Longshore transport refers to the cumulative movement of beach and nearshore sand parallel to the shore by the combined action of tides, wind, and waves and the shore-parallel currents produced by them. These forces usually result in an almost continuous movement of sand either in suspension or in bedload flows (see entry on *Cross-Shore Sediment Transport*). This occurs in a complex, three-dimensional pattern, varying rapidly with time. At any moment, some sand in the area of interest may have an upcoast component while other sand is moving generally downcoast. The separation of the total transport into components parallel and perpendicular to the shore is artificial and is done as a convenience leading to a simpler understanding of a very complex environment. To be meaningful, the rate of longshore transport must be averaged over intervals of at least many wave periods and is typically predicted or measured over much longer times, ranging up to a year (see entries on *Gross Transport* and *Net Transport*). It is also summed algebraically, at least conceptually, in the direction perpendicular to the shoreline. The result is that the transport rate is defined either as the volume of sand passing a point on the shore in a unit time (Watts, 1953), or the immersed weight of sand passing per unit time (Inman and Bagnold, 1963). The latter method accounts for the average density of the sand, which can vary significantly between beaches comprised principally of carbonate rather than quartz sand.

The integral of the transport rate over time results in an estimate of the longshore transport in units of volume or weight, as appropriate. If this integration is done without reference to the direction of movement, upcoast or downcoast, the result is termed gross transport (see entry on *Gross Transport*). On the other hand, if the sign of the direction is included, the result is termed net transport (see entry on *Net Transport*). Net transport can vary from a tiny fraction of the gross transport to a value nearly equal to it, depending on the characteristics of the forcing functions at the site. Estimates of both gross and net values have engineering significance. Jettied harbor entrances, for example, may shoal at a rate related to the gross longshore transport passing them. If the jetties themselves are partial barriers to longshore transport, the net transport can yield guidance to the estimation of accumulation or erosion of sand on either side of the entrance, providing aid in the design of remediation measures.

Longshore transport is the result of a longshore current that conveys sand put in suspension or mobilized on the seabed by waves (see entries on *Waves* and *Coastal Currents*). The longshore current is usually dominated by the flows induced by waves approaching the shoreline at an angle, although this current can be enhanced or reduced by wind-driven or tidal currents (see entry on *Tides*). Larger, more energetic waves mobilize more sand and produce stronger longshore currents so that the magnitude of longshore transport is directly related to the incident wave energy as well as to the angle of wave incidence.

One of the interesting features of longshore transport is that, for the most part, it is impossible to discern directly. The magnitude of the rapid shore-perpendicular motions of the individual sand particles are typically so much greater than the longshore velocity that they prevent the perception of the longshore motion. Even moving back from the particle dynamics and viewing the whole beach face does not provide any clues. If the longshore transport into a reach of shore equals the transport out; the result is no visible change in the configuration of the beach. Only when the transport rate changes along the shore, because of a change in the wave height or approach angle for example, or because of the construction of a barrier such as a groin, does the beach change in a manner than can be readily detected. Typically, these changes occur slowly such that images or measurements over intervals are required to sense them. The terms *littoral drift* or *littoral transport* are occasionally used interchangeably with *longshore transport*.

Prior to the 20th century, it was generally assumed that tidal currents provided the longshore motivation for beach sand. Komar (1976, pp. 183–190) provides an interesting history of the development of the various explanations for the generation of longshore currents by the oblique approach of waves. The relationship between longshore transport and the properties of the incident waves that formed the basis for most of the research in the second half of the 20th century was first suggested by Eaton (1951). The longshore transport volumetric rate was assumed to be proportional to the product of the longshore component of the wave energy flux, evaluated at the breaker zone and the sine of the angle that the breakers formed with the shoreline. This product was variously called the longshore component of either the wave power or the wave energy flux. Inman and Bagnold (1963) modified the theory to correct the volume to an immersed weight, which had the benefit of making the constant of proportionality nondimensional.

Local values of longshore transport are difficult to measure because it typically is a mixture of suspended and bedload transport (see entry on *Energy and Sediment Budgets of the Global Coastal Zone*). Instruments have been developed to measure suspended sediment concentrations at a point, but no satisfactory method of measuring bedload has yet been demonstrated. Largely based on inferences from the suspended sediment concentrations, it is generally believed that longshore transport is at a maximum in two zones. One is under the breaking waves and the other is in the swash zone on the beach face.

The simple analytical expressions for longshore transport, which attempt to predict the total transport across a shore-normal line, have been extended into two-dimensional numerical models. These two-dimensional models, in general, contain no additional physical insights into the sediment transport models, but they do allow the prediction of shore evolution caused by gradients in the longshore transport rate (Hanson and Kraus, 1989).

MACHAIR

Machair is a Gaelic word which applies to those areas of ancient sand dune systems mainly in the Hebrides of Scotland, but also in west Ireland, where long dune grasses have been superseded and the topography is essentially a low, plain surface (Ritchie, 1979). Its main characteristics are summarized below,

1. A level, low-lying, surface at a mature stage of geomorphological evolution, which is part of a very old fully vegetated coastal sand-dune system and is normally marshy in winter.
2. A base of blown sand which has a significant percentage of shell-derived materials and a narrow range of grain sizes.
3. Lime-rich soils with a pH value normally greater than 7.0.
4. A sandy grassland-type vegetation with long dune grasses and other early dune species having been eliminated.
5. Evidence of a history of anthropic interference including heavy grazing (especially rabbits, sheep, and cattle), rotational cultivation and, in places, artificial drainage.
6. A moist, cool location with characteristically strong onshore winds.

The origin of this dune system was more than 7,500 years ago, as a product of the rapid Flandrian marine transgression which began to level off at this time in this region. Powerful onshore Atlantic wave and wind energy transported preexisting glacial, fluvio-glacial, and shell-derived sediments across the extensive low gradient shallow continental shelf. Machair topography is influenced strongly by the underlying, preexisting landforms of the land extension of this shelf. As the sand-body transgressed landwards old organic and sand-rich deposits became exposed on the foreshore. More than 14 sites have been investigated for stratigraphy, pollen, and carbon 14 dating which provide evidence for the sequence of machair evolution. (Ritchie, 1985).

In the Outer Hebrides the total volume of sand in the beach, dune, and machair system has been more or less constant and, has therefore been subjected to extensive recycling. Nevertheless some ongoing supply from shells on the marine shelf is a possible addition to the original sediment bank. The most commonly used model for machair landforms is summarized in Figure M1, which shows the distinction between the actively retreating coastal edge and the mature inland surfaces. Typically, machair will occupy more than 90% of the area of the total dune system. Most low machair plains are deflation surfaces which are close to the winter water table. Machair can also be produced at the landward margin of the system by redepositional encroachment into marsh or loch basins.

Submergence has produced strands and sand flats between and inland of some machair systems. The drying-out time at low tide is insufficient for these areas to provide for secondary sand dune development. The open Atlantic beaches, however, do exhibit normal beach and dune exchanges associated with a retreating system. Wind-erosion with net landwards redeposition is also found in some inland features such as sand hills and ridges, normally initiated by severe overgrazing (Angus and Elliot, 1992). This erosion–redeposition process is the main mechanism for long-term machair evolution and landwards extension. Human interference including artificial drainage has also affected soils and landforms. There is an extensive literature of archaeological research from Bronze Age times, especially in the Western Isles, which has added greatly to the detailed evidence of machair evolution (Gilbertson *et al*., 1999).

The study of machair has been dominated by work done in the Outer Hebrides, notably in the Uist Islands where the machair is almost continuous along the entire Atlantic coastline, and its typology has been dominated by the particular circumstances of these islands. In west Ireland, machair often occurs in bayhead locations (Carter, 1990). In the Inner Hebrides, islands such as Tiree are almost entirely covered by dunes and machair, and the general model which depends on coastal submergence and finite sand supply may not be wholly applicable. Even on the Uist islands machair has developed on different timescales, as determined by location, offshore bathymetry, and coastal configuration (Ritchie and Whittington, 1994).

Machair is not therefore a unique type of coastal sand dune landform. Its age, topography, calcareous soils, and general dependence on geomorphological recycling can be replicated elsewhere but the word "machair" has landscape and cultural connotations which are associated with a distinctive history of land use and tenure which is now preserved only in the Gaelic fringes of northwestern Europe.

MANAGED RETREAT

Managed retreat is a collective term for the application of coastal zone management and mitigation tools designed to move existing and planned development out of the path of eroding coastlines and coastal hazards. This strategy is based on a philosophy of moving out of harm's way, and is proactive in recognizing that the dynamics of the coastal zone should dictate the type of management employed (e.g., identify and map the hazards as a basis for establishing regulations to move property and people away from migrating and/or storm-impacted coastlines).

The term "managed retreat" also is used in a more restrictive sense where shore-protection structures are removed selectively to allow natural coastal environments to be reestablished. For example, Viles and Spencer (1995) describe the creation of a small marsh on Northey Island, Blackwater estuary, Essex, England, by lowering a 200 m section of seawall and building a spillway to allow tidal inundation to be reestablished. This approach of letting parts of a coastline erode in a controlled way to create habitat and manage the coast in a way sympathetic to nature also is known as *managed realignment* (French, 1997). Managed realignment has the advantage that the sediment budget is reestablished.

Need for managed retreat

The Second Skidaway Conference on America's Eroding Shoreline concluded:

> …the American shoreline is retreating. We face economic and environmental realities that leave us two choices: (1) plan a

> strategic retreat now, or (2) undertake a vastly expensive program of armoring the coastline and, as required, retreating through a series of unpredictable disasters. (Howard *et al.*, 1985)

That conclusion applies to developed coasts globally. The recommendation for strategic retreat is synonymous with managed retreat.

The 15 years following the Skidaway Conference proved their predictions to be accurate with the exception that beach nourishment replaced armoring as the preferred engineering method of stabilizing coastlines. Armoring has increased globally (Nordstrom, 1994), and is still a common response to coastline erosion at the individual-property level in the United States. Beach nourishment is proving costly (US Army Corps of Engineers, 1994; Valverde *et al.*, 1999). In the Caribbean and along the Atlantic and Gulf Coasts, the damage from hurricanes is rising (e.g., Hugo, 1989; Andrew, 1992; Opal, 1995; Georges, 1998). Their impact has induced random retreat at the individual-property level, and forced communities to reexamine their coastal zone management strategies. And, although the greenhouse effect is a subject of debate, sea level is rising for most of the world's coastlines, and the rate of rise is increasing.

At the close of the 20th century, a report by the Heinz Center for Science, Economics and the Environment estimated that 10,000 coastal structures in the United States were within the estimated 10-year erosion zone (Leatherman, 2000). As of 1998, coastal counties in the United States exclusive of the Great Lakes, had a total flood insurance coverage of $466,874,000,000 (H. John Heinz III Center for Science, Economics and the Environment, 2000). The best option for many of these properties and their communities is managed retreat. Although "retreat" strikes a negative cord for some, elements of the strategic retreat option increasingly are being incorporated into coastal zone management.

The shift from engineering to "Soft" solutions

Historically, the method of choice to protect beachfront buildings and property was to hold coastlines in place through engineering by armoring (Table M1). By the 1950s and 1960s the realization that coastal buildings were subjected to higher winds and flooding (even those behind seawalls) led many states and communities to adopt more stringent building codes to strengthen buildings in the coastal zone. Coastal management was segmented both in locale and application (e.g., each community or agency focusing on a limited coastal reach or single problem). On barrier islands, the focus was often on the high-tide shoreline rather than a holistic management approach for an entire island or chain of islands. By the 1970s, the US national experience dictated that something be done to control the losses incurred from hurricanes and great storms like the 1962 Ash Wednesday Storm. The tremendous loss of habitat also was being recognized as salt marshes and shell fisheries were lost or closed. The results were two-fold: the National Flood Insurance Act of 1968 (also the result of persistent property loss on riverine floodplains), and the Coastal Zone Management Act of 1972. Building requirements were upgraded, and many coastal states began to define critical environments and control development through permit processes. Communities and states adopted approaches such as zoning and set back requirements. By the early 1980s, Integrated Coastal Zone Management (ICZM) (Clark, 1995) or simply Integrated Coastal Management (ICM) defined strategies in which a variety of management tools were being combined (Table M1). Cincin-Sain and Knecht (1998) define ICM "as a process by which rational decisions are made concerning the conservation and sustainable use of coastal and ocean resources and space" and "is designed to overcome the fragmentation inherent in single-sector management approaches …"

Continued beach loss and the associated losses of storm protection, recreational use, aesthetics, and beach economy, led to greater interest in "soft" solutions such as beach nourishment to combat erosion. Beach nourishment, however, is a modern equivalent of the engineering "fix" to hold the line, and does not recognize the natural dynamics of coastline retreat in areas where sea level is rising. This approach has proven drawbacks including ongoing costs, diminishing sand supplies, shorter half-lives of nourished beaches, and environmental impacts from dredging and sand placement.

Common regulatory methods, such as building codes, requirements for structures to be elevated, and controls on development density and type through land-use planning and most zoning, may lessen the impact of storms, but these methods do not remove development from the hazard zone. In some cases, vulnerability to hazards is increased. Furthermore, these approaches do not recognize coastline retreat as coastal adjustment takes place in response to sea-level rise, changes in sediment supply, variable wave regime, and other controls of coastline equilibrium. High-density development along shores all over the world demonstrate that land-use planning either has not worked or coastal management has come after the fact.

Table M1 General property damage mitigation options on the beachfront (modified after Bush *et al.*, 1996)*

- Hard stabilization
  - Shore-parallel
    - Seawalls
    - Bulkheads
    - Revetments
    - Offshore breakwaters
  - Shore-perpendicular
    - Groins
    - Jetties[a]
- Soft stabilization
  - Adding sand to beach
  - Beach replenishment
  - Beach bulldozing/scraping
  - Increasing sand dune volume
    - Sand fencing
    - Raise frontal dune elevation
    - Plug dune gaps
  - Vegetation
    - Stabilize dunes (oceanside)
    - Marsh (soundside)
- Modification of development and infrastructure (control through zoning, building codes, insurance eligibility requirements)
  - Retrofit homes
  - Elevate homes choose elevated building sites
  - Lower-density development
  - Curve and elevate roads
  - Block roads terminating in dune gaps
  - Move utility and service lines into interior or bury below erosion level
- Managed retreat
  - Abandonment
    - Unplanned
    - Planned
  - Relocation
    - Active (relocate before damaged)
    - Passive (rebuild destroyed structures elsewhere)
  - Long-term relocation plans (zoning, land use planning)
  - Setbacks
    - Fixed
    - Rolling
  - Acquisition
  - Avoidance: recognize hazard areas and avoid
    - Tidal inlets (past, present and future)
    - Swashes
    - Permanent overwash passes
    - Wave-velocity zones

* These management options are listed in increasing order of preference for Integrated Coastal Management (ICM). Historically, early management usually focused on shoreline stabilization, relying on a single mode of armoring. Various mitigation tools have been added to management plans, often in response to deficiencies in earlier plans that were revealed by the impact of the most recent storm.
[a] Jetties are built specifically to protect harbor entrances or maintain inlets, and are not constructed to protect coastlines. They are listed here because they impact adjacent shorelines, and that impact must be considered in management schemes.

Methods of managed retreat

"Retreat" is sometimes used for setbacks (e.g., Clark, 1995), or has been viewed simply as denying property owners the right to construct shore-hardening structures, forcing abandonment (Sturza, 1987). Managed retreat, however, implies applying an appropriate management strategy from a menu of tools, including stabilization techniques in some cases (e.g., particular urban coastlines). Specific retreat mitigation techniques include: abandonment, relocation, setbacks, land acquisition, and avoidance.

Abandonment

Abandonment may be unplanned, or part of a planned strategy of retreat. Historically, abandonment is often an unplanned, post-storm response to destruction of buildings and land loss (e.g., bluff retreat so that reconstruction is impossible). Fallen houses in the water or on the beach are a common sight along open-ocean coastlines after hurricanes and northeasters. Similar scenes are common in the Great Lakes and large embayments like Chesapeake Bay. Destruction may be so complete that the property is abandoned. Ruins of houses destroyed in Hurricane Gilbert in 1988 remained 12 years later along Mexico's Yucatán coast. Entire villages on barrier islands and along eroding bluffed shores have been abandoned. The village of Broadwater, Hog Island, VA, was abandoned in 1933 after losses to storms and shore erosion, although in part it was a short-term planned abandonment as houses were relocated off the island. Earlier, Cobb Island, VA, and Edingsville Beach, SC, had met similar fates. West coast abandoned towns include Bayocean, OR, and Cove Point, WA. Over the last century, 29 villages have been abandoned (lost) to the sea along England's Yorkshire coast.

Planned abandonment can be incorporated into managed retreat in several ways. Long-term planned abandonment can follow what is sometimes called the "do nothing" approach. Buildings are regarded as having a fixed life span, and when their time comes to fall into the sea, bay, or lake, no attempt is made to protect them. Buildings are razed either just before or after failing. Planned abandonment can be achieved by prohibiting post-storm reconstruction, or by requiring relocation landward of the revised post-storm setback control line. The original South Carolina Beachfront Management Act would only allow habitable structures damaged beyond repair (two-thirds or greater damaged) to be rebuilt landward of the no-construction zone (Beatley *et al*., 1994). In part because of a poorly written law, post Hurricane Hugo enforcement led to the famous court case of *Lucas v. South Carolina Coastal Council* in which the plaintiff prevailed, resulting in the law being rewritten and softened. Rebuilding after storms can be discouraged by other methods as well, such as denial of flood insurance and other subsidy programs.

Relocation

For an existing building, the most obvious way to avoid a hazard is to move away from it! For developed coasts relocation is an essential component of managed retreat. So it is with an eroding or shifting high-tide shoreline.

Active relocation is undertaken by moving a building back either before it is threatened, or, if threatened, before it is damaged.

Passive relocation is achieved by rebuilding a destroyed structure in another area, away from the shore and out of the coastal hazard zone.

Long-term relocation usually implies a broader strategy through community zoning or land-use plans that identify a frontal zone of buildings likely to be impacted by known erosion rates or predicted flood levels from storm surge and coastal flooding. These building are then scheduled for relocation over an extensive period (assuming they will not be lost in coming storms). In effect, this is an engineered retreat, and on a barrier island the plan may include creation of new land on the soundside of the island for relocating the structures (Viles and Spencer, 1995). Artificial island migration is achieved, however, because barrier islands are usually backed by sensitive marshes and wetlands, the approach is questionable and raises complicated issues of property rights and changing ownership. This approach is more easily achieved in moving communities off of riverine floodplains and non-barrier coasts.

Even where setbacks are used, a retreating coastline will catch up with the property, and relocation will again become an option. Relocation is often the best economic option (Table M2) even though the up-front cost may be high. One can find examples along almost every coastline where armoring is used in which the cost of seawalls, groins and breakwaters, or nourishment, over the lifetime of the property, exceeds the value of the property, and greatly exceeds the cost of moving the structure.

The 1987 Upton–Jones Amendment to the National Flood Insurance Program (NFIP) allowed owners of threatened buildings to use up to 40% of the Federally insured value of their homes for building-relocation purposes (Wood *et al*., 1990). The law recognized relocation as a more economical, more permanent, and more realistic way of dealing with long-term erosion and flood problems. The NFIP would pay a relatively small amount to assist relocating or razing a threatened house, rather than paying a larger amount to help rebuild it; only to see the rebuilt house destroyed in a subsequent storm, and paying to rebuild again. By March 1995, North Carolina had claims for over 70 relocations and 168 demolitions, and accounted for over 60% of all coastal claims under the program. The National Flood Insurance Reform Act of 1994 ended the Relocation Assistance Program as of September 23, 1995, replacing the Upton–Jones program with the National Flood Mitigation Fund.

Table M2 The advantages and disadvantages of relocating buildings back from a retreating shoreline (modified after Bush *et al.*, 1996)

Advantages
- building moved out of hazard zone, or is less vulnerable to hazards
- natural shoreline processes allowed to continue
- preserves the beach and associated value to community
- high probability of one-time-only cost (economical in the long term)
- cost savings because no public or private money spent on stabilization

Disadvantages
- high initial cost
- politically difficult
- building site must be deep enough to allow suitable moveback, or an alternative site must be purchased
- structure must be of a type and design/construction that allows it to be moved (e.g., a wood-frame house is easier to move than a cinder-block house on a poured concrete slab)
- coastal land is lost

Demolition and relocation activities are eligible for grant assistance under the program, but now compete with other mitigation approaches, including elevation and flood-proofing programs, acquisition of flood-zone properties for public use, beach nourishment, and technical assistance. Some states have encouraged relocation with similar programs (e.g., Michigan) (Platt *et al*., 1992), or require houses to be moveable through the building permit process (e.g., New York).

The relocation alternate often is regarded as too expensive or technically impossible, but the move of the famous Cape Hatteras, NC lighthouse in 1999 again proved the feasibility and economic wisdom of this alternative (Pilkey *et al*., 2000). Relocation is not a new mitigation strategy. Lighthouses have been relocated in North America since the 19th Century. Entire communities have relocated by choice or by necessity when they can no longer defend against the ravages of nature. Discouraged by continual hurricane damage, the citizens of Diamond City, NC relocated in 1899, disassembling their houses and barging them to their new locations. Rice Path, NC relocated because of encroaching sand dunes. FEMA's web site gives examples of recent success stories of relocation. Moving houses and communities off of riverine floodplains is not uncommon (e.g., English, IN; Rhineland, MO; Glasgow, VA).

Deep property lots are an important element in planning for future relocation Deep lots allow homeowners to relocate houses threatened by erosion to another location on their own property. In effect, lot depth determines possible future on-site relocation. While relatively deep lots are found in some coastal communities, new developments are often designed to maximize the number of dwelling units, resulting in small lots. Despite this trend, some communities, such as Nags Head, NC, are now requiring deep lots (oceanside to soundside on barrier islands) in order to provide for relocation.

Setbacks

Setbacks as the name implies are a management tool to keep structures out of extreme-to-high hazard zones, or at least at a distance from the hazardous processes (e.g., coastal erosion, v-zone flooding, storm surge). Klee (1999) reviews two types: "stringline" and "rolling" setbacks. A stringline setback simply requires that new construction be a fixed distance inland from a reference line (e.g., the back of the beach, the vegetation line, the crest of the dune line). The regulatory line is not adjusted for changes such as storm impact. A rolling setback is one in which the regulatory line shifts landward as the high-tide shoreline erodes (e.g., as the bluff edge, back beach, or dune toe retreats).

Although setbacks often are defined as creating zones in which no buildings or structures are allowed, in reality most setback regulations allow for variance application, and in some jurisdictions, liberal granting of variances circumvents management intent.

How far back is a "safe" building setback? The answer is difficult and will vary from place to place according to erosion rates and state and local regulations. No uniformity exists between coastal states' setback regulations in terms of how they are defined or applied (see Leatherman, 2000, table 4.4 for state-by-state summary).

While setbacks put some distance between buildings and the shore, that distance does not remain constant. When high-tide shoreline retreat catches up to the buildings, the original setback distance is of no consequence. Once again, the relocation or abandonment options must be considered.

Acquisition

Land acquisition can be an important component of a managed retreat plan. Land in the public trust through federal, state, and local ownership usually provides benefits in terms of conservation, providing public access to the shore, contributing to recreational and tourism needs, preserving aesthetics, and protecting habitat. Most coastal states have land acquisition programs and governments can purchase land through negotiated purchases where owners voluntarily sell land, or, less common, by eminent domain (condemnation proceedings). Other strategies include tax incentives, donations of conservation easements, trading of land, and transference of development rights. Condemnation usually results in a much higher cost for the land. Most land acquisition programs are hampered by a lack of funding. Florida and California are states with fairly successful programs. Just how well a publicly owned urban coastline can serve its citizens is demonstrated by Chicago's 18-miles of continuous public parkland.

Avoidance

The best way not to experience a hazard is to avoid it! Although the decision not to locate in a hazardous area may not seem like retreat, including areas where no development is allowed because of specific hazards, critical habitats, or sediment sources, is usually part of managed retreat. In this case, zoning can contribute to safe siting of structures away from coastal hazards. In part, setbacks reflect an avoidance approach, however, as noted, setbacks are temporary because coastline retreat will eventually reach buildings that met the original setback requirement. An eroding coastline may be more than just a hazard. Sacrificial coastline may be necessary to preserve the down-drift sediment budget, and Hooke (1998) gives an example in which the South Wight Borough Council (England) does not allow coastal defense works so a cliff-line will continue to erode and provide sediment to the beaches of Sandown Bay.

Again, disincentives may be used in an effort to encourage people not to build in high-hazard zones or in areas of critical habitat. Federal laws such as the 1982 Coastal Barriers Resources Act (COBRA) and the 1990 Coastal Barriers Improvement Act (CoBIA) have designated areas in which development is allowed, but buildings are not eligible for federal flood insurance or any post-storm federal assistance such as small business loans and funding to rebuild infrastructure. After Hurricane Fran in 1996, however, such assistance apparently did go to the community of North Topsail Beach, NC which is located in a COBRA unit.

Nags Head, North Carolina: managed retreat at work

The managed-retreat approach has been successfully implemented by the town of Nags Head, NC. This mitigation strategy stems from a desire to protect Nags Head's family beach atmosphere that attracted the residents in the first place (Bush *et al.*, 1996). Recognizing that hurricanes are inevitable, the Nags Head Repetitive Loss Plan and Floodplain Management Plan's implementation includes an extensive list of pre-storm mitigation measures, town response during a storm event, and post-storm mitigation and reconstruction measures (Nags Head, 1995).

The town adopted building standards more restrictive than required by either FEMA or the North Carolina Coastal Area Management Act (CAMA). Incentives are used to encourage development to be located as far back from the ocean as possible, including strict setbacks (minimum standard of 150 ft (45.7 m) setback from mean high water). Because small, single-family structures are much easier to move, the town has limited the development of oceanfront hotels and condominiums. Deep lots running perpendicular to the shore provide considerable room for relocation. Prior to rebuilding after a storm the Town may require adjoining lots in common ownership to be combined into a single lot. New construction of wood frame, multi-story, multi-family, buildings is not permitted. Strict limits are set on the amount of impervious surfaces within the oceanfront zoning districts that further reduces the amount of real property at risk. The post-storm measures include building moratoriums, policies on reconstruction, and a program for rapid acquisition of land.

The general theme of Nags Head's mitigation plan is based on the recognized history of coastline retreat, and that it is far better to adopt a policy of planned retreat than to wait for a disaster to force retreat. That philosophy is not new to residents of North Carolina's Outer Banks. A landmark property in Nags Head is the Outlaw House, named for the Outlaw family. This structure has been moved back 600 ft (183 m) from the retreating high-tide shoreline in five separate moves over 100 years.

The cost of moving buildings is the best economic strategy because the solution is long-term compared with relying on beach nourishment with an estimated cost of approximately \$2 million per mile (1.6 km). The area's relatively high wave energy would require additional nourishment every three years resulting in an average annual cost of \$3 million. This expenditure would continue as long as replenishment was the chosen mitigation technique. By comparison, the cost of removing structures from the threatened areas is much less. As of the early 1990s, Nags Head had accounted for 78 of the 379 (21%) Upton–Jones petitions submitted nationwide, 55 of which had been approved (Williams, 1993). Of these 55, 35 petitions requested funds for demolition at an average cost of \$74,409, and 19 requested funds for relocation at an average cost of \$30,211 (Williams, 1993). Similarly, an estimated cost for a beach nourishment program along a 4.5 (7.6 km) mile reach of South Nags Head shoreline was about \$9 million every 3 years compared with the retreat option estimated at about \$2 million every 20–25 years.

Relocation is a viable coastal management tool, and need not be considered only for single-family houses. When a structure is moved, the danger is reduced (Table M2).

The 10/100-year relocation concept

The difficulty of applying a managed retreat strategy is exemplified by areas such as the Myrtle Beach Grand Strand, SC, Miami Beach, FL, and other great oceanfront resort communities where a vast number of high-rise condominiums and hotels are right on the high-tide shoreline. At present, beach replenishment is economically feasible for these communities because of the large number of people that use the beaches and the significant revenue generated. The Miami Beach replenishment project, the most successful on the east coast in terms of replenished beach lifetime, has lasted for over 20 years. Along parts of the Grand Strand, SC, replenishment has to be repeated almost yearly. A time will come, however, when the economics of replenishment will no longer be acceptable. The increasing sand volumes needed, the declining sand supplies, and escalating project costs will make nourishment a less acceptable management tool. The time is approaching when serious consideration will have to be given to managed-retreat alternatives such as relocation and land acquisition.

Although the argument is that development along urban coasts is either not feasible or too entrenched to consider managed retreat, the alternative is both feasible and, perhaps, preferable for some communities. The International Association of Structural Movers says that moving large structures is technologically feasible, though expensive. Recall also that relocation can mean demolishing a building and rebuilding its replacement elsewhere. The unanswered question is economics.

Urban communities and owners of large buildings should not exclude managed retreat as a management tool, and need to begin researching the economics of this option. One possibility is a *10/100-year relocation plan* in which a relocation strategy is developed within 10 years and implemented as necessary over the following century (Bush *et al.*, 1996). Cost comparisons of traditional relocation or relocation by demolition and rebuilding should be evaluated against the long-term feasibility of continuing the replenishment option (e.g., the projected sea-level rise, financing requirements, identifying and acquiring distant sand resources, a timetable for obtaining necessary permits, etc.). Whether buildings can be relocated on the present property or off property, within the community or outside must be ascertained. What are the options and questions yet to be raised? A 10-year planning window should set the stage for implementation. Plans will vary by community and coastal type, and will take decades to implement. Virtually all coastal communities will need such programs of managed retreat over the next 100 years, or they will fulfill the prediction of retreating as the result of a series of coastal calamities.

The need for long-term managed retreat

In summary, to hold the line against the sea-level rise for all of the world's developed coasts is unrealistic. Managed retreat may provide the best set of tools for mitigating coastal hazards and reducing property losses. Avoidance remains the best solution for undeveloped and lightly developed areas, while various forms of relocation are the long-term solution for even urbanized shores. Coastal land acquisition is one method of meeting both of these goals, however, greater funding will be needed for future acquisition to succeed. Setbacks are a temporary solution, even when redefined periodically as rolling setbacks. In order for managed relocation to work, integrated land-use planning and zoning efforts will have to take a broader, holistic approach. For example, barrier-island management policies must consider the entire island, moving from a focus on site-specific and linear (island front) regulation to a whole-island perspective, and from shore hardening/hold-the-line programs to approaches which concentrate on preservation, augmentation, and repair of the natural systems.

MANGROVES, ECOLOGY

Introduction

Mangroves have always been considered as marginal ecosystems for at least three main reasons. First, the global mangrove area does not exceed 180,000 km^2 representing less than 2% of the world's tropical forest resources. Second, their discontinuous distribution, at the land and sea interface of tropical and subtropical coastlines, is primarily characterized by tidal regimes, which is a unique forest habitat. Third, the frequent wide fluctuations of environmental factors (dissolved oxygen, salinity, organic, and inorganic suspended matter) have induced in mangrove flora, a complex range of adaptations, lacking in other woody species, unable to compete or to survive in these highly variable and adverse environmental conditions (low oxygen content in soils, sulfate toxicity, high NaCl in water and soils, exposure to hurricanes and surges, muddy soils, instability, etc.). Yet, these ecosystems are highly productive with an average primary productivity often higher than that of neighboring continental forest types.

Many species of invertebrates and vertebrates of commercial value use mangrove habitat for food and shelter during their life cycle. Most mangrove ecosystems around the world have been depleted during the 20th century. Until the 1980s they have been extensively converted to other uses. For the last 20 years, many mangrove areas have come under full or partial protection, and restoration programs are being implemented in almost every one of the 70 countries possessing mangroves.

Most of the mechanisms and processes regulating mangrove ecosystems; primary productivity, food webs, nutrient fluxes, physiological adaptations of plants and animals, etc. are still poorly known, and this fragmentary knowledge is mainly restricted to species of commercial value.

Present distribution of mangroves

Six geographical zones have been recognized (Chapman, 1976; Snedaker, 1982; Rao, 1987; Saenger and Bellan, 1995; Duke *et al*., 1998).

With rare exceptions, mangroves are restricted to coastal areas where mean monthly air temperatures, in winter, are higher than 20°C and where ground frost is unknown (Figure M2). The tallest (up to 35 m tall) and more dense mangroves are found in bioclimatic conditions with high annual rainfall (>2000 mm) and a short dry season (<3 dry months). They can survive in arid areas (Persian Gulf, Mauritania, Red Sea), in the form of low or dwarf, monospecific stands (Dodd *et al*., 1999). The largest contiguous surface area of mangroves, covering more than 6,000 sq. km, is located in the upper Bay of Bengal, on the delta of the Ganges.

Recent estimates (Spalding *et al*., 1997) indicate that the total mangrove area is about 180,000 sq km, most of it being located in South and Southeast Asia (Table M3). A few nations dominate these area statistics. For example, of the approximately 70 countries with this ecosystem, Indonesia, Australia, Brazil, Nigeria have about 43% of the world's mangroves. Indonesia alone has 23% and 12 countries have two-thirds (Table M3). Political and management decisions relating to mangrove stands of these countries will have significant effects on the global status in the future (Hamilton and Snedaker, 1984). It is assumed that at least 30% of these ecosystems are degraded or very degraded.

Productivity goods and services of mangrove forests

Our general knowledge of mangrove structural properties, above ground biomass and litter production (Saenger and Snedaker, 1993) is rather

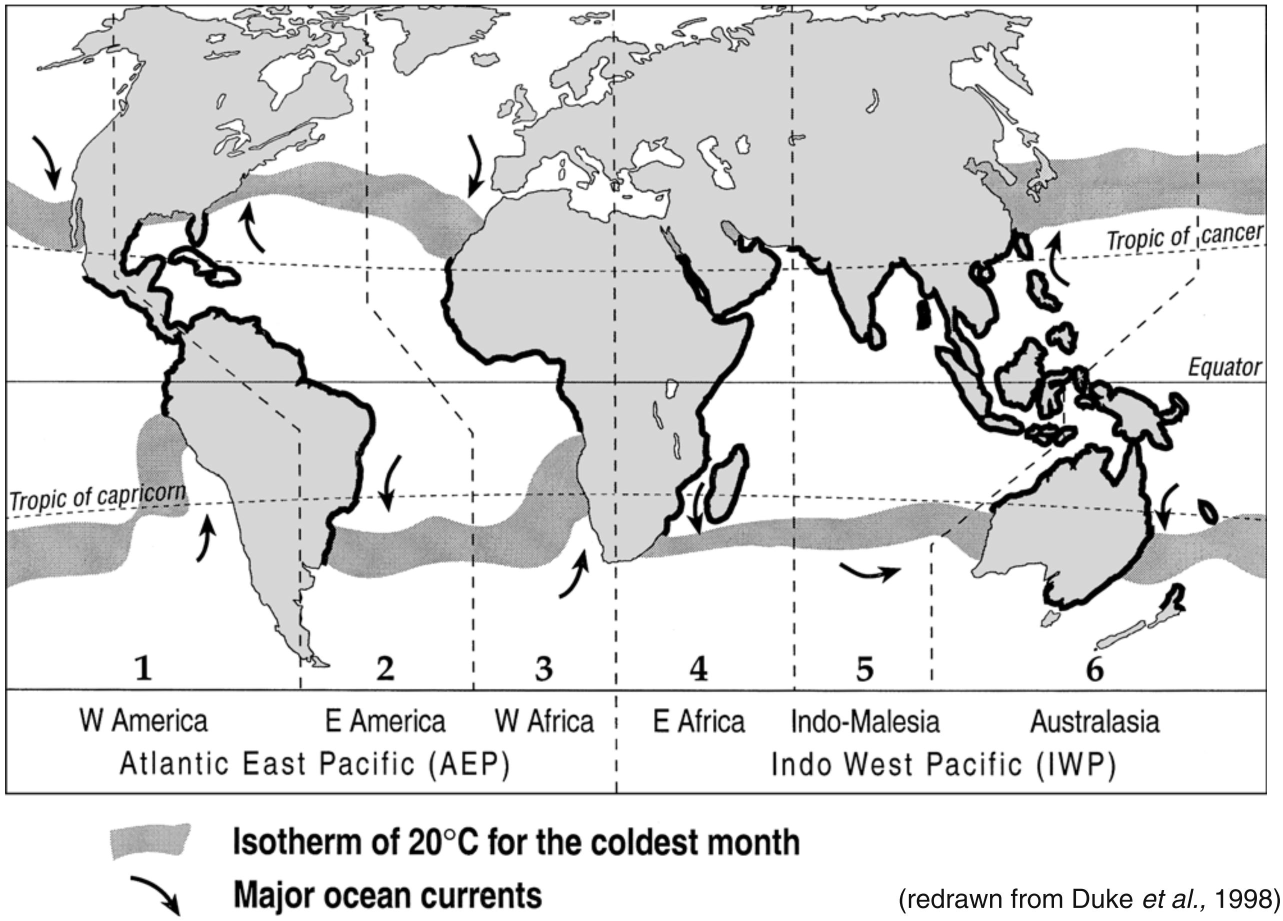

Figure M2 Main biogeographic mangrove area (redrawn from Duke, 1998).

Table M3 Estimates of mangroves areas (after Spalding *et al.*, 1997)

Region	Global (km^2)
South and Southeast Asia	75,173 (41.5%)
Australasia	18,789 (10.4%)
The Americas	49,096 (27.1%)
West Africa	27,995 (15,5%)
East Africa and the Middle East	10,024 (5,5%)
Total area	181,077

Major countries	(km^2)
Indonesia	42,500
Australia	11,500
Brazil	13,800
Nigeria	10,500
Malaysia	6,400
India	6,700
Bangladesh	6,300
Cuba	5,500
Mexico	5,300
Papua New Guinea	4,100
Colombia	3,600
Guinea	2,900
Total	119,100

well-advanced as extensive work has been carried out, especially in Malaysia (Sassekumar and Loi, 1983), Australia and New Zealand (Duke 1988; Woodroffe *et al.*, 1988), USA (Lugo *et al.*, 1980; Twilley, 1982; Lahmann, 1988), Brazil (Adaime, 1985), French Guyana (Fromard *et al.*, 1998). The following general conclusions can be drawn:

- in equatorial and sub-equatorial areas, mangrove height is about 12–20 m, rarely exceeding 25 m, and the litterfall varies from 12 to 16 t. ha^{-1} yr^{-1} (dry material).
- near the tropics, their average height is about 8–12 m and the known mean annual litterfall is of the order of 8 t. ha^{-1}.
- along warm temperate coastlines, where mangroves are exceptionally found (New Zealand), their height does not exceed 4 m and the litterfall declines to 4 t. ha^{-1} yr^{-1}.

High productivity and short retention times of organic matter in most mangrove ecosystems make them extremely important, not only for fisheries (Snedaker and Lugo, 1973). In the last 25 years, it has been shown that mangroves throughout the world serve a multitude of functions for the people inhabiting them (ISME, 1993), but more and more foresters and shrimp farmers are looking at the profits that can be derived from converting the mangroves into fish and shrimps ponds. As clearly shown by recent world satellite surveys (Spalding *et al.*, 1997; Blasco and Aizpuru, 2001) conversion of mangroves to aquaculture, to agriculture, and to urban development are the main causes of mangrove destruction.

Large-scale conversion to agriculture is conspicuous in the Gangetic delta (India and Bangladesh) where the population density exceeds 800 inhabitants km^{-2}, in Myanmar (Irrawady delta) and in most coastal areas of West Africa, from Senegal to Nigeria. Paddy fields, sugar cane, orchards, and oil palm are the main products. Concerning the conversion to aquaculture, fish ponds (*Chanos chanos*) have replaced most mangroves in the Philippines, whereas shrimp farming in Thailand, Indonesia (*Penaeus monodon, Penaeus merguiensis*) and Equador (*Penaeus vannamei*) has converted large areas of mangroves in recent years. In 1977, it was estimated that 1.2 million a of mangroves in the Indo-pacific region has been converted to aquaculture ponds (Saenger *et al.*, 1983). In many countries (Vietnam, Malaysia, Thailand, etc.) highly pyritic soils have lead to high acidity, causing major difficulties for the operators of aquaculture ponds with spectacular declines in yields (less than 400 kg ha^{-1} yr^{-1} instead of 1,400 initially). And the development of acid sulfate soils in drained mangrove areas of West Africa has had catastrophic consequences with failure of rice crops.

Mangroves versus chronic coastal environmental problems

Many investigators have described the building role of *Rhizo-phora*. The actual efficiency of sediment retention is very unequal from one place to another. The coastal afforestation program which is in progress in Bangladesh (Saenger and Siddiqi, 1993), with more than 200,000 ha, demonstrates that plantations with *Sonneratia apetala* contribute both to the acceleration of land accretion and to the stabilization of the exposed soft sediments.

In the last few years, new findings have been published concerning the role of mangroves as biochemical barriers to pollutants. Although metal mass balances in mangroves are still at an exploratory stage, with net import and net export occurring in different oceanographic cycles, the final balance, after a long period of monitoring, seems to be a net import of trace metals, as a result of complex physical and chemical coastal processes (Clark *et al*., 1997; Lacerda, 1998).

Recent studies in coastal Brazil have shown that large heavy-metal concentrations (Hg and Zn) are retained in the rhizosphere sediments under very refractory chemical forms, making their uptake extremely difficult. They are preferably accumulated in perennial tissues, such as below ground biomass and trunks, whereas their concentrations in leaves remain extremely low. Although this is a new field of research there are strong and convergent indications that mangrove soils and plants minimize pollution by heavy metals in tropical coastlines (Lacerda *et al*., 2000).

Concerning trace metals concentration and distribution in mangrove animals (Zn, Cd, Cu, Cr, and Pb), few studies have been carried out on mangrove oysters (*Crassostraea*) and mussels (*Mytella guyanensis*). No general conclusion can be drawn so far because of the scarcity of reliable data.

Flora, zonation, and role of salinity

The earliest mangrove fossil materials (pollen, fruits, hypo-cotyls) have been recorded from Brazil, Europe, Asia and Australia, etc. during the lower Cenozoic, about 55 million years before present (Eocene).

Throughout the world's tropics, growing preferably on muddy soils of deltaic coasts, in lagoons and estuarine shorelines, about 70 species of trees and shrubs, including putative hybrids, are considered as exclusive to the mangrove habitat (29 genera and 20 families) and about 24 are important but not exclusive.

The commonest species belong to three genera: *Rhizophora*, with nine taxa bearing conspicuous stilt roots, *Avicennia*, with eight taxa having dense, slender aerial roots known as pneumatophores and *Sonneratia* (nine taxa) with stout, conical pneumatophores (Table M4).

One of the most conspicuous and enigmatical features in mangrove ecosystems is the zonation of species. Such a common spatial patterning seems to be the result of complex processes involving dispersal strategies, plant succession mechanisms, physiological attributes of species, interspecific interactions, and seasonal fluctuations of physico-chemical parameters (Snedaker, 1982; Smith, 1992).

The importance of salinity has been stressed by most mangrove specialists (Saenger *et al*., 1983; Tomlinson, 1986; Hutchings and Saenger, 1987; Duke *et al*., 1998). Each species of tree and shrub has its own tolerance to salinity concentrations. This partly explains the upstream and downstream distribution of each species. *Avicennia integra, Heritiera fomes, Sonneratia lanceolata* occur upstream, or in freshwater-dominated habitats, where tidal penetration is limited and the average annual water salinity is lower than 20 ppt. The majority of remaining mangrove species (Table M4) are found in the intermediate part of the estuaries (all members of the Rhizophoraceae, *Avicennia alba, Avicennia officinalis, Excoecaria, Lumnitzera, Pelliciera, Xylocarpus*, etc.), indicating that their optimum salt requirements oscillate between 20 and 30 ppt. A few woody species are most generally found at the mouth of estuaries, in downstream and sea-front sectors, thriving year round in highly saline environmental conditions (30–45 ppt); this is the case for *Avicennia marina, Rhizophora mangle, Bruguiera gymnorrhiza, Laguncularia racemosa, and Sonneratia alba*.

