits leads to the formation of calcrete (caliche). It consists of usually a loose thin top soil, underlain by laminar, breccia and massive calcrete consisting of recrystalized carbonate sands devoid of original structures, followed by mottled calcrete including lithocasts and lithoskels associated with vegetation roots and insect casts, and finally the loosely consolidated parent material, usually carbonate-rich dune sands (Scholle *et al*., 1983) (Figure C6). Dune calcarenite occurs across North Africa to the eastern Mediterranean, in South Africa and southern and western Australia.

Dune calcarenite will have a similar impact to beachrock on beach morphodynamics. In addition, because calcrete will affect an entire beach–dune–barrier system, it is usually far more massive than beachrock, and consequently have far greater impact on the adjacent or backing coastline (Short, 2001).

Summary

Carbonate beaches occur throughout the tropics in association with coral reefs, tidal flats, and carbonate banks, and in temperate latitudes adjacent to rocky shores and reefs, and in lee of sea grass meadows and carbonate-rich shelves. Each of these environments produces a range of carbonate detritus sourced from coral fragments, encrusting algae, bryozoa, formanifera, molluscs, echinoids, and other animals. Depending on the erosion and transport processes, the detritus may be deposited at the beach as whole skeletons/shells, through to fine carbonate sands. Once deposited it may contribute to backing coastal dune systems, and be subject to cementation as beachrock in warmer tropical waters, and dunerock in arid to semi-arid carbonate rich beach–dune systems. Once formed the calcarenite can be exposed or submerged as beachrock or calcarenite barrier reefs, causing wave breaking, attenuation and refraction, which control the form of the lee coastline.

CARIBBEAN ISLANDS, COASTAL ECOLOGY AND GEOMORPHOLOGY

Geography

Location and topography

The main line of Caribbean Islands lie in an arc extending north from the coast of Venezuela and then trending westwards towards the southern tip of Florida; while other small group of islands lie off the northwestern coast of Venezuela and off the coasts of Central America. Most of the islands are located in the Tropics, and lie north of the 10°N line of Latitude and south of the 23°N Tropic of Cancer, although some of the islands in the Bahamas chain extend north of this line.

The Greater Antilles, consisting of four major islands—Cuba, Jamaica, Hispaniola and Puerto Rico—are, with the exception of Cuba, fairly mountainous with narrow coastal plains, while Cuba is dominated by extensive lowland plains. The Lesser Antilles consist of two chains, an outer chain from Barbados to Anguilla and continuing north to the Bahamas chain, consists of low-lying islands; while the inner chain from Grenada northwards are mountainous volcanic islands.

Geology

The Caribbean islands are quite young in geological terms, the Caribbean basin began forming less than 200 million years ago. The

West Indian Island arcs have been formed along a stress zone between the North and South American crustal plates. The inner chain of the Lesser Antilles developed along a line of weakness in the earth's crust. A series of submarine volcanoes formed, which rose above sea level to form the islands. Many of these islands still have signs of active volcanism such as, hot springs and sulfur emissions. Indeed there have been major volcanic eruptions in recent years, in particular Chances Peak in Montserrat, which started erupting in 1995 creating a volcanic emergency on the island and causing most of the population to flee to the northern third of the island or to other islands. This emergency continued until 1998, and now at the beginning of the 21st century, only the northern third of Montserrat is habitable and the dome on the volcano continues to grow at a significant rate. Other islands have also experienced eruptions in recent times, for example, Soufrière in St. Vincent and the Grenadines erupted in 1979.

The outer chain of the Lesser Antilles, and the Greater Antilles are older and have a more complicated history, consisting of volcanic episodes, alternating with periods of subsidence and sedimentation (Blume, 1974). The outer chain of the Lesser Antilles consists of islands with volcanic bases capped by thick limestone. Islands such as, Puerto Rico have a central mountainous spine consisting of igneous rocks with coastal plains composed of sedimentary rocks on the north and south coast (Bush *et al.*, 1995).

In more recent geological time there have been major changes in sea level, which have affected the geography of the islands. About 14,000 years ago, the sea level was 68 m below the present level and many associated islands, such as Puerto Rico and the Virgin Islands were joined by dry land. The sea reached near its present level about 5,500 years ago at that point the separation of most islands was completed. Trinidad became an island only in recent geological time, when erosion flooding of the Orinoco River separated it from the mainland across the Serpent's Mouth (Bacon, 1978).

Climate

Lying in the Tropics, the islands have an equable climate with little change in temperature from month to month. Average temperatures in the Bahamas are 25.1°C, and rise toward the equator, for example, 26.7°C in Curaçao. Temperatures vary with altitude and aspect. Precipitation amounts vary from island to island and within islands depending on topography and aspect. Most islands have a wet and a dry season, with the main wet season being from May/June to October/November, some islands may have two rainfall maxima. The dry season is generally from December to April.

The Northeast Trade Winds determine the weather in the Caribbean throughout the year. These blow with great constancy from directions between northeast and southeast. The Trade Winds are strongest between June and July and from December through March. During the first half of the year they usually blow from directions between northeast and east, veering more toward the southeast during the mid and latter parts of the year. The trailing ends of frontal systems moving from west to east over the southern part of the United States sometimes affect the Greater Antilles, particularly between October and April.

The Caribbean Islands lie in the hurricane zone. Many hurricanes originate as tropical waves off the west coast of Africa and travel across the Atlantic Ocean gaining energy from the warm ocean waters. As tropical waves strengthen, they pass through several stages, including tropical depression and tropical storm (see Table C3) before reaching hurricane strength.

A hurricane is an intense low-pressure tropical weather system with maximum surface wind speeds that exceed 118 km/h (74 m/h). Hurricanes are graded according to their sustained wind speed (wind gusts may be significantly higher) using the Saffir–Simpson scale of 1–5, see Table C3. The hurricane season lasts from June 1 to November 30, although rarely hurricanes can occur outside of these limits. September is the month when most hurricanes are experienced. Hurricanes generally move in an east to west/northwest direction across the Caribbean region, although exceptions have been recorded, particularly later on in the hurricane season, for example, Hurricane Lenny, a category 4 hurricane, formed just south of Jamaica in November 1999 and moved in an easterly direction and eventually hit Anguilla and St. Maarten.

Table C3 Categories of tropical low-pressure systems

Category	Sustained wind speed km/h	Sustained wind speed m/h
Tropical wave	Up to 36	Up to 22
Tropical depression	37–60	23–37
Tropical storm	61–117	38–73
Hurricane category 1	118–152	74–95
Hurricane category 2	153–176	96–110
Hurricane category 3	177–208	111–130
Hurricane category 4	209–248	131–155
Hurricane category 5	249+	156+

Oceanography

Water temperatures are generally above 25°C. The region is affected by the North Equatorial Current, which flows generally from east to west across the Caribbean Sea. The surface current then turns northwards through the Yucatan Channel, where a part flows into the Gulf of Mexico and the other part forms the Florida Current, which eventually becomes part of the Gulf Stream.

The average tidal range in the Caribbean is small, 0.3 m (1 ft), and 0.5 m (1.5 ft) at Spring Tides. Most islands experience a semi-diurnal tidal pattern. There are two very deep trenches in the Caribbean Sea. The Puerto Rico Trench follows a west–east trend and extends from north of the Dominican Republic to the northern islands of the Lesser Antilles, the maximum depth is 9,200 m. The Cayman Trench lies between Jamaica and the Cayman Islands.

Waves generally approach the region from the east, varying from northeast to southeast, depending on the Trade Wind regime. As a result, in the Lesser Antilles, where the islands generally trend north to south, there is a very clear distinction between the windward, exposed, east coasts with high wave energy, and the leeward, sheltered, west coasts. This distinction is not always so clear in the Greater Antilles, although here it is often the north and east coasts which are the most exposed to high wave energy.

During the Northern Hemisphere winter months (October to April), swell waves from North Atlantic low-pressure systems are often experienced in the Caribbean Islands. These swell waves travel southwards and impact north, east, and west facing coasts in particular. Also during the winter months, waves between the northwest and northeast may be experienced as frontal systems move across the southern United States and sometimes also affect the northern shores of the Greater Antilles.

Very high-energy waves from "unusual" directions may also be experienced during tropical storms and hurricanes. During such events, hurricane waves may directly impact the normally sheltered west coasts of the Lesser Antilles.

Biogeography

Small islands can be expected to have less diversity of species and habitats than continents. Newly formed islands may be isolated from land areas populated by plants and animals by large expanses of sea. And these islands can only be colonized by those species capable of making the sea crossing, as a result they will have fewer species than neighboring mainland areas (Bacon, 1978). The degree of isolation within an archipelago is another factor. Trinidad was separated from the South American mainland in relatively recent times, thus its flora and fauna are very similar to the neighboring mainland. However, the "oceanic" islands of the rest of the Caribbean have no such obvious relationship with the mainland. Distance from the mainland is another factor, for instance the number of species of amphibians and reptiles decreases northwards throughout the Lesser Antilles.

Coastal characteristics

It has been argued that islands do not have coastal zones, instead the whole island is a coastal system, extending from the highest peak to the offshore reefs. Everything that takes place inland, be it vegetation clearing or pesticide application, also affects the coast. The concept is obviously very relevant in some of the very small islands, such as the low-lying cays of the Virgin Islands and the Bahamas, and also some of the small volcanic islands where there is just one central peak or mountain range, such as Saba and Nevis. And while it also has merit for the mid- to large-sized islands, such as Dominica and Jamaica, for example, it is more difficult to apply here because of the overall complexity of those islands. It has further been suggested (Nichols and Corbin, 1997) that an Island System Management framework represents a way to achieve the objectives of Integrated Coastal Management.

Beaches

Differences in the structure and character of an island's rocks exert a strong influence on the coastline, whether it consists of cliffs, low rocky platforms, or some other form such as beaches or wetlands. With tourism playing such a major economic role in the Caribbean region, beaches are economically the most important part of the coastal zone. With the region's dependence on "sun, sea, sand" tourism, the very economic fabric of some islands is determined by its beaches and their characteristics. This is not to say that beaches are unimportant for island residents, indeed the opposite is the case, since islanders value their beaches highly as places for recreation, sports, and simple enjoyment. Furthermore, island beaches provide natural protection for very valuable real estate located along the coastline.

Morphology. Beaches in the Caribbean Islands range from long straight beaches extending for several kilometers, such as on the east coast of Barbados from what is known as the East Coast Road, just north of Bathsheba, to Long Pond and Greenland; to tiny pocket, bayhead beaches, extending just a few hundred meters, and enclosed by cliffed or rocky headlands, such as Lime Kiln Bay on the west coast of Montserrat. There is endless variety, not only in shape and geomorphology, but also in sediment size and type, and the presence or absence of rivers. Incoming wave energy and the presence or absence of coral reefs, are other important factors controlling coastal morphology.

Beach material. The word "beach" in the Caribbean Islands is usually taken to imply sand beach. However, geologically, beaches may consist of other sizes of particles (clay, silt, sand, gravel, cobbles, or boulders). In this entry, however, and given the regional importance of sand beaches and tourism, the word "beach" implies sand beach, unless otherwise qualified. The color of the beach sand usually reflects its source. In Anguilla, for instance, the beaches are for the most part composed of white calcareous sand, with patches of shells mixed in, this sand is derived from the offshore reefs and the breakdown of the limestone of which the island is composed. In Dominica, many of the beaches are composed of black sand with grains of olivine and magnetite, brought down to the coast by rivers, and derived from the erosion of volcanic rocks. The yellow silica sand along Trinidad's north coast is derived from the erosion of the Northern Range's sedimentary rocks.

Not all beaches consist of sand, larger size ranges from gravel to boulders, make up many beaches in the volcanic islands, for instance at Argyle on the east coast of St. Vincent the beach is composed of large stones and boulders. Some of the more exposed beaches on the south coast of Tortola in the British Virgin Islands are composed of large coral fragments and boulders.

The geology and the wave energy determine the type of material on the beach. Strong wave action washes out the sand particles leaving a steep beach profile as is often found on the Atlantic-facing beaches. While calmer conditions often result in fine sand being deposited and a gently sloping beach. Some beaches have different types of material according to the season, for instance some leeward beaches in the Lesser Antilles have stone beaches during the months with higher wave energy, October to April, while during the calmer summer months, sand is moved onshore to cover the stones.

A rock formation found on many Caribbean beaches, either on the beach or seaward of the beach is called beachrock. This consists of sand grains and other beach material, including stones, cemented together by calcium carbonate. Beachrock forms within the body of the beach, beneath the sand surface and near the water table. Once the covering sand has been eroded, the beachrock formation hardens into rock. Exposures of beachrock are indicative of erosion (Cambers, 1998).

Beach flora and fauna. Conditions above high water mark in the spray zone are very unfavorable for plants because of the dry sand and lack of water. Plants that grow here must store rainwater in succulent tissues, and have small-sized leaves to reduce water loss. Two plants often found above the high water mark are the Beach morning glory (*Ipomoea pescaprae*) and the grass Seashore dropseed (*Sporobolus virginicus*). They stabilize the sand surface and make conditions more favorable for other species such as Beach bean (*Canavalia maritime*), and Sea purslane (*Sesuvium portulacastrum*). However, high waves during storms frequently destroy this temporary beach vegetation, which then has to begin again establishing a foothold on the sand.

Inland from the spray zone there is a belt of woodland trees. These must withstand salt spray, strong winds, and saline soils. Common species include Sea grape (*Coccoloba uvifera*), Seaside mahoe (*Thespesia populnea*) and the West Indian almond (*Terminalia catappa*). These all have deep roots, which play an important role in stabilizing the sand. They also act as a windbreak. Another important tree is the Manchineel (*Hippomane mancinella*), this deep rooting tree plays an important role in slowing down beach erosion, however, the milky juice, which exudes from the branches when cut, may blister the skin, and the green fruits or small "apples" are poisonous. Another tree, the Casuarina (*Casuarina equisetifolia*), is an introduced species, which grows very rapidly in the coastal environment. However, it casts dense shade and produces a "carpet" of thick needles, which reduce the growth of ground cover. The coconut palm (*Cocos nucifera*), while not a native tree (it was introduced from the Indo-Pacific region) is very common in the islands and is often planted by tourism developers. However, it is very shallow rooting and is often the first tree to fall during high winds associated with tropical storms and hurricanes.

The beaches provide a habitat for a variety of crustaceans, mollusks, and other animals. Common species include the ghost crab (*Ocypode*), the Chip-chip (*Donax*), the Sand dollar (*Mellita quinquiesperforata*). Jellyfish sometimes washed up on the beach include the Portuguese man-of-war (*Physalia*), and the Tennis ball jellyfish (*Stomolophus*). Birds seen at Caribbean beaches include the Brown pelican (*Pelicanus occidentalis*), Brown booby (*Sula leucogaster*), and Frigate bird (*Fregata magnificens*).

Sea turtles nest on beaches in the Caribbean Islands, the most common species are the Leatherback (*Dermochelys coraicea*), Green (*Chelonia mydas*), Hawksbill (*Eretmochelys imbricata*), and Loggerhead (*Caretta caretta*). Most of these species are declining as a result of over-harvesting, loss of habitat, etc. Many islands have laws defining closed seasons or total bans on the catching of sea turtles or poaching of their eggs.

Beach changes. Coastlines are areas of continuous change where the natural forces of wind and water interact with the land. These changes have been taking place for millennia. History provides the example of Cockburn Town in the Turks and Caicos Islands, where Back Street had to be renamed Front Street at the beginning of the 20th century as erosion took its toll.

Beach changes have been measured in many of the Caribbean Islands since the 1980s as part of a regional program sponsored by the United Nations Educational, Scientific and Cultural Organization (UNESCO) and the University of Puerto Rico Sea Grant College Program. (This monitoring program is known by the acronym COSALC, Coast and Beach Stability in the Caribbean Islands Project, or as it has been recently renamed "Managing Beach Resources and Planning for Coastline Change, Caribbean Islands".)

Beaches change seasonally in the Caribbean Islands, in many islands a winter/summer pattern can be distinguished, with beaches eroding during the winter months, October to April, as a result of higher Trade Wind waves and winter swells from the North Atlantic storms, and the same beaches accreting in the summer months when wave energy is lower. However, the pattern often varies between different coasts, so it is unwise to generalize.

An initial analysis of the beach monitoring results (Cambers, 1997a) showed that 70% of the beaches had eroded and 30% had accreted. Mean annual erosion rates varied between 0.27 and 1.06 m/yr. Natural and anthropogenic factors are involved. The natural factors include winter swells, tropical storms and hurricanes, and sea-level rise. Among the most important anthropogenic factors are beach and dune mining, building too close to the beach zone, badly placed sea defenses, and deterioration of nearshore coral reefs.

Hurricanes appeared to be the major factor controlling the erosion. For instance, in Dominica (Cambers and James, 1994) there was significant erosion after Hurricane Hugo in 1989, followed by accretion in the years 1990–92. However, the beaches never returned to their pre-hurricane size, before further hurricanes impacted Dominica in 1995.

During 1995, three tropical storms/hurricanes hit the eastern Caribbean Islands within a three-week period: Tropical Storm Iris, Hurricane Luis, and Hurricane Marilyn. There was extensive damage, both to the islands' infrastructure and environment especially erosion of the beaches. The COSALC database was used to determine the extent of erosion of the land behind the beach (dunes or coastal lands) as a result of these events. Dunes on the north coast of Anguilla retreated as much as 30 m as a result of Hurricane Luis. Erosion rates were much lower further away from the hurricane center.

During the last part of the 1990s, the islands in the Lesser Antilles, from Dominica to Anguilla, experienced several tropical storms and hurricanes, leading to serious erosion. These numerous high-energy events appeared to introduce a certain vulnerability to the coastal systems making recovery slower and less sustained.

Beach protection. The increasing coastal development in the Caribbean Islands, particularly over the last two decades, coupled with the ongoing coastal erosion, has resulted in many property owners and sometimes government agencies building structures to slow down or stop the erosion. These structures include revetments, seawalls, groins, and offshore breakwaters. They have had varying degrees of success. Some islands, for example, St. Maarten and Anguilla, have attempted to restore their beaches by nourishing them with sand from offshore. Again, these measures have had varying degrees of success, at Maunday's Bay in Anguilla, the beach was nourished three times during the period 1995–99, only to have the sand washed away by a high-energy or hurricane event in 1997, 1998, and 1999.

There are no easy answers to this dilemma, especially since every beach is individual and must be treated as such. The use of adequate coastal development setbacks, which ensure that new coastal development is placed a "safe" distance away from the active beach zone has been proposed. A methodology has been developed, based on using existing data on erosion, hurricanes, and sea-level rise to determine a specific setback distance for each beach (Cambers, 1997b). Thus, beaches experiencing more erosion have higher setback distances. This methodology is at present being applied in Anguilla and Nevis.

Undoubtedly erosion is going to continue in the Caribbean Islands, and the problems of how to protect beachfront property and to maintain beaches, will likely intensify.

Cliffs and rocky shores

Limestone and volcanic cliffs abound in the Caribbean Islands. Caves and "blowholes" exist in limestone cliffs in many islands, for example, Barbados, Bahamas and Turks and Caicos Islands. Steep rock slopes and cliffs are the most predominant coastline type in some of the volcanic islands, for example, Montserrat and Dominica.

Rocky shores are characteristically areas of rapid erosion, and they provide a great variety of habitats for marine plants and animals (Bacon, 1978). Animals include barnacles such as *Tetraclita squamosa* and *Chthamalus fissus*, snails of the genus *Littorina*, mussels such as *Brachidontes exustus*, and crabs such as the Rock crab (*Grapsus grapsus*). Sea eggs, for example, *Lytechinus*, may be found on limestone and other hard rocks. Green algae are abundant and include *Chaetomorpha* and *Cladophora*, and some species of red and brown species may also occur. Boulders may be seen encrusted with calcareous algae.

Sand dunes

Sand dunes are mounds of sand that often lie behind the active part of the beach. In the Caribbean Islands, they range from very low formations, 0.3–0.6 m in height to large hills of sand up to 6 m high. There may be several parallel rows of dunes. Dunes form when sand is carried by the wind from the dry beach area to the land behind the beach. When the wind encounters an obstacle such as a clump of vegetation it slows and the sand is deposited. Significant sand movement will take place when the wind speed, measured at a height 1 m above the ground, exceeds 6 m/s (Bagnold, 1954). In the Caribbean Islands, average wind speeds equal or exceed this value in the months from June to July and from December through March. During storms/hurricanes, dunes are often eroded and the sand may be deposited offshore, after the storm/hurricane, the sand is returned to the beach and the slow process of dune building may recommence. As a result of Hurricane Luis, dunes in Anguilla showed an average retreat of 9 m, recovery is expected to take decades, if it occurs at all (Cambers, 1996).

Dune vegetation promotes the trapping of sand, however, as with beach vegetation, dune plants have to adapt to harsh conditions including high temperatures, dryness, salt spray, and the deposition of sand (Craig, 1984). Dune vegetation in the Caribbean Islands includes the same plants as those described colonizing beaches. In addition, Sea lavender (*Tournefortia gnaphalodes*) has been observed to be a very effective shrub in stabilizing dunes.

Unfortunately sand dunes are often seen as prime sites for sand mining activities in the Caribbean Islands. Many dune areas have completely disappeared as a result of mining for construction material, for example, at Josiah's Bay in Tortola in the British Virgin Islands, and at Diamond Bay on the east coast of St. Vincent, where extensive black sand dunes, more than 6 m high have now gone. At Isabela on the north coast of Puerto Rico, the mining of an extensive system of dunes has taken place in the last two decades, leaving just a narrow strip of residual dunes, which are sometimes breached during high wave events.

Efforts have been made in some island to restore dunes using sand fences, for example, at Arecibo in Puerto Rico, and Shoal Bay North in Anguilla. Research has shown that a sand fence with a 50% porosity (ratio of open space to total area) can result in a 1.2 m high dune forming in 12–24 months (Clark, 1995). Work with sand fences in the Caribbean islands and elsewhere has shown that one of the critical factors in dune growth is the width of dry sand beach in front of the fence.

Mangroves

In estuaries, lagoons and coastal mudflats, characterized by mud deposits and sheltered wave environments, mangrove ecosystems have developed characterized by trees of the red mangrove (*Rhizophora mangle*). Red mangroves have prop roots and can grow on newly deposited sediments and on sand bars and coral reef crests (Bacon, 1978). Large mangrove swamps can be seen on the Gulf Coasts of Trinidad, and the south coast of Jamaica in the Portland Bight area. As sediment gradually accumulates around the roots of the red mangrove, conditions become suitable for the establishment of the black mangrove (*Avicennia germinans*). This species has a horizontal root system from which arise "breathing tubes" pneumatophores. A third mangrove species grows among both red and black mangroves, the white mangrove (*Laguncularia racemosa*). A fourth mangrove species, Buttonwood (*Conccarpus erectus*) is considered a transitional species between true mangroves and terrestrial vegetation.

Coastal mangroves are very important to fisheries and marine productivity. They provide a habitat, which is a breeding ground and nursery area for many species. Juvenile fishes live in the mangrove swamps until they are mature enough to migrate to the open sea, these include young butterfly fish, angel fish, tarpon, snappers, and barracudas, in addition there are juvenile spiny lobsters and shrimps. Other animals include worms, small crustaceans, and sea cucumbers. Clusters of oysters cling to the red mangrove roots, there are two common species, the mangrove oyster (*Crassostrea rhizophorae*) and the flat tree oyster (*Isognomon alatus*) (Jones and Sefton, 1978). There are also sponges and sea anemones. Numerous insects, lizards, tree snails, and birds also live in the mangrove swamps.

There is a complex food web within the mangroves, starting with the mangrove leaves which fall and decay and are then eaten by shellfish, shrimps, crabs and fishes, which in turn become the prey of other juvenile fishes.

Because of their intricate root systems, mangroves also provide good protection to the coastline during storms and hurricanes. As a result, mangrove lagoons, such as Paraquita Bay in Tortola in the British Virgin Islands, are used as a safe mooring area during storms and hurricanes (Clarke and Lettsome, 1989).

Coral reefs

Among the most ecologically diverse systems in nature, coral reefs play an important role in the protection and formation of many Caribbean beaches. A coral reef is made up of many millions of coral polyps, tiny animals that secrete limestone to form themselves a stony skeleton. A healthy coral reef is home to many different plants and animals. Stony or hard corals are the main reef builders, while soft corals for example, the sea fan (*Gorgonia flabellum*) are flexible.

The main types of reefs found in the Caribbean are fringing reefs, which border a coastline, for example, there are several fringing reefs along the west coast of Barbados; patch reefs, which are isolated clumps of coral sometimes measuring only a few meters in diameter; and barrier reefs, which are separated from the coastline by a deep lagoon or channel, for example, the barrier reef off the east coast of Andros Island in the Bahamas.

Coral reefs are especially important to beaches because they protect the shore from high waves. Fringing reefs and barrier reefs often grow very close to the sea surface. Incoming waves break and expend their energy on the reef, and while secondary waves may reform in the lagoon and ultimately affect the beach, they are much lower in energy. Thus in many ways reefs are also natural breakwaters.

Coral reefs also act as a sand source for many beaches. Many fishes, for example, the Parrot fish (*Scarus*), Butterfly fish (*Chaetodon*), and Trigger fish (*Balistes*), actively feed on the coral, biting off chunks of coral and excreting coral sand, which is then moved towards the beach by wave action.

Coral reefs are vulnerable to natural forces, such as hurricanes, increased seawater temperatures, human activities such as pollution, offshore dredging, and ship anchoring. Hurricane Luis, a category 4 hurricane, passed over Anguilla in 1995. A quantitative offshore benthic survey had been conducted the previous year (1994), and comparing this with a post-hurricane survey in 1996 showed that 61% of the intact live reefs, either hard coral or soft corals, were degraded to rubble or, bare rock. Previously intact, though dead, elkhorn coral reefs

(*Acropora palmata*) were largely reduced to rubble. Damage was most severe at the inshore reefs (Bythell and Buchan, 1996).

It may take some years before the damage to a coral reef is manifested at the beach itself, such as through a reduced breakwater effect. And then, it may be difficult to separate out this cause from other causes of beach erosion.

Sea grass beds

Sea grass beds are important habitats found in shallow nearshore waters. They are often found between the beach and coral reefs. There are three main types of sea grasses: Turtle grass (*Thalassia testudinum*), Manatee grass (*Cymodocea filiforme*), and Shoal grass (*Diplanthera wightii*). Sea grasses are flowering plants, not algae, and they spread mainly through a system of underground creeping stems. They are an important marine habitat for many marine animals and their larval stages. They also provide foraging grounds for commercially important species such as grunts and conch. Sea grass beds maintain clear coastal waters by filtering sediments from the water and holding them down with their complex root systems. Calcareous algae living among the sea grass beds produce carbonate sediment.

Sea grass beds are very vulnerable to hurricanes, and often after a hurricane, beaches may be covered with thick mats of dead sea grass, more than 1 m thick. Hurricane Luis in 1995, reduced the sea grass bed cover by an average 45% in Anguilla (Bythell and Buchan, 1996).

Problems facing Caribbean Islands' coasts

Tourism development. Tourism growth is taking place in most of the Caribbean Islands, indeed the tourism business has been termed "the engine of growth" (Patullo, 1996). The Caribbean's share of world tourist arrivals is less than 2%, but this is triple that of South Asia's share. The insular Caribbean ranked ninth in the world on the basis of its tourism receipts in 1990, and in 1994 the Caribbean Tourism Organization estimated that its 34 member states grossed US$ 12 billion from tourism. Tourism is a big business in the Caribbean Islands.

However, besides bringing economic growth and employment for many, tourism also brings environmental problems, partly because in its early days, in the 1970s and 1980s, tourism growth was largely unregulated. This created a precedent and by the time environmental controls were being brought into place, around the early 1980s, much of the damage had already been done. Islands such as Barbados were already facing serious pollution and degradation of their nearshore fringing reefs, Jamaica was dealing with beach exclusivity such that local residents could no longer gain access to certain prime beach sites, and even small islands, such as Montserrat, were seeing a construction boom and increased mining of their beaches.

Efforts to try and reverse some of these trends dominated the 1990s and are continuing today. However, it is difficult to find many success stories, since environmental concerns usually come second to economic growth priorities. And with so much of the Caribbean's tourism industry, from the hotel rooms to the airlines to the tour operators, being controlled by foreign interests (Patullo, 1996) it is sometimes difficult for the islands to take control of this vitally important industry. Yet, in order for the islands to truly benefit from tourism in the long term, this is what must happen.

Climate variation. Predictions about global climate change as a result of global warming still have a considerable degree of uncertainty. However, climate variation can be traced back over the last century at least, and can be used to predict climate trends in the near future. For instance, hurricanes in the North Atlantic Basin have been shown to have a cyclical pattern (Sheets and Williams, 2001). There are periods of two to three decades when there are many hurricanes—active periods, followed by periods of similar duration when there are fewer hurricanes—quiet periods. Records show that the 1900s to the 1920s was a quiet period, followed by an active period from the 1930s to the 1960s. Recently, there has been a quiet period, which extended from 1971 to 1994. However, since 1995, the Atlantic Basin has entered an active period, with the last five years of the 1990s showing an increased number of hurricanes and in particular an increased number of very intense hurricanes (category 3+). For instance, the years 1995–99 showed an average of four category 3+ hurricanes per year, compared with the previous five years, 1990–94, when the average was one category 3+ hurricane per year.

While these are average figures referring to the entire Atlantic Basin, this trend can be seen in many of the Caribbean Islands, particularly the northern Lesser Antilles, from Dominica to Anguilla, where many islands have experienced at least one hurricane per year since 1995. This climatic variation, while not yet fully understood, appears to be related to several climatic factors such as the rainfall in West Africa, upper level winds and ocean currents. With the massive tourism-related coastal development, which has taken place in coastal areas in the Caribbean Islands since the 1970s, this trend is of considerable concern to the islands.

While not directly related to climate variation, another infrequent phenomenon, about which the Caribbean Islands must become increasingly concerned, is the threat of a tsunami. Given its tectonic instability, the region is long overdue for a tsunami event. The last major tsunami in the Caribbean was on October 11, 1918, when a tsunami generated by an underwater earthquake, hit northwestern Puerto Rico and caused considerable damage as well as more than 100 deaths. The increased coastal development that has taken place in recent decades makes the Caribbean Islands very vulnerable to a tsunami threat. Added to this, is the fact, that as yet, there is no tsunami warning system in place in the Caribbean region.

The challenges for integrated coastal management in the Caribbean Islands. In seeking sustainable development, the Caribbean Islands face many problems. These include their small size, relative isolation, vulnerability to natural disasters, limited economic diversification and access to external capital (Commonwealth Secretariat, 2000). They will have to develop their own solutions to these problems and limitations.

Integrated coastal management is one approach that can be adapted to their needs. This will involve adding an intersectoral, horizontal dimension, which includes civil society, to what is essentially a top–down sectoral system of management in most islands. This will not be easy given the dichotomy of timescales between the political agenda (4–5 years) and the environmental agenda (decades). Lying at the center of all the ongoing efforts to achieve sustainable development and integrated coastal management is the need for effective and efficient communication.

CARRYING CAPACITY IN COASTAL AREAS

The concept of capacity has received considerable attention as a result of increasing anthropogenic pressure in certain natural environments. Much consideration has recently been given to increases in coastal populations, with the implication that the carrying capacity of the world's coast is finite and such considerations form part of several coastal management initiatives (UNEP, 1996).

Johnson and Thomas (1996) argue that present interest in tourism capacity is due to growth in tourism combined with increasing awareness of environmental issues. The concept is particularly important in the coastal zone which is undergoing rapid change as a result of demographic changes and industrialization (see Kay and Alder, 1999, p. 21) in the context of global climate and sea-level change. In its broadest sense, carrying capacity refers to the ability of a system to support an activity or feature at a given level. In the coastal zone, these systems can vary greatly in both scale and type, and range from small salt marshes through large beach resorts to entire continental coasts. The activities or features that they support are also varied and include, for example, beach recreation or species abundance. The term "carrying capacity" does not therefore have a single precise definition. Rather, it is a broad term that covers a range of different concepts. These concepts are related by the idea that systems such as beaches have certain limits or thresholds. For example, a maximum number of animals can be grazed on any given dune system. Attempting to determine the actual limits is often problematic and raises some fundamental questions. In the case of dune grazing, various criteria could be used to define the carrying capacity. This could involve assessing the effects of grazing on, for example, the physical integrity of the site, its ecological status, or its recreational value. In practice, these features may be interrelated.

The situation is further complicated by the subjective nature of certain limits. For example, the point at which the aesthetic impact of grazing becomes unacceptable is difficult to define and may vary from one location or cultural setting to another. In recognition of the diverse nature of carrying capacity as a concept, a variety of types of carrying capacity have been identified. Most of these fall into the following categories: physical, ecological, social, and economic.

Physical carrying capacity: This is a measure of the spatial limitations of an area and is often expressed as the number of units that an area can physically accommodate, for example, the number of berths in a marina. Determining the physical capacity for certain activities can, however, become problematic when subjective elements are introduced. For example, the maximum number of people that can safely swim in a bay depends on human perceptions and tolerance of risk.

Ecological carrying capacity: At its simplest, this is a measure of the population that an ecosystem can sustain, defined by the population density beyond which the mortality rate for the species becomes greater than the birth rate. The approach is widely adopted in fisheries science (e.g., Busby *et al.*, 1996). In practice, species interactions are complex and the birth and mortality rates can balance over a range of population densities. In a recreational context, ecological carrying capacity can also be defined as the stress that an ecosystem can withstand, in terms of changing visitor numbers or activities, before its ecological value is unacceptably affected. This approach raises the difficult question of defining ecological value and what constitutes an unacceptable change in it.

Social carrying capacity: This is essentially a measure of crowding tolerance. It has been defined as "... the maximum visitor density at which recreationists still feel comfortable and uncrowded" (De Ruyck *et al.*, 1997, p. 822). In the absence of additional changes, beyond this density visitor numbers start to decline. The social carrying capacity can, however, be influenced by factors such as the recreational infrastructure, visitor attitudes, and sociocultural norms.

Economic carrying capacity: This seeks to define the extent to which an area can be altered before the economic activities that occur in the area are affected adversely. It therefore attempts to measure changes in economic terms (Rees, 1992). Examples from the coastal zone might include examining the effect of increased numbers of trailer parks on agricultural activity in dune systems.

In addition to these single discipline assessments, there are a number of composite measures such as recreational and tourist carrying capacity. These attempt to define the threshold of an area for tourism or recreation by combining a range of indicators (Sowman, 1987). The actual carrying capacity of a coastal area assessed according to any of the above approaches depends largely on the nature of the area. Carter (1989, p. 357) noted that "Coastal environments vary considerably in their ability to absorb anthropogenic pressure. The carrying capacity of dune grassland is many orders of magnitude below that of rock cliffs." While this may be true, at least in some views of carrying capacity, it should be borne in mind that capacities are not necessarily fixed in time. They can often be altered by management practices for example, the provision of recreational facilities can increase the social carrying capacity of an area. They can also alter in response to wider environmental changes, whereby a change in mean sea temperature could affect the ecological carrying capacity of an area for a range of species, or a shift in social attitudes could alter what was considered acceptable degradation. As Arrow *et al.* (1995, p. 520) have noted: "Carrying capacities in nature are not fixed, static or simple relations. They are contingent on technology, preferences, and the structure of production and consumption. They are also contingent on the ever-changing state of interactions between the physical and biotic environment."

CAYS

Cays are islands that form on coral reefs as the result of wave action accumulating reef-derived sediment in one location. Cays may not rise above the highest tide level, but those that do can quickly acquire a vegetative cover but because they are formed of unconsolidated materials, may remain mobile and unstable.

Accumulation of sediment on a reef top results from the centripetal action of refracted waves around a coral reef. The shape of the reef may mean that even under different wind directions the focal point may remain more or less the same, though a strongly prevalent wind or swell wave direction will favor cay formation. Shape of the reef may also influence the shape of the cay because of the wave refraction pattern it produces. Oval reefs are more likely to produce oval cays, while more elongated reefs produce linear cays. Because relatively small changes in wind direction can produce much greater changes in wave refraction patterns on the elongated reefs, these linear cays may be more unstable. The size of the reef is to some extent irrelevant as cays can be found on reef tops only a hectare in area, or on the largest of reefs. However, on larger reefs the competency of the transmitted wave (the reformed wave after its initial break on the reef crest) to carry sediment may be lost over the wide reef flat before the centripetal focus point is reached, and sediment is more widely deposited as a veneer over the reef flat.

Cay sediments

Because of their microstructure, biogenic sediments are generally bimodal, either coarse (at least gravel size) or sand size. Coarser sediments are almost entirely coral fragments, most commonly clasts of *Acropora* sp. and other branching corals. Considerable energy is required to move such deposits and accumulation of gravel banks is normally found on the windward or high-energy side of a reef no more than 100 m or so from the reef edge. Major episodes of deposition have been described at times of tropical storms. Atoll motus, linear largely gravel islands which are set back from and are parallel to the reef edge are good examples.

The sediments of sand cays are more variable and include fragmented coral, coralline algae, molluscs, *Halimeda* flakes and complete tests of smaller foraminifera (including the "star" sands of some cay beaches). Their size range, however, is remarkably uniform worldwide, commonly in the range of 0–1.5ϕ and sorting is generally less than 1ϕ.

Hydrogeology and cementation

A relatively simple explanation of cay hydrology, the Ghyben–Herzberg model, has generally been applied. It consists of a freshwater lens derived from rainwater, "floating" over the denser seawater. A minimum size of cay is required for it to form and under larger cays the freshwater lens may rise up to a meter above the adjacent sea level and extend several meters down. General flow of water is outwards from the cay center. However, a layered aquifer model (e.g., Oberdorfer and Buddemeier, 1988) that more realistically presumes a Holocene reef overlying Pleistocene reef with contrasting permeabilities is now accepted.

Outflow at the island margins is still present, and is the major process in the cementation of cay sediments beneath the beach as beachrock. Percolating meteoric water is aggressive to the carbonate sediments especially with increasing partial pressure of CO_2 within the cay. However, as this pressure reduces as the groundwater flows out beneath the beach, this process is reversed and cementation takes place.

Cays may also be important nesting sites for birds and their droppings percolate to the water table as guano, where they may accumulate as phosphatic cay sandstone. Both beachrock and cay sandstone are important in providing some stability to coral cays.

Vegetation

Coral cays provide a classic example of vegetation succession, many of the plants being pan-tropical. Seeds either float to the island or reach it through the digestive tract of birds. In time, decaying vegetation adds organic matter to the soil, which allows more advanced plants to become established.

Initial colonizers are robust creepers and vines such as *Ipomoea* sp. and *Canavalia* sp. or salt tolerant succulents such as *Sesuvium* sp. They are followed by grasses (e.g., *Lepturus repens*) then shrubs including *Argusia argentea* or (on coarser or cemented deposits) *Pemphis acidula*. Higher trees, such as *Casuarina equisetifolia* may rise above the shrub layer. As soils become more fertile, an interior forest may become the dominant vegetation with *Pisonia grandis* being the most common on atoll motus and cays of the Pacific.

Because cays are constantly changing and being added to, all stages of the vegetational succession may be found as a concentric pattern on the island.

Classification of coral cays

Cays are classified on the basis of sediment type (gravel or sand), location on the reef (windward or leeward), shape (linear or compact), and stage of vegetation cover (Stoddart and Steers, 1977; Hopley, 1982, 1997). Most mobile and ephemeral are unvegetated sand cays. Vegetated cays are obviously more stable, but linear sand cays may still exhibit a degree of mobility especially the sand spits, which occur at each end of the island. As sand cays become more stable with cemented deposits and vegetation, occasional storms and wind can add to the island height and large stable well-vegetated sand cays may rise as much as 3 m over high water mask (HWM). However, as such cays have been dated to as much as 5,000 years old, in some regions a higher mid-Holocene sea level may have been implicated in their early evolution.

Coarser gravel (shingle) cays develop from linear rubble banks parallel to the reef front, or hammerhead spits behind promontories on the reef front. Though more stable they are more inhospitable to vegetation and their colonization may be slower.

In some parts of the world both windward gravel deposits and leeward sand cays may develop on the same reef top, with the intervening reef flat being subsequently colonized by mangroves. The term "low wooded island" has been applied to these reef islands, which have been described especially from Australia's Great Barrier Reef (Hopley, 1982, 1997) and Indonesia (Tomascik *et al*., 1997). Both of these areas have the greatest diversity of coral cays in the world.

CHALK COASTS

The extraordinary whiteness of chalk has given rise to distinct cliffs visible over large distances. From the Fourth Century BC Greek navigator, Pytheas of Massilia, through Julius Caesar and Shakespeare, to modern writers, chalk coasts were given a unique character. They are most commonly known for their place in Shakespeare's "King Lear," the literature of Maupassant and the paintings of Monet and the wartime nostalgic song, "White Cliffs of Dover." The Romans called England "Albion" because of its white cliffs. The earliest regional study of a chalk coast is Girard's (1907) description of the cliffs of the English Channel. Chalk cliffs occur, however, more widely than these classic locations. Chalk is a $CaCO_3$ limestone found in the Upper Cretaceous outcrops on the European coast, in northern Ireland, Yorkshire and Norfolk, along the southern coast of England from the Isle of Thanet in the east to Beer in the west (Steers, 1946), along the northern coast of France from Calais to the mouth of the Seine (Girard, 1907; Briquet, 1930; Precheur, 1960) and on the islands of Møn, Denmark, and Rügen, Germany.

Chalk coasts are distinctive for four reasons: the relative purity of the chalk itself, their distinctive landscape, their often vertical rapidly retreating cliffs and their place in the geomorphological literature as type locations for particular landforms. The chalk contains veins of flint, a biogenic silica, which are typically nodular in shape, vary in size (long axis) from 2 cm to over 200 cm and can weigh more than 8 kg. They are the main source of beach clasts on these coasts and may exist in their original form, break into smaller angular particles (quickly rounded at their edges), or as rounded pebbles. These pebbles are often the result of erosion of re-worked landslides and fluvio-glacial deposits. Chalk cliffs have been important, but not unique, suppliers of flint shingle to such large and important features as the ness, spit, and tombolo structures of southeast England, including Orfordness, Dungeness, Hurst Castle spit, and Chesil beach (May and Hansom, 2003), and northern France.

Chalk is notable for its whiteness, its purity, and its friability (Hancock, 1976) and is formed mainly of calcareous fossil debris. The white chalk is dominated by two main groups of particle sizes (0.5–4 μm and 10–100 μm). The lower 25–60 m of the chalk is often dominated by chalk-marl facies in which calcareous-rich chalk alternates with marls containing up to 29% clay (Perrin, 1971). The dolomitic chalk outcrops of the Normandy coast, the white chalk of Yorkshire and the White Limestone of Antrim are harder than other chalks because of diagenesis by burial and locally high heat flows. Typically, these harder chalks retreat less rapidly than the other chalk coastlines. Chalk porosity ranges between 35% and 47% (Hancock, 1976), but matrix permeability is exceptionally low. Mass permeability is controlled by joints, fractures, and passages enlarged by solution, all of which are very common in the chalk and have a very important role in the development of some of the more complex chalk coasts.

Cliff forms (Table C4) include very steep slopes, slopes which are strongly faceted, and shallower slopes which are associated with large coastal landslides such as Folkestone Warren (Hutchinson *et al*., 1980). Many chalk cliffs with low mean retreat rates have small slope facets with mean angles between 30° and 42° that are vegetated by chalk downland grasses and flowering plants. On these slopes, there may be skeletal calcareous soils, but occasionally red-brown sandy clay deposits ("*clay with flints*") on the cliff-top are washed down the cliffs and form local pockets of soil.

Some chalk coasts include very intricate cave and inlet and stack and arch features. Caves and inlets usually develop along discontinuities in the rock and give rise to large numbers of narrow inlets. At Flamborough Head, for example, there are more than 55 narrow inlets or geos and around the Isle of Thanet headlands were riddled with inlets and caves, some of which were filled in during coast protection works in the 1960s. The classic erosional cave-arch-stack-stump model found in many school textbooks owes much to the example of differential erosion of the sea along intersecting faults and joints north of Swanage. Stacks are rare features on chalk coasts, usually because the friability of the upper cliffs or the angles of dip are too great to allow classic pinnacle stacks to survive. In contrast, the English cliffs between Beachy Head and the mouth of the Cuckmere River (the Seven Sisters) are one of the best examples worldwide of a cliffed coast where, despite the local effects of jointing, cliff falls and pocket beaches and the larger

Table C4 Major categories of chalk coast—England and France

Category	Main features	Cliff height (m)	Typical rates of cliff-top retreat (m a^{-1})	Length (km) England	Length (km) France
I	Simple plan and profile, former usually similar to beach plan form. Slope angles exceed 75°. Extensive platforms.	Less than 31[a]	0.13–1.33	48	56
II	As I, with many small less steep slope Facets. Platforms narrower usually less than 200 m.	More than 31	0.05–0.51	28	15
III	Cliff with basal rocky pedestal, many Discontinuities, simple upper profile, but complex plan including caves, stacks arches. Platforms common but may be submerged.	Less than 31	0.09–0.14	5	3
IV	High cliffs with complex profile. Plan Usually simple, but upper and lower cliffs exceed 75°. Middle slope typically at mean angles 35°–42° degrees. Boulder fields at cliff foot may affect plan in detail and provide protection for periods of several decades.	More than 31	0.11–0.36	9	22
V	High with extensive and complex Undercliff typically with rotational slides. Upper plan related to mass movements, shoreline plan to debris and boulder fields.	More than 31	0.09–0.36	8	18
VI	Lower steep chalk cliffs with upper concave slope affected by landslides. Simple plan.	Less than 31	0.36	1	10
VII	Steep lower cliff with basal rocky pedestal, many discontinuities. Concave upper profile in overlying sands or clays. Lower cliff has very complex plan including geos, caves, stacks, arches.	Less than 31	0.12–0.95	4	0
Total length of chalk cliffs				103	124

Categories I to VI based on Precheur (1960) and May and Heeps (1985), and category VII based on May *in* May and Hansom (2003).
[a] 31 m = critical height for vertical chalk cliffs (Hutchinson, 1971).

effects of cutting across a series of valleys, the coastline retains a remarkably straight form. It is a prime example of the efficiency of marine processes in maintaining erosion and being able to remove the supply of sediment from erosion. The strength of the chalk is sufficient to maintain a vertical face unlike many other comparable materials where slumping is more typical.

The average annual retreat of the cliff-top edge of chalk coasts ranges from about 0.05 m a^{-1} to over 1 m a^{-1} (May, 1971; May and Heeps, 1985), but many chalk coasts are marked by intermittent cliff changes including some very large falls. Before these falls, the base of the cliff may be undercut in a distinct notch (Hutchinson, 1972) or blocks may be quarried from it. The resultant talus may act as a groin as these large falls can take several decades to be removed. Typical recorded losses include cliff-top area in excess of 7,000 m^2 (May, 1971), 0.5 million tonnes in volume or linear retreat of over 15 m in a single event. In January 1999 a very large fall at Beachy Head on the southern English coast affected a 200 m stretch of a 90 m-high cliff and produced a debris fan over 5 m in height covering some 50,000 m^2. As cliff height and slide volume increase, a "degree of flow" may develop in chalk debris (Hutchinson, 1983). In falls from cliffs between 70 and 150 m in height, a "chalk flow" may carry debris across the shore platforms for distances more than four times the cliff height (Hutchinson, 1980, 1983). These flow slides may occur because high pore-water pressures are generated through the crushing impact of relatively weak blocks of high porosity, near-saturated chalk (Hutchinson, 1984) or as a result of steady-state flows resulting from rapid or undrained loading of the chalk (Leddra and Jones, 1990).

The debris produced by falls varies from clay-sized fines (0.5–100 μm) to boulders of over 1–4 m. Wave action and longshore currents disperse the fines rapidly. Shingle-sized debris is commonly rounded within a few days and is worn down to sand-sized fragments in a few months. The larger material may, however, remain *in situ* for very long periods of time and become colonized by algae and molluscs. The boulders may gradually become smaller, but the platforms often retain a substantial debris cover, with boulder arcs marking the outer edges of the chalk flow debris several decades after the original failure. Intertidal chalk platforms can exceed 1 km in width but are more generally up to about 200 m wide. Their form and development (Wood, 1968) has been attributed to the effects of the geological structures, storm wave action (So, 1965), the presence of flint strata (which may have a very significant armoring effect: May and Hansom, 2003), the tractive effects of beach material (Girard, 1907) and the role of boring organisms (Jehu, 1918). Recorded rates of platform lowering are about 25 mm a^{-1}, but Foote *et al*. (2000) show that micro-erosion rates are very variable and are strongly influenced by platform dwelling organisms. Bioerosion may play a significant role in chalk coast erosion, but further work is needed.

Apart from parts of the Sussex, Kent, and Normandy coasts where walls have been constructed to reduce coastal erosion and protect towns, chalk coasts are little modified by the effects of coastal engineering works and so remain one of the better studied natural cliffed coasts.

CHANGING SEA LEVELS

The geodetic sea level—better known as the geoid—is the equipotential surface between the attraction and repelling forces. The actual sea level—known as the dynamic sea surface—closely approximates the geoid surface. The deviations of the dynamic surface from the geoid surface are caused by different oceanographic, hydrographic, and meteorological forces acting upon the distribution of the water masses. Neither the dynamic sea level nor the geoid remains undeformed with time. Sea-level changes refer to changes in mean sea level. Eustatic changes denote changes in mean sea level over time units larger than daily and annual cyclic changes.

Our only true benchmarks are the former sea-level positions in the field. The present level of those data points are the combined function both of past changes in sea level and past changes in crustal level. In opposite to all types of crustal deformations, we term all different types of sea-level changes "eustatic" (Mörner, 1986). In the old concept of eustasy, all sea-level changes were parallel over the globe (e.g., Fairbridge, 1961). This is no longer tenable; sea-level changes can never be fully parallel over the globe and are often of compensational, even opposed, character (Mörner, 1976). The old and new concepts of eustasy are illustrated in Figure C7.

Water distribution and sea-level changes

The distribution over the globe of the ocean water masses is defined by the Earth's rotational ellipsoid, the geoid topography, and various dynamic forces (air pressure, current bet, coastal runoff, etc.). Any changes in any of those parameters will induce sea-level changes on the local, regional, or global dimension.

Sea level can only change within limits determined by its physical causes. The main sea-level variables are listed and quantified in Table C5. Corresponding rates and amplitudes are given by Mörner (1996a, b).

The global water volume is controlled by glacial eustasy, evaporation/precipitation, loss/gain of water, and steric expansion/ contraction.

The volume of the ocean basins is controlled by tectonic deformation (ocean floor subsidence, mid-oceanic ridge growth, and coastal tectonics).

The distribution of the water over the globe is controlled by Earth's rate of rotation, geoid deformation, and various dynamic forces (air pressure, current bet, coastal runoff).

Actual changes in the sea level represent an intricate interaction of multiple factors requiring understanding of various subjects and

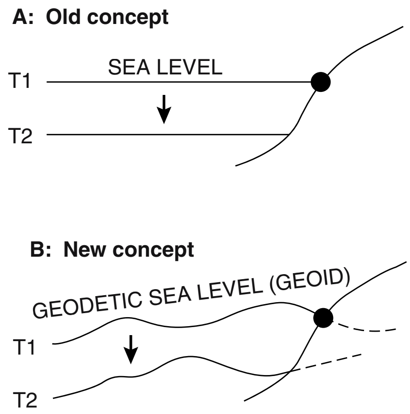

Figure C7 The old and new concept of "eustasy" (after Mörner, 1987) illustrated by the change (arrow) from one sea-level position (black dot and T1) to a new, lower, position (T2). In the old concept (A), any eustatic change in sea level was parallel all over the globe. In the new concept (B), the real sea-level surface is an irregular surface that never remains parallel at a change in sea level.

processes. The dominant controlling factor differs through time and with timescale considered.

On the million-year timescale, sea level is mainly determined by ocean basin volume, mass distribution, and rate of rotation.

On the thousand-year timescale, sea level varies mainly due to glacial eustasy and related glacio-isostasy, earth rotation and geoid shape as determined by lithospheric mass change.

Sea-level changes *on the hundred-year timescale*, seem primarily to reflect changes in water-mass distribution related to changes in the oceanic circulation caused by variations in climate and Earth's rotation rate.

On a yearly scale, sea level varies locally because of dynamic factors and El Niño–Southern Oscillation (ENSO) effects.

Table C5 Sea-level variables and quantities (in meters), for rates, see Mörner (1996b)

Present tides	
Geoid tides	0.78
Ocean tides	up to max. 18 m
Present geoid relief	
Maximum difference	180
Present dynamic sea surface	
Low harmonics	up to max. ~2
Major currents	up to ~5
Earth radial differences	
Equator/polar plane	21,385
Presently stored glacial volume (in meters sea level)	
Antarctica	~60
Greenland	~5
All alpine glaciers	0.5
Glacial eustasy	
Ice Age amplitudes	100–180
Geoid deformations	
On Ma-scale	~50–250
Last 150 Ka (20 Ka cycles)	30–90
Last 20 Ka	~60
Last 8 Ka	5–8
Holocene oscillations	1–2
Global loading models	
Last 20 Ka	some 10–30
Last 5 Ka	some 5 m
Differential rotation	
Holocene Gulf Stream pulses	1.0–0.1
Holocene equatorial current	~1.0
El Niño/ENSO events	0.3
Major current topography	max. 5
Rotation rate and sea level	
Meters sea level per 15 ms rotation	1.0
Air pressure and sea level	
Meters sea level per 1 mb	0.01
Ocean thermal expansion	
Meters sea level per °C per 1,000 m	~0.2

The sea-level debate

Sea-level changes were recorded and debated from the early 18th century (Mörner, 1987). The effects of changes in rotation, in ocean basin subsidence, in deflection of the plume-line and in glaciation were advocated. With the recording of multiple Ice Ages, it became natural to consider cyclic changes in glacial eustatic volume of the oceans (e.g., Daly, 1934).

In the 1960s the debate was intensive whether sea level, after the last glaciation maximum, rose with oscillations in Mid-Holocene time reaching even above the present level (Fairbridge, 1961) or as a smooth line continually rising to its present level (Shepard, 1963). The curves of Jelgersma (1961), Scholl (1964), Mörner (1969), and Tooley (1974) added detailed records from single regions backed up by numerous dates ruling out the occurrence of high-amplitude sea-level oscillations. Assuming that eustatic sea level could be expressed in one globally valid eustatic curve, all differences in observed levels had to be explained in terms of changes in the crustal or sedimentary level. In 1971 Mörner called attention to the fact that most sea-level curves, despite very large differences in level in Mid-Holocene time, converged fairly closely at about 8,000 radiocarbon years BP. This seemed to indicate a major cyclic redistribution of the ocean masses in Holocene time. Later, the explanation became obvious; the geoid relief is subjected to deformation (Mörner, 1976). Consequently, each region has to define its own regional eustatic curve (a global curve became an illusion).

Clark (1980) and Peltier (1998) presented their global glacial isostatic loading models, which called for major sea-level irregularities over the globe.

The "World Atlas of Holocene Sea-Level Changes" (Pirazzoli, 1991) gives a good and comprehensive view of the changes in sea level. Besides global differentiation in the eustatic ocean components, the recorded relative sea-level changes are strongly affected by differential tectonics and sedimentary compaction. Despite this complexity, one may distinguish some general regularities. This is illustrated in Figure C8 where five sea-level curves from quite different parts of the globe are compared. Despite significantly different shapes, trends, and levels, they all show a general rise up to some 6,000–5,000 BP followed an out-of-phase to sometimes opposed oscillatory trend for the last 5,000–6,000 years around the present zero level. The first part records a general glacial eustatic rise in sea level prior to 6,000–5,000 BP plus a local to regional differentiation due to tectonics, geoid deformation, and global isostatic compensation. The second part (the last 5,000–6,000 years) lacks any significant glacial eustatic component and is instead dominated by the redistribution of water masses around the present mean sea level.

The redistribution of water masses during the last 5,000 years seems primarily to be the function of changes in the main oceanic current systems in response to the interchange of angular momentum between the "solid" Earth and the hydrosphere (e.g., Mörner, 1995).

This implies that the Earth was in a totally different mode in the last 5,000 years as compared with the previous 12–13,000 years with different dominant driving forces for the changes in sea level.

To reconstruct past sea-level changes

Field observations of past sea-level positions are the only means of reconstructing sea-level changes in pre-instrumental time. The observational object may be a stratigraphic layer, a morphologic feature or single objects referring to sea-level changes. This object must be fixed in altitude with respect to present sea level (this may range from an absolute level to a relative level). The next step is to interpret the observed field object with respect to the sea level at the time of formation. This implies the study of sea-level relation, sedimentary characteristics, paleoecological inference, paleoenvironmental interpretation, and coastal dynamics. Finally, the object needs proper dating. After all these steps, we have a past sea-level datum or a paleo-sea-level-indicator, which can be used in sea-level curves and sea-level reconstructions. The quality of this datum point depends upon the quality of each individual step in its establishment. The dating of a continuous catching-up coral reef growth may provide an exceptionally continuous record (e.g., Fairbanks, 1989).

We have to understand that there is a long chain of uncertainties concerning sea-level changes as they are interpreted by the investigator, the

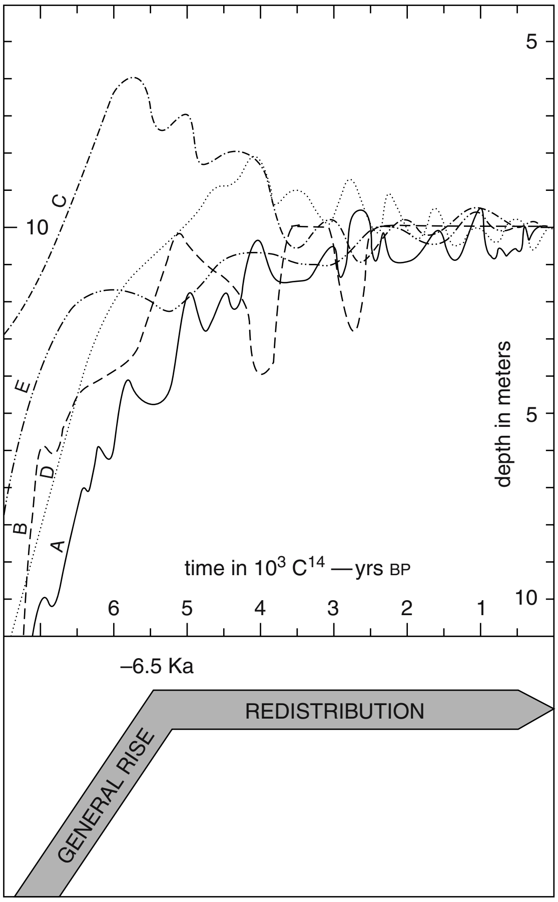

Figure C8 Five sea-level curves (A–E) from different parts of the world (from Mörner, 1996a). Despite tectonic differentiation, all five curves show a general rise up to about 6,000–5,000 BP, recording the end of the glacial eustatic rise in sea level. Thereafter, the curves are characterized by an out-of-phase variability (even opposed) around a base level close to present zero, recording an irregular redistribution of the oceanic water masses over the globe. The lower graph illustrates these two different stages, or modes, of sea-level changes. Reproduced with permission of Zeitschrift fur Geomorphologie.

sea-level changes as they are recorded in the field by fragmentary traces, and the sea-level changes as they actually happened in the past.

Deep-sea records

The deep-sea oxygen isotope records (e.g., Shackleton and Opdyke, 1973) have a predominant control from the changes in ice volume and glacial eustatic changes in oceanic water volume. Therefore, they provide a reasonable reconstruction of the Quaternary glacial eustatic cycles (Figure C9). For the last 140,000 years, there seems to be a good agreement between oxygen isotope variations and actual dates of coral reef levels (e.g., Chappell *et al.*, 1996).

Tide-gauge records

Sea level can be measured by water-marks, mareographs, and tide-gauges. The oldest tide-gauge is the one in Amsterdam from 1682. From a compilation of global tide-gauge station, Gutenberg (1941) tried to reconstruct the mean global eustatic component. He arrived at a value of 1.1 mm/yr rise in sea level. Table C6 includes a number of later estimates, all at about 1 mm/yr.

Tide-gauges record the interplay of changes both in sea level and in land level. Because most tide-gauges are located on harbor constructions, often resting on unconsolidated sediments, subsidence due to compaction is a serious problem.

Satellite altimetry

With the improvement of satellite altimetry (TOPEX/POSEIDON) it has become possible to record changes in the oceanic sea-level position.

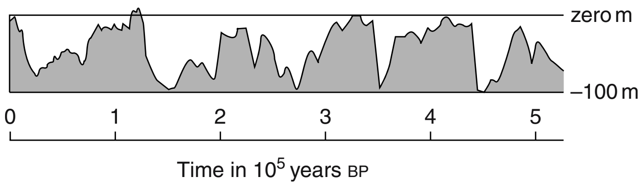

Figure C9 Main Quaternary glacial eustatic cycles as derived from deep-sea oxygen isotope records after Shackleton and Opdyke (1973). A glacial/interglacial sea-level amplitude in the order of 100 m is recorded. It should be noted, however, that improved data sets indicate that the last glaciation maximum was in the order of −120–130 m.

Table C6 Recent, present, and possible future changes in sea level as recorded or calculated from different observational records

Time period	Rates (mm/yr)	Source of information	References
Last 150 years	1.1	Mean of tide-gauges	1
	1.2	Mean of tide-gauges	2
1830–1930	1.1	NW Europe tide gauge data	3
	1.1	Past uplift versus present uplift and eustasy	3
	max. 1.1	Earth's rotation versus tide-gauge	4
Last 100 years	1.0	UK—North Sea tide-gauges	5
	1.1	Fennoscandian tide-gauges	6
1992–96	0.0	Satellite altimetry	7
1997–98	ENSO	Satellite altimetry	7
1999–2000	<0.5	Satellite altimetry	7
2000–2100	0.8	Estimates of all water sources	8

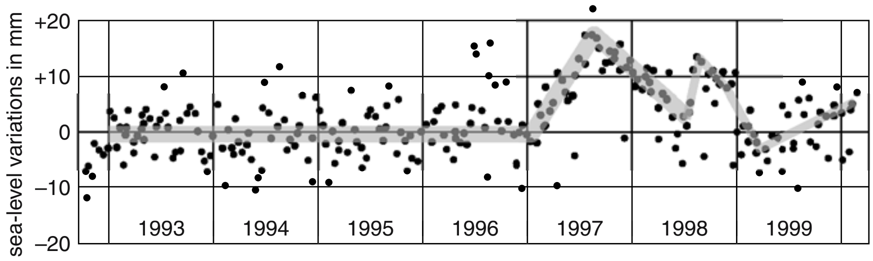

Figure C10 Sea-level changes in millimeters as recorded by TOPEX/POSEIDON between October 1992 and April 2000. The variability is high, in the order of ±5–10 mm. From 1993 to 1996, no trend is recorded, just a noisy record around zero. In 1997 something happens. High-amplitude oscillations are recorded; a rapid rise in early 1997 at a rate in the order of 2.5 mm/yr, followed by a rapid fall in late 1997 and early 1998 at a rate in the order of 1.5 mm/yr, and finally, in late 1998 and 1999, a noisy record with unclear trends. The new factor introduced in 1997 and responsible for the high-amplitude oscillations, no doubt, is the global ENSO event, implying rapid redistribution of oceanic water masses (just as recorded in Figure C8; Mörner, 1995). This means that this data set does not record any general trend (rising or falling) in sea level, just variability around zero plus the temporary ENSO perturbations.

This has opened new means of recording sea-level changes. Previously, we were restricted to changes at the sea/land interface (the shoreline). Now we can record the changes over the entire ocean surface covered by satellites.

Figure C10 gives a satellite record for the time period 1992–2000. From 1993 to 1996, there is hardly any detectable trend, just a noisy variability in the order of ±5–10 mm. From 1997 to 1999 (especially 1997–98), there are rapid high-amplitude perturbations; a rapid rise in early 1997 at a rate of ~2.5 mm/yr, followed by a rapid fall in late 1997 and early 1998 at a rate of ~1.5 mm/yr. These rapid high-amplitude perturbations cannot represent real ocean volume changes, but imply that ocean masses were rapidly redistributed over the globe (including the arctic regions that are not covered by the satellite records), just like what we record for the Late Holocene sea-level changes (Figure C8; Mörner, 1995).

Present sea-level changes

For the last 5,000 years global sea-level records do not concur with a simple trend but rather with site-specific redistribution of ocean masses (Figure C8). The same applies for the present. Despite this, it seems to be possible to detect a slight general rise in sea level since about AD 1850. This is illustrated in Table C6. No acceleration in this sea-level rise can be recorded in the last decades.

Future sea-level changes

Predictions of sea-level changes to be expected in the future must, by necessity, be based on our understanding of the past and present sea-level trends. Considering the past driving forces, the present trend and rates, and possible future variability, there are no reasons to assume any disastrous rise in sea level as often claimed (IPCC, 2001) but rather a value in the order of a moderate rise of 10 cm ± 10 cm in a century.

CHENIERS

Definition and morphology

Cheniers are stabilized wave-built ridges, usually of sand, but sometimes shelly or gravelly, that have been deposited on an alluvial plain of silt, clay, or peat on prograding deltas or coastal plains. They often occur in sub-parallel sets as elongated, narrow ridges (typically up to 3 m high and 40–400 m wide), standing at or slightly above the highest high tide level. The term chenier (Russell and Howe, 1935a, b) comes from the French native word (chêne) for the "live oak" tree (*Quercus virginiana*) which dominates the vegetation on chenier ridges in Louisiana. They differ from beach ridges (*q.v.*) in that they have been built on an alluvial foundation.

Multiple cheniers are separated by relatively wide intertidal or shallow subtidal swamps or mudflats, which are occasionally submerged by high tides or river floodwaters to form temporary lagoons. These intervening areas may either be barren of vegetation or covered at least in part by grasses, salt marsh, or mangroves. The term chenier plain includes these intervening areas as well as the chenier ridges, where at least two successively formed ridges are present (Otvos and Price, 1979). Transgressive cheniers are generally emplaced during storm surges, when large waves on a temporarily raised sea level sweep beach sediment inland. Successively formed cheniers usually occur in a sub-parallel seaward sequence as the coastline progrades. Even where there is a substantial shell content the slopes bordering cheniers tend to be gentle (Byrne *et al.*, 1959). In the fine sandy, shell-free Suriname cheniers the slope is <1 (Augustinus, 1980). Two of the world's largest chenier plains are found along the coasts of Louisiana and Guiana (Figure C11), but smaller chenier plains occur on many coastal plains, often behind embayments.

Chenier coasts are associated with a broad spectrum of tidal amplitudes that range from microtidal (e.g., SW Louisiana) and mesotidal to macrotidal (e.g., Van Diemen Gulf in northern Australia, Gulf of California). Most cheniers are of mid- to late-Holocene age, but there are cheniers of Pleistocene age in the Colorado Delta region of the Gulf of California (Meldahl, 1993).

Due to constructive overwash from storm surges the chenier crests may slightly exceed highest high tide level. As traced laterally along given chenier ridge sets in Louisiana (Figure C12), locally variable sand supply and wave conditions resulted in highly variable ridge crest elevations. Given an adequate coastal sand supply and sufficiently strong onshore winds, cheniers may be capped by small foredunes, or at least

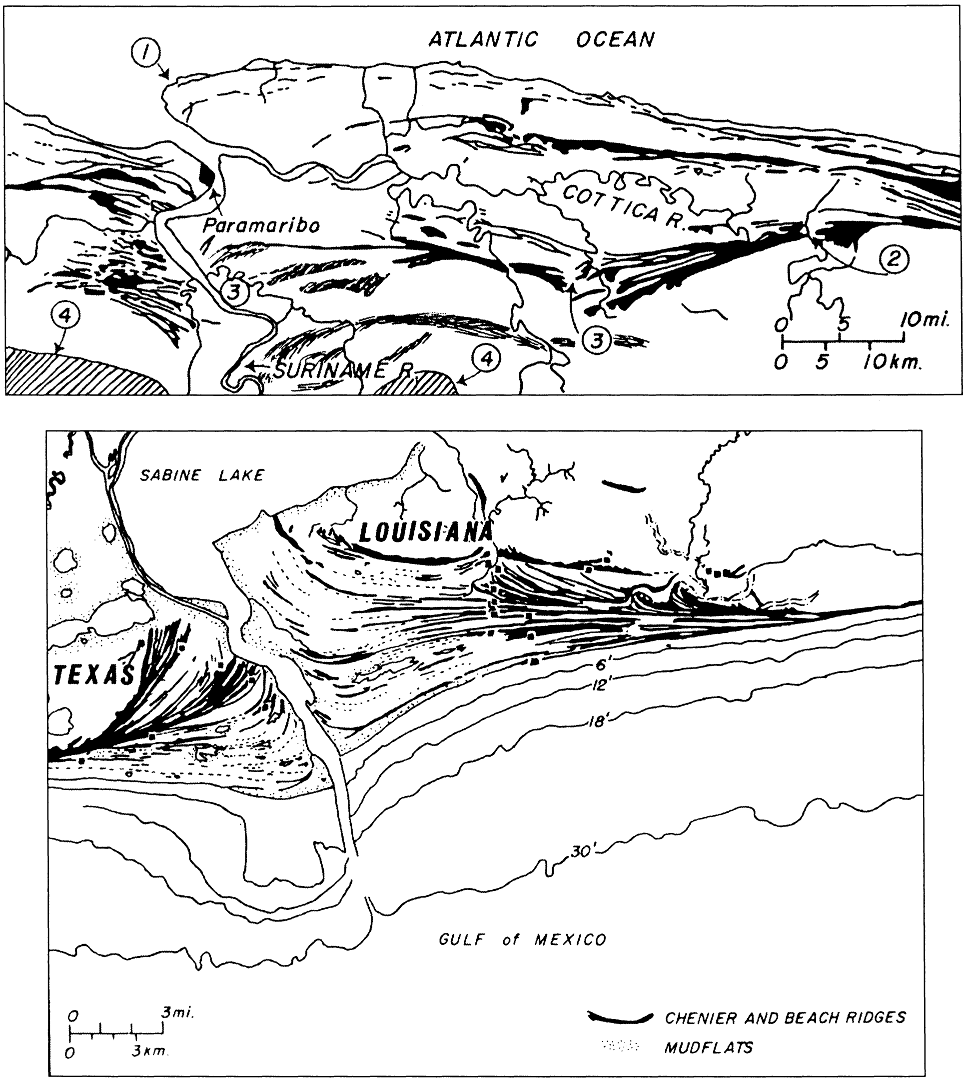

Figure C11 SW Louisiana and Guiana chenier trends and chenier plains (Louisiana after Byrne *et al.*, 1959, Guiana after Vann, 1959; from Otvos and Price, 1979). Reprinted with permission from Elsevier Science.

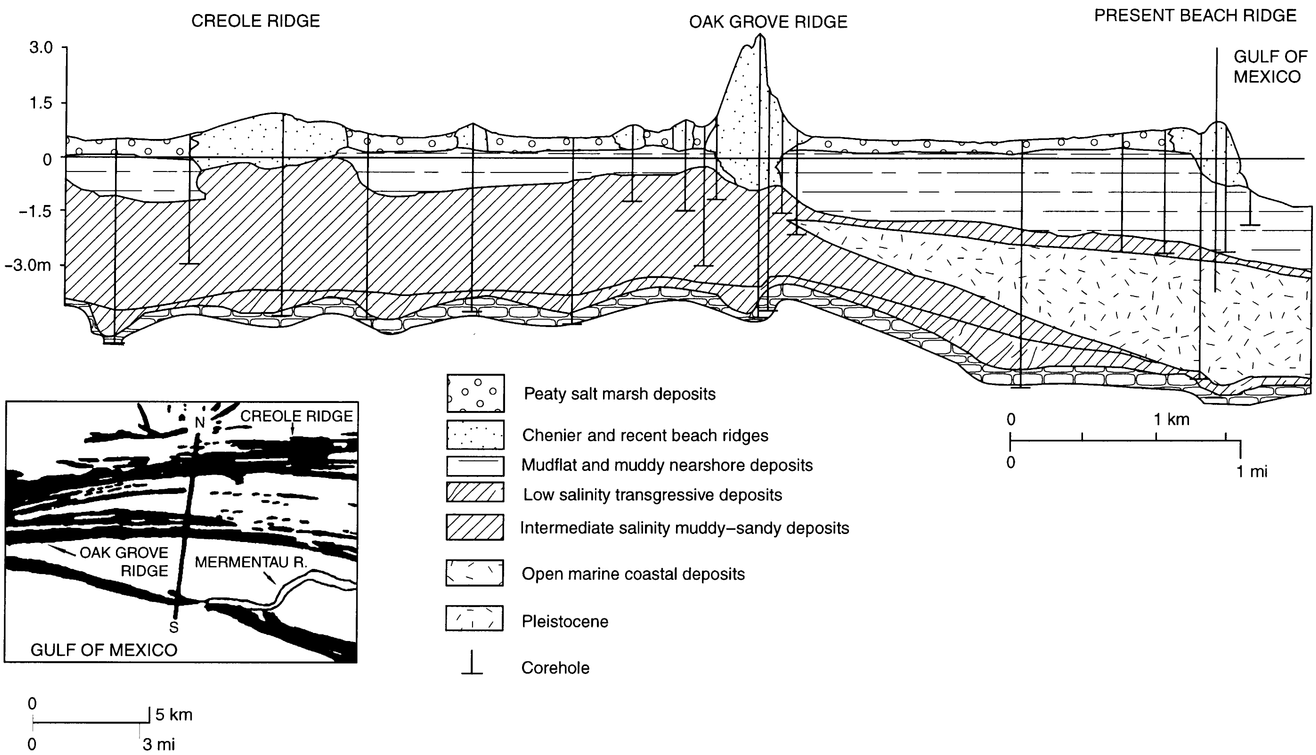

Figure C12 Cross section across Creole and Oak Grove Ridge cheniers, SW Louisiana (after Byrne *et al.*, 1959; from Otvos and Price, 1979). Reprinted with permission from Elsevier Science.

veneered by eolian sand (e.g., Suriname, Augustinus, 1978; SW Louisiana, Byrne *et al.*, 1959). Chenier ridge heights, including those not enhanced by eolian sand accumulation are not related to, or indicative of the elevation of former sea levels.

In small bays mudflat progradation, alternating with sand and shell accumulation and incorporation into developing chenier ridges occur simultaneously (Woodroffe and Grime, 1999). Side-by-side formation of a chenier passing laterally into a sandy beach ridge was described from the northeastern coast of Australia (Chappell and Grindrod, 1984).

Regressive and transgressive cheniers

Regressive cheniers that formed successively along the shore of a prograding delta or coastal plains overlie shallow nearshore marine and intertidal deposits (Figure C13). On tropical shores, these cheniers may extend 1 m or more below the surrounding high-tidal mudflats, down to the buried top of mangrove deposits (Cook and Polach, 1973). Except beneath landward-inclined slopes, formed by overwash, seaward-dipping low angle (<15) lamination and cross-stratification are typical in most of the cheniers. Sandy shell ridges, driven landward over intertidal flats and through mangrove thickets are transported by intermittent wave swash during high tides. Eventually they become stranded and stabilized as transgressive chenier ridges (Figure C13) (Thompson, 1968; Jennings and Coventry, 1973; Woodroffe *et al.*, 1983; Chappell and Grindrod, 1984; Woodroffe and Grime, 1999).

Following the original definition of cheniers as transgressive features (Russell and Howe, 1935a, pp. 27–34; 1935b) several authors defined "true" chenier ridges as landward-driven landforms (Otvos, 2000). However, stratigraphic and morphological data indicate that most Louisiana cheniers are not transgressive. With their shallow ridge bases, transgressive chenier ridges display washover-induced, landward-inclined stratification. They overlie intertidal, low-supertidal mud/marsh surfaces at very shallow depths. Powerful tropical storms often erode and even flatten landward migrating ridges. Even if lesser events effectively translated them landward before and after the storm, the 1974 hurricane surprisingly had no appreciable impact on the landward migration of sand and shell ridges in Shoal Bay, Australia (Woodroffe and Grime, 1999).

CLEANING BEACHES

Beach clean up is yet another environmental grassroot initiative organized by non-governmental organizations (NGOs), later adopted by government on all levels. As is often the case, the research addressing this and similar environmental initiatives is sparse in large part caused by a belated interest on the part of Federal and State agencies.

Beach degradation can be classified in several ways; based on the origin of the waste (*in situ*, oceanic, or land-based); by the way it is conveyed to the beach environment (point-source and non-point source); by the manner in which it appears on the beach (liquid and solid); and by the manner in which it was generated in the first place (natural and anthropogenic). The waste materials that are washed up on beaches include those falling into most but not all of these classifications. Material excluded from beach clean-up initiatives is liquid waste, except in those instances where it has been transformed while on the beach, or during the time it traveled on or in the water column. Examples of such materials include certain hydrocarbon materials that have metamorphosed into "tarballs." Organized beach clean up also excludes organic waste washed up on beaches such as dead vegetative matter and fish and shellfish carcasses, except in those instances where the accumulation of such is the result of fish kills caused by some anthropogenic activity.

Notwithstanding, that solid waste on the nation's beaches has contributed significantly to the public's concern about beach and nearshore water quality (Stratton, 1969), virtually no governmental initiatives were directed specifically at cleaning up solid waste washed up on the nation's beaches prior to 1980. Such efforts were left to local initiatives. One of these was directed by a few NGO's in which the Ocean Conservancy (TOC) formerly known as the Center for Marine Conservation, took an early lead. The other was done by local municipalities, towns, and counties with jurisdiction over beaches. Each of these initiatives is discussed below.

Governmental involvement in beach clean up can be divided into three different approaches. In nearly all instances, beach clean up is done by positioning waste containers on the beach with the expectation that the patrons will deposit their waste in those containers. In addition, many municipalities with few or small beaches will supplement these activities with manual clean up, usually conducted early in the morning before the beach becomes too crowded. On days when the beach is busy, more garbage will be deposited either in the containers or left on the beach, which may attract flies, wasps, gulls, and other animals; resulting in complaints levied against the Parks and Recreation Department. In jurisdictions where beaches are larger and the waste problem more extensive, the physical clean up is done using machinery in the form of a roto-tiller device and a sifting device that separate the sand from any waste materials buried by the wind or human activities. These activities also take place during the early morning.

A less common means of addressing beach waste and beach clean up is the program sometimes referred to as "Carry In, Carry Out." The State of Rhode Island introduced this program on all State beaches during the late 1980s. Each patron is issued a plastic bag together with an entry ticket and is expected to collect all waste material created during the visit and carry it back home at the end of the trip. This program was quite controversial when first introduced as many administrators, especially in communities where these beaches were located, were afraid that the waste generated would become a local problem by people dumping their waste locally. According to at least one Park's administrator, this has not been a major problem for the town. The successful implementation of this program has had several advantages including, reduced clean-up cost for the State, fewer problems with animals being attracted to waste bins, significant reduction in both visual and olfactory impacts eliminated by the absence of overflowing trash cans.

This absence of governmental interests, especially on the Federal level, has contributed to a near dearth of research on the distribution, volume, source of solid waste on beaches, and its impact on the physical and biological environment. This entry is divided into the following sections: origin and extent of the beach clean-up movement; sources, characteristics of and categories of solid waste, concluding with some observations on the status of beach clean up overall.

Origin of beach clean-up initiatives

The first known organized beach clean up took place in 1986 in Texas and was an initiative sponsored by TOC in which 2,800 volunteers collected a total of 124 tons of waste covering 122 miles of coastline. Two years later, TOC's efforts were nationalized in which 47,500 volunteers participated. In 1989, the effort had spread to Canada and Mexico marking the internationalization of the event. Today, more than 90 countries participate on an annual basis. In an effort to disseminate information on beach trash and beach clean up, and share the costs of implementing the program, TOC entered into partnerships with both public and private organizations and businesses. The beach clean up takes place once-a-year, usually the third Saturday in September during which nearly 8.5 million items are collected, sorted, counted, and analyzed.

More than 20 years after beach pollution was first recognized as a serious environmental problem, Congress passed the Marine Plastic Pollution Research and Control Act (PL 100-220) in 1988 that required the National Ocean and Atmospheric Administration (NOAA) to develop a public outreach program as well as implementing Annex V of the International Convention for the Prevention of Pollution from Ships (ICPPS) (see below). The public's interest in marine pollution soon outstripped NOAA's capacity to provide the materials and services needed, with the result that NOAA contracted the Ocean Conservancy to provide these services. This partnership lasted until 1996 when funding ceased. Prior to 1988, the 1972 reauthorized Coastal Zone Management Act (CZMA) included language on marine debris as one of nine objectives for the Coastal Zone Enhancement Grants program by amending section 309 of the Act (P<104–150, §1456b). NOAA's involvement with ocean pollution and beach clean up has continued through the Sea Grant Program where seven Sea Grant Programs have developed statewide beach clean-up programs. In addition 55 state, territories, commonwealths, and dependencies have established similar programs. Some of these are operated as part of the states' coastal management programs while others operate under the auspices of the Environmental Protection Agency (EPA) or private organizations. Some private organizations, including the Professional Association of Diving Instructors (PADI), have also established beach clean-up partnerships with the Ocean Conservancy. Finally, during the late 1980s and early 1990s beach debris was sampled quarterly on eight National Seashores and National Parks (Ribic *et al*., 1997).

The International Marine Organization (IMO) sponsored ICPPS sought to address ship-borne solid waste disposal. This Convention was ratified in 1988 and consists of a series of sector-defined annexes of which Annex 5 deals specifically with the disposal of garbage and plastics. This Annex has 88 participating nations including the United States. The US Coast Guard is the agency that enforces both the ICPPS and the Marine Plastic Pollution Research and Control Act.

Sources, characteristics and categories of beach trash

In the United States, it often takes a focusing event before action is initiated. In the case of beach clean up, the focusing event was the medical waste wash-ups and subsequent beach closures that took place on both Long Island and New Jersey beaches during the period 1989–90. The cost of these events in terms of reduced tourism revenues to coastal communities in both New Jersey and New York has been estimated somewhere between two and five billion dollars (Stewart, 1989). The origin of these materials appears to have been the several dumping sites located in the New York Bight some 12 miles offshore. While the origin of this material was marine, approximately 70% of the waste materials washed up on the nation's beaches came from land and most of that originated from inland sources as opposed to trash left on the beach by beach visitors. The latter has been especially difficult to control from a management and legal perspective (Nollkaemper, 1997). While the beach clean up is a reactive as opposed to proactive program, most of the land-based sources of trash are addressed through existing programs and legislation. Numerous communities, companies, and manufacturers have by now implemented recycling programs enabling a large proportion of the total waste stream from being disposed of in landfills. Much of the land-based trash that eventually finds its way to the beach represents discarded materials on roads, parking lots that are either blown and/or washed into streams (Liffman *et al*., 1997). Of these materials glass and plastic containers, plastic film products (bags, sheets, and other packing materials) represent the most problematic from a marine environmental perspective. Plastic materials are often consumed by fish, marine turtles, and marine mammals, some of which are mistaking these products as their favorite foods like various species of jellyfish including the Portuguese Man-of-War. The ingestion of plastic film has been a major problem for the endangered and threatened sea turtles many of which slowly starve to death following the consumption of plastic bags floating on the surface (Balazs, 1985). One study estimates that more than one hundred thousand marine mammals and more than one million seabirds die each year from ingestion of plastic materials of one kind or another (OCRM, 1991).

Another major plastic component is made up of abandoned fishing gear in the form of nets or rope, most of which consists of non-biodegradable plastic materials. These have resulted in significant impacts in terms of entanglements of both large and small cetacean, a problem Congress recognized by enacting the Marine Mammal Health and Stranding Response Act (1992). This Act established the Marine Mammal Health and Stranding Response Program that enables recognized stranding organizations to collect and disseminate reference data on the health of marine mammals. A related problem impacting sea mammals is the so-called ghost fishing which traps these animals in abandoned or discharged nets and traps which prevents them from surfacing to breathe. Again, Congress stepped in and enacted the Marine Mammal Rescue Assistance Act, 2000 (PL 106-555). This Act provides Federal funding for those organizations authorized to help the release of marine mammals entangled with fishing gear and other anthropogenic materials.

The composition of the debris washing up on the shore represents yet another dimension of the problem and varies from region to region depending upon the major use of the coast, and nearshore and offshore uses. In areas where fishing is important, as in Alaska and the Northeast, lost or abandoned fishing gear represents a much higher proportion of the beach debris compared with regions where fishing is less important. Another activity-based source of beach debris is recreational boating. At least one source suggests that this activity accounts for nearly 60% of all marine generated waste (Eastern Research Group, Inc., 1989). Given that recreational boating continues to grow in popularity, it is likely that this beach debris component will continue to increase relative to other activity-based sources at least until programs and/or legislation have successfully curtailed these contributions. While some attempts have been made to describe regional differences in the types of beach debris (Coe *et al*., 1997; Golik, 1997; Matsumura *et al*., 1997) no uniform classification system has yet been developed. The National Park Service classifies beach debris into seven different groups while TOC has defined a total of 81 different categories. For purposes of illustration the International Coastal Cleanup data for 1996 is summarized in Table C7.

Table C7 Beach debris by type (from Coe *et al*., 1997, with permission of Springer-Verlag)

Debris category	Percent of total
Plastics	61.2
Metal	11.1
Paper	10.8
Glass	10.4
Wood	2.9
Rubber	2.5
Cloth	1.4
Total	100.3

Future trends

As with so many other environmental issues, the beach clean-up initiative is a reactive rather than a proactive program. Unclean beaches represent an aesthetic and potential health hazard as well as a more serious environmental problem that threatens many of our most endangered marine species. Although much has been accomplished in cleaning up the marine environment both here and abroad, much still needs to be done. Remedial work related to beach clean up and marine pollution may be best addressed in two ways: through legal instruments, education and outreach. Each will be discussed briefly below. Several international conventions have been passed in recent years that directly and indirectly seek to limit marine pollution by ships, oil platforms, and other floating or submerged platforms that may emit solid waste to the marine environment. In the United States, the Coast Guard requires each vessel to maintain a log of waste materials discharged. In addition, most ports now have facilities enabling commercial vessels to offload both liquid and solid waste materials while in harbor. These requirements cover all vessels, including recreational and commercial fishing vessels. The issue here has been one of enforcement, which requires actual witnesses of any discharge before the offending vessel can be charged. Perhaps one solution to this problem is to require all vessels, including commercial fishing and recreational boats, to maintain logs on the location, type and quantity of materials discharged whether on or offshore.

While arguments have been made that recreational vessels account for most of the solid waste problems discharged at sea, it is possible that most of these estimates are based on older data, collected and analyzed prior to the implementation of zero discharge zones, and the various campaigns that most states have initiated to make recreational boating more environmentally amenable. Even industry has played a role in disseminating information intended to make boating and boaters more environmentally sensitive. These include the National Clean Boating Campaign (NCBC) which is sponsored by the Marina Environmental Education Foundation. The NCBC is made up of marinas, marine trade associations, governmental agencies, the USCG Auxiliary, several environmental NGOs. While the "Zero Discharge Zone" program initiated in Rhode Island is not directly related to beach clean up, there is overwhelming support within the Rhode Island boating community to support a more aggressive environmental initiative on the part of all levels of government. This suggests that further efforts to communicate the importance of proper bagging and discharge of solid waste will be met with unqualified approval.

CLIFFED COASTS

It has been estimated that there are cliffs, consisting of rock or cohesive clays, around about 80% of the world's oceanic coasts (Emery and Kuhn, 1982). Sea cliffs are found in all types of morphogenic and tectonic settings, although they are generally absent from low-lying, sediment-abundant, Amero-trailing coasts, which have plate collision coasts and high mountains on the opposite side of the continent. Despite the morphological importance of marine cliffs, and the aesthetic contribution they make to the littoral environment, there are only a few systematic descriptions of their form and development in the literature (Trenhaile, 1987, 1997; Sunamura, 1992).

Cliff morphology

The type of scenery that develops on a cliff coast is the product of a number of factors, including the morphology of the hinterlands, present and past climates, wave and tidal environments, changes in relative sea level, and the structure and lithology of the rocks. Although cliff morphology is difficult to classify on the basis of climate or wave regime, some types of cliff are more characteristic of particular morphogenic regions than others (Figure C14).

Steep cliffs usually develop in marine-dominated environments and convex cliffs where subaerial processes dominate. Where both process suites are effective, subaerial processes produce a convex slope in the upper portion of cliffs, while marine processes cut steep cliff faces at their base. Coastal slopes therefore tend to be greater in the vigorous, storm wave environments of the mid latitudes than in high latitudes or in the tropics, where frost and chemical weathering are important. Wave action is generally weak in high latitudes because of sea ice, and in some places coastal configuration. Most steep slopes on these coasts are the product of glacial erosion and there are few true marine cliffs. In the humid tropics, the formation of steep marine cliffs is inhibited by fairly weak wave action, protective coral or algal reefs, and extensive coastal plains. Chemical weathering plays an important role in cliff development, and the weathered material is very susceptible to slumping, mudflows, and other mass movements. Coastal slopes are often covered in vegetation for all but the lowest few meters, and steep cliffs may be restricted to headlands and other exposed areas. Steep, bare cliffs are much more common in the arid tropics, particularly in exposed areas where spray, high evaporation and salt crystallization, alternate wetting and drying, corrosion, and other weathering processes help to steepen coastal slopes and inhibit the growth of vegetation.

There are numerous exceptions to the morphogenic classification of marine cliffs. For example, despite strong waves, there has been only minor modification of glacially sculptured granites in Maine and eastern Canada. On the other hand, despite weak wave action, steep, bare cliffs are common in the limestones of the Canadian Arctic, and they occur throughout the wet and dry tropics where strong waves can be generated by onshore monsoons, tropical cyclones, and Trade Winds.

Geological factors are at least as important as climate and wave regime in determining the relative efficacy of marine and subaerial

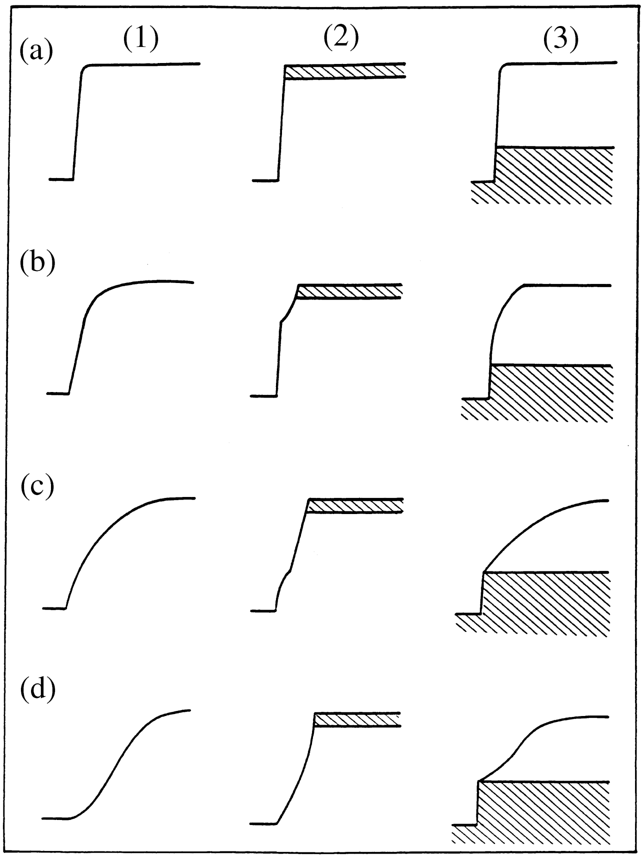

Figure C14 The effect of marine and subaerial processes and variable rock hardness on cliff profiles. Columns (1), (2), and (3) represent homogeneous rocks, harder rocks (shaded) at the top of the cliff, and harder rocks at the cliff base, respectively. Rows (a), (b), (c), and (d) represent environments in which marine erosion is much greater than, greater than, equal to, and less than weathering, respectively. (After Emery and Kuhn, 1982.)

processes, and therefore the shape of cliff profiles (Emery and Kuhn, 1982). For example, weaker material in the upper part of a cliff increases the effects of subaerial weathering, whereas weaker material in the lower part of a cliff facilitates wave erosion. Cliff profiles are also strongly influenced by structural weaknesses, stratigraphic variations, and the attitude or orientation of the bedding (Emery and Kuhn, 1980; Trenhaile, 1987, 1997). Very steep cliffs generally develop in rocks that are either horizontally or vertically bedded, and more moderate slopes in seaward or landward dipping rocks. The relationship between cliff profiles and the dip of bedding and/ or joint planes is very complex, however, and vertical and seaward-sloping cliffs can be formed in horizontal, or seaward or landward dipping rocks.

Composite cliffs have at least two major slope elements. Multistoried cliffs have two or more steep faces separated by more gentle slopes, whereas bevelled (hog's back, slope over wall) cliffs consist of convex or straight seaward-facing slopes above steep, wave-cut faces. Bevelled cliffs can develop in homogeneous rocks where marine and subaerial processes are of comparable importance, or where weaker rocks overlie more resistant materials (Figure C14). High composite cliffs in ancient, resistant massifs developed over very long periods of time, however, and they experienced marked changes in climate and sea level during the Quaternary. Wave-cut cliffs were abandoned during the last glacial stage, when frost and periglacial mass movements were probably dominant processes in the ice-free middle latitudes. The cliffs were gradually replaced by convex slopes developing beneath the accumulating talus, and when the sea rose to its present position marine processes removed the debris and, depending on the relative strength of the waves and the rock, either trimmed the base of the convex slopes to form composite cliffs, or completely removed it to form steep, wave-cut cliffs. Modeling suggests that bevelled profiles develop if the debris reached the top of the cliff during the last glacial stage, and multistoried profiles if the debris only rose part of the way up the cliff face (Griggs and Trenhaile, 1994).

There are usually shore platforms or beaches at the foot of cliffs, but some plunge directly into deep water. Plunging cliffs developed where the postglacial rise in relative sea level was much greater than the rate of sediment accumulation at the cliff foot. Once sea level had become stable, erosion was inhibited by the lack of abrasives at the water level, and reflection of the incoming, nonbreaking waves. Plunging cliffs are particularly common around basaltic islands in the Southern Hemisphere, where there is slow erosion and little longshore sediment transport.

Cliff erosion

The erosion of sea cliffs is episodic, site-specific, and closely related to prevailing meteorological conditions. Although recession rates have been measured in many parts of the world, most are little more than rough estimates. Reported rates vary from virtually nothing up to 100 m yr^{-1} (Kirk, 1977; Sunamura, 1992), and it is difficult to identify patterns that can be correlated with variations in rock type or wave and tidal conditions. A variety of techniques have been used to determine rates of erosion, but the most accurate ones have usually been used over only very short periods of time. Japanese workers have studied the short-term effects of coastal dynamics on cliff erosion. Variations in recession rates were partly explained by differences in the frequency of waves that exceed the minimum height capable of causing erosion, and they increased as the compressive strength of the rocks decreased (Sunamura, 1992); however, many other factors need to be considered. In south Central England, for example, the compressive strength of the rocks decreases toward the east, but this is countered by changes in the fracture pattern, which favors increasing rates of cliff erosion to the west (Allison, 1989).

Other features of cliffed coasts

Small bays, narrow inlets, caves, arches, and stacks are usually the result of erosion along structural weaknesses, particularly bedding, joint, and fault planes, and in the fractured and crushed rock produced by faulting. These features form in rocks which have well defined and well spaced planes of weakness, yet are strong enough to stand as high, near-vertical slopes, and as the roofs of caves, tunnels, and arches. They are therefore uncommon in weak or thinly bedded rocks with dense joint systems (Trenhaile, 1987).

Narrow, steep-sided inlets (geos) often develop along steeply dipping joints or faults in horizontal or gently dipping rocks, and from the erosion of dykes and the collapse of lava tunnels in igneous rocks. The occurrence and morphology of caves are usually controlled by weaknesses associated with joints, faults, breccias, schistosity planes, unconformities, irregular sedimentation, and the internal structure of lava flows. Marine caves are usually quite small, but large karstic caves have been inherited by the sea following cliff recession. It has been assumed that arches and longer tunnels develop through the coalescence of caves driven into the opposite sides of headlands. However, arches near La Jolla, California appear to be associated with coastal indentations and surge channels, that pile up the approaching waves on one side of a point, causing penetration of the weaker rocks at the cliff base (Shepard and Kuhn, 1983). Arches can also be formed by the marine invasion of karstic caves. Fountains of spray are emitted through blowholes when large breakers surge into tunnel-like caves connected to the surface along joint or fault-controlled shafts. Marine inheritance of karstic sinks, sinkholes, and tunnels has produced spectacular blowhole systems in some areas.

Most stacks are the result of the dissection of the coast along joints and other planes of weakness, although some are associated with folding, submergence of tropical tower karst, and differences in resistance associated with solution pipes, induration, or variable lithology. Some stacks develop from the collapse of the roofs of arches, but many form directly from erosion of the cliff face. Spectacular stacks have developed from the dissection of coarse, poorly sorted conglomerates and arkosic sandstones along prominent, well-spaced joint planes in the Bay of Fundy, which has the largest tidal range in the world. Old photographs suggest that these stacks may have life spans, ranging from their initial separation from the cliff to their eventual collapse, of between 100 and 250 years. Notches are ubiquitous at the cliff foot, and they are responsible for the characteristic mushroom-shape appearance of the stacks. Although there is no consistent relationship between the depth of notches on the seaward and landward sides of the stacks, the notches are at higher elevations on the seaward side. The deepest part of most notches is a little below the mean high tidal level, although several are up to a meter or two below it, especially on the landward side of the stacks. Stack morphology and notch depth change in a fairly predictable manner through time, as the stacks become increasingly isolated from the cliff (Trenhaile *et al.*, 1998).

Although it is generally assumed that headlands consist of more resistant materials than those in the adjacent bays, there have been few detailed investigations of variations in rock structure or strength. The occurrence of small bays and headlands often reflects the rather subtle influence of rock structure, including variations in joint density, the orientation of discontinuities, and the thickness, strike, and dip of the beds. Large bays and prominent headlands are more likely to reflect differences in the lithology of the rocks, however, although they could also develop in fairly homogeneous rocks if, as theory suggests, the low cliffs around stream outlets retreat more rapidly than the higher cliffs on the adjacent interfluves.

The plan shape of crenulated coasts may eventually attain an equilibrium state. This would occur when, because of the increasing effect of wave refraction as coasts become more indented, the more resistant rocks on the exposed headlands are eroded by higher waves at the same rate as the weaker rocks in the increasingly sheltered bays are eroded by lower waves. The plan shape would then be maintained through time as the coast retreated landward. As much of the erosive work could have been accomplished in previous interglacial stages, when sea level was similar to the present day, only minor modification of inherited coasts may have been required to attain equilibrium at present sea level; however, we lack reliable, long-term data on cliff erosion rates that are needed to determine whether the plan shape of rock coasts has attained a state of equilibrium.

Inheritance

In many areas, erosional processes are modifying elements of cliffed coasts that were inherited or partly inherited from the past (Bryant *et al.*, 1990; Trenhaile *et al.*, 1999). For example, raised beaches in southwestern Britain contain middle and upper Pleistocene material which suggests that the composite cliffs behind are very old, and dated sediments in marine caves in southwestern Britain, northwestern Spain, off northern France, and in southern Australia have shown that the caves are at least as old as the last interglacial stage (Davies, 1983; Trenhaile *et al.*, 1999). The occurrence of these ancient features is consistent with the paleo sea-level record, which shows that interglacial sea levels were similar to the present level on a number of occasions during the middle and late Pleistocene. Inheritance is most likely to have occurred on tectonically stable coasts, and in resistant, slowly eroding rocks. It is much more difficult to determine whether it has occurred in weaker rock areas, where any till or other sedimentary covers, raised beaches, structural remnants, and other evidence which may have existed would have been removed by fairly rapid wave erosion at the present level of the sea.

Cohesive clay coasts

Cohesive clay coasts have many of the characteristics of weak rock coasts, and they are often fronted by wide shore platforms. Fine-grained sediments lose their cohesion when they are eroded, however, and the debris is generally transported offshore as suspended load. Therefore no permanent or continuous beach develops, and as the eroded material provides no protection to the cliff, the height of the cliff has no effect on the rate of erosion. Variations in groundwater level, which change the strength and stability of clay materials, is a crucial factor in the failure of cohesive coastal slopes. In temperate regions, erosion of cohesive coasts by marine and subaerial processes is often markedly seasonal in nature, reflecting variations in wave energy, temperature, precipitation, and groundwater pressures. There is a strong relationship between landslide and flow activity in cohesive sediments and the occurrence of clays with a high proportion of montmorillonite or other swelling minerals. These minerals increase the frequency and mobility of slope movements, and allow them to occur on more gentle slopes. Shallow sliding occurs as mudslides or, if the water content is very high, as mudflows. Clay cliffs are also susceptible to deep-seated rotational landslides, which occur where basal erosion is rapid enough to remove the mudflow debris and steepen the underlying coastal slopes.