Avicennia marina has the largest, almost continuous, biogeographical distribution of any mangrove species, extending from east Africa to the Red Sea and Pakistan, to the Indian Ocean and the Southern Pacific. Some of its ecotypes are found in the Arabian Gulf, occupying one of the driest mangrove habitats in the world, in which salt concentrations may reach levels that are beyond the physiological limit for other species (Dodd *et al*., 1999). Under laboratory conditions, *A. marina* can survive a very wide range of salinities (Ball, 1996, 1998), from distilled water to salt concentrations as high as 175 ppt. The exact mechanisms of the physiological adaptation to saline environments, involving osmoregulation, ion compartmentation and selective ion uptake by roots, salt excretion, are still unclear.

Several attempts have been made to correlate species richness with important environmental factors, especially in Southeast Asia and Australia (Duke, 1992; Ball and Pidsley, 1998). Although temperature, rainfall, tidal and soil peculiarities, water salinity, etc. are known to be determining factors, the interplay between such factors and species richness is not properly understood.

Mangrove fauna

Most mangrove fauna can be subdivided in three main groups: resident species (occurring primarily in mangroves), seasonal migrants, and occasional mangrove species. In contrast to the list of mangrove plants given in Table M4, associated biota recorded from mangrove often occur in other habitats, adjacent to mangrove.

As a general rule, many species of terrestrial mammals are found in mangrove ecosystems but none seem to be strictly confined to mangroves. Even the estuarine crocodile (*Crocodylus porosus*) one of the largest species, and the endangered Bengal tiger (*Panthera tigris tigris*), common in the mangroves of the Ganges, are not restricted to these ecosystems. In the same way, fruit bats and nectar-feeding bats which often roost in mangroves, the crab-eating Macaque (*Macaca fascicularis*) and the Proboscis monkey (*Nasalis larvatus*) are more abundant in mangroves than in other habitats.

The use of mangrove ecosystems as nursery grounds for larval and juvenile fish was first demonstrated by Odum and Heald (1972) in Florida. The group of fish restricted to mangroves is mainly that of mudskippers, belonging to the gobiid subfamily Oxciderninae, with two genera (*Periophtalmus* and *Periophthalmodon*) and 5–10 species. The main peculiarity of mudskippers which are common practically throughout tropical mangroves, is their ability to withstand exposure to air especially during low tide. According to Hutchings and Saenger (1987) the main importance of mangroves to fish, is the availability of food, especially prawns, for juveniles, and protection, as piscivores are often under-represented in mangroves. Fish fauna is now rather well-known for most mangrove regions (Tholot, 1996).

Most mangrove birds are found in a variety of other habitats but mangroves provide secure roosting sites at high tide and the food for many species. The most spectacular population is probably that of scarlet ibis (*Eudocimus ruber*) in Trinida's Caroni mangrove, gathering more than 20,000 birds.

Mangroves are known to serve as nursery grounds for young crabs and juvenile prawns and as a source of seed for aquaculture. The mud crab (*Scylla serrata*) is probably the most popular Crustacea in coastal Southeast Asian countries. Among molluscs, several oysters (*Crassostrea commercialis, Crassostrea lugubris, Crassostrea iredalei, Crassostrea malabonensis*) and the green mussels (*Perna vividis*) are cultured commercially, whereas the cockle (*Anadara granosa*) has a great commercial value, particularly in Malaysia and Thailand.

Air-breathing Arthropods (Myriapods, Arachnids, and Insects), are probably extremely numerous in all mangroves (Murphy, 1985) in terms of specific biodiversity, but little work has been done so far on the insect fauna. They usually remain in air-filled cavities during high tide; a conspicuous "cave fauna" has been described in the mud-lobster mounds (*Thalassina*). Diptera are richly represented in these ecosystems where highly distinctive and unique genera have been identified; some families are also characteristic of mangroves (Tethinidae, Canaceidae, etc.). Likewise, among Lepidoptera, some butterflies and moths are found only in mangroves, the most diversified being perhaps among Nymphulinae. Finally, some wasp and bee taxa (Hymenoptera) are endemic to mangroves where they may play a noteworthy commercial role (high quantities of natural honey are collected from the mangroves, in Bangladesh).

The complex interactions between invertebrates and plants are very poorly known (Robertson *et al*., 1990), unless they are conspicuous. Many propagules (*Rhizophora, Bruguiera, Avicennia*) are destroyed by borer beetles and a torticoid moth causes mass mortality among *Sonneratia* seedlings.

Mangrove microorganisms

Microbiota are known to play essential roles in mangrove food chain and biogeochemical cycles (carbon, sulfur, nitrogen, iron, phosphorus,

P, Palm; S, Shrub; F, Fern; T, Tree.

etc.), under very peculiar anaerobic and aerobic conditions. Fungi and bacteria may become associated, in mangrove sediments, providing intensive, rapid, and almost continuous recycling of organic matter, during floods, under anoxic conditions, as well as during exposure to air at low tides. Given the high temperature of water and sediments (25–35°C), the primary production is rapidly attacked and decayed.

The role of fungi in the processes of degradation of lignocellulose materials, is still obscure; very little is known, as few species have been tested for their ability to degrade the organic matter (Jones and Hyde, 1988). Even the taxonomic inventory is only now beginning. About 100 species are known today (73 Ascomycotina, 25 Deuteromycotina, and only 2 Basidiomycotina).

From a biogeographical point of view it appears that most mangrove fungi are distributed across the tropical world (Jones, 1996). This could be due either to their very efficient dispersal mechanisms or to an early evolution, before the separation of landmasses.

According to Boto (1988) much further research is needed to properly understand, the exact role of microbiota, especially of bacteria, in mangroves.

Conclusion

These are a few of the many areas that briefly illustrate the extreme complexity of mangrove ecosystems and the numerous issues to be solved. There are a number of poorly understood processes involved in the productivity and biogeography of mangrove species. Some preliminary studies (Duke, 1995; Maguire and Saenger, 2000), are indicating infraspecific variation having a genetic basis. The exact genetic variation within mangrove taxa is unknown.

But there is a danger that most of the natural processes and interactions will never be properly understood, because the mangroves of the world, except in Australia, are being transformed, fragmented, degraded, or converted at a very rapid pace, as a consequence of the population growth in the tropical coastal world (Field, 1996).

MANGROVES, GEOMORPHOLOGY

Mangroves are halophytic shrubs and trees that grow in the upper part of the intertidal zone on the shores of estuaries and lagoons, and on coasts sheltered from strong wave action, as in inlets or embayments or in the lee of headlands, islands, or reefs. They grow sparsely on rocky shores and coral reefs, where their roots penetrate fractures in the rock, and on sandy substrates, but are more luxuriant, forming dense scrub and woodland communities, on muddy substrates and shoals exposed at low tide, particularly where there is a supply of muddy sediment. Where wave energy is low they spread forward to the mid-tide line, but as wave action increases along a coastline the mangrove fringe thins out and disappears. On the other hand, mangroves colonize areas that have become more sheltered as the result of the longshore growth of sand bars, spits, or barriers.

The width of a mangrove fringe generally increases with tide range, and on macrotidal coasts can attain several kilometers, as on the tide-dominated shores of gulfs and estuaries in northern Australia, where wide mangrove areas are backed by sparse salt marshes and saline flats flooded during exceptionally high tides and summer rains. Within the humid tropics mangroves grow to forests with trees 30–40 m high, as on the west coasts of Malaysia and Thailand, in Indonesia, Madagascar, and Ecuador. On drier and cooler coasts within, and outside, the tropics (extending to about 30°N and up to 39°S) mangroves generally form extensive scrub communities (Chapman, 1976).

Where mangroves are spreading seaward there is an abundance of seedlings and young shrubs on the adjacent mudflats and a smooth canopy rising landward as the trees increase in age and size. A receding mangrove coast is indicated by a microcliff and the truncation of the mangrove canopy, so that trunks are exposed with trunks and roots being undercut, or where the mangroves have died, and any seedlings fail to survive.

Mangroves are physically adapted to survive in a marine tidal environment. Some species (e.g., *Avicennia marina, Sonneratia alba*) have root systems with networks of pneumatophores, snorkel-like breathing tubes that project vertically from the muddy substrate (Figure M3), and allow the plant to respire when the tide falls. With the aid of these structures, mangroves can grow in areas submerged by the sea at each high tide, but the need for several hours subaerial exposure between each submergence sets a seaward limit, usually close to mid-tide level. Pneumatophores occupy a roughly circular zone around the stem of each plant, and can be very numerous and closely spaced, with densities of up to 300/m^2. Other mangroves, such as *Rhizophora, Bruguiera, Ceriops*, and *Lumnitzera* species, have subaerial prop or stilt roots that branch downward to the mud and support the stems.

Formation of mangrove terraces

Sediment carried into mangroves by a rising tide is retained by the filtering network of stems, pneumatophores, or prop roots as the tide ebbs. This leads to the gradual building up of a depositional terrace between high spring and high neap tides, with a transverse slope (usually $<1:50$), descending seaward to the outer edge of the mangroves and continuing across the lower intertidal zone, which is either unvegetated, or has patches of seagrass. Terrace formation is also aided by the presence of a subsurface root network, which binds the accreting sediment. The depositional terrace under mangroves is similar to that formed beneath salt marshes (*q.v.*).

Mangroves initially colonize substrates that are stable or slowly accreting, but once established they promote further accretion because they diminish current flow and wave action (Augustinus, 1995). A mangrove fringe also shelters nearshore waters from winds blowing off the land, and thus reduces seaward losses of mud from the shore, whereas shoreward drifting by waves produced by onshore winds and rising tides continues.

On some coasts, the pioneer mangroves are *Avicennia* spp., with pneumatophores that trap muddy sediment and raise the intertidal surface until it is colonized by *Rhizophora* and other mangrove species (Figure M4). On other coasts *Rhizophora* species occupy the seaward margin. To the rear, sedimentation proceeds more slowly, but eventually the terrace is built up to high spring tide level, where the mangroves may be backed by salt marsh or unvegetated dry mudflats. Most mangrove substrates are dominated by muddy sediment, but there is also peat accumulation where the mangrove community generates large quantities of organic matter from decaying leaves, stems, and roots, and from the various organisms that inhabit mangrove areas. In due course, these can form peat deposits, raising the substrate level: on the coast of Florida *Rhizophora* is growing on vertically accreting peat deposits.

Figure M3 Pneumatophores projecting from a muddy intertidal surface around *A. marina* shrubs in Westernport Bay, southeastern Australia. (Copyright—Geostudies.)

Figure M4 Mangroves (*A. marina*) advancing on to intertidal mudflats in Cairns Bay, north-eastern Australia. The darker zones to the rear are *Rhizophora* and other mangrove species. (Copyright—Geostudies.)

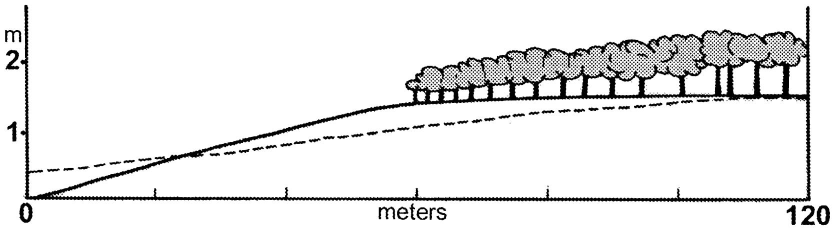

Figure M5 A mangrove terrace formed by vertical accretion of sediment as mangroves spread seaward. If the mangroves then die, or are removed, the intertidal profile is degraded (dashed line). If they revive, the mangrove terrace is restored. (Copyright—Geostudies.)

As the terrace attains high spring tide level it is submerged only by infrequent exceptionally high tides, occasional storm surges, or river flooding. Sedimentation is thus very slow, but accretion of peat and drift litter may raise the substrate to levels where it can be colonized by freshwater and land vegetation, a process that is aided by emergence on coasts where sea level is falling relative to the land.

Sections through mangrove terraces (exposed in the banks of tidal creeks or in microcliffs at the seaward edge) generally show stratified deposits, with layers of fine sand or organic material within the mud. These variations are related to wave conditions, storm waves washing fine sand into the mangroves, and mud accretion continuing as the tides rise and fall in calm weather. Although often characterized as tide-dominated morphology, most mangrove terraces are influenced by wave action as the tide rises and falls. When the depositional terrace is submerged, occasional storm surges may wash sand, gravel, and shelly material up into the mangroves to be deposited as cheniers (*q.v.*). Former cheniers may be indicated by lenticular deposits of coarser sediment within mud in mangrove terrace stratigraphy.

Rates of accretion in mangroves can be measured by laying down marker layers of colored sand, coal dust, or similar material on the surface, and returning to put down borings and measure the thickness of sediment added subsequently. There are often difficulties where burrowing crabs churn up the substrate. Changes can also be measured on implanted stakes. In Westernport Bay, Australia, such measurements showed sustained mud accretion of up to 4.5 cm/yr in the *Avicennia* fringe, with slower deposition at higher levels and continuing vertical fluctuations on adjacent mudflats. In the absence of mangrove vegetation the substrate remains a mobile intertidal slope. The pattern of mud accretion is strongly correlated with the density of the pneumatophore networks which trap and retain muddy sediment, and low accretion mounds form above the general level of the muddy shore within pneumatophore networks around isolated *Avicennia* trees. When pneumatophore networks were simulated artificially by planting a network of wooden stakes a similar accretion mound formed within the staked area, but when the stakes were removed the accreted sediment was quickly dispersed. Mangroves with pneumatophores thus trap sediment as effectively as salt marsh plants (Bird, 1986). Mangroves with prop roots, such as *Rhizophora* spp., may be less effective in trapping mud, but depositional terraces have been formed on coasts fringed by such mangroves.

The widening of a mangrove terrace depends on a continuing sediment supply, as on deltaic and estuarine shores close to the mouths of rivers or within embayments where intertidal muddy areas are extensive. Changes within river catchments, such as deforestation, increase soil erosion and augment the rate of sediment yield to the coast, thereby accelerating accretion in intertidal areas and promoting the spread of mangroves. This has occurred in the Segara Anakan lagoon in southern Java, where a greatly increased sediment yield resulted in siltation and the rapid advance of the mangrove fringe (Bird and Ongkosongo, 1980).

If mangroves are killed or cleared, their substrate is soon lowered by erosion. In Westernport Bay, Australia, mangroves were extensively cleared in the mid-19th century, and the depositional terraces that had formed beneath them were degraded to a steeper transverse slope and dissected, so that the roots of former mangroves were laid bare. Subsequent recolonization of these areas by mangroves was followed by mud accretion, which has rebuilt the depositional terrace (Figure M5) (Bird, 1986).

Nevertheless, the idea that mangroves are land-builders has not been universally accepted (see discussions by Vaughan, 1910; Davis, 1940; Carlton, 1974). Some have suggested that mangroves merely occupy intertidal areas that become ecologically suitable as the surface is raised by accretion, independently of any effects of vegetation, implying that the

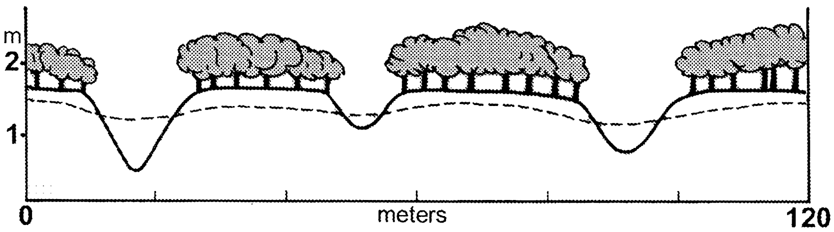

Figure M6 Transverse section across a mangrove terrace with intervening tidal creeks. If the mangroves die, or are removed, the creeks become wider and shallower (dashed line). If they revive, their cross-profile is restored. (Copyright—Geostudies.)

depositional terraces would have developed even if mangroves had not been present (Watson, 1928; Scholl, 1968). Others have deduced an interaction between colonizing mangroves and intertidal deposition (Thom, 1967). It is possible that *Avicennia* and other mangroves with pneumatophores promote accretion and coastline progradation as they spread forward on to the intertidal zone, whereas *Rhizophora* and other mangroves without pneumatophores are less effective in trapping sediment.

Tidal creeks in mangrove areas

As mangrove terraces build up in the form of a sedimentary wedge, there are alternations of tidal submergence as water invades the mangroves and emergence as it drains off. The ebb and flow of the tide forms and maintains a system of tidal creeks, the dimensions of which are related to the volume of water entering and leaving as the tide rises and falls. Typically dendritic and intricately meandering, these are channels within which the tide rises until the water floods the marsh surface; then they become drainage channels into which some of the ebbing water flows from the mangroves. They are thus like minor estuaries, particularly, where they receive freshwater from hinterland runoff. Where cheniers are present the mangrove creek network may be reticulate, as on the Niger delta (Allen, 1965), while straight parallel creeks are more often found where the tide range is large, the transverse gradient small, or the rate of seaward spread of mangroves rapid, as on Hinchinbrook Island, north-eastern Australia.

In the early stages of the formation of a mangrove terrace, tidal creeks are relatively wide and shallow in cross section (like the broad channels on intertidal mudflats), but as the mangrove terrace expands they become narrower and deeper, and their banks higher and steeper. Oversteepening results in local slumping, when blocks of compact mud, often with clumps of mangrove vegetation, collapse into the creek, especially where the banks have been burrowed by crabs.

If the mangrove vegetation dies, or is cleared away, the tidal creeks become wider and shallower, and if revegetation then occurs they again narrow and deepen (Figure M6). There are also changes as tidal creeks meander or migrate laterally, so that mangrove trees are undermined on one bank while mangrove seedlings colonize sediment deposited on the other. Channel banks may oscillate in response to variations in the volume of tidal ebb and flow; they advance during phases of local accretion when the channel diminishes, and recede during episodes of tidal scour, when the channel is enlarged.

Seaward margins of mangroves

Mangrove terraces are being eroded on coasts that are now receiving little or no sediment. Low cliffs have been cut into their seaward margins, particularly on deltaic coasts where the sediment supply has been reduced because of dam construction or the natural or artificial diversion of a river outlet. The seaward edge of mangrove terraces is often undercut by a muddy microcliff up to a meter high. Microcliff recession may be accompanied by continuing vertical accretion of muddy sediment in the mangroves, building up the terrace even though seaward advance has come to an end. In some places, the cliffing results from lateral movement of a tidal channel, undercutting the outer edge of the mangroves, but generally it is due to larger waves reaching the mangroves as the result of deepening of the lower intertidal zone, either because of progressive entrapment of nearshore sediment drifting into the upper vegetated area, or because of continuing submergence of the coast in response to a rising sea level (Guilcher, 1979).

It may be that, as on the sides of developing tidal creeks, seaward margins become oversteepened and cliffed, particularly during occasional storm wave episodes. Cliffing of this kind is repaired if there is an abundant supply of sediment to restore the profile, permitting mangroves to spread again, but if there is a sediment deficit a mangrove cliff will persist and recede until the mangrove terrace has been completely removed.

If global warming proceeds, mangroves are likely to spread to suitable habitats beyond their present poleward limits. A rising sea level will however, impede the seaward advance of mangroves, and increase erosion on their seaward margins, except where there is a compensating increase in sediment supply. It has been estimated that a sea-level rise of more than 1.2 mm/yr will lead to widespread destruction of mangroves and erosion of their substrates (Ellison and Stoddart, 1991).

MANGROVES, REMOTE SENSING

Introduction

Most research activities and published documents (at least 95%) on the biology and ecology of mangroves concern the factors influencing the productivity, the biodiversity, and the biogeographical distribution. Naturally, the biodiversity itself and the adaptive mechanisms to salinity and waterlogging constitute major fields of research. In comparison, published documents on the use of remote sensing for mangrove studies are in a minority.

In recent years, "Remote Sensing" has become a term applied to all kinds of information acquired by satellites, although in its broad sense, it refers to the gathering and analysis of images acquired by sensors and cameras located at some distance from the target of study including aircrafts, balloons, etc. (Haines-Young, 1994). The main advantages of satellite over aerial photographs have often been advocated, especially by foresters, who rightly insisted that large-scale surveys are feasible through computer processing. In addition, monitoring events such as erosion, degradation processes, human impacts, flooding, phenology, etc. can be carried out as each satellite makes regular overhead passes on a fixed orbit.

A brief review of the most commonly used remote sensing technology for mangrove studies is given here. The capabilities and constraints of spaceborne instruments are outlined. This entry focuses only on conspicuous achievements from a few square kilometers to the whole tropical coastal world.

Sensors characteristics

The application of remote sensing tools to mangrove forests began tentatively in the early 1970s with some optimistic attempts to use Landsat MSS data, with a ground resolution of about 60–80 m (*"ground or spatial resolution"* is *"the minimum distance between two objects that a sensor can record distinctly"*— Simonett, 1983), in huge mangrove areas, especially in the Gangetic delta which has the largest contiguous mangroves in the world. The main hope was to increase the frequency of forest observations and inventories, especially in remote fast changing areas, where access and fieldwork are particularly difficult. At best, the repeated frequency was 16 days and 4 spectral bands were available in the visible (VIS) and near-infrared (NIR) wavelengths. Since 1982, Landsat satellites have an instrument (Thematic Mapper) with a ground resolution of 30 m and 7 spectral bands including middle-infrared (1.57–1.78 μm) and a thermal-infrared (2.10–2.23 μm). After the launching in 1986 of the first high-resolution satellite, SPOT 1, operating at 20 m in a multispectral mode and at 10 m in a panchromatic mode, and an improved repeat cycle, the possibility of acquiring accurate data, for almost all mangroves of the world, has been conspicuously increased. This is how the first World Mangrove Atlas was achieved and published (Spalding *et al.*, 1997), followed by the first worldwide mangrove inventory carried out by the European Community (Aizpuru *et al.*, 2000).

These instruments, including radar, generate a signal only in each of a small number of very broad bands (Table M5). In the case of radar, SAR (Synthetic Aperture Radar) data, the spatial resolution is rather good (6–25 m) and these products are widely available since the end of

Table M5 A summary of the main satellites used for vegetation mapping

the 1990s from a number of recent spacecrafts (ERS-1, ERS-2, JERS, Radarsat ...). Mangroves have already been studied at various research levels with radar, which have the ability to penetrate clouds, permitting very frequent repetitive observations. Most of these instruments are primarily dedicated to physical oceanography and polar observation. Their use for environmental applications is yet very limited. When SAR data are used for mangrove studies, they are often processed in combination with optical data as one of the major issues is the suppression of the random noise associated with SAR data (the speckle), which induces strong limitations for the delineation of coastal units and land cover types (Mougin *et al*., 1993; Kushwaha *et al*., 2000; Phinn *et al*., 2000; Proisy *et al*., 2000).

More complex hyperspectral scanning systems are now providing new types of data sets. They measure the intensity of the radiations received from coastal ecosystems in each of a large number and very narrow bands (50–300 bands, about 2 or 3 nm each). MODIS (MODerate resolution Imaging Spectro-radiometer) is already in space on EOS (Earth Orbiting System) satellite launched in 1999. Several comparable instruments are airborne: VIFIS (Variable Interference Filter Imaging Spectrometer) with 64 spectral bands, AVIRIS (Airborne Visible InfraRed Imaging Spectrometer), CASI (Compact Airborne Spectrographic Imager), etc. Since 1981, tens of thousands of photographs, including color infrared, have been taken from the space shuttle orbit and stereoscopic coverages are available. To date, very high-ground resolution data (about 1 m) have not been made available to scientists mainly for security reasons. They are progressively appearing on the market (IKONOS data).

All these sophisticated instruments are generating an incredible amount of digital georeferenced data, covering all the ecosystems of the coastal world in a repetitive manner. Have we been able to develop the necessary technology to adapt the quality and the Timescale of observation to the magnitude and rapidity of human-induced degradations in mangrove areas?

Basic principles

Each satellite has its own technical properties designed for specific missions. Whatever satellites are used, the physical principle remains almost constant, based on the fact that different mangrove subtypes show different reflectance patterns. Spaceborne sensors measure the solar radiation that are reflected or radiated by the "targets." The "reflectance" of a given ecosystem (a mangrove with *Nypa fruticans* or a salt marsh with Chenopodiaceae) is the ratio between the reflected solar energy and the incident solar energy. In order to minimize the distortions induced on each signal by the atmosphere and to take into account the sensors–object–sun geometry, several corrections have to be applied to raw recorded data before they are processed (i.e., atmospheric and geometric corrections). Ultimately, it is quite obvious from Table M5 that spatial and temporal resolutions determine the type of information that can be derived from satellites (Holben and Fraser 1983; Graetz, 1990; Blasco and Aizpuru 2001). It is implicit that permanent global monitoring of mangroves, at high spatial resolutions (Landsat TM, SPOT HRV and HRVIR, IRS1C-LISS-III, ERS, etc.), is practically not feasible and that local mangrove monitoring at low spatial resolution (NOAA-AVHRR, SPOT-VEGETATION) is also impossible (Justice 1985; Townshend and Justice, 1986; Malingreau *et al*., 1989).

The different coastal ground units reflect differently in the VIS parts of the spectrum (dense continental green trees, wet clayey soils, sandy beaches, mangroves ...) as well as across all the wavelengths from the ultraviolet to the thermal-infrared and microwaves (Figure M7). Some signals are not reflected but are radiated by ground units especially in the thermal-infrared. The different patterns of reflectance from different ecosystems are often termed "spectral signatures."

Usually the "signal mangrove" is distinct from others coastal ecosystems for two main reasons:

1. It is necessarily confined to the nearshore tropical intertidal zone.
2. It is the result of two main signatures often recognised in the VIS and NIR domains:
   - The evergreen character of mangrove trees leads to strong reflectance in the NIR channel (0.7–1.1 μm), generally coded in red on a color composite.
   - The permanently wet soils which have a noteworthy reflectance in the red channel (0.6–0.7 μm), generally coded in green on a color composite.

This is why dense mangroves always appear dominantly in a reddish violet color, turning to bluish violet in open mangrove stands. A given tall dense mangrove stand with *Rhizophora* sp. (Malaysia) may have the same "signature" as a low thicket with *Avicennia marina* (New Zealand). This is one of the major limitations of these technologies, especially in forestry in general, where one of the main goals is to discriminate the species of trees and to estimate the structure of the forest and the size of its components.

In order to transfer experimental results to field situations, several "vegetation indices" have been proposed. The most commonly used is the Normalized Difference Vegetation Index (NDVI). It relies upon differential reflectances of the mangrove canopy (which is always green) in the red wavelength (here the response is mostly determined by the absorption band by the chlorophyll) and in the NIR wavelength, where the response is the result of scattering determined by the cuticles of leaves and the density of the cover.

$$\mathrm{NDVI} = \frac{\mathrm{NIR} - \mathrm{VIS(red)}}{\mathrm{NIR} + \mathrm{VIS(red)}}$$

The thermal domain (4 to 12 μm or bigger wavelength range) has not been exploited so far in mangrove deforestation processes, although a local sharp increase in surface brightness temperature could most probably be related to the replacement of dense mangrove stands by the so called saltish "blanks" which are barren soils, almost denuded of any vegetation. One of the limitations of the thermal domain is due to the fact that the relationship between the size of barren mangrove area and the temperature of the concerned pixels is difficult to establish. Thermal-infrared radiation allows rapid measurement of variations of

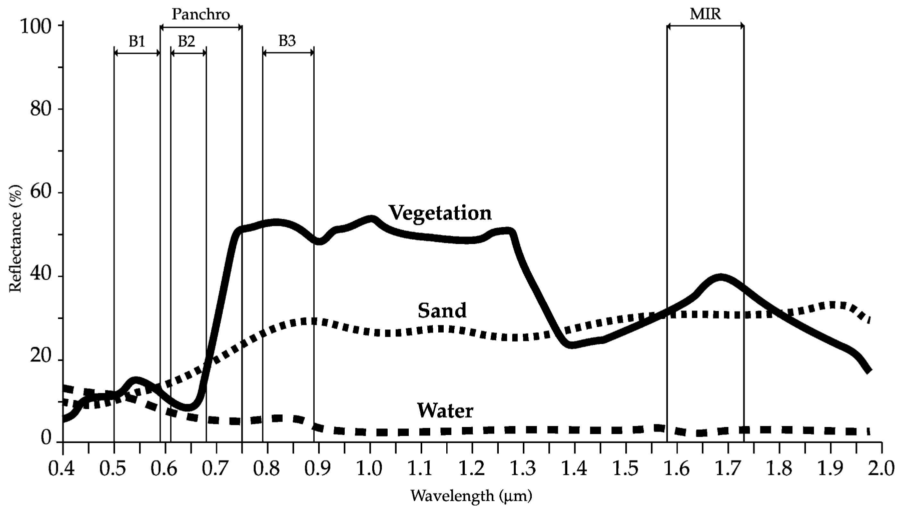

Figure M7 SPOT4-HRVIR: Spectral signatures from representative land cover types in mangrove areas.

water surface temperature. On the other hand, most features to be analyzed and mapped in coastal areas are narrow and linear. They are not always observed from space and may be lost at inadequate resolutions.

To date, the most common resolutions of satellites used for coastal surveys range between 10 and 30 m (SPOT, IRS, Landsat TM). When these resolutions are available, they lead to rather accurate maps at 1/50,000–1/100,000 scales. When these resolutions are not available, a number of statistical problems arise linked to difficult comparisons of maps drawn at different scales.

For each object and each pixel, the ecologist has at his disposal its reflectance, its longitude and latitude. This is why remote sensing data are usually exploited with the help of Geographic Information Systems (GIS). These databases and software combine time-independent parameters (geology, physiography, average climatic parameters, etc.) and a number of parameters whose values vary with time (phenology of trees, stand density, radiometry, etc.).

A lot of frameworks have been proposed to guide the existing classification systems; they combine various concepts from remote sensing, plant biogeography, landscape ecology, etc. (Phinn *et al.*, 2000).

Processing methods

In terms of forestry and vegetation classification, mangroves belong to the broad class of "closed evergreen tropical forest." Mangrove subtypes are identified according to the species composition, the structure of the stand and the ecological status (salinity of water and soils, climatic aridity, etc.), but neither the floristic composition nor structural properties nor environmental parameters are perceptible from space, which identifies only the spectral and textural parameters of the top canopy. This explains the low statistical separability of dense mangrove subclasses in the VIS and NIR wavelengths of high-resolution satellite data. This relates to the canopy architecture and the textured nature of reflectance patterns in which variance within forest classes can be greater than between forest classes (Hill, 1999; Kay *et al.*, 1991). Then, the easiest way to increase the spectral separability is to consider that the criteria of density of the cover is the starting point of any mangrove classification system.

Many approaches have been suggested for satellite image processing. None of them is yet fully convincing. They logically fall into four main groups:

1. *The visual interpretation* is probably the commonest but least explicit. In this case, a digital image has been converted into a photographic product which is studied by eye, with reference to field data. The delineations obtained with this empirical method are often interpreter-dependent.
2. *In the unsupervised classification*, the data are digitally processed with automatic enhancement techniques. One of major limitations of these approaches is caused by the fact that there are sometimes no significant difference between the spectral properties of mangroves and other neighboring ecosystems.
3. *Supervised classifications* are the most frequently described in the scientific literature. Field data, assisted or not with a Global Positioning Systems (GPS), are used for the selection of training samples to direct this type of classification, using several algorithms such as the maximum likelihood, the minimum distance, etc. (Figures M8 and M9). Practically, the scientists use existing maps as a reference in order to obtain a preliminary image segmentation, separating mangrove areas from other plant communities.
4. Finally, *temporal series*, principal component analysis, bands ratios, vegetation indices which convert multispectral information into a single index, etc. constitute another group of methods rather often employed.

According to the aims of the study and the concerned area, each method has its own advantages and insufficiencies. To evaluate each method, a rigorous quantification of its accuracy would be necessary. However, such a test is very rarely carried out (Green *et al.*, 1998).

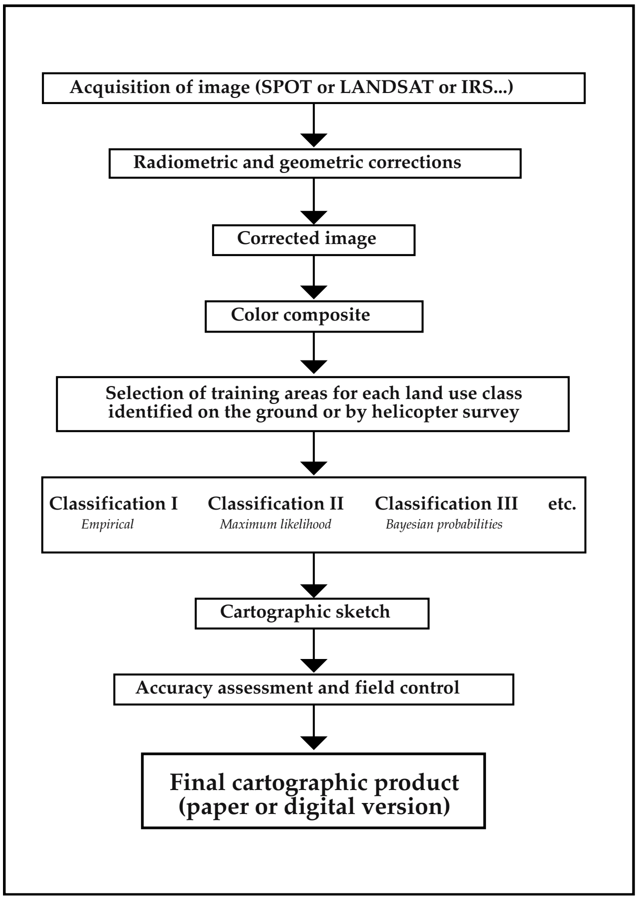

Figure M8 Classical approach for mangroves mapping using remote sensing data (supervised classification).

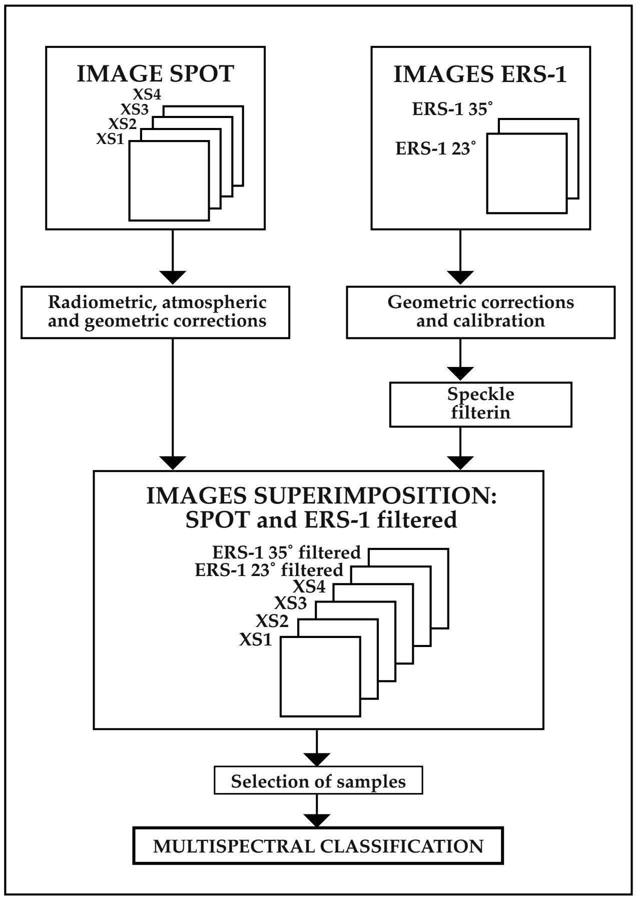

Figure M9 Synergy between SPOT and ERS-1, general methodology.

Mangrove features discriminated from space

The level of discrimination achieved with remote sensing products varies from one sensor to another and according to the processing method. As a general rule, when the amount of field data increases, the quality of the image processing improves. Almost all authors using aerial photos distinguish floristic classes labeled by genera and species. This level of discrimination which separates *Rhizophora apiculata* from *A. marina* stands is impossible at present from space. With spaceborne sensors, the easiest and primary objective is to separate mangroves from non mangrove vegetation (Biña *et al*., 1980). Some authors confess their inability to discriminate satisfactorily these two classes with SPOT XS (Green *et al*., 1998).

Several attempts have been carried out to distinguish stand density classes (Aschbacher *et al*., 1995) and height classes (Gao, 1999). All these individual attempts are to be considered as preliminary research findings. From a practical point of view, it appears that seven most useful physiognomic classes can be currently detected and mapped, with or without GIS assistance, from space products:

Dense natural mangroves. This is the most important class, often located in protected areas. These stands are multi-specific and the ground coverage exceeds 80%.

Degraded mangroves where the ground coverage by trees and shrubs is about 50–80%. The spectral signal integrates the response of chlorophyllous elements and water-soaked soils.

Fragmented mangroves (or mosaics) where the remaining mangrove trees have a ground coverage about 25–50%. In such a case, the signal is primarily determined by the moist soils although the response of the remaining green vegetation is noticeable.

Leafless mangroves. As mangroves are almost always evergreen trees, a strong absorption in the NIR band (0.70–0.95 μm) has to be considered as totally abnormal, being induced either by a mass mortality of mangrove trees (Gambia, Côte d'Ivoire, etc.) or by an unexplained disease (cryptogamic, virus, insects, etc.).

Mangrove deforestation areas or clearfelled mangroves. Forest exploitation and clearfelling are dominant causes for the destruction of mangrove ecosystems (Saenger *et al*., 1983). Any opening in a mangrove canopy can be detected from space because corresponding pixels have been replaced either by water at high tide or by crusts of sodium chloride deposits during the dry season, at low tide.

Mangrove converted to other uses. The most conspicuous human impacts on mangrove ecosystems is their conversion to shrimp ponds (Thailand, Ecuador, Viet Nam, Indonesia, etc.) or to agriculture (mainly paddy fields in Asia and West Africa). The signals of irrigated crops, mainly paddy fields and sugarcanes, being very distinct from that of mangroves (strong absorption in the NIR band), the delineation of these conversions has become routine work from space.

Restored mangroves and afforestation areas. Recently accreted intertidal zones bearing dense vegetation often correspond to mangrove restoration sites (Field, 1996) or to afforestation activities. The monitoring of such areas has become effective from space at the mouths of the Ganges (Bangladesh) where the rate of survival and growth of *Sonneratia apetala* Buch-Ham is distinctly different from one island to another (Saenger and Siddiqi 1993; Blasco *et al*., 1997). Another interesting example is found in the Mekong delta (Viet Nam), near the capital city Ho-Chi-Minh, where *Rhizophora apetala* Bl. has been extensively replanted. In any case, dense monospecific planted stands have a high photosynthetic activity causing high absorption of photons and low response in the wavelength 0.6–0.7 μm, which make them rather easily discriminated from space.

Accuracy assessments carried out so far for each classification algorithm or for each discriminated class, lead to extremely variable results (Hudson and Ramm, 1987). In a vast mangrove area like the Ganges (India and Bangladesh), the "dense mangrove class" which is the largest class, covering an area exceeding 6,000 km^2, may present a classification performance of 90%, although some restored mangrove areas are often assigned either to fish ponds or to rice fields or to salt marshes or even to algal deposits, because the high physiognomic diversity of planted mangroves (age of the plantation, density, species diversity, substrate, etc.) induces very diverse spectral responses. For small areas, the existing possibilities to improve the accuracy of the maps and to increase the number of discriminated classes have been described by Ramsey *et al*. (1998).

Conclusion and issues

According to the latest mangrove resource assessment (Aizpuru *et al*., 2000) carried out with space products, the total extent is about 170,000 km^2 and the world's mangrove regression during the last decade has been about 1,030 km^2 y^{-1}. A critical analysis shows that remote sensing utilization for mangrove studies is still limited for several technical reasons. It appears from what has been said that the enormous commitments made to promote remote sensing technology during the last 30 years have not yet given access to the data actually needed by modern ecological researchers, that is, identification of trees, structure of stands, physical or biological stresses, sediment load and geochemistry of brackish waters, etc.

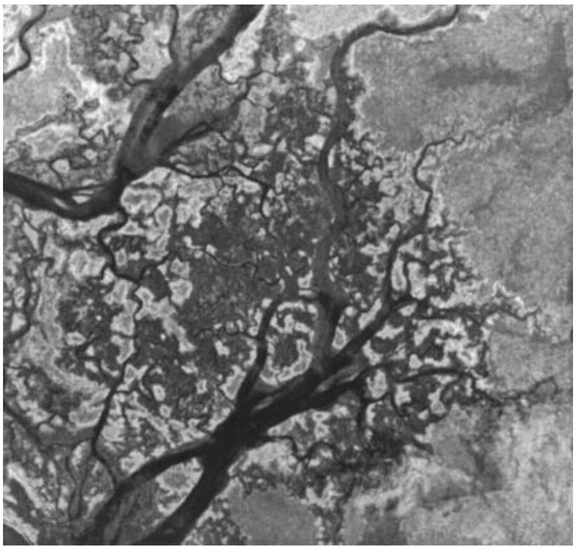

Figure M10 Mangrove studies from space (part of SPOT data KJ 022/333 dated 21/10/93). The fragmentation of the habitat appears clearly. Dark patches correspond to mangrove types. ((c) cnes 1993-distribution Spot Image.)

Regarding the inventory and monitoring of mangrove ecosystems using satellite data, there is no worldwide standard method which could be applied straight away. At local levels, a periodic survey of mangroves from space is operational (Figure M10). The permanent monitoring of these ecosystems, at local and regional levels, is premature.

Oil spills detection from space is by no means an easy task. Such pollution events are causing great damage every year in mangrove ecosystems of Nigeria, the Caribbean, the South China Sea, etc. either by oil tanker accidents, by illegal tanker cleaning, or by oil leaks from platforms or wells, etc. Recent advances have been achieved primarily because hydrocarbon compounds at the surface of the sea reduce water surface roughness which can be detected on SAR images.

The accuracy of each mangrove map and statistics is extremely difficult to assess rigorously. It is probably included between 50 and 90% in most studied cases. Combining data sets generated from field surveys, aerial photographs, especially color infrared, and high-resolution satellite products (TM or SPOT and SAR) lead to a more accurate appraisal of mangrove resource and local ecological conditions than does the analysis of high resolution satellite data alone. The merger of these sources of data produces classified maps, which include many features not separable solely by existing space data.

Finally, remote sensing specialists recognize that the technology has so far been less successful in coastal areas than in continental zones. The reasons lie in questions of spatial and temporal scales and on the physics of coastal signals often distorted by marine aerosols and warped by the proximity of the ocean (Cracknell, 1999). However, the synergy, between optical and SAR data and the new data provided by hyperspectral scanning systems and by very high-ground resolution tools, leave little doubt that a new breed of remote sensing is emerging.

MAPPING SHORES AND COASTAL TERRAIN

Maps of coastal features and their associated physical, chemical, and biological attributes depict spatial relationships at an instant in time. Despite the dynamic state of nearshore coastal terrain, large interior and upland areas away from the shore remain relatively stable. Maps of these relatively stable areas provide a basis for many activities ranging from interpreting the geologic history of a region to long-term planning and management of coastal resources. Maps of shores and coastal terrain continue to be the most useful and effective way of communicating spatial data to scientists, government officials, resource managers, planners, and the general public. Whether in hard copy or digital form, maps serve as the basic tool for synthesizing and presenting complex scientific information about past, present, or future environmental conditions. Maps also provide inventories and establish baseline conditions for documenting and monitoring coastal change.

Modern mapping of shores and coastal terrain evolved substantially during the 20th century. As recently as the early 1900s, classical stratigraphic nomenclature was used universally to subdivide coastal strata on the basis of named formations and their interpreted geologic ages. A consequence of this historical geologic method of mapping was that all late Pleistocene and Holocene sediments, regardless of their origin, were identified as undifferentiated Quaternary alluvium (Qal). Although classical stratigraphic coastal mapping persisted until the 1960s, earlier observations by physical geographers and geomorphologists laid the groundwork for recognizing that patterns of topography and soils could be used to interpret preserved depositional features such as ancient rivers, deltas, beaches, and dunes. By the 1930s, morphological mapping criteria were well established in the Gulf Coast region of the United States where the petroleum industry promoted detailed mapping of coastal depositional surface structures. This need-driven systematic regional mapping of coastal plain sediments in conjunction with an improved understanding of coastal processes eventually led to alternative coastal and subsurface mapping concepts including morphostratigraphy, genetic stratigraphy, and eventually sequence stratigraphy.

The sources of data used to map coastal terrain varies widely depending on the applications and anticipated needs to characterize the coastal lands and surrounding submerged areas. Continuous spatial coverage is provided by conventional aerial photographs and advanced satellite images (including radar, Advanced Very High Resolution Radiometer (AVHRR), and interferometric Synthetic Aperture Radar (SAR), whereas line or profile data are available from geophysical surveys (seismic reflection, airborne electromagentic, ground-penetrating radar), lidar missions, and Global Positioning Systems (GPS) surveys. Although point data are by definition discontinuous, most point data such as textural and geochemical attributes measured at sample sites or monitoring stations can be interpolated and mapped to provide continuous spatial coverage if the spatial distribution of discrete sample sites is sufficiently dense. Most of the recent advances in technology used as sources of data or for mapping shores and coastal terrain are discussed in other sections of this encyclopedia.

Maps of coastal terrain are presented in a variety of formats and at various scales depending on the intended use. Small- scale maps are commonly generalized and serve as executive summaries, whereas large-scale maps are normally intended as work maps because they provide the necessary detail for site-specific analyses. Before the common use of computers capable of storing and manipulating large electronic files, coastal maps were hand-prepared by skilled cartographers. The pre-electronic methods of coastal mapping and types of maps produced by state and federal agencies in the United States were summarized by Ellis (1978). Since coastal maps were printed for mass distribution, a popular format has been large atlases containing bound or unbound sheets of maps. Large format atlases are still widely used for convenience despite the high coasts of printing and problems associated with filing and storing oversize documents.

Standard techniques for comparing and displaying multiple layers and generating derivative map products now involve the use of Geographic Information Systems (GIS). Furthermore, compact disks and internet websites are used routinely for rapid dissemination and mass distribution of electronic map images.

Coastal mapping strategies

Maps of shores and coastal terrain are prepared for many different purposes. Early mapping strategies were developed primarily for scientific purposes and the newly acquired knowledge that would improve our understanding of earth history. Later, it was realized that maps of coastal terrain have exceptional societal value when applied to coastal zone management objectives. Examples of coastal mapping applications are public policies and regulations that depend on credible scientific data such as inventories of natural resources and identification of hazard prone areas.

Morphostratigraphy

Morphostratigraphy mapping of coastal terrain involves correlating surficial features by integrating physical characteristics such as landform preservation, slopes, elevations, soil composition, and degree of dissection. Generally, the purpose of morphostratigraphic mapping is to reconstruct the paleogeography and thus the geologic history of a region. An example of the morphostratigraphic approach is the map of extensive coastal plain terraces prepared by Cooke (1930). Although morphostratigraphic mapping is no longer widely used for generating coastal map products, it is a valid technique for some applications.

Genetic stratigraphy and depositional systems

Observant field geologists in Europe and North America have long recognized the genetic implications of many common sedimentary deposits (e.g., fluvial, marine, glacial). However, the concepts of genetic stratigraphy and mapping coastal depositional systems and depositional facies tracts were not formalized until the late 1960s. Genetic stratigraphy incorporates lithofacies and biofacies attributes, three-dimensional geometries, vertical sedimentary successions, and lateral facies relationships to interpret the origins of sedimentary deposits and to reconstruct the paleogeography at the time of deposition (shore position, depositional strike, and dip).

Fisher *et al*. (1972) used the advanced concepts of genetic stratigraphy to map the late Quaternary depositional systems of the Texas coast as a principal framework for environmental geologic applications. The regional environmental geologic maps of coastal Texas were published as an atlas series that included explanatory text and extensive tables of statistics for each coastal region. Within each region, maps of topography and bathymetry, active physical processes, biologic assemblages, man-made features, current land use, physical properties, and mineral resources complemented the maps of coastal depositional systems. The environmental geologic atlas focused on the upland costal terrain, whereas a companion atlas containing a series of maps of the same regions and at the same scale focused on the coastal wetlands as well as sediment textures, sediment geochemistry, and benthic organisms of the adjacent submerged lands (White *et al*., 1983). Together, the environmental geology and submerged lands atlases represented a remarkable achievement considering that a large number of diverse color-separated maps and texts were systematically prepared and published for an entire coastal region before the advent of computer-assisted mapping and commercial development of a GIS.

Natural resources

Maps of coastal terrain are also used to delineate the natural biological and economic resources of a region. Maps of biological resources include the distribution and composition of diverse wetlands, reefs (coral and oyster), faunal assemblages, fishery habitats, and areas of environmental protection, or concern such as breeding or nesting grounds. In the United States, coastal wetlands are mapped periodically as part of the National Wetlands Inventory (Cowardin *et al*., 1979).

Economic coastal resources can be specific mapping targets, or they can be derived from other map types, such as maps of depositional systems or coastal subenvironments. Typical mineral resources that are mapped include sand and gravel for construction aggregate and beach nourishment, shell deposits as a substitute for lime or road material, and beach placers and heavy mineral deposits that are mined for their metals and precious stones. *Mining of coastal materials* is discussed in another section of this encyclopedia by Osterkamp and Morton.

Coastal processes and natural hazards

During the latter half of the 20th century as coastal populations throughout the world rapidly increased, the need also dramatically increased for maps depicting areas threatened by natural coastal hazards such as beach erosion, storm flooding, storm-surge washover, earthquakes and liquefaction, tsunamis flooding, landslides, subsidence, and active faulting. Most developed countries have national or regional mapping projects designed to identify the areas of greatest vulnerability where most people, infrastructure, and economic development are at risk. Many state and provincial governments also have produced hazard maps designed to minimize the loss of lives and property damage associated with short-term high-energy events such as storms, tsunamis, and landslides or long-term permanent hazards such as submergence.

Baseline inventories and coastal monitoring

Maps of coastal terrain can serve either as catalogs of natural resources or as historical snapshots of dynamic conditions. As coastal maps grow older, one of their principal uses is to document changes in the status or trends of coastal features and attributes. Much of our current understanding of coastal dynamics originated as a result of comparing old coastal charts and maps with more modern depictions. Some common parameters used to document coastal changes are topography and bathymetry, *shoreline position* (defined here as the high-water line or high-tide shoreline), nearshore morphology (sea cliffs, barrier islands, tidal flats, and inlets), wetland distribution, sediment composition and texture, sediment geochemistry (trace elements, metals, pollutants), and land use. Most of these variables are subject to natural change and all of them are susceptible to changes induced by human activities.

Coastal mapping and monitoring have become routine activities of many government agencies because they promote acquisition of historical data that can be used to quantify environmental change. These activities also allow compilation of empirical data for developing and testing predictive models and forecasting future conditions. Physical and chemical parameters that are suitable for detecting and monitoring rapid environmental changes (geoindicators) have been selected and described by an international working group (Berger and Iams, 1996). The preferred coastal geoindicators of environmental change, which are shoreline position and wetlands distribution, are commonly presented on maps of coastal shores and terrain.

Coastal mapping applications

Global syntheses

During and after World War II, global mapping of shore types was a high priority because of important military applications. Of critical concern were the coastal conditions that would be encountered during amphibious operations as well as other factors such as vehicular trafficability and suitability of the coastal materials for road and airport construction. Global coastal classifications typically involve aerial photograph and map compilations that compare and contrast various attributes of the shore and adjacent land.

Most modern classifications use an integrated approach that emphasizes tectonic setting (passive or trailing margins, active or leading margins, marginal seas), morphology (coastal plains, mountains, sea cliffs), biogenic characteristics (coral reefs, marshes, mangrove forests, swamps), depositional origin (deltaic, barrier–lagoon, chenier plain, eolian, glaciated), and terrain composition (gravel, sand and mud, bedrock, ice). These classifications can be combined with climatic overprints (tropical, temperature, glacial, desert) and modifying processes that shape the landscape such as relative sea level (emergent, submergent), tide range, wave energy, wind regime, and volcanic activity to produce a wide range of map units or layers. Examples of these global coastal classifications were presented and discussed by Putnam *et al*. (1960), and Davies (1980), among others.

Hazards mitigation

A modern trend in computer-assisted mapping of coastal terrain integrates sophisticated computer applications and a GIS to generate indices or some other quantitative attribute that can be used to classify coastal terrain with respect to some anticipated hazard. Cooper and McLaughlin (1998) reviewed the purpose and techniques of 18 coastal mapping applications based on multivariate indexing. These techniques typically employ an additive or multiplicative algorithm of weighted variables or factors to generate a quantitative index. The indices can be analyzed using various multivariate statistical techniques to group the quantitative results into classes that represent levels of hazard vulnerability or risk. This type of computer-assisted quantitative analysis has the appearance of being objective and highly precise, but uncritical acceptance of the computed results can lead to erroneous scientific conclusions and policy implications. Expert levels of scientific knowledge and experience are critical to the outcome of the methods and are absolutely necessary to test the mapped results for both accuracy and reliability.

Resource protection and management

Some mapping applications are intended specifically for environmental protection and resource management. Examples are the Environmental Sensitivity Index (ESI) maps (Michel *et al.*, 1978). ESI mapping represents a conceptual advancement that recognizes different susceptibilities to environmental damage from oil spills depending on characteristics. For example, marshes and other wetlands are highly sensitive to environmental damage from oil spills, whereas concrete seawalls are not. The ESI method of classifying features has gained wide acceptance and is now a standard resource management tool used to develop contingency plans in the event of an oil spill or to minimize environmental damage during the cleanup operations of a spill.

Integrated maps and predictive models

Now that coastal change is recognized as an important societal issue, questions are asked about how much land will be lost in the future, where the shore will be at some particular time, and which communities will be flooded if sea level continues to rise. Several methods (models) have been developed to map projected shoreline positions or zones of flooding based on assumptions regarding past shoreline positions or estimated rates of future sea-level rise. Unfortunately, all the predictive models are limited because they cannot anticipate significant changes in the factors that cause or control coastal changes and therefore the forecasts may not be very accurate. Despite large uncertainties regarding the model results, some planners may want to examine maps based on model predictions because they provide at least some basis for deciding about future use and development of the coast.

Model-derived maps that forecast future coastal conditions can be either qualitative or quantitative. Qualitative predictions of coastal evolution are based on general understanding of how nearshore environments respond to changing oceanic conditions. Studies of modern coasts show that a rapid rise in sea level will cause narrowing of some barrier islands and accelerate the migration of other barriers while saltwater marshes will replace fresh and brackish water marshes. Also during a rapid rise in sea level uplands are converted to wetlands, flood plains are enlarged, and the area that would be inundated by storms of historical record are increased. These nonquantitative predictions of coastal change are useful for dramatizing what will happen in the future, but they are of little use when it comes to knowing where and when the changes will occur.

Maps displaying quantitative predictions of future coastal conditions rely on statistical models, geometric models, or numerical (deterministic) models. Even though all of these models can be used to predict future coastal conditions, they are based on completely different assumptions and analytical methods. For example, statistical models do not attempt to understand the causes of coastal change. Instead, they depend on actual observations that presumably include the important parameters that cause coastal change. Geometric models emphasize how coastal change is controlled by elevations, slopes, and shapes responding to increased water levels. Numerical models attempt to explain coastal change as a series of equations that are written to represent physical conditions and coastal processes.

Both geometric and numerical models of coastal change commonly rely on the concept of a nearshore profile that is in equilibrium with the coastal processes. Coastal engineers have suggested that offshore profiles are smooth and have a concave shape that is controlled only by the size of sand grains and the dissipation of wave energy (Dean, 1991; Bodge, 1992). Based on these and other assumptions, the generalized shape of the offshore profile is expressed as a mathematical equation (Bruun, 1962; Dean, 1991) that relates the profile shape to sediment characteristics. Investigations of offshore profiles, however, show that a single mathematical expression does not adequately represent all offshore profiles (Bodge, 1992). Pilkey *et al.* (1993) discussed the assumptions of the equilibrium profile and presented strong arguments that challenge the validity of the concept. Because an equilibrium profile does not exist at most coastal sites, they also questioned the validity of coastal change models that incorporate equilibrium profile conditions. An incomplete understanding of complex coastal processes and the lack of an equilibrium profile are the main reasons why geometric and numerical models are unable to give reliable predictions of coastal changes several decades into the future.

Maps derived from statistical models

Simple statistical models assume that coastal change in the future will be similar to that recorded in the past. Therefore, the historical record of observed changes is the best predictor of future changes. Simple statistical models also reduce the observed coastal changes to a single value, which represents the average rate of movement. Dolan *et al.* (1991) summarized the most common statistical analyses of shoreline movement and described the advantages and disadvantages of each technique. However, none of the linear time-averaging techniques used to calculate rates of change are appropriate if the historical record contains large reversals in the trend of coastal change. To accommodate irregular shoreline movement, Fenster *et al.* (1993) developed a statistical method of analyzing historical shoreline changes and determining which data should be used to predict future changes.

Maps dereived from statistical models have distinct advantages because the historical data are real and easy to obtain, and the analysis is easy to understand. These maps also present some disadvantages. The data are not broadly applicable, the analysis assumes uniform (linear) responses even though they may be irregular (nonlinear), statistical analyses can be strongly biased by data clusters and anomalous events, and physical processes summarized in coastal change records may not adequately represent future conditions. The most severe limitation of historical projections is that they are incapable of accurately predicting future responses if some condition is greatly altered. Predictions of climate change (Titus, 1988) indicate that the rate of sea-level rise will probably accelerate and other factors such as variable substrate composition, sediment influx, and storm activity could invalidate the extrapolation of even recent rates of coastal change.

Maps derived from geometric models

Maps generated from geometric models are based on the premise that coastal change is caused primarily by a relative rise in sea level. They also employ several simplistic assumptions such as a smooth, curved equilibrium profile (no offshore bars) that does not change shape as the beach retreats. Also these models allow only for onshore and offshore movement of sediment (no net alongshore movement) and they presume a water depth on the profile beyond which no sediment is eroded or deposited. These generalized assumptions must be valid in order for the models to make accurate predictions. However, none of the assumptions can be universally demonstrated with field data (Pilkey *et al.*, 1993).

Simple coastal submergence models, such as the one used by Daniels (1992), employ ground slopes, elevations, and projected sea levels to predict future shoreline positions and areas of permanent inundation. This static topographic technique, which does not account for coastal erosion or sediment transport, is used to estimate areas of inundation, potential losses of wetlands caused by flooding, or transformation of wetland types. Coastal flooding models that assume one-dimensional passive inundation may be adequate for predicting inundation and land loss around estuaries, but they are inappropriate for predicting inundation and land loss around estuaries, but they are inappropriate for predicting coastal change along ocean beaches. This is because simple submergence models may greatly underestimate the landward retreat of shores that erode as a result of sea-level rise.

Bruun (1962) presented the first and most frequently applied geometric model that graphically relates shoreline recession to a relative rise in sea level. Most numerical models employ the Bruun Rule or a similar relationship to estimate the horizontal movement of the shoreline for a particular sea-level rise scenario. The original mathematical expression of the Bruun Rule assumes (1) an equilibrium offshore profile, (2) material eroded onshore is directly deposited offshore with no gain or loss in sediment volume, (3) only cross-shore transport occurs, (4) the increase in offshore profile elevation is equal to the rise in water level so that water depth remains constant, (5) the profile shape remains unchanged as it is shifted landward and upward, and (6) there is a water depth on the profile beyond which there is no active sediment transfer. The stringent closed-system requirements of an equilibrium profile, fixed closure depth, negligible net alongshore transport, and conservation of sediment volume across the same profile cannot be met at most coastal sites.

The fundamental issue involving predictive geometric models is the shape of beach and nearshore profiles for it is this parameter that determines the horizontal displacement of the shoreline relative to an incremental rise in sea level (Bruun, 1962). According to the Bruun Rule, shoreline recession is 50–100 times the rise in relative sea level (Komar *et al*., 1991); however, paleogeographic maps reconstructed from the late Wisconsin/ Holocene sea-level history show that shorelines actually retreated 1,500–2,500 times the vertical rise in sea level over broad continental shelves.

Some field tests have supported the general concept of the Bruun Rule (Hands, 1983) at least along coasts where profiles could rapidly equilibrate relative to the rise in sea level. However, the Bruun Rule commonly does a poor job of predicting changes at a specific site. If the Bruun Rule only approximates general erosion trends, then it may have little relevance to many map applications. Komar *et al*. (1991) recommended using large error bars with coastal predictions derived from the Bruun Rule as a reminder of the large uncertainty associated with the method.

Geometric models predict only maximum potential coastal change and therefore they are unable to accommodate such things as the time lag before equilibrium conditions are reached. Another major deficiency of most geometric models is that they fail to take into account sediment transport or its long-term equivalent, sediment budget. An exception to this general statement is the geometric model of Everts (1987), that does include gradients of alongshore sediment transport.

Maps derived from combined statistical and geometric models

Some methods of predicting coastal change combine long-term rates of change, determined by air photo methods (taken as background change), with shoreline retreat predicted by the Bruun Rule. Future sea-level scenarios, such as those forecast by Environmental Protection Agency (EPA) (Titus, 1988), provide the input for estimating probable magnitudes of sea- level rise for the period of interest. An example of the hybrid method of mapping predicted coastal response was presented by Kana *et al*. (1984) in their analysis of potential inundation at Charleston, South Carolina.

Although most coastal change models focus on coastal erosion and inundation, one model has been developed to map wetland changes as a result of predicted sea-level rise. Park *et al*. (1989) developed the SLAMM model (*S*ea *L*evel *A*ffecting *M*arshes *M*odel) to analyze what impact a long-term (>100 years) accelerated rise in sea level would have on the composition and distribution of coastal wetlands. The model starts with initial conditions (wetland classes and elevation at a particular site) then predicts future conditions in time steps by combining geometric inundation (sea-level rise scenario) with coastal erosion (Bruun Rule). Although the model does not explicitly simulate salinity changes, it does accommodate sediment accumulation as well as inland wetland migration and conversion of biotic assemblages. Results of the study (Park *et al*., 1989) suggested that nearly half of the existing marshes and swamps in the contiguous United States would be lost to open water if sea-level rises 1 m during the next century. These models also predict a net loss of wetlands because old wetlands will be destroyed faster than new marshes can form.

Maps derived from numerical (deterministic) models

Most numerical models, also known as deterministic models, presume that coastal changes are mainly caused by wave energy. Like the geometric models, most of the deterministic models also assume a smooth, curved offshore profile that does not change shape as the beach retreats, only onshore and offshore movement of sediment, and a water depth on the profile beyond which no sediment is eroded or deposited. Most of these models also assume that sea level remains constant for the period of time that coastal change is being predicted. At many coastal sites these assumptions are either invalid or oversimplifications. Most numerical models are designed to predict changes of short coastal segments and for brief periods (less than a decade). They are intended to evaluate the effects of coastal structures on shoreline evolution or to simulate specific conditions such as storm-induced beach erosion or bathymetric changes (Kriebel and Dean, 1985). An extensive review and critique of numerical model assumptions and limitations was provided by Thieler *et al*. (2000).

Numerical models of coastal change require site-specific values for such parameters as wave climate, alonshore and crossshore sediment transport, and sediment budget. The common lack of local oceanographic and geological data coupled with the fact that nearshore hydrodynamics are nonlinear and therefore, nonadditive means that prediction confidence rapidly declines after the first few years of simulation. Subsequent simulations are further hampered by a poor understanding of nearshore physical relations, especially the relations of sediment transport to forcing events and profile recovery after storms that is necessary as a starting point for the next simulation. The result of this uncertainty is a probability distribution of shoreline positions with confidence bands that define an envelope of possible future shoreline positions. Verification of these models is also hampered by the need for detailed oceanographic data collected for the same time period as the observed shoreline changes. This generally means a short historical record when both shoreline movement and oceanographic data were available. Numerical models also rely heavily on intuition and extensive local experience of the user at the site being modeled. If the local data and engineering expertise are not available, then the model results may be erroneous.

Kriebel and Dean (1985) formulated a procedure for estimating cross-shore sediment transport resulting from the nearly instantaneous beach and dune erosion during a storm. Although this model is based on the equilibrium profile concept, it addresses the problem of maximum erosion potential not being achieved because of rapidly changing conditions during the storm. Instead, it emphasizes nearshore profile adjustment that depends on the storm surge. This model employs a generalized beach/dune profile where the dunes form the onshore limit of sediment motion. Thus, it is not applicable to overwash beaches where dunes are low or absent and surface elevations are below the storm surge elevations. The Kriebel and Dean model has some applications with regard to delineating erosion hazard zones and locating coastal structures, but it addresses only one phase of beach cyclicity and therefore, it is inappropriate for predicting long-term coastal changes.

GENESIS (Generalized Model for Simulating Shoreline Change) is a one-dimensional numerical model used to predict changes in shoreline position caused by coastal structures (Hanson, 1989). In addition to the basic assumptions of numerical models, GENESIS assumes that all sediment transport is alongshore and it does not recognize onshore and offshore sediment movement. The model can handle a shoreline up to 100 km long, but a prediction period of only 10 years. Basic input parameters are starting shoreline position, wave statistics, beach profiles and bathymetry, boundary conditions, and the configurations of engineering structures. Although GENESIS is capable of simulating longer shorelines and greater durations than most other models, it is not applicable to open-coast changes that are tidally dominated, storm-induced, or caused by water-level fluctuations. Its greatest utility is for predicting transitions from one beach stability state to another (Hanson, 1989).

Advanced mathematical models that can accurately predict coastal changes are still in the formative stages of development, because the coastal processes being simulated are complex and existing equations do not adequately describe sediment transport across the beach and offshore profile (Komar *et al*., 1991). Furthermore, there is a general lack of field data (wave climate. wave-field transformation, nearshore currents, sediment budget, offshore bathymetry) for calibrating the models. Although some of the numerical models incorporate future magnitudes of sea-level rise, a fully three-dimensional model has not been developed that will distinguish among different pathways of coastal evolution depending on variable rates of sediment supply and sea-level rise. For example, slow rates of sea-level rise typically allow eroding barrier islands to maintain a dune ridge that retards erosion. In contrast, rapid rates of rise cause dune breaching, washover, and eventually barrier migration. During highest rates of sea-level rise the barrier is drowned in place, overstepped, and partially preserved on the inner shelf. Furthermore, the models do not adequately provide for variable sediment textures. The existing models have been developed, tested, and verified for sandy beaches but not for muddy shores despite the fact that many eroding coasts are composed of thin sand beaches overlying muddy estuarine and marsh deposits.

Hazards such as beach erosion and permanent flooding of many coastal regions were reasonably consistent and predictable before large-scale high-value economic development, because unaltered processes and the geologic framework primarily controlled them. However, post-development human modifications have caused large-magnitude imbalances in the natural forces. As a consequence of this induced disequilibrium, future predictions of coastal change will be more difficult to make and will require better quantification and incorporation of human alterations and interventions such as land reclamation, shore stabilization, and beach nourishment (Morton and McKenna, 1999).

Existing needs and future directions

In most developed or developing countries, recent increases in coastal populations and the increased levels of education and interest of coastal residents have led to a dramatic increase in the demand for coastal maps. Now, coastal regulators and property owners alike can gain easy access to the basic map products that are used to establish and enforce coastal zone management policies. While the demand for coastal maps has increased, the earth and biological sciences have evolved from being qualitative and descriptive to being much more quantitative and process-oriented. A result of these improved technical capabilities has been the generation of more quantitative maps that are used to convey rates of change or levels of risk, and to forecast future impacts of changing processes or coastal conditions.

Quantitative hazard mapping (Gornitz *et al.*, 1994; Shaw *et al.*, 1998) gives the appearance of being precise, but values of risk or vulnerability that are selected arbitrarily have no specific validity with regard to physical processes and probable future conditions. In fact, there is no scientific way of equating assigned scores or rankings to predictable coastal responses. Ordinal rankings are useful for relative comparisons of hazard vulnerability, but they are commonly subjective and depend entirely on the values assigned to the individual factors and then how the calculated scores are assigned to a particular level of risk. Clearly, there is a need for better representation of integrated hazard risk and vulnerability of coastal areas. The trend toward quantitative indices to assess coastal hazard vulnerability is commendable, but there needs to be more scientifically objective critical analyses of both the input and the results. For example, what does coastal vulnerability actually translate to: is it increased beach erosion, or increased flooding of the landform? The implied coastal responses to a particular hazard, for example, to a relative sea-level rise, are not well-defined and because of the ambiguity, the vulnerability indices are difficult to evaluate.

The ordinal rankings or scores for mapping coastal vulnerabilities are questionable for the following reasons. First, there is too much subjectivity in deciding which physical parameters to include. There are a number of parameters that seem obvious (land elevation, rates of relative sea-level change, land composition, vulnerability to storm impacts), but many other parameters are commonly included and there is no objective way of deciding how many parameters to include, and which set of parameters and algorithms provides the most accurate results. In addition, there is the problem of how to integrate each potential hazard into an aggregated value. Currently, the reported methods take parameters that are quantifiable (rates of shoreline movement or sea-level change, tide range, wave energy) and convert them to an index assuming that the cumulative interactions of the parameters are either additive or multiplicative. There is no physical theory involved in this approach, simply a forced numerical ranking. Another problem involves weighting individual parameters or groups of parameters to achieve a desired result. And finally, there is the problem of how to express the integrated value in terms of low, intermediate, or high risk. An example would be the use of statistics, such as the application of quartile statistics, to achieve a subdivision of low, moderate, high, and very high hazard risk. This approach is convenient and numerically defensible, but the results may not have anything to do with the actual responses of beaches and barriers to rising sea level and potential increased storminess in the future.

The hazard index algorithms commonly used typically yield comparable, but untenable hazard rankings for areas that are remarkably different from a geological and oceanographic perspective. For example, results of the hazard assessment by Gornitz *et al.* (1994) suggest that the Chandeleur Islands of Louisiana and the barrier island at Nags Head, North Carolina are equally vulnerable to future sea-level rise. Coastal geologists familiar with both of these areas agree that the rapidly retreating low-profile washover barriers of the Chandeleur chain are much more vulnerable to both short-term ephemeral flooding by storms as well as long-term permanent inundation by a eustatic rise in sea level than the barrier coast at Nags Head. This type of application error is a result of trying to integrate disparate data into a common coastal hazard index by using simple additive (linear) assumptions that do not accurately portray the physical processes and properties of the nearshore environments.

Rates of shoreline change are generally reported as single values without the benefit of error bars indicating the uncertainty of projected shoreline positions. Furthermore, errors associated with the predicated rates of change are magnified by as much as 60 times when they are used to map projected erosion zones (National Research Council, 1990; Morton and McKenna, 1999). Therefore, minimizing the uncertainty of these predictions should be a primary objective of coastal research.

Another limitation of many coastal maps is that they become obsolete quickly. In contrast to classical stratigraphic maps of coastal terrain that were not time-dependent, many maps prepared today for risk assessment (beach erosion, flood-prone areas), resource inventory (wetland distribution), or pollution characterization (contaminated sediments) are subjected to relatively rapid change. Because these maps can be outdated quickly, there is a need for planned periodic revision.

Maps of shores and coastal terrain are much more advanced technologically and more specific in their application now than when they were first prepared. A consequence of these improvements is the present requirement of increased scientific accuracy. In the past, mislocation of a geological contact was of academic concern, but it had essentially no impact on public policy and coastal regulations. Now maps of flood or washover hazard zones, setback lines, and rates of shoreline movement can dramatically influence potential land use and economic value of coastal property. As the severity of the consequences of coastal change in densely developed areas increases (coastal erosion, sea-level rise), so does the need for accurate scientific maps.

MARINE DEBRIS—ONSHORE, OFFSHORE, SEAFLOOR LITTER

Introduction

Marine debris is a problem that affects beaches/coastlines and the seafloor at all depths, and its impact is of global significance. It has been recognized as a serious pollutant for around 30 years, but has only gained widespread recognition in the past decade or so. Cleanup schemes, particularly those requiring public participation, have led to greater public awareness. This though does not appear to have led to any great reduction in the amounts of debris being found on beaches worldwide. Marine debris has been defined as "any manufactured or processed solid waste material (typically inert) that enters the marine environment from any source" (Coe and Rogers, 1997, p. xxxi). Marine debris is also often termed marine or beach litter. The sources of this form of pollution may be from the land (e.g., direct from beach users or from rivers) or from the ocean itself (e.g., from ships or offshore installations). Once in the marine environment debris may remain for many years, particularly if it is plastic and numerous worldwide beach-based debris studies have recorded plastic as the dominant material (e.g., Garrity and Levings, 1993, in Panama; Jones, 1995, in Australia). Indeed, plastics have been considered an environmental and pollution threat to the marine realm whose importance will incrementally increase through the 21st century (Goldberg, 1997). The problems created are chronic and potentially global, rather than acute and local or regional as many would contemplate.

Sources

Marine debris sources can be broadly classified into two groups: seaborne sources and land-based sources. Most concern has focused on debris discharged from vessels, but there is now extensive evidence that landborne discharges are a major source of marine debris. It has been stated that landborne sources are believed to be a much more significant contributor of pollutants to the marine environment than are vessels (Faris and Hart, 1995). Land-based debris can enter the sea through rivers, or can be blown, washed, or discharged directly from land. The absence of sewage treatment installations, the presence of combined sewer overflows, storm water discharges, run-off from landfills sited nearby rivers and in coastal areas, the absence of waste services or landfills in rural areas, recreational beach users, and fly tipping, all contribute to debris ending up on beaches or in the oceans.

Identifying from which source debris has originated is an altogether more difficult task. On occasions the source of the pollution is clear and local (Walker *et al*., 1997), but all too often the sources are not so obvious and can be international either in terms of shipping, or land-based litter from other continents, for example, American litter on west coast European shores (Olin *et al*., 1995). The movement patterns, sinks, and degradation rates of marine debris are still not completely understood, although there is significant recent research in this area (Williams and Simmons, 1997). In these circumstances, one cannot generalize or make assumptions about sources, site-specific measurements will almost always be required (Earll *et al*., 2000). Possible sources, whether geographical or socio-demographic, can only be established by recording the maximum amount of detail concerning the debris item (Williams *et al*., 1999). At present, there is no accepted methodology that enables researchers to link litter items to their source, the conceptual step taken to link litter to a source requires the following:

- the identity of the item is known or at least described systematically,
- the function and application of the item is understood, and
- that quantities of the item are measured.

Studies of why littering takes place in particular situations, for example, fly-tipping, or failure to use port reception facilities, are likely to be very important in the future as greater emphasis is placed on this aspect.

Case studies—extent of problem

The source of marine debris found on beaches worldwide varies widely. As previously stated, there are certain site-specific elements that influence the source of litter and these can differ from beach to beach. Comparisons of debris amounts are generally complicated by differences in methodology among studies, beach substrates, and environmental factors influencing the transport of debris items. Although comparisons are difficult, certain similarities can be noticed. In a survey of debris along the Caribbean coast of Panama, Garrity and Levings (1993) found that 56% of the items were made of plastic; 89% of this plastic debris being related to consumer or household goods; that the country of origin of the debris was related to distance from the survey site. Garrity and Levings (1993) concluded that (1) local household waste, (2) shipping, and (3) nearshore marine activities were the major sources of debris. They found no evidence of substantial input from industrial, recreational, or offshore commercial fishery sources.

Corbin and Singh (1993) in a study of Caribbean island coastlines showed that the amount and kind of items found were associated with types of coastal activities and variations in population density. Even though the study area was a busy lane for liners and other ships passing through the Panama Canal, little evidence was found of debris from distant sources or debris discarded from cruise ships washing up on the coast. A study of marine debris at Bird Island, South Georgia, by Walker *et al*. (1997) helps to illustrate the problem of generalizing the sources of such wastes. The findings were that the source of much of the marine debris was from local fisheries, with the majority of debris originating from jettisons by long-line fishing vessels.

Williams and Simmons (1997) conducted surveys on beaches fringing the Bristol Channel, UK, an estuarine area with relatively low levels of shipping. Very low amounts of foreign material were encountered during the study, suggesting low levels of ship discards. In contrast to this, studies carried out by the Tidy Britain Group in other parts of the United Kingdom have found that the primary sources of debris within their study area originated from shipping vessel sources. As stated earlier, comparisons between locations are difficult, any generalization about sources, persistence, and dynamics of marine litter would therefore be unwise.

Results from studies initiated in the Mediterranean showed that certain portions of this area do not have large amounts of litter emanating from seaborne or riverine sources, but rather from the high numbers of beach users. The importance of location is shown in that, "there are indications that most Mediterranean coastal litter is land-based, in contrast to the reported marine-based litter on the western European shores" (Gabrielides *et al*., 1991, p. 437). Debris on beaches is a world-wide problem and there is no region that has escaped this form of pollution.

Problems—socioeconomic—tourism, fishing, health, aesthetic

Effects on humans

Numerous studies of beach litter have commented on the potential danger to visitors, mainly from foot lacerations caused by stepping on glass or discarded ring pull tabs (Olin *et al*., 1995; Williams *et al*., 2000). Other, more dangerous items have been encountered on beaches that are less expected. Munitions and containers of corrosives have been found washed ashore along with pyrotechnics, packaged hazardous goods. A further example occurred in 1993, off the coast of France, with an accident involving the ship "*Sherbo*" in which 60,000 bags of a pesticide similar to nerve gas were lost overboard (Olin *et al*., 1995).

Attention has turned recently to the less obvious health risks that can feature on beaches. These items are medical waste and sewage-related debris. Although the risks are considered to be relatively low, any contact with infected sanitary products or fluids in syringes or other medical equipment, or ingestion of any of these could cause disease. Forty needlestick accidents on bathing beaches were reported between 1988 and 1991 to the UK Public Health Laboratory Service Communicable Disease Surveillance Centre. Medical wastes have appeared on holiday beaches and in some places sharp containers are now being issued to lifeguards, who are advised not to go barefoot on these beaches (Philipp, 1993). Studies carried out in Panama by Garrity and Levings (1993) also encountered significant levels of medical waste.

Debris on beaches is not just a health problem for those visitors who always remain on land, as bathers are also at risk. It provides information on ocean debris even though it is uncertain whether beach litter is representative of the ocean litter (Jones, 1995). It is however, the *only* realistic indicator of the amount and type of debris present in the ocean (Walker *et al*., 1997). Sewage-related debris on a beach would seem to suggest that the adjacent waters are contaminated with sewage which means a health risk to sea users. Bathers exposed to sewage-contaminated water have a higher risk of skin and ear infections. In 1990, it was reported to the UK House of Commons that the aesthetic quality of recreational waters is becoming more important as the public becomes increasingly aware of the risks (House of Commons Environment Committee, 1990).

Public attention to problems relating to the coastal zone have been based more upon public perception than on any scientific knowledge or evaluation of sources, fates, and environmental effects. Associations have been made between the public perception of items affecting the aesthetic appearance of bathing water and bathing beaches and the gastrointestinal symptoms experienced after bathing in sewage polluted water (Nelson *et al*., 1999). Another viewpoint could be that the public debate on sewage in bathing water has rarely made any distinction between the aesthetic impact and actual health risk.

Economic effects

The problem of litter in the environment leads not only to potential health risks, but also to economic losses. Stranded debris has direct and indirect social and economic costs to coastal communities, with the financial strains imposed by such debris not always easy to quantify, or to appreciate. Economic loss has been split into two areas, first loss to fisheries, and also loss to tourism.

Fisheries. The economic impact of debris on fishing has been studied over many years. Such losses have occurred due to the fouling of trawl nets by bottom debris, blocking of water intake pipes by plastic sheeting and, propeller foulings (Jones, 1995). Damage to ships following collisions with debris at sea have also been reported. Costs result mainly from repair of damage and lost time.

"Ghost fishing" affects commercial fishing interests. This hazard occurs as a result of lost or abandoned nets and traps, which leads to the capture of target and nontarget species. This will reduce reproductive potential, as immature fish that have not produced offspring are removed from the population (Pollard *et al*., 1999). Large items of debris are capable of tearing nets and other fishing gear and the presence of certain debris can lead to entire catches being discarded. Data is limited as to the costs incurred due to these encounters with litter.

An extensive study carried out by Nash (1992), concerned the impacts of debris on a group of subsistence fishermen. The findings were similar to others relating to commercial fishing, including propeller entanglements, fouling of nets, damage to fishing gear. One exception was that during the gathering of shellfish and mollusks by hand, waste such as glass can lead to foot or hand injury.

An important distinction between commercial and subsistence fisherman is that even a minor decrease in yield can lead to a lack of provision for the latter with respect to basic needs, such as food. This can lead to abandonment of fishing completely (Nash, 1992). The knowledge that marine debris can cause livelihoods to be lost might be a greater spur for authorities to deal with the problem than knowing about the damage to wildlife.

Aesthetic quality, perception, and tourism. The loss of tourism and recreational potential are very real impacts of marine debris. A coastal community that relies heavily on tourism for its livelihood can have its income severely depleted by marine debris (Corbin and Singh, 1993). Perhaps the greatest impact associated with marine litter is not to organisms, but to the economic loss associated with the reduction of amenities. The money that can be made, or indeed lost, from tourism and related industries is enormous; the UK maritime leisure industry is worth £8 billion Sterling a year, with £6 billion relating to seaside holidays (Maritime Technology Foresight Panel, 1996).

The aesthetic value of beaches can be reduced by the appearance of plastics, sewage-related debris, and other items of litter. People prefer to visit clean beaches, with both land and water free of litter, rather than those containing various assortments of marine debris. The public may avoid certain beaches if they find their appearance unacceptable (Williams *et al*., 2000). The effect of aesthetic issues on the amenity value of marine and riverine environments has been defined by the WHO as: loss of tourist days; resultant damage to leisure/tourism infrastructure; damage to commercial activities dependent on tourism; damage to fishery activities and fishery-dependent activities; damage to the local, national, and international image of a resort (Philipp, 1993). Many of these problems are manifest in developing regions such as the small island states of the South Pacific, where natural resources may be limited and economic development is largely dependent upon coastal tourism (e.g., Gregory, 1999). Particular problems lie with waste disposal and management whether it is generated on land or vessels at sea. On an atoll or small high island an ever-expanding mountain of waste is difficult, if not impossible to handle. There are sharply conflicting interests between the sophisticated demands of most tourists and the environmental degradation inflicted upon local inhabitants who also have aspirations for a better lifestyle.

When considering aesthetics, one must remember that it is usually a subjective and intangible concept. Aesthetics is a branch of philosophy concerned with the essence and perception of beauty and ugliness. Aesthetics also deals with the question of whether such qualities are objectively present in the things they appear to qualify or whether they exist only in the mind of the individual. In essence, whether objects are perceived by a particular mode—the aesthetic mode, or whether instead the objects have, in themselves, special qualities—aesthetic qualities.

With regard to marine debris and aesthetics it would seem that the perception is almost universal amongst the population and therefore, the consideration of litter is perhaps less subjective. Cause and effect relationships have been established regarding public perception and lost revenue. Beach closures along with public perception of contaminated bathing areas in 1987 and 1988 resulted in approximately US$2 billion of lost revenue for New Jersey and New York states, the losses were ascribed to debris (Rees and Pond, 1995).

As well as losses from tourism there are continual costs of beach cleanup efforts that take time and money. Cleaning the coast costs local authorities thousands of US dollars per year, additional costs are incurred when hazardous containers are found and have to be recovered from beaches. The cities of Santa Monica and Long Beach in California, USA, each spent more than US$1 million in 1988–89 to clean their beaches and costs continue to rise (Kauffman and Brown, 1991). A European example is the Swedish Skagerrack coast where more than 6,000 m^3 of litter was collected in 1993. Approximately 9,000 working days over 4–5 months with a total cost of around £1 million Sterling, gives the fiscal price of clearing marine litter at £156/m^3 (Olin *et al*., 1995). Harbor authorities in the United Kingdom also have to pay for the costs of keeping navigational channels free from litter. At Studland, Dorset, UK, one million visitors per year along a 6 km stretch of beach results in 12/13 tonnes of litter collected weekly in the summer months at a cost of £36,000 Sterling per annum (Williams *et al*., 2000). If any area is consistently polluted with debris then this can lead to falls in property values (Rees and Pond, 1995).

Biologic interactions

The impacts of marine debris on wildlife are generally divided into two groups: entanglement and ingestion although fouling organisms and blanketing effects also warrant serious consideration (Winston *et al*., 1997). Entangled animals can drown, be fatally or seriously wounded, or have reduced ability to catch food, travel, or avoid predators. Ingested material can block and damage digestive tracts and reduce feeding (Jones, 1995). It is estimated that over one million birds and 100,000 marine animals and sea turtles die each year from entanglement in, or ingestion of, plastics (Faris and Hart, 1995). Of the 115 species of marine mammal, 47 have been known to become entangled in and/or ingest marine debris (Pollard *et al*., 1999).

Entanglement

Entanglement of marine animals in debris can be broadly split into four areas:

- Large items of debris trap animals, which may result in the drowning of air-breathing species, asphyxiation of fish species that need constant movement to respire, or death by starvation or predation (Pollard *et al*., 1999). Large or heavy pieces of debris are also liable to drag animals down.
- Smaller items of debris greatly increase drag factors. This will lead to an increased vulnerability to predators and a decreased ability to forage, which ultimately leads to starvation.
- Smaller debris items can become snagged on the seafloor trapping animals, or entangling birds and other animals on land.
- Entangled objects can tighten around the animal leading to restrictions in growth. This can lead to death or inhibit the ability to reproduce (Faris and Hart, 1995), and can also affect feeding.

The dangers to marine animals and birds caused by entanglement in man-made debris have been well documented. In areas of particularly heavy maritime traffic or where oceanic currents naturally accumulate surface material, these problems can be particularly acute (Walker *et al*., 1997).

A study carried out by Lucas (1992) on Canadian beaches between May 1984 and September 1986 produced data on beach litter composition and entanglement of marine animals. Results found that Harbor and Gray seals were entangled on Sable Island beaches in strapping, net, rope, and other items. Of 241 Gray seal pups handled during research, 2.5% were entangled. Further findings included, seabirds tangled in trawl net, six-pack yokes, and balloon ribbons; a Sable Island horse was also found on the beach, with both hind legs entangled in a bundle of plastic strapping. The discovery of the entangled horse indicates the threat posed to terrestrial animals, as well as marine species, from marine debris.

Ingestion

The problem of ingestion appears to have attracted less attention and research than the entanglement of animal species. Plastic ingestion often leads to a less acute effect than entanglement; this could be due to the gradual accumulation of plastic debris in the guts of some animals. Some species may be able to regurgitate or excrete debris, but some plastics do not appear to pass through the intestines of certain seabirds as there is a marked absence of debris from droppings (Faris and Hart, 1995).

Epibionts, encrusters, fouling, and associated biota

Freely drifting plastic artifacts and other synthetic materials provide habitats for many opportunistic colonizers, and may act as attachment surrogates for natural floating substances such as logs, pumice, and some surface-dwelling, free-swimming larger marine animals. Studies of beach-cast plastic debris from shores of the western North Atlantic and the Southwest Pacific have revealed more than 100 epibiont and associated motile taxa (Winston *et al*., 1997). The initial colonizers following biofilm development, are filamentous algae, hydroids, ascidians, and other soft fleshy organisms. These do not long survive desiccation and disintegration once exposed to the elements in harsh beach environments. As a consequence, the record is biased toward resistant, hard-shelled, and crustose organisms, that typically includes barnacles, bryzoans, tube worms, mollusks, foraminifera, and coralline algae, as well as some more resistant sponges and hydrozoans. Of these, the most common taxon is bryozoa with over 60 identified species represented. The extent of bryozoan cover and species diversity is latitudinally dependent. Species richness is greatest in low latitudes and decreases polewards in both hemispheres (Winston *et al*., 1997).

The biologic communities of pelagic plastics may find side-by-side associations of related species inhabit quite different environmental niches. A single item recovered from a northern New Zealand beach hosted barnacles typical of sheltered shores (*Balanus modestus*), more exposed coasts (*Balanus trigonus*), and drifting objects (*Lepas anatifera*) and another carried a motile crab fauna represented by common algal dwellers, rocky shore taxa, and a pelagic species. There is also evidence that some other taxa may reproduce as they are buoyed along on their floating debris island (Winston *et al*., 1997). Larger floating objects or aggregations of debris may also attract resident schools of fish, which in turn bring birds and marine predators.