Hutchinson's (1973) form/process classification of cliffs in the London Clay of southeastern England is considered to be generally representative of slopes in stiff fissured clays (see *Mass Wasting*). Three types were distinguished, based on the relative rates of basal marine erosion and subaerial weathering:

1. Type 1 occurs where the rate of basal erosion is broadly in balance with weathering and sediment is supplied to the toe of the slope by shallow mudsliding. Removal of the mudslide debris stimulates further sliding, and unloading, softening, and weathering of the exposed clays.
2. Type 2 is found where basal erosion is more rapid than weathering. Waves remove all the material supplied by mudslides and erosion, and undercutting of the *in situ* clay steepens the profile. This eventually causes a deep-seated mass movement, which is characteristically a rotational slide involving basal failure. The sea removes the slump debris and toe erosion then steepens the slope until another failure occurs.
3. Type 3 coastal slopes develop where there is no basal erosion. When a cliff is abandoned by the sea or coastal defenses are constructed at its base, debris is carried to its foot by shallow rotational slides. Therefore, abandoned cliffs often have a steeper upper slope on which landsliding is initiated, and a flatter lower slope where colluvium accumulates. The slides eventually become quiescent when slope gradients have been reduced to the ultimate angle of stability against landsliding, and hill wash and soil creep gradually convert the bluffs into a series of undulations and then into smooth slopes.

Hutchinson's (1973) three cliff types also develop, in response to long-term changes in lake level, along the northern shore of Lake Erie. Variations in wave intensity and the type of glacial sediments in the cliffs, however, also account for the simultaneous distribution of the three cliff types along this coast (Quigley and Gelinas, 1976). Hutchinson's classification is also generally applicable to cohesive cliffs in Denmark, although there are some significant differences resulting from glacio-isostatic recovery and changes in relative sea level (Prior and Renwick, 1980). Despite the general applicability of Hutchinson's model to a wide range of cohesive sediments, however, alternate models of cliff retreat are relevant to specific areas.

CLIFFS, EROSION RATES

Cliff erosion occurs when the assailing force of waves acting on the cliff face is greater than the resisting force of the cliff-forming rocks. Sunamura (1977) has indicated that a fundamental relation governing cliff erosion may be expressed by:

$$dX/dt = K \ln (F_w/F_r), \qquad \text{(Eq. 1)}$$

where X is the erosion distance, t is the time, F_w is the wave assailing force, F_r is the rock resisting force, and K is a constant with dimensions of [LT^{-1}]. This equation indicates that erosion takes place if $F_w > F_r$, whereas no erosion occurs if $F_w \leq F_r$. The erosion rate, dX/dt, is an instantaneous rate which is expressed in terms of the slope of the tangent line to a curve showing the temporal change in erosion distance. Accurate and continuous monitoring of erosion distance in the field is extremely difficult, so that instantaneous erosion rates have not been obtained. Instead, the average rate, $\Delta X/\Delta t$, has been widely employed, in which ΔX is the erosion distance during a certain period of time, Δt. Depending on the length of Δt, erosion rates are highly fluctuated. Erosion distances have been documented by a variety of techniques (Sunamura, 1992) such as sequential aerial photographs, historic maps, and *in situ* measurements including surveys, micro-erosion meters, and pegs.

Short-term versus long-term erosion rates

On the north shore of Long Island, New York, a hurricane of September 14, 1944 cut back the cliff composed of glacial deposits a horizontal distance of over 12 m in a single day (Davies *et al*., 1972). This provides a striking contrast to an 80-year average of 0.5 m/year for this coast (Bokuniewicz and Tanski, 1980). Similar examples can be taken from some locations along the California coast (Griggs and Savoy, 1985). During January storms of 1983, waves removed about 14 m of cliff top in one section of Miocene mudstone–siltstone cliffs at Santa Cruz, which had receded at an average rate of 0.2 m/year from 1931 to 1982. Near Capitola, 10 km east of Santa Cruz, a sea cliff of the same geology was cut back 1.5–3 m overnight by the storms, a long-term average recession rate including this site being only 0.3 m/year. Thus, a short-term erosion rate based on the time interval including such a storm event makes the long-term average rate very unreliable.

Temporal variations in erosion rates

On the coast where the resisting force of rocks can be assumed to be time-independent, fluctuations of the wave assailing force are responsible for temporal changes in erosion rates. The wave force is obviously dependent on wave energy level in the offshore region. As seen from equation 1, erosion occurs only when the assailing force exceeds a threshold value. The occurrence frequency of waves that actually cause erosion is, therefore, important when considering erosion rates: the more frequently large waves attack a coast during a certain period of time, the more severely the cliff recedes to produce a higher erosion rate. A study by Sunamura (1982) on two Tertiary cliffs in Japan indicates that short-term erosion rates are closely related to the frequency of erosion-causing waves.

The wave assailing force is greatly controlled by water level, nearshore topography, and talus or ice cover at the cliff base. Fluctuations of these controlling factors produce temporal variations in erosion rates. The most important factor in dramatic erosion is an abnormal rise in water level, known as storm surges. A remarkable water level rise may occur on tidal coasts when storm surges superimpose on high tides. The well-known 1953 North Sea storm surge caused drastic erosion of glacial-sand cliffs at Covehithe, Suffolk, England (Williams, 1960). The storm surge with a maximum height of 2.3 m occurred at high tide yielding a total sea-level rise of 3.5 m above mean sea level. A glacial-sand cliff was cut back 9 m due to the action of storm waves during about 2 h at the peak of the surge.

Beaches working as a buffer diminish drastically depending on wave and tidal conditions as seen at Big Lagoon, north of Eureka on the northern California coast (Savoy and Rust, 1985). A sandy cliff backing a beach has receded at a long-term average rate of 0.6 m/year. During the winter of 1982–83, combinations of storm waves and high tides removed the beach, and the cliff was cut back more than 9 m in this time period.

Fronting beaches frequently experience change due to sediment imbalance caused by human activities such as harbor works, dam construction on rivers, and beach mining or filling. A reduction in beach levels stemming from human action has produced unintentional results of rapid erosion of sea cliffs in some areas. An example of this sort of erosional events can be taken from the Half Moon Bay area of central California (Lajoie and Mathieson, 1985). The construction of a breakwater at Princeton Harbor in the northern part of Half Moon Bay was made between 1956 and 1960. The breakwater interrupted southward littoral drift, resulting in depletion of beaches in front of sea cliffs composed of unconsolidated materials at El Granada adjacent to the south of the breakwater. This caused remarkable changes in erosion rates before and after the engineering work, from 0.1 to 2 m/year. Some other studies dealing with cliff erosion intensified by anthropogenic factors have been reviewed in Sunamura (1992).

The influence of underwater morphological change on temporal variations in long-term erosion rates has been reported from Dunwich in Suffolk, England (Robinson, 1980). Glacial–sand cliffs were cutting back at an annual rate of: 1.6 m/year from 1589 to 1753, 0.85 m/year from 1753 to 1824, 1.5 m/year from 1824 to 1884, 1.15 m/year from 1884 to 1925, and 0.15 m/year from 1925 to 1977, the last being extremely low. This drop in the erosion rate during the recent 50 years can be attributed to the reduction in wave energy arriving at the coast. The energy reduction was due to a significant divergence in wave refraction, produced by a changing bottom configuration associated with the steady northward growth of Sizewell Bank, which took place during the past century.

Talus and ice cover protect the foot of cliffs from wave attack until they are removed by the wave and current action, giving rise to no erosion. Such a protective effect has been observed on the Ohio shore of Lake Erie (Carter and Guy, 1988).

Spatial variations in erosion rates

The long-term erosion rate masks the variation in short-term erosion rates and shows a site-specific value. This value fluctuates from place to place depending on the local variation in the wave assailing force and the rock resisting force. Suppose that several cliffs with rocks of different resistance are exposed to a similar wave climate; then the long-term erosion rate, R^*, may be described from equation 1 as:

$$R^* = K^* \ln (F_w^*/F_r^*) = K^* (A - \ln F_r^*), \qquad \text{(Eq. 2)}$$

where F_w^* is the long-term averaged assailing force and F_r^* is the resisting force which is considered here to be time-independent, and K^* and A ($= \ln F_w^*$) are constants. This equation indicates that so-called "harder" cliffs have lower erosion rates. The relationship between R^* and F_r^* for cliffs on the Pacific coast of eastern Japan (Sunamura, 1992) and on the Mediterranean coast of southern Italy (Budetta *et al*., 2000) can be well expressed in terms of equation 2 (Sunamura, 1992).

Assuming that cliffs with similar lithology are subjected to the different wave climate, the long-term rate should be higher where wave conditions are more severe, if other controlling factors are constant. Since F_r^* is constant this time, one may obtain from equation 2.

$$R^* = K^* (B + \ln F_w^*), \qquad \text{(Eq. 3)}$$

where $B = -\ln F_r^* =$ constant. Sunamura (1992) discussed the R^* versus F_w^* relationship using data of the long-term erosion rate in the central part of the north shore of Lake Erie, where cliffs cut in glacial deposits have developed with no marked alongshore variations in their geotechnical properties, but different exposures to waves.

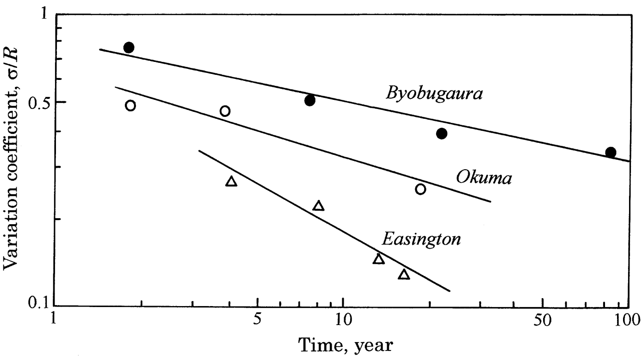

Figure C15 The variation coefficient of the erosion rate, σ/R, plotted against the length of time for the three cliffs. Data from Sunamura (1973) for Byobugaura and Okuma, and from Richards and Lorriman (1987) for Easington.

Alongshore changes in beach width give rise to spatial variations in erosion rates, if other factors are uniform. An example has been reported from the south shore of Lake Erie (Carter *et al.*, 1986); cliffs composed of glaciolacustrine clay were receding from 1876 to 1973 at an annual rate of 1.3–2 m/year where the beach had a width of 0–6 m, whereas only a few to 10 cm/year on the shore with wide beaches (>24.3 m).

The presence or absence of beach sediments at the cliff base, which can work as an abrasive tool to intensify the wave assailing force, yields spatial variations in the erosion rate. Robinson (1977) reported that on the northeast Yorkshire coast of England, erosion rates of Upper Lias shale cliffs fronted by beaches were 15–18.5 times higher than those with no beaches.

Water-level changes induced by local tectonic movement may control of the wave assailing force, which results in regional variations in long-term cliff erosion rates. The influence of the relative sea-level change caused by an earthquake on cliff erosion has been reported from the coast of Oregon in the Pacific northwest of the United States (Komar and Shih, 1993).

On a coastal strip where the respective alongshore variations in the wave assailing force and the cliff resisting force are considered to be uniform, it is anticipated from equation 1 that any location along the coast has receded at the same rate, that is, there is no spatial variation in erosion rate. Actually, however, there are considerable alongshore fluctuations when considering erosion rates in a short-time period. Figure C15 is a plot of the variation coefficient, σ/R, against the length of time, where R is the space-average value of erosion rates and σ is the standard deviation of R; the value of σ/R increases with increasing variability. Larger fluctuations in shorter-term erosion rates reflect sporadic and localized occurrence of mass movement, which results in talus formation at the cliff base, increasing alongshore variability in the wave assailing force. The degree of erosion-rate variation becomes smaller as the timescale lengthens (Figure C15), suggesting that parallel recession of the coastline will take place over a long period.

CLIFFS, LITHOLOGY VERSUS EROSION RATES

Lithological control of erosion rates

When the assailing force of waves acting on the cliff base is greater than the resisting force of rocks forming there erosion occurs, resulting in augmentation of the instability of an overall cliff profile, eventually leading to intermittent mass movement. Depending mainly on lithological factors such as geological structures, stratigraphic features, and geotechnical properties, the mode of mass movement is generally classified into four types: falls (e.g., Jones and Williams, 1991), topples (e.g., Davies *et al.*, 1998), flows (e.g., Grainger and Kalaugher, 1987), and slides (e.g., Hutchinson, 1986). Cliffs recede with one or hybrid types of these failure modes. Cliff recession has been documented by a variety of techniques (e.g., Sunamura, 1992), of which the most popular one is to measure distances on sequential aerial photographs and/or historic maps. Average erosion rates are determined by dividing the measured distances by the length of time interval. Orders of erosion rates summarized on a lithological basis are generally: 10^{-3} m/year for granitic rocks; 10^{-3}–10^{-2} m/year for limestone; 10^{-2} m/year for flysch and shale; 10^{-1}–10^{0} m/year for chalk and Tertiary sedimentary rocks; 10^{0}–10^{1} m/year for Quaternary deposits; and 10^{1} m/year for unconsolidated volcanic ejecta (Sunamura, 1983). These results show that lithology and cohesiveness of the cliff material greatly control the erosion rate. It should be noted, however, that toe erosion by waves originally causes cliff retreat.

Instantaneous erosion rates can be described by the following equation (see *Cliffs, Erosion Rates*):

$$dX/dt = K \ln (F_w/F_r) \qquad \text{(Eq. 1)}$$

where X is the erosion distance, t is the time, F_w is the wave assailing force, F_r is the rock resisting force, and K is a constant with dimensions of [LT^{-1}]. This equation holds when $F_w \geq F_r$; otherwise, $dX/dt = 0$. A short-term erosion rate is highly variable with time (see *Cliffs, Erosion*

Rates), so let us consider a long-term erosion rate, a site-specific value reflecting relative magnitude of wave action to rock strength.

Parameters for rock-mass strength against wave erosion

To find the most suitable parameter for expressing rock resistance to wave erosion, various strength measures have been tested in cliff erosion studies: compressive strength (e.g., Tsujimoto, 1987; Carter and Guy, 1988), tensile strength (e.g., Tsujimoto, 1987), cohesive strength (McGreal, 1979), shear strength (Zeman, 1986; Kamphuis, 1987), penetration strength (Yamanouch, 1977), and Schmidt hammer rebound value (Jones and Williams, 1991), and compressive strength converted from Schmidt hammer readings (Budetta *et al.*, 2000; Stephenson and Kirk, 2000a). Of these parameters compressive strength is found to be positively related to other measures and is a widely used parameter with testing criteria having been well established, so it is suitable to use this measure as a representative strength parameter when considering the intact part of cliff-forming materials (Sunamura, 1992).

Resistance of the cliff material against wave force is quite different according to the presence of discontinuities such as cracks, cleavages, joints, faults, and bedding planes, some being inherent in lithology and others being of tectonic origin; cracks and joints especially can also be brought about by weathering if rocks are prone to weather. When waves hit a cliff with joint- or fault-associated openings, the air in the interstices is suddenly compressed, which results in pressure increase. Measurements of dynamic pressure inside a crevice in a vertical cliff set up in a wave flume indicate that a considerable increase in pressure can be produced depending on the size of opening and input wave height (Sunamura, 1994). Such pressure increase exerts an excessive outward stress on the sidewall of the opening as well as on its roof. As the opening grows, the wave assailing force inside the opening begins to increase its intensity, which in turn gradually widens and deepens the opening, which causes a further increase in the assailing force, finally leading to removal of blocks bounded by joints and faults.

Thus, discontinuities in the cliff material play a significant role in the erosion process. To assess the influence of discontinuities on the overall cliff resistance against wave action, Tsujimoto (1987) employed a nondimensional parameter, V_f/V_l, where V_f and V_l are the sonic velocities measured, respectively, in the field on a rock mass with discontinuities and in the laboratory on an intact rock specimen. With increasing degree of fracturing, V_f decreases, so that the value of V_f/V_l reduces from unity and approaches to zero. Tsujimoto attempted to evaluate F_r multiplying this parameter by compressive strength of an intact rock specimen, S_c:

$$F_r = B\,(V_f/V_l)\,S_c = B\,S_c^*, \qquad \text{(Eq. 2)}$$

where S_c^* [$= (V_f/V_l)\,S_c$] is the overall strength of a rock mass and B is a constant. Budetta *et al.* (2000) proposed a similar strength measure: $F_r = J_p S_c$, in which J_p depends on the volume of a rock mass and on joint condition factors such as the roughness and alteration of joint walls and the size of joints. The measure was tested in the Cilento area of southern Italy.

Long-term erosion rates versus rock-mass strength

Suppose that cliffs with rocks of different resistance are exposed to a similar wave climate; then one obtains from equations 1 and 2:

$$R^* = K^*\,(\ln C^* - \ln S_c^*), \qquad \text{(Eq. 3)}$$

where R^* is the long-term erosion rate, K^* is a constant, and $C^* = \ln (F_w/B) =$ const. Using data collected by Tsujimoto (1987) from open coasts of Japan, the R^* versus S_c^* relationship is plotted in Figure C16, where R^* values denote erosion rates averaged over a long period of time, more than 30 years. The erosion rates are around 1 m/year for Quaternary deposits and Pliocene sedimentary rocks which have strengths in a range of 0.1–3 MPa; they are on the order of 10^{-3}–10^{-2} m/year for Miocene sedimentary rocks with a strength of about 10 MPa; and they are almost 0 m/year for hard rocks (>20 MPa) such as andesite and basalt, the data of these being plotted on the x-axis. The curve in Figure C16 is drawn as a result of a best fit of equation 3 with the data except the four data on the x-axis. The general trend is well described by equation 3 with $K^* =$ 0.2 m/year and $C^* = 10$ MPa, although large scatter in the data is seen. Such scatter could be attributed to: (1) cliff resistance to wave erosion cannot be properly evaluated by S_c^*, only for some lithology, and (2) F_w does not always take on a constant value.

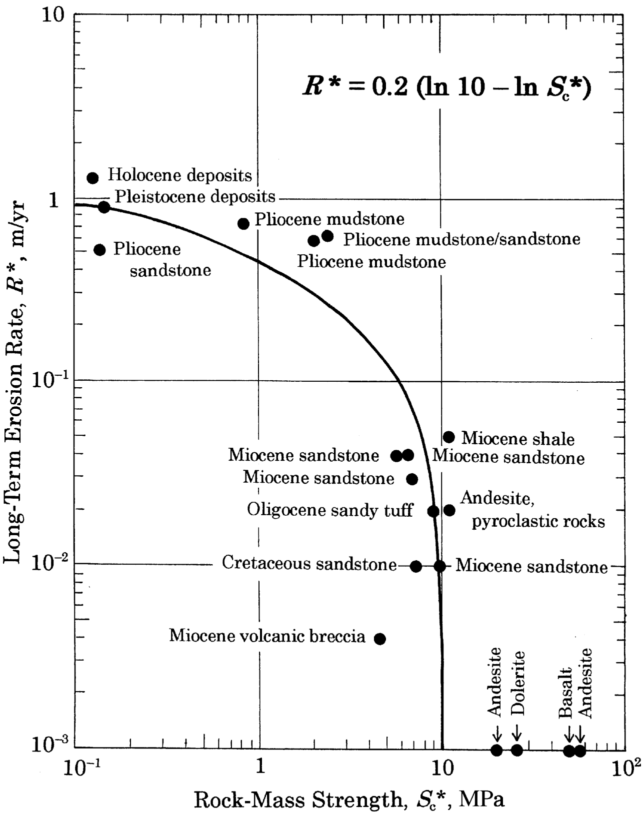

Figure C16 Relationship between long-term cliff erosion rate and cliff-forming rock-mass strength of cliffs on open coasts of Japan. The arrowed data denote that erosion rates are almost null. Data from Tsujimoto (1987).

One of major factors not considered in equation 3 is deterioration of the superficial part of a rock mass due to various types of weathering: alternate wet/dry weathering, frost action, salt crystallization, and the combined action of these. Mottershead (1994) examined this type of deterioration through strength testings on Lower Cretaceous sandstone used in sea walls at Weston-super-Mare, Avon, UK. The result indicated that the strength of weathered (honeycombed) rock is approximately 20% of that of fresh rock. Stephenson and Kirk (2000b) reported that considerable reduction in compressive strength (up to 50%) due to wet/dry weathering has occurred on limestone forming shore platforms at Kaikoura, New Zealand. Other factors responsible for strength reduction are fatigue effect by repetitive action of waves and biological activity, the former having still been unquantified, while the latter giving a significant influence, in some instances, as demonstrated by the fact that compressive strengths of sandstone and siltstone riddled by boring mollusks are found to have only 20–25% of the strength of solid (intact) rocks (Healy, 1968).

CLIMATE PATTERNS IN THE COASTAL ZONE

Decadal climate changes are associated with the systematic variations in global patterns of atmospheric pressure, temperature, and sea surface temperature that persist from a year or two to multiple decades. These climate changes have major impacts on coastal processes, modifying wave climate, rainfall, river sediment flux, sand transport paths, coastal erosion, sea level, and inundation. Understanding of the types and causes of climate change is in its infancy. *El Niño/Southern Oscillation* (ENSO) patterns that generate storms comparable to extreme seasonal events may occur every 3–7 years and appear to be associated with other longer period changes. The *Pacific/North American* (PNA) pattern of pressure anomalies and its sea surface temperature equivalent, the *Pacific Decadal Oscillation* (PDO), are associated with multidecadal periods of more intense El Niño type weather, alternating with decades of more intense *La Niña* weather, the complementary phase to El Niño. Similarly, a *North Atlantic Oscillation* (NAO) is associated with decadal changes in atmospheric pressure fields between Iceland and Portugal that alter North Atlantic wave climate and Caribbean hurricane tracks.

Background

The worldwide connection of weather patterns (teleconnections) was first addressed in detail by Sir Gilbert Walker (1928). He identified weather patterns with three global reversals in atmospheric pressure and temperature, the Southern Oscillation, the NAO, and the North Pacific Oscillation. Nile River floods, monsoon reversals in India, rice crop failures in Japan, and droughts in Australia were associated with these global reversals. Although there were little data at that time, Walker emphasized that ocean temperatures play a most important part in world weather. The advent of detailed global databases and rapid computer modeling in recent times has fueled a renewed understanding of the extent and duration of these climate events. Proxy records obtained from Greenland ice cores, tree rings, coral reefs, fish scales, and ocean sediments show that abrupt fluctuations in climate have occurred throughout the Holocene. These shifts may occur within a few years and extend for decades to millennia (e.g., Soutar and Isaacs, 1974; Meko, 1992; Cole *et al*., 1993, 2000; Heusser and Sirocko, 1997; Gupta *et al.*, 2003). These past events and the presently occurring climate changes are generally thought to be related to the extreme phases of the ENSO phenomenon.

Hypotheses explaining the causes of unusual ENSO events are numerous and range from the extrusion of hot lava on the sea floor to variations in the intensity of the sun's radiations. Most climate modelers favor a complex set of changes in the interaction of the atmosphere and ocean that cause fluctuations in trade winds, monsoon intensity, and sea surface temperature (e.g., Somerville, 1996; Pierce *et al*., 2000). Although the causes of climate change remain obscure, a clear pattern of atmosphere–ocean events associated with ENSO phenomena has emerged. It is this pattern that gives rise to three-month forecasts of ENSO events. However, ongoing ENSO events are superimposed on a progressive rise in mean global temperature. Consequently, their effects are likely to be less predictable and perhaps more intense than previous events (Inman and Jenkins, 1997; Timmermann *et al*., 1999; Fedorov and Philander, 2000).

Short-term climate patterns

The seasonal variations in the exposure of the hemispheres to the sun produce changes in the duration of daylight and the angle of the sun's irradiance. These effects modulate solar heating, resulting in variation of the earth's atmospheric pressure field which in turn induces seasonal climatic effects. Seasonal variations are enhanced by the higher convective effects of land and the greater concentration of landmass relative to water in the temperate latitudes of the Northern Hemisphere (Figures C17(a), (b)).

On occasion, the typical seasonal weather cycles are abruptly and severely modified on a global scale. These intense global modifications are signaled by anomalies in the pressure fields between the tropical eastern Pacific and Malaysia known as the ENSO (e.g., Diaz and Markgraf, 1992). The intensity of the oscillation is often measured in terms of the *Southern Oscillation Index* (SOI), defined as the monthly mean sea-level pressure anomaly in millibars normalized by the standard deviation of the monthly means for the period 1951–80 at Tahiti minus than at Darwin, Australia (Figures C17(a), (b), lower). A negative SOI (lower pressure at Tahiti, higher pressure at Darwin) is known as an *El Niño* or warm ENSO event, because of the arrival of unusually warm surface water off the coast of Peru at the time of Christmas, hence the term El Niño. Warm water also occurs along the coast of California, and both regions experience unusually heavy rainfall. A positive SOI is known as *La Niña* and it signals the occurrence of colder than normal surface water in the eastern Pacific, but stronger trade winds in the Pacific and southwest monsoons in the Indian Ocean with heavy rainfall in India and on the Ethiopian plateau (Inman *et al*., 1996).

During El Niño events the combination of low pressure over the Pacific Ocean and the thermal expansion of warm water cause an increase in water level along the eastern Pacific Ocean. The water level increases by 20–30 cm during strong El Niño events and is depressed an equivalent amount during strong La Niña events. The water level increases lead to significant coastal inundation and sea cliff erosion during the intense storms that are common to El Niño events.

Decadal climate patterns

ENSO events occur with dominant spectral peaks at about 3 and 6 plus years. However, these ENSO events are modified by climate changes that occur on decadal timescales of one quarter to one half century. These changes are often discussed in terms of two atmospheric patterns, the PNA and the NAO, and a sea surface temperature pattern, the PDO. Both PNA and PDO are long period, multidecadal analogs of the seasonal variations of global pressure and temperature and are related to Walker's (1928) North Pacific Oscillation. NAO is a periodic intensification or relaxation of the January phase of the pressure variation (Figure C17(a)). These decadal climate patterns are disguised (aliased) by the interannual changes because they have the same structure and appear as extreme cases of the interannual patterns. This aliasing has delayed the general understanding and acceptance of these concepts.

The PNA pattern is associated with an atmospheric dipole in pressure anomaly over the Pacific Ocean/North America region whose polarity reversals lead to wet and dry climate along the Pacific coast of North America (Wallace and Gutzler, 1981). High-pressure anomaly over the North Pacific Ocean and low-pressure anomaly over the North American continent result in dry (La Niña dominated) climate along the coast of central and southern California, while the opposite polarity in these dipole patterns leads to wet (El Niño dominated) climate (Figures C18(a), (b)). Inman and Jenkins (1999) show that the twenty coastal rivers of central and southern California have streamflow and sediment fluxes during the wet phase of PNA (ca. 1969–98) that exceed those during the preceding dry phase (ca. 1944–68) by factors of 3 and 5, respectively. The sediment flux during the three major El Niño events of the wet phase averaged 27 times greater than the annual flux during the dry phase.

The PDO is a long-lived sea surface temperature pattern with cool and warm phases similar in structure to the La Niña/El Niño phases of ENSO cycles (Goddard and Graham, 1997; Mantua *et al.*, 1997). Although the phase transitions of PNA and PDO may differ slightly in space and time, both events persist for decades and produce the most visible climate signatures in the North Pacific (Francis and Hare, 1994; Minobe, 1997). The El Niño dominated phase of the PDO cycle is characterized by a weakening of the trade winds that results in an eastward movement (slosh) of the warm pool of equatorial water normally contained in the western Pacific by the trades during La Niña conditions (Cole *et al.*, 2000). The sequence of events leading to and associated with the warm (El Niño) phase of the PDO is illustrated in Figure C19. It has been suggested that the breakdown from a prevailing La Niña to an El Niño occurs when brief bursts of westerly winds near the dateline begin the easterly transport of warm water. The positive feedback from the warm water further decreases the trade winds, beginning the transformation to an El Niño (e.g., Fedorov and Philander, 2000).

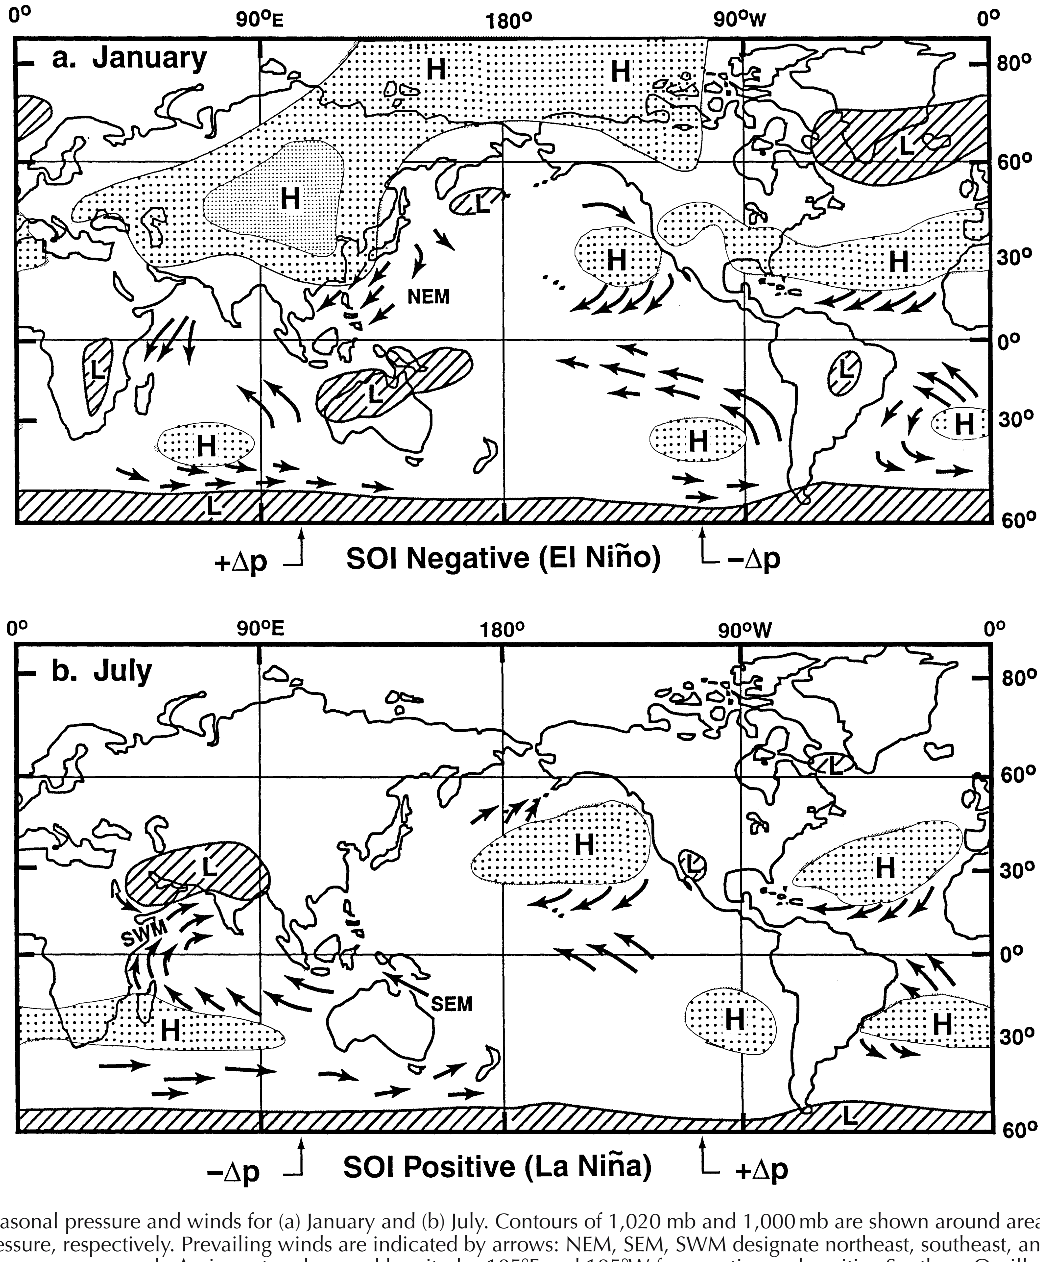

Figure C17 Seasonal pressure and winds for (a) January and (b) July. Contours of 1,020 mb and 1,000 mb are shown around areas of high (H) and low (L) pressure, respectively. Prevailing winds are indicated by arrows: NEM, SEM, SWM designate northeast, southeast, and southwest monsoons. The pressure anomaly Δp is centered around longitudes 105°E and 105°W for negative and positive Southern Oscillation Indices (SOI, modified from Inman *et al.*, 1996).

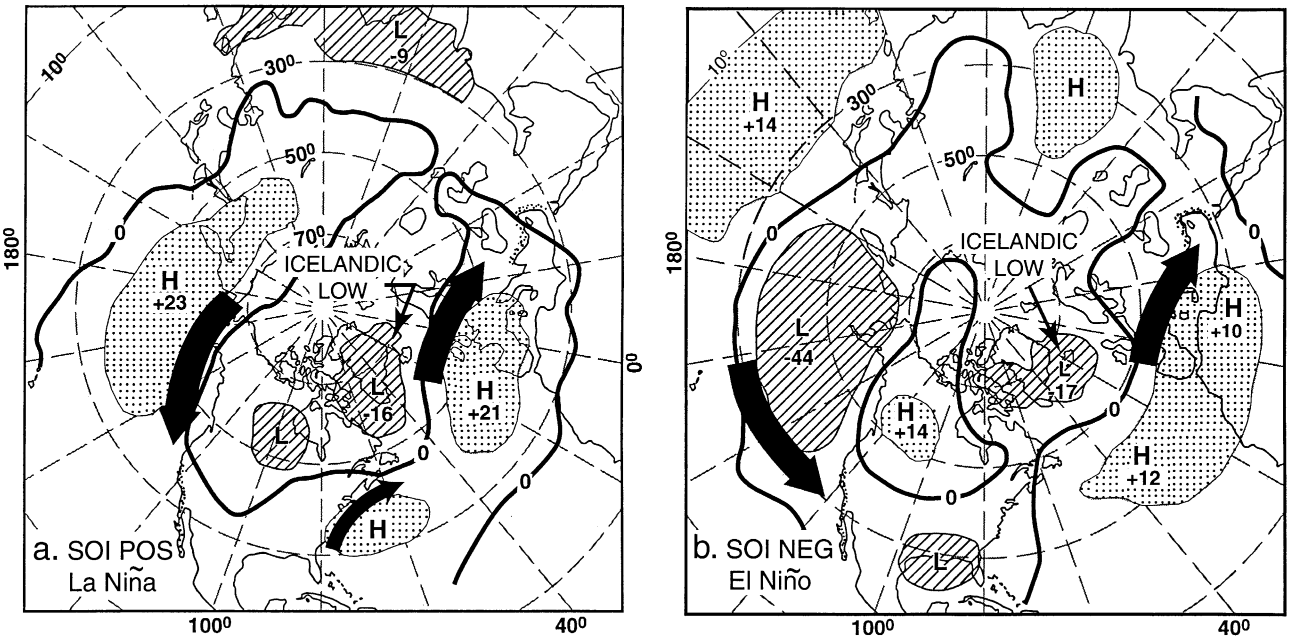

Figure C18 Storm track enhancement (arrows) associated with 700 mb atmospheric pressure anomalies during (a) La Niña and (b) El Niño dominated climate patterns (modified from Inman *et al.*, 1996; pressure data from Redmond and Cayan, 1994).

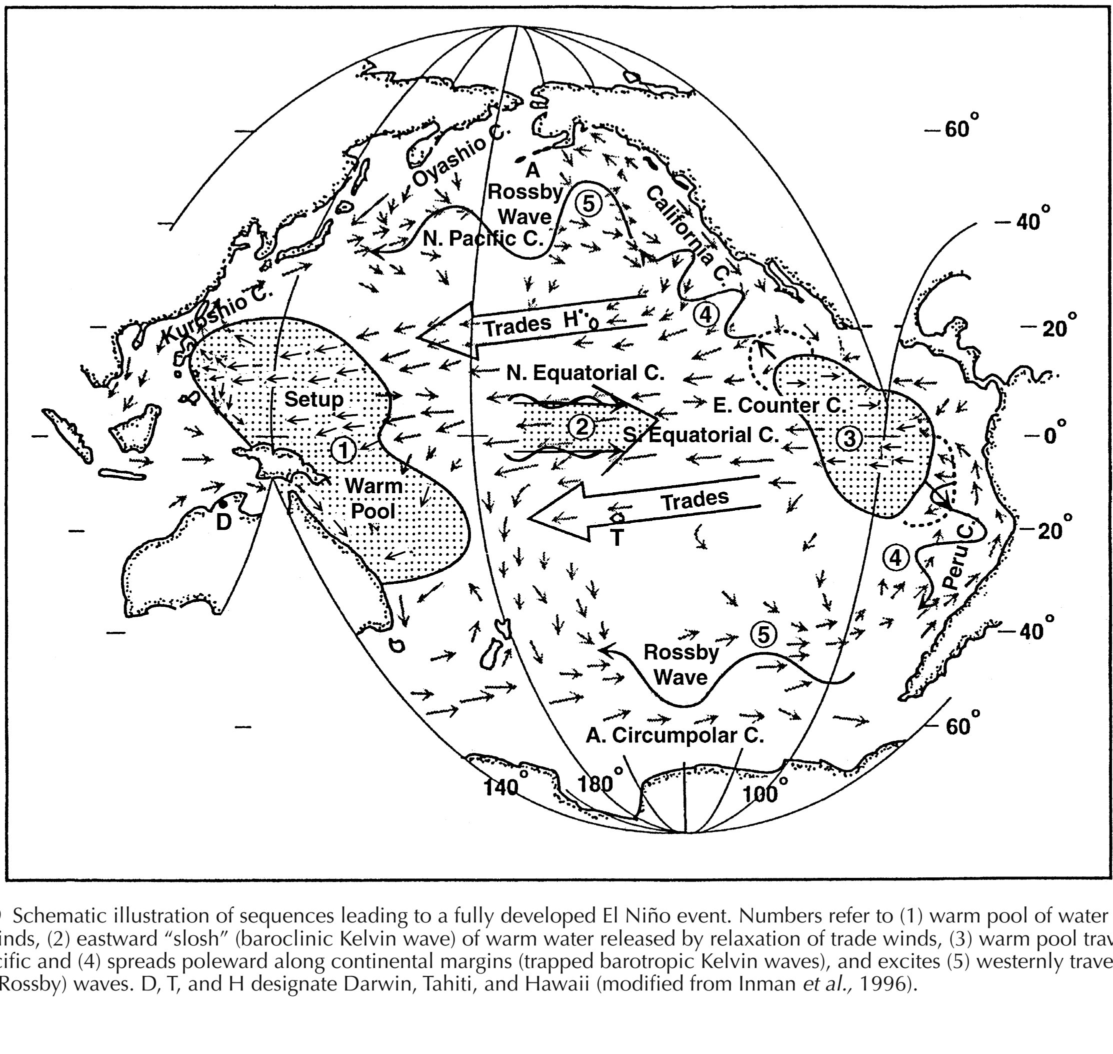

Figure C19 Schematic illustration of sequences leading to a fully developed El Niño event. Numbers refer to (1) warm pool of water setup by trade winds, (2) eastward "slosh" (baroclinic Kelvin wave) of warm water released by relaxation of trade winds, (3) warm pool travels to eastern Pacific and (4) spreads poleward along continental margins (trapped barotropic Kelvin waves), and excites (5) westernly traveling planetary (Rossby) waves. D, T, and H designate Darwin, Tahiti, and Hawaii (modified from Inman *et al.,* 1996).

The stronger trade wind systems during the cool (La Niña) phase of PDO are part of a general spin-up of the atmospheric circulation, which causes the North and South Pacific Gyres to rotate faster. Both effects (wind and current) induce upwelling that maintains cold-water masses along the west coast of the Americas, which sustains the typically cool dry coastal climate of these regions during the La Niña dominated periods of the PDO and PNA. In contrast, the strengthened trade winds of the La Niña period are associated with higher rainfall on the windward sides of Hawaii and other high islands in the trade wind belt. Higher than average rainfall occurred at Hilo and Lihue in the Hawaiian Islands during the La Niña dominated period 1943–68, and lower average rainfall during the subsequent El Niño dominated period 1969–98. However, the El Niño period included episodic Kona storms and the occurrence of hurricane Iniki.

The NAO is an atmospheric dipole that retains its polarity with a low over Iceland and a midlatitude high that enlarges and contracts (Wallace and Gutzler, 1981; Hurrell, 1995). The Icelandic low remains more or less in place while the midlatitude high-pressure anomaly changes in size, strength, and latitude (Figure C18). During La Niña the high-pressure anomaly is stronger and centered over the Bay of Biscay and Spain; during El Niño the high expands but weakens and is centered around 30° North Latitude over the eastern North Atlantic and North Africa. Figure C18 shows that during La Niña events, storm tracks end near the Black Sea causing droughts in Israel; during El Niño the storm tracks end in Israel bringing rain and high waves. The biblical 7-year floods on the Nile River are associated with La Niña intensification of the southwest monsoon over the Indian Ocean (Figure C17). These monsoons bring heavy rainfall over the high Ethiopian plateau that induces flooding on the Nile River.

The dipole systems of the PNA and NAO redirect the tracks of traveling storm fronts, causing changes in coastal wave climate. The strongest pressure gradients occur along the boundaries of the pressure anomalies of the PNA and NAO patterns and these boundaries indicate the prevailing storm paths. Figure C18(a) (La Niña) shows large areas of high pressure over the North Pacific and North Atlantic. These high-pressure areas enhance storm tracks as shown by the arrows for waves approaching North America and Europe, with the prevailing North American storm tracts directed at the Pacific northwest and along the Atlantic east coast. In the eastern Pacific, the principal wave energy during La Niña dominated climate (1943–77) was from Aleutian lows having storm tracks, which usually did not reach southern California. Summers were mild and dry with the largest summer swells coming from very distant Southern Hemisphere storms. The wave climate in southern California changed with the El Niño dominated weather of 1978–98. The prevailing northwesterly winter waves were replaced by high-energy waves approaching from the west or southwest (Figure C18(b)), and the previous Southern Hemisphere swells of summer were replaced by shorter period tropical storm waves during late summer months from the more immediate waters off Central America. The east coast of North America is out of phase with the west coast for severe weather. Heavy rainfall and numerous, powerful Caribbean hurricanes and northeasters occur typically during La Niña years (Figure C18(a)) (see entry on *Energy and Sediment Budgets of the Global Coastal Zone*).

COASTAL BOUNDARIES

Introduction

Worldwide, coastal boundaries range from limits of international jurisdiction in the sea to local property lines along or near the shore.

A full examination of the multitude of shore and sea boundaries in all coastal nations is, of course, beyond the scope of this entry. Instead, the primary focus will be on the definition and demarcation of the legal boundaries between public and private coastal property in the United States.

The entry will also discuss (1) the American federal-state submerged lands boundary, as well as (2) offshore boundaries delimiting the extent of the territorial sea, the contiguous zone and the exclusive economic zone.

In examining coastal boundary principles, it is helpful to agree upon definitions of various legal and technical terms. Although recognizing that different terms are, or have been, used elsewhere, this entry will use certain words and phrases in a specific manner.

For example, in this entry the main categories of coastal property (Shalowitz, 1962; Graber, 1980) will be referred to as uplands, tidelands, and submerged lands, defined as follows:

Uplands are lands above (landward of) the mean high-water line (a technical term to be defined later). They are sometimes referred to as littoral lands or fastlands. (The owners of these lands are littoral owners; they are sometimes referred to, imprecisely, as riparian owners. Technically, "riparian" refers to the banks of a river.)

Tidelands are lands between the mean high-water and mean low-water lines. They are sometimes described as lands over which the tide ebbs and flows. Tidelands are adjacent to uplands on the landward side and to submerged lands on the seaward side. Tidelands are sometimes called the foreshore, shore, or wet-sand area.

Submerged lands are lands below (seaward of) the mean low-water line.

For consistency, this entry will use the word "define" to refer to the legal definition of a coastal boundary, and "demarcate" to refer to the process of locating a boundary on the ground.

In the United States, no single uniform rule governs the determination of the public–private coastal property boundary; under the federal system, each state generally can fashion its own property laws. Under certain circumstances, however, the federal rule of coastal boundaries controls over conflicting state law. The mean high-water line—the modern, technically precise equivalent of the vague English common-law term "ordinary high-water mark"—defines the public–private property boundary under the federal rule and in most states, but some states use the mean low-water line or other lines (Shalowitz, 1962, 1964; Maloney and Ausness, 1974; Graber, 1980).

Before discussing the definition of, and methods of demarcating, the public–private boundary, this entry will summarize (1) pertinent scientific and technical aspects of the tide and tidal datums, and (2) the relevant historic and legal background.

The tide and tidal datums

Most US public–private coastal property boundaries are defined by the course of the tide, and tidal datums generally are used in demarcating the location of the boundary on the ground.

The *tide* is the periodic rise and fall of the surface of the sea resulting from the gravitational attraction of the moon and sun acting upon the rotating earth. A lunar (or tidal) day is 24 h and 50 min, and a lunar month is $29\frac{1}{2}$ days. The *range of the tide* is the difference in the height between the successive high and low tides. The range varies from day to day and from place to place.

Spring tides, or tides of increased range, occur twice during each lunar month as a result of the sun and moon being in line with each other and earth (in conjunction) at new moon and full moon. *Neap tides*, or tides of decreased range, occur twice during each lunar month as a result of the sun and moon being at right angles to earth (in opposition) at the moon's first and third quarters (the moon in quadrature). In most places, however, spring and neap tides occur a day or two after the corresponding phase of the moon because of a lag known as phase age (Shalowitz, 1962; Maloney and Ausness, 1974; Hicks, 1975).

Tides can be classified by the frequency and uniformity of the high and low waters. Along American coasts, there are three principal types of tide: the diurnal, semidiurnal, and mixed. The *diurnal* (daily) type of tide, in which there is only one high water and one low water in a tidal day, is common along most of the Gulf of Mexico coast. The *semidiurnal* (semidaily) type of tide, with two high waters and two low waters each tidal day, predominates along the Atlantic coast (and throughout the world). The *mixed* type of tide, in which there are two high waters and two low waters in a tidal day but with significant differences in the heights of the two highs or the two lows, or both, is found along the Pacific coast (Shalowitz, 1962; Hicks, 1975).

Tidal datums are vertical datums defined by phases of the tide, such as high water. They are used as references for heights on land and depths in the sea, and in demarcating certain US coastal property boundaries, and the limits of the territorial sea, the contiguous zone and the exclusive economic zone (Shalowitz, 1962, 1964; Hicks, 1975).

The National Ocean Survey (NOS), the American federal agency responsible for maintaining tide gauges and preparing nautical charts, determines the elevations of various tidal datums at control tide stations based on 19 years of data. The 19-year period, known as a *tidal epoch*, is deemed to constitute a full cycle because the most significant tidal variations complete their cycles during 19 years. Tidal datums are local datums, accurate only for the location of the tide station from which the tidal information is obtained, and should not be extended into areas having different topographic features without substantiating measurements (Shalowitz, 1962; Maloney and Ausness, 1974).

The standard tidal datums determined by NOS are:

Mean higher high water (MHHW): The arithmetic mean of the higher-high-water heights of a mixed tide over a specific 19-year tidal epoch; only the higher high water of each pair of high waters of a tidal day is included in the mean.

Mean high water (MHW): The arithmetic mean of the high-water heights over a specific 19-year tidal epoch; for a semidiurnal or mixed tide, the two high waters of each tidal day are included in the mean.

Mean sea level (MSL): The arithmetic mean of hourly water elevations over a specific 19-year tidal epoch.

Mean low water (MLW): The arithmetic mean of the low-water heights over a specific 19-year tidal epoch; for a semidiurnal or mixed tide, the two low waters of each tidal day are included in the mean.

Mean lower low water (MLLW): The arithmetic mean of the lower-low-water heights of a mixed tide over a specific 19-year tidal epoch; only the lower low water of each pair of low waters of a tidal day is included in the mean.

The MHW and MLW tidal datums are the principal tidal datums used in U.S. coastal property boundary demarcation, and the MLLW tidal datum is used in determining the offshore boundaries along America's Pacific coast (Shalowitz, 1962, 1964; Hicks, 1975; Hull and Thurlow, 1975).

Historic and legal background

The English common law and, to a lesser extent, the civil law of Continental Europe provide the backdrop for the development of American rules defining coastal property boundaries and governing public and private rights in the seashore.

The civil law of Continental Europe originated in early Roman law, which proclaimed the sea and seashore *res communes*, or "common to all," and not subject to private ownership. Private littoral ownership generally extended only to the line of the highest winter waves (Maloney and Ausness, 1974; Graber, 1980).

In contrast, early English kings appear to have granted favored lords title to and exclusive private rights of fishery in many tidal areas. As the English common law evolved over many centuries, however, it became the general rule that the Crown has *prima facie* title to, and the public certain rights to use, tidelands and navigable rivers. The *jus publicum*, as the public rights are termed, is similar to the early Roman public rights to use the seashore. It is these English common-law rights, as expanded and refined, that became what is referred to in the United States today as the public trust doctrine (Shalowitz, 1962; Maloney and Ausness, 1974; Graber, 1980).

Circa 1568–69, during the reign of Queen Elizabeth I, Thomas Digges, a lawyer, engineer and surveyor, wrote a treatise asserting the Crown's ownership of the lands beneath tidal waters. Although the courts did not embrace his theory immediately, the doctrine of the Crown's *prima facie* title to tidelands became well established under English common law by the end of the 17th century. Sir Matthew Hale, an influential jurist who was to become chief justice, espoused Digges' theory in the treatise *De Juris Maris*, written ca. 1666–67 (Maloney and Ausness, 1974; Graber, 1980).

In the early days of the American colonies, there were no specific restrictions on conveyances of tidelands by colonial proprietors, provided there was no impairment of navigation. For example, a 1641–47 Massachusetts Bay Colony ordinance (general law) authorized the extension of littoral owners' titles seaward to the low-water mark or to 100 rods (1,650 feet) beyond the high-water mark, whichever was more landward. Later, however, application of the evolving English common law became more widespread in the colonies, partly because of the English authorities' desire to unify the colonies for commercial gain (Maloney and Ausness, 1974; Graber, 1980, 1982a).

With the American Revolution, the former colonies, by virtue of their new sovereignty, succeeded to the rights of the English Crown and Parliament in colonial tidelands. Absolute title to all tidelands was vested in the original states, except for those lands that already had been validly granted into private ownership. In 1789, the original states surrendered to the federal government some of their rights in the tidelands by adopting the U.S. Constitution, which provides the bases of the federal government's commerce clause powers and its admiralty jurisdiction. The term "federal navigational servitude" refers to the federal government's paramount authority to control and regulate the navigable waters of the United States under the commerce clause (Graber, 1980, 1981a).

In 1845, the U.S. Supreme Court declared that as new states are subsequently admitted to the Union, they are deemed to have the same sovereignty and property rights as the original 13 states. This concept is known as the equal-footing doctrine. As the United States acquired additional territory, title to all lands beneath tidal and other navigable waters vested in the nation, subject to valid grants by prior governments, in trust for future states. Upon creation of a new sovereign state from such acquired areas, or from the lands formerly within an older state, the new coastal state became vested with title to all lands underlying tidal waters. The after-admitted states' sovereign title to tidelands, except for those lands already validly granted into private ownership, is absolute, although subject to the public trust easement and the federal government's paramount navigational servitude and admiralty jurisdiction (Shalowitz, 1964; Graber, 1980).

In England, during the 18th and early 19th centuries, the common law used the term "ordinary high-water mark" to describe the property boundary between the sovereign's foreshore, or tidelands, and the adjoining private littoral lands. The imprecision of this term may be traced to Lord Hale's 1666–67 treatise. He classified the shoreline on the basis of what he perceived to be three types of tide: "(1st.) The high spring tides, which are the fluxes of the sea at those tides that happen at the two equinoxials. (2^{d}) The spring tides which happen twice every month at full and change of the moon. (3^{d}) Ordinary tides, or nepe [sic] tides, which happen between the full and change of the moon." (Shalowitz, 1962; Graber, 1980).

Apparently, Lord Hale introduced the concept that what he termed "nepe tides" should be considered the "ordinary tides" for property boundary purposes. In his treatise, he concluded that lands subject to inundation by tides of the first two of his three classes can be privately owned, but that the foreshore owned by the Crown extends landward as far as it is covered by the "ordinary … or nepe [sic] tides." (Shalowitz, 1962).

As pointed out by Aaron L. Shalowitz, the author of the landmark treatise, *Shore and Sea Boundaries*, and a lawyer and engineer for the U.S. Coast and Geodetic Survey, NOS's predecessor agency:

> "… Lord Hale's designation of 'neap tides' shows that it is susceptible of two interpretations: (1) all the tides that occur between the full and change of the moon, and (2) only those tides that occur twice a month at the time of the first and third quarters when the moon is in quadrature" (Shalowitz, 1962, p. 91). Based on today's knowledge of the types of tide, Lord Hale was both unscientific and ambiguous in equating what he termed "nepe tides" with "ordinary tides."

It was not until 1854, long after the American Revolution, that the English high court clarified the definition of the common-law term "ordinary high-water mark" in the *Chambers* decision (*Attorney-General* v. *Chambers*, 1854). The lord chancellor ruled that the boundary was to be determined by using "the line of the medium high tides between the springs and the neaps," excluding both the neap and spring tides.

Public–private coastal property boundary rules

The United States has a wide variety of federal and state legal rules governing (1) the definition of the property boundary between public and private coastal lands, and (2) the legal effect of such physical shoreline (see *Coasts, Coastlines, Shores and Shorelines*) changes as accretion and erosion (terms to be defined later). In most situations, the applicable state law governs.

In many states, however, the federal government originally owned littoral lands that it later granted into private ownership. If there is a conflict between the federal and state rules on the definition of the boundary in those states, or on the legal effect of physical shoreline changes, the federal law controls when title to an upland parcel is derived from a federal grant (Maloney and Ausness, 1974).

Federal rule

The federal rule defines the property boundary as the intersection of the MHW tidal datum with the shore. The rule was first stated by the U.S. Supreme Court in the 1935 *Borax* decision (*Borax, Ltd.* v. *City of Los Angeles*, 1935). At issue was the location of the boundary between upland owned by Borax, as successor to a federal grantee, and the adjoining tideland held by the City of Los Angeles under a California legislative grant.

Borax argued that the boundary should be determined under what it asserted to be the California rule: by using only the high "neap tides." Borax would have gained land thereby because a boundary using a tidal datum based on only the high "neap tides" would be more seaward, or lower, than one derived from a mean of all the high tides. The Supreme Court rejected the "neap tide" argument, holding that the extent of land under a federal grant is a federal question, and thus the boundary between the upland and the adjoining tideland is determined under federal law.

Before clarifying the federal upland–tideland boundary rule, the *Borax* Court reviewed Lord Hale's 1666–67 treatise on the types of shorelines, which had referred to "nepe tides" in an unscientific manner, and the 1854 English *Chambers* decision that the "ordinary high-water mark" was to be determined by excluding both the neap and spring tides and using only the intermediate, or medium, tides. In *Borax*, the Court equated the common-law term "ordinary high-water mark" with the technically precise phrase "line of mean high water." (The boundary is also referred to as the "mean high-water line" and "mean high-tide line.") The Court held that when federal law applies, the public–private coastal property boundary is located by using the MHW tidal datum, as determined by the agency then known as the Coast and Geodetic Survey (now NOS) based on 18.6 years (now rounded to 19 years) of data.

State rules

State property boundary rules are the result of various state constitutional and statutory provisions as well as case law. The majority of the states follow the English common-law concept that the boundary is the "ordinary high-water mark," or its updated, technically precise counterpart, the mean high-water line.

In general, subject to many qualifications, 16 coastal states use the mean *high*-water line as the boundary. They are: Alabama, Alaska, California (subject to the "neap tide" language discussed below), Connecticut, Florida, Georgia, Maryland, Mississippi, New Jersey, New York, North Carolina, Oregon, Rhode Island, South Carolina, Texas (as to lands under common-law grants but not as to lands derived from Spanish or Mexican grants) and Washington. (Maloney and Ausness, 1974; Graber, 1980, 1981b, c, d, 1982b, c, 1983a, b, c, 1984a, b, d, 1985b, 1986a, b, 1988, 1989.)

California's so-called "neap tide" rule originated in the state Supreme Court's 1861 *Teschemacher* decision (*Teschemacher* v. *Thompson*, 1861). The court echoed Lord Hale's 17th-century treatise equating "nepe" or "neap tides" with "ordinary tides" for boundary purposes. Despite an 1872 statute providing that the "ordinary high-water mark" is the seaward limit of upland, California courts continued to refer to "neap tides," although generally in a nontechnical manner, in defining the boundary. Finally, in 1966, in the *Kent Estate* decision, the appellate court held that the boundary is to be determined by using the 19-year mean of the high "neap tides." (*People* v. *Wm. Kent Estate Co.*, 1966). The court apparently attempted to define "neap tides" in a technical manner, but overlooked the fact that there usually is a lag of a day or two between quadrature of the moon and the minimum or neap range of the tide. Although the decision has not been overruled, other modern California decisions, as well as recent statutes, refer to the "line of mean high tide" in defining tidelands, so there is some uncertainty as to the state's boundary rule (Graber, 1981b).

Six Atlantic coast states have departed from the English common-law rule and utilize the mean *low*-water line, or variations of it, as the public–private coastal property boundary. They are: Delaware, Maine, Massachusetts, New Hampshire, Pennsylvania, and Virginia (Maloney and Ausness, 1974; Graber, 1980, 1982a, 1984c, 1985a, c, 1987a, b).

Louisiana, with its French and Spanish heritage, accepts the line of the highest winter tide, a version of the civil-law rule. In Texas, if the original source of upland title was a prestatehood Spanish or Mexican grant, the line of MHHW, another variation in the civil-law rule, is the boundary. Hawaii adheres to its aboriginal, customary concept that the public–private boundary follows the upper reaches of the wash of the waves (Maloney and Ausness, 1974; Graber, 1980, 1981d, 1982d, 1983d).

Despite these generally applicable state rules, the boundary in a specific situation may differ. For example, even in states with a high-water boundary, certain tidelands, or both tide and submerged lands, may have been sold into private ownership by the state, and still are privately held.

Fixed or ambulatory boundaries

The location of the public–private coastal property boundary sometimes is permanently fixed, due to, for example, litigation or a boundary line agreement. In addition, on a rocky coast, for all practical purposes, the boundary may amount to a fixed line (though it is possible that the tidal datum could change or that the coast might erode in the future).

However, in most situations, particularly on sandy shores, the boundary is an ambulatory, or moving, line as the result of natural and/or artificial causes. The main types of physical changes (Maloney and Ausness, 1974; Graber, 1980, 1982c) are as follows:

Accretion: Addition to land along the shoreline resulting from the gradual, imperceptible deposit by the water of sand, sediment or other material; the word *alluvion* refers to the deposit itself, but sometimes is used synonymously with accretion. The test of what is "gradual and imperceptible" is: "Though the witnesses may see, from time to time, that progress has been made, they could not perceive it while the progress was going on." (*County of St. Clair* v. *Lovingston*, 1874).

Reliction: Land formerly covered by the water that has become dry by the gradual, imperceptible recession of water.

Erosion: Gradual, imperceptible action wearing away land along the shore by currents, waves, wind, and other elements.

Submergence: Disappearance of soil under the water and formation of a body of water under it.

Avulsion: Sudden change in the shoreline.

Generally, subject to qualification, the littoral owner benefits as the boundary moves seaward with accretion and reliction, but loses as the boundary shifts landward with erosion and submergence. Avulsion, however, does not result in a change in the legal boundary (Maloney and Ausness, 1974; Graber, 1980, 1982c).

In allowing littoral owners to benefit from accretion, the federal rule and most coastal states' rules do not distinguish natural accretion from accretion due to artificial, or manmade, causes (e.g., a breakwater or pier). Generally, however, a private littoral owner is not entitled to benefit from accretion caused by his or her own intentional acts, such as filling adjoining tide-covered lands (Maloney and Ausness, 1974; Graber, 1980).

In its 1967 *Hughes* decision, the U.S. Supreme Court ruled that the federal rule controlled over Washington state law with regard to accretions to private upland property derived from a federal grant. Washington claimed the state as tideland owner was entitled to the accreted land under an 1889 state constitutional provision denying littoral owners any right to accretions between their property and the ocean. The Court, citing its 1935 *Borax* principle that federal law governs the question of ownership of property within a federal grant, expanded the rule so it also determines the issue of ownership of accretion to that land (*Hughes* v. *Washington*, 1967).

In its 1982 *California* decision, the U.S. Supreme Court held that federal rather than state law controlled in a dispute over accreted land along the Pacific Ocean adjoining a Coast Guard facility. It was undisputed that the upland parcel had been continuously owned by the federal government since California's admission to the Union in 1850, and that the accretion had been artificially caused by construction and maintenance of nearby U.S. jetties. Under the state rule, California as tideland owner would have been entitled to such artificially accreted land (*California* v. *United States*, 1982).

When state rules of accretion apply, the pertinent state's laws must be examined. As previously mentioned, in most states, the littoral owner benefits from accretion, whether it results from natural or artificial causes. California, however, denies the upland owner any artificially caused accreted land; the boundary is to be determined when the shoreline was in its "last natural position," before it was changed by the artificial condition (Graber, 1981b, 1982c).

Demarcation of coastal property boundaries

Over time, the methods of demarcating (locating on the ground) and delineating (showing on a map) public–private coastal property boundaries have evolved from relatively primitive and inexact techniques to extremely sophisticated and precise procedures.

Early methods

The ocean's edge is, of course, a natural boundary, and is depicted on the oldest maps of coastal areas. But until seashore property values escalated in the 20th century, the location of the public–private property boundary was only an approximation. This has been called the first generation of coastal boundary determination by Paul T. O'Hargan, a coastal surveying authority who wrote that it "took the form of an educated guess." This resulted from a lack of data and the difficulties of surveying these boundaries. In many sections of the United States, there were insufficient tidal datums or the means to establish them (O'Hargan, 1975, p. 6).

Current procedures

After the appropriate legal rule defining the coastal property boundary has been identified, a land surveyor or engineer must apply that rule to the site in question to locate the boundary on the ground.

Boundaries defined in terms of the tide involve two engineering components: (1) a vertical one, based on the height of the tide and constituting a tidal datum, such as MHW, and (2) a horizontal one, related to the line where the tidal datum intersects the shore to form the tidal boundary, such as the MHW line (Shalowitz, 1962, 1964).

With the availability of tidal datum elevations published by the federal government, more precise boundary demarcation became possible in the United States (O'Hargan, 1975). The tidal datum elevations published by NOS, however, are accurate only for the locality of the relatively few control tide stations where tidal observations have been made during a full 19-year tidal epoch. There can be widespread differences in the elevations of datums from point to point along the coastline or even in the same bay or inlet (Hicks, 1975).

Unless the site of the boundary to be demarcated is in the immediate vicinity of a control tide station, it is usually necessary to establish one or more subordinate short-term tide stations where tidal observations can be taken. To derive the mean 19-year values needed for determining boundaries, the records from the local, or secondary, stations are simultaneously compared with the control station's records (Hull and Thurlow, 1975; O'Hargan, 1975; Cole, 1983).

The second, or land, component of the property boundary may consist of rock, sand, marsh, mangroves, or another type of vegetation. The nature of the coast where the boundary is being demarcated and delineated may, of course, affect the choice of the procedure used by the surveyor or engineer.

In what O'Hargan termed the second generation of coastal boundary determination, the technique of using contours became common (O'Hargan, 1975). Under this procedure, the surveyor or engineer uses leveling and conventional horizontal surveying techniques on the assumption that the datum line (derived from simultaneous comparisons of the control and the local, or secondary, tide stations) is a level topographic contour in the vicinity of the datum determination (Hull and Thurlow, 1975).

In 1974, however, this contour procedure was criticized at a convention of the American Society of Photogrammetry because the underlying assumption is sometimes incorrect: the variations in tidal datum elevation even at points quite near one another can be extensive (Guth, 1974). In what O'Hargan called the third generation of coastal boundary determination, several new approaches were developed as an outgrowth of that criticism, such as the extrapolated water elevation (EWE). "In this method, the tides are used to make a 'mark' on tide staffs set along the mean high water line. In other words, the datum is extrapolated from a single tide station to various places along the line to be located" (O'Hargan, 1975, p. 24). Florida almost immediately adopted the new procedure as the most accurate method of surveying these boundaries (Guth, 1976).

Various other procedures for determining the property boundary are in use, including biological interpretation by remote sensing imagery and photogrammetric analysis of aerial photographs (Hull and Thurlow, 1975).

Locating historic boundaries

In some situations, the public–private coastal property boundary must be determined as of a date in the past. In California, for example, it frequently is necessary to locate the "last natural position" of the shoreline because of the state rule that the upland owner is not entitled to artificial, or manmade, accretions (Graber, 1981b).

When called upon to demarcate and delineate the "last natural position" or some other historic location of the line in question, a surveyor or engineer must be thorough and innovative. He or she must search for and analyze all available pertinent historic materials, such as old U.S. Coast and Geodetic Survey topographic surveys and hydrographic and navigational charts, and the accompanying field notes and descriptive reports. Other professionals, such as geologists or oceanographers, may be needed to assist in the investigation of the "last natural" or other historic location of the line in question.

Other American coastal boundaries

Although this entry has focused on American public–private coastal property boundaries, there are many other categories of U.S. regulatory, political, and jurisdictional boundaries near or offshore from the coast. This section briefly discusses some of them.

Federal-state boundary

Before World War II, it generally was assumed that states owned the submerged lands offshore from their tidelands. In the postwar years, however, the United States challenged coastal state assertions of title. In 1947, in *United States* v. *California*, the U.S. Supreme Court held that California did not own the marginal belt extending three geographic (nautical) miles from its coast and that the federal government, not the state, has paramount rights in, and power over, that belt, an incident of which embraces control over the resources in the underlying soil, including oil (*United States* v. *California*, 1947). Similar decisions were handed down in 1950 concerning Louisiana and Texas (Shalowitz, 1962; Graber, 1981a).

In 1953, Congress responded to these decisions by enacting the Submerged Lands Act. This law (1) quitclaimed to the coastal states U.S. title claims to certain submerged lands, and (2) defined the submerged lands confirmed to the states in terms of state boundaries as they existed when the state became a member of the Union or as previously approved by Congress, but not extending seaward from the coastline of any state more than three geographic (nautical) miles (one marine league) in the Atlantic and Pacific Oceans or more than nine geographic (nautical) miles (three marine leagues) in the Gulf of Mexico (Submerged Lands Act, 1953; Graber, 1981a). (For simplicity, the text will use only the word "miles," omitting the qualifying words "geographic (nautical)." A geographic mile equals 1.151 statute miles and 1 statute mile equals 1.609 km.)

The Submerged Lands Act has had the general effect of resolving the federal-state boundary at either 3 or 9 miles offshore. The act specifies the "coast line," for purposes of locating the seaward boundaries of the states, as "the line of ordinary low water … ." (Submerged Lands Act, 1953, §3). There has been considerable subsequent litigation between the United States and various coastal states involving specific areas. The U.S. Supreme Court accepted assertions by Florida and Texas that their maritime boundaries extend three leagues (9 miles) into the Gulf of Mexico, but rejected similar claims by Louisiana, Mississippi, and Alabama (Shalowitz, 1962; Graber, 1980, 1981c, d, 1982d, 1986a, 1988).

Federal outer continental shelf

Legally, the outer continental shelf consists of submerged lands subject to federal jurisdiction immediately seaward of the 3- or 9-mile belt of submerged lands owned by the states. In 1953, Congress passed the Outer Continental Shelf Lands Act authorizing the federal government to lease oil, gas, and other mineral resources within the area of submerged lands between the seaward limit of the states' submerged lands and the edge of the continental shelf (Outer Continental Shelf Lands Act, 1973).

Limits under international law

The United States, like other coastal nations, exercises maritime jurisdiction over various zones in the seas adjoining its coasts. Under international law, these national zones include not only the continental shelf but also the territorial sea, the contiguous zone, and the exclusive economic zone. The breadth of the territorial sea and other zones is measured from a baseline, which usually, but not always, is "the low-water line along the coast as marked on large scale charts officially recognized by the coastal [nation]." (Convention on the Territorial Sea and the Contiguous Zone, 1958, art. 3). Along America's Pacific coast, which has a mixed tide, the NOS's charts delineate the MLLW line, instead of the MLW line (Shalowitz, 1962, 1964).

Under international law, each coastal nation is entitled to assert a territorial sea immediately seaward of its inland waters as wide as 12 miles from the baseline. In the territorial sea, the nation has sovereign rights but must allow free passage to foreign vessels. Traditionally, the United States had claimed a territorial sea only 3 miles wide, but on December 27, 1988, President Reagan asserted an American territorial sea with a 12-mile breadth (Proclamation No. 5928, 1988).

The contiguous zone is a zone of the high seas seaward of, and adjacent to, the territorial sea. In this zone, the coastal nation is authorized to prevent infringement of its customs, fiscal, immigration, and sanitary regulations (Convention on the Territorial Sea and the Contiguous Zone, 1958). Under international law, the contiguous zone may not extend more than 24 miles beyond the baseline used for measuring the width of the territorial sea (Law of the Sea Convention, 1982).

Until the end of World War II, waters seaward of the territorial sea and the contiguous zone generally were deemed to be the high seas and not subject to any coastal nation's jurisdiction. However, some nations unilaterally asserted their exclusive rights to offshore fisheries and other resources. The Third United Nations Conference on the Law of the Sea authorized coastal nations to establish 200 mile-wide exclusive economic zones in which they could explore, exploit and manage living and nonliving resources. The national jurisdiction within the zone extends 200 miles seaward from the same baseline used to measure the width of the territorial sea (Law of the Sea Convention, 1982).

The United States asserted a 200 mile-wide fishery zone in 1976 (Fishery Conservation and Management Act, 1976). President Reagan declared the establishment of the nation's 200-mile-wide exclusive economic zone in 1983 (Proclamation No. 5030, 1983).

Conclusion

Over the last 65 years, the American legal system, with some notable exceptions, has made remarkable progress in clarifying the old English common-law definition of the boundary between public and private coastal property.

This welcome improvement may be traced to 1935, when the U.S. Supreme Court handed down a landmark decision equating the vague common-law phrase "ordinary high-water mark" with the technically precise term "line of mean high water." By doing so, the Court provided a scientifically and technically sound basis for the federal rule defining the legal boundary. In addition, the decision inspired some state legislatures and courts to follow suit by clarifying their state boundary rules. It also enabled surveyors and engineers, using procedures that have become more sophisticated over time, to accurately locate the boundary on the ground under the modern rules.

Some issues concerning the definition and demarcation of coastal boundaries are still unresolved, but the progress made since 1935 suggests that the legal system will be able to work with the scientific and engineering communities to resolve those problems.

Although the process of clarifying the public–private coastal property boundary has been a major development, there have also been significant trends concerning offshore boundaries, especially since the end of World War II. The bitter dispute between the federal government and coastal states over control of submerged lands was largely resolved by Congress in 1953 and in several later court decisions. The political solution: dividing ownership of the submerged lands between the United States and the states. And in international law, developments since 1976 have led to an expanded American territorial sea and new 200-mile-wide U.S. fishery and exclusive economic zones.

While the law relating to coastal boundaries, like property law generally, is rooted in the past, it can no longer be assumed that the pertinent legal rules are immutable. Like the shoreline of a sandy beach, change seems inevitable.

COASTAL CHANGES, GRADUAL

The concept of gradual coastal change can be seen as embracing different contexts, both spatial and temporal. It is conceivable that gradual change may include those depositional and erosional events that have taken millions of years to produce present-day coastal landforms at one end of the spectrum, while at the other end slow and imperceptible accretion to beaches after storms may represent another form of gradual change. Therefore, a wide-ranging time frame may be used covering geological, engineering, and arguably event scales as depicted in Figure C20.

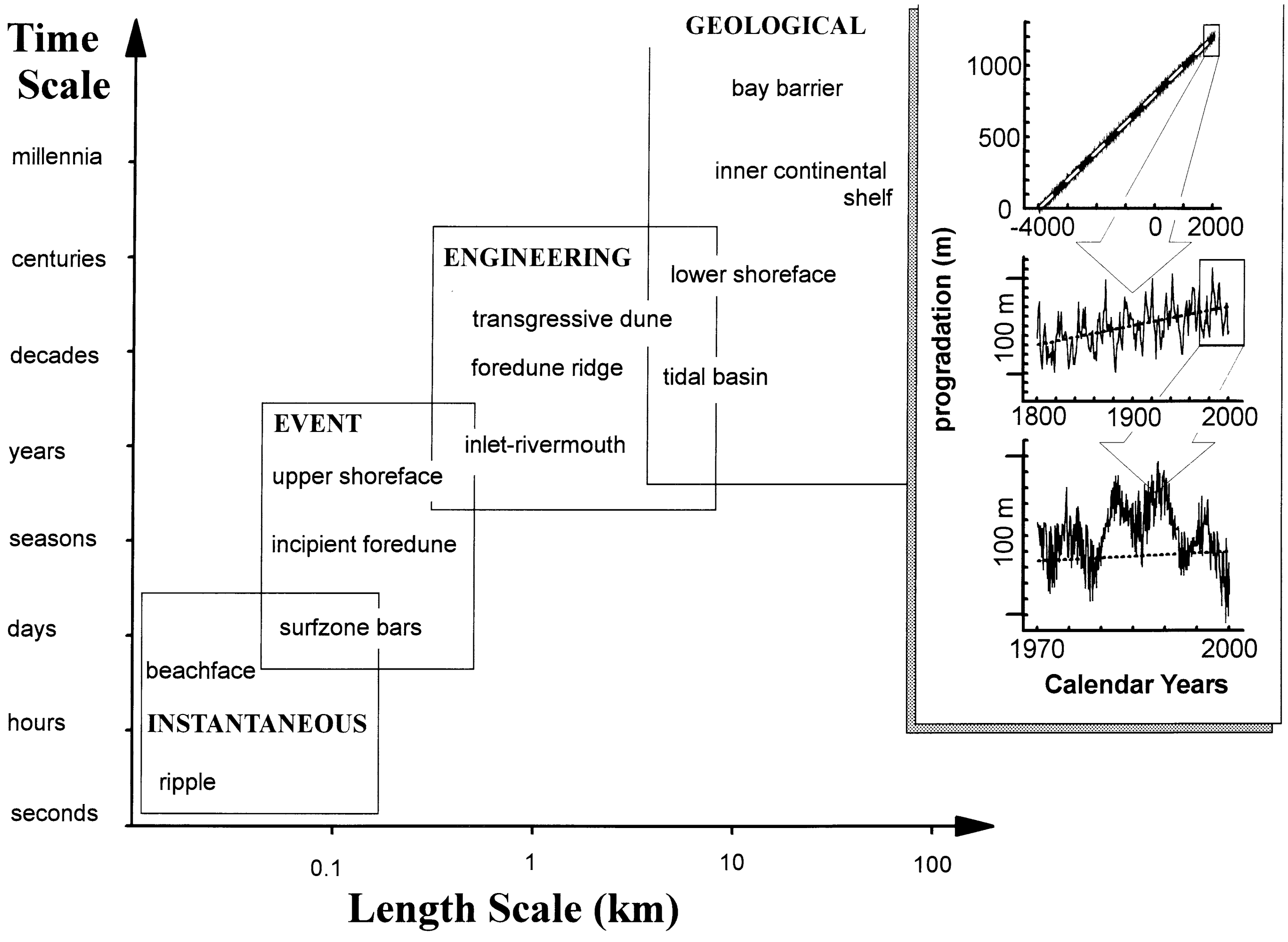

Figure C20 Spatial and temporal scales of coastal geomorphic change depicting examples of features formed at different scales and how oscillations in magnitude and frequency of processes may be superimposed on longer-term trends (e.g., progradation of a strandplain with beach cut and fill cycles superimposed as at Moruya, New South Wales, Australia, see Thom and Bowman, 1981).

This figure demonstrates how high frequency, low magnitude processes at shorter time scales can be superimposed on longer-term oscillations and trends at scales of millennia and longer term as reflected in depositional and erosional land forms.

Cenozoic geologic scale

Coastal geomorphologists have a long-standing interest in the evolution of coastal landforms from Tertiary to Quaternary times. Many coastal regions show an historical imprint or inheritance of depositional or erosional processes reflecting changes in shoreline position as sediments accumulate or cliffs erode. In glaciated areas, the impact of gradual coastal accretion or erosion from Tertiary times is rarely apparent. Similarly, where tectonic and volcanic activities prevail there is little evidence of shoreline features of pre-Quaternary age. However, tectonic uplift as seen, for instance, along the Huon Peninsula in Papua New Guinea, can provide a mechanism for preserving the remnants of gradual coral reef accumulation over hundreds of thousands of years which correlate very well with glacial to interglacial climatic and eustatic cycles (Chappell and Shackleton, 1986).

Classic thinking in coastal geomorphology, epitomized by the work of Douglas Johnson (1919), dramatically demonstrated the nature of gradual change following the application to coasts of the Davisian cyclic model in geomorphology. Assumptions built into this model may be queried, but the basic notion of change driven by the interaction of marine forces (especially waves) and the land still underpins any conceptual framework for understanding how coasts evolve over time. The importance of sea-level change during the Quaternary is now seen as a major factor in coastal geomorphology, a phenomenon of relatively limited significance in the Davis/Johnson model. Shepard, Russell, Fairbridge, Armstrong Price, Steers, and Guilcher (and others) are of a generation that assessed coastal landforms in different regions of the world from a Quaternary perspective. They showed how erosional, and especially depositional landforms, over time, have changed their character under different sea-level conditions. Many coastal regions experienced post-depositional modification and transformation after primary wave, tidal and wind processes have performed their work (Thom, 1975).

The Australian coast contains many examples of gradual change in coastal environments during the Cenozoic. These features have formed since dislocating tectonic forces that ripped the continent apart from Gondwana remnants essentially stopped operating about 60 million years ago. On the east coast, the narrow continental shelf has been subjected to very slow marginal subsidence. This has facilitated two geomorphic outcomes: shelf-edge accretion of a sediment wedge ca. 500 m in thickness, and an inner-shelf abrasion surface up to 10 km wide and ca. 1,000 km long (the East Australian Marine Abrasion Surface—EAMAS). The surface is now veneered with late Quaternary sediments and is entrenched by infilled paleo-valleys carved by rivers draining to lower sea levels. The surface culminates on the landward side with discontinuous marine cliffs cut into Mesozoic or Paleozoic rocks often over 100 m in height and representing truncated spurs and ridges of drowned valleys and plateaux (as seen around Sydney). We are uncertain of the precise age of initiation of the surface and cliffs, but it is easiest to conceive of these features as time-transgressive evolving progressively over millions of years during periods of relatively higher sea level.

Another large-scale Australian example that reflects gradual accumulation of sediments are the barrier-lagoonal deposits formed over millions of years within the lower Murray-Darling basin. In this region, relative sea level since the early Tertiary has fallen. Sands, including heavy minerals such as ilmenite, form horizontally stacked barriers which in Quaternary times have been partially reworked into terrestrial dune fields. Similar "stepped" or extensive strand plains initiated in the Tertiary and extending through the Pleistocene into the Holocene have formed in southwest Western Australia near Perth, in parts of southeast Brazil, and along the Atlantic coastal plain of the United States.

Holocene geologic scale

At the other end of the geologic scale are coastal phenomena which are the result of processes operating at or close to present sea level over the last 6,000 years or so. Within this time frame, erosion and/or deposition can initiate and reconstitute sand barriers, tidal flats, river mouths, tidal deltas, coastal dunes, and rock platforms at the macro scale, and a myriad of landforms at a micro scale. Use of techniques of drilling and dating have enabled age structures and sedimentary histories to be reconstructed from Holocene deposits in coastal areas of many parts of the world.

In areas of postglacial rebound beach deposits dated 6,000 years BP may occur 100–150 m above present sea level (e.g., Gulf of St Lawrence), whereas for areas marginal to the great deltas, like the Mississippi, deposits of similar age may have gradually subsided below sea level and be buried by younger sediments (see Carter and Woodroffe, 1994). In contrast, those coasts experiencing a much more passive neotectonic regime, such as eastern Australia, witness beach/foredune ridge accumulation at about present sea level not only in the Holocene, but also in the last and penultimate interglacials (Roy *et al.*, 1994; see Hopley, 1994, for a review of gradual coral reef accumulations in similar tectonic settings).

One conclusion which can be drawn from an analysis of Holocene sand barriers is how gradual processes of accretion are periodically interrupted by erosion or reduced rates of accretion. The result is a strand plain with distinct linear ridges (beach or foredune) parallel or sub-parallel to the present shoreline. Changes in sediment budgets are critical in the gradual evolution of strand plains. As pointed out by Cowell *et al.* (1999) sand may be supplied from the shoreface as well as littoral sources in order for accretionary processes to work. Closed sediment compartments highlight the effectiveness of gradual onshore transport of sediment from the lower shoreface in certain areas (see Figure C21; Roy *et al.*, 1994). These areas are in contrast to those "leaky" compartments dominated by littoral sand transport associated with river mouth (inlet) or headland bypassing.

Engineering scale

Even closer to the present are those features which result from erosion or deposition over periods of two years or more. Increasingly, coastal

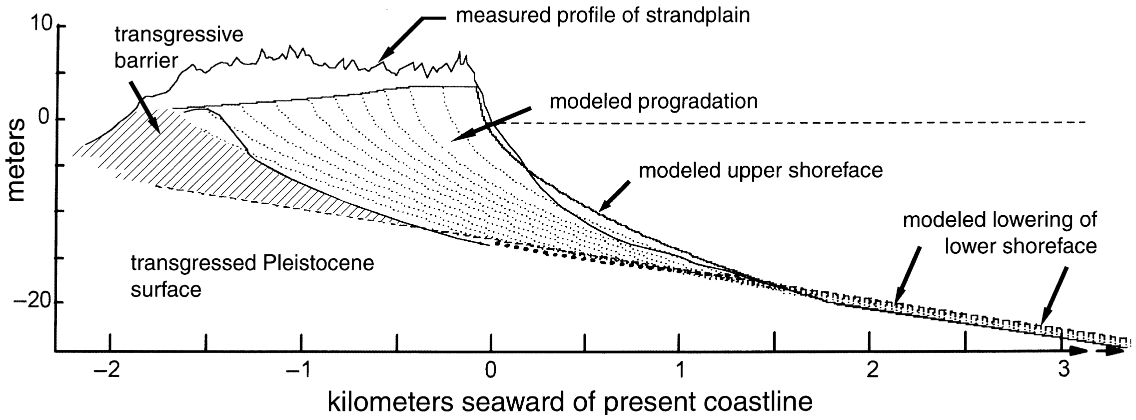

Figure C21 Simulated strandplain development during the Holocene at Tuncurry, New South Wales, Australia (after Cowell *et al.*, 1999). The simulation involved a constant sea level for 6,000 years and an across-shore sand supply from lower to upper shoreface averaging 1.1 m^3 per meter of shoreline together with a steady increase in depth of the lower shoreface at a rate of 0.002 m/y decreasing linearly with distance to 10 km seawards of the present coastline forming 80% of sand now in the strandplain.

geomorphologists are recognizing the impact of oscillations in climatic conditions leading to changes in beach volume, beach alignment, inlet openings/closures, river-mouth bar migration, dune vegetation recovery, etc. However, some of these changes may reflect "self-organization" of morphodynamic conditions involving positive and negative feedback effects independent of climatic forces (see Cowell and Thom, 1994, citing field studies in the United States, Netherlands, and Australia).

Recovery of the subaerial beachface in width and thickness following a period of sudden storm wave erosion is well documented in coastal literature (Komar, 1998). Storm impacts in winter followed by gradual summer accretion are characteristic of many coasts in North America (e.g., California) and Europe. The severity of impact may be enhanced during El Niño years as in Oregon, and that gradual beach recovery may take longer after such severe winter events (see Komar, 1998 for description of El Niño storm impacts). Contrasting situations occur in the southwestern Pacific where beaches may accrete through many years (winter and summer) influenced by El Niño only to erode drastically in La Niña or storm-dominated periods (Thom and Hall, 1991). The role of the Pacific Decadel Oscillation (PDO) as a factor in driving beach cycles of erosion and accretion is now seen as a significant phenomenon which may explain the timing of events that do not easily fit ENSO patterns. El Niño and La Niña can be seen as phenomena lying on top of the large-scale temperature and sea-level height distributions determined by the PDO.

Understanding processes of gradual beach accretion is of significance in beach management. Monitoring beach change by photogrammetric and/or field survey methods yields valuable information on how quickly all or part of a beach may recover following a stormy period. Beaches and foredunes in New South Wales took 5–10 years to reach pre-storm positions following the last major episode of erosion in 1974 (Thom and Hall, 1991). During phases of "gradual and imperceptible" accretion, landowners with land title tied to an "ambulatory" boundary (such as mean high water mark) may seek a redetermination of their land title to claim accreted land. Under the English "doctrine of accretion" exported to many other countries, the boundary remains fixed if sudden erosion cuts back into this new land. A consequence is for landowners to seek to defend their properties with seawalls and bulkheads against erosion. Beach amenity can suffer as a result of these actions (Titus, 1998).

Gradual change in coastline position and form, in tidal flat morphology, in the nature of inlet openings, and in the vegetative cover of coastal dunes are phenomena that affect the lives of millions of people. Understanding the dynamics of gradual changes in coastal geomorphology requires monitoring and historical reconstruction using a variety of techniques and analytical procedures. The use of simulated modeling, as seen for instance with the Shoreface Translation Model developed by Cowell *et al.* (1995), highlight a way of achieving such an understanding when coupled with a knowledge of geomorphic history and processes (see Figure C21).

COASTAL CHANGES, RAPID

Introduction

There are many definitions of what might be called rapid events occurring on coastlines from sea-level movements caused by global warming and/or cooling (10's to 1,000's of years) to tsunamis that occur in seconds. In this entry the types of rapid changes discussed will be of the more instantaneous nature from *tsunamis* (*q.v.*) to *storm surges* (*q.v.*), the type of damage done and what the events leave as a trace in the geologic record. These phenomena were deemed sufficiently important by UNESCO/IGCP (International Geological Correlation Program) to form an IGCP project (IGCP 367) that lasted for 5 years (1994–98), where over 500 people from 70 countries were involved working on almost every aspect of rapid change in the coastal zone. Much of this entry will be drawn from the five volumes produced from that project (Scott and Ortlieb, 1996; Shennan and Gehrels, 1996; Murray-Wallace and Scott, 1999; Scott, 1999; Stathis *et al.*, 2000).

Climatic events

Storms

By far, the most dramatic of climatic events are hurricanes or typhoons as they are called in the Pacific. These events produce profound changes on coastlines and particularly man-made structures in the coastal zone. The effects are of two types, wind damage and water damage from elevated tides and torrential rains causing coastal flooding. At the center of a hurricane winds can reach over 200 km/h and storm tides can be as much as 8 m above normal. The amplitude of the storm tide depends on the barometric pressure (the lower the pressure, the higher the tide), the wind speed which causes the water to pile up onshore and the natural state of the tide (i.e., high versus low tide stage). The worst scenario for high storm tides is low pressure and high winds coinciding with a normal high spring tide.

The type of damage done by wind consists of knocking down of forests as occurred in hurricane *Hugo* in South Carolina (USA) in September of 1989 when the eyewall swept through a national forest and simultaneously knocked down most of the forest in a few seconds. Together with that it also destroyed many coastal man-made structures. Probably the most damage and deaths were caused by the storm surge, which at the eyewall location was 6 m above normal. However, even 50 km from the direct hit, the storm surge was almost 3 m. A purely human problem was sorting out which phenomenon caused the damage, the wind or the water, because many people did not have government flood insurance, which meant that their losses were not covered by their commercial hurricane insurance.

Maybe not too surprisingly the traces left in the naturally occurring geologic record are much less profound. At the eyewall hit of *Hugo*, there was a 10 cm sand layer but at a location 50 km north there was no sedimentological trace and in the extensive marsh areas there was not even a thin sand layer (Collins *et al*., 1999), the natural systems can act as a buffer to storm events, perhaps a lesson to the human population.

The hurricanes do leave a trace in nontidal *coastal inlets* (*q.v.*) of either small sand layers or reworked microfossils, which can be used to build a chronology of storms on some coastlines (Liu and Fearn, 1993; Collins *et al*., 1999). Also strong surges and sustained winds (either from hurricanes or long lasting winter storms such as "nor'easters" on the Atlantic coast of North America) can create washovers and change inlet positions in *barrier island* (*q.v.*) systems.

Global warming

This effect causes a general sea-level rise on scales from 10's of years to 1,000's of years both by melting of glacial ice caps and steric expansion of the ocean, which may amount to 30–40 cm. Depending on the coastal gradient this may or may not be significant.

It is difficult to measure these changes (Pirazzoli, 1991) because they are usually on the order of a few centimeters. Mostly they have been detected by *tidal gauges* (*q.v.*) for the last 50 years (Pirazzoli, 1991) but these measurements are sometimes questionable. Some *biological markers* are now capable of measuring very small changes (± 5 cm) in sediment records (Scott and Medioli, 1986) such that it is possible to measure rapid sea-level changes in the late Holocene (e.g., Scott and Collins, 1996). It is these mid-Holocene measurements that may help us to understand the suggested *sea-level rise* (*q.v.*) to be caused by anthropogenic *global warming* (*q.v.*).

Seismic events

Earthquakes

Sudden land movements on coastlines can either instantly emerge or submerge coastlines and any structure that might be in the way. This is particularly a problem around earthquake prone coasts such as the Pacific Rim and most of the northeastern Mediterranean.

The type of records preserved are often in coastal marshes because they remain depositional and their strong vertical zonations help to show sharp vertical surface changes, that is, sudden change from forest to marsh if the land drops or vice versa if the land emerges (Atwater, 1987; Atwater *et al*., 1995; Shennan *et al*., 1999). There are outstanding records of these phenomena all up and down the west coasts of both North and South America. In rocky coastline areas, *biological markers* maybe uplifted far above their natural range, providing a good indication of rapid change and the magnitude of that change (Ortlieb *et al*., 1996).

Extended records of these events have been documented in the northwestern part of the United States and southern British Columbia, Canada that show a 300–500 year periodicity for magnitude 8 or 9 (on the Richter Scale) earthquakes (Atwater, 1987) over the last several thousand years. Until recently, it was difficult to plan based on a 300-year return time but Shennan *et al*. (1998, 1999) found in two separate places that there appeared to be a precursor event between one and three years prior to these events that could be detected in coastal forest sequences that submerged during a major seismic disruption. The most compelling evidence is from the traces left by the Great Alaska Earthquake of 1964 that was the second largest seismic event ever recorded at 9.2 on the Richter Scale. The evidence from this quake is convincing because unlike the prehistoric quakes in Oregon (Shennan *et al*., 1998), in Alaska, we know exactly when the event occurred and we know absolutely that the forest layer was above tidal influence before the March 26, 1964 quake. What is seen is a small change in both diatom and foraminiferal assemblages in the forest *before* the quake that indicate a slight subsidence, maybe 30 cm, that was not detected by anyone living there or by macro-vegetation (Scott *et al*., 1998; Shennan *et al*., 1999). So it is possible that there may be a technique now that we can use as an early warning system for these mega-quakes.

Tsunamis

Tsunamis (*q.v.*) are perhaps the most spectacular and frightening of the coastal effects caused by earthquakes. They are large wavelength, fast moving waves resulting from the rapid land slumps or uplifts caused by earthquakes in offshore areas. When they are in the deep water of the open ocean they are hardly noticeable but when they reach the shallow coastal regions the energy is converted to wave height, which in many cases can reach as high as 20 m. The most recently documented cases at this writing were the 1994 Java (Dawson *et al*., 1996) and the 1998 Papua New Guinea tsunamis where several thousand people were killed (McSaveney *et al*., 2000).

Tsunamis also leave highly detectable traces in coastal deposits in the form of sand layers contained in marsh or nontidal *coastal pond* sediments. However, these traces cannot be reliably separated from hurricane layers, so if both phenomena occur in the same area it could be confusing to sort out which is which. As with storm traces, the best evidence for offshore transport is the presence of marine microfossils. Many times the tsunami will leave no trace if it travels over hard substrates.

The occurrence of tsunamis is limited largely to the Pacific Rim where they can occur either very close or very far from the actual seismic event; an example of a distant catastrophic tsunami was the killing of several people and destruction caused by a tsunami in Crescent City, California (USA) resulting from the 1964 Alaska earthquake whose epicenter was several thousand kilometers to the north.

Sedimentation/erosion events

Natural changes

There are rapid events in coastal areas caused simply by rapid sediment events that may be a result of flood deposits, rapid deforestation caused by forest fires, or any type of event that changes the sediment budget in a dramatic sense to cause a shift in morphology of the coastline. In the case of a forest fire, large amounts of erosion as a result of deforestation would place sediment into *coastal inlets* (*q.v.*) causing rapid infilling or conversely, if a sediment source is reduced it can cause the shoreline to retreat rapidly in the absence of any other effects (e.g., sea level or storms).

Anthropogenic causes

By far the most spectacular rapid sedimentation events are caused by human intervention. They are almost too numerous to mention but almost every marine *delta* (*q.v.*) in the world is being influenced by sediment starvation which causes rapid land loss as the delta continues to subside with no replenishment of sediment (e.g., the Nile and Mississippi Deltas). The starvation results from dams either that trap the sediment upstream (the Nile) or diversions of the rivers, which do not allow the river to switch back and forth (the Mississippi).

Other less spectacular but damaging rapid sedimentation events are caused by careless placement of structures on the coast that impede *sediment transport* (*q.v.*) rapidly changing the balance of erosion/sedimentation.

Summary

Rapid coastal changes can take many forms; only a few of the most obvious examples are discussed here. Often the geologic record of these events is difficult to detect, especially in dynamic coastal environments, where tidal activity reworks most of the record. The records are best in nontidal *coastal ponds and inlets* where an extreme event brings in allochtonous sediment that is then sandwiched in quiet water, often organic deposits and are relatively simple to detect and date.

COASTAL CLIMATE

Three factors are important in an explanation of coastal climate. The first is the juxtaposition of two surfaces, land (or in some cases, ice) and water, of very different properties. The second is the geographic location of the coast with respect to continental masses and global-scale atmospheric and oceanic currents of air and water, respectively. The third is the topography of the coast and its hinterland. We must also take into account temporal and spatial scale issues so as to order the different aspects and to maximize our understanding of coastal climates. Scale will be used as an organizing framework in the following account.

Several useful data and information sources exist for an entrance into the topic of Coastal Climatology. One is an encyclopedia entry under the same topic name by Walker *et al*. (1987) in *The Encyclopedia of Climatology*. A second is the Master Environmental Library that is an online data source for environmental data for coastal modeling applications (Allard and Siquig, 1998).

Time and space scales

Climatologists recognize different types of climate according to their time and space scales. The local wind currents that redistribute sand around a beach sand dune and the different temperatures on the sunny and shaded side of a stand of beach grass would be in the realm of *microclimatology*. Different climates formed by the different surfaces and local climatic interactions as one might traverse the sand of a barrier island, the water of its related lagoon, the inland coastal marshes, and the forest or agricultural land of the immediate hinterland would constitute a study of *topoclimatology*. A sea breeze might penetrate inland some 75 km from the shore on a given day and would represent a phenomenon studied in *mesoclimatology*. Climatic variable value gradients parallel to the coastline are usually much steeper than those that are perpendicular to the coastline. The geography of the US Pacific Northwest (PNW), for example, gives rise to well-marked gradients in values of climatic variables both in the latitudinal (north–south) direction but also in the longitudinal (west–east) direction. This is not uncommon for coastlines that have some north–south alignment. The location of a coast in relation to global latitude, continental geography, hemispheric-scale winds and storm tracks in the atmosphere, and surface water currents in the ocean, and the state of teleconnective indices such as the Southern Oscillation and North Atlantic Oscillation, would help explain its *macroscale climatology*. The passage from micro to macroscale defines a scale hierarchy. Most scale hierarchies in Earth Sciences, including coastal climates, have at least three characteristics. First, events on the larger scales tend to set the context for those on the scale below. Second, explanation of events on one scale is best given by reference to events on the scale immediately above and below the scale and phenomenon in question. Third, at least at the lower end of the hierarchy, there tends to be a direct relationship between time and space scales. For example, ephemeral events, like an eddy in the wind, happen on small time and space scales while some other events, like a hurricane, sometimes take many days to run their course and have the potential to affect a relatively large geographic area.

Microscale coastal climates

Wind is the principal climatic variable at the microscale in coastal climates and its interaction with topographic and biologic factors has long been studied. Three factors are important at this scale. First, wind at coastlines tends to come from a predominant direction often from offshore. This has the effects of distributing sand and sand dunes in particular ways, and of sometimes shaping the vegetation canopies. The actual type of sand dune formed has been suggested to be a function of the supply of sand, the density of vegetative cover, and the average wind speed (Strahler and Strahler, 1992, p. 406). Second, the capacity of wind to carry sand is an exponential function of its velocity. Thus when wind speeds are decreased, by, for example, the presence of vegetation or a fence on a beach, then sand and other particles being transported are rapidly deposited. Vegetation and wind thus have a synergistic interaction in stabilizing sand movement. Third, typically wind velocity increases logarithmically with height. This fact needs to be taken into account when designing high-rise buildings in coastal environments. Pilkey *et al*. (1998, p. 254) have noted that at any given height pressure from the wind is greater near the shore than it is inland.

Topoclimatology

The coast, interpreted broadly, may be formed of many different surfaces including water, sand, soil, rock, and a variety of vegetated and urban surfaces. Each one of these surfaces has a different energy and moisture balance, and depending on its roughness, a different degree of momentum transfer with the atmosphere. These differences might not be too important on the topoclimate scale on a coastline with a steep cliff topped with relatively homogeneous vegetation because the climatic differences would be overwhelmed by both smaller- and larger-scale processes. However, the differences are important on a coastline typified by a barrier island, lagoon, and hinterland series on days when the large-scale wind is not too strong. The differences are important because they will form a set of distinctly different microclimates that will relate, at least, to the flora and fauna of the area.

Salt transport by wind is also important at this scale. The concentration of salt particles near the surface in coastal climates is directly related to the wind speed (Bigg, 1996). A high number of salt particles makes the coastal air very hazy. The salt particles attract water vapor and play an important role in raindrop formation. Damaging salt spray can sometimes have a pruning effect on coastal vegetation. How far inland or how high up a cliff this effect can occur is determined by wind flow and its interaction with topography on the scale in question. Soils near coasts are typically high in salts transported by wind from the ocean.

Mesoclimatology—the land–sea breeze circulation

It is the different properties of the water and land surface that ultimately lead to the land–sea breeze phenomenon—one of the most studied features of all aspects of coastal climates. The circulation is developed at mid and low latitude coasts on days when larger-scale wind systems are not predominant. Anticyclonic weather in summer time provides an ideal context. The circulation is found both on maritime and freshwater coasts. At the surface of the Earth, the land–sea breeze circulation takes the form of winds coming from water surface during the day and from the land during the night. The surface of a water body usually manifests only a small daily range of temperature. Oke (1987) has outlined the four reasons for this. Solar radiation can easily penetrate a water surface and thus heats a deep layer and not just the surface itself. Convection currents and mass transport in the water permits any heat gain or loss to be spread throughout a large volume of water. Evaporation from the water surface cools the water surface and helps promote vertical mixing within the water itself. Water has a high thermal capacity compared with soil and thus takes about three times the amount of heat to raise its temperature by 1°C as for the same volume of soil. Thus there is a reduced flow of sensible heat from the water surface to the air compared with that over the land during the day. This leads to a reduced warming rate of the air over the water compared with that over the land surface. As described by Oke (1987), greater sensible heat flow over the land in the morning heats the air columns more rapidly and to greater heights than over the water. The atmospheric pressure well above the surface of the land is higher than at the same level over the water. The resulting horizontal pressure gradient results in airflow at upper levels toward and out over the water surface. This flow ultimately produces a higher atmospheric pressure at the surface over the water that, in turn, forms a cross-coastline flow of air from the water to the land. This surface level flow is known as the *sea* or *lake breeze*. The *land breeze* starts in the evening because of the greater contraction and cooling of the air columns over the land compared with the sea.