There is evidence that passively drifting islands of plastic and other debris may be a vector for local, regional, and transoceanic dispersal of marine organisms and perhaps even some terrestrial ones (Gregory and Ryan, 1997). For example, the common Indo-Pacific oyster *Lopha crista-galli* has been found on a southernmost New Zealand beach attached to a tangled mass of rope, while Florida debris carried a previously unrecorded bryozoa (*Thalamoporella* sp.) similar to a Brazilian species (Winston *et al*., 1997). It has also been suggested that some terrestrial flora and fauna elements could be picked up during a stranding episode, to be later floated off and carried away by offshore winds (Gregory, 1991). While pelagic plastics may have less potential than ballast waters for the introduction of aggressive, habitat-harming alien taxa, it is not a threat that should be ignored. Gregory (1991) suggested that alien species rafted on drifting plastic could pose threats to the biota of sensitive and/or protected nearshore environments and perhaps the delicately balanced terrestrial ecosystems of small oceanic islands. These are factors that need to be taken seriously by those having stewardship responsibilities for conservation or heritage estate. An example is Codfish Island lying a short distance offshore from Stewart Island, southern New Zealand. This is a managed refuge for a small population of a large flightless parrot, the kakapo (*Strigops habroptilus*) which is nearing extinction. The arrival of rats, mustellids, or cats on the island through rafting from the mainland some 4 km away could be disastrous for the survival of this species.

Public perception

The appearance of clear water does not necessarily mean that the water is uncontaminated, but the presence of certain items on a beach may, however, imply poor microbiological water quality. Likewise, a beach that is free from any trace of litter does not imply that the sanitary quality of the sand is good. Particular litter items attain a higher degree of emotional response within the general public than others. Sewage-related debris (SRD), and medical and hazardous items arouse greater levels of offense, or feelings of unpleasantness, than do more general items of litter such as beverage containers or confectionery wrappers. Sewage-derived debris has a greater social impact than any other aesthetic pollution environmental parameter (Williams *et al*., 2000). The UK House of Commons Committee stated that "while the risk of infection by serious disease is small, the visible presence of fecal and other offensive materials carried by the sewerage system can mean serious loss of amenity and is therefore an unacceptable form of pollution" (House of Commons Environment Committee, 1990, p. xvii).

Methodologies

Surveys can be focused on beaches, seas, or rivers where debris is used as an indicator of oceanic, riverine, estuarine, or lake conditions (Williams *et al*., 1999). Many studies monitoring marine debris have concentrated on specific items or categories: for example, Jones (1995) dealt with fishing debris. Other studies though have been less specific and these have assessed areas of land or water for amounts and composition of marine debris (e.g., Corbin and Singh, 1993). Beach surveys are often based on relatively small areas of study, with low numbers of surveyors involved in the collection of data. Larger-scale studies often require many more people to collect data if they are to be completed at low cost within an acceptable time frame, and not all of these surveyors can be expected to have had previous experience of carrying out litter surveys. However, the use of members of the public or local interest groups in such studies has the added value of raising public awareness and indirect education (Williams *et al*., 1999). This can be witnessed in public participation schemes such as Beachwatch in the United Kingdom, the Campaign for Marine Conservation in the United States, and Pitch-In-Canada.

Surveys are used to determine the amount and type of debris in a specified area at a certain time and to determine how types and amounts of debris change with time. Studies may be simple enumeration studies, assessing types and litter quantities, or they can be more detailed, indicating age and origin of items. For example, Gabrielides *et al*. (1991), Corbin and Singh (1993), Jones (1995), and Walker *et al*. (1997).

Beach studies face problems in that the amount of debris is influenced by beach dynamics, oceanic circulation patterns, weather, debris characteristics, cleaning operations, and offshore recreation, and commercial practices (Faris and Hart, 1995). The many different methods employed in collecting data for beach debris surveys make result comparisons very difficult. There is as yet no single accepted methodology for assessing beach litter.

Campaigns and initiatives to combat marine debris

There are a number of campaigns and public participation schemes that aim to raise awareness and reduce the marine debris problem. Education and public awareness are key elements in the reduction of marine debris. Public involvement in beach litter management takes two forms: Direct action such as beach cleanups and monitoring; and indirect action, such as education, award schemes, and legislation. The involvement of the public in beach monitoring and cleanup programs has a dual advantage in that it allows a large sample size to be achieved, and raises awareness among society which will then translate into effective individual action to reduce litter at source. Some of the campaigns worldwide are: The Center for Marine Conservation in the United States; Coastwatch Europe; Beachwatch in the United Kingdom, run by the Marine Conservation Society; and Pitch-In-Canada. There has been some concern that where volunteers are involved in the collection of data that it can lead to spurious results. Trials by the Tidy Britain Group in the United Kingdom showed that volunteers frequently incorrectly identify litter items. An opposing view has been presented in other research (Williams *et al*., 1999), although it has been found that particular *items* are consistently misidentified by the public, for example, cotton bud sticks (Q tips).

Beach cleaning

Beach cleanups provide a way of collecting data on the types and quantities of marine debris. Beach cleans cannot permanently solve the problem of marine debris as they do not reduce quantities at source, even though there is intense pressure to clean a beach, especially by authorities wishing to promote tourism. However, cleanups are really only applicable locally, are expensive if undertaken by mechanical means and labor-intensive. Conversely, if volunteers are employed the costs are minimal. However, cleanups *per se* do not resolve the problem if they do not address the *issues of prevention at source* and it is the links to sources that represents the future challenge (Earll *et al*., 2000; Williams *et al*., 2000).

There are, in essence, two methods of beach cleaning: Mechanical beach cleaning involves motorized equipment utilizing a sieve effect which scoops up sand and retains the litter, therefore, it is not selective. Most sieve machines are coarse-grained allowing items such as cigarette stubs and cotton bud sticks to pass. The use of mechanical beach cleaners may threaten the stability of some beaches, through the removal of organic matter which forms the “glue” holding sand grains together (Pollard *et al*., 1999). The passage of such vehicles over the beach interferes with beach ecology and it is a costly method. This method though is limited in that it cannot be used on pebble beaches. The advantages of such mechanical cleanups are that it is fast and can provide an apparently pristine beach for visitors and can cover a large area. In areas with hazardous or sanitary waste it negates the need for picking up material so reducing potential health risks to individuals (Williams *et al*., 2000). The alternative to mechanical methods is manual beach cleaning. These are often carried out where the expense of a mechanical device is prohibitive, or the substrate is not receptive to such machines. Manual cleans organized as community events on small areas may ensure that the beach is cleaned of small items missed by mechanical cleans (Pollard *et al*., 1999).

The offshore: (pelagic marine debris)

While significant quantities of land-sourced debris and litter have been reported from harbor and inshore waters for some time, knowledge of amounts and distributions is limited. Heyerdahls's (1971) observations from the raft *Ra* on its slow drift across the equatorial Atlantic provided an initial demonstration of the extent to which surface waters were becoming contaminated by pelagic marine debris. Whether it is for coastline or high seas surveys it is convenient to separate plastic litter into four size categories (micro-litter < 1 mm; meso- 1–10 mm, mostly pellets or nibs of virgin resin; macro—mostly degradational flakes and smaller items to 10 cm; mega—larger items >10 cm). Systematic investigations to establish quantities and distribution of pelagic plastic litter have been sporadic and are based on either surface towed neuston (or pleuston) nets or have used sighting surveys from vessels on passage. The former have focused primarily on meso-litter, mostly plastic pellets or nibs, and the latter on macro- and mega-litter items identifiable with the naked eye from a vessel's deck or bridge.

There is little information available about the quantities and distribution patterns of plastic micro-litter. The source lies in some propriety hand cleaners and cosmetic preparations, and air-blast cleaning media as well as from degradation and disintegration of larger debris items. There can be little doubt that micro-litter is now globally dispersed.

Plastic meso-litter, mainly in the form of nibs or pellets of virgin polystyrene and polyethylene, has a universal presence in oceanic surface waters. The greatest densities have been noted in coastal and shelf waters off major urban and manufacturing centers—some quoted maximum pellet densities include $>100{,}000$/sq. km off the eastern seaboard of North America; $>40{,}000$/sq. km in waters of Cook Strait, New Zealand; 1,500/sq. km in the Sargasso sea; and 1,500–3,600/sq. km in the Cape Basin Region of the South Atlantic west of South Africa.

Mega-litter quantities have been reported from all marine waters since the casual and anecdotal comments made by Heyerdahl (1971) brought this problem to the fore. Distribution patterns for plastic litter in all size categories across the high seas are similar. The greatest densities, whether measured by weight or item count are to be consistently found in coastal and shelf waters adjacent to and down drift from major urban and manufacturing regions. On the open ocean, distant from land-based sources it tends to concentrate along oceanic fronts and in large eddy systems or gyres.

Concentrations of macro- and mega-litter are also present along many shipping routes particularly those of the North Atlantic and North Pacific. They are much less across the South Pacific where shipping traffic is sparser and industrial developments are fewer and distant.

The seafloor: (benthic marine debris)

The seafloor from intertidal and shallow sublittoral to outer shelf, slope, and abyssal depths has been identified as an important sink for marine debris (Goldberg, 1997). An early demonstration of this came with the recognition of plastic film accumulating on the floor of the Skaggerack by Hollström (1975). The problem is now appreciated to be a global one with many observations made by divers, through video footage from remotely operated vehicle (ROV's) as well as sampling by bottom trawls. Data has been obtained from varying depths and at many widely separated places. Latterly there have been several studies presenting substantial data on types, amounts, and distribution of marine debris on the seafloor, and although bottom trawl sampling is the preferred technique, methodologies vary, making comparisons difficult; for example, 6.5 m beam trawl pulled for 25–90 min (Kanehiro *et al*., 1995); haul of 6 h at 3.5 knots (Stefatos *et al*., 1999); benthic tows along a 1.85 km track (Hess *et al*., 1999); Moore and Allen (2000), towed along isobath for 10 min at 0.8–1.2 m/s; trawl times of 5–30 min, and also estimates of densities from a submersible along tracks of 730–6,500 m (Galgani *et al*., 2000); furthermore, in each of these studies, the categories of marine debris identified differ.

The quantities of sunken litter being reported are high. Litter densities on the seafloor of central Tokyo Bay, Japan, ranged from ca. 25,000–ca. 60,000 items/sq. km (Kanehiro *et al*., 1995). Of this, plastics comprised 80–85% with fishing-related items between 2.7 and 9%. Quantities had not significantly changed over a four-year period (1989–93) and land-based sources were considered to be of most importance. Stefatos *et al*. (1999), recognized that marine debris concentrations on floors of the enclosed Patras and Echinadhes Gulfs, western Greece, reached 240 and 89 items/sq. km, respectively. They noted that these differences could be related to land-based sources for the former and shipping traffic in the latter. From studies of inshore waters around Kodiak Island, Alaska, Hess *et al*. (1999) showed that fisheries-related and other plastic debris quantities were greatest in inlets (20–25 items/sq. km) and least in open waters outside inlets (4.5–11 items/sq. km). These differences were considered to reflect variations in fishing effort and water circulation patterns. Moore and Allen's (2000) shelf survey of the southern California Bight, ranked quantities of anthropogenic and natural debris into four broad categories (trace, low, moderate, high) on the basis of number and weight of items determined from standardized trawl times along isobaths between depths of 20 and 200 m. Bathymetrically, the proportion of area with anthropogenic debris increased with increasing distance along a broad offshore front, from inner to outer shelf. This suggested a source that lies in disposal practices from boating activities. The most comprehensive and thorough reports are those coming from European and western Mediterranean waters (see Galgani *et al*., 2000). Densities found were highly variable between and within separate sampling areas. Near metropolitan areas they could exceed 100,000 items/sq. km but elsewhere maximum values were lower (50,000 items/sq. km in the Bay of Biscay; 600 items/sq. km in the North Sea 200 km west of Denmark). It was also noted that concentrations of debris (to densities >50,000 items/sq. km) were encountered at depths of >2,000 m on floors of canyons along the Mediterranean coast of France. Variations in distribution patterns were attributed to geomorphologic factors, local anthropogenic activities, and land-based river inputs.

Mechanisms by which the mostly neutrally buoyant plastics in marine debris reaches the deep-seafloor are poorly understood. Significant quantities of land-sourced materials on submarine canyon floors to considerable distances offshore, suggest rapid transport through nearshore zones and entrainment in bottom hugging currents. Density increases following rapid and heavy fouling may be sufficient to permanently sink them. On the other hand, grazers may clean covered surfaces leading to "yo-yo like" episodes of submergence and resurfacing until permanent settlement to the seafloor is effected. As well as biofilm development, plastic sheeting may also attract nonliving detritus, which with photodegradation and progressive embrittlement leads to density increases taking it to the seafloor without the need for invoking downwelling and/or entrainment.

The epibionts of benthic plastic debris are not as well known as those of pelagic items. Accounts are limited (e.g., Hollström, 1975) but indicate a hard ground biota characterized by bryozoans, sponges, and foraminifera, with barnacles, mollusks, and polychaetes is typical. At shallow, photic zone depths, there is development of crustose (coralline) red algae as well as soft brown and green algae. Bryozoa are generally the dominant epibiont of both pelagic and benthic plastics.

Plastic sheeting together with larger, more solid items and discarded fishing gear is an undesirable addition to the deep-seafloor and potentially damaging to the environment (Goldberg, 1997). The blanketing effects of sheeting may damage biotas of both soft sediment and rocky hard ground substrates at all depths from intertidal to the abyss. They may lead to anoxia and hypoxia induced by inhibition of gas exchange between pore water and seawater (Goldberg, 1997). Ironic as it may seem, could benthic plastic debris standing above the seafloor enhance or enrich local biotic diversity in the short term, for in the long term it is doomed to permanent internment in a slowly accumulating sediment cover?

Degradation

Breakdown of plastics mainly takes place through photodegradation which leads to surficial cracking followed by embrittlement and ultimately complete disintegration into powder. Biodegradation is seldom important with most plastics that enter the marine realm. Physical abrasion is also a mechanism for the breakdown of plastics along coastlines—particularly high energy cliffed and rocky shores. Degradation performance is generally measured through changes in tensile strength and viscosity although UV and laser spectroscopy are other approaches. Several studies have shown that the rates of weathering of polyethylene and other plastics are substantially reduced when floating in seawater compared to those when exposed outdoors to normal atmospheric conditions. Enhanced photodegradable polyethylene also degrades more slowly under marine conditions. Alternatively, expanded polystyrene foam is known to deteriorate more rapidly in seawater than on atmospheric exposure. Material that has been buried for some time in beach/riverine sediments retains much of its tensile strength and may be exhumed during episodes of erosion (Gregory, 1999). Plastics sinking to the deep seafloor will not be subject to photodegradation and if resistant to biodegradational processes will be preserved there until burial is completed.

MARINE PARKS

There is a wide and growing range of marine parks. They include designated natural marine areas, such as the coral reefs off the coast of Al Fujayrah in Abu Dhabi, which were declared the country's first marine parks in 1995, the Great Barrier Reef, and artificial tourist facilities, such as Seaworld California in San Diego and Marineland Canada near Niagara Falls. The latter often include captive marine life, including marine mammals, as well as recreational features and structures such as water-slides. They attract large numbers of visitors and for many people are their first introduction to the marine world. They are, however, controversial because of their use of captive mammals, such as dolphins, although concern for animal welfare means that the best operate with very high standards of care and carry out important research. Some natural marine parks use underwater observatories to provide dry access to the undersea world, for example, in the Marine Park and Underwater Observatory at Coral World on the northeast coast of St. Thomas in the US Virgin Islands. The majority, however, depend upon boat and diving access to the marine world, for example, in the Pulau Weh Marine Park in western Indonesia and the Malindi Marine Park on the coast of Kenya.

The terminology used to describe Marine Parks varies from country to country depending upon the specific legal designation used, and the term "Marine Park Area" is also commonly used. Many marine parks also form parts of a worldwide pattern of Marine Protected Areas (MPAs), which include a wide range of legislative and conservation practice. However, not all marine parks are marine protected areas and not all marine protected areas form parts of marine parks.

Historical background

Although the First World Conference on National Parks held in 1962 expected governments of coastal countries to address the creation of marine parks or reserves to protect underwater areas as urgent, the response was very mixed, and in many countries very little action occurred.

Ray (1976) suggested that marine areas could be reserved to achieve several objectives:

1. Conservation of habitat
2. Protection of species habitat
3. Conservation of important breeding areas
4. Conservation of aesthetic values
5. Protection of cultural and archeological areas
6. Provision of sites for interpretation, education, tourism, and recreation
7. Provision of areas for research
8. Provision of areas for monitoring the effects of human activities, and
9. Acting as areas in which to train personnel in protected area management.

In 1988, the International Union for the Conservation of Nature (IUCN) defined a MPA as "any area of intertidal or sub tidal terrain, together with its overlying water and associated flora, fauna, historical and cultural features, which has been reserved by law or other effective means to protect part or all of the enclosed environment." The IUCN Commission on National Parks and Protected Areas (1994) recognized that protected areas were managed for six main reasons:

1. Strict protection (i.e., strict nature reserve or wilderness area, e.g., Laut Banda, Indonesia);
2. Ecosystem conservation and recreation (i.e., National Park e.g., Ras Mohammed National Park, Egypt);
3. Conservation of natural features (i.e., Natural Monument);
4. Conservation through active management (e.g., habitat or species management area, e.g., Galapagos marine reserve, Ecuador);
5. Landscape or seascape conservation and recreation (protected landscape or seascape, e.g., Northern Sporades, Greece);
6. Sustainable use of natural resources (managed resource protected area, e.g., Kiunga Marine National Reserve, Kenya).

IUCN proposed that marine parks should be large (more than 1,000 ha), and have both high marine conservation value and high recreational potential. Educational and recreational use in these areas should be controlled at a level which ensured that the area's natural or near natural state is maintained. In contrast, marine reserves should be areas which have some outstanding ecosystem feature and/or species of flora or fauna of natural or scientific importance or they should be representative of a particular marine area. They may contain fragile ecosystems or life forms, be areas of biological or geological diversity, or be of particular importance for the conservation of genetic resources. These reserves should be large enough to ensure the integrity of the area, to protect communities and species, and to maintain natural processes. However, IUCN also expects that they can accommodate a wide range of human activities which are compatible with their primary goal in marine and estuarine settings (Box M1).

When MPAs are selected, their special importance is usually because (Norse, 1993) they are:

1. areas of high diversity;
2. areas of high endemism;
3. areas of high productivity;
4. spawning areas that serve as a source of recruits;
5. nursery grounds; and
6. migration stopover points and bottlenecks.

Thus, although there is strong support for the co-establishment of marine parks and MPAs, the reasons for the designation of MPAs can be in conflict with the expectation that marine parks are for recreation as well as conservation. Furthermore, as Gibson and Warren (1995) stress, legislative requirements for the creation of MPAs depend upon a combination of national and international law. For example, the Law of the Sea Convention (articles 192 and 194) imposes an "obligation on States to protect and preserve the marine environment and requires

Box M1 IUCN recommends that a national system of marine protected areas should have the following objectives

- To protect and manage substantial examples of marine and estuarine systems to ensure their long-term viability and to maintain genetic diversity
- To protect depleted, threatened, rare or endangered species and populations and, in particular, to preserve habitats considered critical for the survival of such species
- To protect and manage areas of significance to the life cycles of economically important species
- To prevent outside activities from detrimentally affecting the MPAs
- To provide for the continued welfare of people affected by the creation of MPAs
- To preserve, protect, and manage historical and cultural sites and natural aesthetic values of marine and estuarine areas, for present and future generations
- To facilitate the interpretation of marine and estuarine systems for the purposes of conservation, education, and tourism
- To accommodate within appropriate management regimes a broad spectrum of human activities compatible with the primary goal in marine and estuarine settings
- To provide for research and training, and for monitoring the environmental effects of human activities, including the direct and indirect effects of development and adjacent land-use practices.

Based on Kelleher and Kenchington (1992, p. 9)

them to take action to prevent, reduce or control pollution from any source." In addition, there are obligations under the International Convention for the Prevention of Pollution from Ships 1973 (MARPOL) and the Ramsar Convention (1971), and through the International Maritime Organisation and the UNEP Regional Seas Programme to identify areas which are sensitive and should be avoided by shipping. It is not surprising, therefore, that there is so much variety amongst the world's marine parks.

Marine parks in practice

Practice varies from country to country, but many of the fundamental principles for marine park conservation and management were developed in the Great Barrier Reef of Australia. Different approaches were adopted by Japan, but both countries provide good examples of approaches to marine park establishment.

Australia's Great Barrier Reef Marine Park Act 1975 is one of the earliest examples of applying the conservation philosophy of the World Conservation Strategy. The Great Barrier Reef is the world's largest system of corals and associated life forms. It extends along the north-east coast of Australia for almost 2,000 km from the Tropic of Capricorn to about 9°S. It is a complex maze of 2,500 individual reefs ranging in size from under 1 ha to over 100 sq. km. The Reef Region exceeds 350, 000 sq. km (135, 000 sq. miles)—an area slightly larger than Poland. In the south, the Reef is wider than 100 km and is characterized by patch reefs separated by narrow winding channels or open water. To the north, the Reef is much narrower, occasionally less than 30 km, with a series of linear ribbon reefs at its eastern edge.

The Great Barrier Reef has a long history of use for fishing, with Australian aboriginal fishermen using it 15,000 years ago. With the arrival of Europeans, it became widely used for commercial fishing, including pelagic and demersal fish, prawns, scallops, turtles, and beche de mer. In addition, it is a prime location for scientific research and for a wide range of recreational activities. Between 1960 and 1983 the number of trawlers fishing within the Reef region grew from 250 to 1,400 with a turnover of about $(A) 40 million in 1983 (Kelleher, 1985). Tourism is a very important economic activity throughout the region with more than two million visitor trips to the Reef, island, and adjacent mainland in the 12 months ending in March 1980 (Kelleher, 1985). By 1997, the annual value of tourism was estimated to exceed $(A)1 billion and the direct economic value of commercial fisheries at about $(A)200 million. There are an estimated 24,300 privately registered boats involved in recreational fishing as well. In 1997, the Great Barrier Reef Marine Park Authority (GBRMPA) recorded 1.6 million visitor-days. Accessibility has improved greatly as high-speed catamarans with speeds between 25 and 35 knots have brought the Reef within 1 hr travel time from mainland towns.

The Great Barrier Marine Park Act 1975 (Section 7(1)) established the GBRMPA with the following functions (Kelleher, 1985):

(a) To make recommendations to the Minister in relation to the care and development of the Marine Park including recommendations from time to time, as to
   (i) the areas that should be declared to be parts of the Marine Park and
   (ii) the regulations that should be made under this Act
(b) To carry out, by itself or in co-operation with other institutions or persons, and to arrange for any other institutions or persons to carry out, research and investigations relevant to the Marine Park;
(c) To prepare zoning plans for the Marine Park in accordance with Part V;
(d) Such functions relating to the Marine Park as are provided for by the regulations;
(e) To do anything incidental or conducive to the performance of any of the foregoing functions.

The Park is divided into six Sections, each with a zoning plan, which aims to allow any reasonable activity, but is designed to ensure that

1. the natural qualities of the Park are conserved for users, both today and in the future;
2. suitable areas are identified where reasonable uses are permitted;
3. incompatible activities are separated; and
4. these activities do not cause unacceptable damage (Kelleher, 1985).

GBRMPA followed five phases in establishing zoning plans for each Section of the park (Kelleher, 1985):

1. All the available information on the section in industry and government reports and the scientific literature and maps was collected, collated, and studied.
2. A public participation program, using both specially prepared information as well as extensive use of the media, advised of the intention to prepare a zoning plan and sought information from the public.
3. A draft zoning plan was prepared using both the information review and the information provided by the public.
4. A second public participation program using the same approaches was used to gather comments on and reactions to the draft zoning plan.
5. After taking all comments received into account the final zoning plan was submitted to the Minister to seek approval before laying the plan before Parliament. After 20 days without any motions against the plan in either House of the Australian Parliament, the Minister published the date upon which the zoning plan would come into force. The first zoning plan, for the Capricornia Section covering over 11, 800 sq. km (4,558 sq. miles), went into force in July 1981.

The GBRMPA thus came into being after extensive public consultation and was firmly established within the legal structures of Australia. Marine Parks need to have both the support of the wide variety of stakeholders in them and it is essential that appropriate legal arrangements are in place to maintain their protected status. However, the legal processes used may not be consistent with the customary practices of indigenous peoples who live and use them. Their interests must be safeguarded, not least because they are often custodians of information about the ecology and heritage of these sites.

Monitoring and research are very important for both the establishment of Marine Parks and their sustainable management. The GBRMPA identified three information and research needs (Kelleher, 1985):

1. Information management, to ensure that information is available for analysis and interpretation.
2. Analysis of use to understand how the area is used, the effects of these uses on physical, biological, and economic processes, and their intensity, patterns, and rates of change. Changes which may be due to external factors such as sea-level rise or climate change and effects which are related to the uses themselves can be identified.
3. Resource analysis building up an inventory of the physical, chemical, human, and biological processes.

This approach to resource analysis, use analysis and information management has provided a model for the approach to marine parks. It acknowledges that marine parks are valued economic and social resources where the use of the resources must be monitored, managed, and if necessary changed to ensure the longer-term survival of the park's habitats and economy. The process of marine park management is a continuous one and in July 1998 the GBRMPA was restructured in order to strengthen its focus upon four major critical issues:

1. fisheries;
2. tourism and recreation;
3. water quality and coastal development; and
4. conservation, biodiversity, and World Heritage.

These four themes have increasingly become concerns for many marine parks and protected areas, for sometimes they are victims of their own success. As they attract visitors, so the pressures both within the parks and along adjacent coasts have grown. At the same time, there has been a growing recognition that management of the water quality of these areas depends upon management of the catchments that drain toward them. The emphasis has shifted toward more holistic management of the coastal zone within which the marine parks are sited.

Whereas, the GBRMPA approach applies to a specific very large feature, the Japanese approach is designed as a frame-work for the development of marine parks, many of which are small in comparison, throughout Japan. In 1931, Japan passed a National Parks Law to allow the creation of parks for protection of scenery and for recreation (Marsh, 1985). Between 1934 and 1936, 12 areas were designated, including some coastal sites, the largest being the Inland Sea (Seto Naikai). The Natural Parks Law of 1957 defined the purpose of parks as

> the protection of places of scenic beauty, and also, through the promoted use thereof, as a contribution to the health, recreation and culture of the people.

The Law provided for three types of parks: National Park, Quasi-National Parks, and Prefectural Nature Parks. By the mid-1980s, Japan had 27 National Parks, 54 Quasi-National Parks, and 297 Prefecture Nature Parks, many of which were coastal in location. Following the First World National Parks Conference in 1962 which drew international attention to marine parks, the Nature Conservation Society of Japan (NCSJ) set up a marine parks investigation committee in 1964. In 1966, the Ministry of Health and Welfare financed the investigation and in 1967, the NCSJ committee became an independent foundation: the Marine Parks Center of Japan. In 1970, the Natural Parks Law was amended to allow the creation of marine parks within national parks. Ten were designated immediately and a further 12 in 1971. By 1985, there were 23 Marine Parks adjacent to 10 National and 13 Quasi-National Parks. They included 57 Marine Park Areas (special zones within marine parks) totaling 2,387 ha and ranging in size from 3.6 ha to over 233 ha. Marine Parks aim at "preserving beautiful underseascapes." Criteria for selection required (Marsh, 1985) that:

1. both land and sea areas surrounding the Marine Park Area are designated as National or Quasi-National Park and that nature conservation on land can be fully ensured;
2. the seabed topography is typical of the area and undersea fauna and flora abundant;
3. seawater should be transparent and unlikely to become turbid or polluted;
4. water depths are not more than 20 m;
5. there are slow currents and the park is sheltered from violent waves;
6 on land, there should be enough space to construct such facilities as landing piers, rest houses, visitor centers, and car parks;
7. there should be coordination with local fisheries concerning their use of the Marine Park, and;
8. the slightest risk of destruction of under-seascapes by all kinds of industrial exploitation should be prevented.

A marine park is defined as the total area comprising three zones:

1. Ordinary Area—including that part of the park within 1 km of the coastline.
2. MPA: the areas within the park having specific features warranting the most protection.
3. Ordinary or buffer zone including the area within 1 km of the MPA.

In practice, most Japanese marine parks are divided into two zones: the Ordinary Area zone including the sea within 1 km of the MPA or the coastline and the MPA core zone.

For some countries, the criteria are simpler, but explicit. For example, the 38 Malaysian marine parks were established in order to protect and conserve (1) the marine ecosystem, especially the coral reefs, for the management of the fisheries resources in the coastal waters in order to maintain/increase fish landings and (2) the coral reefs for research on biodiversity, and for the purposes of education and recreation/eco-tourism. There is thus a very strong emphasis on the economic importance of these areas for fisheries and tourism.

In contrast, in some regions where mass-tourism was established early and has ceased to grow rapidly, marine protected areas may be an effective way to restore damaged environments. For example, after tourism to Spain slowed down in the 1990s, it decided to establish a protected area every 30 km along the coast to ensure the maintenance of marine and terrestrial fauna and flora. Many sites that have been partly damaged could be restored, in particular around the main areas of interest for tourism (Gubbay, 1995). Spain has created some 25 protected areas on the Mediterranean coastline, 6 related to the coast or sea. MPAs come under the jurisdiction of the Ministry of Agriculture, Fisheries and Food and include a wide range of sites both in reasons for designation and in size (Table M6).

In contrast, Finland has designated MPAs within the context of the needs of a Regional Sea: the Baltic. Finland is a signatory to the Helsinki Convention that requires its members to protect the marine environment and biodiversity (HELCOM, 1996). Both marine and coastal biotopes are included within the framework of HELCOM initiatives for the protection of species, habitats, and ecological processes including the establishment of coastal and marine Baltic Sea Protected Areas (BSPAs). This is unusual in that it recognizes that MPAs are often natural units which cross national marine boundaries and that cooperation within Regional Seas is essential. Finland has eight proposed BSPAs, most of which are already protected as National Parks. For example, the Archipelago National Park, established in 1983, forms the core of a larger Archipelago Sea Biosphere Reserve established by UNESCO in 1994. It consists of around 1,000 islands and islets with important bird areas forming clusters separated by large expanses of open water. Although it is open to the public, there are restrictions, including prohibition of landing, especially during the nesting season.

Italy has designated more than 70 marine and coastal protected areas, including Marine Natural Reserve (MNR), Nature Reserve (NR), Special Protection Area (SPA), Fisheries Reserve, Biogenic Reserves, Recreation Parks, State Reserves, Marine Reserves and Parks, and Marine Sanctuaries. The designations take into account such treaties as the Mediterranean Action Plan and the Ramsar Convention (WCMC, 2001). As well as subscribing to internationally recognized initiatives, due to its position sharing borders and waters with seven states, Italy

Table M6 Spanish MPAs and other Spanish-protected areas of international importance

MPAs (Mediterranean coast)	Biosphere Reserves	World Heritage Site
Medas Islands Marine Reserve (40 ha)	Donaña National Park	Salinas de Ibiza y Formentera Nature Reserve
S' Arenal Regional Protected Landscape (400 ha)	Island of Minorca	(protecting oceanic *Posidonia* sea grass beds)
Tabarca Marine Reserve (1463 ha)	(including protection of the sea adjacent to protected core areas)	
Columbretes Natural Park and Marine Reserve (5,766 ha)		
Archipelago de Cabrera National Park (Balearic Islands) (10,000 ha)		
Cabo de Gata Nature Park and Marine Reserve (26,000 ha)

has agreements with them for protection of the marine and coastal environment. For example, an international marine reserve was established between Sardinia and Liguria (Italy), Corsica (France), and Provence (France and Monaco) in 1993. There is thus considerable variety in the approach taken within Europe as areas that have often been exploited for centuries are given protection and restoration is undertaken.

In North America, both the United States and Canada have identified a wide range of areas which should be designated as MPAs, including marine parks. MPAs are frequently protected primarily to conserve important biological or historical features, but many are also marine parks although they are not so designated because they allow access for recreational activities. In Michigan, for example, the Great Lakes Bottomland Preserves are designated in order to protect shipwrecks of historical importance. The Michigan Department of Natural Resources Underwater Salvage Committee has emphasized that, whereas underwater parks would provide physical facilities for recreational divers such as slipway access and interpretation programs, bottomland preserves are intended to be set-aside areas where little or no salvage will be allowed and they are recognized as areas of distinctive historic and/or recreational interest.

The United States has a very large number of MPAs, but only one area specifically designated as a Marine Park (Julia Pfeiffer Burns MP in California) and there are 13 State Marine Parks (2 in Washington and 11 in Alaska). There is a single Aquatic Park at Estero Bay in Florida. This is not uncommon. South Africa, for example, has only two Marine Reserves and the United Kingdom has no Marine Parks, although it has a very large number of MPAs.

Canada has a long-established system of national parks, the first being established in 1885 in part of what is now the Banff National Park. However, its marine national park system only came into effect in 1986 with the National Marine Parks Policy. In contrast to many countries, Canada has based its marine parks system on the fundamental principle that it should protect the country's major biogeographical provinces, specifically the Arctic, Atlantic, and Pacific marine environments and the Great Lakes, by sampling their representative, outstanding, and unique characteristics. This is based upon a broad-scale hierarchical system of biogeographic units or "marine regions" (Mondor, 1992). In establishing the marine parks, the emphasis has been upon ensuring that there is a steady movement toward each marine region being represented: for example, the St. Lawrence River Estuary marine region is represented by the Saguenay Marine Park. For countries that are working toward establishing marine parks, this well-tried approach is recommended by IUCN, but for many less-developed countries, there is neither the funding nor information to carry out such a comprehensive approach. Establishment of marine parks may be as a result much more ad hoc.

The variety of existing practice in selection of MPAs has led IUCN to draw upon best practice and experience to identify criteria for deciding upon areas within MPAs or for determining their boundaries (Box M2).

Box M2 IUCN criteria for inclusion within MPAs and delimiting boundaries.

- Naturalness
- Biogeographic importance
- Ecological importance
- Economic importance
- Social importance
- Scientific importance
- International or national significance
- Practicality/feasibility

Seven-stage sequence of decision-making in establishing and managing an MPA

(1) Legal establishment of boundaries
(2) Zoning
(3) Enactment of zoning regulations
(4) Specific-site planning
(5) Specific-site regulation
(6) Day-to-day management
(7) Review and revision of management

At each stage, the following should be taken into account

- Geographical habitat classification
- Physical and biological resources
- Climate
- Access
- History
- Current usage
- Management issues and policies
- Management resources

Economic value of marine parks

The economic value of marine parks has been the key driver for much of their development especially in tropical areas where coral reefs are often the main attractions and where, as a result, considerable tourism income is generated. Marine parks both attempt to provide appropriate levels of protection to the natural resources of the parks and to maximize tourist income. These objectives, however, are often incompatible. However, organizations such as the Marine Conservation Society have played a role in developing codes of conduct for divers, which point out the risks of permanent damage to coral. There may be conflicts between traditional users of newly designated parks, especially fishermen, and in some areas, for example, the Seychelles, steps were taken to allow traditional uses to continue. Dixon and Sherman (1990) showed that the Virgin Islands National Park produced considerable profits for the local economy.

Involvement of the community

Ultimately, the success and sustainability of marine parks depends upon the people who use them as visitors and the local community that often depends upon them for its livelihood. So, for example, in the Balicasag Island Municipal Marine Park in the Philippines key elements in its development included involving the project community worker into the community and baseline data collection, education, organization of a resource management core group, building responsibility around beneficial projects, and formalizing the community in management of the park. Continuity of management was essential for success—it means that the local community has a consistent point of liaison within the park (White and Dobias, 1990). If visitors enjoy the parks, but cause irretrievable damage to the ecosystems and disrupt the livelihoods of the human communities which depend upon food from the sea, they will destroy for future generations the same opportunity to enjoy and wonder at the beauty of the undersea world. Users are expected to respect and to help preserve the parks. This depends upon responsible use and it is now common to inform recreationists, especially divers, of good practice. Typically, this information is available both on websites as well as at the parks themselves. It usually focuses on

1. *Good diving practice*, such as obtaining local diving information from qualified local diving operator before diving and maintaining proper buoyancy control. This includes being aware of and obeying all the marine parks regulations.
2. *Prevention of direct damage* to coral reefs, by using rest floats provided by the park authorities, and using only the mooring buoys in the parks. Dropping anchors on reefs causes serious damage.
3. *Avoidance of impacts* on the underwater plants, animals, and fish. This means being aware of potential impacts on aquatic life through interactions with it; leaving litter, feeding fishes or provoking them, and collecting corals and shells for souvenirs should be avoided. Underwater photography is encouraged instead. There is also an expectation that any environmental disturbances or destruction observed during dives are reported to marine park centers so that park staff can prevent further damage or reduce its impact.
4. *Involvement in and support* for marine park activities, such as education and practical conservation work to help conserve the marine habitats and species.

Note. The International Union for the Conservation of Nature (IUCN) World Conservation Monitoring Centre (WCMC) in Cambridge, England, is the most important source of information regarding protected sites. Further reading on this topic may be found in Cognetti (1990), Forest and Park Service (2000), Halsey (1985), Kenchington (1991), Kenchington and Hudson (1984), and Salm and Clark (1984).

Conclusion

Marine parks, MPAs, and similar designations have a common goal: better understanding of the marine environment for the benefit of all who depend upon them. They depend upon sustained resources and incomes, the latter often from tourism, but this can be a source of conflict. Fortunately, there is a growing awareness, often because of the excellent public education programs that many parks run, that these are areas which must be nurtured and managed with the highest quality of understanding of their natural and human systems. Lien and Graham (1985) recognized that the establishment of marine parks would be difficult but rewarding. Marine ecosystems would present new challenges, partly because of the natural characteristics and partly because legal and constitutional problems would confront park managers and planners. They anticipated that research, management, and education would present technological problems which would need new and creative approaches. It would be untrue to say that all those challenges have been overcome, but the spread of marine parks, the common acceptance that these represent a window on the ocean commons and the increased use of new technologies to explore, understand, explain, and nurture the marine ecosystems mean that the challenges which Lien and Graham foresaw have been identified and confronted. As these areas come under greater pressure during the early 21st century, the challenges will remain.

MARINE TERRACES

A marine terrace is any relatively flat, horizontal, or gently inclined surface of marine origin, bounded by a steeper ascending slope on one side and by a steeper descending slope on the opposite side. In temperate regions, marine terraces often result from marine erosion (abrasion or denudation) (*marine-cut* terraces, or shore platforms) or consist of shallow-water to slightly emerged accumulations of materials removed by shore erosion (*marine-built* terraces). In intertropical regions they may also result from bioconstruction by coral reefs and accumulation of reef materials (reef flats).

The development of a series of elevated, stepped marine terraces usually corresponds to the superimposition of eustatic changes in sea level and of a tectonic uplifting trend. Uplifted terraces act in this case as a continuous tape recorder, each step developing when the rising sea level overtakes the rising land. Each raised terrace, eventually capped by marine and/or alluvial materials, is a fossil counterpart of the present-day terrace, platform, or reef flat. For relatively rapid uplift rates (e.g., >1 mm/yr), each marine terrace corresponds to a different interglacial period or stage and ages usually increase with elevation, the uppermost levels being also the less well-preserved. For slower uplift rates, marine terraces may have a polycyclic origin, sea level returning again at the terrace level after a period of exposure to weathering.

When reconstructing past sea-level changes from the study of datable raised marine terraces, two assumptions are usually made: (1) that the eustatic sea-level position corresponding to at least one raised terrace is known and (2) that the uplift rate has remained essentially constant in each section. From these assumptions, the eustatic sea level can be calculated for each dated terrace (Pirazzoli, 1993). Bloom and Yonekura (1990) proposed a calculation procedure in which the assumption of a constant rate of dislocation becomes unnecessary when a sequence of dated emerged terraces is found at different heights on several transects.

Example of a sequence of stepped Quaternary marine terraces: Sumba Island, Indonesia

An exceptional sequence of raised coral reef terraces is preserved at Cape Laundi, on the north coast of the island, between the present sea level and an ancient patch reef now at 475 m above sea level. At least 11 terraces are wider than 100 m, 6 of them even being over half-a-kilometer-wide. Most of these terraces are polycyclic in origin and can be subdivided into a number of secondary levels by more or less continuous scarps or by alignments of fossil reef ridges. ESR, Th/U, and ^{14}C date estimations of almost unrecrystallized corals, most of them in growth position, have made possible the identification of the younger terraces (up to isotope Stage 9 (ca. 330 ka ago) and of those corresponding to isotope Stage 15 (ca. 600 ka ago). When the most likely uplift trend deduced from the present altitude of dated terraces (ca. 0.5 mm/yr) is extrapolated to the whole raised section, most geomorphological features appear to correspond to interglacial stages, up to Stage 27 (ca. 0.99 Ma) for the uppermost patch reef (Pirazzoli *et al*., 1993) (Figure M11).

Paolo A. Pirazzoli

Figure M11 The uppermost sequence of marine terraces at Cape Laundi, Sumba Island, Indonesia. Behind the very wide Terrace II (in the foreground, at elevations between 135±10 m and 110 ± 5 m, developed during isotope Stages 9 and 7), six major steps of coral reef terraces, visible in the background up to 475 m, developed between about 330 ka and one million years ago (Photo B466, September 1988).

MASS WASTING

Mass wasting, the movement of material downslope by gravity, occurs as slopes evolve toward stable, equilibrium forms. Active coastal slopes are often in short rather than long-term stability, because of wave undercutting, oversteepening, and the removal of basal debris. For convenience, a distinction is made in this discussion between the types of mass wasting that occur on rock and cohesive clay coasts. Some slope movements occur on both types of coast, however, and many cliffs consist of variable combinations of rock and clay. Nevertheless, translational slides and the free fall of material from steep slopes tend to be typical of rock coasts, whereas deep rotational slumps and shallower slides and flows of wet material are more common on cohesive clay coasts (Trenhaile, 1987, 1997; Sunamura, 1992; Viles and Spencer, 1995).

Rock coasts

Fresh rock surfaces and the presence of debris at the foot of cliffs testify to the importance of rock falls on many coasts. Although they occur more often than deep-seated slides, most falls are much smaller, and they are therefore less frequently reported. Rock falls are particularly common in well-fractured rocks where there is undercutting by wave action, bioerosion, or chemical solution, or differential erosion of weaker rocks at the cliff base. In cool environments, rock falls tend to occur when frost is most active, although this may reflect high water pressures in rock clefts generated by snow melt and precipitation in spring and autumn, rather than the effects of frost action. It has also been suggested that tides can generate damaging fluctuations in water pressure in rock cliffs. This could explain why the size and frequency of rock and slab falls in the Bay of Fundy, for example, increase eastwards, as the tidal range increases. Many falls are caused by the reduction in confining pressures resulting from cliff erosion and retreat, and the formation of tension cracks parallel to the cliff face. Deep tension cracks in massive, cohesive rocks allow large slabs, as opposed to rock rubble, to be released. Slabs can also topple or overturn by forward tilting, particularly in rocks that consist of columns defined by joints, cleavage, or bedding planes which dip into the rock mass. Topples are able to occur on slopes whose gradients are lower than those associated with landslides.

Rock and slab falls, sags, and topples and other surficial failures are generally the result of weathering, basal erosion, and hydrostatic pressures exerted by water in rock clefts, whereas deep-seated slides occur in rocks that have been weakened by alternate wetting and drying, clay mineral swelling, or deep chemical weathering. Translational movements occur along straight slide surfaces. They are structurally controlled, and are usually associated with seaward dipping rocks, alternations of permeable and impermeable strata, massive rocks overlying incompetent materials, or argillaceous and other easily sheared rocks with low bearing strength. The failure surface is frequently a bedding, cleavage, or joint plane. Deep-seated rotational slumps are most common in thick and fairly homogeneous deposits of clay or shale, but more irregular slumps can occur in rock, where they tend to combine the characteristics of slumps with those of translational slides.