Oke reports that the daytime sea breeze circulation has greater vertical and horizontal extents and larger wind speeds than the land breeze because it is driven by solar forcing. Typically, the sea breeze might have a velocity of 2–5 m/s, a depth of 1–2 km, and extend inland as far as 30 km. The land breeze characteristically has a velocity of 1–2 m/s and a smaller extent than the see breeze. If the sea breeze is forming in a location where there is cold upwelling water, then the air formed over this water may be cool enough to continue the sea breeze circulation all through the night and not have a land breeze develop at all.

The sea breeze brings with it air that is cooler and more humid than the air found over the land. This cool air plows underneath the warmer air over the land and forms a localized cold front known as a *sea breeze front*. The sea breeze front gradually advances inland during the day and is associated with the development of sea breeze cumulus clouds. These clouds are often taken by the counter (seawards) flow above the surface and dissipate because they are decoupled from their moisture source. Purdom (1976) showed that some parts of the front displayed higher concentrations of convection than in others. He found that the shape of the coastline in some places created stronger upward vertical velocities. Kingsmill (1995) documented for summer months the collision of a sea breeze front traveling from the east side of the Florida peninsular with a gust front traveling from the west. Interestingly, he found that convective activity was most prominent just prior to the collision of the two fronts rather than at the time when the two collided. Oke (1987) has suggested that if the sea breeze travels far enough inland then the influence of the Coriolis force will affect its direction and the breeze will end up traveling parallel to the coast. A fairly deep penetration of the sea breeze front inland was observed in April 1999 at Wokingham, which is 75 km inland from the southern coast of England. The passage of the front was accompanied by an increase of the dew point temperature of 4°C and a change of wind direction from 70° to 210° (Burton, 2000).

The climatology of sea (lake) and land breezes is highly variable depending on the particular location being considered. A 15-year study of Lake Michigan found that lake breezes tend to occur more frequently along the eastern shore of Lake Michigan than along the western shore (Laird and Kristovich, 1998). In addition, there was a gradual increase in the number of lake breeze events from May through August, then a slight decrease into September. The distribution of the frequency of land breezes is similar to that of the lake breezes from May through September, however, they occur about 10% less often than the daytime lake breeze circulation. Typically, sea breeze activity is observed on the south coast of England on 75 days during the year (Burton, 2000).

The land–sea breeze circulation has many practical implications. Oke (1987) quotes one study in which tobacco leaves near the coastline of Lake Erie were damaged by ozone that had been formed over the lake from lakeshore city pollutants and then transported back over the shore and tobacco crop by the lake breeze. In another study, quoted by the same source, blister rust disease impacted pine trees 15–20 km from the Lake Superior lakeshore. This impact was thought to be due to spores from bushes located between the diseased trees and the lake and transported out over the lake at night, back aloft by the counter airflow of the land breeze, and then descending upon the pine trees. Michael *et al.* (1998) showed that during spring and summer, sea breeze circulations can strongly influence airport operations, air-quality, energy utilization, marine activities, and infrastructure in the New York city region. Here, the investigators found the geographic configuration of region presents a special challenge to atmospheric prediction and analysis. The New Jersey and Long Island coasts are approximately at right angles to each other; additionally Long Island Sound separates Long Island from the mainland of Connecticut. The various bodies of water in the region (Atlantic Ocean, Long Island Sound, New York Harbor, Jamaica Bay, etc.) have different surface temperatures. In addition the urbanization of the New York area can modify atmospheric flows.

Apart from land–sea breeze phenomena mesoscale wind fields in general are very important in influencing the coastal and coastal ocean processes. Considerable attention is being given, for example, to the effect of wind on driving and directing freshwater plumes from rivers entering the ocean. This has many implications for cross continental shelf transport (Lohrenz, 1998).

Macroscale climatology

The location of the coast in the world determines in large part its overall climate. A first order classification of coasts on this scale would include tropical windward coasts, tropical leeward coasts, mid- and high-latitude windward coasts, mid- and high-latitude leeward coasts, and ice-influenced coasts. Each of these categories would be modified according to whether or not the hinterland of the coast contained mountains. Examples of climate data from such categories are given in Table C8. Walker *et al.* (1987) quote other ways of classifying coastal climates.

Under the classification suggested here the extremes for high precipitation are seen in the tropical and mid-latitude windward coasts with mountains such as, respectively, on the island of Maui and other islands in Hawaii, and the PNW of the United States. In the case of the north coast of Maui, Hawaii, onshore moist tropical air is lifted up and cooled against the mountains giving rise to some of the world's highest precipitation values. Similar orographic effects occur at the coast of the PNW but here it is moist, mid-latitude Pacific air that is uplifted often during mid-latitude storms, which provides intense precipitation. The extreme for low precipitation is found on tropical coasts on the western sides of continents, as for example, on the coast of Peru. Air flows down the mountain sides of the Andes mountains in Peru and northern Chile and thus is warm and dry when it reaches the coast. More importantly this coastline, and others in this category, has a cool ocean current offshore. Upwelling of cold water gives rise to fog that is often the only source of precipitation in this climate. Ice-ocean boundaries are not considered to be coastlines by some (Walker *et al.*, 1987) but since they form a distinctive interface on the Earth's surface they will be briefly mentioned here. Thus the "coasts" with the lowest temperatures are those formed by the meeting of ice masses and the sea such as the Greenland and Antarctic ice cap coasts. Such coasts are often marked by strong, katabatic winds blowing from the ice cap. Katabatic winds are winds formed from cold, relatively dense air flowing down a topographic feature. The climate of the other categories of coasts is intermediate between the extremes described here.

One of the most important features of coastal macroclimate is the storm. Both tropical storms (hurricanes) and mid-latitude storms or cyclones heavily impact the geologic, biologic, and human dimensions of a coast. Sometimes it is the presence of the coast itself that helps cause or enhance the storms. Cyclogenesis is enhanced, for example, at the east coast of the United States as upper-level disturbances cross the Appalachian mountains and then cross the strong baroclinic zone of the atmosphere near the coast. At the coast, the cyclones flow parallel to the landmass in winter and a strong cooling of air on the landward side leads to the formation of macroscale fronts (Rotunno, 1994).

Considerable time is spent researching the frequency and magnitude of coastal storms. Waves generated by mid-latitude storms, for example,

Table C8 Climate data for selected coastal areas

are responsible for much of the coastal erosion that occurs along the Atlantic coast of the United States. Dolan *et al*. (1988) found that at this location, the five-month period December through April had 63% of all the storms for the area. They also found a systematic increase between 1942 and 1984 in the number of storms occurring in May and October resulted in the lengthening of the storm season and a more abrupt transition between the winter and summer storm regime. The authors were able to construct a map of the mean cyclone track and frequency of all the mid-latitude storms in their data set that produced significant waves at Cape Hatteras. The storm track runs Southwest to Northeast following the coast of the Carolinas and continuing out to sea at Cape Hatteras. Locally the storms following this track are called Nor'easters and they often do considerable damage to the coast. The secular variation of such storms is very important. Hayden (1981) discovered that in the early years of the 20th century there was a trend toward increased cyclone frequency over marine, as opposed to continental, areas of the Atlantic US coast. He also found decadal changes in coastal cyclogenesis with a maximum in the record up to 1978 occurring in the 1950s.

It is possible that decadal changes in the frequency of storms whose predominant wind directions is different can lead to marked geographic effects. At Hog Island, Virginia there is a clear dynamic coastline change pattern: erosion occurs on the north when accretion occurs on the south, or *vice versa*. This kind of cyclic process of coastline changes may repeat every 190 years on Hog Island. Currently, the southern part of Hog Island just ended the erosion processes, while the northern part just ended the accretion processes. It is hypothesized that the changing geography of the island on this timescale may be related to the frequency of storms that either have winds with a predominant northeasterly or southeasterly component.

Damage to coasts is also done by Tropical Cyclones that go by different names in different parts of the world—hurricanes, for example, in the Atlantic and typhoons in Southeast Asia. For a tropical cyclone to be called a hurricane there must be a sustained wind of 33.5 m/s (75 mph) or more. Such systems can have diameters exceeding 300 km. Very large typhoons in the western North Pacific can have diameters up to 3,000 km and are sometimes called super-typhoons. Hurricanes are placed into five categories in the United States. Category 1 has wind speeds of 119–153 kph; category 2, 154–177 kph; category 3, 178–209 kph; category 4, 210–249 kph; and category 5, has wind speeds in excess of 249 kph. In the following discussion, I will use the term hurricane as being synonymous to tropical cyclone.

Hurricanes are features of coastal climate mainly during the late summer and autumn seasons since they depend upon high Sea Surface Temperatures (SSTs) as one factor in their initial formation. Hurricanes impact the tropical, subtropical, and mid-latitude coastlines that are mainly on the east coasts of continents or coasts that face south in the Northern Hemisphere and *vice versa*. Hurricanes usually weaken after passing the coastline and moving inland because they depend upon the warm moist ocean surface for their energy. Besides high winds the storms are noteworthy for bringing large quantities of rain to the coast. Sometimes tornadoes are spawned as well. Hurricanes represent an interesting interaction between meso- and macro-climatology since their formation and track once formed is often a function of the macroscale features such as upper atmosphere wind fields. Much coastal damage is done by the interaction of the hurricane with the ocean. The resulting formation of storm surges brings extra high flows of ocean water over the coastline. The storm surge of a category 5 hurricane could be 5.5 m (18 ft) above normal sea level.

As with mid-latitude cyclones, interdecadal variability in frequency is well marked in hurricanes. Hurricane frequency in the Atlantic decreased from the 1890s to the 1920s and 1930s, increased during the 1940s to 1970s, and then decreased in the last part of the 20th century

(Riehl, 1987). The latter decrease coincided with the development of much coastal property in the Southeastern coast of the United States.

Ice-influenced coastlines have their own interesting climatological features besides the katabatic winds already mentioned. An interaction between macro and mesoscale events gives rise to strips of open coastal water surrounded by ice-covered ocean. The open water areas are called polynyas and they typically open and close over the time period of a few days. They are partly formed by coastal winds pushing the ice offshore and are associated with a complex set of water and atmosphere density and flow interactions (Chapman, 1999). The polynyas, sometimes called leads, are large sources of sensible heat to the atmosphere in winter with heat fluxes locally exceeding 500 W/m^2. In summer, the comparatively low albedo of the open water compared with that of nearby ice allows the absorption of solar radiation that warms the water. The fractional lead coverage in the Arctic Ocean as a whole is 1% in winter and greater than 20% in late summer (Curry and Webster, 1999).

There are also phenomena of dynamic climatology existing where coastlines are backed by mountain areas. Rotunno (1994) describes how Kelvin waves may propagate along the basin-wall-like sides of an ocean basin such as at the Pacific coast of North America. Here also strong alongshore jet streams have been documented as a result of the mountains. Phenomena that appear similar to flow separation in classical fluid dynamics have been found to occur in the lee of capes and other coastline salients.

Temporal climate variability in coastal climates

All coastal climates are subject to climate variability on a variety of timescales. The presence of the ocean water has a moderating effect on the climate of the nearby land at all the timescales. Climate variability at coastlines is therefore usually less than that in interior continental landmasses but can still be significant especially at the longer timescales. We may examine an example from the PNW of the United States to demonstrate the kinds of climatic variability that can occur at, or near, a coast over a variety of timescales.

Major changes in the climate of the PNW from glacial to interglacial have been described by Worana and Whitlock (1995). The extreme glacial climate, a little inland from the coast, had a mean annual temperature that was likely to have been 7°C lower than today with the January temperature 14°C lower. Conditions were also probably drier than today with the Polar Front jet stream flowing well to the south. After the last retreat of the ice the climate was warmer. Between 10,000 and 5,600 BP (Early Holocene) temperature is believed to have increased and effective moisture decreased as summer droughts became a climatic feature associated with an expansion of the subtropical high pressure in the eastern Pacific Ocean. On the next timescale down, some cyclic coastal climatic behavior has been suggested. Sediment cores from anoxic basins reveal a 60–70-year cycle of warming and cooling over the past 1,500 years (US GLOBEC, 1994). The last cycle in this pattern, which ecologically is associated with sardine dominance over anchovy and *vice versa*, is seen with warming around 1925, cooling at 1948, and a return to warming about 1977. Ware and Thompson (1991) regard the 60-year cycle in Southern California data as being consistent with their belief that pelagic fishes are responding to a 40–60-year oscillation in primary and secondary production that, in turn, is being forced by a long-period oscillation in wind-induced upwelling. Trenberth (1993) reviews coupled General Circulation Model (GCM) output and suggests, under current projections of CO_2 increase, the western coast of North America is expected to warm by about 1.0–1.5°C by the year 2030 and that northern regions will warm more rapidly than southerly regions. The hydrologic cycle is expected to intensify by about 10% leading to greater amounts of evaporation and precipitation. Trenberth (1995) has also suggested that the relative frequency of the El Niño mode in the past decade "may well be one of the primary manifestations of anthropogenic global warming." There are also interdecadal scale variations in PNW coastal climate. Mantua *et al.* (1996) described a Pacific Decadal Oscillation (PDO) in SSTs that has many implications for salmon production. It has been shown that the PDO manifests itself in coastal climate by giving rise to four distinct climatic periods. The periods are 1896–1915, wet and cool, 1915–46, dry and warm; 1947–75, wet and cool; and 1976–94, dry and warm. The dominant source of variation on the quasi-quintennial scale is related to the El Niño–Southern Oscillation (ENSO). Low Southern Oscillation Index (SOI) values (El Niños) are correlated with reduced precipitation (Redmond and Koch, 1991), snowpack and streamflow in the PNW (Cayan and Webb, 1992). The PNW also tends to display warmer winter temperatures and drier than usual winters under El Niños conditions (Redmond and Koch, 1991). At the opposite end of the oscillation Kahya and Dracup (1993) are among several investigators to demonstrate that high precipitation and high streamflow values in the coastal PNW are often associated with La Niña years. Superimposed on ENSO-scale climatic variability is the variability on the interannual and shorter timescales such as the passage of individual mid-latitude cyclones and anticyclones.

Future research

There is an unlimited amount of work to do on coastal climates. Working through the scales we may suggest the following areas of important research. First, it would be interesting to document the differences in the surface energy budget values across the different surfaces of the subcomponents of the shoreline—barrier island, marsh, lagoon, etc. Second, it is important to find out what are the interactions between the mesoscale and macroscale events with respect to coastal climates. How, for example, do sea breeze fronts affect other weather systems occurring inland? Much more has to be found out about the effect of varying SSTs on weather systems passing over them. This is particularly the case where SSTs show a large range of different values over a short distance. The Gulf Stream ocean current and areas of coastal upwelling water are cases in point. There are many local dynamic features that need investigation such as the trapping of atmospheric waves under marine temperature inversions and low-level coastal atmospheric jet streams. Interdecadal variation in the climatic variables of coastal climate must be established and, if possible, explained. This is important because of the huge amount of coastal development that has happened and will continue to occur worldwide. Finally, the affect of potential global climate change on coastal climates over the next 100 years must be studied. This topic has not received too much attention so far because the global climate models tend to operate at a coarser spatial scale than one that allows a coast to be specifically considered.

COASTAL CURRENTS

Introduction

Coastal currents are coherent water masses in motion that are found in the region between the coastline and the edge of the continental shelf. Coastal currents are important because the coastal zone is the place where most nutrients, pollutants, and sediments are introduced into the ocean, and where most larvae are generated and dispersed. Coastal currents are responsible for the transport and dispersal of these biological, chemical, and geological tracers in the water. For example, predictions of the advection and diffusion of spilled oil is dependent upon knowledge of the currents near the coast. Coastal currents often are considered as being made up of two components, alongshore, or parallel to the coast, and cross-shore, or perpendicular to the coast. Away from the influence of inlets or river mouths, cross-shore flows are typically weaker than alongshore flows, yet the larger gradients in cross-shore properties make the cross-shore flows better at redistributing those tracers. In addition, if a current is periodic, such as a tidal current, even though it may be quite strong, it may not result in significant net transport. A non-periodic event-driven current such as from a storm may result in a significant net transport. Some currents that are persistent and result in significant transport of water are named after an adjacent landmass, such as the California Current and the Kuroshio Current. In general, currents are classified by the processes that form them (Wright, 1995). Some of the most important currents that exist near the coast outside of the surf zone include (1) wave-driven currents, (2) tidal currents, (3) wind-driven currents, and (4) buoyant plumes.

Types of coastal currents

Wave-driven currents

Periodic water particle movements are associated with the passage of wind-generated surface gravity waves. The back and forth currents due to waves have a relatively short period, up to about 20 s. The horizontal orbital velocity of water motion is a function of wave amplitude, wave period, wavelength, and water depth (Komar, 1998). According to linear wave theory, the water motion under waves in deep water is circular, with horizontal motions being comparable to vertical motions. The diameter of the circular motion decreases exponentially with water depth, so that in deep water, the influence of the surface wave can no longer be felt. In intermediate water depths the motions are elliptical, becoming smaller and flatter as the bottom is approached, and in shallow water the water motions are back and forth. In deep water, where linear wave theory is best applied, there is no net transport of water due to the passage of a wave. In shallow water, however, linear wave theory breaks down. According to nonlinear Stokes theory, the velocity magnitude is increased and the duration shortened under the crest of the wave, and the velocity magnitude is decreased and the duration lengthened under the trough. The result of this asymmetry in orbital motion is a non-periodic current, or mass transport in the direction of wave propagation, which is called Stokes drift. This mean current can be large for large amplitude and short period waves, but is a small fraction of the instantaneous wave speed, only a few centimeters per second for long period swell.

Tidal currents

Tides and tidal currents in the ocean basins are produced by the interaction of a rotating earth with the gravitational forces of the moon and the sun (see *tides*) (Mofjeld, 1976; Bowden, 1983). These oceanic tides impinge on the continental shelf and produce sea-level oscillations and currents in the coastal zone at tidal frequencies. The dominant fluctuations are either semi-diurnal (twice a day), diurnal (once a day), or a combination of the two. For example, on the East Coast of the United States the tides are semi-diurnal, whereas on the Gulf Coast they are diurnal. The difference is due to the interaction between the forcing and the natural frequencies of the tidal basin. Most coastal environments also have longer variations in the tides and tidal currents with periods of about two weeks. These fortnightly variations result in stronger spring tides and weaker neap tides. Tidal heights (up to a few meters) and tidal currents (up to several tens of centimeters per second) are periodic, thus they result in little net transport, despite excursions of several kilometers per tide. The horizontal component of tidal currents on the continental shelf tends to change direction and amplitude during each tidal cycle. An arrow denoting the current's speed and direction would trace an ellipse with each tidal period. If the direction of the current is restricted by a boundary, as near a coast, then the ellipse will become more elongated, with the long axis aligned parallel to the coast. The speed of a tidal current may increase when the current goes around a headland, passes through a restriction, or passes from deeper to shallower water.

Wind-driven currents

The drag of the wind on the sea surface results in the formation of waves and in the generation of a surface current. The wind-generated current is strongest at the surface and decreases with depth. The magnitude of the surface current depends on the wind speed and on the roughness of the sea surface due to waves, which effects the transfer of energy from the wind to the water. Based on field observations, the magnitude of the surface current is approximately 3% of the wind speed and the direction of the wind-driven current is nearly aligned with the direction of the wind, but not exactly. Due to the rotation of the earth, the Coriolis force causes the wind-generated current to veer to the right of the wind in the Northern Hemisphere and to the left of the wind in the Southern Hemisphere. Various theories predict that the surface current will be directed between 10° and 45° to the right (left) of the wind in the Northern (Southern) Hemisphere, and that the current vector will rotate further to the right (left) with increasing depth below the surface. This rotating current direction and decreasing speed with depth is known as the Ekman spiral. The total transport averaged over the entire Ekman spiral is at right angles to the direction of the wind and is known as Ekman transport. The turning of the upper layer is reduced, however, in shallow water where the water depth is less than the Ekman depth.

Upwelling and downwelling circulation

When the wind blows parallel to the coast and the wind-driven Ekman transport is away from the coast, then the water near the coast will set down causing a lowering of sea level. The sloped sea level will induce an onshore-directed pressure gradient, which when balanced against the Coriolis force will lead to a shore-parallel geostrophic flow in the same direction as the wind beneath the surface Ekman layer. In addition, water near the coast will rise, or upwell, to replace the surface water that is transported offshore. Upwelling circulation is very important because it brings cold, nutrient-rich water from depth to the surface, which can enhance biological productivity. Many of the largest producing fisheries in the world occur in regions of coastal upwelling. Downwelling flows result when the wind is in the opposite direction, causing onshore-directed surface Ekman transport. In the downwelling case, sea level rises against the coast as surface waters are brought from offshore to onshore. In some cases, there can be an interaction between the shore-parallel wind-driven flow and the upwelling or downwelling waters that enhances the coastal flow. As an example, Korso *et al.* (1997) described how cold upwelled water along the coast of Oregon and southward-directed wind-driven surface currents interact resulting in an increased coastal jet occurring along the upwelled front.

Buoyant plumes

Currents arise in the coastal ocean from the flow of freshwater out of rivers and estuaries. Currents result from both the difference in the height of the water between the river and the ocean and from the density difference between the fresh water and the salty ocean water. Upon entering the ocean, the positively buoyant plume will spread laterally on top of the ocean water and thin. After leaving the confines of the river or estuary, the plume will also be acted on by the Coriolis force. The degree of turning of the plume due to the earth's rotation depends on the width of the river mouth, the thickness of the plume, and the Coriolis parameter, which varies with latitude (Garvine, 1987). The boundary of the plume where the water density changes rapidly is known as a front. Fronts are important because they mark zones of flow convergence. Plume currents can be affected by existing tidal currents and by the wind. For example, Stumpf *et al.* (1993) observed a buoyant plume move at speeds of up to 11% of the wind speed. The enhanced speed of the plume relative to normal surface drift is due to reduced friction between the buoyant plume and the underlying ocean water.

Coastal currents and boundaries

Regardless of their origin, coastal currents are effected by their proximity to a boundary, either the seafloor or the atmosphere. Boundaries tend to modify ocean currents through the action of friction. The regions, or layers, in which currents are modified are called boundary layers. Boundary layers near the bed and near the surface can be 5–20 m thick, so on the inner and middle continental shelf, the dynamics of the boundary layers can make up a significant percentage of the water column. In the bottom-boundary layer the flow depends not only on the near-bottom current, but also on the presence of surface gravity waves. This *wave–current interaction* (*q.v.*) tends to modify the near-bed flow. Currents in the bottom-boundary layer can also be complicated by the presence of density stratification and bed morphology (see *Shelf Processes*).

In a narrow zone immediately adjacent to the coast, nearshore currents result when wave asymmetry and breaking cause significant mass transport of water in the direction of the shore. Important nearshore currents include undertow, rip currents, and longshore currents (Komar, 1998) (see *Surf Zone Processes*).

At the outer boundary of the coastal zone, open-ocean currents flowing along the continental slope can at times influence coastal currents. For example, ocean currents such as the California Undercurrent off the US west coast can influence shelf currents by impinging onto the shelf, by entraining water from the shelf, or by inducing flow on the shelf through pressure gradients between the two water masses.

Measurement techniques

Ocean currents are studied experimentally, through field measurements, and theoretically, through the use of mathematical models. Currents are measured with a variety of instruments, including mechanical rotor-type, electro-magnetic, and acoustic current meters. The choice of which current meter to use depends on among other things the environment in which the measurements are made. In the surf zone, currents are typically measured by mounting electro-magnetic current meters to fixed poles jetted into the bottom. Divers deploy the current meters and the data are logged in real-time through a cable to shore. Shelf and slope currents are measured using current meters on a mooring with a weight on the bottom to anchor the mooring in place and a float at or near the surface to hold the mooring vertical. Alternatively, current meters are placed on a tripod, a pyramid-shaped frame that sits on the bottom. Current meters deployed on the shelf and in deeper water are self-contained, requiring an underwater power supply and data acquisition system to store the data until the instrument is recovered. In the past decade acoustic current meters that provide a profile of currents through the water column, as opposed to at a single point, have been used extensively to provide detailed information on coastal currents.

COASTAL HOODOOS

Introduction

Hoodoo is a descriptive and collective term used by Thornbury (1969) to describe such topographic forms as columns, pillars, and toadstool rocks of bizarre shapes. He recognized that differential weathering helped to develop and modify such outstanding topographic forms. In Bryan's study (1925), he also concluded that those he studied in the southwestern United States were chiefly the work of rainwash plus effects of mechanical and chemical weathering. Basically, the term bears no genetic meaning, but was used as a descriptive term to describe those small landform features of odd shapes. Hoodoos occur in various environments and are associated with many different types of rocks. Previous studies of such hoodoos indicated that differential weathering almost always played an important role in sculpturing their forms. Hoodoos often became a scenic attraction rather than a geologic subject to be appreciated by visitors. Near Tuscon, USA, on the way to Mt. Lemmon, from Windy Point to Geology Vista, highly weathered granitic rocks display hoodoos by the roadside. The place became a vista point and the hoodoos became an attraction for visitors to stop and take pictures. Actually, wherever hoodoos were found, whether they occurred in deserts, on coastal platforms, at the edge of highly dissected terrain or at riverbanks, they often became a site for visitors' appreciation. They are almost always recognized as earth's miracles and definitely as earth's heritage sites. In this regard, hoodoos are more of an artistic and aesthetic subject than a geological phenomenon.

Coastal hoodoos are relatively well studied. Trenhaile (1987) and Ollier (1984) described in detail the processes that caused the formation of hoodoos on coastal platforms and other coastal environments. Trenhaile pointed out that salt weathering which includes hydration, thermal expansion, and crystallization of various salts are important to form such features as tafoni and honeycombs.

He also pointed out that honeycombs are best developed in the zone above the level of normal wave action, but that periodically experiences heavy spray and splash during stormy weather. Bartrum and Turner (1928) first drew attention to the lowering, smoothening, and leveling of inter-tidal rock platforms by weathering processes apparently associated with pools of standing water. Water layering weathering includes alternate wetting and drying (slaking), salt crystallization, and many other chemical weathering processes. Collectively, they serve as a delicate process to sculpture hoodoos. Case hardening which often accompanies water layer leveling on platform surface often causes the formation of boxwork or frame-like patterns and weathering pits, which have raised rims. Some pits resemble miniature volcanoes with water-filled craters (Ollier, 1984). He described elevated pits from Cape Patterson, Victoria as follows: "Small pits are filled by the tide or by rainwater and this keeps the immediately surrounding rock wet, while the platform around is reduced in height by wetting and drying. Eventually the pits comes to be like a miniature volcano with the crater filled with water and so kept wet, rising above a miniature plain which occasionally dries out." Other papers which described water layer weathering and salt weathering include Evans (1970), Gill *et al.* (l981), Goudi (1993), Mustoe (1982), Wellman and Wilson (1965). Pedestal rock is another type of hoodoo often seen in the coastal environment. Pedestal rocks are mushroom-like rocks, which are projections of solid bedrock formed by flaking and hydration in a desert environment (Ollier, 1974). Ollier also described pedestals from Cape Patterson, Victoria, and indicated that they were formed by blocks of arkose resting on a coastal mudstone platform. Hills (1971) described similar features formed by a fallen block lying on a platform and others formed by large calcareous concretions that now stand on pedestals above a water-layer lowered platform surface.

Hoodoos in Yehliu, Taiwan

Such hoodoos, including elevated pits, pedestals, tafoni, honeycombs, and others are well developed in the Yehliu Scenic Area in Taiwan. These hoodoos were studied by Hsu (1964), Lu (1978), Wang and Lee (l984, l994), Hsu (l988), Hong and Huang (2001).

The most abundant hoodoos in Yehliu are pedestals, which are locally called mushroom rocks. One of the pedestals looks like a western queen's head and was called the Queen's Head (Figure C22). Next to the pedestals is a layer with many Ginger Rocks, which are stand-up calcareous concretions originally occurring in a thin bed (Figure C23). It is quite significant for so many concretions, widely distributed, but limited to a bed of less than 1 m. This thin bed is the key bed that can be used for tracing and correlation of sedimentary strata. Candle Rocks are lower in the sequence stratigraphically (Figure C24). They belong to another sandstone bed with randomly distributed concretions. Concretions exposed often led to the formation of elevated pits after uplifting and erosion. Furrows developed around the concretions, which were filled with water frequently. Surrounding the furrows is a zone of hardening which became relatively raised. After further uplifting, the Candle Rock becomes higher and an apron-like fringe area developed gradually. As a whole they are elevated pits as described by Ollier (1984). The size of the Candle Rocks found in Yehliu may reach a height of 1.5–2.0 m, and a diameter of 2 m.

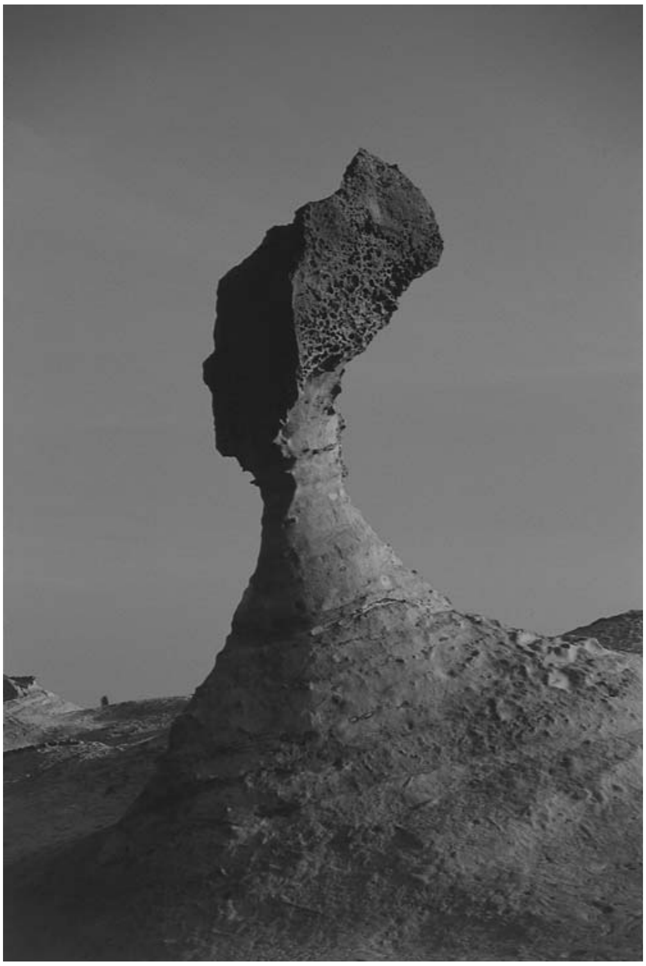

Figure C22 Queen's Head, a pedestal rock.

Figure C23 Ginger rocks, which are concretions stand out after lowering of adjacent ground.

Geology of the pedestal rocks in Yehliu, Taiwan

The Yehliu coastal scenic area is located approximately 15 km to the northwest of Keelung City, Taiwan. The area is a promontory, approximately 1.5 km long and only about 400 m wide. Part of the promontory is so narrow that it is actually penetrated by sea caves or narrow openings along joints.

Strata exposed in Yehliu area are mainly bedded sandstone of Miocene age. These tilted strata strike N40E and dip at an angle of

Figure C24 Candle rocks, which are elevated pits as described by Ollier (1984). At the very center is a concretion.

18°–22° to the SE. The strata can be subdivided into eight units based on their lithological and morphological characteristics. Many sandstone beds are calcareous and rich in concretions. Pedestal rocks are mushroom-shaped, with a resistant head rock supported by a neck rock made of an underlying, less resistant rock. In general, a pedestal rock is 1.5–3 m high and composed of a head, a neck, and a base. The spheroidal head is 1.5–2 m in diameter and honeycombed. The neck, instead, is smooth-surfaced and thinner than the head. The distribution of the pedestals is clearly lithologically and stratigraphically controlled. They form a parallel and linear array regularly arranged on the tilted shore platform. The thin, calcareous sandstone bed in which the pedestals occur is tilted and protected from direct wave attack by another set of sandstone beds, which form small ridges. From top to bottom the upper rows of pedestals are about 2–4 m above sea level, and the lower pedestals are just above the sea level. The same sandstone bed exhibits no signs of pedestal development under the sea surface. A closer look at the pedestals clearly reveals that these pedestals start to develop once they left the sea surface. Gradually they became separated blocks to form pedestals with no neck, then with a thick neck, and then with a thin neck. Finally the neck broke, the head fell and the pedestal's life ended. The plane which connects the top of the pedestals inclines at an angle of 17°–20°, whereas the surface (actually the shore platform) which connects the bottom of the pedestals has an inclination of about 11°–13°. This is another indication that pedestals grew taller and higher as the shore platform was weathered lower. Those parts that rose above the sea earlier were weathered more. The pedestal rocks, which are higher in elevation, are taller and usually have a thinner neck. Those that stand lower are short and have a massive neck. The height of the pedestals are 1.5–3 m. The tallest is about 3.5 m. The diameter of the head may reach 1.6 m. The spaces between the pedestals average to a distance of 2–3 m. The total number of pedestals is about 180.

Owing to weathering of the calcareous sandstone, the surface crust of the head is dark colored compared to other parts of the pedestal and to those parts of the same bed below the sea level. Gauri (1978) gave a good explanation of the weathering process which formed such a dark-colored crust on a lime-rich rock.

Physical properties of the head and the neck of the pedestals are studied both in the field and in the laboratory. As a result of various means of mechanical tests, such as the Schmid Hammer Test, Slaking Durability Test, and Point Load Test, it is known that there is a difference in the physical strength of the different parts of the pedestals. The head of the pedestals is of much greater strength than the neck.

Water absorption by the head is also slightly lower than the neck, which indicates that the neck rock may have more open crevices that allow water to penetrate.

Microscopic study of thin sections of rock specimens from different parts of the pedestal also reveal important information. The head rock is composed of well-sorted quartz grains cemented mainly by calcite. The neck rock is composed of less well-sorted quartz grains but cemented by calcite and iron minerals. Thin-section study of the surface crust of the head rock, which is darker in color and honeycombed, indicates an enrichment of calcite and clay minerals as cemented materials (Wang and Lee, 1994; Hong and Huang, 2001). The result of microscopic study again supported the interpretation by Gauri (1978).

Wang and Lee (1984, 1994) in their study, concluded that differential weathering, including alternate wetting and drying, salt crystallization and other chemical processes accompanied by uplifting and erosion are responsible for the formation of the pedestals. Based on coral reef dating, estimated uplift rate of the area (about 2 mm/year), elevating of the red oil-painted safety markers on the platform (which is about 1–4 cm above the adjacent ground, and the first time the park placed the paint is about 50 years ago), and other evidences such as the height and the spacing between the pedestals, Wang and Lee (1984, 1994) estimated that the age of the pedestals is not more than 4,000 years since their first appearance above the sea level.

Weathering in the Coastal Zone

COASTAL LAKES AND LAGOONS

Description

Coastal lakes and lagoons are bodies of water occurring in topographic depressions (basins) that are separated from the sea by narrow barriers of land. A range of coastal water bodies exists from areas totally encompassed by land to areas primarily exposed to the sea. The enclosed features, which are primarily shielded from the sea, are called coastal ponds and lakes. Bodies of water with outlets to the sea are called coastal bays and lagoons depending on their shapes. Oertel (1985) called these features *barrier* lagoons because of their association with coastal barriers. In general, coastal lakes and lagoons form secondary coastlines behind the main ocean coastline. The interior shores of these secondary coasts are shielded from direct exposure to ocean waves.

Formation

Coastal lakes and lagoons are a natural result of barrier formation. The formation of coastal barriers causes separation of the coastal ocean from an inland body of water. The diversity of water-surface configurations of "coastal barrier water bodies" is caused by variations in basin and barrier formation. The formation of basins and barriers in the coastal zone is influenced by both marine and terrestrial processes. Sea-level rise is a third factor influencing the formation of basins and barriers. The three main processes of barrier formation that produce coastal water bodies are upbuilding of shoals and bars (de Beaumont, 1845), embayment of interior shores by spit progradation (Gilbert, 1885), and inundation of lowland areas by sea-level rise (McGee, 1890).

Drainage basins and interfluves form irregular topography with contrasting elevations. Rising sea level inundates the lowland areas and leaves the interfluve areas emergent. The distal ends of interfluve areas (necks) are called headlands. Headland shores are often seaward of an inundated shore forming an irregular coastline. Gilbert (1885) illustrated that sediment eroded from headlands moves laterally along the shore. The direction and nature of migration determines the type of secondary landforms that may be developed. The lateral transport and deposition of beach materials onto primary landforms may simply result in the development of broader beaches. Aggrading beaches may advance across smaller headlands or small stream valleys. These features are called barrier beaches and when they block stream drainage to the sea, the resulting water bodies are coastal ponds or coastal lakes.

The creation of coastal ponds is totally dependent on the relationship between the aggradation rate by littoral processes and the flushing rate by stream discharge. Along a given reach of shore the littoral drift of material may vary considerably. Aggradation is related to sediment supply and wave-driven longshore current discharge. Low littoral sand-transport loads may be flushed easily from small channels. However, high-load currents may fill even relatively large channels. The flushing ability of a channel is related to the volume of water that is moved through the channel. At tidal inlets, the discharge through a channel is controlled by basin size and tidal prism. Thus, inlet flushing and inlet filling are governed by characteristics of both the terrestrial and marine environments.

Coastal lakes

There are two principal groups of coastal lakes: coastal barrier lakes and "cats-eye" ponds. *Coastal barrier lakes* occur in small drainage basins that have been dammed-up by littoral drift. The supply of sediment for littoral drift on the Atlantic Coastal Plain of the United States is variable, but the main sources are from reaches of shore between major rivers and estuaries (not the rivers and estuaries). Although these reaches of shore may not extend out into the ocean, they are often called headlands because of their distal position at interfluves between river systems. Barrier lakes are most common where small drainage basins occur adjacent to broad, high headland areas where there is abundant littoral drift to block the drainage to the sea.

The shapes of lakes and orientations of lake shorelines are principally controlled by antecedent topography. Since coastal lakes are water bodies occupying inundated drainage basins, their shoreline orientations and lake shapes are controlled by the hypsometric relationships of v-shaped drainage basins and sea level. Since most basins slope seaward, the deeper and broader parts of the lakes are at the seaward sides of lakes. In plan view, this gives lakes a generally triangular or delta (Δ) shape, with the apex of the triangle pointing landward and the base of the triangle along the seaward shore. During flooding of some basins, only the steep "thalweg" sections of streams are initially flooded, and therefore these barrier lakes are linear in shape.

Since coastal lakes have no access to the coastal ocean, the only source of salt-water intrusion into coastal lakes is through the porous sediment along the seaward shore of the lake. However, lake water levels are generally above sea level and hydraulic-head differences cause groundwater seepage from the lakes toward the coastal sea rather than a flux from the ocean to the lake. Therefore, coastal barrier lakes are generally fresh, although occasional overwash or tidal pumping can produce ephemeral periods of low salt concentrations.

Cats-eye ponds are another type of coastal lake. They are given their name because of their lenticular shape like a cat's eye. Cats-eye ponds are generally smaller than coastal barrier lakes. They occur in the immediate proximity of the shore in beach and dune environments. They are bodies of water trapped in relatively young secondary landforms. The dynamic nature of the shore makes these features relatively ephemeral.

Cats-eye ponds have two general modes of formation. One mode involves beach spits and the other involves dune ridges. Beach spits occur at curves in high-water shorelines that produce small beach headlands. Refraction of littoral sediment transport around beach headlands produces sand bodies (spits) that prograde oblique to the original high-water shoreline. Gaps between spits and the original shore form linear depressions (runnels). If a shore continues to accrete seaward of a runnel, then the swale becomes a semi-permanent linear depression in the backshore. The accumulation of water in these swales produces cats-eye ponds. Since the bases of these systems are very close to sea level, tidal pumping and salt intrusion are common.

A second means of cats-eye pond formation occurs at shores that have prograded seaward leaving a field of secondary dune ridges on their path. This is most common at inlets near the ends of barrier spits and islands. Secondary dune ridges and intradune swales are rapidly colonized by dune plants. As the landscape and plant succession matures, two processes occur that contribute to pond formation. After years of precipitation and evaporation, older landscapes on the backshore develop shallow groundwater layers. Because of irregularities in topography the water table tends to be closer to swale surfaces than the surfaces of the dune ridges. During wet seasons the water table may actually intercept the swale surface creating ponds. However, water-table depths in backshore areas are notoriously variable and swales may dry-out during periods of low precipitation–evaporation relationships. The other main factor effecting pond development in swales is the succession of vegetation on the swale surface. At mature landscapes, the density of plants in a swale is high and the swale surface is enriched with living and dead organic material. The organic material is less permeable than the original sand surface. Rainwater percolates into the groundwater at much slower rates in the organic-enriched zones and some surface water eventually gets perched above the swale surfaces forming ponds. Again, these ponds tend to be ephemeral and although occasional overwash or tidal pumping can produce low salt concentrations, cats-eye ponds tend to be fresh.

Coastal lagoons

Coastal lagoons are generally much larger than coastal lakes. There are two main modes of coastal lagoon formation as described above (Gilbert, 1885; McGee, 1890). Under the inundation model of formation (McGee, 1890), lagoons commonly occur at moderate-sized drainage basins that feed into the coastal ocean (Figure C25). Lagoons form when basins are flooded by the coastal sea and a small conduit is maintained that allows a free exchange of water between the lagoon and the sea. Since the inlet is at the shore, the drift of littoral sands tends to fill the inlet channel. The maintenance of the inlet is dependent on the ability of tidal currents to remove incoming sands at a greater rate than littoral input. However, both of these parameters can be quite variable along a reach of shore and numerous combinations resulting in different rates. In general, the lagoonal tidal prism is the main source of flood and ebb-discharges that flush the inlet channels. The magnitudes of littoral drift are principally governed by sand sources and wave climates. When there is sufficient wave-energy, large headland areas may provide large discharges of sand to the littoral system. In areas of low-littoral drift, small tidal currents may flush a sufficient volume of sediment to allow flushing of the entrance area. Inlets in areas of larger littoral drift require large tidal prisms and fluid discharges to flush sands from inlet channels. At relatively large drainage basins influenced by low-littoral drift rates, inlets are broad and are generally called estuary entrances.

Coastal lagoons in flooded drainage basins inherit the shapes of the basin contours. This generally produces triangular or delta-shaped (Δ) water bodies with coast-parallel seaward margins and v-shaped landward margins. Rehoboth Bay, Indian River Bay and Assawoman Bay

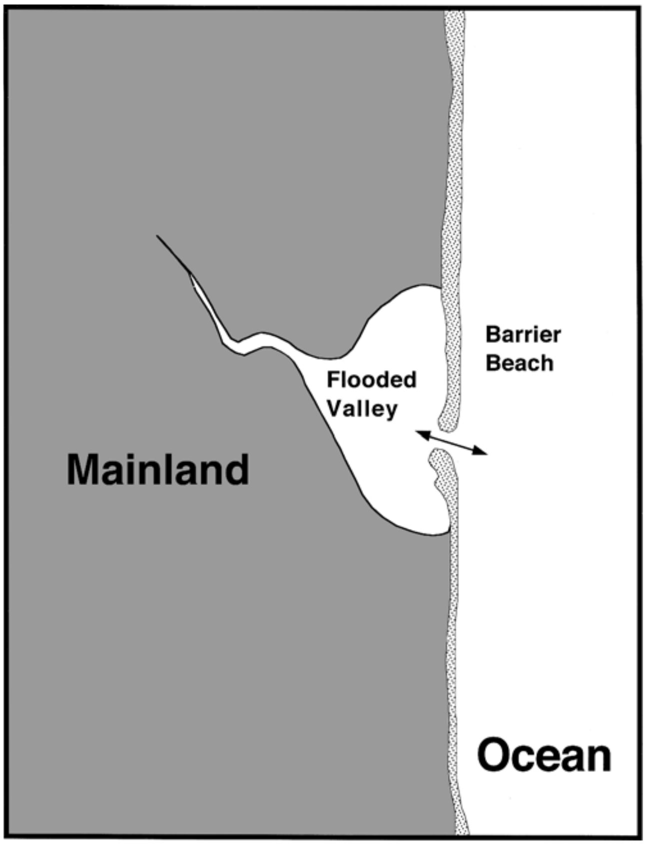

Figure C25 Sketch map illustrating an *inundation model* for coastal barrier lagoon formation. Sea-level rise causes the flooding of a coastal valley, while lateral beach migration creates a partial barrier between the flooded valley and the coastal sea.

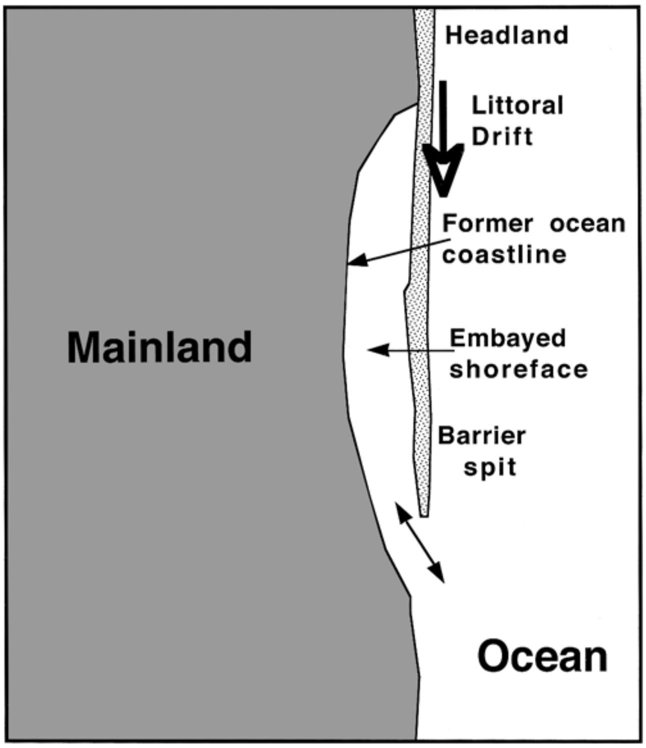

Figure C26 Sketch map illustrating a *spit embayment model* for coastal barrier lagoon formation. Lateral spit migration creates a partial barrier between the coastal sea, and a recessed section of the former ocean coastline. The barrier spit embays the recessed coastline and the former shoreface.

along the Delaware headland are good examples of this *delta bay* type of coastal lagoon. With prolonged sea-level rise, inundation may submerge the interfluve between two adjacent basins causing adjacent delta bays to coalesce. The landward high-water shoreline of a coalesced system takes on the irregular contour shapes of antecedent topography (Figure C25).

The spit-embayment model of lagoon formation (Gilbert, 1885) involves the use of littoral processes to build sand bodies seaward of a previously smoothed and straightened coastline (Figure C26). This type of lagoon formation is probable along wave-dominated coasts with regressive seas or very slow shifts in sea level. In order to build a second offset coastline, a large headland area is generally required. Spit growth from the headland engulfs a portion of the recessed mainland shore and shoreface forming a coastal lagoon. In the spit-migration model, the ocean-spit generally develops parallel to the mainland high-water shoreline and the water-surface area takes on a rectangular shape.

While the mainland and ocean high-water shorelines are generally near parallel, the actual high-water shoreline along the backbarrier of a spit tends to be wavy because of washover processes. Spits are generally narrow, low-profile sand bodies that are subject to overwash during storms. During overwash, sand is dispersed landward across the spit and deposited in fans. Multiple washover fans often coalesce along the backbarrier forming a wavy or scalloped shore.

During the Holocene, transgressing seas have been rising over the much of the world's coasts and mainland shores of lagoons are shifting landward over subaerially sculptured topography. Thus, during the present transgressive stage of Earth history it is improbable that high-water shorelines along the mainland and backbarrier margins in coastal lagoons are parallel. Oertel *et al.* (1992) illustrated the relationships among sea-level rise, antecedent topography, and lagoonal landscapes. They found that during transgression, lagoons evolve from marsh-choked basins to open-water basins. Oertel and Kraft (1994) illustrated the relationships among rising sea level, antecedent topography and several different types of marine barriers along the middle Atlantic Coast of the United States. They used the elements of coastal compartments described by Fisher (1967) as a means of linking different barrier and lagoon types with antecedent topography.

Coastal lagoon circulation

Coastal lagoons are inherently different from estuaries because of their circulation characteristics. Circulation in estuaries is largely governed by the mixing of large volumes of freshwater with seawater that enters through broad inlets. Coastal lagoons generally have relatively small amounts of freshwater and mixing is driven by tidal exchanges through narrow inlets. The percentage of the tidal prism to the total capacity of the lagoon is therefore very important.

The total capacity (volume) of the basin is the product of the wetted-surface area and the average depth of the basin. Coastal Plain lagoons generally have depths ranging from 2 to 3 m, however maximum depths of almost 30 m have been measured in tidal channels of many coastal lagoons. If lagoon floors are relatively smooth, average depths of 2–3 m can be used to determine basin capacity. However, the floors of most coastal lagoons have been shaped by the flooding of antecedent topography during the Holocene transgression. Thus, a reliable average depth can only be gained via a complete hypsographic analysis of the basin. Oertel *et al.* (2000) introduced the term hydro-hypsography to describe the surface area to depth relationships in a flooded basin. An analysis involves determining the area of slabs of water (w_{slab}) at increments of depth from the deepest part of the basin to the surface. From these slabs an accurate volume of the lagoon (Ω_L) can be determined.

$$\Omega_L = \Sigma(w_{\text{slab1}} + w_{\text{slab2}} + w_{\text{slab3}} + \ldots + w_{\text{slabn}}).$$

An average hydrologic depth (HD) can be obtained by dividing the lagoon volume (Ω_L) by the lagoon surface area (A_L).

$$\text{HD} = \Omega_L / A_L.$$

In relatively small lagoons with large entrance areas, the tidal phase lag between the inlet and the mainland is small and the tide is essentially a standing wave. The tidal prism can be estimated by obtaining the product of the tidal range and the area. The comparison of tidal prism

(Ω_T) with lagoon capacity is a first-order estimate of hydraulic turnover time (HTT).

$$HTT = \Omega_L / \Omega_T.$$

In shallow lagoons with large tidal ranges, HTT may be as short as 1–2 tidal cycles. Large lagoons with small tidal ranges may have very large HTTs.

Mixing in coastal lagoons is governed by both tidal exchange and wave stirring. The relatively shallow depths of most coastal lagoons are above the wave bases of locally generated waves. At lagoonal depths of 2–3 m, most of the lagoonal water column can be readily stirred by wave energy.