Coastal landslides have been particularly well-documented in the Chalk along the southern coast of England and along the Pacific Coast of the United States. In southern England, most slides have occurred where chalk and other arenaceous and calcareous sedimentary rocks are underlain by clay, shales, marls, or mudstones. Most slides are deep-seated rotational movements, although they also involve mudslides, slab failure, surficial sliding, toppling, sagging, and rock falls. Many slides have occurred in seaward dipping igneous and sedimentary rocks on the coast of northern Oregon, and along seaward-plunging synclines in southern California. A bentonite bed in shales and limestones provided an incompetent horizon for sliding at Portuguese Bend, near Los Angeles, whereas the large block glide at Point Firmin, about 8 km to the east, occurred along the bedding planes of shales that dip seawards at between 10° and 22°.

Cohesive masses fail when there is a critical combination of slope height and angle, in relation to the strength and bulk density of the material. The occurrence of joints, bedding planes, faults, and other discontinuities are more important, however, than the strength of the rock *per se*. Terzaghi (1962) considered the effect of the joint pattern on the critical slope angle of cliffs—the steepest gradient which can be maintained in long-term stability. His analysis showed that slope stability in jointed rocks largely depends upon the joint pattern and orientation, and to a lesser extent upon the effective cohesion of the rock mass. The principles of rock mechanics are increasingly being applied and incorporated into simulation models to determine failure mechanisms and to account for erosion rates and variations in the form of coastal cliffs, and to account for the formation and shape of marine caves (Davies and Williams, 1986; Allison and Kimber, 1998). In southern Wales, for example, it has been shown that translation failures commonly result from the formation of tension cracks near the cliff face, and toppling where there are tension cracks and basal undercutting. Translational failure is dominant where mudstones are prevalent at the cliff base, but toppling is more common where limestones provide a fulcrum at the foot of the cliff. The safety factor is inversely related to the ratio of the depth of undercutting at the cliff base to the distance of the tension crack from the cliff face. Numerical modeling, based on a range of geo-technical parameters, has also been used to predict the most likely modes of failure in the cliffs of southwestern Wales (Davies *et al.*, 1998).

Landsliding events are generally triggered by the build-up of groundwater, and they tend to take place during or shortly after snowmelt, or prolonged and/or intense precipitation. Groundwater reservoirs provide a water supply that is less dependent on seasonal rainfall, and further instability can result from the ponding of water in surface depressions that were created by older landslide events. Water washes out beds of sand in potential slide masses, causing swelling and the generation of pressures in argillaceous rocks, it generates high pore and cleft water pressures, and it softens colluvial materials allowing them to flow. The lubricating effect of water is not considered to be important, however, and the increase in weight of the potential slip mass as a result of water absorption is only of minor significance. Water can initiate slides in permeable rocks that overlie impermeable materials, and where massive, heavy rocks are on top of wet, impermeable clay or shale. Water from septic systems, irrigation, runoff disruption, and other human activities are playing increasingly important roles in some areas (Griggs and Trenhaile, 1994). For example, septic tanks and cesspools associated with residential development may have exacerbated slope instability at Portuguese Bend in southern California, and irrigation may have played a similar role at Point Firmin.

There is also a close cause-and-effect relationship between wave action, which undercuts and steepens coastal slopes, and the occurrence of landslides. Therefore, the degree of protection afforded to a cliff by beach material can be of enormous importance in determining its stability. The damming of rivers and the building of groins and other coastal structures has reduced longshore sediment transport in some areas, depleting beaches and exposing the cliffs to more vigorous wave action. For example, at Newhaven, in southern England, the build-up of coarse clastic material behind a jetty has provided protection to the cliff behind, whereas interruption of the littoral drift by the development of Folkestone Harbor may have been responsible for the increased activity of slides in the late 19th and early 20th centuries.

Changing sea level, whether on a geological or tidal time scale, causes the water table to fluctuate within potential slide masses. Pore and cleft water pressures vary with tidal ebb and flow, and cliffs may be most unstable when there are high water tables and low tides. Landslides can occur during high tidal periods, however, because of the increased ratio between pore pressures and the total overburden at the base of the slide (i.e., increased buoyancy at the toe of the slope) (Muir-Wood, 1971). In addition to the buoyant effect of the water, it has been suggested that the Portuguese Bend landslide in southern California is most unstable during high tidal periods because of increased pore water pressure, and saturation of the slide material and the basal shear plane at the base of the slide.

Cohesive clay coasts

The erosive resistance of a cohesive material is complex—it depends upon the water content and the properties of the pore water and eroding fluid, as well as the clay content and its plasticity, structure, consolidation pressure, and compressive or shear strength. Small pieces of clay can be eroded by pitting and flaking, but larger units can be removed by spalling along fractures and sandy planes.

Cliffs of sand and gravel tend to erode more rapidly than silt and clay, although this can be partly offset by the formation of protective, coarse-grained beaches at the cliff base. The accumulation of coarse sediment determines the accessibility of the cliff base to wave action. Rates and modes of cliff erosion can therefore vary according to the amount of beach material and the morphology of the beach profile (Jones and Williams, 1991; Shih and Komar, 1994). Eroded fine-grained cohesive sediment is generally carried offshore as suspended load, and as it provides no protection to the cliff, there is generally no relationship between the height of a clay cliff and its rate of erosion.

Because of variations in wave energy, temperature, precipitation, and groundwater pressures, the subaerial and marine erosion of cohesive coasts in temperate regions is often markedly seasonal in nature (Brunsden, 1984). The strength and stability of clay materials is affected by variations in the groundwater level. Mass wasting also occurs where grains are removed by seepage or piping of outflowing groundwater, which causes back sapping and collapse of the free face, often by toppling. Although seepage is generally associated with coarse silts to fine sands, it can also occur in clays, and it often develops at the base of water bearing fine, predominantly cohesionless, material underlain by an aquiclude.

There is a strong relationship between the frequency and mobility of slope movements in cohesive sediments and the presence of clays with a high proportion of swelling minerals. For example, mudslides in Denmark occur in clays that are dominated by swelling montmorillonite minerals, and the most mobile and furthest advanced portion of a mudflow in northeastern Ireland has the highest montmorillonite and illite to kaolinite ratios. Although slides occur in materials with the highest proportion of swelling clay minerals and the highest plasticity on St. Lucia and Barbados, soil plasticity is also sensitive to the types of exchangeable metal cations held in association with the clay minerals. The occurrence of large amounts of sodium in montmorillonite-rich clays, for example, increases their plasticity.

Shallow sliding occurs in cohesive sediments as mudslides or, if the water content is very high, as mudflows (Figure M12). High moisture content is not required for flow initiation in fine-grained, cohesionless materials, but it must be above the liquid limit if there is a high proportion of clay. Mudslides have a bimodal shape, consisting of fairly steep feeder flows and gently sloping accumulation flows composed of single or overlapping lobes of clay and other debris. Shallow rotational sliding produces miniature slump blocks along the frontal edge, which has a steeper slope than the accumulation area. The feeder zones begin to move with the seasonal rise in groundwater levels. Surface and subsurface movements in the accumulation zone are largely by shearing at its boundaries, and material can be incorporated in the mudslides from below. Other material is added to the flows by falls and slides from the bowl-shaped head zone and from the sides, and it may help to trigger rapid surges, usually following periods of heavy rainfall. Deep-seated rotational landslides also occur where basal erosion is rapid enough to remove the mudflow debris and then steepen the coastal slope.

Hutchinson's (1973) form/process classification of cliffs in the London Clay of southeastern England is based on the relative rates of basal marine erosion and subaerial weathering (see *Cliffed Coasts*):

1. Type 1 occurs where the rate of basal erosion is broadly in balance with weathering and the rate of sediment supply to the toe of the slope by shallow mudsliding. The slope undergoes parallel retreat and erosion only removes slide material, as opposed to *in situ* clay (Figure M12).
2. Type 2 cliffs occur where basal erosion is more rapid than weathering. The cliff experiences cyclical degradation, with slope steepness varying between upper and lower values corresponding to toe erosion and degradation and deep-seated, slump-dominant modes, respectively (Figure M13).
3. Type 3 cliff slopes develop when a cliff is abandoned by the sea and debris is carried to its foot by a series of shallow rotational slides. Abandoned cliffs therefore often have a steeper upper slope on which landsliding is initiated, and a flatter lower slope where colluvium accumulates.

Spatial variations in cliff type along the shore of Lake Erie reflect variations in wave intensity and the type of glacial sediment, whereas

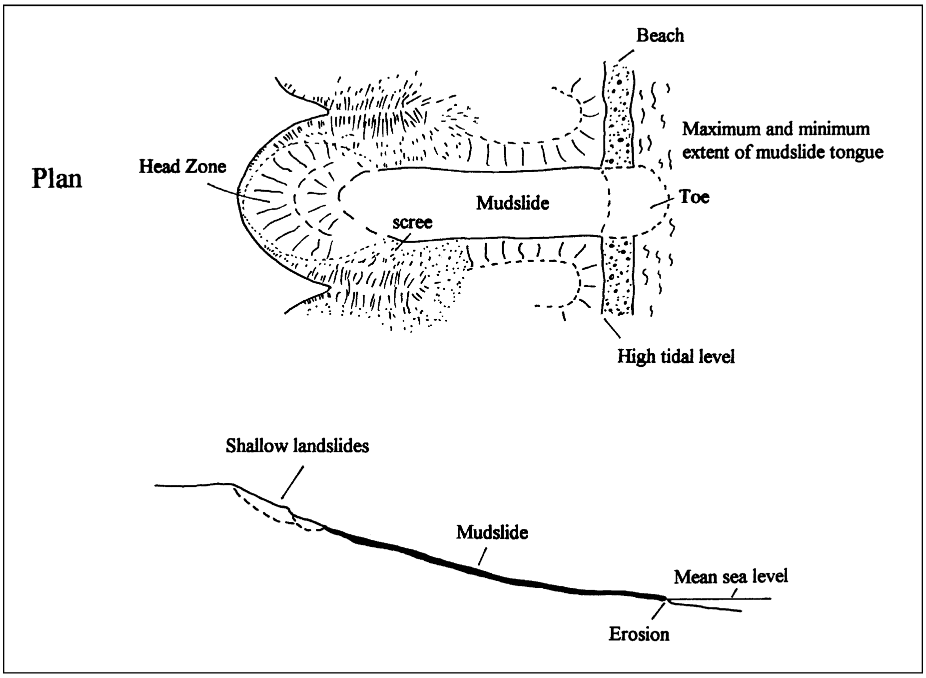

Figure M12 Mudslide in London Clay cliff with moderate wave erosion (from Hutchinson, 1973 by permission of Building Research Establishment Ltd, UK).

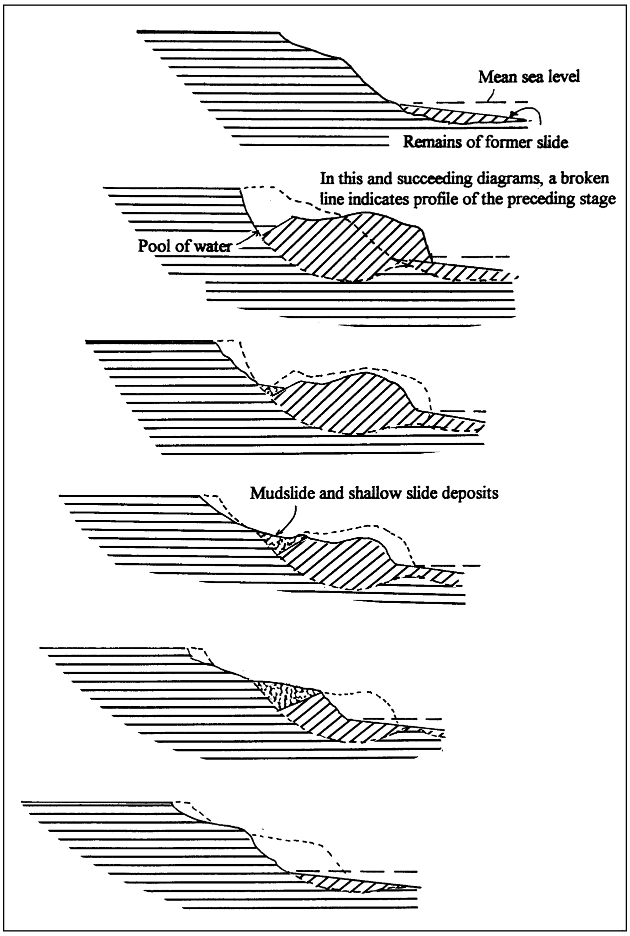

Figure M13 The cyclical behavior of London Clay cliffs with strong wave erosion (from Hutchinson, 1973 by permission of Building Research Establishment Ltd, UK).

temporal changes occur in response to changes in lake level. Type 1 cliffs develop during periods of normal lake levels, when there are moderate rates of cliff retreat; type 2 during periods of high lake levels and rapid cliff retreat; and type 3 during periods of low water levels and slow basal erosion. Quigley *et al.* (1977) distinguished four types of cyclical instability in this area, according to variations in cliff height, wave height, and rates of cliff retreat. Although Hutchinson's classification is also generally applicable to cohesive cliffs in Denmark, glacio-isostatic recovery and changes in relative sea level are responsible for some significant differences.

Hutchinson's model is generally applicable to a wide range of cohesive sediments, but alternate models of cliff retreat are relevant to specific areas. For example, shallow, planar landslides have been found to be more important than larger but less frequent rotational landslides in glacial sediments in northeastern Ireland. Bromhead (1979) considered that the transition from one type of cliff to another largely depends upon the nature of the material at the crest of the slope, and to a lesser degree on its groundwater hydrology, rather than on the relative rates of subaerial and marine erosion. He suggested that mudsliding dominates if the material at the crest of the slope is similar to that in the rest of the slope. Mudsliding is inhibited, however, if there is stronger or better drained material at the crest. The lack of protective debris at the cliff foot then allows wave action to erode and oversteepen the cliff, ultimately precipitating a deep-seated rotational landslide. These slides tend to be of the multiple rotational type when the cliffs are capped with a thick, hard, and jointed caprock.

METEOROLOGICAL EFFECTS ON COASTS

The most dramatic and long-lasting meteorological impact on many coasts is in response to storms. Virtually, every continent on earth is variously impacted by storms, the degree to which being a function of many factors including storm intensity, duration and path, as well as antecedent geology of the inner shelf and coast. Cyclones that exert important controls on coasts are generally categorized as hurricanes, tropical, and extratropical storms. Land- and sea-breezes are observed along many coasts and are in response to differential temperatures during day and night; onshore winds during the day develop nearshore sea state, whereas offshore flow in the evening causes wave decay close to shore. Neither effect can equal the impacts of waves, currents, and winds generated during cyclones. The low latitudes are dominated by tropical storms and hurricanes, whereas the mid- and higher-latitudes experience extratropical storms and weather fronts. Frontal systems are associated with extratropical cyclone development.

Mid-latitude cyclones and their associated fronts significantly impact all of the coasts of the United States, although the frequencies of major storms decrease from north to south along both the Atlantic and Pacific coasts. Along the Pacific northwest and New England coasts, mid-latitude cyclone frequencies can range upwards to two or three storms per week during winter months, with average frequencies decreasing to one or less a month in southern Florida and southern California. Seasonally, mid-latitude cyclones occur year round along northern coasts, although frequencies and intensities are much lower in the summer. Local and regional coastal configuration and orientation strongly modify exposure to storm processes. For example, Cape Hatteras on the Atlantic and Point Reyes on the Pacific coast are particularly vulnerable given their orientation. Similarly, the northern Gulf of Mexico experiences significant coastal change during frontal events given its general east–west orientation. As an example of rapid and intensive cyclogenesis, the "Storm of the Century," an intense extratropical cyclone, comparable in strength to a category 1 hurricane, formed in the western Gulf of Mexico in March 1993 and inflicted major damage along the Gulf Coast's beaches and low-lying areas (Schumann *et al*., 1995).

Cold fronts are usually initiated by outbreaks of cold air (Polar air masses) from Canada, which advances south, and southeast where they ultimately encounter warm air. Each year up to 30 fronts move south and significantly impact the Gulf of Mexico and southeast Atlantic beaches. As the frontal systems push south, strong southerly winds ahead of the fronts generate deepwater waves whose significant wave height may exceed 5 m. Considerable water level set up occurs along the ocean-facing beaches. A considerable degree of beach erosion and dune breaching accompanies this pre-frontal stage, particularly along low-lying coasts such as Louisiana. This pre-frontal period can last up to several days preceding the arrival of the front. During this period, a considerable volume of water is funneled into the bays, lagoons, and sounds behind the barrier coasts causing elevated water levels. As the front moves across the coast a dramatic wind shift from the south to the north occurs over a matter of hours. While nearshore waves are suppressed in the Gulf and Atlantic during this period of strong northerly winds, high frequency, steep waves are generated in the bays and lagoons where fetch lengths permit. During this post-frontal phase significant wave heights approaching 3 m have been measured in some bays fringing the northern Gulf. Research now suggests that these frontal passages cause dramatic changes to the soundside beaches of the southeast and Gulf bay shores and is the primary process behind chronic coastal erosion.

Each year several of the mid-latitude cyclones evolve into powerful coastal storms with typical storm tracks from southwest to northeast along the Atlantic coast. These storms have traditionally been called Nor'Easters because of the strong winds that blow from the northeast ahead of the warm fronts. The most severe occur in October and November and again in March and April. These storms usually develop and intensify as they move parallel to the coast toward the northeast. The Ash Wednesday storm of 1962 was one of the most powerful Nor'Easters to impact the East coast of the United States. Generating deepwater significant wave height in excess of 10 m, the Ash Wednesday storm caused severe erosion along a 1,000 km stretch of coast from North Carolina to Long Island, New York. Because of the danger to life and property and the importance of predicting the explosive dynamics of storm development, a concerted research effort has been directed toward enhancing our comprehension of these systems. After the Ash Wednesday storm, a detailed compilation of powerful coastal storms was compiled (Mather *et al*., 1964) and more recently, the major coastal storms from New England to Florida have been classified by synoptic weather situations and evaluated in terms of changing frequencies of severe events through many decades (Dolan and Davis, 1992).

Tropical storms and hurricanes also impact the entire US mainland coast from New England to Texas, and to a much lesser extent, southern California. The season extends from June through November and thus there is overlap with mid-latitude cyclones in the fall. Unlike mid-latitude cyclones, tropical storms and hurricanes originate over the eastern tropical Atlantic, Caribbean Sea, and Gulf of Mexico. Tracks are generally westward over the tropical Atlantic then recurve northward to the North American coast (Figure M14).

Hurricanes are much smaller than mid-latitude cyclones, and unless the track is close to and parallel with the coast, the severe impacts are restricted to much shorter segments of the coastline (Muller and Stone, 2001).

A direct strike by a major hurricane is more devastating than mid-latitude cyclones because wind speeds, storm surges, and waves are generally much higher. Because of the counter-clockwise circulation of surface winds in a hurricane in the Northern Hemisphere, wind speeds, surge, and waves are generally higher to the right of the system than to the left. Severe morphological change and destruction to infrastructure along coasts is most often limited to a coastal segment no more than 25–50 km to the right of the location at which the storm makes landfall (Muller and Stone, 2001). At many locations in the southeastern United States, tropical storms impact the coast as frequently as once every three to four years on average, whereas the recurrence of major hurricanes is much more infrequent. As an example, in south Louisiana and south Florida the recurrence interval for these storms is every 10 to 15 years on average, and only once every 100 years along the more sheltered coast of Georgia (Elsner and Kara, 1999; Muller and Stone, 2001). In recent years, there has been considerable research conducted on decadal or longer storm-track patterns which result in long runs of years with very limited storm activity followed by shorter runs of years with frequent storms (Gray, 1999). Since the mid-1990s, the clustering of storms has resulted in a marked increase in beach erosion along significant portions of the southeastern United States (Stone *et al*., 1996, 1999). In turn, this has resulted in a marked increase in new beach nourishment and renourishment projects costing tens of millions of US dollars.

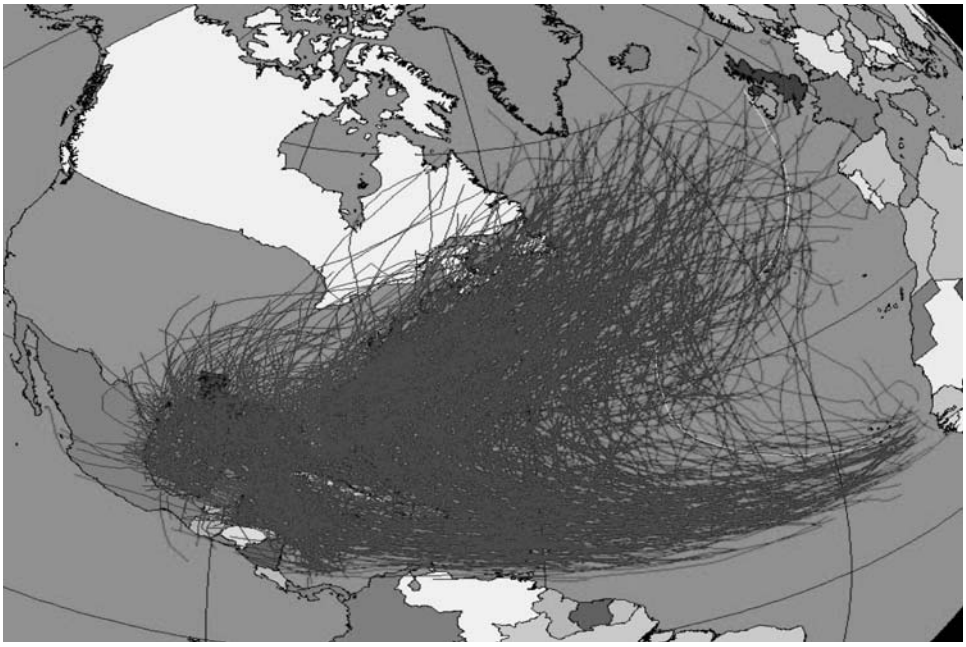

Figure M14 North Atlantic hurricane tracks from 1886–1996. (Data obtained from National Oceanic and Atmospheric Administration, National Hurricane Center.)

The coast of southern California and Baja California are also susceptible to tropical storm and hurricane impacts that move from southern Mexico northwestward parallel with the coast. Each hurricane season there are numerous tropical storms and hurricanes generated off the southwestern coast of Mexico, however, most storms eventually move to the west out to sea. The rare storm that affects southern California is feared more for heavy rains and subsequent flooding rather than high winds, surge, and waves. One of the most memorable of these events caused much unexpected flooding in the Los Angeles basin in September 1939 (Hurd, 1939).

The coasts of the Great Lakes are subject to frequent mid-latitude cyclones, normally moving from southwest to northeast across the lakes and eventually down the St. Lawrence River valley to the Atlantic. Frequencies of mid-latitude cyclones and associated fronts can be as high as six or more per month from October to May, with frequencies and especially intensities much lower in summer. Similar to the Atlantic coast, the truly destructive great storms occur most frequently during fall and spring. Cold fronts in the late fall and early winter, when lake waters are much warmer than cold polar air behind the fronts, are also associated with Great Lakes snow squalls occurring along the eastern and southeastern lake shores. This is pronounced where the orographic effects of hilly terrain amplify the lake effect snow squalls. These are most apparent over the Keweenaw Peninsula in Upper Michigan, and southeast of Lake Erie and Ontario in New York.

Along the Pacific coast from the Canadian to Mexican border, mid-latitude cyclones are again the primary storm events, with the season extending normally from October through April. There are more storms at northern rather than southern locations, with southern California experiencing approximately one to two storms at most per month. These storms tend to originate along the eastern coast of Asia or over the Gulf of Alaska, so that the storms arrive in an occluded stage, with the warm and cold fronts not particularly noticeable at the surface. Instead, the warm tropical air in these systems has typically been lifted above the surface, resulting in very large storms with gale-force winds along the coasts, and widespread precipitation occurring as snow in the mountains. Precipitation and melted snow can generate mudflows and floods that endanger and destroy homes in the narrow canyons near the coast. These storms tend to stall along the coast so that the duration of storm weather can often last for two to three days, with high waves generated by southwesterly winds causing significant erosion of beaches along the Pacific coast. This problem is exacerbated when the storms coincide with high astronomical tides.

MICROTIDAL COASTS

Coasts where the tidal range (difference between successive high and low tide levels) does not exceed 2 m are commonly referred to as microtidal (Hayes, 1979; Davies, 1980; Cooper, 1994). Such coasts may be composed of a variety of materials and occur in all latitudinal zones and in a variety of energy settings. Their common characteristics are derived from the fact that their small tidal range focuses marine action (via waves and tidal currents) into a relatively narrow vertical range. Hayes (1979) identified a generalized link between tidal range and coastal morphology. Microtidal coasts were characterized by long, narrow barriers with abundant washover features, well-developed flood-tidal deltas, and small ebb-tidal deltas. These characteristics have often led to application of the term "wave-dominated" to such coastlines, although Davis and Hayes (1984) demonstrated that this is not universally true. Some microtidal coasts do exhibit dominance of tidal currents over waves and some macrotidal coasts exhibit wave-dominance. The west peninsular coast of Florida is a good example of a microtidal coast on which wave energy (and sediment supply) is low and yet large tidal deltas develop that are more characteristic of tide-dominated conditions (Davis and Hayes, 1984). Microtidal coasts are widespread in oceanic areas (most Indo-Pacific islands), in some semi-enclosed seas (Mediterranean, Baltic, Gulf of Mexico), on parts of continental margins (S.W. Africa, S. Australia, central Brazil, Antarctica) and on lake shorelines (US Great lakes, African Rift lakes).

Open coast morphology

Wave processes on microtidal coasts are generally the principal agent of morphological change and sediment transport. Waves constantly expend their remaining energy at the same elevation and thus their effectiveness in coastal modification and sediment transport is greatly enhanced in comparison with areas of greater tidal range.

On coasts where little sediment is available, wave action that is concentrated in a narrow zone may give rise to a well-developed intertidal shore platform, an erosional feature produced by undercutting and removal of rock or semi-consolidated material. In tropical or warm temperate zones, the production of an erosional notch and shore platform on limestone coasts may be aided by chemical processes of weathering. Trenhaile (1980) has established that tidal range does exert a strong control on shore platform morphology.

Where sediment is available, wave processes are effective in reshaping sediment bodies (beach and beachface) by cross-shore and longshore transport. Depositional shores on microtidal coasts thus tend to be rapidly modified by wave processes to attain a form of equilibrium. Examples of such forms include static equilibrium (where wave energy is equalized along the shore), dynamic equilibrium (where sediment input is balanced by sediment losses), and graded equilibrium (where sediments are sorted along the shore by size such that at all points they just exceed the transport capacity of waves) (Carter, 1988). Concentration of energy in a narrow vertical band enhances the development of coastal cells that develop in response to wave and current conditions. Some of the best literature on microtidal coasts is based on studies in the US Great Lakes shores and the lack of tidal influence has enabled some basic concepts in coastal geomorphology to be investigated (Dubois, 1975).

Because of the limited intertidal area and relatively narrow beaches that limit the potential for entrainment of sand by wind, sand dunes tend to be poorly developed on microtidal coasts and those that are present often owe their existence to oblique onshore winds and/or a falling relative sea level tendency. In contrast, the lack of regular wetting of the beach surface by tidal action may enhance the potential for deflation by wind on microtidal beaches.

River influences

Rivers that enter the sea on microtidal coasts experience limited tidal influences in their lower reaches. Thus, estuaries tend to be shorter than those of areas with greater tidal range. In addition, if sediment is available in the vicinity of the river mouth, this may be reworked by waves to form a rivermouth barrier that encloses the estuary mouth temporarily or permanently. In a review of the effects of tidal range on tidal inlet morphology, Hayes (1979) noted that microtidal examples tended to have well-developed flood-tidal deltas and relatively poorly developed ebb-tidal deltas as a result of high wave energy. Deltas in microtidal coastal areas exhibit a range of morphologies in accordance with the level of wave energy. The Mississippi delta, for example, has a distinctive birds foot morphology indicating the relative ineffectiveness of waves in modifying it, whereas the Sao Francisco in Brazil comprises a series of beach ridges that represent the wave modification of deltaic sediment delivered to the coast. In few instances, however, does a single process operate to the exclusion of all others and it is worth noting in this regard that the Mississippi delta does contain chains of barrier islands that are the wave-reworked sections of the delta and which form after fluvial dominance has diminished.

Human modification

Microtidal coastlines do not contain appreciable intertidal areas and their relative constancy of water level has rendered them favorable for certain forms of human exploitation, particularly for shipping and more recently for recreation. Microtidal coastal areas have recently seen an increase in marina development, particularly in milder climatic regions such as the Mediterranean and Gulf of Mexico.

Development of recreational facilities on microtidal beaches has the advantage of a relatively constant beach area at all tidal stages and thus avoids the regular variability of available space that characterizes beaches of high tidal range. This apparent stability, is however, often deceptive in the longer term. Storms on microtidal coasts may produce elevated sea levels through surges that temporarily raise water levels and which may enhance erosion of backshore areas. Since such storms may be relatively infrequent, a number of such areas have been deemed stable and have been developed. Subsequent erosion of these areas by enhanced wave action has threatened developments and given rise to a succession of shore protection works.

It is interesting to note that human modification of tidal inlets (for example, by barrage construction or inlet closure) may diminish tidal range and produce a change in coastal type in the vicinity of the inlet to microtidal conditions.

MIDDLE AMERICA, COASTAL ECOLOGY AND GEOMORPHOLOGY

Introduction

There are several reasons why geomorphology, ecology, and integrated coastal management, have gained attention globally in Mesoamerica (Middle America, Central America). From the coasts of this region, energy, materials, and food are extracted, cities are developing, industries and port are growing, transport and tourism are in expansion, and general infrastructure and environmental technology marketing are increasing (Windevoxhel *et al.*, 1999; Yáñez-Arancibia, 1999, 2000). Under this approach, during the 1990s more than 75 million US dollars have been destined for initiatives and regional projects on integrated coastal zone management, only in Central American countries, by international agencies (Rodriguez and Windevoxhel, 1996).

In this framework the "coastal zone" is a broad geographic space of interactions between the sea, the land, freshwater drainage, and the atmosphere, in which the principal interchanges of materials and energy are produced between the marine and terrestrial ecosystems.

Traditionally, Central America includes the following countries: Belize, Guatemala, Honduras, El Salvador, Nicaragua, Costa Rica, and Panama. Nevertheless, from a "mesoamerican" point of view and from an ecological approach because of tropical latitudes, and littorals in two oceans—Atlantic and Pacific—southern Mexico and northern Colombia will be considered, in this paper, as part of the complex of Middle America, because all are integrated components of the functional structure of coastal zone in Central America. The central America coastal zone posseses extensive scenic and geographical wealth as well as great ecological biodiversity (ecosystems, habitats, forcing functions, biological species, functional groups).

Middle America is a "neotropic mosaic." A mosaic of authors' training and experiences; a mosaic of roots and cultural heritage resources; a mosaic of social development; a mosaic of ecosystems and ecological approaches; a mosaic of biogeographical regions and biodiversity; a mosaic of climatic zones; a mosaic of pristine areas as well as highly degraded zones. Because of this, to deal with common terms of reference, the purpose of this is to focus on the tectonic history, the regional geography and geomorphology, and to analyze the major ecological systems, as the key focus for understanding the geomorphology/ecology of coastal zones in Middle America (i.e., continental shelf, coastal lagoons and estuaries, mangroves, and coral reefs).

Central America—Antilles tectonic history

The tectonic history of Central America and the Antilles is extremely complex (Burke *et al.*, 1984; Buskirk, 1992). Geological studies are fragmentary, and the application of plate tectonic theories to detailed areas has been controversial (Donnelly, 1985; Coates *et al.*, 1992; Suárez *et al.*, 1995). Measurements of present-day plate motions can give a picture of recent movements but the older history of the area is more difficult to interpret; much geological evidence is missing.

The tectonic hypothesis of Duncan and Hargraves (1984) provides the best framework for the Buskirk (1992) zoogeographic analysis for understanding Mesoamerican ecological relationships. Based on plate tectonics determined from the geometry of hotspots on the earth's mantle, the Duncan and Hargraves model reconstructs the evolution of the Caribbean region as follows. In the Cretaceous, as the North and South American plates moved farther apart, subduction movements of the Pacific ocean floor under the west side of the Americas formed the proto-Antilles island arc. In the late Cretaceous, an oceanic plateau formed behind that arc and began to push it northeastward between the continents. This motion was halted at about the Eocene and Oligocene when the arc collided with the Bahamas platform. At this time, subduction of the Pacific ocean floor under the west side of the oceanic platform, in combination with uplift of older Cretaceous island arc features, formed the lower Central American arc. Since the Oligocene there has been eastward movement of the Caribbean plate. Subduction of the Atlantic ocean crust beneath the eastern margin of the Caribbean plate has formed the Lesser Antilles island arc. A subduction zone along the Pacific side of Mesoamerica forms the western boundary of the Caribbean plate.

To this framework, Buskirk (1992) added information about the Greater Antilles used in preparing the sketches in Figure M15. Solid

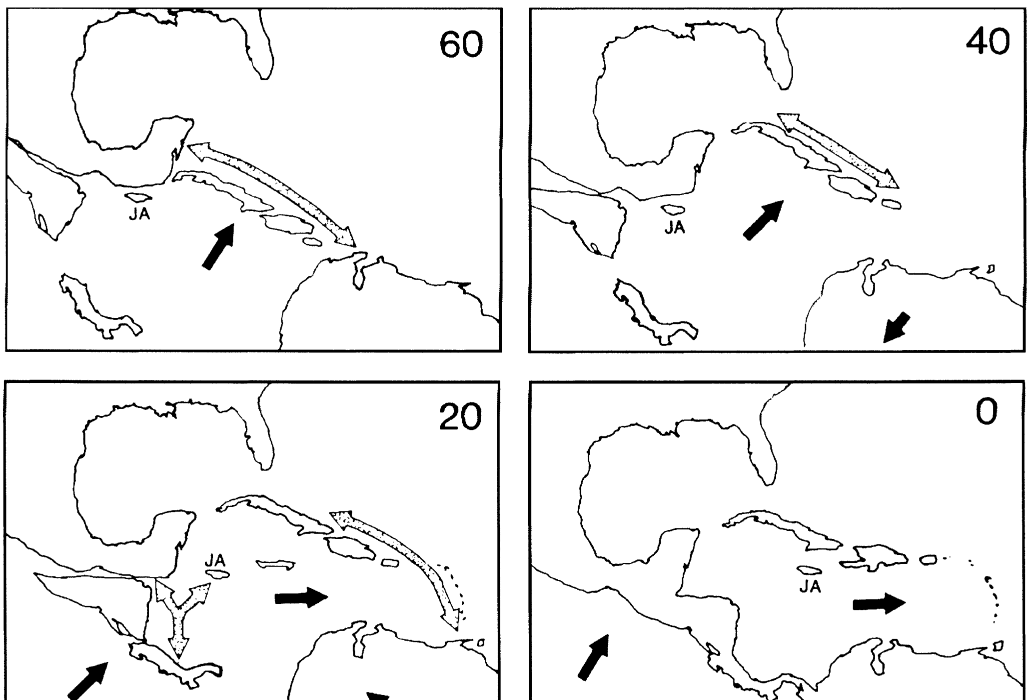

Figure M15 Hypothetical sketch of Mesoamerican and Caribbean history at 60 (Paleocene), 40 (late Eocene), 20 (early Miocene), and 0 (Present) millions years before present (after Buskirk, 1992). Land outlines do not indicate shoreline at those times but are merely for recognition of the present-day terrains. Solid arrows indicate the predominant direction of tectonic movement. Stippled arrows indicate suggested dispersal pathways.

arrows indicate the direction of major tectonic movements. Land outlines do not indicate coastlines at the time, but are merely for recognition of the relative location of present-day terrains. The position of the Honduras–Nicaragua and Costa Rica–Panama blocks is based on the model of Duncan and Hargraves (1984). Although each of the blocks might be considered a tectonic unit for the last 50 million years, both have been changing extensively during that time with much shearing and internal deformation.

It is suggested that the Greater Antilles island arc (Cuba, northern Hispaniola, and Puerto Rico) moved northeastward during the late Cretaceous after fragmenting its western end (to form Jamaica) in a collision against Mexico–Guatemala. Pollen data from the Eocene and Oligocene of Cuba and Puerto Rico indicated that there was frequent dispersal between the island of this northern Caribbean arc (Buskirk, 1992). Jamaica was largely inundated during this time. Since the mid-Tertiary it has moved as the eastern end of the Nicaraguan block.

In Figure M15 (after Buskirk, 1992), probable prevalent pathways of dispersal at 20, 40, and 60 million years ago are suggested by the stippled arrows. Probably, there was a period of dispersal between North and South America in the Cretaceous or early Tertiary, despite the lack of geological evidence for an emergent island arc at that time. In about the Miocene (beginning 23 million years ago), as the Lesser Antilles island chain became prominent, there was dispersal from South America into Puerto Rico, Hispaniola, and Cuba. As Jamaica become emergent, it initially was colonized mostly by the Central American terrapins.

Following the emergence of Jamaica, therefore, geological changes altered the potential for dispersal of terrestrial organisms between Jamaica and Mesoamerica. In the Miocene, the emerging island was situated closer to Central America than presently, and shallow reefs or emergent limestone banks could have provided stepping-stone conditions for dispersal between Jamaica and the Mesoamerican island chain. During the Pliocene, as Jamaica uplift increased, tectonic activity slowly moved the island eastward as the rise between it and the Nicaragua subsided.

Regional geography and geomorphology

It is not only the tectonic history or the relative areas of continental shelves and the open tropical oceans we need to quantify, if we want to understand the basis of Mesoamerican coastal ecosystem productivity. Rather, we must also know the geographical and geomorphological characteristics of continental shelves, shallow bays, and coastal lagoons and estuarine system features. Are they narrow or wide, flat or steep, what are their superficial deposits, what is the geology of the coastline that lies behind them, and do they lie on the east or the west of the Mesoamerica continental mass? All these characteristics—quite apart from the circulation of water masses over them and the seasonality of river discharges—determine the kind and quantity of ecosystem productivity and biomass production (Deegan *et al*., 1986; Longhurst and Pauly, 1987).

Tectonic activity causes shelves to be narrow on active, subducting margins as along the Pacific coast of Mesoamerica, and allows them to be wider along passive margins, as on the eastern coast of the American continent (Kolarsky *et al*., 1995; Parkinson *et al*., 1998). The insular arc in the Caribbean protects shelves from wave action and allows the development of relative wide shelves, such as the Campeche Sound (Mexico), the Magdalena basin (Colombia), or the Orinoco delta (Venezuela) in the northern and southern end of the Atlantic Mesoamerican coastal zone. But earthquakes associated with coastal subduction has been clearly correlated with benthic organisms (Cortés *et al*., 1992).

Major rivers can modify the morphology of continental shelves: the Grijalva/Usumacinta (Mexico), Dulce (Guatemala), Magdalena (Colombia), and Orinoco (Venezuela) rivers have all widened the adjacent continental shelves and have built fans of sediment down the continental slope on the Atlantic coast of Mesoamerica, even the influence of the Amazon from Brazil must be considered as important in the coastal ecology of Middle America. Figure M16 shows the astonishing manner in which a few major tropical river systems dominate the global transport of sediments from the continents to the ocean coast in Middle America. Recent references for Colombia are (Restrepo and Kjerfve, 2000a,b). This amount of sediment discharged to the coastal zone is reflected in the distribution of the sediments of tropical continental shelves and seas, and in the high turbidity of coastal seas in the monsoon-type regions of Mesoamerica (i.e., Tabasco-Campeche Mexico, Costa Rica, Panama–Colombia).

The superficial geology of continental shelves is determined by processes that also determine coastal morphology, working in concert with several important biogenic processes of sediment production. Shelf sediment in the Middle America coastal zone includes inorganic components such as sand derived from weathering of rock, and transported by wind, longshore currents, or rivers, and also silts and clays that are mostly river borne. The organic components of shelf sediments include terrestrial plant debris in all stages of decomposition which is either riverborne as particulates, or flocculated from dissolved organic material at the fresh/saltwater interface in the estuaries (i.e., Gulf of Fonseca shared by El Salvador, Honduras, and Nicaragua; Sierpes delta in Costa Rica, both areas in the Pacific coast). The remaining shelf deposits are oolite sand formed by precipitation from dissolved calcium; shelf-sand and large particles of calcareous material derived from molluscan benthos; reef corals and coraline algae, produced largely *in situ* and not transported great distances; and finally, small particulate organic material from planktonic communities of plants and animals.

Contrary to general conceptions, tropical continental shelves dominated by the effects of mangroves or reef corals are more the exception than the rule (Longhurst and Pauly, 1987). Mangroves are important only where deltaic or a low-lying coastal plain occurs (Kjerfve, 1990; Wolanski and Boto, 1990; Jimenez, 1994; Kjerfve, 1998; Yáñez-Arancibia and Lara Domínguez, 1999); and coral reefs are important only where negligible amounts of terrigenous material reach their habitat (Wolanski and Choat, 1992; Kjerfve, 1998; Cortes, 2002).

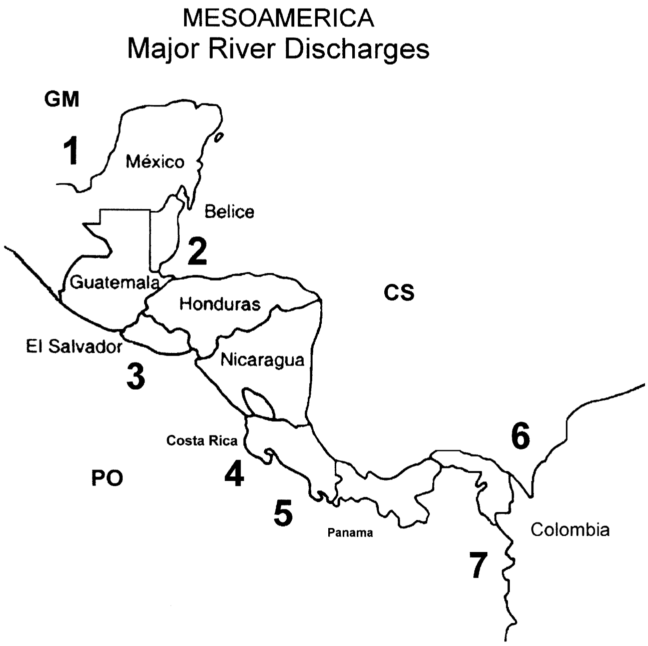

Figure M16 River transport of water and silt to the continental shelf from the major drainage basins for Middle America. Water discharge in $m^3\ s^{-1}$, and sediment yield in million tons per year. (1) Mexico, Grijalva-Usumacinta 4,400 $m^3\ s^{-1}$; 126×10^6 tons yr^{-1}. (2) Guatemala, Rio Dulce 1,100 $m^3\ s^{-1}$. (3) El Salvador/Honduras/Nicaragua, 834 $m^3\ s^{-1}$. (4) Costa Rica, Gulf of Nicoya Tempisque River 50 $m^3\ s^{-1}$. (5) Costa Rica, Terraba-Sierpes Deltaic River 338 $m^3\ s^{-1}$; 2×10^6 ton yr^{-1}. (6) Colombia, Magdalena Deltaic River 7,200 $m^3\ s^{-1}$; 144×10^6 tons yr^{-1}. (7) Colombian western discharge 8,020 $m^3\ s^{-1}$; 16×10^6 tons yr^{-1}. GM = Gulf of Mexico, CS = Caribbean Sea, PO = Pacific Ocean.

Major ecological systems

Continental shelf

The eastern Mesoamerican shelf is much more complex, and dominated by terrigenous deposits principally near the mouths of the Grijalva/Usumacinta, Dulce, Magdalena, Orinoco rivers, where spectacular mud regions dominate. This is also true in the Terraba-Sierpes river delta on the western coast of Costa Rica. The continental coastline of Central America is much folded and fractured by tectonic activity, and has basins formed by calcareous deposits. The wide, very shallow Yucatan shelf has offshore banks (notably Campeche Bank), at least one being of atoll form, and the shelf sediments are predominantly calcareous. Along the northern South America coast (the southern end of Middle America), which itself is much altered by large tectonic faults, a shelf is lacking in the Pacific, but because of the outgrowth of the Magdalena estuary in the Colombian Atlantic a significant portion of shelf exists. Off Venezuela, the shelf deposits are terrigenous and the shelf itself is complex, with the deep Cariaco Trench intruding. Offshore, the Antilles and Caribbean islands are rocky, or bear coral reefs, and the geological environment resembles the western Pacific, an impression strengthened by the occurrence off Belize and Cancun (Mexico) of a Barrier reef complex similar in structure if not in extent to the Great Barrier Reef of Australia.

The western coast of Middle America is dominated by an active subduction zone almost the full length of the continent. Coral reefs and banks are largely absent, and mangroves dominate only along parts of Central America (Chiapas Mexico, Guatemala, Gulf of Fonseca El Salvador/Honduras/Nicaragua, Terraba-Sierpes Costa Rica, and Colombian coasts). Despite the absence of major rivers, terrigenous material is very important. The continental shelf is very narrow. In the Panama Bight, silt and terrestrial organic material contribute to muddy deposits, especially closer to the coast; here, the outer shelf tends to have sandier deposits. The shelf is very narrow or absent off Middle America, where depths fall away down the continental slope to 6,000 m in the Middle America Trench. Only off Panama and the Gulf of Tehuantepec in southwestern Mexico is there a significant width of shelf (Tapia García, 1998); elsewhere, only in isolated bays and gulf are there shallow areas resembling continental shelf habitats.

Coastal lagoon systems

Coastal lagoons here include lagoons, estuaries, and deltaic plains, in the sense of Day and Yáñez-Arancibia (1982), Kjerfve (1986), Yáñez-Arancibia (1987). These systems occur in all tropical oceans (Kjerfve, 1994). They are a specially prominent topographic feature on both the Atlantic and Pacific coasts of Middle America, including the northern (Mexico) and southern (Colombia) end (Yáñez-Arancibia, 1999). Many stretches of coastline are backed not by solid land, but by coastal lagoons behind barrier island, open to the sea to various degrees, with or without rivers, and of great significance in some coastal fisheries as nursery grounds (Lasserre and Postma, 1982; Kjerfve, 1994).

Lagoons not associated with coral reefs are most strongly developed on coasts with a history of submergence during the Holocene post-glacial sea-level rise during the last 10,000 years or so (Kjerfve, 1986, 1990). Lagoons may also form behind the cuspate spits that accrete at the mouth of open estuaries and delta mouths, as in Tabasco/Campeche Mexico (Yáñez-Arancibia and Day, 1988). Special evaporative mechanisms may also build lagoons in arid or semiarid regions, characterized by ephemeral inlets (Kjerfve, 1994). The formation and maintenance of a lagoon's coastal barrier depends on a balance between the supply of sedimentary material and its removal to deeper water by wave action. Sediment may be supplied to the outer side of the barrier by longshore currents and normal wave action, or may enter the lagoon itself by beach "washover" during storms as in Amatique Bay Guatemala; Terminos Lagoon, Mexico, Gulf of Fonseca El Salvador/Honduras/Nicaragua (Yáñez-Arancibia and Day, 1988; Yáñez-Arancibia *et al.*, 1999). It may also accumulate by the settlement of riverborne silt, by flocculation of organic material at the saltwater–freshwater interface, or by local estuarine plant production especially by a mangrove ecosystem and associated coastal wetlands (i.e., La Encrucijada Chiapas, Mexico; Tortugero, Costa Rica).

The primary determinant for the existence of lagoon–barrier coasts is a relative small tidal range (Kjerfve, 1986). In microtidal (<2 m) environments as in Middle America, wave action is especially important in maintaining linear barrier islands. There is a relationship between tidal range and the width and number of the mouths of tidal channels by which lagoons open to the sea. In the Middle America region, there are few, narrow entrances, and barrier islands are long and narrow. Also of great significance for lagoon geomorphology is the pattern and amount of river discharge that they receive and must carry to the sea; in many places, remains of terrestrial plant cover destroyed by deforestation are having important effects on the sedimentary regime within lagoons. Precipitation/evaporation rate is a further important factor in the evolution and environmental behavior of lagoons once formed. Lagoons in Middle America are in a state of continuing evolution, and many are already filled in by sea-sand transport and the accumulation of both terrigenous sediments and biogenic material. Nevertheless, the remaining complex dominates the coastal ecology in Central America and it is an important factor in the coastal productivity and subsequent fisheries in the region. This family of coastal lagoons differs from those that are formed in association with coral reefs as in Yucatan Peninsula, Mexico, or Belize.

Shelf–estuary–lagoon relationships

There is a general relationship between the amount of water and terrigenous sediments discharged onto continental shelves, and the production there of fish that has been studied particularly well in the Gulf of Mexico (Deegan *et al.*, 1986; Sánchez-Gil and Yáñez-Arancibia, 1997), confirming the linkages between shelves, estuaries, and coastal lagoons, coupled with river discharge budgets, estuary area, intertidal area, coastal vegetation area, and fishery harvest (Figure M17). Such relationships probably can also occur in the Gulf of Fonseca influence area, the Gulf of Nicoya and Gulf Dulce influence areas, and Terraba-Sierpes estuarine plume, in the Pacific coast of Middle America, assumed by analyzing the reference of Jesse (1996), von Wangelin and Wolff (1996), Wolff (1996), Vargas (1996), Leon-Morales and Vargas (1998), Dittmann and Vargas (2001). Seasonally, there is a natural alternation between dry-season conditions with the river discharge, and rainy season when the river discharge dominate the deltaic conditions, as well as the winds regime and tidal range throughout the year.

As we might expect from the greater relative area of reef, rock, and especially soft bottom habitats off deltaic systems in the Atlantic coast of Middle America, Longhurst and Pauly (1987), based on selected references, can distinguish four species assemblages of fish that comprise the coastal demersal resources in the tropical west central Atlantic coastal ocean:

1. *Lutjanid community*. Fauna of rock, coral, and coral sand from Florida to Brazil, which is dominant on the Bahamas, the Antilles, and the other Caribbean islands; and on the coast of Yucatan to Panama (Balistidae, Logocephalidae, Lutjanidae 14 spp., Pomadasyidae 3 spp., Serranidae 11 spp., Synodidae), see Longhurst and Pauly (1987), Lowe-McConnell (1987), Arreguín *et al.* (1996).
2. *Subtropical sciaenid community*. Fauna of soft deposits from the Gulf of Mexico to at least Cape Hatteras, and especially well developed near river mouths influence, including the Mississippi and Grijalva/Usumacinta deltas (Branchiostegidae, Clupeidae, Gerreidae, Polynemidae, Serranidae, Bothidae 19 spp., Sciaenidae 19 spp.), see Longhurst and Pauly (1987), Sánchez-Gil and Yáñez-Arancibia (1997).
3. *Tropical sciaenid community*. Fauna of the soft inshore muddy and soft sand deposits from the southern coast of the Caribbean to Cape Frio in Brazil (Dasyatidae, Ariidae 6 spp., Clupeidae, Gerreidae, Heterosomata 3 spp., Ephippidae, Pomadasyidae, Sciaenidae 19 spp.), see Longhurst and Pauly (1987), Lowe-McConnell (1987).
4. *Sparid community*. Fauna of the sandy and muddy sands of the subtropical regions north of Cape Hatteras and south to Cape Frio with very attenuated representation through the tropical region, that is, Yucatan to Venezuela (Ariidae, Carangidae 9 spp., Clupeidae, Mullidae, Sciaenidae, Sparidae 10 spp., Synodidae or Synodontidae),

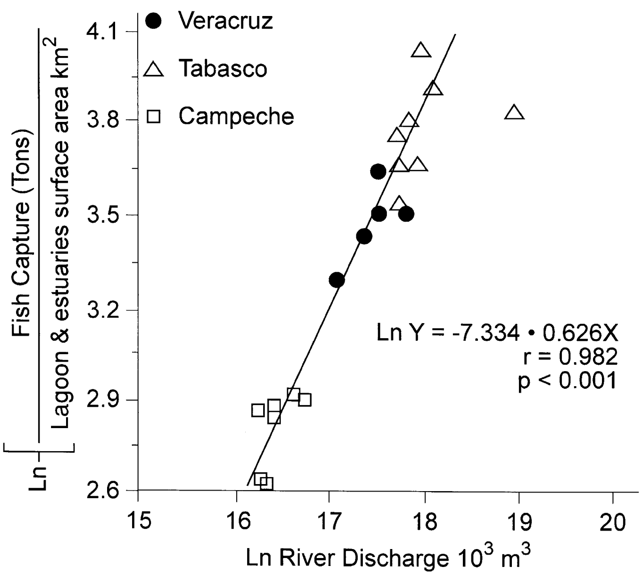

Figure M17 Linear logarithmic regression between fishery harvest per unit open waters (lagoons and estuaries) and average river discharge. The data are from the states of Veracruz, Tabasco, and Campeche in Mexico.

see Longhurst and Pauly (1987), Lowe-McConnell (1987), Sánchez-Gil and Yáñez-Arancibia (1997).

In the Pacific of Middle America important progress has been done for fish and benthos species assemblages, and after analyzing Jesse (1996), Wolff (1996), Vargas (2001), and Dittmann and Vargas (2001), some analogies can be found in the coastal demersal resources in the tropical coastal zone in the Mesoamerican Pacific in comparison with the Caribbean coast.

Because relatively few fish species are wholly adapted to a life cycle within a lagoon–estuarine system *sensu-stricto*, Longhurst and Pauly (1987) pointed out a controversial discussion on the topic. But it is clear—nevertheless—that in the tropic of Middle America, and especially in monsoon-type areas where estuarinization of the continental shelf occur, the distinction between estuaries and the neritic sea is slighter than in non-monsoon type areas (Yáñez-Arancibia, 1985; Yáñez-Arancibia *et al*., 1994). This approach can be easily applied in Tabasco/Campeche, Mexico; Amatique Bay, Guatemala; Magdalena delta shelf Colombia; Gulf of Fonseca, El Salvador/Honduras/Nicaragua; Gulf of Nicoya, Costa Rica.

There are also sufficient descriptions of specialized estuarine fish fauna for it to be clear that this is often a reality in the tropics of Middle America and adjacent sub-tropical regions, where the size of the estuary and its tidal regime permit a relatively long flushing period. If the Guntherian hypothesis of estuarine-dependence of continental shelf fish stocks can not be valid for the tropical regions as a whole (Longhurst and Pauly, 1987), at least it can be applied without any doubt in tropical America especially in soft bottom communities on the shelf associated with extensive deltaic systems, river discharge, and broad areas of coastal vegetation (Deegan *et al*., 1986; Pauly, 1986, 1998; Pauly and Yáñez-Arancibia, 1994; Sánchez-Gil and Yáñez-Arancibia, 1997; Baltz *et al*., 1998; Chesney *et al*., 2000; Lara-Dominguez, 2001, i.e., Figure M17).

As a consequence, some important points have emerged from those studies; (1) The utilization of the lagoon–estuarine environment is an integral part of the life cycle of numerous fishes, particularly in the Neotropics (Middle America). (2) The lagoon–estuarine environment is mainly utilized by juveniles and young adults. (3) There are a greater number of fish species in tropical and subtropical lagoon–estuarine ecosystems than in comparable temperate or boreal systems. (4) Second-order consumers are more abundant and diverse than first-order consumers or top carnivores. (5) Functional components are (a) freshwater spawners occurring in waters <10 ppt salinity, (b) brackish water groups limited to 10–34 ppt salinity, (c) marine spawners occurring in waters > or = 35 ppt salinity. (6) Three groups of fish occur in lagoon–estuarine systems (a) resident species, those which spend their entire life cycle within coastal lagoons, (b) seasonal migrants, those which enter the lagoon during a more or less well-defined season from either the marine or the freshwater side and leave it during another season, (c) occasional visitors, those which enter and leave the lagoon without a clear pattern within and among years. To these, two other groups may be added: (d) marine, estuarine-related species, those which spend their entire life cycle on the inner sea shelf under the estuarine plume influence, and (e) freshwater, estuarine-related species, those which spend their entire life cycle in the fluvial-deltaic river zone, associated with the upper zone of the estuarine system. Finally, if the "recruitment" both biological and fishery, utilize coastal lagoons and estuaries, those resources are "estuarine-dependent," but if that resources utilize regularly the option of the estuarine plume on the continental shelf, they are "estuarine-related" or estuarine opportunistic.

An advanced approach, following shelf–estuary–lagoon relationships, and the compressive models of trophic fluxes in key coastal Mesoamerican ecosystems, has recently been done. Construction of mass-balance trophic models of aquatic ecosystems, including complete food webs, from primary producers to top predators, allows numerous inferences on ecosystem status and function and can serve as a base for dynamic simulation models, as well as comprehension of shelf–estuary–lagoon relationships and the coastal ecological processes evolved. In Mesoamerica, this is a clear coastal ecological perspective, that is, in the southern Gulf of Mexico (Pauly *et al*., 1999), in the Dulce Gulf (Wolff *et al*., 1996), and in the Gulf of Nicoya (Wolff *et al*., 1998).

For instance, the Dulce Gulf acts differently from most tropical coastal ecosystems, as it is dominated by biomass and energy flow within the pelagic domain and resembles rather an open ocean system than an estuarine one. Due to its low benthic biomass and low overall productivity there seems no potential for a further development of the demersal and semi-demersal fishery inside the Gulf; and an increase of the fishing pressure on pelagic fish would seriously threaten the large resident predators, such as dolphin, sharks, and large birds species (Wolff *et al*., 1996). In the Gulf of Nicoya, the model shows that shrimps occupy a central role within the Gulf as converters of detritus and other food into prey biomass for many predators, that seem to be simultaneously affected by the over exploitation of this resource (Wolff *et al*., 1998), as occurs in classical tropical coastal estuary–shelf relationships.

In the southern Gulf of Mexico, the trophic model shows the estimation of the primary production required to sustain fisheries offshore, coupled with tropical lagoon–estuarine systems (Terminos Lagoon), which can be determined given knowledge of fishery catches, from the trophic levels of the exploited groups represented in those catches, and the transfer efficiency between trophic levels (Pauly *et al*., 1999).

These examples will be more useful the smaller the scale that is used for the spatial stratification of the overall models; also more local models will mean more consideration of local data and constraints and hence a more realistic overall model and more realistic aggregate statistics (i.e., primary production required to sustain the fisheries of those key coastal ecosystems in Mesoamerica).

Mangroves, coral reefs, islands, and other related ecosystems

Not only coral reefs, or river basins and associated wetlands, are a common coastal landscape in Middle America, but the most important critical habitats are the mangroves in the coastal zone (Jiménez, 1994; Kjerfve, 1998; Yáñez-Arancibia and Lara-Domínguez, 1999). The relative importance of mangroves for each Central America country is illustrated by Windevoxhel *et al*. (1999). This rough representation shows that mangroves are the most important forest formation in certain countries and they should be given priority in management and conservation. The entire coast is characterized by the presence of mangroves, with nine species present in five genera on the Pacific, and four genera on the Caribbean and the Atlantic coast of Mesoamerica. Central America possess 8% of the world's mangroves, and represents 7% of natural forest in the region (Jiménez, 1994; Suman, 1994). The greater extensions of mangrove on the Pacific are found off the coast of southwestern Mexico, Guatemala, Costa Rica, Panamá, and the Gulf of Fonseca (Table M7). Pacific mangroves maintain lesser biodiversity associated with root systems than those in the Caribbean, where the small changes of tides provide conditions of environmental stability for root-associated organisms, including important sea grass beds associated with mangrove systems, as in Campeche and Yucatan Peninsula Mexico, Honduras, Nicaragua, and Costa Rica. However, Pacific mangroves are more extensive due to the greater tides and coastal topography. These conditions offer greater areas that exclude competitors and favor facultative halophytes with saline intrusion. On the Caribbean and the Atlantic coast of Mesoamerica, the most extensive areas of mangrove are found in Honduras and Nicaragua, and also southeast México.

In general terms, Pacific coast coral reefs are less extensive and diverse than those on the Caribbean (Cortés, 2002). Live coral formations have been described in El Salvador, Costa Rica, and Panama. Coral communities in the Pacific are richer off the southwestern coast of Costa Rica, and particularly in Panama, where at least 21 species have been reported (Cortes, 1997a). On the Caribbean side, coral reefs can be found in all of the countries in the Atlantic coast of Mesoamérica (Cortés, 1997b). The Belize coral barrier or reef system (Mexico, Belize, Guatemala, Honduras) runs more than 220 linear kilometers and contains atolls and other formations practically unique in the Caribbean Sea. More than 60 species of coral have been reported to exist on the coast (Woodley, 1995; Gibson and Carter, 2002), but the total number of species associated with the coral reef system is still uncertain. Offshore the Antilles and Caribbean island are rocky, or bear coral reef, and the geological environment recalls that the western Pacific, an impression strengthened by the occurrence off Belize and Cancun (Mexico) of a barrier reef complex similar in structure, if not, in extent, to the Great Barrier Reef of Australia.

The Pacific coast has long sandy beaches with a broad range of texture and color, and predominant clear coastal waters. Beaches on the Caribbean and the Atlantic coast are less extensive as a result of current patterns and sea cycles, as well as the oceanographic and geomorphologic factors, and because the presence of important river basins, predominant turbid coastal waters, with the exception of Yucatan Mexico, Belize, and southeastern Costa Rica.

Islands and islets abound on the Caribbean coast. There are some 2,400. In Campeche Mexico, Isla del Carmen is a barrier sandy island on the Usumacinta delta; but mostly associated with coral formations, as in Yucatan Peninsula Mexico (Cayo Arcas, Alacranes, Chinchorro, Isla Mujeres, and Cozumel), Belize (the Keys), Honduras (Bay Islands

and Cochinos Keys), Nicaragua (Miskitos, Cisne, and Maiz Keys), and Panama (Bocas del Toro and San Blas Archipelago). In comparison, there are few islands on the Pacific coast except for Panama, with some 200. There is a small group of islands in the Gulf of Fonseca (including Meanguera, Meanguerita, Amapala, and El Tigre). A group of eight islands are found in Costa Rica's Gulf of Nicoya, with the Chira island and Murcielago island located to the north, and Isla del Caño 11 km in front of Peninsula de Osa. Coco Island, 500 km to the southwest of the continent, marks the most distant territorial point of the Central America region.

Physiographic variability is also present on the sea bottoms. The Mesoamerican Trench extends all along the Central America Pacific and has a maximum depth of 6,662 m. The Caribbean Cayman Trench has a maximum depth of 7,680 m, with depths up to 2,000 m off Belize.

The largest regional outcrops of ocean waters are found off the Pacific gulfs of Fonseca, Panama, and Papagayo. These are caused by the Caribbean's seasonal winds, which push water out to the sea causing outcrops of colder water richer in nutrients. This effect is also true in the Gulf of Tehuantepec in the southwestern Mexico caused by the seasonal winds coming from the Gulf of Mexico throughout the Tehuantepec Itsmo. As it is typical of tropical seas, the Caribbean's surface water is mixed very little with colder deep waters which are richer in nutrients, and as a result the open seas are low in primary productivity. The greatest wealth, in terms of Caribbean productivity, is associated with the presence of coral reefs, mangroves, and other important ecosystems (i.e., deltas) on which regional fishing depends.

Global ecological scenario: synthesis

The physiographic, hydrological, climatic, physiochemical, bathymetric characteristic, and habitat heterogeneity, littoral currents, and extension of continental shelf, previously described determine productivity, as well as the quantity and distribution of Central America's coastal-marine resources. Likewise, this distribution has historically conditioned utilization of resources and their relation to socio-economic development in the region. Traditional numbers indicate that Central America possess 6,603 km of coast, representing approximately 12% of the Latin America and Caribbean coast. These contain some 567,000 ha of mangroves, 1,600 km of coral reef, and about 237,650 km of continental platform where multiple activities of economic and social importance are carried out (Windevoxhel *et al.*, 1999). The region has potential for utilizing more than 1.1 million km^2 of exclusive economic zone (Table M7). Nevertheless, and following the "Mesoamerican" approach focused on in this entry, these numbers should be much more impressive considering the states of Chiapas, Campeche, Yucatan, and Quintana Roo in southern Mexico, as well as Colombia, and this is true for the length of the marine coast and its natural resources, shelf to 200 m depth, exclusive economic zone, urban population in coastal cities, average annual volume—metric tons—of goods loaded and unloaded as crude oil/gas products and dry cargo, tourism, and fish products (Yáñez-Arancibia, 1999).

The Central America coast consists of numerous peninsulas, gulfs, and bays favoring a high degree of physiographic diversity. Extensive intertidal zones and well-developed coastal barriers encircle great coastal protected waters. On the Pacific, coastal cliffs are highly developed in Costa Rica, and partially developed in El Salvador, Nicaragua, The Gulf of Fonseca, Panama, and Colombia; while Guatemala and Mexico have no coastal cliffs. On the Caribbean side, the coast tends to be quite flat and cliffs are nonexistent due to less drastic geological and geomorphologic processes, with some local exception in the Dulce River low basin in the Atlantic coast of Guatemala. There are very important mega-lagoon/estuarine systems in Mesoamerica, that is, Terminos Lagoon Mexico (Yáñez-Arancibia and Day, 1988), Amatique Bay, Guatemala (Yáñez-Arancibia *et al.*, 1999), Gulf of Fonseca, El Salvador/Honduras/Nicaragua (Gierloff-Emden, 1976), Gulf of Nicoya and Gulf Dulce Costa Rica (Voorhis *et al.*, 1983; Vargas, 1995; Lizano, 1998), and the Panama Bay.

Climatic conditions vary latitudinal along the Pacific coast. A dry zone from northern Costa Rica to Guatemala experiences water shortage for at least five months; transition toward a system of greater moisture is presented in Guatemala; rainfall is extremely heavy in southwestern Costa Rica and Panama, where shortage occurs no more than one of two months (Jiménez, 1999). The particular characteristics of the Caribbean coast determine differences between this area and the Pacific. For example, while tides on the Pacific reach up to 6 m (extreme), those on the Caribbean and the Atlantic of Mesoamerica coast are around 30 cm (extreme). Dominant winds on the Caribbean coast produce waves up to 3 m, higher than those on the Pacific. Pacific coast rivers are short and highly dynamic, and discharge significant volumes of sedimentation from May to November during the rainy season. Rivers on the Caribbean tend to be longer and discharge is greater and more stable as a result of topographical conditions and almost year-round precipitation, and in the case of the northern end of Mesoamerica (Pacific and Atlantic of Mexico) with a significant seasonal pulse in September–October.

MINING OF COASTAL MATERIALS

Mining is the process of extracting rock and mineral material from near-surface sources of the earth. It may include small, local borrow pits with no supporting infrastructure or large-scale operations with permanent facilities for removing, loading, and transporting the resource. Considering only coastal areas, those adjacent to the shoreline and extending seaward through the breaker (surf) zone (U.S. Army Coastal Engineering Research Center, 1966) and landward through the highest surfaces subject to modern processes of wave alteration, the area represented (based on estimates by Kuenen, 1950) is a little less than 1% of the global surface. The coastal zone, as used here, includes all parts of barrier islands, lagoons, tidal flats, and mangrove swamps, but does not include embayments and fiords, permanently exposed parts of deltas, lands bordering estuaries (such as the Bay of Fundy), and other inland tide-influenced areas.

Energy conditions within the coastal zone, as evidenced by the landforms, are very high. The zone typically encompasses a transition from terrestrial fluvial and eolian to marine processes, but in high latitudes may be transitional from glacial or periglacial to marine ice-shelf conditions. Everywhere coastal areas are subject to retreats and advances of the shore owing to deposition or erosion by oceanic currents, isostasy, and especially, change in sea level related to storage and melting of glacial ice. Recently, a relative rise in sea level has been augmented or induced in some low-lying coastal areas as a result of large-volume subsurface fluid withdrawal. The geologic history of these processes defines the changing positions of coastal zones relative to the rock and mineral resources stored in and supplied to them, and determines the volumes and concentrations of materials that may have economic value.

Most of the economically recoverable coastal-zone resources worldwide are sand and gravel deposits and heavy-mineral placers locally embedded in them. Occurrences of these resources are typically results of combined rock-fragment transport by water and ice from terrestrial areas, reworking by both marine and eolian currents, and either sea-level stability or inundation by rising sea level. Conversely, where tectonics or marine-circulation patterns produce nondeposition of terrigenous clastics or erosion of rocky shores, limestone and building stone may be exposed and available for mining. Authigenic mineralization in nearshore areas, especially of phosphorite, may require specific conditions of upwelling of nutrient-rich seawater in relatively stable areas of continental margins.

Sand and gravel

Deposits of sand and gravel are the most widespread and are probably the most economically important non-energy resource of global coastal zones (Cruickshank and Hess, 1975; Williams, 1986). Estimated global reserves of sand and gravel on continental margins are 2 orders of magnitude greater than those of terrestrial supplies; the proportion of these deposits that occur within coastal zones is uncertain but is no doubt substantial (Cruickshank, 1974). Principal uses of the resource include aggregate in cement and asphalt for construction, road base, earth fill, beach restoration, and a variety of industrial products dependent on silica sand and other sand-sized minerals (Langer and Glanzman, 1993). Increasingly during the latter 20th century, deposits of coastal-zone sand and gravel near urban areas were mined as an alternative to the extraction and shipping of dwindling terrestrial supplies from greater distances. During this same period there was also a shift from onshore to offshore mining. Because sand with physical properties comparable to those of beaches is needed for beach replenishment, shallow offshore sand accumulations near the sand-deficient beaches, such as shoreface, tidal deltas, and shoals, have become preferred mining sites.

Movement of erosion products from land areas by late-Quaternary fluvial and glacial action, and the flooding of the deposits by elevated sea level related to deglaciation and eustatic change, are the main processes by which the enormous reserves of global sand and gravel have developed and been preserved (Williams, 1986). Where wide continental shelves are tectonically inactive, these sand and gravel resources mostly remain concentrated in the nearshore depositional environments, generally being moved only short distances by marine currents and wave action.

Mining of coastal-zone sand and gravel only recently has become important on a global scale as fluvial sand and gravel deposits near coastal cities have been depleted. Harbingers of this trend especially have been urban areas of small- to medium-sized islands, where limited onshore supplies of fluvial sand and gravel have been nearly exhausted, leading to the dredging and use of coastal and offshore supplies. Since 1987, for example, an average of nearly 25 million tons of sand and gravel has been dredged annually from deposits off coastlines of Great Britain (Hitchcock *et al*., 1999), accounting for perhaps a fourth of the national demand. In Japan, about half of recent aggregate needs have been met by mining marine supplies, and almost all remaining sand and gravel reserves of Puerto Rico are offshore (Rodriguez, 1994). Extending the estimates of Williams (1986), 20% or more of the sand and gravel needs of the Netherlands and Denmark are met by nearshore sources; adjacent to the New York metropolitan area about 1.5 million m^3 of coastal-zone sand and gravel are extracted annually, in part as an aid to navigation.

Placer minerals

Placers, heavy minerals (specific gravity > 2.85) released by rock weathering and generally concentrated mechanically by fluvial or littoral processes, occur in coastal areas where the minerals are derived locally from bedrock or from rocks of inland drainage basins that supply detritus to the coastal zone. Following transport from the rock source to a coastal environment, placers may be concentrated by tides, waves, and nearshore currents wherever shore processes are neither strongly erosive nor depositional (Rajamanickam, 2000). Thus, depending on provenance, the ability of water, ice, and wind to transport mineral particles varying in size and specific gravity, and fluctuations of sea level, coastal-zone placers occur as flooded fluvial and glacial deposits, disseminated beach deposits, or eluvial deposits (Garnett, 2000a; Kudrass, 2000; Yim, 2000).

Fluvial placers include nodules of gold and cassiterite (SnO_2) that have been transported short distances from their sites of origin by high-energy streamflows and deposited among coarse alluvial deposits of stream channels. Although wave action leads to concentration of these high-density minerals, deposition typically occurs during periods of lowered sea level when fluvial processes moved the placers into what is now the coastal area. Coastal-zone deposits of gold have been mined in Alaska, the South Island of New Zealand, southern Argentina and Chile, and the Philippines (Garnett, 2000a), and deposits of cassiterite have been extracted from coastal Indonesia, Malaysia, Burma, Thailand, China, Australia, and Cornwall, Great Britain (Yim, 2000). Although of relatively low specific gravity (3.5), but having extreme hardness and thus resistance to abrasion, diamond also occurs as placers in flooded paleo-river courses of coastal (and deeper marine) zones, often having originated far inland (Garnett, 2000b). Coastal diamond deposits are mined from Namibia and western South Africa; mining of diamonds off northern Australia, southern Kalimantan (Indonesia), and elsewhere generally has not proven profitable (Garnett, 2000b).

Disseminated beach deposits, or beach placers (specific gravity 2.85 to about 5.5), are not sufficiently heavier than most sediment particles (specific gravity about 2.7) to permit concentration by processes of fluvial sorting. Instead, sand-sized fluvial deposits of these light heavy minerals, especially rutile (TiO_2), ilmenite ($FeTiO_2$), magnetite (Fe_3O_4), zircon ($ZrSiO_4$), garnet ($Fe_3Al_2(SiO_4)_3$, monazite ($[Ce,Y]PO_4$), sillimanite (Al_2SiO_5), and, to a lesser degree, diamond, become concentrated in surf zones through wave sorting during periods of stable or rising sea level (Kudrass, 2000; Rajamanickam, 2000). Coastal-zone deposits of these minerals have been mined in Australia (rutile, zircon, garnet, monazite), South Africa (diamond, ilmenite), New Zealand (magnetite), India (ilmenite, zircon, rutile, garnet, monazite, sillimanite), Brazil (zircon, monazite), and Florida (zircon).

Other than gold and cassiterite, which are very heavy and tend to remain near the host rocks from which they were derived, the principal eluvial mineral of economic importance is phosphorite, formed mainly of varieties of apatite ($Ca_5[F,OH](PO_4)_3$) and defined as having a P_2O_5 content of at least 5% (Riggs, 1979). Unlike other heavy minerals, exploitable deposits of coastal-zone phosphorite can be formed authigenically by deposition of nutrient phosphorus during periods of low sedimentation in zones of upwelling submarine currents. The phosphorite becomes concentrated through microbial processes and later, if affected by sea-level change, further concentration of primary phosphate grains may occur by coastal-zone wave action (Riggs, 1979; Burnett and Riggs, 1990). Examples of economically minable phosphorite deposits occur along the coasts of Chile and Peru and in the Atlantic Coastal Plain of Florida and North Carolina (Riggs *et al.*, 1991).

Limestone and shell

The mining of coastal-zone limestone largely is limited to areas where terrestrial resources are otherwise unavailable within economical depth or transport distance, or are preferred owing to features such as shell content or purity. Examples are shallow-marine limestones bordering volcanic islands, coral and oyster reefs, and chalks and coquinas of nearly pure $CaCO_3$. Along tectonically active coastlines where terrestrial sediment is poorly stored, carbonate rocks of any age may be exposed and available for extraction. In contrast, shallow-marine lime precipitates and organic carbonates, principally shells, accumulate mainly on stable continental platforms having virtually no detrital deposition. Exceptions are those lagoonal areas where shell concentrations are so large that the muddy matrix can be removed economically. Where shells of marine organisms are concentrated as unlithified calcareous clasts, the resource may be mined as a source of lime for cement in addition to its aggregate properties (Cruickshank and Hess, 1975). In the Bahamas, deposits of precipitated aragonite and aragonitic oolites are mined as a source of pure calcium carbonate. Although these sources of lime, measured in billions of tons along the Grand Bahamas Bank, for example, may be mined locally, the value of limestone and shell deposits extracted annually is small compared to those of sand and gravel and heavy minerals.

Building stone and crushed rock

Coastlines of tectonically active areas, volcanic islands, and areas subject to isostatic rebound following glaciation typically have a narrow coastal zone bordered by bedrock. Where the mining of building stone and crushed rock for aggregate from inland sources is restricted owing to land use or environmental concerns, rock may be quarried at the landward edge of the coastal zone. Historically, these rock quarries have been small and the amount of rock extracted for building stone and aggregate has been of minor economic importance. Beginning about 1990, however, restricted access to available inland rock reserves in areas of high population density, such as western Europe, resulted in the establishment of superquarries at coastal exposures of granite, quartzite, gneiss, limestone, and sandstone. Examples of active superquarries, those yielding at least 5 million tons of rock annually, are in Scotland, Norway, and Mexico. Other coastal superquarries are planned for the Shetland Islands, the Western Isles of Scotland, Canada, Ireland, Norway, and Spain (Pearce, 1994).

Evaporites

The mining of offshore evaporite deposits, particularly halite, gypsum, and anhydrite, is limited mostly to coasts of countries where inland supplies are not readily available and importation costs are prohibitive. Thick beds of evaporites are mined in several regions of the United States, for example, but the needs of the Philippines are satisfied partly by the extraction of about 0.6 million tons of marine salt annually (Lyday, 1995). Similar quantities of salt are mined in Indonesia but the portion taken from coastal or marine environments is not specified (Kuo, 1995). Particularly along coasts of arid lands, such as those of the Arabian Peninsula and the Caspian Sea, evaporation of runoff and near-surface ground water concentrates dissolved solids beneath sabkhas. Extensive resources of potassium and magnesium in these areas, both as brines and in bedded evaporites, are likely to be extracted from these areas in the early 21st century.

Potential environmental impacts

Mining is a human disturbance that can have adverse environmental consequences if steps are not taken to prevent alteration of physical processes and degradation of water quality. In some well-documented examples, coastal sand extraction clearly has lowered beach and dune elevations, which subsequently has caused increased storm flooding, washover, and beach erosion (Zack, 1986; Nichols *et al.*, 1987; Webb and Morton, 1996). A well-documented example of damage due to reduced beach elevation, washover, and sea-cliff erosion occurred in the early 1900s at the fishing village of Hallsands, on the south Devon coast of England. The village was destroyed during intense storms following extensive dredging of tidal-zone sand and gravel (Worth, 1923; Robinson, 1961).

Where fluvial sand and gravel have been mined from stream channels entering the ocean or in lagoons, excavation pits filled with anoxic water may alter nearshore circulation patterns and degrade water quality. In other examples, subtidal sand extraction for beach nourishment has altered nearshore currents and wave refraction patterns, causing or accelerating erosion of the adjacent beaches (Combe and Soileau, 1987; Rodriguez, 1994). Diamond mining along the west coast of South Africa has disrupted the intertidal fauna, destroyed kelp beds, adversely affected lobster habitat, and vast areas of dunes have been destroyed to get to the underlying placer deposits. Controversy surrounds the possible adverse biological effects of hydraulic dredging in lagoons and other nearshore waters. Clearly, dredging of living reefs is deleterious, but the conclusions are less certain about the permanent damage to benthic organisms caused by increased concentrations of suspended sediment associated with offshore dredging (Blake *et al.*, 1996).

In most countries, sand mining from beaches and dunes begins as small, local operations because the resource is abundant and extraction costs are low. These operations, now illegal in the United States, continue until government authorities recognize that the practices cause permanent environmental damage, and then policies are formulated to mitigate future damage from sand extraction. Depending on the government's ability to enforce the regulations, mining practices may continue illegally where the economy is depressed. Most countries with coastal rock resources suitable for superquarry development are imposing standards for licensing designed to protect scenery and recreation, marine biota, and water and beach resources.

MODELING PLATFORMS, TERRACES, AND COASTAL EVOLUTION

Terraces and their associated platforms and sea cliffs are the wave-cut and wave-built features associated with the land–water interface of seacoasts and lake shores. Along ocean coasts, they are the primary signature of the stillstands in water level during the transgressions and regressions of Pleistocene and Holocene epochs. The mechanics of terracing are fundamental to understanding the evolution of today's coastlines with their platforms, sea cliffs, barriers, spits, and capes. Coastal evolution models must incorporate processes that treat sediment transport and deposition as well as the abrasion and cutting of bedrock formations. This can be accomplished by coupled models, one treating the mobile sediment and the other bedrock cutting.

Background

Early studies of terraces, platforms, and sea cliffs include the work of de Beaumont (1845), Cialdi (1866), Fisher (1866), and Gilbert (1885). Gilbert's study of the active topographic features along the shores of the Great Lakes, supplemented by the visually distinct lake levels of the Pleistocene fossil shores of Lake Bonneville in Utah, provided the most detailed insight into the formation of platforms and terraces. He describes the wave-quarried hard rock platforms as *wave-cut terraces* backed by sea cliffs and the depositional features comprised of littoral drift as *wave-built terraces*. He also studied the terrace relations to changing lake level. Emery (1960), Shepard (1963), and others used this nomenclature with *marine terrace* as a more general term for wave-cut and wave-built terraces along ocean coasts.

However, as pointed out by Trenhaile (1987), platforms may not be wave-cut but formed by other processes such as solution. He prefers *shore platform* as a more general term for rock surfaces of low gradient within or close to the intertidal zone. He uses the term *wave-cut terrace* to refer to the specific category of platform formed by waves (Trenhaile, 2002). Sunamura (1992) classifies shore platforms developed during the present sea level as (1) sloping, (2) horizontal, and (3) plunging cliff. A more descriptive nomenclature for the latter two would be (2) step platform and (3) submerged platform. Generally, types (1) and (2) develop from cliff recession, with the step in platform (2) caused by differential erosion of rock strata. Plunging cliff platforms have sea cliffs that extend below the present water surface before joining a submerged platform. The submerged platform is a remnant feature from rapid sea-level rise and/or land subsidence. In what follows we will discuss numerical modeling of wave-cut terraces. These features consist of rock platforms backed by sea cliffs that were formed during the present stillstand in sea level as well as relic terraces now found on the continental shelf buried under Holocene sediment (Figure M18).

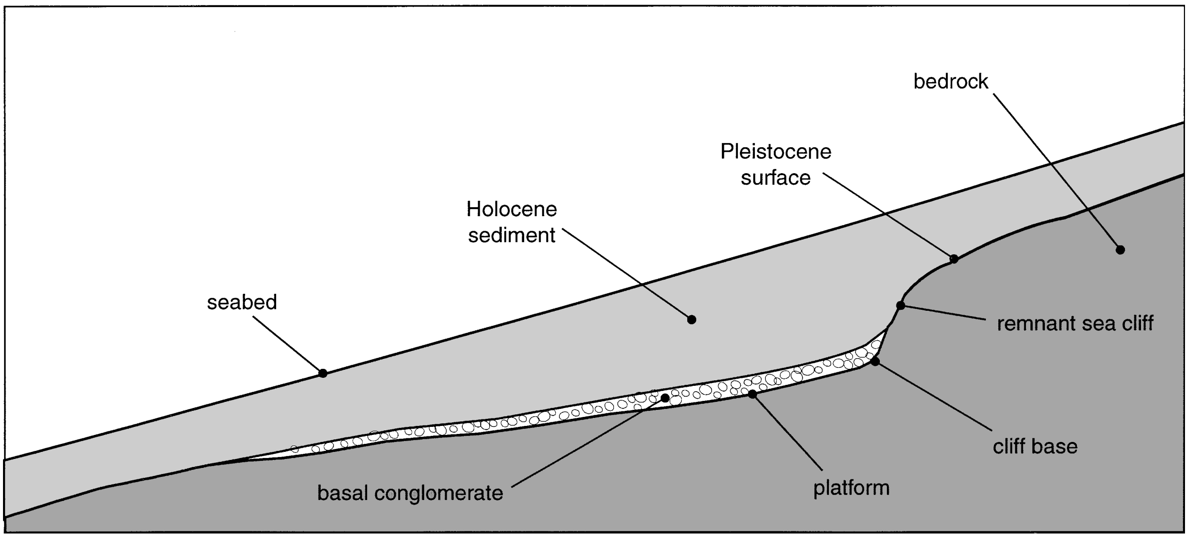

Figure M18 Illustration of wave-cut terrace notched into the bedrock and now found on the shelf by seismic profiling below a cover of Holocene surface sediment.

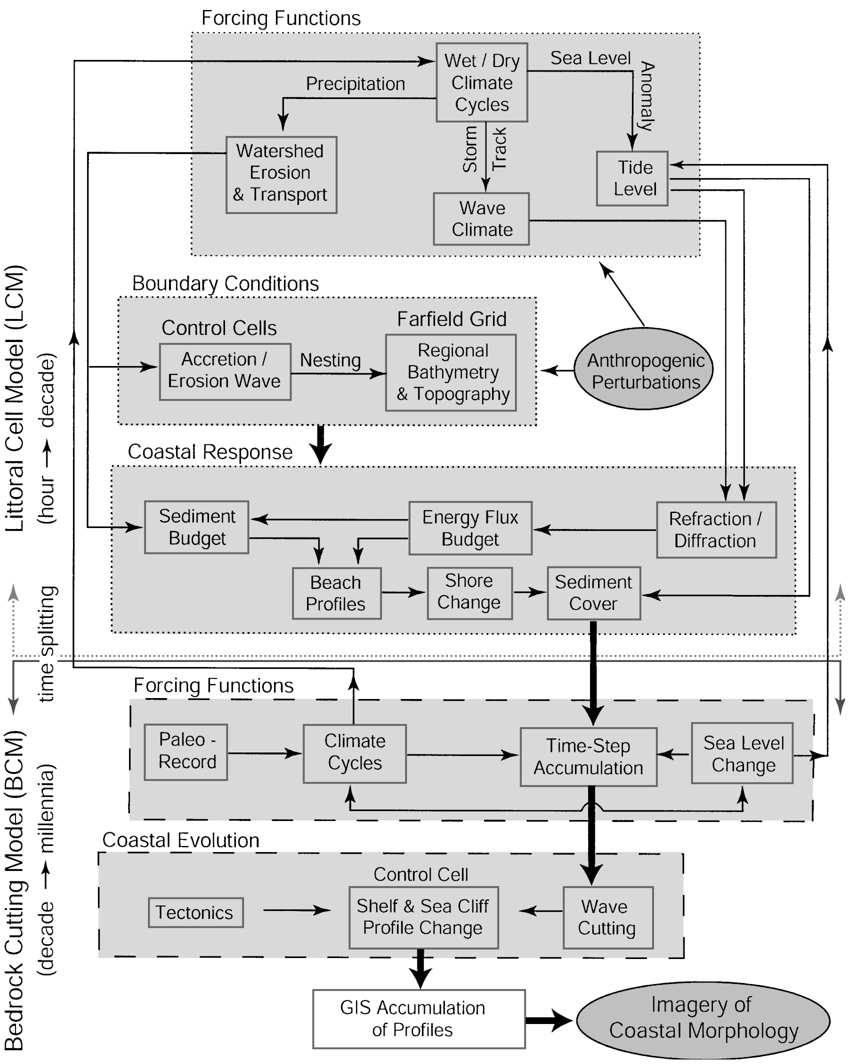

Figure M19 Architecture of the Coastal Evolution Model consisting of the LCM (above) and the BCM (below). Modules (shaded areas) are formed of coupled primitive process models (after Inman *et al.*, 2002).