Multiple-shore transgression

Coastal lakes and lagoons form a coastal boundary zone with three shores. A mainland shore is located along the landward side of a coastal lake or lagoon. A second shore is located along the outer margin of the lagoon on the backbarrier side of an island or spit. A third shore is not in the lagoon but is located along the seaward side of a barrier island or spit and is exposed to ocean waves. Only the mainland and backbarrier shores are in the lagoon; however, ocean shore dynamics have a strong influence on the dynamics of the backbarrier shore.

The high-water shorelines at the mainland and backbarrier shores both respond to Holocene sea-level rise in the same way. As water levels rise, the lagoon inundates the mainland and backbarrier surfaces. Thus, the rate of landward shift of the mainland high-water shoreline ($-\Delta Sl_m$) is coupled with the slope of the antecedent surface. Inundation over gently sloping surfaces is rapid, whereas inundation of steep slopes is slower. At Coastal Plain slopes of 0.05–0.10° and sea-level rise rates of 15 cm per century, high-water shorelines along the mainland can shift landward 86–172 m per century. Since the slope of the mainland surface changes with distance from the coast, rates of recession may increase or decrease as slope changes. Increases and decreases in the rate of landward shift would tend to cause an increase and decrease in lagoon capacity, respectively. The actual capacity of the basin is dependent on the rates of movement of both the inner and outer shorelines of the lagoon.

The high-water shoreline along the backbarrier of the lagoon is more dynamic than the mainland high-water shoreline because the land surface is more dynamic. While inundation of the backbarrier by sea-level rise tends to expand the lagoon capacity, sedimentation along the backbarrier shore tends to shrink lagoon width. The backbarrier margin of a lagoon generally remains stable for long periods of time. However, during storms, sand may wash across a barrier spit or island and be deposited at the backbarrier shore in washover fans. The intermittent overwash events cause the high-water shoreline to prograde into the lagoon ($-\Delta Sl_{bb}$). The relative rates of both the inner and outer high-water shorelines of a lagoon are major factors effecting the lagoon capacity.

$$\Omega_L \propto (-\Delta Sl_m) - (-\Delta Sl_{bb})$$

The migration rate of the mainland shoreline ($-\Delta Sl_m$) is a passive process caused by inundation of the land surface during sea-level rise (Figure C27). However, the landward migration of the high-water shoreline along the backbarrier ($-\Delta Sl_{bb}$) is an active process requiring a wave-energy source to transport sand across a barrier and deposit it as washover fans along a backbarrier shore. The temporal and spatial patterns of backbarrier high-water shoreline migration by overwash are controlled by the wave climate and the elevation of barrier beaches, respectively. In general, the backbarrier high-water shorelines of narrow, low-profile barriers migrate landward at faster rates than at wide, high profile barriers.

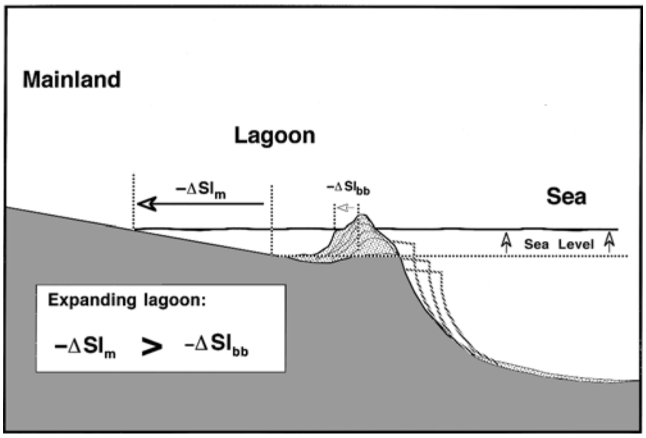

Figure C27 Cross-sectional sketch of a coastal barrier lagoon illustrating a scenario for lagoon expansion during sea-level rise. In this scenario the landward shift of the mainland high-water shoreline ($-\Delta Sl_m$) in response to sea-level rise exceeds the landward shift of the backbarrier high-water shoreline ($-\Delta Sl_{bb}$) in response to prograding washover fans.

Coastal lagoon sedimentation

The main sources of sediment contributing to basin fill come from denudation of the mainland, material flooding through tidal inlets and aggradation of wash-over fans along the backbarrier of islands and spits. Fine-grained sediments are generally associated with the shallower boundaries of the lagoon where marsh vegetation enhances sedimentation of silts and clays. During the Holocene transgression, fringe-marsh facies along lagoonal mainland shores are the basal deposits accreting above the antecedent surface (Oertel *et al.*, 1989). In the northern temperate environments of North America, the main source of fine-grained sediment is from the reworking of older sediments of lagoon floors. In the southern temperate zones, a larger contribution is made from fluvial sources and marsh plants. Coarse-grained sediments occur at flood deltas, the floors of shallow wave-stirred bays, subaqueous washover fans and deep current scoured channels. The flood delta and washover fans are new sources of sediment to coastal lagoons, whereas the sandy floors of wave-stirred bays and deep scour channels are lag deposits.

The relationship between basin capacity and the relative amount of sedimentation in a basin was described by Nichols (1989). When relatively minor amounts of sediment fill only small volumes of a lagoonal basin, then the lagoons are described as *deficit*. When large amounts of sediment fill major amounts of a lagoonal basin, then the lagoons are described as *surplus*. Lucke (1934) presented a model for surplus conditions where tidal inlets were the major source of sediment to coastal lagoons. Relatively coarse-grained littoral sediments are swept into tidal inlets by wave and tidal currents. Most of these sediments are deposited in the inlet areas in the form of flood deltas. Lucke (1934) assumed that coastal lagoons have an initial "open-water" state, and that the littoral sands flooding through inlets would eventually fill the basins forming marsh-choked lagoons. Coarse sediments can also enter lagoons during storm surges when portions of the island are overwashed, dispersing sand to the lagoon floor along the backbarrier of a barrier island. However, the relative amount of sediment accumulation in a basin is related to both sediment input and basin capacity. As noted above, basin capacity changes in response to sea level rise and barrier morphodynamics. Thus, when the rate of lagoon constriction is very rapid, then moderate volumes of sediment input may fill and create surplus conditions.

When the rate of lagoon expansion is very rapid, then even moderate volumes of sediment input may be smaller than the volume increase created by lagoon expansion. These deficit conditions were described by Oertel *et al.* (1992). During the Holocene transgression, lagoons along the mid-Atlantic region of the United States evolved from shallow to deep-water basins. In this region, sea-level rise has maintained deficit lagoons with large open-water bays rather than marsh-choked lagoons. The deficit nature of the lagoons can also be recognized in the stratigraphic record. Transgressive lagoonal sediments of Hog Bay, Virginia, USA have a coarsening upward sequence indicative of lagoonal inundation (Oertel *et al.*, 1989). Basal facies representing the initial inundation of the antecedent soil surface were mottled, poorly sorted sands enriched with fine-grained sediments in flasers. Muddy sediments with sand lenses indicative of fringe marshes occurred above the basal facies. Fringe marsh facies graded into clean muddy laminae with low percentages of sand that are characteristic of low marsh sediments. When the sea level rose above the low marshes, the upper portion of the sequence was reworked by lagoonal waves. The waves winnowed the fines from the area leaving a lag of sandy sediments that characterize open bays in a coastal lagoon.

COASTAL MODELING AND SIMULATION

General concepts and terminology

Modeling and simulation can be considered as the complex of activities associated with constructing models of real-world systems, like the coast, and simulating them on the computer. Fundamental to simulation is the process of formulating a computerized model of the coast, and conducting experiments with this model on a digital computer for the purpose of understanding the dynamics at work in the system. This undertaking of modeling and computer simulation of a dynamic system may lead to a new understanding that would not follow directly from the original knowledge about the system (Bossel, 1994).

Using a computer to simulate the dynamics of the coastal system requires that a set of assumptions taking the form of logical or mathematical relationships be developed and formulated into a model. Models can be considered as imitations or approximations of prototypes. Models are not reality, and no model, however complex, can be more than a representation of reality (Bekey, 1977). Depending on the degree of complexity, models can be homomorphic or isomorphic. Homomorphic models are the result of both simplification and imperfect representation of reality. Isomorphic models show a one-to-one correspondence between the elements of the model and the system being represented, and they also have exact relationships or interactions between the elements (Shannon, 1975). While models can be classified in several ways based on their operational parameters, it must be emphasized that computer modeling represents the integrated development of mathematical equations, logical rules, and a computer program embodying the equations, the logical rules and the solutions to them.

Why simulation of the coastal system

Conventional techniques of analytical modeling and analysis are inadequate for understanding the coast, which can be viewed as a complex, dynamic large-scale system or super- system with an integrated arrangement of separate units or component systems, which vary in morphological form, pattern and configuration (Lakhan, 1989). An increasing number of researchers (e.g., Lakhan and Jopling, 1987; Briand and Kamphuis, 1990; Lakhan and LaValle, 1990; Larson *et al.*, 1990; Lakhan, 1991; de Vriend, 1991; Oelerich, 1991; Win-Juinn and Ching-Ton, 1991; Abdel-Aal, 1992; Horn, 1992; Lakhan and LaValle, 1992; Lakhan *et al.*, 1993; Warren, 1993; Black, 1995; Stive and de Vriend, 1995; de Vriend and Ribberink, 1996; Holmes and Samarawickrama, 1997; LaValle and Lakhan, 1997; Sierra *et al.*, 1997; Black *et al.*, 1999) have, therefore, concentrated on the use of computer-based models to gain insights on the complex interactions among interdependent entities (e.g., waves, winds, and currents), which have cumulative impacts on the coastal system. Simulation models are preferred over analytic models because analytic models require many simplifying assumptions to make them mathematically tractable, whereas simulation models have no such restrictions. In brief, a simulation model has several advantages (Adkins and Pooch, 1977). They include the following:

1. It permits controlled experimentation. A simulation experiment can be run a number of times with varying input parameters to test the behavior of the system under a variety of situations and conditions.
2. It permits time compression. Operation of the system over extended periods of time can be simulated in only minutes with ultra fast computers.
3. It permits sensitivity analysis by manipulation of input variables.
4. It does not disturb the real system.

One of the most attractive features of coastal simulation models is based on the fact that their use permits manipulation in terms of real-time of minutes which would take years for the prototype. Of the numerous modeling types (see Lakhan and Trenhaile, 1989; McHaney, 1991) there are two broad types of simulation modeling: continuous simulation and discrete-event simulation. The distinction is based on whether the state can change continuously or at discrete points in time (Miller *et al.*, 1999).

The process of simulating the coastal system

The theoretical and applied literature on modeling and simulation provide the fundamental rules, which can be used to design simulation models of the coastal system. While variations exist in the terminology used and the emphasis placed by different authors (e.g., Law and Kelton, 1991; Pooch and Wall, 1993; Bossel, 1994; Cloud and Rainey, 1998; Zeigler *et al.*, 2000) on each simulation rule and procedure, a realistic and credible simulation model of the coastal system can be formulated by carefully considering each of the following:

(1) Objective Specification, and System Definition;
(2) Model Conceptualization and Formulation;
(3) Data Collection and Model Parameterization;
(4) Model Translation;
(5) Model Verification;
(6) Model Validation; and
(7) Sensitivity Analysis and Results Interpretation.

(1) Objective specification, and system definition

With a dynamic simulation model, it is possible to understand how the coastal system changes over time and also gain an understanding of the dynamics at work in the system. Once a decision has been made to develop a dynamic simulation model, the problem to be investigated and the objectives to be attained must be specified. The components to be included in the model and the abstractions made of them are governed by the objectives (Zeigler, 1984).

After the objective of the simulation model is outlined, the system to be modeled must be defined. In brief, the coastal system is a complex decomposable large-scale open system whose states change in response to both exogenous and endogenous forces. As a real-world system, it is a composition of interacting component systems and associated sub systems. For modeling purposes, caution must, therefore, be taken in demarcating and specifying not only the boundaries of the large-scale coastal system, but also each of the sub systems. Since it is unlikely that the whole coastal system will be modeled the boundary conditions must be portioned into the segment of desired interest. To do this, one must understand the system environment and states. "It must be recognized that any given point in time, a large number of coastal entities interact with a large variety of macro and micro morphological states to produce an apparently random spatial and temporal pattern" (Lakhan, 1989, p. 20). Changes in the state of the coastal system are also affected by a set of poorly understood entities—the components of the system—the processes that are interacting over time, in this case the waves, tides, winds, currents, etc. In defining the coastal system the simulationist must contend with the fact that the coast with its interacting component systems can undergo a sequence of ill-defined transitory states or display cyclic or periodic behavior patterns. It must be realized, therefore, that in order to define the boundaries of the coastal system of interest, it is necessary to identify and evaluate the key system entities and attributes, and their interrelationships over a sufficiently long span of time.

(2) Model conceptualization and formulation

Before the model is developed the simulationist must take cognizance of the fact that like most natural systems the coastal system is governed by a large number of interdependent entities and their attributes, and is complicated by the presence of several feedback mechanisms, some positive and some negative in complex feedback loops (Lakhan, 1989). Hence, it is difficult to identify and separate the independent and dependent entities, which control a portion or the whole coastal system. Here it should be noted that, although complex systems and their environments are objective (i.e., they exist), they are also subjective in that the particular selection of the elements (entities) to be included or excluded, and their configuration are dictated by the researcher (Shannon, 1975). The aim of most simulationists to build a model that has high face validity whereby the model meets specified performance requirements.

For explanation purposes, a simple conceptual model, which can be eventually developed into a highly detailed model to simulate spatio-temporal nearshore behavior, is presented in Figure C28. More entities and attributes have not been included in the model because of the notions of either Occam's razor (see Checkland, 1981) or Bonini's paradox (see Dutton and Starbuck, 1971), which both stress the need for the development of parsimonious models which are simple and straightforward. Essentially, the assumptions and functional relations expressed in the model must be kept as simple and realistic as possible because if the assumptions incorporated in the model are complex, and their mutual interdependencies are obscure, the simulation program will be no easier to understand than the real operating processes (Dutton and Starbuck, 1971). With this knowledge in mind, the model presented in Figure C28 has only the important functional entities and attributes of the coastal system. This conceptual model assumes that the nearshore system is an open system, which is influenced by nearshore waves, with the antecedent nearshore morphology regulated by the energies of wave refraction and reflection. The model also includes the currents and tides that affect the nearshore system in different locations over time. Long-term spatial and temporal changes in nearshore morphology are influenced most by the impacts of longshore currents and sediment supply. The conceptual model emphasizes the entities of waves and currents because they are by far the largest contributors of energy to the nearshore system (US Army Engineer Waterways Experiment Station, Coastal Engineering Research Center, 1984).

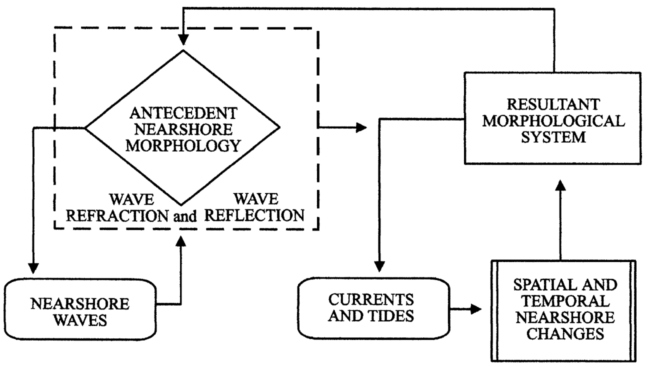

Figure C28 A simple conceptual framework for modeling nearshore changes.

Processes such as tides and local currents also have significant influences on the overall behavior of the nearshore system.

(3) Data collection and model parameterization

One of the principal tasks in the coastal simulation process is to gain adequate information and data on the entities and attributes which govern the coast. The data are necessary for the parameterization of the simulation model. The data must be collected over a continuous and long period of time, so that the time series provide accurate insights on the nature of the entities, which impact on the coastal system. The data must also be homogeneous and free from measurement errors. Since the use of raw empirical data in a simulation model implies that all one is doing is simulating the past (Shannon, 1975), it is imperative to analyze empirical data and identify the probability distributions of those attributes (e.g., wave heights, wave periods, and longshore current velocities) which are to be incorporated in a stochastic simulation model. The model will then use the data indirectly by drawing variates from the selected statistical distributions. The specification of a statistical distribution from which values of the variable (e.g., wave height or wave period) are selected randomly, implies the parameterization of a stochastic model. For a stochastic model, multiple runs must be conducted for each combination of the independent variable values. The inherent randomness of a stochastic model is not required for a deterministic model, which does not use probability distributions. The deterministic model can be parameterized for every combination of independent variable values or for all possible combinations of input variable values.

Selection of the appropriate theoretical distributions for parameterizing a stochastic coastal simulation model can only be done after empirical data are analyzed to see whether they conform to at least one of the known theoretical distributions. To select a theoretical distribution, it is necessary to establish a null hypothesis, and test the deviation of the empirical distribution from the selected theoretical distribution. This is done by testing the distributional assumption and the associated para-meter estimates for goodness-of-fit. The goodness-of-fit that is chosen to test how well the selected distribution fits the observed data depends on several considerations; among them sample size, type of data, and nature of distributional assumptions. Computer programs with the capabilities of running chi-square, Kolmogorov–Smirnov, Cramer–von Mises, and Moments goodness-of-fit tests can be used to check whether a set of empirical data follow or conform to any of the known theoretical distributions. Lakhan (1984) found that with the chi-square goodness-of-fit test, long-term mean wave height and wave period data are Rayleigh distributed; tidal range is normally distributed; longshore current velocity is exponentially distributed; and sediment size is lognormally distributed. Hence, a model to simulate spatial and temporal coastal behavior can be parameterized with these distributions.

If it is found that at a set level of significance, the empirical coastal data cannot be fitted to any of the known continuous or discrete distributions, then it is possible that the data are not independent and uncorrelated. To determine if this is the case the simulationist must use the data to compute the autocorrelation functions. If the analyzed coastal data are found to be autocorrelated, then the model can be parameterized with autocorrelated variates. When the coastal data fit a known theoretical distribution at a specified level of significance, and also are autocorrelated, then the model can benefit from being parameterized with autocorrelated distributed variates. An easily implemented and computationally efficient method for the generation of autocorrelated pseudo random numbers with specific continuous distributions can be found in Lakhan (1981).

The decision to use a particular parameterization procedure depends principally on the length of the simulation run and the nature and characteristics of the entities and their corresponding attributes, which govern any particular coastal system. If the collected coastal data are poorly correlated, and also cannot be "fitted" to any of the known theoretical distributions, then one option will be to use the empirical form of the distribution function. It should be noted, however, that the use of an empirical distribution function is generally not desirable in a stochastic simulation model of the coastal system. In the absence of coastal data, theoretical principles governing the coastal entities can be used for employing appropriate theoretical distributions in the stochastic coastal simulation model.

(4) Model translation

Once the coastal system model is developed with the appropriate equations, theoretical distributions, data specifications, logical rules and constraints, a computer program must be written to implement the model.

The computer program will embody the necessary logical rules, the equations and their solutions, etc. The model must be programmed for a digital computer using an appropriate computer language. The language can be either a general purpose programming language or dedicated simulators and simulation languages. For various aspects of coastal simulation researchers (e.g., LaValle and Lakhan, 1997; Rodriguez-Molina and Garcia-Martinez, 1998; Yu *et al.*, 1998) have demonstrated the applicability of the FORTRAN general purpose programming language.

There are now numerous simulators, discrete simulation languages, continuous simulation languages, and combined simulation languages (Dessouky and Roberts, 1997). The simulators are application-specific modeling tools while the simulation languages have features that facilitate a broad range of modeling applications. While the selection of a dedicated simulation language is a matter of convenience (Nikoukaran and Paul, 1999) it is, nevertheless, worthwhile to consider the specific features and flexibility of simulation programming languages for coastal simulations. In brief, the use of a special purpose simulation language can shorten the development of the computer program, and also allow for faster coding and verification. In addition, a special purpose simulation language may incorporate several simulation functions, which permit the advancement of simulation time, generation of random variates, and execution of simulation events at discrete and continuous time periods.

(5) Model verification

Model verification is essentially the process of substantiating that the model is transformed from one form into another, as intended, with sufficient accuracy. The accuracy of converting a model representation in flowchart form to an executable computer program is evaluated in model verification (Balci, 1997, p. 3). From a software engineering point of view, a computer program must work according to its specifications. The manner in which the program is designed and written is as important as whether the program works. Good programming practice can involve modular programming, and checking intermediate simulation outputs through tracing and statistical testing per module (Kleijnen, 1995). In software testing the program errors must be detected. Debugging is part of the testing process (Weiner and Sincovec, 1984). Static and dynamic approaches can be used for testing the accuracy of computer programs (Sargent, 1982, 1992). In static testing, the computer program of the formulated model is analyzed to determine if it is correct by using such techniques as correctness proofs, syntactic decomposition, and examination of the structural properties of the program. Dynamic testing, on the other hand, consists of different strategies, which include bottom-up testing, top-down and mixed testing (a combination of top-down and bottom-up testing). In dynamic testing, the techniques which are often applied are internal consistency checks, traces, and investigations of input–output relations.

The verification technique of stress testing is based on the notion that while bugs in the program are both embarrassing and difficult to locate they do not manifest themselves immediately or directly, they may, however, show up under stress. With stress testing the parameters of the model are set to unusually high or low values, and then the model is checked to see if it "blows up" in an understandable manner (Bratley *et al.*, 1987). For reliable programming results from the study of large, complex systems, such as the coastal system, software developers can also adopt a system called the Capability Maturity Model, established by the United States military, and currently overseen by the Software Engineering Institute in Pittsburgh, PA.

(6) Model validation

The major task of validating the computer simulation model must be accomplished, once it is ascertained that the computer simulation program is performing exactly the way it is intended. Without discussing the various validation approaches (see Banks *et al.*, 1986a, b; Balci and Sargent, 1984; Sargent, 1988; Balci, 1997) put forward in the simulation literature, it should be stressed that validating computer simulation models is difficult because simulation models contain both simplifications and abstractions of the real-world system. The philosophy of science teaches that models cannot be validated, because doing so implies that the model represents truth (see Popper, 1968). For practical purposes, it makes sense to require that the model faithfully captures the system behavior only to the extent demanded by the objectives of the simulation study. An experimental frame of interest is first determined, and replicative validity can be affirmed if, for all the experiments possible within the experimental frame, the behavior of the model and system agree within acceptable tolerance (Zeigler *et al.*, 2000).

The coastal simulationist can only develop a valid model by making certain that there is very close correspondence between the model and the coastal system. This is done by building a model that has high face validity. The model will be valid if it accurately predicts the performance of the coastal system. If this is not achieved then it is necessary to examine, and change if necessary, the structural and data assumptions of the model. Another form of validity is structural validity, which requires that the model not only is capable of replicating the data observed from the system, but also mimics in step-by-step, component-by-component fashion the way in which the system does its transitions (see Zeigler *et al.*, 2000).

(7) Sensitivity analysis and results interpretation

Sensitivity analysis is an unavoidable step in model validation. The goal of performing sensitivity analysis of a simulation is to determine the effect of input variation and the effect of input uncertainty on the output data (Fürbringer and Roulet, 1999). In any coastal simulation, sensitivity analysis will involve changing the model's input by a small amount and checking the corresponding effect on the model's output. If the output varies greatly for a small change in an input parameter that input parameter may require reevaluation (see Law and Kelton, 1982). It is best to run the model several times with variation in the parameter values. The desired goal is to determine if the basic pattern of the results is sensitive to changes in the uncertain parameters. In execution of the model with different input parameters, it is necessary to check whether the reference mode is obtained with each sensitivity test. If the simulation results are in agreement with the reference mode then the model can be considered robust.

The robustness of the simulation results can be tested by performing additional simulations with different initialization parameters. This comprehensive sensitivity analysis can provide insights on whether the obtained simulation results conform to reality. To interpret the simulation outputs and make inferences on how the coast or any type of system operates, it is necessary to have both theoretical and practical knowledge of the statistical aspects of simulation experimentation (initial conditions, data translation, replications, runlength, etc.) and data outputs. The same principles that apply to the analysis of empirical data also apply to the analysis of simulated data (LaValle and Lakhan, 1993). Statistical tests will vary depending on whether the model is stochastic or deterministic. Lakhan (1986) and Lakhan and LaValle (1987) found that a stochastic simulation model on nearshore profile development will produce output data which are subject not only to random characteristics, but also to various degrees of correlation. Interpreting these results requires the utilization of a statistical methodology which will highlight the stochastic and other properties of the simulation outputs.

COASTAL PROCESSES—See BEACH PROCESSES

COASTAL SEDIMENTARY FACIES

Introduction

Coastal sedimentary environments include a variety of physical and biological processes, which act on coastal sediment to produce associations of composition, texture, primary sedimentary structures, and fossils. These associations constitute sedimentary facies, lithologically distinct, genetically related components of a sedimentary system, or environmental facies, whereby a set of specific environmental processes imparts a distinctive character to a sediment. Coastal sedimentary facies provide the signature of specific types of coastal deposits and facilitate their identification in the geologic record.

This entry describes some of the more common clastic sedimentary facies associated with open coasts and coastal embayments. For a review of carbonate coastal facies, the reader is referred to Demicco and Hardie (1995). The discussion here also does not address facies of high-latitude coasts or low-latitude coasts dominated by mangrove swamps (see Hill *et al.*, 1995; and Cobb and Cecil, 1993, respectively). Many of the facies described here form in both marine and lacustrine settings, although tidally influenced facies are restricted to the marine environment

For more detailed information on coastal sedimentary facies, the reader is referred to the excellent summaries provided by Reineck and Singh (1973), Davis (1985), Walker and James (1992), Galloway and Hobday (1996), and Reading (1996).

Coastal sedimentary processes

A complex array of processes influence coastal sedimentary facies (Figure C29). Of these the most important are waves, tides, and biogenic processes. Sediment input is also critical to the facies character (grain size) and to the nature of the preserved deposit (sedimentation rate).

Waves may exist as "seas," driven by local winds, or as "swell," generated by distant storms. Swell tends to have longer period and to influence the seabed to greater depths than do local sea waves. "High-energy" coasts are likely to be dominated by swell. "Low-energy" coasts receive smaller everyday waves, but can experience very large waves during storms.

Waves move sediment by two mechanisms. The passage of waves induces a back and forth orbital motion at the bottom. In water that is deep relative to the size of the wave, this motion is symmetrical in velocity and duration of flow. In shallower water, the motion becomes asymmetric, with short relatively strong landward flow under the crest of a wave and a more prolonged, weaker, seaward flow under the trough (for the conditions under which this asymmetric flow occurs, see the "Stokes wave" field in Komar, 1976, Figure 3–17). The orbital velocity asymmetry is important for promoting the onshore transport of coarser material and bed load in general.

Waves also, as they encounter the shore, generate sustained flow in the form of shore-parallel longshore currents and seaward-directed rip currents. These currents, which form nearshore circulation cells, not only transport sediment, but also shape the nearshore morphology into bars and troughs.

Tides influence sedimentary facies in two ways. The rhythmic rise and fall of the sea changes water depth and locally exposes extensive intertidal flats. It also generates tidal currents that flow alternately landward (flood tides) and seaward (ebb tides). In morphologically complex bays, either the flood or ebb tide is likely to predominate at any one location.

The response of sediment to these fluid motions depends in large part on its textural nature, which is determined partly by local dynamic processes and partly by what is available to the system. Grain size is also a major influence on the rate and style of bioturbation, which combined with the frequency and intensity of physical processes determine the degree of preservation of physical structures. Bays typically contain abundant silt and clay, which are borne in suspension or move in small aggregates (particularly as fecal pellets) along the bottom. Between the tidal ebb and flood, at high and low water, the flow diminishes, allowing the settling of suspended sediment. This sediment may immediately accumulate on the bottom or it may be concentrated into a dense, highly concentrated fluid that hugs the bottom before deposition.

Biogenic processes are import in the development of coastal facies. Biogenic effects include bioturbation, the generation of distinctive traces, contribution of shell detritus, the fixing of suspended fine sediment by filter feeding and vegetative baffling, and the binding and bioerosion of the substrate. These processes depend on many factors, but faunal activities are particularly sensitive to variations in salinity. Faunal traces in brackish environments tend to be simpler, less diverse,

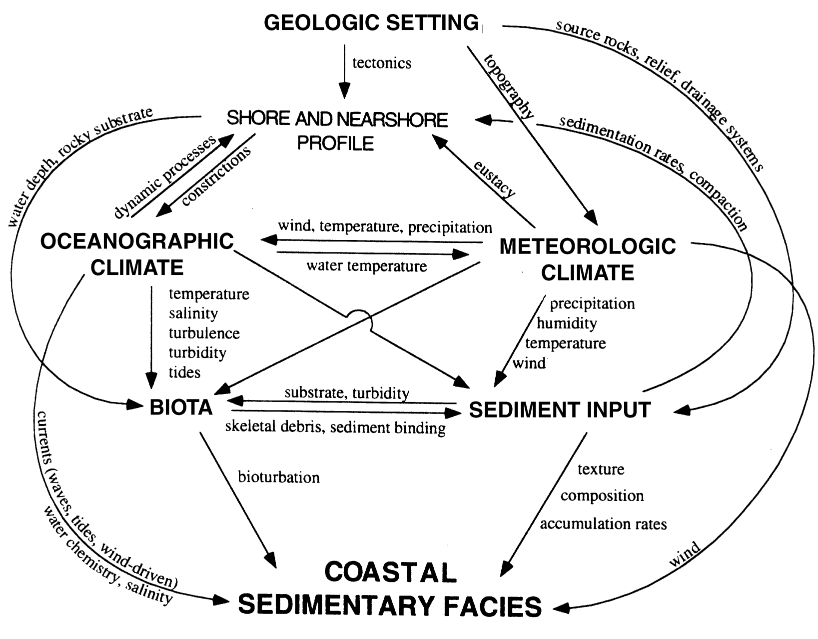

Figure C29 Interacting environmental factors and resulting processes that control the development of coastal facies (modified from Clifton and Hunter, 1982).

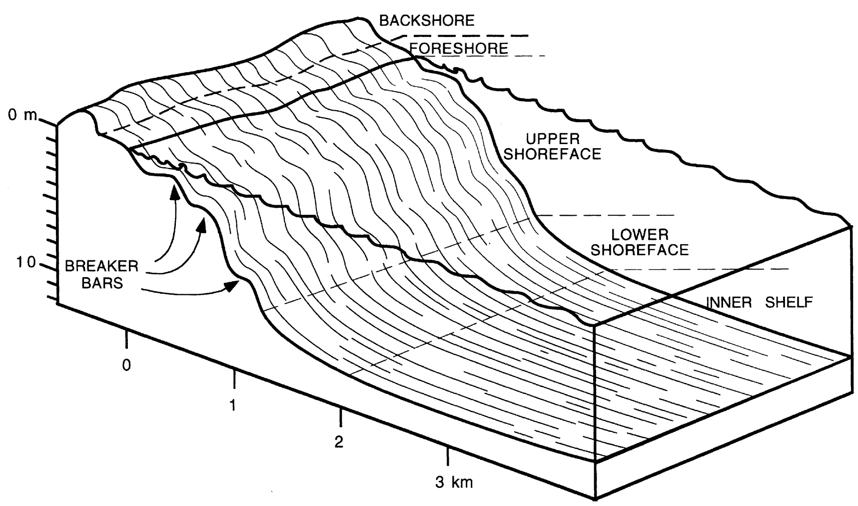

Figure C30 Typical morphologic zonation of a wave-dominated open coast. Considerable vertical exaggeration.

and more likely to be dominated by a single ichnogenus (Pemberton and Wightman, 1992) than those made in oceanic salinities.

Sedimentary facies of wave-dominated open coasts

Waves are most important on open coasts, where the tides mostly only raise and lower the water level. A fundamental aspect of most open clastic coasts is the *shoreface* (Figure C30), a relatively steeply inclined (1 : 200) ramp that extends offshore from the intertidal *foreshore* zone and merges with a nearly flat (1 : 2,000) inner shelf or basin floor. Its origin is discussed by Niederoda and Swift (1981). The shoreface-shelf transition lies at depths that range from 2 to 30 m. On prograding coasts, where the sedimentation rate is commonly sufficient to allow for a wave-induced equilibrium profile, the base of the shoreface rarely exceeds a water depth of ten or so meters.

The *upper shoreface* is equivalent to the nearshore zone, where wave-generated currents predominate. Upper shoreface facies are generally the coarsest part of the coastal system and are characterized by high-angle trough cross-bedding, that is directed parallel to the shoreline (in response to longshore currents) or offshore (in response to rip currents). Modern medium- to coarse-grained nearshore zones are dominated during fair-weather by medium-scale lunate megaripples (dunes) that face and migrate in an onshore direction. Cross-bedding produced by these structures seems rarely preserved, however, in ancient upper shoreface deposits, which seem dominated by storm effects. If gravel is present, it typically is well sorted into discrete beds and layers, and gravel and shells commonly form erosional lags within the deposit. Small, shore-normal gravel-filled gutter casts exist at the base of some gravel beds. Burrowing is common and is dominated by the *Skolithos* ichnofacies, characterized by mostly vertical cylindrical and U-shaped burrows, the dwelling structures of suspension feeders or passive carnivores (Pemberton *et al.*, 1992). The trace *Macaronichnus* is common in fine sand of high-energy coastal deposits and feeding pits of rays or other vertebrates may occur. The thickness of upper shoreface deposits generally ranges from 1 to 8 m, depending on the intensity of wave energy.

A *lower shoreface* facies is identifiable in most pebbly shoreface deposits. This facies, 1–3 m thick, consists of small pebbles of relatively uniform size in a matrix of well sorted fine to very fine-grained sand. The pebbles occur as scattered clasts, in small clusters, or as thin discontinuous stringers 1–2 pebbles thick. The associated sand may be laminated or structureless, and is indistinguishable from inner shelf sand. The facies results from a combination of offshore transport from the upper shoreface during storms and onshore transport of most of this material by the shoaling waves in the aftermath of a storm. Winnowed by the waves, the coarser material moves landward more slowly and some is trapped in burrows, swales, or other depressions on the seafloor. In the absence of pebbles, the upper shoreface facies may be the only recognizable shoreface component.

On transgressive coasts, *shoreface-attached ridges* extend obliquely into the sea. These ridges, composed of fine to coarse sand, are tens of kilometers long, several kilometers wide, and 5–15 m high. Cores through shoreface-attached ridges show that they consist of an upward-coarsening accumulation of storm-event beds (Rine *et al.*, 1991). Some shoreface-attached ridges show evidence of both storm and tidal influences in their internal structures.

The *beach foreshore* facies lie within an intertidal zone subject to the swash and backwash of the waves. Foreshore sands are typically very well sorted and characterized by planar lamination. Foreshore deposits are generally 1–2 m thick, and if the grain size permits, show an upward-fining. Individual lamina may show inverse grading. Placers of heavy minerals define the upper part of some foreshore deposits. Small vertical burrows and the trace *Macaronichnus* typify the ichnologic signature of the foreshore.

Nonmarine coastal facies of the open coast include eolian dunes, characterized by large-scale landward dipping foresets and backshore facies of wind/tidal flats. The character of the *backshore* facies depends on the specific setting and the amount of vegetative growth. Backshore sand is commonly fine and well sorted; layers of pebbles and coarser sand are introduced during floods, and layers of muddy and/or peaty sediment can develop under wetter conditions. Structures such as climbing adhesion ripples or vertebrate footprints document subaerial exposure. Roots are common, and substantial coals may directly overlie the foreshore facies in some ancient deposits.

Mudflats dominate some open coasts proximal to, or down-current from, the mouths of large mud-bearing streams (see Augustinius, 1989). In settings such as the coast of Surinam, inshore fluid mud maintains its presence by frictionally reducing the energy of incoming waves. Episodically, mud deposition ceases, either during storms or because the mud moves along the coast in discrete waves, and sandy beaches develop. A return to muddy deposition isolates the sandy sediment in shore- parallel ridges or *cheniers*. Cheniers on the coast of Surinam are about 2 m high and contain a combination of steeply and gently landward dipping cross-beds or, where fine-grained, gently landward and seaward-dipping cross-beds. Cheniers adjacent to the Mississippi River contain shell aggregates concentrated by storm waves. Mud in the associated flats may be laminated to structureless; mudflats covered by salt marshes will contain root or rhizome structures.

Sedimentary facies of deltaic coasts

Deltas form where sediment discharged at the mouth of rivers exceeds the capacity of marine processes to redistribute it fully. As sites of substantial sediment accumulation, deltas form a volumetrically important part of the sedimentary record. Deltas fall into three end-member types depending on whether they are dominated by rivers, waves, or tides. River-dominated deltas are lobate and commonly quite muddy; the modern Mississippi River delta is a prime example. Wave-dominated deltas have a classic deltoid shape and are more likely to be sandy; the

Niger River delta is a commonly cited example. Tide-dominated deltas are less common, and tend to be muddy or sandy and highly embayed. The Fly River delta of Papua New Guinea is a primary example.

*Distributary channel*s, which develop on delta plains where a primary fluvial channel diverges into a series of straight or sinuous distributaries, are common to all types of delta. A balance of fluvial discharge and tidal range determines the extent of salt water intrusion into the lower reaches of the distributary and the degree of tidal influence. Distributary channel floors are erosional and typically littered with lags of mudclasts and/or plant detritus. Three-dimensional subaqueous sand dunes in the thalweg produce trough cross-bedding. Higher on the channel banks the sediment becomes finer and is likely to be dominated by ripple bedding. Reversals of cross-bedding direction will occur where tidal range is sufficiently great. The nature of burrowing depends on salinity ranges in the distributary. If salinity is low or highly variable, the burrow types are likely to be greatly restricted.

The deposits of the distributary channels typically display an upward coarsening, and may pass upward into muddy levee deposits where complete. Clinoforms may mark the upper part of a distributary channel fill. Cross-sections of the deposits formed by relatively straight distributary channels show a deep central channel flanked by broader lateral extensions ("wings") near the top.

The banks of the distributary channels are capped by *levees*, ridges composed of fine-grained sediment at either side of a channel. Levee deposition occurs during submergence associated with major floods. Internal structures of levees include ripple lamination and small-scale cross-bedding, roots, and in some cases bioturbation.

Deltaic bays are associated with lobate (typically river-dominated) deltas and represent settings of low energy in which the prevailing sedimentation is from suspension, including much organic matter. Episodic influxes of silt and fine sand during floods produce coarser laminae, which may be well preserved in brackish settings where faunal reworking is diminished. The shallower parts of deltaic bays commonly are somewhat sandier and may display evidence of wave reworking in the form of hummocky cross-stratification. Plant growth along the edge of a bay may inhibit the development of normal beaches.

Crevasse splays and deltas accumulate where floodwaters breach a levee and carry fine sand and silt into an adjacent deltaic lake or bay. The resulting lobate deposits become progressively thinner and finer with distance into the bay. Internal sedimentary structures include ripple- and planar-lamination, climbing ripples, trough cross-bedding, and mud drapes. Graded beds, and, near the breach, erosional surfaces, define the deposits of separate floods. Dewatering or other deformational structures are fairly common in these rapidly deposited sands. The upper part of individual flood deposits may be bioturbated, where salinities permit. Splays may amalgamate into coarsening-up crevasse deltas, which resemble other small deltas.

Distributary mouth bars develop where distributary channels of a river-dominated delta debouch into a basin (Figure C31). They consist of coarsening-up accumulations of fine-grained or silty sand. Deposition occurs mostly during flood stage, but the resulting deposit can be partly reworked by waves or tidal currents. Internal structures include ripple, climbing ripple, and planar-lamination. Flaser bedding may be present, as well concentrations of wood or finely divided organic detritus.

Beyond the actual mouth of a distributary lies the *delta front*, an area dominated by flood deposition and possible reworking by waves. Delta front deposits of river-dominated deltas typically consist of interbedded fine to very fine grained sand and mud. Ripple lamination is a common internal structure of the sands, although storm waves can also generate hummocky cross-bedding in this environment. Some graded sand beds appear to be deposited by sediment gravity flows, and deformational structures are common. Bioturbation may be intense to limited depending on the volume of freshwater discharged into this setting. Delta front deposits grade down into *prodelta* muds that form the deeper-water foundation of a delta. Facies on the fronts of wave-dominated deltas may be indistinguishable from those of an open-coast wave-dominated shore.

Tide-dominated deltas have received less study than river-dominated deltas. Here, tidal influence on river flow may extend up-river well beyond the distributary system. Many of the facies (tidal channels and flats) associated with tide-dominated deltas are similar to those discussed in the section on embayment facies. Tidal *sand ridges*, 10 km or more long, several kilometers wide and as much as 10 m high, are common in the funnel-shaped mouths of tide-dominated deltas. Where studied, these ridges display an upward coarsening from interbedded sand and mud to cross-bedded sand. Mud drapes and flaser bedding are common.

Fan deltas are a special type of delta that exists where an alluvial fan builds into a marine or lacustrine basin. Alluvial fans are constructed by a combination of fluvial processes and episodic debris flows; because they typically lie proximal to highlands, alluvial fans are generally composed of coarse sediment. Where waves are too small to redistribute this sediment, it accumulates on the shoreline in the form of a *Gilbert delta*, with steep, nearly planar, foresets that extend to the floor of the adjacent

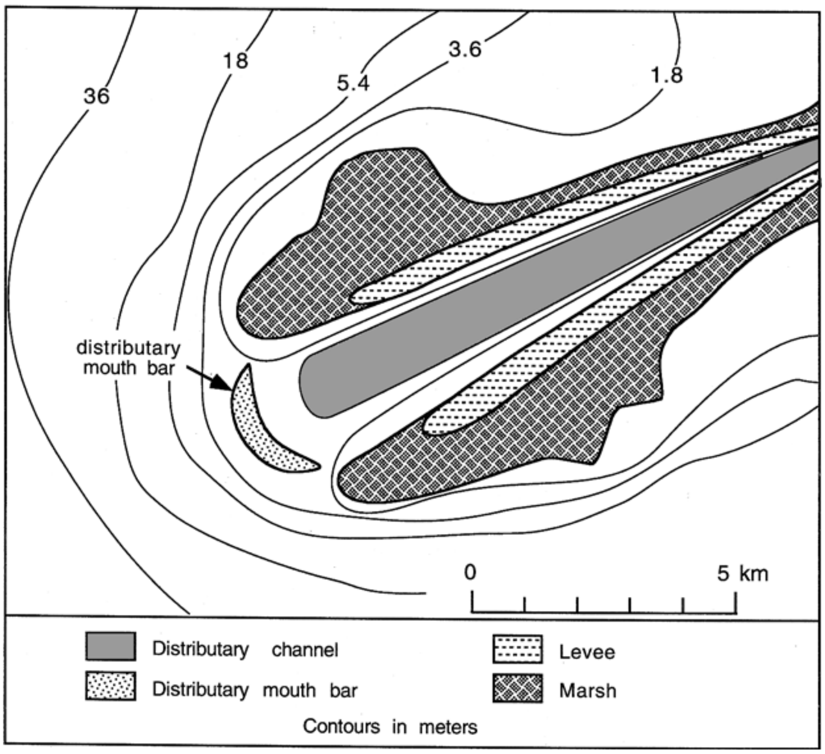

Figure C31 Morphologic elements and facies at the mouth of a river-dominated delta lobe.

basin. Such foresets may define a deltaic unit tens of meters, thick. Sediment slides down the foresets in grain flows, in which the coarser material outruns the finer component. As a consequence, Gilbert deltas are likely to show an overall upward fining from their bases. Individual foreset layers, however, tend to display an upward coarsening normal to the stratification in response to the grain flow process that created them.

Gilbert deltas form in settings other than fan deltas, wherever coarse sediment is introduced into a basin with relatively low wave energy. Braided streams carrying a coarse sediment load commonly create Gilbert deltas where they encounter a shore. Alluvial fans differ from braid plains by containing debris flow deposits composed of unsorted layers of sand, mud, and gravel with little internal structure. Subaerial debris flows on fan deltas flows can extend across the strand line and compose much of the subaqueous part of the delta.

Sedimentary facies of coastal embayments

Coastal embayments are bodies of water somewhat restricted from the open sea. They include river mouths, drowned river valleys, and lagoons or other bodies of saline water isolated from the open sea by a barrier island or spit. Estuaries are semi-restricted bodies of water in which river discharge measurably dilutes the salinity. Lagoons may have no significant freshwater input.

Embayments are subject to a complex interplay of waves, tides, and river discharge. Of these processes, tides typically predominate. Generally, the limited wind fetch in embayments precludes the development of large waves. River discharge, an important factor in many embayments, need not be present. Dalrymple *et al.* (1992) provide a useful model of estuarine facies that recognizes an inner area dominated by fluvial processes, a central area of mixed energy in which both river flow and tidal currents are significant, and an outer area dominated by waves and tides.

Within embayments, specific sedimentary environments produce distinctive facies. In addition to the factors noted above, bay facies depend on the degree of subaerial exposure provided by the tides. Subtidal facies are never exposed, intertidal facies are exposed by the astronomical tides, and supratidal facies are inundated only during coincidence of high astronomical and high meteorological (storm surge or river flood) tides. This section addresses the most common sedimentary facies formed in coast embayments.

Tidal basins as used here are subtidal parts of a bay, which lack discrete tidal channels. As a consequence, tidal currents tend to be feeble, and the sediment largely undisturbed by physical processes. The substrate here is typically fine-grained and dominated by biogenic processes. Commonly the sediment is totally bioturbated. Mollusk shells are common, either as clasts or *in situ*. During periods of minimal sedimentation, articulated and disarticulated shells can form a pavement on the bay floor leading to discrete shell layers in the resulting deposit.

Tidal channels provide a focus for tidal flow within a bay. Their size ranges from tens of meters to kilometers across and meters to tens of meters deep. Their substrate ranges from gravel to mud depending on the nature of river influence and the texture of sediment available to reworking by tidal currents. Typically, tidal channels cut into older sediment or bedrock, and their floors are littered with coarse detritus: shells, pieces of wood, mud clasts, and, today, human debris. Where tidal channels erode into a relatively consolidated muddy substrate, organisms, such as decapods may bore into the older material. The filling of these borings by channel-floor detritus generates a *Glossifungites* ichnofacies (MacEachern *et al.*, 1992). Less cohesive substrates are likely to become colonized by bivalves, producing a thin interval of *in situ* shells below the base of a channel. Where sand is abundant, two- and/or three- dimensional dunes typically occupy a channel floor, producing trough or tabular cross-bedding. Otherwise, channel-floor deposits are likely to be thoroughly bioturbated, owing to slow rates of sediment accumulation.

Because tidal channels tend to migrate, their banks are either erosional or accretionary (Figure C32). Accretionary tidal channel banks form a volumetrically important part of many ancient bay fills. Because accretionary banks are sites of deposition, internal physical structures are likely to be preserved. The nature of accretionary bank stratification depends greatly on sediment texture. Sandy banks are likely to preserve cross- bedding or ripple lamination. With increasing mud, the bedding style changes progressively from wavy (scattered clay drapes) to mixed (roughly equal quantities of sand beds and clay drapes) to flaser (mud encasing sand ripples) to laminated (mud with scattered sand laminae). Rhythmic stratification is common, owing to the regularity of tides or seasonal processes. Tidal channel bank deposits generally (but not invariably) show an upward fining. The migration of tidal channel banks produces large clinoforms that are evident in good exposures.

Tidal sand bars are ridges of sand within tidal channels. Such bars may be entirely subtidal or include both subtidal and intertidal components. Subtidal bars are 1–15 km long, have length to width ratios greater than three, and have a relief of as much as 20 m (Dalrymple and Rhodes, 1995). The larger ones approach the size of tidal sand ridges of large open embayments and seaways (see Houbolt, 1968). Sand waves (dunes) typically mantle the bar surfaces and internal structure consists of trough and tabular cross-bedding. Where bars are less active, their internal structure is likely to consist of sets of cross-strata separated by bioturbated intervals, owing to low rates of aggradation and bedform migration. Larger bars commonly separate areas of flood- and ebb-dominance. Like the tidal sand ridges in the North Sea, these ridges commonly are asymmetric whereby the steeper side faces in the direction of dominant sand transport. As a consequence the dip cross-bedding foresets is unidirectional in the direction of subordinate sand transport. Where tidal sand bars extend into the intertidal range, the vertical sequence likely to result if the bar were fully preserved consists of a lower subtidal and intertidal cross-bedded interval overlain by tide flat and salt marsh deposits (Dalrymple *et al.*, 1990).

Intertidal flats are sandy or muddy areas of low relief that are alternately exposed and inundated by astronomical tides. Sedimentation rates are low and bioturbation predominates unless physical or chemical

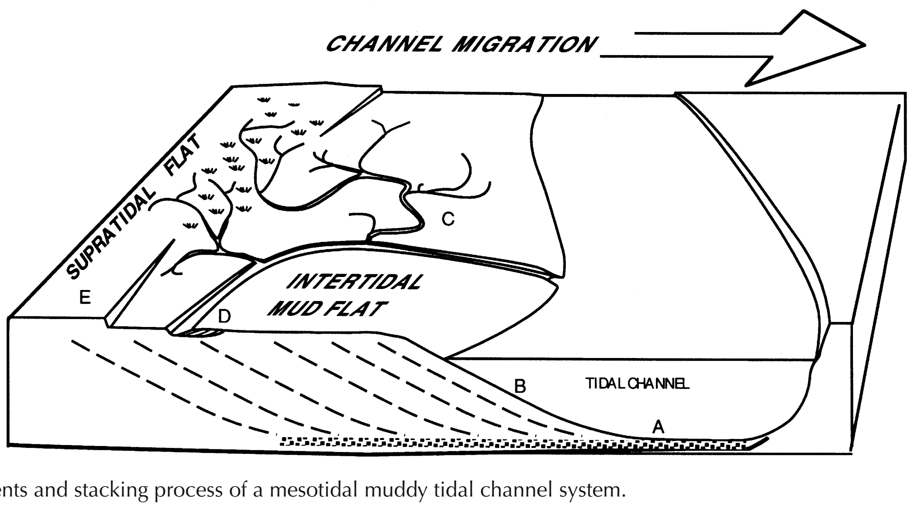

Figure C32 Components and stacking process of a mesotidal muddy tidal channel system.