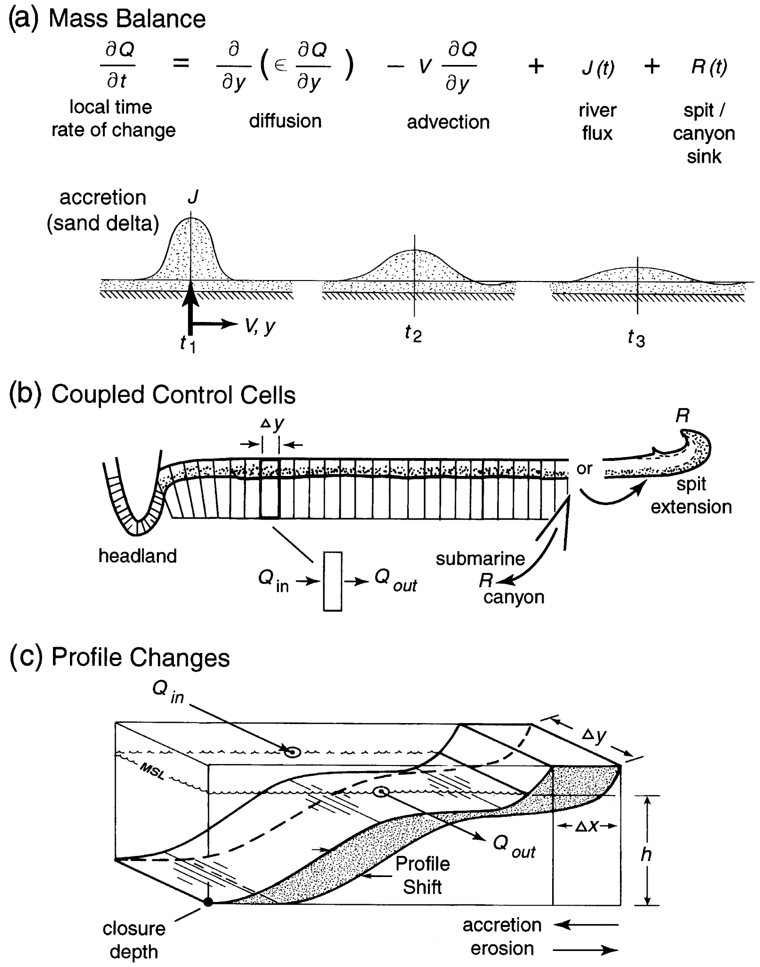

Figure M20 Computational approach for modeling shoreline change (after Inman *et al.*, 2002).

The present configuration of coastlines and their associated terraces and sea cliffs retain vestiges of the previous landforms from which they have evolved. Coastal evolution is a Markovian process where the present coastal features are dependent on the landforms and processes that preceded them (Inman and Nordstrom, 1971). This means that modeling coastal evolution must move forward in time from past known conditions and be evaluated by the present before proceeding to the future. Thus, paleocoastlines with their wave-cut terraces become time and space markers for modeling coastal evolution.

Numerical modeling of landforms

Physical models have provided insights and guidance to many of the processes leading to coastal evolution (e.g., Inman, 1983; Sunamura, 1992). Generally, these efforts are limited by the uncertainties between laboratory experiments and the time and space scales of the landforms they represent. These uncertainties are circumvented by numerical models where the temporal and spatial scales of the landforms are applied to the laws governing geomorphology.

Numerical modeling of landform evolution is a rapidly expanding field driven by the need to understand the environmental consequences of climate change and sea-level rise. Numerical modeling has been enabled by the revolution in computational power, graphical representation, and ever-expanding digital databases of streamflow, wave climate, sediment flux, and landform topography (Inman and Masters, 1994). Several two-dimensional models have been developed for the formation of wave-cut and wave-built terraces at various sea-levels. Storms *et al.* (2002) describe a process-response model for the development of barrier beaches during sea-level rise, and Trenhaile (2002) developed a model for the formation of rock platforms during changing sea level.

The Storms *et al.* (2002) model uses energy and mass flux balances to solve for incremental changes in the cross-shore profiles of mobile sediment in the Caspian Sea. On the other hand, the Trenhaile model uses a force-yield criterion to calculate the incremental erosion of steep, rocky submarine slopes. The latter model does not balance the budget of energy flux and, for certain selections of model parameters, requires a greater expenditure of energy in cutting rock than is available in the incident waves. This deficiency can be overcome by the energetics-based rock cutting model of Hancock and Anderson (2002). Developed for the formation of strath terraces in the Wind River valley during the Quaternary, the model includes sediment transport, vertical bedrock cutting that is limited by alluvial cover, and lateral valley-wall erosion. When reformulated for wave-forcing and sea-level change, their approach is applicable to wave-cut terraces.

Architecture of a coastal evolution model

Here, we describe the broad outlines of a three-dimensional coastal evolution model developed under funding from the Kavli Institute (Inman *et al.*, 2002). The model is functionally based on a geographic unit known as a littoral cell. A littoral cell is a coastal compartment that contains a complete cycle of sedimentation including sources, transport paths, and sinks. The universality of the littoral cell makes the model easily adaptable to other parts of the world by adjusting the boundary conditions of the model to cells characteristic of different coastal types (see entry on *Littoral Cells*).

The Coastal Evolution Model (Figure M19) consists of a Littoral Cell Model (LCM) and a Bedrock Cutting Model (BCM), both coupled and operating in varying time and space domains determined by sea level and the coastal boundaries of the littoral cell at that particular time. The LCM accounts for erosion of uplands by rainfall and the transport of mobile sediment along the coast by waves and currents, while the BCM accounts for the erosion of bedrock by wave action in the absence of a sedimentary cover. During stillstands in sea level along rock coasts, the combined effect of bottom erosion under breaking waves and cliffing by wave runup carves the distinctive notch in the shelf rock of the wave-cut terrace (Figure M18).

In both the LCM and BCM, the coastline of the littoral cell is divided into a series of coupled control cells (Figure M20). Each control cell is a small computational unit of uniform geometry where a balance is obtained between shoreline change and the inputs and outputs of mass and momentum. The model sequentially integrates over the control cells in a downdrift direction so that the shoreline response of each cell is dependent on the exchanges of mass and momentum between cells, giving continuity of coastal form in the downdrift direction. Although the overall computational domain of the littoral cell remains constant throughout time, there is a different coastline position at each time step in sea level with similar sets of coupled control cells.

Time and space scales used for wave forcing and shoreline response (applied at 6 h intervals) and sea-level change (applied annually) are very different. To accommodate these different scales, the model uses multiple nesting in space and time, providing small length scales inside large, and short timescales repeated inside of long time scales.

The LCM (Figure M19, upper) has been used to predict the change in shore width and beach profile resulting from the longshore transport of sand by wave action where sand source is from river runoff or from tidal exchange at inlets (e.g., Jenkins and Inman, 1999). It has also been used to compute the sand-level change (farfield effect) in the prediction of mine burial (Inman and Jenkins, 2002).

Bedrock erosion

The BCM (Figure M19, lower) models the erosion of bedrock by wave action during transgressions, regressions, and stillstands in sea level. Because bedrock cutting requires the near absence of a sediment cover, the boundary conditions for cutting are determined by the coupled mobile sediment model, LCM. When LCM indicates that the sediment cover is absent in a given area, then BCM kicks in and begins cutting. BCM cutting is powered by the wave climate input to LCM but applied only to areas where mobile sediment is absent. Time-splitting logic and feedback loops for climate cycles and sea-level change are imbedded in LCM together with long runtime capability to give a numerically stable couple with the BCM.

Bedrock cutting involves the action of wave-energy flux to perform the work required to notch the country rock, abrade the platform, and remove the excavated material. Both abrasion and notching mechanisms are computed by wave-cutting algorithms. These algorithms provide general solutions for the recession of the shelf and sea cliff. The recession is a function of the amount of time that the incident energy flux exceeds certain threshold conditions. These conditions require sufficient wave-energy flux to remove the sediment cover, and a residual energy flux that exceeds the erodibility of the underlying bedrock. The erodibility is given separate functional dependence on wave height for platform abrasion and wave notching of the sea cliff.

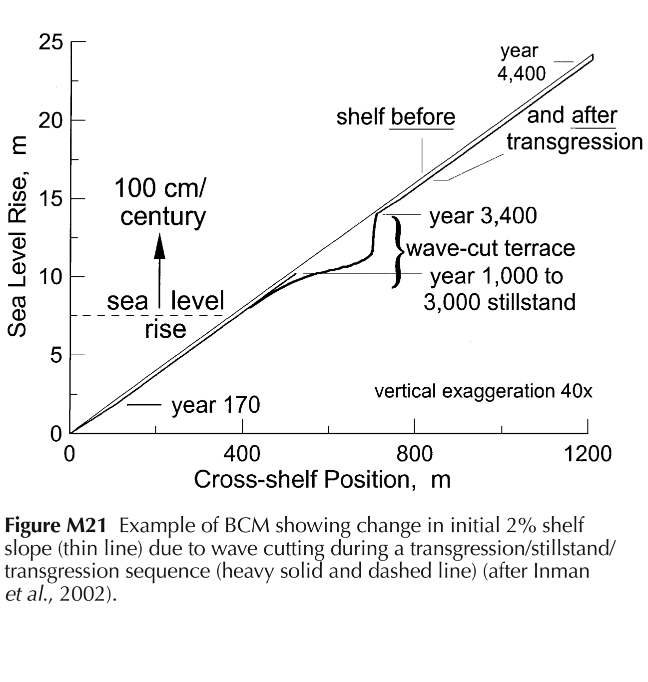

Figure M21 Example of BCM showing change in initial 2% shelf slope (thin line) due to wave cutting during a transgression/stillstand/transgression sequence (heavy solid and dashed line) (after Inman *et al.*, 2002).

The erodibility for platform abrasion increases with the 1.6 power of the local shoaling wave and bore height, commensurate with the energy required to move the cobbles in the basal conglomerate that abrade the bedrock platform (Figure M18). As a consequence, recession by abrasion is a maximum at the wave breakpoint and decreases both seaward and shoreward of that point. In contrast, the erodibility of the notching mechanism is a force-yield relation associated with the shock pressure of the wave bore striking the sea cliff (Bagnold, 1939; Trenhaile, 2002). The shock pressure is proportional to the runup velocity squared, and its field of application is limited by wave runup elevation. Wave pressure solutions (Havelock, 1940) give a notching erodibility that increases with the square of the wave runup height above water level.

An example of terrace cutting by the BCM is shown in Figure M21 where a constant sea-level rise of 100 cm/century over a continental shelf sloping 2% was interrupted by a 2,000-year stillstand. The wave cutting was driven by a two-decade continuous wave record reconstructed for the southern California shelf by wave monitoring (Inman *et al.*, 2002). This data was looped 220 times to provide forcing over the 4,400-year long simulation. Inspection of the figure shows that the shelf slope receded about 15 m during the periods of rapid sea-level rise. During the 2,000-year stillstand, a wave-cut terrace was formed with about a 150 m wide wave-cut platform and a 3 m high remnant sea cliff. These dimensions are in approximate agreement with evidence of wave-cut terraces along the California coast (Inman *et al.*, 2002). However, models of terrace cutting at paleo-sea levels will always require input of proxy wave climate appropriate for the location being modeled as well as the proper erodibility coefficients for the bedrock at that location (see entries on *Climate Patterns in the Coastal Zone*, and *Energy and Sediment Budget of the Global Coastal Zone*).

MODES AND PATTERNS OF SHORELINE CHANGE

Introduction

It is estimated that worldwide 70% of all beaches are eroding (Bird, 1985); in the United States this percentage may approach 90% (Heinz Center, 2000). Nearly every developed shoreline in the United States is retreating, and the coast is on a collision course with seaside development. This problem is manifest in the United States where heavily developed barrier islands are experiencing sea-level rise and beach erosion. For example, Galgano (1998) demonstrated that more than 86% of US East Coast beaches are eroding. With property values estimated at over $3 trillion for the US East and Gulf Coast barriers, these policy decisions invariably have important economic consequences for coastal communities. Consequently, a precise understanding of shoreline (defined as the high water line or wet–dry boundary) change using accurate shoreline change models and geomorphic characteristics is paramount.

Managing beach erosion is a difficult challenge for government agencies. The costs of erosion are often burdensome. Also, there is a paucity of long-term beach erosion data, and we still do not thoroughly understand how shorelines change over time. Consequently, policy decisions are regularly based on statistical modeling without a comprehensive understanding of patterns of shoreline change (Leatherman, 1993). The methodology frequently employed is to determine shoreline change rates for an entire reach using simple statistical analyses of erosion.

Barrier islands are naturally dynamic landforms and inevitably change position and shape depending upon the changing relationship between coastal processes, the geologic framework, and human intervention. To date, a great deal of research has focused on understanding beach (profile) dynamics and defining shoreline (planform) change. Initially these studies focused on beach structure and beach-shoreface equilibrium models, generally over limited spatial and temporal scales-measured on the order of years and decades (e.g., Dean, 1977; Bruun, 1988). More recently, coastal geomorphologists have presented new theories for their long-term change and evolution over much longer time frames (e.g., Hayes, 1979; Leatherman *et al*., 1982; Anders *et al*., 1990; List and Terwindt, 1995; McBride *et al*., 1995).

Modes of shoreline change

It is generally accepted that there is geographic diversity in coastal landforms. This diversity is a result of the differences and combined effects of coastal processes and antecedent geology; shoreline change and coastal configuration are the integrative result. A "mode" of shoreline change is defined as a discrete pattern of shoreline movement identified through recognition of a unique change in shape, a rate of movement, or a cycle of change.

Modes of shoreline change may occur as two-dimensional (linear) or three-dimensional (alongshore) transformations operating over variable temporal and spatial scales, caused by the interaction of coastal processes within the constraints of geologic controls and sometimes with anthropogenic influence (e.g., inlet jetties). A mode of shoreline change can likewise depict a specific stage in an ordered sequence of shoreline development, whereby successive modes are dependent on preceding environmental factors and conditions for their existence (e.g., mesotidal barrier inlets). Modes of shoreline change identified to date are given in Table M8.

What relevance can be associated with the delineation and analysis of modes of shoreline change? Understanding modes of shoreline change provides a standardized geomorphic framework upon which shoreline change data can be more accurately interpreted. Purely statistical methods of shoreline change analysis (e.g., the "black-box" approach) often yield misleading results. Defining modes of change based on geomorphic principles and hence understanding the reasons for shoreline change yields a practical management tool. For many years, coastal scientists have been mapping historical shoreline positions to calculate rates of change (Heinz Center, 2000). Nonetheless, traditional uses of these data (e.g., statistical prediction of future shoreline positions for building setback codes) has been rather confined and flawed (Douglas *et al*., 1998). Determination of an average shoreline rate of change and an understanding of the temporal and spatial variability associated with this change can be useful only if the causes of the change are recognized and understood.

Wave versus tide energy

Processes that operate along the coast give rise to changes in barrier island size, shape, orientation, and position. Price (1953) first illustrated how wave and tidal energy were primary controls on shoreline processes and beach planform. In a later publication, Price (1956) suggested that the bottom profile and geologic structure of the nearshore have important influences on beach morphology based on his analysis of low-energy coastlines in the Gulf of Mexico. He concluded that the most important geomorphic control on depositional coasts is the type and magnitude of hydrologic energy in the region. Davies (1964) illustrated that the two most significant hydrologic factors are wave energy and tidal current energy, both influenced by tidal range.

Hayes (1975) was the first to interpret the combined influence of wave energy and tidal range on barrier island morphology on a global scale. As a result of Hayes' (1975) work and later research by Nummendal *et al*. (1977), morphogenetic nomenclature of tide-dominated, wave-dominated, and mixed energy became widely accepted classifications for barrier systems (McBride *et al*., 1995). Hayes (1979) showed how tidal range influences barrier island morphology because the effectiveness of wave action is attenuated, and tidal current activity is increased as vertical tidal range increases. Hence, in microtidal ($T_R < 2$ m), wave-dominated conditions, barrier islands are long and narrow, and are characterized by only a few ephemeral inlets. In contrast, short, stubby "drumstick" barrier islands are manifest in mesotidal ($T_R = 2$–4 m) conditions. In this case, barrier morphology is linked to the presence of relatively stable inlets. Large ebb-tidal deltas are associated with these inlets and are common on mesotidal coastlines. The interaction of these large ebb-tidal deltas with wave energy, combine to play a significant role in shaping the coastal configuration and morphology of adjacent barrier islands by accumulating and storing large quantities of sand-sized sediment which becomes available to the island on occasion and by inducing littoral current reversals driven by wave refraction. The end result is the characteristic "drumstick" shape (Hayes, 1979).

Davis and Hayes (1984) concluded that the "standard" definitions of wave-dominated (microtidal) and tide-dominated (mesotidal) coasts are

Table M8 Proposed shoreline classification types based on modes of shoreline change (after Leatherman, 1993)

Type	Classification
1	Simple linear retreat
2	Alternating erosion and accretion
3	Progressive erosion alongshore
4	Storm punctuated erosion
5	Inlet-induced erosion
6	Cyclic shoreline change
7	Mesotidal barrier behavior
8	Apparent island rotation
9	Pre-Holocene controlled configuration
10	Progressive erosion temporally
11	Cape-like features
12	Spit elongation

based solely on the analysis of moderate wave-energy environments and are not adequate to explain the numerous exceptions to these broad classifications. Hayes' (1975, 1979) classification is based largely on coasts with moderate wave energy. In their analysis of Gulf of Mexico shoreline types, Davis and Hayes (1984) explained that tidal prism (the volume of water that must be exchanged through a tidal inlet) represents one of the more important, but frequently discounted factors in determining the morphology of barrier islands. In the Gulf of Mexico, which has a diurnal tide, there is no relationship between tidal range and tidal prism because of the large lagoons and bays. Nonetheless, large tidal prisms, especially in areas of low wave energy, can explain large, well-developed ebb-tidal deltas and the characteristic drumstick shape. They suggest that a continuum between processes exists, and it is therefore possible to identify three types of coasts: (1) wave dominated, (2) tide dominated, and (3) one balanced between tides and waves.

Cape development

The importance of wave energy and tidal currents to the morphology of coastal landforms has been used to explain the development and morphology of cape-like features (Davies, 1964). Over the past three decades, the genesis and morphology of cape-like features has led to a great deal of study and scientific speculation. Most early models attributed the formation of cape-like features to accretional processes through the action of waves and currents, eddies from large ocean currents, and geologic controls. Hoyt and Henry (1971) observed that that the popular models of cape formation based on modern processes (e.g., wave refraction, sediment transport and deposition) did not explain the association of capes with major rivers and their similarity to ancestral capes in the region. Hoyt and Henry (1971) rejected the premise that waves and currents transport sufficient sediment out of adjacent embayments because it is not consistent with wave refraction and the concentration of wave energy on promontories. Their analysis of the Carolina capes suggests that erosion is the predominant process shaping the modern coastal configuration. The Carolina capes are most likely the result of the retreat and reworking of ancestral Pleistocene river deltas during Holocene sea-level rise. Moslow and Heron (1981) supported the theory that the modern coastal configuration of these well-known capes can be attributed to the erosion and gradual landward retreat of formally larger antecedent capes.

Finkelstein (1983) proposed a model for the development of sedimentary capes on straight shorelines through development of a large recurved spit at a littoral barrier. Using Fishing Point, Virginia at the southern end of Assateague Island as an example, Finkelstein (1983) demonstrated that cape-like features might occur where an inlet traps a large volume of littoral sediment. In the case of "cape" Assateague, a large volume of longshore sediment (115,000 m^3/yr) is trapped updrift of Chincoteague Inlet. This cape has developed since 1859 and has a pronounced influence on the shoreline by sand-starving the barriers islands to the south (Rice and Leatherman, 1983). The impoundment of longshore sediment in the cape has starved the downdrift beaches to the extent that a 5-km offset is observed on the islands to the south, and erosion rates of 10+ m/yr are observed for tens of kilometers to the south. The net result is a highly concave shoreline extending 35 km south of the cape, termed an "arc of erosion" (Leatherman, 1993).

Dolan *et al.* (1979) hypothesized that capes will develop along the Virginia barrier island chain. In their analysis, the authors postulated that the pronounced growth of the bulbous updrift ends of drumstick barrier islands were an indication of cape development. Unfortunately, they did not recognize the cyclic change of accretion and erosion of the bulbous ends of drumstick barrier islands that operates on timescales of decades to centuries. Hence, their prediction of cape development was flawed.

Leatherman *et al.* (1982) conducted a geomorphic analysis of long-term (>100 yr) shoreline change maps and geomorphic data to explain the coastal configuration and varied patterns of retreat of the Virginia barrier islands. They showed how sediment supply, controlled by the net southerly littoral drift, and the influence of inlets played a critical role in individual island adjustments. Antecedent Pleistocene topography beneath the barrier islands influences inlet position and stability. Differential subsidence and littoral sediment starvation have triggered a more rapid landward migration in the northern group of islands. Finally, wave refraction over the inner continental shelf has induced wave focusing on the southern two groups of barrier islands, causing more changes in orientation than the northern group. The presumed capes are in reality drumstick barrier islands behaving as described by Hayes (1979), and the recorded changes in the coastal configuration of the Virginia barrier islands suggests that a smoother shoreline configuration (e.g., opposite of capes) can be anticipated in the future (Leatherman *et al.*, 1982).

Tidal inlets

Tidal inlets represent the most important feature along a sandy coastline in relationship to littoral processes. The preeminent role of inlets in the cyclic nature of barrier island morphodynamics was introduced by Hayes (1975, 1979). Dean and Walton (1975) indicated that tidal inlets represented the largest sediment sink of beach sand along the coast and are believed to be responsible for much of the beach erosion in Florida.

Hayes (1975) pointed out that microtidal inlets are more dynamic than their mesotidal counterparts. Mesotidal inlets are more stable and are strongly associated with Pleistocene drainage channels. Halsey's (1979) research along the Delmarva Peninsula strongly suggested that inlet channels are correlated with relict thalwegs (the deepest part of a stream channel) of ancient streams. Further, the higher interfluves become the loci or "nexus" for barrier island formation.

The critical role played by inlets, natural and jettied, in controlling the morphology and orientation of shorelines is well documented. There is growing research dedicated to determining the spatial extent of the downdrift effect of inlets (FitzGerald and Hayes, 1980; Leatherman *et al.*, 1987). The critical role played by inlets is their cumulative influence on the regional orientation and composition of coastal reaches.

Tidal inlets are dynamic features and can dramatically affect the morphology of adjacent barrier shorelines (Hayes, 1975). The processes of inlet migration can bring about erosion and deposition to flanking barrier islands. This arc of erosion is possibly the most dramatic influence of tidal inlets on adjacent barrier islands. Finkelstein (1983) illustrated how Chincoteague Inlet served as a littoral barrier and caused an arc of erosion extending 35 km downdrift. Wave refraction associated with large ebb-tidal deltas has been shown to cause reversals in the longshore transport system, resulting in onshore or alongshore sediment transport and ultimately unique changes in beach planform (Hayes, 1979).

The degree to which inlets modify the adjacent shorelines is a function of their tidal range. In most instances tidal range correlates well with the size of tidal inlets. South Carolina offers an excellent example of the role of tidal inlets on coastal orientation and morphology. FitzGerald *et al.* (1978) illustrated how the number of inlets along the South Carolina coast is correlated to tidal range. Along the northern segment of the South Carolina coastline, the mean tidal range is 1.5 m. In this area, tidal inlets comprise less than 2% of the total shoreline. In contrast, the southern segment of this coast has a tidal range of 2.2–2.5 m. Accordingly, the amount of tidal inlet shoreline increases to 25%. Since the processes related to ebb-tidal deltas can directly control the morphology of adjacent barrier islands, tidal inlets will have a greater influence on shoreline morphology along barrier island coastlines with increased tidal ranges (FitzGerald *et al.*, 1978). Nummendal *et al.* (1977) noted that the erosional and accretional nature of South Carolina's barrier islands is intimately connected with the change of tidal inlets. Increasing tidal ranges south of Cape Romain dictate larger and more numerous tidal inlets and therefore increased seaward transport of littoral sediments. FitzGerald *et al.* (1978) proposed that the three primary types of shoreline change in South Carolina were associated with three types of tidal inlets.

Brown (1977) recognized three distinct geomorphic zones along the South Carolina coast. The northern segment, or the arcuate strand, is relatively stable through time and is characterized by few inlets. A cuspate delta occupies the central portion of the coastline. In the south where there are numerous inlets, barrier islands with highly variable shoreline change rates predominate (Brown, 1977). Anders *et al.* (1990) showed in their analysis of shoreline movements in South Carolina that the greatest variability of shoreline change rates was in the vicinity of coastal inlets. These findings were supported by Hubbard *et al.* (1977) who pointed out that the arcuate strand beaches of northern South Carolina are stable everywhere except in the vicinity of tidal inlets. Only where there are 15–20 km between inlets does one escape their influence on the shoreline. These observations were supported on a more quantitative basis by Galgano (1998), who demonstrated that tidal inlets control shoreline change on 70% of the beaches on the mid-Atlantic coastline.

Leatherman (1984) demonstrated the dramatic influence of jettied inlets on the long-term evolution of a barrier island. In a natural system, it is generally accepted that the long-term evolution of a barrier island will follow a general model of landward migration through time. In this scenario, the entire system (e.g., the barrier, bay, and mainland shoreline) will migrate as a geomorphic unit and retain the same general configuration. Leatherman (1984) provided an example where the system has been altered to the extent that large-scale evolution of a coastal unit is fundamentally changed. Ocean City Inlet was stabilized by jetties in 1934/35. These jetties had a very rapid and pronounced influence on the morphology of northern Assateague Island. The jetties interrupted a longshore sediment flow of 140,000 m^3/yr. Further, the ebb-tidal delta captured an estimated 6,000,000 m^3 of sand, thus completely depriving the downdrift beaches of sand and creating an arc of erosion that extends some 10 km downdrift. Northern Assateague Island, which eroded at an historical rate of 0.6 m/yr prior to inlet stabilization, reached rates averaging 11.5 m/yr (Leatherman, 1984).

Leatherman (1984) indicated that the implications of this dramatic increase in erosion will have important consequences on the long-term evolution of northern Assateague Island, Maryland. The northern segment of the island will not migrate landward as an entity as some predict in accordance with accepted models of shoreline change. If sea level alone were the driving influence behind this migration, this assumption would be essentially correct, but sea-level rise represents only a small percentage of the erosion potential and the bay is shrinking in width over time. Leatherman (1984) theorized that there would be a loss of a section of the barrier island with the opening of the mainland to ocean waves in the foreseeable future, similar to what occurred at Nauset Beach, Chatham, Massachusetts (Leatherman, 1984).

Leatherman *et al*. (1987) modeled the erosion of northern Assateague Island to quantitatively determine its future movement. The authors proposed that the arc of erosion will continue to migrate southward through time, and this pattern of shoreline evolution can be mathematically modeled. The northernmost 10 km of the island currently represents the arc of erosion. There is no terminal end to this arc in a temporal sense. In other words, the arc of erosion will continue to migrate southward through time. Further, the area of maximum erosion will migrate downdrift so that the erosion rate will represent a non-steady-state condition. Leatherman *et al*. (1987) determined that because of the island's low elevation and narrow width, a storm will cause inlet breaching by the year 2020 with loss of the northern portion of the island as the sand is welded onto the mainland (unless artificial beach nourishment is undertaken).

Barrier migration

Tidal inlets have been ascribed an increasingly important role in barrier island migration. Most existing barrier islands are believed to have originated 7,000–8,000 years ago and have migrated to their modern positions with post-glacial sea-level rise. A number of theories describing the mechanisms for barrier island migration have emerged. Perhaps, the most widely accepted theory is the concept of continuous, albeit intermittent, barrier island migration by shoreface retreat (Leatherman, 1983). Research by Kraft (1971), Kraft *et al*. (1975), and Belknap and Kraft (1985) using extensive core samples and radiometric data demonstrated how barrier islands migrate landward and upward on the continental shelf during periods of sea-level rise. The landward migration or "roll-over" of barrier islands in a transgressive environment is a central issue in the study of modes of shoreline change.

Early researchers (e.g., Godfrey and Godfrey, 1973) held that overwash was the most important agent in landward migration. Field data supported what was intuitively obvious—that wave-driven overwash sediments were transported across the island, causing bayside accretion. Hence, landward migration was accomplished by a steady progression of beach erosion and bayside accretion. McGowan and Scott (1975) supported this hypothesis suggesting that overwash events transported considerable volumes of sand to the landward side of the island. Therefore, in a condition of dynamic equilibrium, the barrier island profile does not change its size or shape, but instead maintains its volume and migrates landward with equal magnitudes of seaside erosion and bayside accretion.

Later, work by Armon (1979) in Canada and Leatherman (1979) in Maryland countered that inlets played the predominant role in barrier island migration. Using extensive on-site surveys of overwash fans on Assateague Island, Leatherman (1979) showed that overwash processes were most important for building the vertical elevation of the barrier island. But overwash processes do not transport sufficient volumes of sediment to the bayside to maintain barrier island width. Barrier island width is maintained by inlet processes through the creation of large flood tidal deltas. Relict flood deltas serve as the platform onto which overwash and aeolian sediments accumulate.

Leatherman and Zaremba (1986) researched the long-term evolution of Nauset Spit, Cape Cod, Massachusetts to determine the relative influence of inlet and overwash processes on barrier island migration. The lateral growth of the spit is largely controlled by inlet dynamics as inlets migrate downdrift (south), whereas overwash during major storms events caused substantial widening of this very narrow barrier spit in local areas. Overwash is the primary means of transporting sediment across barriers backed by glacial headlands or extensive salt marshes because the establishment of an inlet channel is precluded. Overwash in these circumstances tends to be the most effective barrier migration process through interaction with aeolian transport and dune-building processes in the subaerial zone. This vertical accretion permits the barrier island to maintain its elevation during landward retreat.

Time frames for barrier migration

While the mechanisms and geometry for barrier island migration and modes of shoreline change are intuitively well understood, the time frames decidedly are not. Much speculation exists in the literature and some envision that barrier island migration occurs extremely rapidly—on the order of 50–100 years. The implied assumption in their argument is that the barrier will conserve its mass and move as a unit. Others imply that in some situations, barrier islands are overtaken by sea level and drown in place (e.g., Rampino and Sanders, 1980). This barrier island drowning model has never been observed or supported by data (Panageotou and Leatherman, 1986). Recent studies (Schwab *et al*., 2000) substantiate the findings of Panageotou and Leatherman (1986) that the 18-m isobath off Fire Island, New York is not a drowned barrier island.

Time frames for shoreline movement are a subject of much debate, and the literature is replete with examples of shoreline movements at all timescales. Moody (1964) showed how a single, large storm event could displace the shoreline by a hundred meters in a matter of a few days, but a continuum exists between short-term storm events to long-term evolution (e.g., order of centuries). In addition, a very high degree of post-storm recovery has been observed, even after great storms (Morton *et al*., 1994; Douglas *et al*., 1998).

The prevailing theme in geomorphic literature is that barrier islands are continuously migrating landward in response to sea-level rise. In doing so, they maintain their mass through equal amounts of seaside erosion and bayside deposition (from overwash events). However, quantitative studies at Fire Island, New York and Hatteras Island, North Carolina indicated that both sides of the islands are eroding rather than migrating (Leatherman, 1987). Therefore, beach erosion does not necessarily signify barrier island migration. Migration denotes a change in the barrier island's centroid; this is not accomplished by erosion alone. Barrier island migration is a time-averaged phenomenon. This migration is not a continuous process, but instead is caused by episodic and site-specific, storm-generated events over longer-time frames.

Leatherman (1987) presented geomorphic and shoreline change map data that indicated that many barrier islands are thinning by bayside and oceanside erosion to some critical barrier width. Once the barrier island has achieved this critical width, migration by inlet and overwash processes will become effective in barrier island translocation. McBride *et al*. (1995) observed this slimming-down process in their study of long-term barrier island behavior in the Gulf of Mexico. They concluded that when shore position is monitored over time, shoreline change could be quantified and classified into a number of geomorphic response types as a function of scale. These studies indicate the need for the longest possible period of record of shoreline position data in order to make the correct geomorphic interpretation.

McBride *et al*. (1995) conducted a quantitative analysis of historical shoreline position over a spatial scale of 10–100 km. Their analysis provides a scientific basis for documenting process-response relationships that shape regional coastal morphodynamics. Even though "megascale" shoreline change studies are typically under-sampled spatially, this type of data is essential for formulating realistic research and management strategies regarding form/process relationships. The authors identified eight geomorphic response types to classify barrier coasts on a "mega-scale;" that is coastal reaches of 10–100 km at time frames of decades to centuries (Table M9). The authors inferred that sea-level rise is one of the major factors that controls the occurrence of these geomorphic response types along the barrier chains in Georgia and Louisiana. In regions where sea-level rise occurs at lower rates, sediment supply appears to be the dominant factor.

Antecedent geology

Contemporary literature offers a growing number of works that assign increasing importance to the role of antecedent geology controlling coastal configurations and modes of shoreline change. Many early researchers understood that there were important geologic controls

Table M9 Megascale geomorphic response types (after McBride *et al.*, 1995)

Classification	Response Type
Simple	Lateral movement
	Advance
	Dynamic equilibrium
	Retreat
Complex	In-place narrowing
	Landward rollover
	Breakup
	Rotational instability

influencing coastal configurations. Price (1953) was perhaps the first to establish the important influence of antecedent topography on coastal landforms, but this research was hindered by the absence of quantitative and stratigraphic data.

Kraft (1971) conducted studies of Holocene sediments in coastal Delaware, illustrating that Holocene sediments are deposited over a complex Pleistocene unconformity. Large, modern depositional features, such as spits, baymouth barriers, and tidal deltas in Delaware are in large measure related to the presence and relative relief of the subsurface Pleistocene topography. Kraft (1971) showed how relict drainage patterns influenced the location of modern tidal inlets and shoreface sediment types. Further, Pleistocene headlands served as focal points for barrier island formation. In similar research, Halsey (1979) suggested that inlet channels along the Delmarva Peninsula were strongly correlated to relict stream thalwegs, and interfluves have become the loci for barrier island formation.

Kraft *et al.* (1975) presented a detailed study of the geologic structure of the Delaware coast and the influence of Pleistocene topography on modern barrier island change. Relict drainage systems, Pleistocene headlands (subsurface and subaerial) and relict barrier formations combined to create a complex system of "coastal anomalies" in what is an otherwise straight coastal configuration. These "coastal anomalies," or bulges and re-entrants along the coast, were quantified by detailed shoreline change mapping of the Delaware coast by Galgano (1989). This mapping indicated the spatial diversity of modes of shoreline change within a coastal compartment.

Davis and Kuhn (1985) conducted research along the western coast of Florida and determined that antecedent geology played a vital, but very different role in controlling shoreline change. This segment of the Florida coast is atypical for a microtidal coast in that it is composed of numerous drumstick barrier islands with stable inlet channels and large ebb shoals. Core samples and seismic profiling revealed that pre-Pleistocene geologic formations were responsible for this somewhat uncharacteristic situation. The data revealed that a subtle, but well-defined limestone ridge of Miocene age with a relief of approximately 1 m underlies the modern barrier islands. Further, shoreward of the barriers, the irregular limestone surface slopes gradually toward the Gulf of Mexico. Davis and Kuhn (1985) indicate that the limestone platform is instrumental in controlling the location of the barrier islands and attenuating wave energy.

Oertel *et al.* (1992) interpreted the function of antecedent topography in barrier lagoon development. Microtidal lagoons are relatively wide and open, with few marshes. Conversely, mesotidal lagoons are narrow with numerous marshes. The authors theorize that pre-Holocene topography is the key determining influence for this phenomenon. Oertel *et al.* (1992) suggested that lagoon floors along tide-dominated coasts reflect the antecedent topography, which is dominated by well-defined fluvial channels and interfluves. The interfluves produce shallow areas in the lagoon, which become colonized by marshes. In the microtidal setting, the floors of barrier lagoons are initially smooth after formation.

The major theme in much of this research is that passive margin coastlines, such as the US Atlantic coast, are significantly influenced by the geologic framework. Some of these barriers have been shown to be perched barriers, resting on a pre-Holocene structure that controls modern beach dynamics and morphology (Kraft *et al.*, 1975). Along other segments of the Atlantic coast, bathymetric features on the inner shelf modify waves and currents, ultimately affecting patterns of erosion and deposition. Riggs *et al.* (1995) presented a detailed appraisal of the influence on geologic structure on the North Carolina coast. Their research suggested that some shoreline features in North Carolina are controlled by pre-Holocene stratigraphic framework and beaches are perched on pre-Holocene sediments.

Riggs *et al.* (1995) subdivided the coastal zone into two distinct segments. North of Cape Lookout, the geologic framework consists of a Quaternary sequence; while the segment to the south is dominated by Tertiary and Cretaceous units that crop out across the coastal plain and along the shoreface. Superimposed on this regional framework is a relict drainage system resulting in a series of fluvial channels infilled by modern sediments separated by larger interfluves; this results in shorefaces which are either non-headland or headland-dominated.

Statistical modeling

One of the fundamental objectives of coastal geomorphology is to determine shoreline trends. To this end, coastal scientists have applied different statistical techniques to predict future shoreline positions. In the past several years, this practice has assumed increased significance because many coastal states are using historical shoreline change data to project shoreline position for application in land use policies, primarily in establishing building setback lines and insurance zones (Heinz Center, 2000).

The selection of an appropriate statistical model for shoreline change is a matter of some contention because it is critical to the final result. This problem is amplified because shoreline position data are typically limited and spaced irregularly through time. The principal issue is which shoreline positions represent the actual trend (i.e., not post-storm or wintertime shoreline data), what is the minimum acceptable period of record, how far into the future can the trend be usefully predicted, and which technique will best extrapolate the actual trend? The fundamental consequence of statistical modeling, regardless of the relative complexity, is that it will lose its physical and practical meaning if the geomorphic setting is not considered (Leatherman, 1993).

Fenster *et al.* (1993) proposed a new method, the Minimum Descriptor Length (MDL), for predicting shoreline change rates and forecasting future shoreline positions. This method selects the model (e.g., linear regression or polynomial) on the basis of the trend of the most recent data. It is predicated on the appearance of trend reversals within the data record and depends on the persistence of the data. The authors, however, neglected to disclose the quality of the prediction beyond a few years, nor did they adequately test the model against a spectrum of real data. Crowell *et al.* (1997) used the MDL to predict trends using a temporally rich set of sea-level rise data, replete with interannual variations, to assess the ability of the MDL to predict future trends against the established record of sea-level rise. That research demonstrated that the MDL is not a useful predictor of long-term trends. Crowell *et al.* (1997) concluded that in spite of interannual variability in the data, the most reliable *long-term* forecast of shoreline position will be made from linear regression using the longest possible time series. Finally, Galgano and Douglas (2000) illustrated the necessity to use more than 80 years of data to determine a shoreline change trend. At time frames less than 80 years simple calculations of change rate can actually produce the wrong sign (i.e., accretion versus erosion), and will likely produce a two or three sigma error in the trend. Furthermore, Galgano and Douglas (2000) demonstrated that the incorporation of post-storm and winter shoreline position data violate the assumptions of the linear regression model when mixed with summer shoreline position data.

Conclusions

Beach erosion and changes in coastal configurations are complex physical processes encompassing a number of natural and human-induced factors. These alterations drive the evolution of coastal configurations that generally conform to observable patterns; these modes of shoreline change are defined as a discrete pattern of shoreline movement identified through recognition of a unique change in shape, a rate of movement, or a cycle of change. Natural conditions that drive these changes include such variables as sea-level rise, tidal variations, wave energy, sediment supply, antecedent geology, seasonal variations in wave energy, and the episodic influence of storms. Humans influence the spatial and temporal variability of shoreline change by building structures (e.g., groins and jetties), dredging, damming rivers, and beach nourishment projects.

Spontaneous variations in natural processes and the effects of human activity on the coast drive spatial and temporal variations in shoreline change and the evolution of coastal landforms. Therefore, we should not anticipate that shoreline change rates and coastal configurations will remain uniform through time, instead we should realize that accelerations and declarations in rates of erosion/accretion and trend reversals could occur. Reliance on statistical methods of shoreline change analysis can often yield misleading results, whereas defining modes of change based on geomorphic principles and hence understanding the reasons for shoreline change provides a practical management tool.

MONITORING COASTAL ECOLOGY

Introduction—human action

Early human coastal development was probably in harmony with coastal processes, modifying the habitats rather than destroying them. As human populations have increased and land-use intensified, these habitats have come under greater pressure. Intensive agriculture, afforestation, and infrastructure development, including the mass tourism boom in many areas, have resulted in the destruction of natural areas especially along the shores of the Mediterranean (Doody, 1995). The impact on the environment increased the perception that coastal areas are vulnerable. This has led to the remaining areas, especially those dominated by "natural" landscapes, to be considered particularly precious. National and international legislation seeks to prevent further damage and destruction in these "fragile" environments.

Faced with mounting pressure on coastal and marine resources, there is increasing concern about the ability of the coast to sustain the many uses to which it is put, including those involving socio-economic development. This has been brought into sharp focus with the recognition that global warming is a reality and that one of its consequences is a rising sea level. If sustainability of use is to be achieved then understanding coastal processes and human influence on them is a prerequisite for management, policy, and planning. The way in which this understanding is achieved lies in the survey of landforms, habitats and species, and monitoring or surveillance of change in relation to natural process and the impact of human activities.

An historical legacy

Knowledge of the status and distribution of landscapes, habitats, and species provide essential baselines against which to measure change. Some of the earlier historical maps are important in this context. While they do not provide detailed information about habitats or species distribution, they can give great insights into long-term change. Early maps of the Suffolk Coast in eastern England around the time of Henry VIII, for example, show the configuration of the coast in the vicinity of Orford, then an important port (Anon, 1979). When compared to more recent maps a picture of change can be built up, which gives an indication of the scale and time scale over which it occurs (Figure M22).

This historical perspective is important to our understanding of the coast and coastal systems and the way in which they react to the impact of human actions over time scales longer than that of a single generation. In the United Kingdom, for example, there are a number of early texts which look at coastal issues from the point of view of the engineer and discuss these in terms of "Coast erosion and protection" (Wheeler, 1903; Matthews, 1934) and "Shoreline problems" (Carey and Oliver, 1918), or in relation to the creation of new land from the sea (Du-Plat-Taylor, 1931). Wheeler (1903) provides a series of geographical descriptions of the coast of England and short essays on northern France, Belgium, and Holland. A more systematic survey of the coastline of England and Wales was undertaken at the request of the Ministry of Town and Country Planning in 1943 (Steers, 1946) which was later extended to Scotland (Steers, 1973). These studies give a description of the geology, geomorphology, and geography of the coast and helped form the basis for planning policy on the coastline of Great Britain in later years.

Though useful, this historical approach can only give a broad indication of change. It does not provide the more detailed information required for the management of individual sites and resources or unravel the many and often complex changes, which characterize the coast. For this targeted surveys are needed, together with a detailed research, surveillance and monitoring. These aspects are dealt with next.

Definitions

Survey

Surveying involves the collection of both quantitative and qualitative information about a feature or features using a standardized methodology, but where there is no pre-formed view on the likely findings. Thus, other than identifying what will be surveyed (a species, plant community, habitat, or human activity) the primary aim is to obtain information on the nature, scale, and location of the chosen subject.

Surveillance

Repeat surveys provide a means of identifying change over time, for example, in the status of habitats and species or the rate of exploitation of a natural resource. As with the original survey there is no predetermined notion as to what change might be expected. The purpose of the new survey is to establish the nature of any change from the previous "norm."

Monitoring

This implies the need to assess and understand the outcome of a particular course of action, such as the management of a habitat or species or the extent to which resource depletion is sustainable. This may relate to compliance with a standard or deviation from an acceptable state.

Survey

In order to assess the significance of a particular feature it is essential to know where it is, how widespread and how much of it exists. Survey is the first basic tool in assessing the value of a particular coastal feature and as an aid to its conservation and management.

Habitat survey

Systematic surveys of landscapes, habitats, and species are a first stage in understanding the coast especially when considering its conservation. For example wide-scale habitat surveys are used to describe the nature conservation resource within a country as an aid to the selection of sites for statutory protection. In the mid-late 1980s in the United Kingdom, the nature conservation agencies (notably the Nature Conservancy Council) commissioned a series of coastal habitat surveys of Great Britain covering salt marshes (Burd, 1988), sand dunes (Dargie, 1993, 1995; Radley, 1994) and shingle structures (Sneddon and Randall, 1993). Attempts have been made to bring information together at a wider European scale but these are hampered by the variety of definitions and survey methodologies used and can only give a broad indication of the nature and scale of the resource (Dijkema, 1984; Doody, 1991). Site-specific surveys are often much more detailed and are used as a basis for developing management strategies such as those for the conservation of the flora and vegetation of the Wadden Sea islands, in the southern North Sea (Dijkema and Wolff, 1983).