A. Tidal channel floor composed of bioturbated shell and other lag; Numerous burrows/boring into firm ground beneath the channel floor form a *Glossifungites* ichnofacies; B. Tidal channel accretionary bank, composed of stratified mud and sand; C. Tide flat, underlain by bioturbated mud/or sand; D. Accretionary bank of runoff channel, composed of finely interlaminated sand and mud rich in organic detritus. Low-angle mud across-stratification; E. Supratidal flat, inundated only during combinations of high spring tides and meterologic tides, such as storm surges. Underlain by laminated very fine sand/silt and mud. Numerous root or rhyzome structures.

factors inhibit faunal colonization. An example is on flats exposed to very high tidal range (macrotidal flats). Here, the difference between high tide under neap and spring tidal conditions is sufficient to provide an upper flat that is only inundated during high-spring tides. This intermittent exposure precludes the development of a mature infauna, and stratification is preserved in the form of flaser, mixed, wavy, or lenticular bedding, depending on the proportion of sand and mud. Where mesotidal conditions (tidal range 2–4 m) obtain, the difference between high spring and neap tides is less and bioturbation prevails in nearly all of the flat sediment.

Most muddy tidal flats are crossed by narrow, dendritic *runoff channels* (tidal creeks), typically 1–2 m deep. Most runoff channels have an erosional and an accretionary bank. Sedimentation on the accretionary banks is very rapid and the sediment commonly displays laminae that reflect individual tides as well as neap and spring tidal cycles. Despite their meandering appearance, the rate of channel migration is slow, owing to the erosional resistance of the muddy substrate. Sediment that accumulates rapidly on accretionary banks is prone to slumping into the channel, where it is flushed out by the tidal currents. The limited channel migration produces muddy clinoforms or cross-strata, 1–2 m thick, characterized by finely interlaminated sand, mud and organic detritus, and sporadic slump structures. Runoff channels on sandy tidal flats generally lack well-formed accretionary banks, and the associated distinctive facies.

Salt marshes are common on the upper part of many intertidal flats or marine delta plains (see Frey and Basan, 1985). The substrate may be completely bioturbated or display faint rhythmic lamination. The organic content is typically high, and root or rhizome structures are typical. *Supratidal flats* lie higher still and are inundated only under combinations of high- astronomical and high-meteorological (river flood or storm surge) tides. Stratification, in the form of rhythmic alternations of silt and organic-rich mud, is typically crossed by numerous roots or rhizomes. Commonly the laminae form sets of several distinctive layers, probably deposited at successive high tides during a single meteorological event.

Bayhead deltas are common in estuarine bays. These may take the form of a small river delta, displaying a transition from muddy sediment in the most basinward, deeper parts to sandy sediment in the upper, river-dominated part. Fluvial or distributary channels cap the upper delta surface. The resulting deposit shows an upward coarsening. Evidence of tidal influences, such as tidal bundling or reversals in ripple-lamination or cross-bedding, can serve to distinguish this type of small delta from those produced by crevassing.

In estuaries with a large tidal range, such as San Francisco Bay, the bay head delta comprises a complex of anastomosing channels without a clear deltaic form. In this setting, the bayhead delta consists of tidal channels that gradually transform landward into fluvial channels. The interface between salt and fresh water (head of the salt-water wedge) is typically very turbid and the site of rapid deposition from suspension. As with tide-dominated deltas on an open coast, the tidal influence on river flow may be expressed many kilometers upriver from the head of the salt-water wedge.

Washover fans are lobate accumulations of sand on the seaward side of lagoons, formed where storm waves breach a barrier and sweep sand into the adjacent lagoon (Leatherman *et al*., 1977). Bases are erosional, commonly marked by a shell lag. Internal structures include inversely graded planar lamination, ripple lamination, and climbing ripples, antidune stratification and, particularly at landward margins, landward-dipping cross-bedding. Tops of individual overwash accumulations can be bioturbated or contain rootlets.

Sedimentary facies of inlet areas

Tidal inlets form a fluid interface between bays and the open coast (see Boothroyd, 1985). Inlets may range from simple channels a few meters deep and tens of meters wide to complexes of channels and shoals more than 10 km or more across wide at the mouths of large embayments. Individual channels in this setting may be tens of meters deep and hundreds of meters wide. Inlet sediment is mostly sand, and occurs in a setting where tidal flow is likely to be at its highest. As a consequence, inlet channels are typically floored by two- and three-dimensional dunes. Individual channels may be dominated by either ebb or flood tide. Lag deposits of shells and or pebbles (where the adjacent shoreface is gravelly) are generally present, and may contain species representative of both open coast and bay. Trough and tabular cross-bedding and abundant burrows characterizes the resulting deposit.

Small inlets tend to migrate laterally along the coast, particularly where wave-driven longshore sediment transport is significant. Larger inlets may be more stationary, but interior inlet channels may migrate

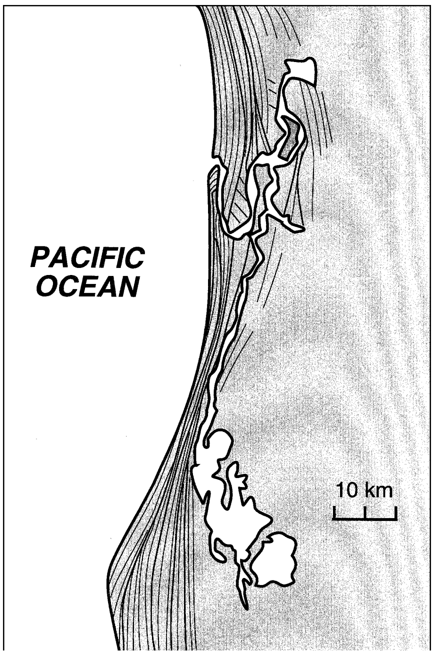

Figure C33 Beach Ridges indicating progradation on the Nayarit coast of Mexico (after Curray *et al*., 1969). Each ridge marks a previous position of the coastline.

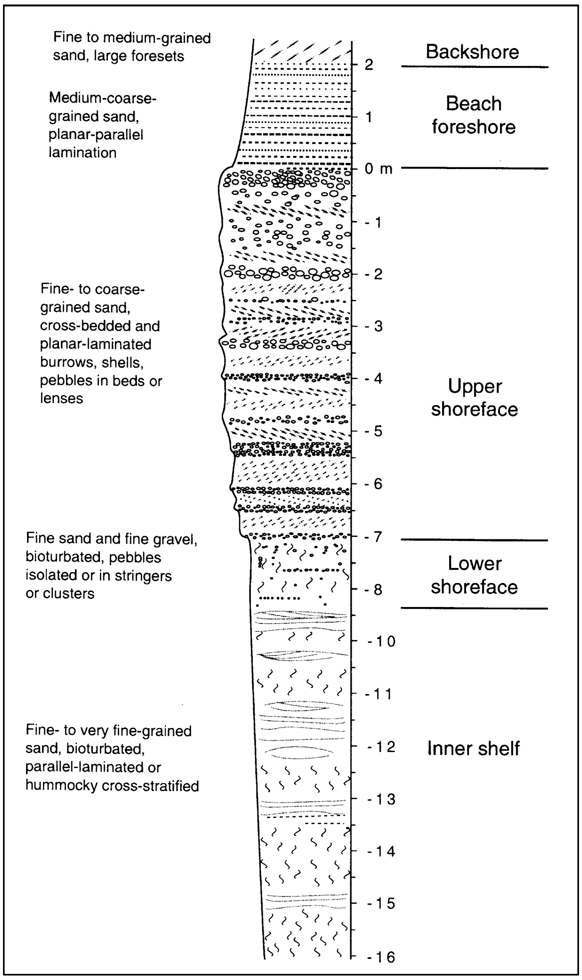

Figure C34 Typical shoreface succession on a prograding pebbly, high-energy coast.

rapidly. In Willapa Bay, Washington, for example, a primary inlet channel, 25 m deep and 600–700 m wide, has moved laterally more than a kilometer in the past 50 years. Inlet facies in such a setting are likely to consist of a lower part composed of cross-bedded sand produced in the primary channel overlain by the deposits of smaller tidal channels and wave- and tide-influenced shoals. Channel migration can produce clinoforms, the thickness of which depends on the depth of the channel. The lateral extent of inlet deposits depends on the degree of inlet migration. Extensive migration will generate laterally extensive inlet facies within a coastal succession.

Lobate bodies of sand, *flood tidal deltas*, form sandy ramps on the bayward side of many inlets. Where the tidal inlet migrates, flood tidal deltas may compose laterally extensive sand bodies along the seaward side of a lagoon enclosed by a barrier island. Initially these deltas form as a set of lobes building into the bay, covered by straight to sinuous two-dimensional landward-facing dunes (Hine, 1975). As they mature, tidal flow is concentrated into channels, ultimately producing a low, seaward-facing ramp dissected by broad flood-dominated tidal channels (Boothroyd, 1985). The resulting deposit is dominated by landward-directed trough and tabular cross-bedding and contains internal erosional surfaces capped by shell lags.

Ebb tidal deltas form on the seaward side of inlets, where they are subject to the influence of both waves and tides. Off large embayments, these deltas may be quite large, exceeding10 km in width and extending 5 km or more into the adjacent sea. Off smaller inlets on a transgressive coast, the deltas may form the nucleus of shoreface attached ridges (McBride and Moslow, 1991). Flood- and ebb-dominated tidal channels cross the shoal constituting the delta: typically the ebb flow is concentrated in the deeper channels. The combination of flood tidal flow and wave swash can produce a generally landward orientation to bedforms on the delta platform (Boothroyd, 1985). Upward-fining storm beds with erosional bases are common, particularly in the shallower parts of an ebb tidal delta.

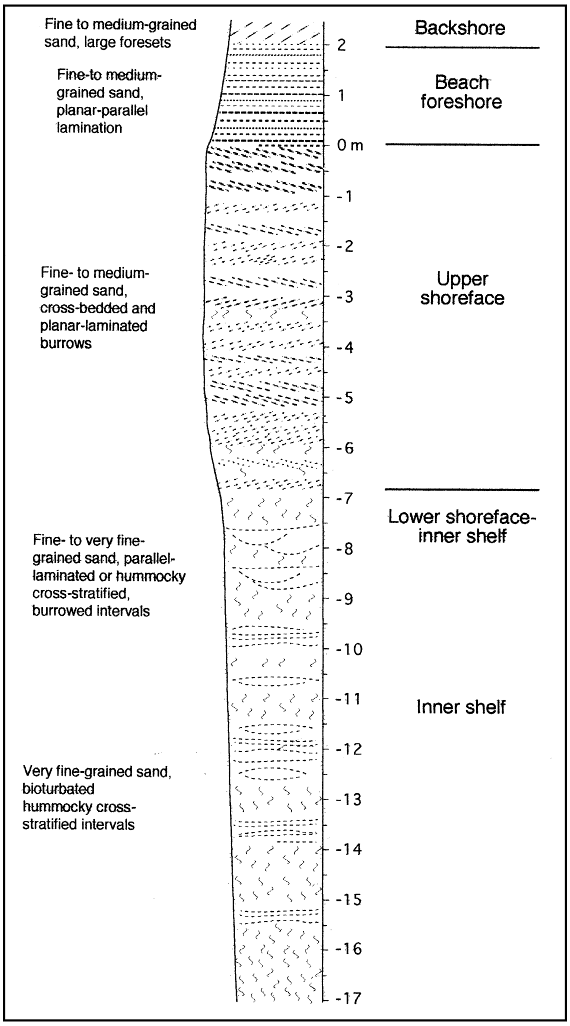

Figure C35 Typical shoreface succession on a prograding finer-grained, non-pebbly, high-energy coast.

Preservation of coastal sedimentary facies and resulting facies successions

Thick accumulations of coastal facies typically reflect a record of fluctuating sea level superimposed on a setting of overall tectonic subsidence. The shore response to sea-level change depends on the rate of sedimentation. In general, the influx of sediment at the shore promotes progradation, whereby the additional sediment forces the shore to shift basin-ward. Today, most prograding open coasts are characterized by a series of each ridges, each marking an earlier position of the shore (Figure C33) The resulting accumulation conforms to Walther's Law, which holds that a vertical arrangement of related facies conforms to their lateral distribution at the time of deposition. Progradational successions show an upward-shallowing, produced as shallower water facies encroach over their deeper water counterparts. On deltaic or other open coasts, the result typically generates an upward-coarsening interval. Progradation also occurs on a smaller scale where a bayhead delta builds into an estuary, or a crevasse delta builds into a deltaic bay. Figures C34–C36 show examples of progradational successions.

Fining-up facies successions are generated within bays and on deltas by the lateral migration of tidal or delta distributary channels. In these cases, the shallower parts of the system consist of intertidal flats or salt marshes, or, with distributary channels, levees. Figures C36 and C37 show examples of fining-up successions produced by migrating channels.

Although progradation is the most common circumstance of preservation of coastal sedimentary facies, not all facies are preserved. Those

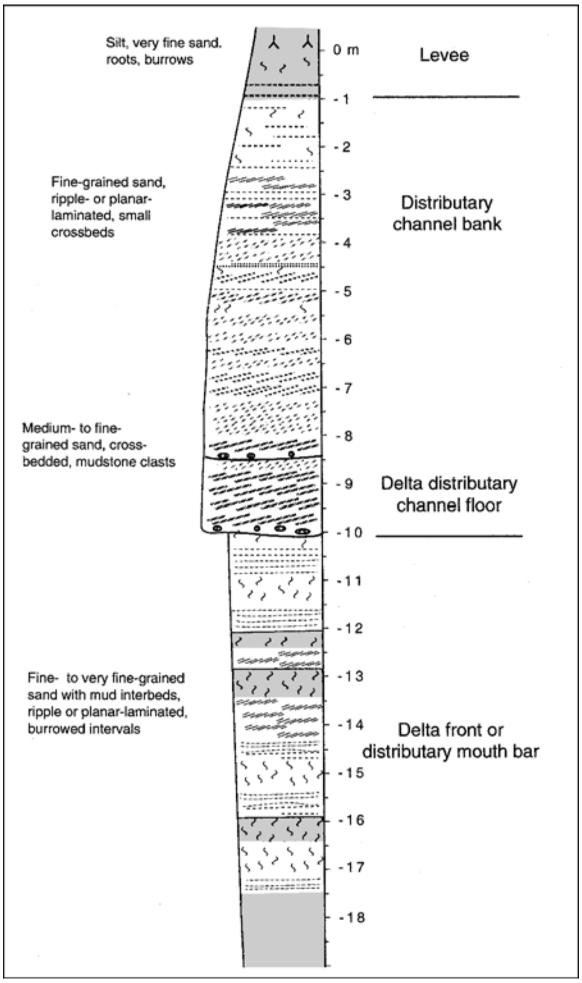

Figure C36 Stratigraphic succession produced in the upper part of a prograding river-dominated delta.

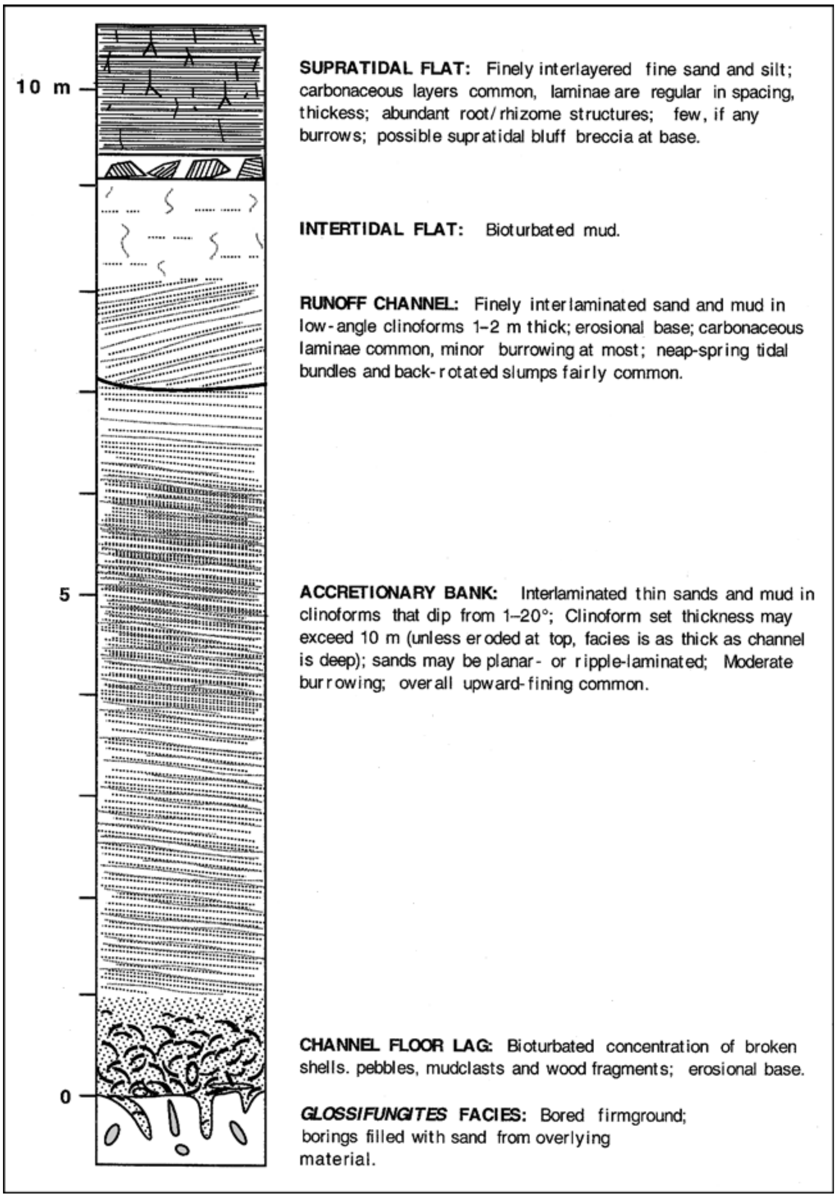

Figure C37 Vertical facies succession produced by migrating muddy tidal channel system. Thickness of sequence depends on depth of tidal channel and degree of subsequent erosion of upper part of succession.

associated with features that stand in relief above other, more landward, features are likely to be destroyed as progradation progresses. Breaker bars, for example, are common features of many upper shorefaces (Figure C30). During progradation, the seaward migration of the bar troughs that lie to landward erases much, if not all, of the bar. Similarly, distributary mouth bars have a limited potential for preservation. During the seaward migration of a distributary mouth system, distributary mouth bars are likely to be eroded and cannibalized by the distributary channel that created them. If that channel avulses, however, the associated bar may be preserved as a feature with limited lateral extent.

Where relative sea level falls during progradation a “forced regression” ensues. Wave erosion associated with the readjustment to a new, lower base level can create a “regressive surface of marine erosion”. The amount of sediment removed by this erosion depends on the rate and degree of base level fall and prevailing wave energy. Commonly the surface marks an abrupt change from shelf to shoreface deposits.

Progradation may occur during relative sea-level rise, if the rate of sedimentation is sufficiently high. But commonly, a rise in base level is associated with deposition in the feeder systems. With the resulting reduction of sediment contributed to the coast, marine transgression occurs, whereby the shoreline shifts landward.

During transgression, some facies are likely to be preserved and others lost. During lowstands that commonly precede transgression, coastal rivers incise valleys near the coastline. Estuarine facies deposited in these valleys at the lowstand or during the initial rise tend to be largely preserved through a transgression.

A different situation prevails on the open coast. The natural product of waves and coastal winds is a shoreface and beach capped by a foredune ridge. In most wave-dominated settings, enough sand exists that a small rise in relative sea level is met by an upbuilding of the shore to a topographically higher position. Where a sea-level rise causes a reduction in sediment input to the coast, a basin forms behind the beach ridge and a barrier island is created. Most present-day coasts fronted by barrier islands are in a state of transgression.

Barrier islands formed during transgression have a limited potential for preservation. The landward translation of a shoreface erases the deposits that lie landward from its base, leaving an erosional (*ravinement*) surface overlain by shelf facies (Figure C38). Commonly this surface is the only preserved expression of a transgression.

Under conditions of rapid accommodation and sufficient sediment supply, however, lagoonal facies are preserved (Figure C39). These may occur in inverted succession, whereby the landward-most facies (lagoonal marshes and back-bay muds) are overlain by sandier deposits

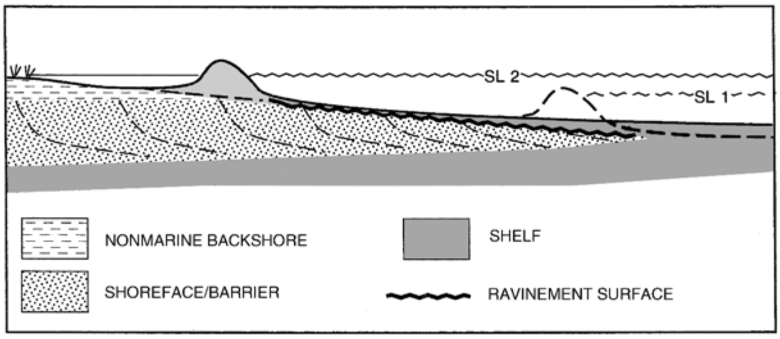

Figure C38 Transgressive erosion caused by the lateral translation of the shoreface (see Brunn, 1962). None of the transgressive coastal facies are preserved, and the transgression is recorded by an erosional ("ravinement") surface overlain by deeper water typically shelf) deposition.

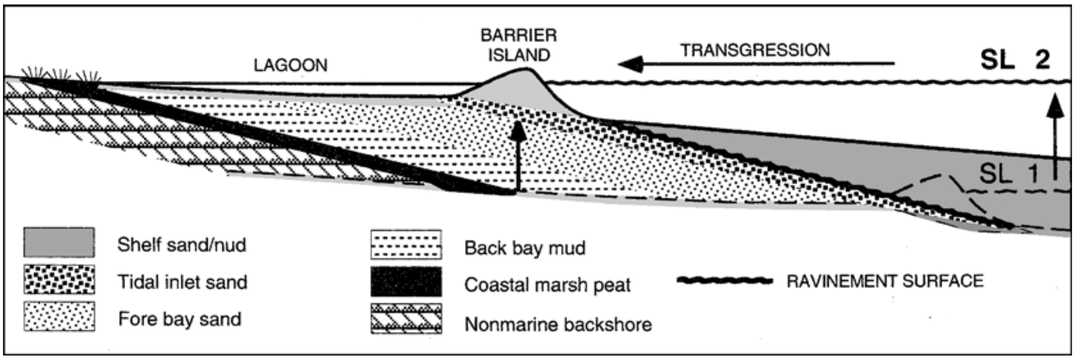

Figure C39 Transgressive succession produced in settings with rapid accommodation and adequate sedimentation. A lagoonal succession develops as the lagoonal facies are buried by the landward-migrating barrier. It is capped by a "ravinement" surface overlain by shelf facies.

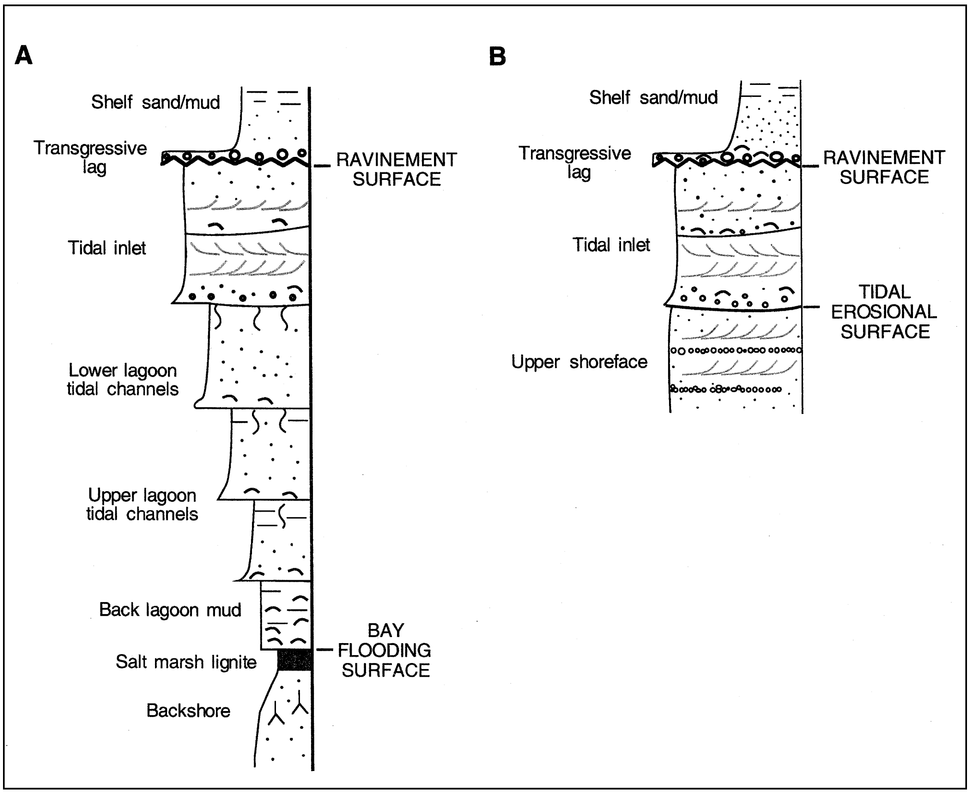

Figure C40 Vertical successions produced by preservation of transgressing lagoons. (A) High rate of accommodation. (B) Modest rate of accommodation.

associated with the approach of the transgressing barrier and capped by tidal inlet facies just below the ravinement surface (Figure C40A). The thickness and organization of these transgressive lagoonal deposits differs depending on the balance between accommodation and sedimentation. Although most are but a few meters thick, some can exceed 20 m. Most display a basal "bay-flooding surface" and a capping ravinement surface, although vigorous tidal currents and low rates of accommodation may in some places lead to the erosion of the lower part of the succession (Figure 40B).

COASTAL SOILS

Introduction

The occurrence of soil in coastal zones is not a simple matter to resolve. Summarized coastal zones form a global perspective that only briefly indicates potential occurrence of soil in relation to coastal landforms, maritime climates, drainage, vegetation, and time available for formation. Increased understanding of coastal soils is, however, only possible from the purview of specific examples that illustrate soil distribution patterns in terms of sequences based on soil-forming factors of topography (toposequences), time (chronosequences), climate change (climosequence), and biological factors (biosequence). The conceptual frameworks for the models were initially postulated by Jenny (1941) and subsequently enhanced by various other researchers (e.g., Butler, 1959, 1967; Runge, 1973; Huggett, 1975). The value of these sequential paradigms is that they provide visualization of complex interrelationships in a framework that clarifies and elucidates coastal-soil transition inland from the shore.

The models are relatively uncomplicated in young (Holocene), more or less uniform parent materials such as those which may occur in small deltaic areas, mangrove swamps, coastal alluvium, and dunes. Complications arise along most coasts because coastal fringes reflect polygenetic development where exceedingly old parent materials and associated soils may occur juxtaposed to incipient pedogenesis. *Environmental complexity* in coastal areas where there is rise and fall of relative sea level, stillstands and diastems, increase and decrease of sediment supply, delta progradation and retrogradation, alluvial channel avulsion, development of deltaic superlobes, chenier formation, climatic change, and so forth, is manifested in weathering zones and soils that provide clues to evolutionary sequences as does the stratigraphy and nature of the included materials. Examples of depositional sequences are reported by Davis (1978), Milliman and Meade (1983), Liu and Walker (1989), Less and Lu, (1992), Roberts and Coleman

(1996), Saito *et al*. (2000), and Yatsko (2000), among others, for a variety of coastal settings. Dune systems, including large eolianites, which can be just as complicated as deltaic sequences, often provide stratigraphy with intercalated Paleosols (e.g., Fairbridge, 1950; Cooper, 1966; Denny and Owens, 1979; Hearty and Kindler, 1997). Pedogenic inertia and persistence (e.g., Huggett, 1975; Finkl, 1980) is another problem where older soils (which in turn may be initial parent material for soil forming under new environmental conditions) may occur in geomorphically young coastal landscapes.

Thus, coastal soils *sensu stricto* are often regarded as those soils that are derived form marine or estuarine parent materials that have recently been exposed subaerially to pedogenesis viz. acid sulfate soils, etc. Others might be related to coastal dunes, beach ridges, chenier plains, salt marsh, or upland freshwater marsh. The soils mostly range in age from late Holocene to early Pleistocene, reflecting a chronosequence that is geologically very young. This restricted point of view excludes many coastal sectors where soils of great age may be found, especially in the intratropical zones where coastal erosion may expose intensely weathered deposits as coastal cliffs in laterite (e.g., Hays, 1967; Petit, 1985; Retallack, 1990; Wang, 2003). Coastal soils *sensu lato* include a very wide range of possibilities as almost any kind of soil may occur in coastal zones. Fortunately, the possibilities are not endless and there is some order to apparent chaos of haphazard occurrence. Some clues as to potentialities for soil distribution patterns, at myriametric scales, on coasts may be gleaned from the morphological classification of coasts on the basis of plate tectonics (e.g., Inman and Nordstrom, 1971) where tectono-physiographic settings limit the scope of pedogenesis. Trailing continental margins provide large expanses of coastal plain sediments, as occurring along the eastern seaboard of the United States, south of Washington, DC, where there are thick weathering sequences composed of residual oxidized materials and soils developed in alluvial, estuarine, and marine deposits (e.g., Markewich *et al*., 1986). In the vicinity of major rivers, especially on the southern coastal plain of the United States, major floodplains and deltas give rise to organic-rich soils. The coastal plains of southern Florida give rise to Holocene calcareous soils on slightly higher elevations whereas, lower poorly drained sites contain a suite of organic and muck soils related to Everglades, sloughs, swales, and other karst depressional areas that became infilled with fine-grained materials mixed with organic materials following the Holocene transgression (e.g., Gleason *et al*., 1984; Finkl, 1994, 1995; Lodge, 1994).

Leading continental margins, such as that occurring along the mountainous and (strike-slip) faulted North American west coast where an oceanic plate is subducted below an overriding continental plate, provide a completely different set of tectono-physiographic conditions for soil development. Uplifted marine terraces contain soils of different ages, depending on the rates of uplift and number of terraces along the coast. Tsunami deposits, which are preserved in protected areas, provide allochthonous arenaceous parent materials for soils (Clague *et al*., 1999) that date back to the penultimate great Cascadia earthquake 1,000 years ago. Coastal valleys in Oregon and Washington often retain interesting stratigraphy, where earthquake-induced subsidence leads to the burial of alluvial and marsh soil profiles and the development of younger soils in the new parent materials above (e.g., Nelson and Kashima, 1993). Pedogenic environments along these kinds of tectonic coasts where there are active seismotectonic regimes, as in Greece (Maroukian *et al*., 2000) and throughout much of the Mediterranean region and elsewhere, are much more dynamic than the quiescent trailing margins.

Finally, there is the ultimately confounding situation where former coastlines are now stranded long distances from present shores. Many of these rocky shores (e.g., Johnson, 1992; Libbey and Johnson, 1997) provide parent materials for subsequent soil development (neopedogenesis of soil materials), but these occurrences can hardly be considered "coastal" in that pedogenesis is now unrelated to coastal factors of soil formation, other than coastal–marine parent material. Coastal Paleosols are, however, usually associated with modern as well as ancient coastlines whether at present sea level, emergent, or submerged. Emergent examples are best known and have been extensively studied along with Quaternary geomorphology and stratigraphy, for example, in Papau New Guinea (e.g., Bloom and Yonekura, 1985), Barbados (e.g., Radtke, 1989; Schellmann and Radtke, 2001), Bermuda (e.g., Hearty *et al*., 1992), Bahama Islands (e.g., Hearty and Kindler, 1997), Point Peron in Western Australia (Fairbridge, 1950), Chile and Argentina in South America (e.g., Rutter *et al*., 1989), and many other coastal areas too numerous to mention. Notable within the present purview of coastal soils, however, is the study by Schellmann and Radtke (2003) who employ morphologic, pedostratigraphic, and chronostratigraphic assessments of marine terraces along the Patagonian Atlantic coast. Many of these studies were used for reconstruction of local sea-level history, including evidence in southwestern Western Australia for a higher relative mean sea level (MSL) during the Holocene (Fairbridge, 1961; Playford and Leech, 1977), but as discussed by Searle and Woods (1986) evidence for the ± 3 m oscillations proposed by Fairbridge can be elusive. Still other ancient shorelines, instead of experiencing terrestrial sequestration from the sea, are found as drowned relicts. Examples are reported form Hawaii (Fletcher and Sherman, 1995), but there is no mention of included drowned soils.

Deltaic plains, such as the Mississippi River delta deposits, provide similar examples where constructive (alluvial accumulation, build up and soil formation) and destructive cycles (e.g., subsidence and drowning) present complex pedogenic environments that respond to fluvial-deltaic processes and longer-term base-level changes (Roberts and Coleman, 1996). Callaway *et al*. (1997), studying sedimentary accretion rates on low tidal-amplitude sites along the Gulf of Mexico, found evidence that contravened previous hypotheses concerning the relationship between tidal range and marsh vertical accretion rates. They found that there was little correlation between mineral and organic matter accumulation rates, with average organic matter accumulation rates showing less variation compared to mineral matter accumulation. There thus may be limits to annual rates of organic matter accumulation. Sediment addition is, however, clearly required for maintenance of coastal marsh soils (e.g., DeLaune *et al*., 1987, 1990).

There are many different soil classifications in use today throughout the world (see discussions in Finkl, 1981), but none feature-specific sections on coastal soils *per se*. Rather than being perceived as a disadvantage, this situation is advantageous because soils occurring in coastal environments are hierarchically related throughout comprehensive soil classification systems and placed within continental or international schemes that facilitate reference and comprehension. Prominent among the major soil classifications are efforts by American, Australian, Canadian, French, German, Brazilian, and Russian soil researchers but the system employed here is the one adopted by the Food and Agricultural Organization FAO of UNESCO. The FAO system (FAO–UNESCO–ISRIC, 1988; FAO, 1991) is employed because it is specifically designed as an international system and because it provides a comprehensive inventory of world soil resources in the form of electronic databanks and maps. Although this is the primary organizing or categorical basis for discussing coastal soils, classes in other systems are sometimes equally valid (Spaargaren, 2000) and they are sometimes referred to for ease of reference and also to avoid unnecessary complications that would arise from correlation with other systems. Local soil classification schemes often reflect regional or cultural bias in their geography and therefore international efforts are encouraged (e.g., Finkl, 1982a, b). As already appreciated by many coastal researchers, they must be ambidextrous when dealing with coastal soil morphology, genesis, and classification. Unless otherwise stated, classificatory units referred to here belong to the international FAO system of soil classification, but similar and related terminology is also employed from the US soil classification system as applied in *Soil Taxonomy* (Soil Survey Staff, 1975) and keys (Soil Survey Staff, 1992). The following descriptions are based on FAO major soil groups.

Histosols

The major soil groups of Histosols (from Gr. *Histos*, tissue) include a wide variety of peat and muck soils that range from moss peats of the boreal tundra, moss peats, reeds/sedge peats, forest peats of the temperate zone, and mangrove and swamp forest peats of the humid tropics (Spaargaren, 1994; Inubushi *et al*., 2003). Histosols are unlike all other soils in that they are formed in and by "organic soil material" with physical, chemical, and mechanical properties that differ strongly from those of mineral soil materials. They develop in conditions where organic materials are produced by an adapted (climax) vegetation, and where biochemical decomposition of plant debris is retarded by low temperatures, persistent waterlogging, extreme acidity, oligotrophy and/or the presence of high levels of electrolytes from organic toxins. Organic soil material contains more than 12% organic carbon by weight (20% OM). The diagnostic horizons for Histosols are the histic and folic horizons. Other diagnostic horizons used to separate soil units in Histosols are termed sulfuric, sulfidic, and salic. The combination of specific environmental conditions, composition of the organic soil material, and degree of decomposition produces six soil units that include: Gelic Histosols (permafrost occurs within 200 cm of the soil surface), Thionic Histosols (there is a sulfidic or sulfuric horizon starting within 125 cm of the surface), Salic Histosols (there is a Salic horizon starting within 50 cm of the surface), Folic Histosols (folic horizon present), Fibric Histosols (more than two-thirds of the organic soil material consists of recognizable plant material), and Haplic Histosols (other units).

Histosols form where the rate of accumulation of plant debris exceeds the rate of its decay (e.g., Nyman *et al.*, 1993). In practice, Histosols occur where microbial decomposition of plant debris is impaired by: cold temperatures, excessive wetness, salts or other toxins, and severe aridity or oligotrophy. Histosols under the permanent influence of groundwater, unless artificially drained (e.g., "low moor peats") occur in low-lying positions in fluvial, lacustrine, and marine landscapes, mainly in temperate regions but also to limited extents in the tropics. Other soils occurring in the same environment include Fluvisols, Gleysols and, in coastal regions, Solonchaks (e.g., adjacent to coastal mangrove peats). In lacustrine landforms and in coastal marsh embayments, Histosols may be associated with Vertisols, such as that occurring on the Texas Gulf Coastal Plain (e.g., Stiles *et al.*, 2003). Oligotrophy and prolonged wetness are primarily accountable for the low decay of organic debris. In the wet tropics (mainly the Indonesian region surrounding the Sunda Flat), their formation is conditioned by high rates of organic matter production from the climax forest vegetation. Change in use of tropical peatlands can affect the decay rates of organic matter and production of methane and nitrous oxide gases viz. conversion from secondary forest peatland to paddy fields, as reported for Kalimantan in Indonesia (Inubushi *et al.*, 2003). In addition to land-use change as a forcing function for pedogenic succession, similar migration of soil properties are associated with tidal inundation along transgressive coastal areas such as around the Chesapeake Bay on the eastern US coastal plain. Hussein and Rabenhorst (2001) report, for example, pedogenic transformation of Ultisols to Alfisols and eventually to Histosols in response to sea-level rise, based on changes in sodium adsorption ratios and exchangeable sodium percentages. Salinization and alkalization processes as a function of tidal inundation frequency across low-lying coastal landscapes produce lateral changes in pedogenic properties that ultimately relate to different profile characteristics and classification of soils. Lateral pedological linkages exist with a variety of other soil groups, including Podzols, Fluvisols, Gleysols, Cambisol, and Regosols.

The global extent of Histosols is about 275 million ha (FAO, 1991) (Table C9), roughly half of which are located in the Arctic zone, one-third in temperate lowlands, and one-sixth in tropical lowlands (Spaargaren, 1994). An example of the latter case is the subtropical Florida Everglades, which constitute the largest single body of Histosols in the world (Stephens, 1956, cited in Amador and Jones, 1995). A large area of cold region organic soils occurs on the southern and southwestern subArctic margins of Hudson Bay (Manitoba, Ontario, Quebec) and around Great Bear Lake (Northwest Territories) in Canada. Here, Cryic Fibrisols (with frozen subsurface) occupy about 171,715 km^2 of coastal plain (Clayton *et al.*, 1977).

In lower latitude coastal areas, continually rising sea level has caused brackish or saline waters to engulf drowned river valleys (rias) or to extend over formerly upland soils. This has led to the formation of coastal marsh Histosols in several geomorphic settings (Darmody and Foss, 1979). As sea levels continue to rise, marsh margins are pushed landward and the organic materials continue to thicken so that the older and deeper Histosols generally exist nearer the open water (e.g., Nyman *et al.*, 1993; Rabenhorst, 1997). Although distant from high-latitude glacial activity, coastal Histosols at lower latitudes were impacted by glacio-eustatism (e.g., Rabenhorst and Swanson, 2000). During the glacial maximum (~20,000 yr BP) when large quantities of water were bound in glacial ice, eustatic sea level was at least 150 m below present MSL. Deglaciation cycles caused sea level to rise at such a rapid rate (~10–20 mm a^{-1}) that initially vegetation could not colonize tidal regions. Approximately 3,000–5,000 years ago, sea-level rise slowed so that marsh vegetation became established and organic parent materials began to accumulate (Bloom and Stuvier, 1963; Redfield, 1972). As sea level rose, organic materials accumulated in Histosols so that coastal marshes and mangroves generally accreted at about the same rate. Peat accretion in coastal areas presently ranges from 3 to 8 mm a^{-1}, which is much higher than in non-coastal regions. The highest rates of sea-level rise may, however, be too great for marsh systems to maintain and some areas suffer marsh loss and degradation (e.g., Huiskes, 1990; Nyman *et al.*, 1993; Boesch *et al.*, 1994) where Histosols are eroded, degraded (e.g., Mendelssohn and McKee, 1988) or drowned. Loss may also occur in response to subsidence (primarily as microbial mineralization of soil organic matter), such as in areas of the Florida Everglades where drainage of coastal wetlands (Everglades marsh) (Finkl, 1995) has exposed organic soils subaerially (Stevens *et al.*, 1984) and their surface elevations may decrease by as much as -2.5 cm a^{-1}.

The Florida Everglades is the largest continuous sedge moor outside of the Pleistocene glaciated area of the United States (Gleason *et al.*, 1984). The expansive coastal wetlands and freshwater marsh of southern Florida are a result of the very slow relative rise of sea level during the past 3,200 years (average rate of 4 cm per century) (Spackman *et al.*, 1966; Wanless *et al.*, 1994). A large number of coastal sediment bodies in southern Florida were initiated or stabilized between 3,300 and 3,000 yr BP and again approximately between 2,300 and 2,500 yr BP (Wanless *et al.*, 1994). The origin and development of those coastal and shallow-marine carbonate and clastic sediment bodies is dependent on the interactive roles and timing of sea-level changes, climatic fluctuations, storm influences, vegetative colonization, preexisting topography, and provision of detrital (input or recycled) siliciclastic and carbonate sediment. Of these, the rate of sea-level rise was the primary control on the clastic, carbonate, and organic sediment bodies of southern Florida.

As one of the largest marshes in the world, the Everglades peat deposits are commonly differentiated into subtypes based on compositional variation, thickness, and degree of weathering. Water is required for the formation of peat soil because it restricts atmospheric oxygen from the soil; without oxygen, microorganisms cannot decompose dead marsh plants as fast as they accumulate. Ever-thicker deposits of peat are deposited until an elevation is reached where the surface dries enough that oxygen-dependent decay (the opposing aerobic process), or fire, prevents accumulation (Lodge, 1994). Freshwater peats of the Everglades merge southwards with mangrove peats on the tidal plain fronting Florida Bay. Occupying more than 400 ha of marshland, the Everglades Peat forms from degraded saw grass in long-hydroperiod habits. It is the most abundant peat occurring in the Everglades Basin. The Loxahatchee Peat, covering about 29,000 ha, occurs in deeper marsh areas and contains less saw grass remains and more evidence of slough vegetation such as the roots, rhizomes, leaves, and seeds of water lilies. Very poorly drained organic soils of the Everglades usually have a surface layer of black muck (sapric material—organic material that is too finely divided for identification of plant remains) that overlies black or reddish-brown muck subsoils that in turn rest on sand, limestone bedrock, or other materials (McCollum *et al.*, 1978). The term *muck* refers to highly disintegrated peat soils that are composed of more mineral than organic matter (see discussion in Brown *et al.*, 1990). *Marl* is the product of periphyton. During the dry season, the organic material (dead algae) in the periphyton mass oxidizes, leaving the calcium carbonate particles as a light-colored soil. Marl is descriptively called *calcitic mud* and is the main soil of the short-hydroperiod wet prairie habitats near the margins of the southern Everglades where bedrock lies close to the surface (Lodge, 1994). Marl and peat soils are opposites, requiring aerobic and anaerobic soil conditions, respectively. Peat cannot accumulate in shorter hydroperiod marshes where marl persists, and acid conditions within a peat soil dissolve marl and prevent its accumulation. However, there are large areas in the northern Everglades where a thick layer of marl underlies peat. This occurrence is evidence that the hydroperiod increased substantially in those areas as the Everglades ecosystem evolved. Much of the Everglades region is flooded during the summer rainy season, which is a natural process essential to the health of this wetland. Many areas of urban development, especially on the coastal plain of southeast Florida, occur on former Everglades (wetlands that were drained as part of reclamation programs) (Finkl, 1995) where Histosols have been stripped away and building sites 'demucked' and filled with dredged materials. The region is, however, prone to returning to its natural wetland condition during high rainfall events making localized sectors of the region susceptible to flooding (Finkl, 2000).

Acid sulfate soils

Acid sulfate soils occupy an area of some 24 million ha worldwide where the topsoil is severely acid or will become so if drained (Ritsema *et al.*, 2000). An equal area of these soils may be thinly covered by peat and nonsulfidic alluvium (van Mensvoort and Dent, 1997). Acid sulfate soils are typically associated with mangrove forests that once covered 75% of the coastlines in tropic and subtropical countries (Quarto and Cissna, 1997). Estimates of the extent and distribution of acid sulfate soils suffer, however, from the lack of field surveys, few reliable laboratory data, and from variable definition. More significant than their areal extent is their location where they are concentrated in otherwise densely settled coastal and floodplains, mostly in the tropics, where development pressures are intense with few suitable alternatives for expansion of farming, or urban or industrial development. Two-thirds of the known extent is in Vietnam (e.g., Mekong River Delta), Thailand, Indonesia, Malaysia, western Africa (Senegal, Guinea Bissau), northern Australia, and on coastal plains in southern China (e.g., Pearl River Delta). By far, the largest use of acid sulfate soils is for rice cultivation

Table C9 Main kinds of soils occurring in coastal areas, based on a world reference base for soil resources, indicating the different types of soil cover in relation to landscape features and associated linkages with related soils

Soil group (FAO)[a]	Area ($\times 10^6$ ha)[b]	Major subdivisions[c]	Associated soils[d]	Lateral linkages or intergrades[e]	Landscape position, climate, drainage, topography, or parent materials
Histosols	275	Gelic, Thionic, Salic, Folic, Fibric, Haplic Histosols	Fluvisols, Gleysols, Solonchaks, Vertisols	Podzols, Fluvisols, Gleysols, Cambisols, Regosols	Low-lying positions in fluvial, lacustrine, and marine landscapes. Solonchaks often adjacent to coastal mangrove peats
Anthrosols	NA	Hydragric, Irragric, Cumulic, Hortic Anthrosols	Border most of the major soil groups where soils have been strongly influenced by man	Includes coastal archaeological sites	Old cultivates sites, excluding paddy soils, on coastal plains, river valleys, deltas, etc.
Leptosols	1,655	Lithic, Cryic, Skletic, Rendic, Mollic, Umbric, Dystric, Eutric Leptosols	Regosol, Cambisol, Podzol, Calcisol, Luvisol, Histosol, Anthrosol	Wide range of intergrades	Tropics to polar tundra, coastal lowlands to mountains
Cryosols	1,800	Histic, Thixotropic Cryosols	Histosols, Gleysols, Stagnosols, Cambisols	Gelic or cryic units of Histosols, Gleysols, Podzols, Planosols, Glossisols, Stagnosols, Cambisols	Arctic coastal plains of NE Eurasia, Alaska, Yukon, and NW territories of Canada; islands of Siberian, Beringian, and North American sectors of the Arctic Ocean; coastal Greenland
Fluvisols	350	Thionic, Salic, Vertic, Mollic, Calcaric, Umbric, Dystric, Eutric	Cambisols, Regosols, Arenosols, Leptosols, Gleysols, Solonchaks	Arenosols, Cambisols, Fluvic Gleysols, Salic Fluvisols (intergrade to Solonchaks)	Large deltas and fans viz., Ganges, Mekong, Mississippi, Niger, Po, Rhine; major river floodplains; coastal barriers; tidal flats
Solonchaks	260–340	Gleyic, Stagnic, Mollic, Gypsic, Calcic, Sodic, Haplic Solonchaks	Chlorida and sulfate soils	Salic Fluvisols, Thionic Fluvisol—Solonchak intergrades	Coastal salt lakes, lagoons, pans; chloride facies—soils of marine origin under mangrove; neutral chlorido-sulphate soils—of marine origin but enriched by sedimentary gypsum deposited by rivers; acid sulphate soils—soils of marine origin under mangrove as in Gambia, Senegal, Guinee Bissau
Gleysols	720	Cryic, Thionic, Plinthic, Arenic, Mollic, Umbric, Fluvic, Calcic, Haplic Gleysols	Leptosols, Vertisols, Fluvisols, Solonchaks, Stagnosols, Histosols, Regosols	Histi-Mollic, Histi-Umbric Gleysols, Fluvic Gleysols (intergrades to Fluvisols)	Sandy to loamy (sometimes clayey) textural classes of parent material on alluvial, fluvial, fluvioglacial deposits in riverine or coastal areas. Common in depressional and organic-rich coastal areas; for example, Arctic coastal plains, coastal Alaska; Florida Everglades
Podzols	485	Gelic, Gleyic, Stagnic, Humic, Duric, Umbric, Cambric, Haplic	Histosols, Gleysols, Cryosols, Cambisols, Ferralsols, Planosols, Glossisols	Podzol–Histosol–Gleysol sequences, Cambisol–Podzol sequence	Sandy deposits affected by illuviation and cheluviation, boreal climatic zone, coniferous vegetal cover, temperate and tropical wet climatic areas. For example, NE and NW coastal Canada, Scandinavia, NW coastal Russia; coastal plain of Florida; southwestern Australia; coastal Indonesia
Sesquisols	60	Petric, Aeric, Albic, Stagnic, Humic, Eutric, Haplic Sesquisols	Ferralsols, Alisols, Acrisols, Lixisols	Found in association with Gleysols and Stagnosols in areas conditioned by hydromorphy; with Feralsols, Alisols, Acrisols, and Lixisols in better drained positions in the landscape	Usually ancient landsurfaces truncated by modern coastal erosion or in close proximity to the sea; older coastal plains; for example, western Africa, western India, Mekong catchment, northern and southwestern Australia, eastern Amazon region

Table C9 (*Continued*)

Soil group (FAO)[a]	Area ($\times 10^6$ ha)[b]	Major subdivisions[c]	Associated soils[d]	Lateral linkages or intergrades[e]	Landscape position, climate, drainage, topography, or parent materials
Ferralsols	750	Humic, Geric, Gibbsic, Lixic, Rhodic, Eutric, Plinthic, Gleyic, Haplic Ferralsols	Cambisols, Acrisols, Nitisols, Gleysols, Planosols, Arenosols, Sesquisols	Intergrades to Cambisols, Acrisols, Nitisols, Gleysols, Planosols, Arenosols, Sesquisols	Mid- to end-Tertiary peneplains; for example, Brazilian Shield, French Guyana, Senegal, Madagascar, northern and SW Australia; extreme tropical and subtropical weathering
Planosols	130	Gelic, Vertic, Histic, Mollic, Umbric, Dystric, Eutric Planosols	Vertisols, Acrisols, Luvisols	Stagnic Solonetz, Albic Sesquisols, Stagnic Gleysols; related soils with abrupt textural change but insufficiently wet to show reduction by surface water would fall into Luvisols, Lixisols, Alisols, Acrisols	Low-lying, nearly level fluvial or marine terraces, depressional lands on coastal plains, including wetland rice paddies; most extensive in climes with a strongly seasonal variation in rainfall that results in intermittent saturation and reduction of upper soil horizons
Solonetz	135	Gleyic, Stagnic, Salic, Albic, Mollic, Gypsic, Calcic, Haplic Solonetz	Linked through sodic units to Vertisols, Solonchaks, Gleysols, Calcisols	Salic Solonetz, Sodic Solonchaks; through sodic properties in Vertisols, Solonchaks, Gleysols, and Calcisols; with Gleysols and Stagnosols through the Gleynic and Stagnic Solonetz soil unit	Solonetz landscapes are governed by microrelief, waterlogging at the surface, and salinity in the profile; lake terraces, river deltas, depressions along liman coasts; Rio de la Plata deltaic plain in Argentina; coastal South Australia and coastal southeastern Western Australia
Calcisols	800	Petric, Luvic, Sodic, Cambic, and Haplic Calcisols	Vertisols, Solonchaks, Gleysols, Solonetz, Luvisols	Calcic Gleysols, Calsic Gypsicsols, Calcic Luvisol	Arid coastal regions viz. Baja, California; Patagonia and Argentine Pampa; coastal Atacama; Namibia; coastal northern Africa; Nullarbor Plain in Western Australia and coastal plain in South Australia
Alisols	>100	Plinthis, Gleyic, Humic, Vertic, Ferric, Chromic, Luvic, Haplic Alisols	Ferralsols, Nitisols, Acrisols, Lixisols, Vertisols, Cambisols	Vertic Alisols, Alic Nitisols, Alic Acrisols; facies of other highly weathered soil units in intertropical regions	Coastal plain in southern USA; parts of intertropical coastal India, Africa, and northern Australia
Acrisols	>900	Plinthic, Gleyic, Humic, Arenic, Albic, Ferric, Haplic	Lixisols, Luvisols, Alisols, Nitisols, Glossisols	Planosols, Lixic Ferralsols, Arenosols, Regosols, Cambisols	Ancient shield landscapes, in tropical regions, that are truncated by coastal plains or marine erosion; coastal plain is southeastern USA, Caribbean Central America coastal lowlands, Orinoco deltaic plain, western Africa, Southeastern Asia, Indonesia
Luvisols	650	Gleyic, Albic, Vertic, Calcic, Ferric, Chromic, Dystric, and Haplic	Alisols, Lixisols, Acrisols, Nitisols, Glossisols, Solonetz	Luvic Chernozems, Luvic Gypsicsols, Luvic Phaeozems, Luvic Calcisols, Luvic Arenosols	Humid to subhumid temperate regions of western Europe (Belgium, The Netherlands, coastal Germany), parts of the Mediterranean region, southern Australia (extreme southwestern Western Australia, central South Australia), eastern Indian coastal regions, Sri Lanka
Lixisols	435	Plinthis, Gleyic, Humic, Arenic, Albic, Ferric, Haplic	Nitisols, Alisols, Acrisols, Luvisols, Glossisols	Ferralsols, Regosols, Cambisols, Luvisols	On stable shield landscapes in tropical regions; in seasonally dry tropical, subtropical, and warm temperate regions, on Pleistocene and older surfaces (including. Alluvial fans); coastal savanna regions

Cambisols	1,500	Gelic, Gleyic, Vertic, Fluvic, Mollic, Calcaric, Ferralic, Dystric, Chromic, Eutric Cambisols	Luvisols, Alisols, Acrisols, Lixisols, Nitisols, Ferralsols	Regosols, Leptosols, Gleysols, Fluvisols, Acrisols, Sesquisols	Islands (Puerto Rico, Madagascar, New Zealand, Papua-New Guinea); Atlantic Spain and Portugal; Mediterranean Spain, France, western Italy, Turkey; southeastern Australia
Arenosols	900	Leptic, Albic, Protic, Gypsiric, Calcaric, Luvic, Ferralic, Cambic, Haplic	Regosols, Leptosols, Cambisols, Gleysols, Fluvisols	Acrisols, Lixisols, Ferralsol, Planosols, Histosols, Anthrosols, Solonchaks, Regosols, Leptosols, Calcisols	Dry tropical and temperate interior regions, but some coastal areas in western Africa, western Madagascar, and northwestern Australia
Regosols	260	Gelic, Anthropic, Tephric, Gypsiric, Calcaric, Dystric, Eutric	Arenosols, Leptosols, Gypsisols, Ferralsols, Cryosols	Found in all landscapes of the world; intergrades and extragrades may develop into many other soils, depending on the most important soil forming factor(s)	Shallow, weakly developed mineral soils in the initial stages of soil formation; all coastal landscapes

Notes: Compiled from Spaargaren (1994).

[a] Based on the FAO World Reference Base (WRB) major soil groups, compiled and revised from the FAO/UNESCO International Reference Base for Soil Classification and the Legend of the Soil Map of the World (FAO-UNESCO, ISRIC, 1988).

[b] Total area (in millions of hectares) is based on estimated WRB worldwide occurrence of the soil group; coastal occurrences are a smaller subset of unknown areal extent.

[c] Major subdivisions that are proposed to separate the soil groups on the basis of diagnostic properties. Not all of the soil units listed occur in coastal areas as major soils, but they are listed for completeness, where they may be found in specialized environmental situations.

[d] Other soil groups that occur in the same general area or environment; soil groups were not differentiated on the basis of climate in order to keep the number of units manageable. Differences in topography, drainage, and other diagnostic properties and materials result in a range of different soil groups that occur in close geographic proximity to each other.

[e] Lateral linkages are commonly intergrades that merge soil units in time and space. These units also reflect the spatial integration of soil properties in the coastal landscape where differences in the factors of soil formation (i.e., topography or relief, time, drainage or hydrology, organics, parent or initial materials) may lead to rapid lateral changes in soil units. Relief, drainage (or lack thereof, salt spray, or influence of tidal waters), parent materials (terrestrial versus marine sediments), and time (especially in regard to young soils forming in marine sediments) are particularly relevant to coastal soil distribution patterns.

Figure C41 Initiation of mangrove foothold on intertidal marine platform on Eva's Cay, west (bank or leeward side) of Salt Pond on Long Island, Bahamas. Carbonate muds and micritic sediments show initial phases of biochemical weathering as mangroves colonize the area. Accumulation of organic debris derived from the mangroves eventually results in dark coloration of chemically reduced muds. Mangrove soils often show light (thin bands) and dark (thick bands) lamination in the profile because pedogenesis is interrupted by storm waves that deposit new unweathered materials on top of pedogenically altered materials. This mangrove mud is minimal as the stand is only just taking a foothold; older, well-developed mangrove forests such as that occurring in the world's largest estuarine delta (2,600 km^2) along the Indian coast southeast of Calcutta in West Bengal as Sunderbans (beautiful forests) and many other tropical coastal locations feature thick organic-rich profiles.

viz. the Balanta system in western Africa (van Ghent and Ukkerman, 1993) where land is ridged annually to a height commensurate with the expected freshwater flood of the rainy season. The ridging and annual turning speedup removal of soluble toxins from the surface soil, but the system is declining because of the heavy labor demand and low financial returns.

Acid sulfate soils exhibit enormous spatial variability that is tied to the dynamic estuarine, deltaic, and flood plain environments in which they occur. Figure C41 shows typical colonization by mangroves into carbonate intertidal flats that will eventually become sites for accumulation of organic debris derived from the mangroves. Organic-rich muds will eventually develop and be accompanied by pedogenesis. Significant spatial variability occurs at myriametric scales from pyrite-plugged pores to the fine-grained soil matrix to infield, local, and regional soil patterns (Dent, 1986). Remote sensing is widely used in tropical, tidal environments because surveys are arduous and difficult due to mosquitoes and crocodiles. Acid sulfate soils also exhibit significant temporal variability that is associated with their defining characteristics of acidity and related toxicities. Almost uniquely, acid sulfate soils export their problems in drainage and floodwaters.

Evident in acid sulfate soils are patterns related to sedimentary history viz. the common distinction between highly sulfidic, unripe clays or peat in backswamps and riper, coarser textured soils, or even calcareous soils on levees and creek fillings. Soil patterns are not always visible at the surface because present landforms and vegetation may be only partly and indirectly related to the environment of sulfide accumulation. The area may, for example, have been buried by peat or nonsulfidic alluvium, fresh waters may have succeeded brackish, and new plant communities have replaced prior ones.

Sulfidic soils that oxidize and generate H_2SO_4 when drained are referred to as *potential acid sulfate soils* (Wang and Luo, 2002). If they have been drained and are generating H_2SO_4, they are called *raw acid sulfate soils*, but if they have passed through the acid-generating phase but remain severely acid, they are referred to as *ripe acid sulfate soils*. Sulfidic materials include marine and estuarine sands and clays, gytja in brackish lakes and lagoons, and peats that originally formed in freshwater but which have been inundated subsequently by brackish water. The common factors are: (1) supply of organic matter, (2) severely reducing conditions caused by continuous water logging, and (3) a supply of SO_4^{2-}, usually from tidewater that is reduced to sulfides by bacteria decomposing organic matter, and (4) a supply of Fe from the sediment for the accumulation of iron sulfides which make up the bulk of reduced S compounds. These conditions are fulfilled in tidal swamps and salt marshes where thick deposits of sulfidic clay have accumulated in concert with Holocene sea-level rise (e.g., Pons and van Breeman, 1982; Dent and Pons, 1995). As sedimentation raises the soil surface above MSL, topsoil accumulates under better drainage as a nearly ripe, mottled layer that contains little or no sulfide. Sulfidic clays may be buried by peat or nonsulfidic alluvium where freshwater conditions succeed brackish water.

Reclamation and drainage of sulfidic soils causes dramatic changes. When insufficient carbonate is present to neutralize the H_2SO_4 generated by oxidation of sulfides, extreme acidity develops within weeks or months. Raw acid sulfate soils, characterized by a pH < 3.5, contain jarosite but frequently display a black subsoil as some of the SO_4^{2-} generated by drainage is reduced to FeS deeper in the profile. Experiments on acid sulfate soils in the southern coastal regions of Guangdong, China, for example, show that the sulfur content of acid sulfate soils is 2–6 times higher than that of coastal Solonchaks and 3–9 times higher than that of paddy soil (Wang and Luo, 2002). The potential acidity is 2–3 times higher than the actual acidity and the amount of lime required to correct the potential acid ranges from 143.5 t ha^{-1} to 2687.5 t ha^{-1}.

Acid sulfate soils cause on-site problems and also in adjacent areas with the latter attracting attention (Dent, 1986). On-site problems include Al toxicity in drained soils, Fe and H_2S toxicity in flooded soils, salinity, and nutrient deficiencies. Engineering problems include: (1) corrosion of steel and concrete, (2) uneven subsidence, low bearing strength, and fissuring leading to excessive permeability of unripe soils, (3) blockage of drains and filters by ochre, and (4) difficulties of establishing vegetation cover on earthworks and restored land. Off-site problems stem from drainage effluents, earthworks, excavations, and mines.

The acid drainage waters carry Al released by acid weathering of soil minerals and heavy metals that are released by oxidation of sulfide minerals. Episodic release of toxic drainage waters may occur, for example, at the onset of the wet season after a period of low water table during which oxidation has taken place.

Gleysols

Gleysols (from Russian local name *gley*, mucky soil mass) or soils with gleyic properties are permanently wet and reduced in the subsoil (e.g., Schlichting, 1973), and periodically to permanently wet in the topsoil (Spaargaren, 1994). Mainly found in periodically poorly drained depressions, valleys, and low-lying coastal areas, the solum is either mottled (in case of temporary aeration) or has colors reflecting reduction. These redoximorphic features form under the influence of poorly to well-drained groundwater regimes. Typical gleyic soils are classified as Gleys or Groundwatergleys in many European systems of soil classification (e.g., Austria, Germany, France, Switzerland, United Kingdom), although in the German classification the periodically flooded soils of coastal regions are separated as *Marschböden* from normal Gleysols. Gleysols are found in nearly all climates, from perhumid to arid conditions, and cover an area of almost 720 million ha (FAO, 1991) (Table C9). In regions with permafrost (e.g., Arctic Canada, coastal plain of northern Siberia), Cryic Gleysols occur in association with Cryosols and Gelic Histosols. In the lowlands of the temperate latitudes, they are formed in alluvial sediments associated with Fluvisols near riverbeds in coastal areas, and with Histosols. In the humid tropics, they are found in valleys associated with Acrisols, Lixisols, Nitisols, Alisols, or Ferralsols.

Gleysols (Eutric Gleysols, FAO) are a dominant soil of Canada, with major areas occurring in the subArctic and Hudson Bay Lowland (Clayton *et al*., 1977). Most Gleysols occur on nearly level to undulating topography, particularly where associated with lacustrine, alluvial, or marine deposits that are moderately calcareous and loamy in texture. Cryic Gleysols occur throughout the entire Arctic region of northern Canada, including the Arctic islands extending from the Labrador coast to the Yukon–Alaska border. About 37,698 km^2 or 0.4% of Canada is mapped as dominantly Cryic Gleysols; these areas occur in the Northwest Territories and Yukon. They are found within the Mackenzie Delta and the Arctic Coastal Plain. Gleysols are often spatially associated with Podzols and Luvisols.

Anthrosols

These soils result from human activities that produce profound modification or burial of the original soil horizons. In the 1988 Revised Legend of the Soil Map of the World (FAO–UNESCO–ISRIC, 1988), these are "… soils in which human activities have resulted in profound modification or burial of the original soil horizons, through removal or disturbance of surface horizons, cuts and fills, secular additions of organic materials, long-continued irrigation, etc.…" Implicit in this general definition is the recognition of a distinct set of anthropedogenic processes that are associated with characteristic anthric diagnostic horizons. Anthropogenic soil materials that result from anthropogeomorphic processes are better considered as "non-soil," unless they are subjected to a sustained period of pedogenesis (Spaargaren, 1994). Many different soil classification systems from around the world make provisions for these kinds of soils. Continuous cultivation of paddy soils often produces a hydragric horizon that also includes redoximorphic and illuviation features in the subsoil. Many Anthrosols occur in coastal deltaic environments, especially in Southeast Asia and Indonesia. The Mississippi Delta region in the United States contains extensive areas of Anthrosols that are now subject to drowning by relative sea-level rise and contribute to the land-loss problem in coastal Louisiana (Boesch *et al*., 1994).

Leptosols—Entosols, Regosols, Lithosols, etc.

The name Leptosols (from Gr. *leptos*, thin) is used in the FAO *World Reference Base for Soil Resources* (Spaargaren, 1994) for shallow soils overlying hard rock or highly calcareous material, and soils that have, by weight, less than 10% fine earth material. Leptosols occupy more than 1,655 million ha from the tropics to polar tundra (Table C9). Different names have been used in reference to these kinds of shallow, rocky soils. The term *Lithosol* was applied by Thorp and Smith (1949) to denote azonal soils having an incomplete solum or no clearly expressed soil morphology and consisting of freshly or incompletely weathered mass of hard rock or hard rock fragments. *Rankers* were defined as soils that have a dark-colored surface horizon, rich in organic matter with a low base status that is overlying unconsolidated siliceous material exclusive of alluvial deposits or hard rock. The name *Rendzina*, as first used by Sibirtzev (1901), was originally assigned to intrazonal soil on calcareous rocks. *Regosols* were first defined by Thorp and Smith (1949) as an azonal group of soils consisting of deep unconsolidated rock (soft mineral deposits) in which few or no clearly expressed soil characteristics developed.

Leptosols represent the initial phases of soil formation and as such, they are of great significance because they are the forerunners of the young or weakly developed soils of other units. These soils occur in landscapes where deposition or erosion, resistant bedrock, inert parent material, saturation, or human activity was limited normal pedological development. These soils commonly form on mountains, sand dunes, flood plains, and riverine lunettes, and coastal plains. In northern Canada, for example, Cryic Orthic Regosols in Arctic Lowlands commonly occupy gently undulating coastal plains developed on stony or sandy glacial till and marine deposits and occupy upwards of 1,305,423 km^2 (Clayton *et al*., 1977), but not all of this area is coastal. Parent material lithology is a factor that may inhibit pedogenesis where resistant bedrock, for example, increases runoff and erosion, and thereby decreases weathering. These soils also form in sandy parent materials that have an abundance of rock fragments. When parent materials consist of quartzitic sands without coarse fragments, such as in many sand dunes, profile development is also retarded.

Coastal dunes are built of beach sand blown onshore. Calcareous sand may give rise to calcareous eolianite, as on the coast of western Victoria (Australia), southwestern Western Australia, Bermuda, and the Bahamas. Quartz sand dunes are common in eastern Australia and grew particularly large during the last Ice Age, when sea levels were low and wide sandy flats were exposed (Ollier and Pain, 1996; Short, 2003). The high dunes of Queensland such as Fraser Island are the highest dunes in the world. Leptosols are also associated with beach ridges (Tanner, 1995) that are formed as beaches with broad curved shapes and lengths often of many tens of kilometers, as seen in this aerial photograph of a pocket beach in the Bahama Islands where the beach ridges mirror successive storm deposit build up (Figure C42). Cheniers on the Yangtze Delta (China) are also tens of kilometers in length (Yan *et al*., 1989), up to 500 m wide, and similar to bight coast cheniers (Otvos and Price, 1979) along the Louisiana—Texas coast. As wind blows sand from the beach to make ridges, these accumulations eventually become stabilized to support soil formation. Beach ridges often join together to make a chenier or beach ridge plain (cf. Figure C42) where the ridges usually consist of coarser materials than the intervening swales. The more inland ridges are older than nearshore ones and composition of the ridges may be quite variable. A recent study by Rink and Forrest (2003) regarding the accretion history of beach ridges on Cape Canaveral and Merritt Island, FL, estimated ridges to be 4000 $\pm$ 150 years old on the peninsula and about 43,000 years old on the more landward Merritt Island. Average ridge spacing was 109 $\pm$ 20 m, giving an average ridge accumulation rate of 80 $\pm$ 8 years per ridge on the cuspate foreland. The ridge accumulation rate is related to storm frequency (tropical storms or hurricanes); soil formation proceeded on the ridges subsequent to deposition. On a coastal plain in southeastern Australia, for example, the inland beach ridges are quartzitic in composition and date back to the Miocene, whereas the nearshore sets are calcareous and formed throughout the Quaternary to the late Holocene (Cook *et al*., 1977). Many Tertiary marine beaches are now found high and dry in Western Australia, at places like Eneabba, Yoganup, and Minninup (Lissman and Oxenford, 1975) that are now some distance inland from the present shore of the Indian Ocean. More recent beach ridge systems are described for the inner Rottnest Shelf coast near Perth in southwestern Australia by Searle *et al*. (1988) where the main geomorphic components in the area are shore-parallel Pleistocene eolianite ridges and their associated intervening depressions, and the Holocene units in basins, slopes, banks—nearshore platforms, beaches, and beach–dune complexes.

Anaerobiosis may slow pedogenesis where there are persistent high water tables that prevent leaching of soil constituents, inhibit redox cycles, or preclude subsurface horizon development. Poorly drained floodplains and coastal marshes host these kinds of soils.

Cryosols

Cryo-hydromorphic soils occur in Arctic, subArctic, and boreal regions under cold continental, (sub)humid, or semiarid climatic conditions. They support a characteristic vegetation cover of dominantly taiga, forest-tundra, or tundra with a ground cover of lichen moss. These soils have permanently frozen subsoil, often at a shallow depth of $<$1 m, and occupy enormous areas (1,800 million ha) typically on Arctic coastal

Figure C42 Beach ridge plain near the southern tip of Eleuthera Island, Bahamas. The succession of calcareous beach ridges represents a developmental sequence of deposition, often associated with phases of storminess, where younger dunes and soils developed on them occur closer to the shore and older dunes and associated soils occur farther inland. Stages of soil development are usually referred to as chronosequences, where greater profile differentiation occurs on the older dunes. Minimal profile developed associated with weak phases of pedogenesis produce Leptosols (Lithosols), Arenosols, and Cambisols on the seawardmost ridges. Other types of calcimorphic soils occur inland in association with longer times for pedogenesis to precede.

Figure C43 Organic-rich soil developed in fluvial-deltaic sediments flanking the Ijsselmeer. These soils, reclaimed by diking and drainage, are susceptible to flooding and find use as pasture lands and reserves. Many soils developed in parent materials derived from marine sediments become extremely acid when drained due to oxidation of sulfur compounds. The low pH values of acid sulfate soils preclude many uses.

plains (Table C9). Some show a significant accumulation of organ matter (dominantly weakly decomposed tissues of oligotrophic plants) at the surface, others are mainly mineral (or organo-mineral) in nature. They are saturated with water during the entire period of thawing, but lack features associated with reduction or redistribution of iron. The more mineral soils often show the peculiar phenomenon of thixotropy. Thixotropic properties are defined as the ability of relatively compact fine-textured soil materials to transform under pressure into an apparent liquid and unstable state when saturated with loosely bound water (quicksand-like property). When pressure weakens, the material gradually regains its initial compactness. Cryosols have been previously described in Russia as Peaty Frozen, Taiga Frozen, Gleyic Frozen, and Destructive Taiga Frozen soils and more recently as Homogeneous (or Peaty-Duff) and Thixotropic Cryozems. In Canada they are known as Organic and Turbic Cryosols. In *Soil Taxonomy* (Soil Survey Staff, 1975, 1992), they correspond with soils having a pergelic soil temperature regime.

Fluvisols

The central concept of this group relates to soil developed in fluvial (alluvial) sediments. Fluvisols were previously recognized by a variety of names including but not limited to swamp soils, Lithomorphic soils, Brown soils, Groundwater Gley soils, and Vaaggronden ("Vague soils," Netherlands). Whatever the name, these soils are deposited in aqueous sedimentary environments viz. (1) inland fluvial and lacustrine environments, (2) marine environments, and (3) coastal saltings or brackish marsh environments, of which deltas are a special case (Dreissen and Dudal, 1989). Fluvisols occupy significant areas on deltas and fans, coastal barriers, and tidal flats (350 million ha) (Table C9). On aggrading coastlines, combinations of sand or shingle spits and offshore bars allow dunes to accumulate, giving shelter to a nearshore zone where silts and organic muds accumulate in low-energy or quiescent environments. Tidal inundation brings additional supplies of new suspended sediment that flocculates in the water column but which eventually settles to the bottom to help accretion of marsh soils. Aggradation of marsh surfaces takes place relatively slowly and is often associated with strictly zoned vegetation according to the length of time the marsh is inundated. Creeks give tidal waters access to the marsh at flood tide and drain the marsh at ebb tide. Deltaic systems develop where rivers debouching in the sea bring significant amounts of material, providing coastal conditions are satisfactory for sediment accumulation, as seen here in Figure C43 along the Netherlands coast. In the intertropical regions, particularly, the conditions are such that reducing conditions may be developed in which the sulfates in the seawater are reduced to pyrites. Sediments containing pyrites may become parent materials for acid sulfate soils.

Fluvisols show clear sedimentary layering or stratification in a major part of the profile. Soil formation may have affected the upper part of the profile to produce dark-colored surface horizons that are high in organic matter and which form in comparatively little time (Figure C44). Also, the material in the upper part of the profile below the surface horizon may have lost evidence of sedimentary layering due to weathering and have acquired the color and structure of stronger developed soils. These juvenile soils tend to show little evidence of weathering and soil formation below 25 cm depth, except possible gleying. Permanent or seasonal saturation with water, causing recurrent anaerobic conditions and low biological activity, tends to preserve the original stratified nature of the original deposits. Consequently, the more important linkages of Fluvisols are with other weakly developed soils viz. Cambisols, Regosols, Arenosols, Leptosols, Gleysols, and Solonchaks.

Figure C44 Core from a polder soil in The Netherlands. Depending on the nature of sediment grain-size distributions in the original marine sediments, soil texture can range from sand to clay. The flights making up this continuous core show minimal effects of pedogenesis due to the high groundwater table and reducing conditions. The upper part of the soil profile may show redoximorphic properties (e.g., mottles) due to fluctuating water tables and alternation of reducing and oxidizing conditions. The length of the hydroperiod in the upper part of the profile largely determines surface soil characteristics.

Solonchaks

Solonchaks (from Russian *sol*, salt, and *chak*) are widespread in arid and semiarid regions, occurring widely (covering 260– 340 million ha) in many parts of Asia, Australia, South and North America, China, and the Middle East (Table C9). Salts responsible for salinity have many origins in parent materials that are related to marine deposition; volcanic, hydrothermal, and eolian processes; and lithologic properties of initial materials. Mangrove deforestation contributes to salinization of coastal soils, erosion, land subsidence, and release of carbon dioxide to the atmosphere. The presence of these salts, the amount of osmotic pressure of the soil solution, or the toxicity of a given ion leads to special landscapes, either occupied by salt-tolerant (halophyte) vegetation or characterized by the complete absence of vegetation (salt lakes, salt lagoons, salt pans, etc.), depending on the degree of salinity.

Two chemical criteria are used to define these soils: (1) the solubility product of the accumulated salts or of salts that may form and (2) the ion concentration in the soil solution. To be considered salt-affected, the soils must contain an important quantity of salts that are more soluble than gypsum ($CaSO_4 \cdot 2H_2O$: log Ks is -4.85 at 25°C), thus also more soluble than calcium carbonate, jarosite, and iron sulfide. For this reason, gypsiferous soils, calcareous soils, and soils with jarosite are excluded from the Solonchaks and have a home in the Gypsisols, Calcisols, and Thionic Fluvisols, respectively (Spaargaren, 1994). These soils must also have a total salt concentration of the soil extract, expressed as the electrical conductivity (EC) within a depth of 125 cm of the surface. This minimum value, measured in a saturated paste extract (or in a 1 : 1 extract for very sandy soils) must be: (1) >15 dS m^{-1} (or mS cm^{-1}) at 25°C, if the pH is less than 8.5 (neutral salts) or (2) more than 8 dS m^{-1} if the pH is more than 8.5 (for alkaline carbonate soils) or less than 3.5 (for acid sulfate soils other than Thionic Fluvisols).

Chloride soils are of marine origin but influenced by the potential acidity of the soils under mangrove. The pH is very acid to acid (3.5–5) in reaction, calcium is almost lacking and sulfates, entirely derived from seawater, are present in only very small quantities compared to chloride. Sodium is dominant in the soil solution (CL $\gg SO_4 > HCO_3$; Na $\gg$ Ca). White salt deposits ($NaCl$, $CaCl_2$, $MgCl_2$) may occur at the soil surface as crusts or efflorescence, which seasonally can turn into brown powdery surface layers. Examples are noteworthy in Gambia and in the Casamance region of Senegal.

Neutral chloride–sulfate soils are mostly of marine origin, but can be enriched by sedimentary gypsum deposited by rivers. When the pH is near neutral, sulfates and chlorides occur, and carbonates, sodium, calcium, and magnesium are in variable proportions and exceed bicarbonates present in variable quantities. Salt deposits are mostly $NaCl$, $CaCl_2$, and $MgCl_2$ associated with gypsum in the profiles. These soils are widespread and examples can be found in the alluvial plains, chotts, and sebkhas of North Africa, the Mexican Lagunas or playas, along the Euphrates River in Syria and Iraq, and in salt flats elsewhere.

Acid sulfate soils of marine origin are formed in potentially acid environments of mangrove vegetation (mangals) where acidification is promoted by dry periods in some tropical regions. When the environment becomes extremely acid (pH < 3.5), the result is acidolyse of clay and liberation of aluminum, iron, and magnesium; there is little calcium and chloride in these systems. The lack of bases and very low pH prevents the formation of jarosite. Examples occur in Gambia, the Casamance region of Senegal, and in Guinee Bissau. In reduced condition, these soils classify as Thionic Fluvisols as they have a sulfidic horizon; in oxidized and acidified states, these soils may classify as Salic Fluvisols if the EC is sufficiently high.

Carbonate soils include alkaline bicarbonate–sulfate soils and strongly alkaline carbonate soils. They form in aerobic environments with the production of sulfates from sulfides present in the original marine muds. The liberated acidity is neutralized by an excess of sodium and calcium carbonates in the biogeochemical system. Variations of these soils are found in the polders of Tchad, New Caledonia, the Balkan region, and Australia. The Solonchaks occupy the lower parts of landscapes where runoff, seepage, and shallow groundwater can accumulate; they are separated from most other soils by having a high salt content at or near the ground surface.

Podzols

The term *Podzol*, meaning "white earth" is derived from the Russian terms *pod* (beneath) and *zol* (ash). These soils are widely known as acid ashy-gray sands over dark sandy loams (Buol *et al*., 1980). These two contrasting albic and spodic horizons, with an abrupt boundary between them, make these soils among the most dramatic, eye-catching, and photogenic soils in the world (Figure C45). The setting in which such a soil is produced requires the combination of soil-formation factors that yield necessary conditions where there is accumulation of iron, aluminum, and/or organic matter in a subsoil horizon. Podzols thus occupy large areas where there are sandy parent materials from the tropics to the boral climatic zone (485 million ha, Table C9). Many kinds of vegetation, including, grasses, can yield certain organic compounds that enhance podzolization, but litter from a certain few species of plants in particular foster such accumulations viz. the hemlock tree (*Tsuga canadensis*) in forests of northern latitudes, the kauri tree (*Agathis australis*) of New Zealand, and heath (*Calluna vulgaris* and *Erica* sp.) in northern Europe. Podzsols additionally occur under a wide variety of trees (e.g., *Picea, Pinus, Larix, Thuya, Populus, Quercus, Betula*) and understory plants in moist climatic zones that are cool (e.g., Humid Meso- and Microthermal climates). Humic Podzols (Cryohumods in *Soil Taxonomy*) occur as dominant soils in Canada, for example, in the Maritime Provinces (e.g., Cape Breton and Newfoundland), in the coastal forests of the British Columbia mainland, and on coastal islands (Clayton *et al*., 1977). Extensive areas of these soils occur on the humid subtropical coastal plain of the southeastern United States. Impressive are the 9 m thick Bh horizons in Spodosols on the North Carolina Coastal Plain (Buol *et al*., 1980). Ages of these soils are extremely variable, some Spodosols being able to form relatively quickly. Burges and Drover (1953), for example, reported evidence that 200 years were required to leach calcite from beach sand in New South Wales, Australia, but 2,000 years to produce an iron-Podzol, and 3,000 years to produce an iron–humus Podzol with pH as low as 4.5. An iron-Podzol in coastal California has been estimated at about 1 million years (Jenny *et al*., 1969). On coastal dunes in cooler climates, Podzols may develop within a few centuries, but in warmer or less-humid climates Podzols require several millennia or longer periods to form (Sevink, 1991). Dune soils are easily leached because of their high permeability and low water-storage capacity. Although sometimes high in carbonates, the acid buffering capacity of the non-calcareous fraction (e.g., quartz) is generally very low. As a consequence, acidification proceeds rapidly with concurrent changes in soil-forming processes and profile characteristics. Rates of leaching and acidification are high in climates with a large precipitation surplus and low decomposition rates (because of low temperatures). In arid climates, leaching will be strongly reduced and mobile components such as carbonates and gypsum may accumulate within the solum. Accumulations of secondary carbonates (e.g., caliche, kunkar) are frequently cited in studies of Holocene dyer systems in drier coastal zones.

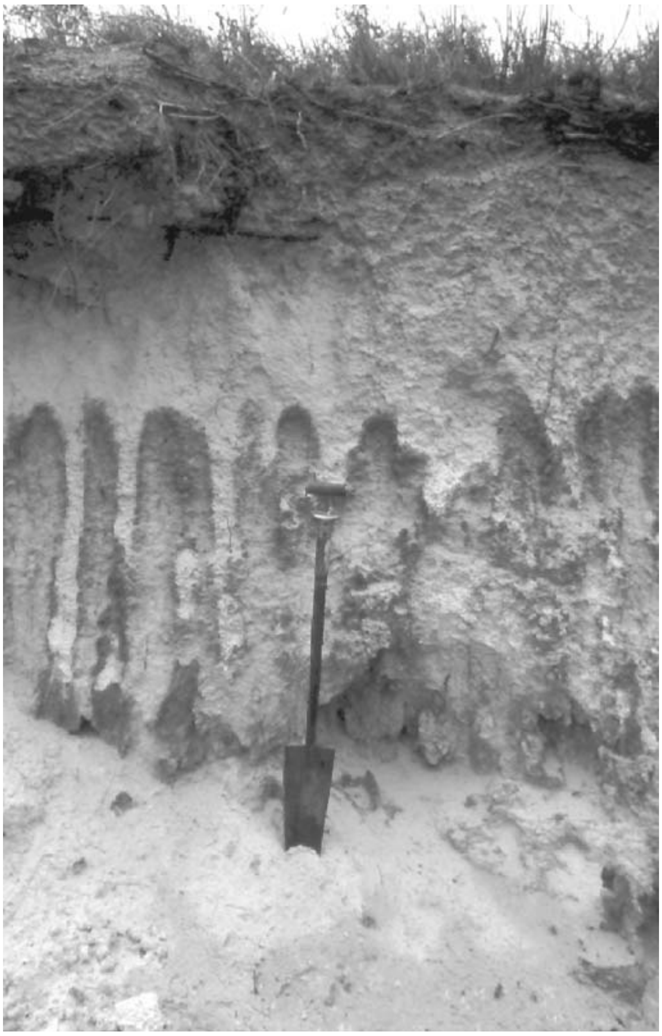

Figure C45 Spodozol (Podzol) developed in siliceous, Pleistocene-age Pamlico Sands overlying a portion of the limestone Atlantic Coastal Ridge along the subtropical southeast coast of Florida. Here, prominent albic tongues (eluvial zone) extend at least 1.5 m into the organic- and iron-rich spodic horizon (illuvial zone). These coastal Spodosols are extremely photogenic due to the extreme biochemical differentiation within the profile, dramatic contrasts in soil color, abrupt wavy horizon boundaries, and thick profiles.

Podzolization is thus a bundle of processes that bring about translocation, under the influence of the hydrogen ion, organic matter, iron, and aluminum (and a small amount of phosphorus) from the upper part of the mineral solum to the lower part (Buol *et al*., 1980). Cheluviation, the dominant process of soil formation of Podzols, involves the combination of two processes: (1) weathering of primary minerals (especially phyllosilicates) by organic complexing acids and (2) translocation of organic matter both in the weathering of primary minerals and in the translocation of Al and Fe complexes. These processes lead to special morphological and analytical characteristics that are used to identify a soil material as Podzolic. Cheluviation affects large areas of soils in the boreal zone. The process is also active in humid regions, especially in the temperate zone but also in the equatorial realm where many examples of Podzols have been described.

Podzols are soils characterized by the presence of an illuvial spodic horizon. In this horizon, amorphous compounds have accumulated consisting of organic matter and aluminum, with or without iron or other cations. The process of translocation and accumulation, known as cheluviation, is usually shown by the occurrence of an albic (bleached) horizon underlain by a spodic horizon. The illuviation of organic compounds can often be demonstrated by the presence of thick cracked organic coatings on the skeleton grains within the spodic horizon. In coarse sandy materials, Podzol morphology is well expressed and strong contrasts occur between eluvial (albic) and illuvial (spodic) horizons (cf. Figure C45). In most Podzols, where clay percentage is often less than 10%, coarse texture ranges from sand to sandy loam. Accordingly, water retention capacity is low, less than 50 mm and, although Podzols develop in humid climates, they often show moisture stress. Podzols are very acid soils, with a pH ranging from 3.5 to 4.5 in surface horizons; the pH may increase up to 5.5 in lower horizons. The cation exchange capacity (CEC) is mostly due to the organic compounds present and base saturation is always very low. Organic matter has a high C/N ratio especially in the surface horizons (C/N = 25 or more) and in the spodic (C/N = 20 or more), indicative of low biological activity and slow degradation of organic matter.

The limits of the Podzols are determined by the minimum expression of the spodic horizon and the minimal contrast between the eluvial and illuvial horizons. Soils showing evidence of illuvial organo Al/Fe complexes but lacking sufficient amounts of it to qualify for Podzols, form intergrades with Cambisols, Arenosols, and Gleysols. Podzols and intergrades are typical of a soil mantle on sandy coastal plains with poor quartzitic materials affected by a shallow water table.

Sesquisols, Ferralsols, Alisols, Acrisols, Lixisols

Sesquisols are soils either containing at shallow depth a layer indurated by iron (petroplinthite), or at some depth mottled material that irreversibly hardens after repeated drying and wetting (plinthite). *Plinthite* is an Fe-rich, humus-poor mixture of clay with quartz and other diluents that occurs as redoximorphic concentrations in platy, polygonal, or reticulate patterns (Shaw *et al.*, 1997). These kinds of soils occur mainly in the tropics but examples are common to old landscapes in (sub)tropical and temperate regions. Those with a shallow petroplinthite horizon are known as (high level) laterites, ironstone soils, or Sols ferrugineux tropicaux a cuirasse. They have widespread occurrence in western Africa, especially in the Sudano-Sahelian region where they cap structural tablelands; they are also common in central-southern India, the upper Mekong catchment, northern Australia, and the eastern part of the Amazon region (Table C9).

The Sesquisols with plinthite are known as Plinthosols, groundwater laterite, sols gris lateritiques, or Plinthaquox (Soil Survey Staff, 1992). They are found in extensively flat terrains with poor internal drainage, such as the late Pleistocene or early Holocene sedimentary basins of eastern and central Amazonia and the central Congo basin, but also on coastal plains such as in southwestern Western Australia (e.g., Swan Coastal Plain, Ridge Hill Shelf, Donnybrook Sunkland). Well-drained soils with loose ironstone concretions (sesquiskeletal material) are frequent nearly everywhere in the tropics and subtropics, in many landscape situations. The material is the result of former plinthite formation, subsequent hardening, and transport or re-weathering.

The central concept of Sesquisols is one of a soil affected, at present or in the past, by groundwater or stagnating surface water in which iron has been segregated to such an extent that a mottled (redoximorphic) layer has been formed which irreversibly hardens when exposed to air and sunshine. Included in the concept are those soils that have a hardened layer at shallow depth. The most important characteristic of Sesquisols therefore is the presence of plinthite and petroplinthite. Plinthite is an iron-rich, humus-poor mixture of kaolinitic clay with quartz and other diluents. It commonly occurs as red mottles in platy, polygonal, or reticulate patterns, and changes irreversibly on exposure to a hardpan or to irregular aggregates on exposure and repeated wetting and drying with free access of oxygen. In a perennial wet soil, plinthite is usually firm but can be cut with a spade. A plinthic horizon is at least 15 cm thick in which plinthite takes up 10% or more by volume. Petroplinthite is a continuous layer of indurated material in which iron oxides are an important cement and in which organic matter is absent, ore present only in traces. The Fe_2O_3 content is generally greater than 30%. The continuous ferruginous duricrust layer may be either massive, reticulate, interconnected platy, or columnar pattern that encloses non-indurated material. The indurated layer may be fractured, but then the average lateral distances between fractures is 10 cm or more and the fractures themselves do not occupy more than 20% by volume within the layer.

Sesquisols dominantly occur in intertropical regions and have linkages with Ferralsols, Alisols, Acrisols, and Lixisols. Sesquisols may occur in distinctly different landscape positions. Petric Sesquisols occupy the higher landscape positions, often as a result of landscape inversion due to lowering of the erosion base (McFarlane, 1976). They now form tablelands and are usually freely drained. The other Sesquisols are found mainly in depressions or other areas with impeded drainage. On the Coastal Plain of Georgia (USA), for example, most soils have sandy surface horizons with high infiltration rates; many, however, have slowly permeable subsoil horizons with high concentrations of plinthite (Shaw *et al.*, 1997) where only 10% platy plinthite is necessary to perch water (Daniels *et al.*, 1978). These soils have developed from Miocene aged sediments and are classified in *Soil Taxonomy* in fine-loamy, siliceous, thermic families of Plinthaquic, Aquic, Arenic Plinthic, Plinthic, and Typic Kandiudults. In Georgia, more than 1.5 million ha of soils containing plinthite have been mapped. Sesquisols are found in association with Gleysols and Stagnosols in areas conditioned by hydromorphy, and with Ferralsols, Alisols, Acrisols, and Lixisols, which occupy the better-drained positions in the landscape.

Ferralsols

Tropical weathering and pedogenesis produces Ferralsols that are characterized by a colloidal fraction dominated by low-activity clays (1 : 1 alumino-silicate minerals) and sesquioxides. These highly weathered soils lack rock fragments with weatherable minerals and are characterized by the presence of low-activity clays and a uniform morphology that lacks distinct horizonation. If there is sufficient iron in the original material, these soils are reddish in color and contain a weak pedal structure; there are few marks of other soil-forming processes such as clay accumulation through translocation. Secondary accumulation of stable minerals such as gibbsite or iron oxyhydrates may be present in concretionary forms (e.g., pisolites) as part of the fine earth fraction. Typical soils are situated on old geomorphic surfaces, which formed through erosion and deposition, and occur today as relict landscapes over large areas (750 million ha, Table C9). Having formed in transported and reworked colluvial materials, these strongly weathered soils have little relationship with underlying geological strata. As a result of transport and deposition, the soils may be stratified (e.g., McFarlane, 1976; Finkl, 1980, 1984). In extreme stages of weathering in a free leaching environment, there is relative accumulation of sesquioxides and small amounts of 1 : 1 alumino-silicate minerals (e.g., kaolinite) as well as resistant minerals such as anatase and rutile. The sesquioxide minerals include goethite, hematite, and gibbsite; the alumino-silicate minerals are generally degraded kaolinites and some muscovite. In this weathering environment, neogenesis of alumino-silicates is rare with the possible exception of aluminum chlorite.

Occurring on geomorphically old surfaces, these soils are associated with Cambisols in areas with rock outcrops or where rock comes near to the surface. On the stable surface they occur together with Acrisols, which seem often to be related to the presence of more acidic parent materials (e.g., gneiss). On more basic rocks they occur associated with Nitisols, with no apparent relation to underlying rocks or topographic positions. Near valleys, Ferralsols merge into Gleysols.

Alisols (from L. *alumen*, alum), occurring in humid (sub) tropical and warm temperate regions, are acid soils with a dense layer of illuviated clay in the subsoil; they cover more than 100 million ha worldwide (Table C9). The intense weathering processes in these soils degrade 2 : 2 and 2 : 1 clay minerals and release large amounts of aluminum to create a very acid environment. Alisols correlate partly with Aqults, Humults, and Udults in *Soil Taxonomy* (Soil Survey Staff, 1975, 1992), the Ferialsols or sols fersiallitiques tres lessive in French systems (e.g., AFES, 1992; CPCS, 1967), and Red Yellow Podzolic soils with a high clay activity in the Brazilian soil classification.

Acrisols (from L. *acris*, very acid) are characterized by a subsurface accumulation of activive clays, a distinct clay increase with depth, and a base saturation (by 1M NH_4Oac) of less than 50%. The soils have been named Red–Yellow Podzolic soils, Podzó licos vermelho-amarelo distróficos a argila de atividade baixa, sols ferrallitiques fortement ou moyennement désatures (CPCS, 1967), Red–Yellow Earths, Latosols, and oxic subgroups of Alfisols and Ultisols. The later have been redefined as kand- and kanhapl- great groups in *Soil Taxonomy* (Soil Survey Staff, 1975, 1992). These soils are common in tropical, subtropical, and warm climatic regions, on Pleistocene and older surfaces that take up more than 900 million ha worldwide (Table C9).

The dominant characteristic of Luvisols (from L. *luere*, to wash) is textural differentiation in the profile that forms a surface horizon depleted in clay and an accumulation of clay in the subsurface argic horizon. These soils are further characterized by moderate to high-activity clays and low aluminum saturation. These soils are known as sols lessivés in France, Parabraunerde in Germany, pseudo-Podzolic soils in Russia, Gray–Brown Podzolic soils in earlier US terminology or as Alfisols in *Soil Taxonomy*.

Lixisols (from L. *lix*, lye) are characterized by a subsurface accumulation of low-activity clays (cation exchange capacity is less than 24 cmol(+)/kg) and moderate to high base saturation. They show a distinct increase in clay content with depth. These soils have been named Red–Yellow Podzolic soils, Podzó licos vermelho-amarelo eutróficos a argila de atividade baixa, sols ferrugineux tropicaux lessives, and sols ferrallitiques faiblement désaturés appauvris (CPCS, 1967), Red and Yellow Earths, Latosols, and oxic subgroups in *Soil Taxonomy* (Soil Survey Staff, 1992). Limits and linkages of Lixisols, Acrisols, Alisols, and Luvisols is entirely based on analytical properties. Therefore, in areas where these kinds of soils have CECs close to this value, they will merge into each other.

These soils, which are relict (out of pedogenic phase with the present environment) and not related to contemporary soil-forming processes in coastal zones, are nevertheless important pedogenic and geomorphic features along many coasts; they occur about 435 million ha worldwide (Table C9). Although commonly associated with truncated landsurfaces that produce coastal cliffs such as those seen on marine sediments along the eastern boundary of the Guiana Shield in northeastern South America (Valeton, 1981); the coastal Trivandrum district in southern Kerala (India) (Karunakaran and Roy, 1981); Long Reef Beach near Sydney, New South Wales (Retallack, 1990); Darwin, Northern Territory (Australia) (McNally *et al.*, 2000); and as lateritic spurs and benches along the Darling Fault Scarp in southwestern Australia (e.g., McArthur and Bettenay, 1960), these weathering profiles also occur as reefs on seaward sloping surfaces that extend below present MSL (Short, 2003) in the Northern Territory and into the Gulf of Carpentaria (Hays, 1967). Interestingly, these Tertiary and older weathering profiles extend from northern Australia to the southern boundary of Papua New Guinea but are now drowned by the eastern Arafura Sea and Torres Strait. Depending on the thickness of the weathering profile and its intersection with present MSL, a variety of materials may occur along the shore with beaches or marine terraces developed in saprolite, pallid zones, mottled materials, or ferruginous duricrust.

In the case of the Darwin porcellanite (Darwin Member of the Bathurst Island Formation), a siliceous duricrust that was produced by leaching and replacement of preexisting rocks, the degree of alteration is less than that found in silcrete (McNally *et al.*, 2000). Pisolithic ferricrete (lateritic or ironstone “pea gravel”) occurs in close association with the porcellanitic duricrust throughout the Darwin area. A karst-like relationship between the two types of duricrust (porcellanite versus ferricrete) is exposed along road cuts in Darwin, as described by McFarlane *et al.* (1995) where the ferricrete fills cavities in the porcellanite. This ferricrete is pedogenetically unrelated to the old lateritic pallid zone that developed in the Cretaceous sulfide-bearing marine muds following the retreat of the early Cretaceous sea. Porcellanization around Darwin is mostly confined to lower Cretaceous rocks that weathered to form the pallid zone of a laterite profile 50–70 million years ago. This deep weathering profile was later silicified in a number of cycles that were most intense during the Miocene (Milnes and Thierry, 1992). Both silicification and ferruginization continue to the present day, as evidenced by cliff-base 1940s junk that has been cemented together in a kind of “bottlecrete” by iron-charged spring waters. Silicified and ferruginous “beachrock” occurs at Fanny Bay (Darwin) between the present high and low tide lines. McNally *et al.* (2000) report that these beachrocks occur in a groundwater discharge zone, indicating that some duricrusts have developed since the postglacial sea-level stabilization around 6,000 BP. Marine erosion along the Darwin coast cut marine benches and eroded cliffs into deep mantles of chemical weathering that retain lateritic and siliceous Paleosols. Slumps of pallid zone materials at the cliff base provide residual lithogenic quartz and secondary (epidiagenetic) agglomerated porcellanized particles as beach materials. Parts of the beachface are silicified and ferruginized to form an unusual kind of “beachrock.” Younger coastal soils have developed in the older deep weathering profiles that are exposed along the shore. Complicated polygenetic laterite profiles are also reported from Hong Kong (e.g., Wang, 2003) where pedogenic and ground-water origins represent paleosurfaces that require prolonged subaerial exposure, quiescent tectonism, and a certain level of climatic stability.

Planosols

Planosols (from L. *planus*, flat) have a bleached, light-colored eluvial horizon that abruptly passes into dense subsoil with significantly higher clay content. These soils typically occur in seasonally or periodically wet, level areas, often above normal flood levels of nearby rivers or estuaries. Planosols occur on nearly level river or marine terraces in Southeast Asia from Bangladesh to Vietnam, southern Brazil, southern and eastern Africa, and southern Australia. On a global scale, Planosols occupy about 130 million ha (Table C9). Melanization, the addition of dark-colored organic matter, is the process by which a dark surface horizon extends down into the profile. This bundle of specific processes includes: (1) extension of roots from grasses in the profile, (2) partial decay of organic materials in the solum, (3) reworking of the soil and organic matter (bioturbation) by earthworms, ants, rodents, with the development of krotovinas (folled burrows), (4) eluviation and illuviation of organic colloids along with some mineral colloids, and (5) formation of resistant “ligno-protein” residues that give a dark color to these soils (Buol *et al.*, 1980).

Cambisols

Cambisols (from L. *cambiare*, to change) are moderately developed soils that are characterized by slight to moderate weathering of parent materials. They do not contain appreciable amounts of illuviated clay, organic matter, aluminum and/ or iron compounds. These soils are particularly common in temperate and boreal regions that were influenced by ice during recent glacial periods. The poorly developed profiles result because soil parent materials are young and because soil formation is slow under low temperatures (or even permafrost) of high latitudes in northern Russia and Canada. Cambisols also develop in pre-weathered, old parent materials where they occur in association with highly developed soils such as Acrisols and Ferralsols. The largest continuous surface of Cambisols in warm regions is found on young alluvial plains, terraces, and deltas of the Ganges–Brahmaputra river system. Cambisols are also quite common in arid climates, where they are closely associated with Calcisols. Cambisols cover an enormous are of about 1.5 billion ha worldwide (Table C9) and constitute the third largest major soil grouping in the FAO Revised Legend (FAO, 1991). The minimum degree of soil development present in Cambisols separates them from Regosols. Leptosols are not permitted to have a cambic horizon and the shallowness of Leptosols separates them from Cambisols. When the cambic horizon reaches its maximum expression, Cambisols border soils defined by an argic horizon (e.g., Luvisols, Alisols, Acrisols, Lixisols, Nitisols), a spodic horizon (Podzols), or ferralic horizon (Ferralsols). Definition of these horizons is such that the cambic characteristics are excluded.

Arenosols