Species recording

Establishing the location and population numbers of birds, (wintering and breeding) is also an essential prerequisite for the selection of sites to

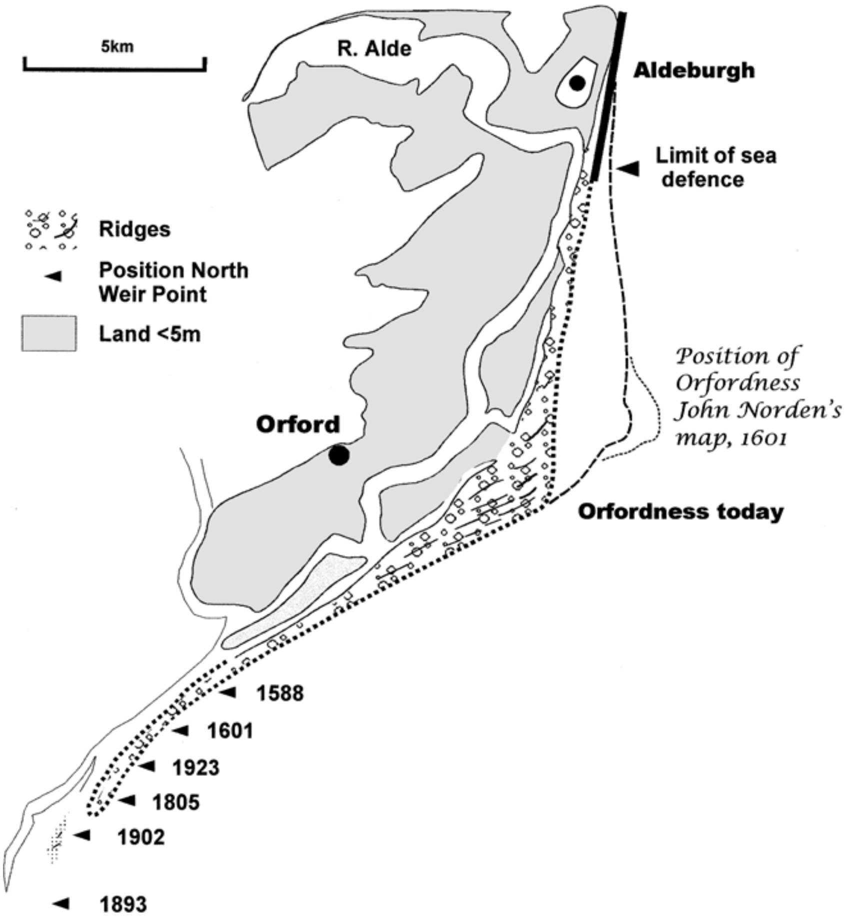

Figure M22 Change along the Suffolk coast between 1530 and 1963 derived from maps in Anon, 1977. (Adapted from Doody, 2001.)

protect rare and specialized species. It is important to know where the majority of a population of a restricted species resides during critical periods of its life cycle. For example, most of the world population of the gannet *Morus bassanus* nest on the coast of Great Britain and Ireland. In the case of this species it is even more important for the protection of the species, to know that 90,000 breeding pairs (approximately 5% of the total population) occupy one small site, the Bass Rock in south east Scotland. Similar considerations apply to other vulnerable and specialist species such as marine turtles which need to come ashore to nest on sandy beaches. Knowing where these are, and the number of breeding individuals is an essential prerequisite for any conservation program.

The results of habitats and species surveys can therefore provide:

- Summarized data from local to regional and national levels;
- Detailed maps showing distribution of vegetation, habitats, or breeding species;
- The basis for selection of important conservation areas;
- An assessment of the degree of conservation protection.

This information alone, tells us little about change, whether it is in terms of distribution, life-cycle movements, or population status. For this more frequent surveys are needed.

Identifying and understanding change—species studies

Managing the coast, whether for rare plants, specialist animals, important habitats, or human activities requires information on change and the causes of the change. If these show detrimental effects, either to the resources themselves, or knock-on effects to other interests, then it is essential to know what these are. By way of illustration, three elements can be discerned when monitoring individual species:

1. A species is rare or of special interest and managed to protect the population—are we being successful?
2. The species is invasive and we need to assess if our control measures are effective.
3. The species provides an indicator of change in the environment (Keddy, 1991).

Each of these is considered by reference to three examples:

1. Bird migration studies.
2. The expansion of *Spartina anglica* into many salt marshes throughout the temperate regions of the world.
3. Population studies of sea birds.

Bird migration

Determining whether a resident animal species is stable, declining, or increasing is relatively easy since recording breeding success or overall population numbers may be all that is required. However, unravelling the status of a migrant species is much more difficult. In this context, a systematic approach has been adopted for monitoring bird populations involving the use of bird-ringing techniques. The original purpose of this was to unravel the mysteries of bird migration. However, knowing the pattern of movement is only part of the story. These studies also provide a vital tool for helping to determine the life history and population dynamics of many bird species. The information needed includes the distances traveled, the stopping off (refuelling) points, and the routes over which migration takes place, as well as studies of the bird's breeding success and physical condition. Armed with this information it is possible to begin developing conservation strategies for species which may breed in the Arctic, winter in estuaries in the southern North Sea or even as far away as South Africa (Figure M23).

The importance of these studies is reflected in North America by the fact that the US Fish and Wildlife Service maintains a Division devoted to migratory bird management. Organizations undertaking such survey work, include the International Shorebird Survey which has been

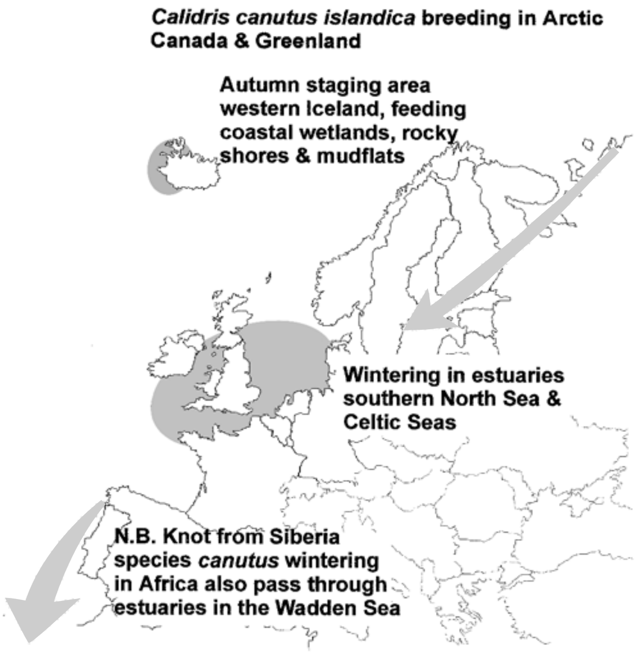

Figure M23 Migration patterns of the knot *Calidris canutus islandica* (see also British Trust for Ornithology, Migration Atlas Project). (Adapted from Doody, 2001.)

gathering standardized information on the numbers of shorebirds congregating at migratory stopover sites in the spring and fall since 1974. Standardizing and coordinating national studies using agreed practices for data collection and computerization are also recognized as part of the process. In North America, a "Migration Monitoring Network" was established in 1998 to coordinate activities including establishing standards and guidelines for the operation of monitoring programs. In Europe, in order to understand the significance of different parts of the species life cycle and the influence of human and other factors upon them, a European Union for Bird Ringing coordinates continent-wide research projects. This work is also used to monitor bird populations against international conventions and is a prerequisite for effective protective measurements for the many declining bird species, especially in their more vulnerable locations.

In the United Kingdom, the WeBS (Wetland Bird Survey) Low Tide Counts are part of a joint scheme coordinated by the British Trust for Ornithology. In this case, counts are made on about 20 selected estuaries each winter (November–February) to determine the distribution of birds during low tide and to identify important feeding areas that may not be recognized during Core Counts which, on estuaries, are mostly made at high tide. In this context, British estuaries are known to be important wintering areas for several waders (including the knot) that breed in Arctic Canada and Greenland, and staging areas for those that breed in Siberia and winter in Africa. The pattern of bird ringing recoveries, combined with the knowledge of breeding success and observed changes in wintering numbers provide the basis for assessing the status of the species. Evidence from bird counts in estuaries in the southern North Sea suggest that knot numbers have recovered from losses in the 1980s, though only to about 70% of its numbers in the 1970s. The reasons why the numbers have not returned to their previous levels are not clear. Loss of intertidal habitat through land-claim and deterioration in the quality of habitat at its wintering sites are implicated, in the absence of major change in breeding success. This has important implications for policy in relation to land claim around the estuaries of the southern North Sea, where large wintering populations of this species occur (Doody, 2001).

Spartina invasion

The invasion of non-native species and their effect on a wide variety of habitats and species is a major conservation (and in places economic) concern. The precise pattern of change is often impossible to predict. For example, no one could have anticipated the impact of a chance meeting between two species originating on opposite sides of the Atlantic on salt marshes throughout the world. An American plant, *Spartina alterniflora* was brought to Southampton, in England in ships ballast in the early 1800s. Hybridization between this species and the British *Spartina maritima* prior to 1870 produced a sterile hybrid *Spartina* × *townsendii*. Further change resulted in a natural fertile amphidiploid *S. anglica* being formed (Hubbard and Stebbings, 1967). At first the plant was heralded as an aid to land claim though latterly, as the new species spread in just a few decades to many estuaries in England and Wales, it began to cause concern to conservationists and others (Adam, 1990; Gray and Benham, 1990).

Monitoring this change took place through a variety of ad hoc approaches including field survey (Hubbard and Stebbings, 1967; Burd, 1988) and more localized research studies, Langstone Harbour (Haynes, 1986) and Poole Harbour (Gray and Pearson, 1986). The overall picture, which emerges is of a highly invasive species, which has had a profound effect on salt marshes both in England and throughout the world. These studies were not coordinated, yet together they provide a fascinating account of the scale and impact of change. This example serves to emphasize that there is often no one approach to monitoring and that especially over the medium to long-term a variety of methodologies, if properly interpreted, can provide an understanding of what is happening. From this an assessment of policy and management responses is possible, which in the case of *Spartina* has resulted in major efforts to control its spread both in England and Wales, and in the United States (Wecker, 1998).

Seabirds as indicators of change?

Once the status of a species has been determined, it is possible to relate any change, whether it is declining or expanding, to environmental or other human factors. These changes can be used not only as a means of assessing the population itself, but also as an indication of the state of other environmental conditions. For example, in the coastal environment the status of breeding seabirds might be used as an indication of the health of fish stocks. However, before such a causal link can be established, between a decline in a seabird population and a reduction in fish stocks other factors must be eliminated. These include:

- suitability of the nesting site (increases in grazing pressure may make burrows used by petrels and puffins more susceptible to collapse);
- incidence of predation (increases in predatory birds due to increased fishing effort and greater quantities of discarded offal causing death to young and/or reduced availability of food as parents are forced to disgorge before reaching their young);
- impact of offshore oil pollution and death of adult birds;
- changes in weather patterns.

Any or all of these could have an adverse effect on population size, which may hide the long-term implications of over-fishing. However, once these factors are recognized, and analyzed, change in animal populations can provide an important indicator of wider environmental damage. One of the special strengths of the use of bird population information, lies in the standardized methodology used for collecting data and the relatively long time frame over which the monitoring has been carried out.

Indicators for integrated coastal zone management

The above discussion shows how change in individual populations provides information, which is not only relevant to the conservation or control of the species being recorded, but can also be an indicator of the state of the wider environment. The examples given above involve quite simple interactions, though even these require detailed investigation to establish why change is occurring. When looking at the coast more widely, especially when socio-economic issues are included, assessing cause and effect, and hence policy implications can become highly complex and a real challenge. Making sense of the plethora of sometimes contradictory information, requires a systematic approach to its use. Although approaches differ in detail the basic sequence is the same and involves identifying the pressures which influence the state of the environment and the impact on human health and ecosystems. Society responds with various policy measures, such as regulations, information and taxes, or management action, which can be directed at any part of the system. The way in which this process develops and the factors important to the way in which it operates is illustrated next.

Taking stock

Taking stock of information on the environment is the first stage in any strategy to identify key issues for policy formulation and management action. In the United Kingdom in 1984 the need for an assessment of the status of the North Sea and its resources was recognized. As part of this assessment "a comprehensive description of the coastal margin of the North Sea and Celtic Seas, their habitats, species and human activities" was initiated. The resulting documents (Doody *et al*., 1993; Barne *et al*., 1995–98) and associated electronic publications provide a description of the whole of the coastal and marine environment of the United Kingdom and Ireland, the human use to which it is put and policies and organizations responsible for management. The subjects covered were determined by the wide range of stakeholders involved in the process, who also helped to identify the key information requirements and issues on the basis of their own knowledge and understanding. The results gave an insight into what has happened and a baseline to assess the need for action and monitor the effectiveness of policy decisions and management.

State of the coast reporting

The scale and range of information available to facilitate the understanding of the coast and its policy and management requirements at national level also is large and complex. When more than one nation state is involved the situation becomes even more complex. Different approaches, methodologies, and languages across national boundaries increase the barriers to the collection and collation of information. However, despite this State of the Environment reporting is used to address issues in geographical areas, including several, which cross national boundaries. A comprehensive review of the state of the Arctic has been prepared (Nilsson, 1997). In Europe, in addition to the European Union's general State of the Environment Report the "Dobris Assessments," there are other reports covering the regional seas, for example, the "Mediterranean Sea: Environmental State and Pressures" (Izzo, 1998). Few of these reports deal specifically with the coast most are either general State of the Coast reports or, as in the last case, are largely concerned with marine issues. However, as a methodology all have the characteristics of being comprehensive in their approach and including a variety of key stakeholders in their preparation.

Key issues

Stock taking and/or State of the Coast Reports provide a means of identifying key issues. These are important for the identification of indicators used in predicting change and the efficacy of policy implementation and management action. The key issues also help to identify key pressures on the system; another important element in reporting on the state of the system. A list of the issues most relevant to the coastal zone is given above, derived from various sources (Table M10).

Table M10 A list of key issues adapted from publications covering different levels of administration in the European Union

Key issues (not specifically coastal) derived at European level are:
- Socio-economy
- Transport
- Agriculture
- Energy
- Tourism
- Industry
- Households
- Air quality and ozone (stratospheric and tropospheric)
- Climate change
- Water stress
- Eutrophication
- Acidification
- Noise
- Biodiversity and landscapes
- Exposure to chemicals
- Health and environment
- Land and soil degradation
- Waste management

(after Stanners and Bourdeau, 1995)

In the North Sea key issues are
- Heavy metal contamination
- Artificial radionuclides
- Oil
- Shipping
- Nutrients
- Fisheries
- Organic contaminants
- Protection of habitats and species

(after Quality Status Report, 1993)

More specific key issues identified for the coastline of England and Wales
- Sea-level change and increased storminess
- Quality of bathing waters and beaches
- Loss of habitats and implications for biodiversity
- Pollution by hazardous substances
- Development pressures on the coast

(after Environment Agency, 1999)

Understanding the coast—research

Research is vital to understanding the way in which coastal systems develop, especially in helping to unravel cause and effect when considering the impact of policy and management action. This is particularly important in such a dynamic environment where coastal processes are often key in determining the nature of the coast and its ability to sustain human use.

Research

There are extensive research programs throughout the world designed to provide the necessary understanding of the impact on and limits to the use of the coast and its resources. Two approaches will be used to illustrate some of the techniques employed to identify the nature and scale of change and the underlying processes which "drive" the "natural" coast, namely *Lacoast* (*La*nd cover changes in *Coast*al zones) which uses satellite images to assess land-cover changes in coastal zones and *LOIS* (the *L*and *O*cean *I*nteraction *S*tudy) which is designed to gain an understanding of, and an ability to predict, the nature of environmental change in the coastal zone around the United Kingdom.

Lacoast. The aim of the Lacoast project is to assess quantitative changes of land cover/land use in European coastal zones during the last decades. It is being undertaken by the Agriculture and Regional Information Systems (ARIS) unit and the Space Applications Institute (SAI) at the European Union's Joint Research Centre. The project covers the entire coastal zones of 10 European Member States and includes a 10 km wide strip of land bounded by the coastline. This project provides quantitative estimates of land cover and land use change in the coastal zone, focusing in particular, on those caused by human activities. Where changes are observed, an exercise to identify and interpret the factors responsible for change is undertaken. The results so far have provided data relevant to environmental status and policy formulation at national and European scales helping to:

- identify major change at national levels;
- identify hot spots of change that when combined with other information can show trends in development pressures; and
- show the nature of human activity and hence the key issues requiring a change of policy and/or management action.

LOIS. The Land–Ocean Interaction Study, a 6-year multi million pound project (1992–98) funded by the United Kingdom's Natural Environment Research Council, involved more than 360 scientists from 11 institutes and 27 universities. It collected a vast amount of data and is a major research investment aimed at improving the understanding of the way in which coastal systems interact. As its title implies, it was designed primarily to help elucidate the relationships that exist between the exchange, movement, and storage of materials at the land–ocean boundary. Some 300 papers have been submitted to academic journals, possibly half the number that will finally be published, and a series of CD-ROMs produced (Natural Environment Research Council, 1998). Thus, as a research enterprise it is deemed to have been very successful.

A review of the main findings of the study suggests that there are some important broad conclusions to be drawn from the work—conclusions that have a more general value to the process of integrated management. For example, new insights to nutrient budgets show that 90% of the fluxes occur during only 5% of the time, that is, "pulses" are very important in delivering nutrient loads to the sea. This finding is important to any monitoring program designed to measure changes in nutrient levels since it would be easy to miss these important events. The work has also helped establish the validity of technologies, such as remote sensing, in identifying vegetation patterns, thus providing the possibility for a more cost-effective methods of survey and monitoring. A better understanding of sediment budgets and their relationship to erosion in an estuarine system has also been established. This leads the way to interpreting land– sea-level change and the implications for erosion and flooding.

Conclusion

Determining the status of the coastline its landscapes, habitats, and species concentrations and human interactions is a product of a wide variety of methodologies. These range from anecdotal observations to sophisticated, targeted research programs using modern technologies. Two phases can be discerned in the process of developing an understanding of the impact of human use on the ability of the environment to continue to sustain that use. The first involves a "stock take" of existing information which can be summarized as including the following:

1. *Geological, geomorphology, climate and sea level* variables, which provide the driving forces for the development of coastal systems.
2. *Coastal habitats and species* information, which set a baseline for the selection of important conservation areas (e.g., the European Union Habitats Directive).
3. *Human uses and activities* including the location and scale of infrastructure and intensity of use.

This can be described a "passive" stage in the context of monitoring as it is concerned initially with the location and scale of the resource or activities which take place there, rather than attempting to identify change and the causes of change. Undertaking an audit of coastal information as described above will also help to identify gaps in information and hence the need for updated or new surveys, and to assess their scale and frequency. Defining key issues for policy formulation and establishing the key human uses requiring surveillance or monitoring, is the next important step. Armed with this analysis it should be possible to develop a more "active" interaction between the provision of information and decision making. This may be summarized under four headings:

1. *Monitoring* to help identify and assess impacts, determine action and give feedback on its effectiveness.
2. *Surveillance* to identify unforeseen change and where appropriate ensure compliance with agreed legislative or other control mechanisms.
3. *Prediction* of the possible outcome of policy decisions whether in reaction to an unforeseen incident (e.g., oil pollution) or "natural" event (e.g., sea-level rise).
4. *Assessing* the effectiveness of action (management) is the final stage if we are to learn from good and bad practice.

One key aspect of the coast is its unpredictability. Identifying change without knowing what that change might be (surveillance) is therefore potentially very difficult. However, retrospective comparisons of maps, published works, the use of satellites and research (e.g., into sediment fluxes) as has been shown above, all help understanding. Twice daily tidal cycles are predictable, storms and tidal surges are not. It is often these events which cause substantial change. Similarly, cliff erosion rarely takes place on a small and regular basis and none of these unpredictable events are easily monitored. However, detailed surveillance of individual habitats can be effective and help elucidate wider scale change.

Monitoring—salt marshes and sea-level change

Salt marshes are important habitats and occur around the coast throughout the world. In addition to their nature conservation interest as habitats for specialist plants and animals, they also form part of the functioning system of coastal wetlands (in estuaries and tidal deltas). In some areas, salt marshes are eroding and a number of factors have been implicated including pollution and sea-level rise. However, a question arises as to whether this erosion is part of the natural dynamic or a longer term, and ultimately more significant change, resulting from global sea level rise or other more local effects caused by human intervention. Clearly determining the appropriate policy response will depend on understanding the extent to which human action is responsible for the observed change.

Visual and anecdotal evidence from south east England suggested that the salt marsh resource had eroded at a considerable rate during the 1980s and early 1990s. This in turn appeared to be the reason why a number of sea-walls were being undermined with an increased risk of flooding to adjacent low-lying land (Figure M24). In an area already experiencing a relative rise in sea level of 5.4 mm per year due to isostatic change and sea-level rise this suggested that threats to life and property were intensifying. Detailed field survey and comparison between sets of aerial photographs appeared to confirm anecdotal evidence and the salt marshes were assessed as eroding at an alarming rate (Burd, 1991).

On the face of it sea-level rise appears to be the main cause of loss. However, even if it is the main agent, many other factors come into play. Tides and tidal range, sediment availability, and the nature of the coast all influence the development of salt marsh. Local weather conditions including rainfall, discharge rates of rivers, and the state of the tide all contribute to the incidence and severity of flooding. Erosion rates depend on the strength of the feature being affected by the erosive force. Changes in sea level *per se* (eustacy) are the result of global forces associated with the atmospheric temperature whether due to human influences or not. In areas where the land level is stable or sinking (isostacy) there will be an inundation of the coast. Given all these factors it may be impossible to determine the precise reasons for the loss of salt marsh. Despite this, the fact remains that salt marshes are eroding and as a consequence sea-walls are being undermined and land threatened with flooding. Thus, the measurement of change in salt marsh provides a very powerful indication that an adverse change is taking place and one which needs to be addressed.

Figure M24 Land below the 5 m contour potentially at risk from coastal flooding and over-topping by the sea in Great Britain. (Adapted from Doody, 2001.)

Satellites as a means of monitoring coastal change

Using satellites to look at the environment of the earth is an important part of the space program. Remote Sensing Satellites provide information on a variety of features including physical oceanography, polar science, and climate research. However, satellites are currently under-utilized as a source of surveillance and monitoring data for coastal zone management (Doody and Pamplin, 1998). Part of the problem lies in the absence of any strong link between those concerned with the management and conservation of coastal areas and those interpreting satellite data or developing new missions. Examples of the former might be the "field ecologist" or conservation site manager, the latter the satellite "technocrat."

The key point in relation to the use of satellites lies in the fact that more frequent observations can be made and that these can, despite the initial costs of the data acquisition, may be more cost-effective than carrying out detailed and time consuming field survey. Although not all coastal habitats lend themselves to this approach and while cliffs (Figure M25) present special difficulties, flat expanses of tidal land (Figure M26), sand dunes and shingle beaches, and structures do not.

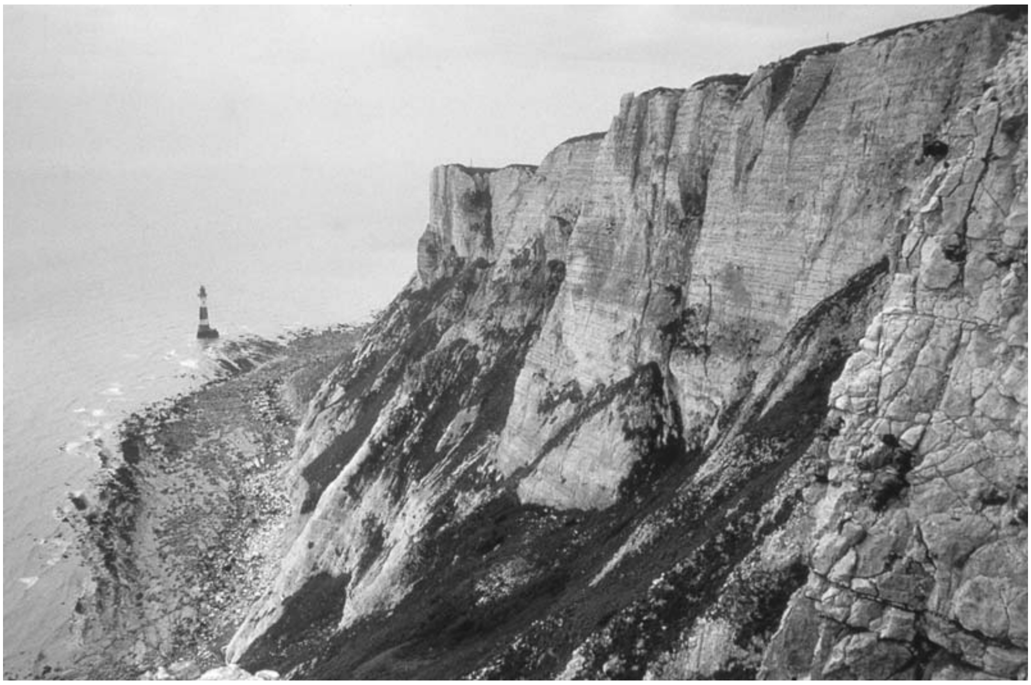

Figure M25 Cliffed landscapes require oblique photography to show features, the chalk cliffs of Beachy Head, southern England (original photograph JPD).

Figure M26 Tidal sandy flats are easily discerned from satellite images, Brancaster, North Norfolk, England (original photograph JPD).

Time scales for change are also an important factor. While satellites can cover large areas and record cumulative effects they are less good at measuring more rapid change. Until recently, a further impediment was the scale of resolution, which limited the level of detail that could be obtained. As the frequency of survey and resolution improves so will the ability of the imagery to provide more effective surveillance of the coastal zone. This will not negate the need for more traditional forms of survey and monitoring. Sloping landforms, detailed vegetation studies and measurements of river flows, sediment movement, tides, etc. will still require traditional approaches to research, survey, and monitoring. The point is that satellites can and should be used more extensively for monitoring and surveillance of the coastal zone.

Indicators for policy response and management action

The importance of the coast to the economic and social fabric of society in many parts of the world, increases the need for more widely based monitoring, encompassing both environmental and economic issues. Linking these into an assessment of the effectiveness of policy and

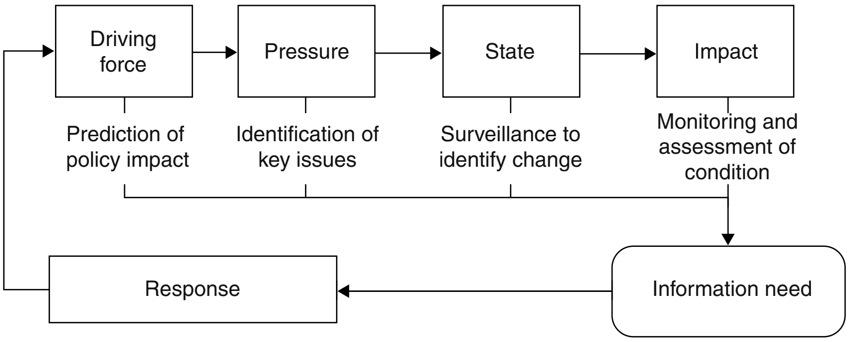

Figure M27 The European Environment Agencies modified United Nations' Pressure–State–Response model. This shows driving forces (e.g., industry and transport) producing pressures on the environment (e.g., polluting emissions), which then degrade the State of the environment and have impacts on human health and ecosystems. Society responds with various policy measures, such as regulations, information and taxes, or management action which can be directed at any other part of the system.

action, add another dimension to the complexity of the monitoring system. Information on future trends on the state of the environment and prospects for socio-economic and sectoral aspects are crucial for determining progress against policy targets and to ascertain among other things:

- whether current policy measures are to be expected to deliver the required improvements taking into account trends in external factors;
- whether additional polices might be considered as necessary to achieve the expected improvements;
- whether new policy needs are likely to emerge in uncovered areas.

At this stage, in the discussion monitoring has moved from being a concern of individual sectors or research academics, to being at the center of policy formulation and decision making. Developing indicators as an integral part of a strategy for policy formulation is a common approach (Figure M27). Using a variety of techniques involving, existing information and new data derived from remotely sensed sources and traditional survey, monitoring and research, it is possible to establish an integrated approach which matches the needs of the coastal zone. For example, we should be able to measure salt marsh change, relate this to sea-level rise, and provide a means of assessing different options for sea defense according to economic and social criteria.

The use of remote sensing techniques will not provide information on bird migration routes or the population density and success rate of breeding birds. Nor will it replace survey and surveillance of narrow beaches or vertical cliffs, or detailed vegetation maps needed for site management. These forms of data acquisition will still be required, as will the view of the informed "specialist," or "local" knowledge. When linked to the more traditional forms of survey, monitoring and research, and other programs designed to synthesize and summarize existing data, an interactive information system which provides support for coastal management decisions can be devised. This will require a multidisciplinary approach, if the demands for more integrated management of the coast and in the coastal zone are to be realized. The communication options afforded by the Internet also provide an opportunity to involve, and exchange information between the many relevant sectors operating on the coast. Achieving integration between the historical legacy of information, survey, surveillance, and monitoring as well as research, and across the environmental and the socio-economic divide is the challenge for monitoring environmental and human well-being and hence the future of the coast.

MONITORING COASTAL GEOMORPHOLOGY

Coastal engineering and research, management of natural resources, beach and wetland restoration, navigation improvements, and military operations all share the need for copious amounts of data. These data typically are used to evaluate and monitor a specific reach of the coast. Ideally, a coastal monitoring program employs a multidiscipline approach in diagnosing the beach and nearshore zone. Many large programs such as the US Army Corps of Engineers' Shinnecock Inlet Study (Morang, 1999; Militelo and Kraus, 2001; Pratt and Stauble, 2001) or the Kings Bay Coastal and Estuarine Physical Monitoring and Evaluation Program (Kraus *et al*., 1994) collect data for a range of physical conditions such as wave climate, the morphology of the beach and nearshore surface, and accretion and erosion trends across and along the shoreline (high-tide line or coastline) under investigation. These collections allow scientists and engineers to understand the coastal processes and their variability in response to waves, currents, winds, and tides.

The high-energy, often hazardous coastal environment is one of the most difficult places on earth in which to collect data. Consider the enormous forces concentrated in the narrow coastal zone: in hours, beaches disappear; in days, new inlets are cut; in a generation, rock cliffs crumble. Even the most massive coastal works have often been buried in sand, swept away, or pounded into rubble. How are instruments expected to survive in this harsh environment? Despite the engineering challenges, scientists and engineers, who never feel that they have enough data, continue to develop innovative techniques and instruments to help them answer some of the elusive questions about the sea and the land it touches.

This entry summarizes the various types of *field* data that are typically collected for coastal research and engineering and briefly introduces some of the most common instruments. We exclude data developed in physical or numerical models, although clearly these are important tools also used by coastal scientists. Biological monitoring is covered in a companion paper in this volume.

The quality of a field study depends on several factors:

1. Scientists must recognize the many problems, assumptions, and limitations in field data collection and make adjustments for them before attempting an interpretation. For example, a single cross-shore beach profile may not be representative of the beach topography during much of the year (e.g., possibly the survey was made after a storm when the beach was in an unusually eroded state).
2. The appropriate phenomena must be monitored to answer the engineering or scientific problem being investigated. For example, wave data are needed to choose appropriate stone size for a breakwater. But, an offshore ocean wave gauge may not provide useful wave statistics if the coast has complex topography with headlands and bays. A nearshore gauge is needed here.
3. Many of the techniques used to monitor processes or structures in the coastal zone are exceedingly complex. Inexperienced users should consult experts to prevent making important decisions based on poor data or data that do not truly answer their questions. Example 1: It is easy to purchase aerial photographs and interpret some sort of a shoreline (simply draw a line at the edge of the water). But what does this "shoreline" really mean, and can it be compared with shorelines identified from other dates that were based on different field techniques or criteria? Example 2: Offshore sand sources are being examined with geophysical techniques to determine if the sand is suitable for beach renourishment. Low-frequency acoustic systems may detect adequate quantities of material, but the resolution is too low to reveal that the sand contains interbedded layers of coral fragments. Here, a combination of low- and high-frequency systems should have been used, combined with core samples. Example 3: A series of cross-shore beach profiles show that a significant amount of sand was lost from the subaerial beach after a storm battered a recently placed beach fill, leading an analyst to conclude that this sand is lost. However, the profiles were wading-depth only. If sled profiles that spanned the entire active zone had been collected, the analyst might have detected that much of the sand lost from the beach had accumulated in the offshore sand bars and that the total sand volume in the active zone was almost unchanged.

Classes of monitoring techniques

Coastal monitoring can be divided into three general classes of techniques, each of which use specific instruments and analysis methods (Table M11). Note that a comprehensive study might employ instruments and data from all three classes.

1. *Remote sensing methods*: instruments provide information about the land and the sea from a distance without being in physical contact (e.g., aerial photography, laser imaging).
2. *In situ instruments*: instruments are placed *in* the media being studied, such as current meters moored in the ocean.
3. *Sampling methods*: devices retrieve a sample of the material being examined (i.e., water, ice, sediment, biological material) so that the scientist can conduct more detailed examination in a laboratory.

Remote sensing and geophysical methods

Remote sensing methods include familiar and well-proven technologies such as aerial photography (first used in World War I), satellite imaging systems in the 1970s, and laser bathymetry in the 1990s. See Philipson (1997), Henderson and Lewis (1998), Lillesand and Kiefer (1999), and Rencz and Ryerson (1999) for manuals on various sensing technologies. All remote monitoring methods require measuring and recording some form of acoustic or electromagnetic energy and then relating the resulting data to specific earth parameters (Table M12).

The term "geophysics" is defined as the "study of the earth by quantitative physical methods" (Bates and Jackson, 1984, p. 209). Geophysical methods are a form of remote sensing in that a researcher uses a tool to remotely image the seafloor or the strata below. The result is a depiction of the subsurface geology, a mathematical model based on varying acoustic impedances of air, water, sediment, and rock. The model, which must be interpreted, is based on numerous assumptions, and the user must always remember that the real earth may be very different

Table M11 Classes of monitoring systems for coastal studies

Type	Characteristics	Examples	Advantages	Disadvantages
Remote sensing	Distant from the area or media being studied (without physical contact)	• Air photographs • Video monitoring • Electromagnetic geophysics • Acoustic geophysics	• Broad coverage • Cover large area in short time • Suitable for hostile environments (military applications or harsh weather)	• Interpretation is a model—must be verified with some field data or *a priori* knowledge. • Resolution often too coarse for shoreline mapping or morphology studies • Occasionally challenging or conflicting interpretation
In situ	Measures parameter from within the media	• Current meters • Wave gauges • SBT (salinity bathythermographs) • Strain gauges • Tracking devices on turtles, whales	• Often better resolution than remote systems • Good temporal coverage • Can sometimes be used to monitor changing phenomena not accessible remotely	Point source sampled over time—must interpolate spatially
Sample recovery	Retrieves a portion of the material	• Plankton tows • Coring devices • Seafloor grab samplers • Sediment traps	• Allows detailed analysis in laboratory of the "real" material • Re-analysis possible for different properties	• Point data only—may not be representative spatially or temporally • Preservation and archiving of samples is expensive

Table M12 Remote sensing systems

Energy type	Examples	Common applications
Electromagnetic	Radar, Synthetic Aperture Radar (SAR)	Ocean wave measurement Ground-penetrating radar Object identification (military)
	Laser	Terrestrial topography (LIDAR) Bathymetry (SHOALS)
	Multi-spectral	Satellite (LANDSAT, SPOT, AVHRR)
	Visual wavelengths	Aerial photography (features, terrain)
	Infrared	Aerial photography (plant life)
Acoustic	Low frequency (<1 kHz)	Petroleum exploration, deep penetration Earth properties research, earthquake monitoring
	Medium frequency (0.5–7 kHz)	Seismic equipment (boomers, sparkers): near-surface strata, geohazards, sand resources, rock outcrops
	High frequency (12–450 kHz)	Bathymetry: sea bottom features, nautical charting Side-scan sonar: seafloor features, archaeology, shipwrecks, pipelines, breakwaters Multi-beam bathymetry: structures, breakwaters, detailed sea-bottom inspection

than the model printed on paper or displayed on his monitor. This warning notwithstanding, geophysical (particularly acoustic) methods, have proven to be extremely powerful tools in numerous coastal applications, including:

- Determining water depth (bathymetric or hydrographic surveys)
- Imaging the sea bottom to identify surficial sediments, measure bottom features such as ripples, and locate abandoned structures and hazardous debris
- Measuring the thickness of strata to locate suitable quantities of sand for beach renourishment
- Mapping gas pockets, rock outcrops, and other geological hazards
- Identifying coral, fish reefs, and other biologically sensitive areas
- Mapping cultural and archaeological resources such as sunken ships and pipelines.

Echo sounders or depth-sounders, side-scan sonar, and subbottom profilers are three classes of equipment commonly used to collect geophysical data in marine exploration. All three are acoustic systems that propagate sound pulses in the water and measure the lapsed time between the initiation of the pulse and the arrival of return signals reflected from target features on or beneath the seafloor. Other geophysical methods, such as magnetic, gravity, and electrical resistivity, laser line scan and electronic still cameras can be used in specialized engineering applications (Griffiths and King, 1981; Reed, 2001), but are not as common in reconnaissance coastal studies.

Until the 20th century, measuring water depth consisted of the slow and laborious use of sounding poles and lead lines (Shalowitz, 1962). The introduction of acoustic echo sounding after World War I revolutionized charting, and for the following 70 years, single-beam acoustic depth-sounders were used for most bathymetric surveys. In the United States, offshore waters are normally surveyed by the National Oceanic and Atmospheric Administration (NOAA) (Umbach, 1976), while navigation channels, canals, and rivers are surveyed by the US Army Corps of Engineers (USACE; USACE, 1994). Most nations have standards that specify procedures to achieve required horizontal (positioning) and vertical (water depth) accuracies. The International Hydrographic Organization (IHO) has published universal standards for bathymetric surveys for the organization's member states (IHO, 1998). An exhaustive bibliography of hydrographic charting technology is listed in IHO (2001). Multi-beam echo sounders, becoming increasingly common now, are improvements on the traditional single-beam systems because they allow very detailed imaging of underwater structures and topography (Figure M28) (Cowls, 2000).

Side-scan sonar provides an image of the aerial distribution of sediment, surface bed forms, and large features such as shoals and channels. It can thus be helpful in mapping directions of sediment transport and areas of deposition or erosion. Belderson *et al.* (1972), Leenhardt (1974), Flemming (1976), Mazel (1985), and Fish and Carr (1990) provide additional details on the use and theory behind side-scan sonar. Skilled interpreters have long been able to use side-scan sonographs to visually identify seabed sediments, but this practice normally required some *a priori* knowledge of the survey area. New acoustic approaches have recently been developed that mathematically distinguish seafloor characteristics based on scattering parameters and waveform shapes (Whitehead and Cooper, 2001). Side-scan sonar also is a powerful tool for offshore engineering and construction, where it is used to survey structures, inspect rock jetties and breakwater units, track pipelines and telephone cables, and identify hazards such as shipwrecks (Figure M29). Up through the 1980s, most side-scan systems recorded on analog paper charts, but during the 1990s, modern computers have revolutionized the display of side-scan data, making possible real-time three-dimensional (3D) display of side-scan and multi-beam data (McAndrew, 2001).

Subbottom profilers, as the name implies, are used to examine the stratigraphy below the seafloor. The principles of subbottom seismic profiling are fundamentally the same as those of acoustic depth-sounding, but subbottom acoustic transmitters and receivers employ lower frequency, higher power signals to penetrate the seafloor (Sheriff, 1977; Sieck and Self, 1977). "High-resolution" generally means that the surveys are intended for engineering purposes or for identifying strata and structures in the uppermost 50 or 60 m of the sediment column. Typical applications include reconnaissance geological surveys, foundation studies for offshore platforms, hazards surveys to locate buried debris and gas pockets, and surveys to identify mineral resources (sand for beach renourishment). Figure M30 is an example of subbottom profiling in a tropical area with coquina limestone reefs.

Figure M28 Multi-beam acoustic data from Shinnecock Inlet, Long Island, New York, December 1998. Sand waves are evident in the inlet, and the highly irregular bottom near the west jetty indicates scour holes. North is to the top of the image. (Data collected and processed by State University of New York, Stony Brook.)

Ground-penetrating radar (GPR) uses electromagnetic energy to image subbottom sediments. Radiowave energy is transmitted through the sediment and reflects from materials as a function of variations in dielectric constants and electrical resistivity (Daniels, 1989; Sellmann *et al.*, 1992). The main limitation of GPR is that it must be used in freshwater environments such as the Great Lakes or reservoirs, but FitzGerald *et al.* (1992) and van Heteren *et al.* (1994) have successfully used GPR to delineate structure and stratigraphy of beach ridges in New England.

A single geophysical method rarely provides enough information about subsurface conditions to be used without sediment samples or additional data from other geophysical methods. Each geophysical technique typically responds to different physical characteristics of earth materials, and correlation of data from several methods provides the most meaningful results. Morang *et al.* (1997a) provide more details on geophysical systems and provide tables that list frequencies and resolution. *All geophysical methods rely heavily on experienced operators and analysts*. Inexperienced users should seek help both in contracting for surveys and in interpreting records.

Aerial photography is a traditional technology that continues to be very useful in monitoring coastal morphology, evaluating changes in wetlands and deltas, and mapping urban areas. Historical photographs, often dating to the 1930s, are invaluable in evaluating 20th century changes to beaches and coasts. Figure M31 is an example of photographs taken three days after the Great New England Hurricane in 1938. These photographs document the opening of Shinnecock Inlet, Long Island, New York. Photogrammetry methods are covered in another entry in this volume.

Since the mid-1990s, Light Detection and Ranging (LIDAR) survey systems, based on lasers mounted in aircraft or helicopters, have been used around the world to obtain high-resolution topographic measurements. Most of these systems are for land use only, but one particular system, the Scanning Hydrographic Operational Airborne Lidar Survey (SHOALS), is now regularly used by the USACE to survey coastal waters and inlets. The system is based on the transmission and reflection of a pulsed coherent laser light from an aircraft or helicopter equipped with the SHOALS instrument pod and with data processing and navigation equipment (Lillycrop and Banic, 1992; Estep *et al.*, 1994; Irish *et al.*, 2000; West *et al.*, 2001). In operation, the SHOALS laser pulses 400 times per second and scans an arc across the aircraft flight path, producing a survey swath equal to about half of the aircraft altitude (usually 300–500 m). A strongly reflected light return is recorded from the water surface, followed closely by a weaker return from the seafloor. The difference in time of the returns corresponds to water depth. Data density can be adjusted by flying higher or lower, at different speeds, or by selecting different scan widths.

SHOALS has revolutionized hydrographic surveying in shallow water for several reasons:

1. The most important advantage is that the system can survey up to 35 km^2/h, thereby densely covering large stretches of the coast in a few days. This capability enables almost instantaneous data collection along shores subject to rapid changes.
2. The system can be mobilized quickly, allowing broad-area post-storm surveys or surveys of unexpected situations such as breaches across barriers.
3. SHOALS can survey directly from the nearshore zone across the beach, allowing efficient coverage of shoals, channels, or breaches that would normally be impossible or very difficult to survey using traditional methods, especially in winter. The system can now survey bluffs up to 10 m high, allowing a single platform to provide topographic and bathy-metric data.

The main limitation of SHOALS is its critical dependence on water clarity. Maximum survey depth is over 30 m in clear water, like the Caribbean Sea, but the laser signal is drastically attenuated if the water is turbid due to suspended sediment, algae, or surf. Sometimes, a survey has to be delayed until a particular time of the year to be successful in an area that experiences river runoff or algae blooms. For example, the SHOALS survey at Shinnecock Inlet, on Long Island, New York, had to be carefully scheduled to avoid algal blooms (Figure M32). Because of the immense amount of data that the system collects, data processing, archiving, and management are a challenge.

Airborne LIDAR Bathymetry (ALB) is a major advance in military operations because of its ability to rapidly survey unfamiliar littoral

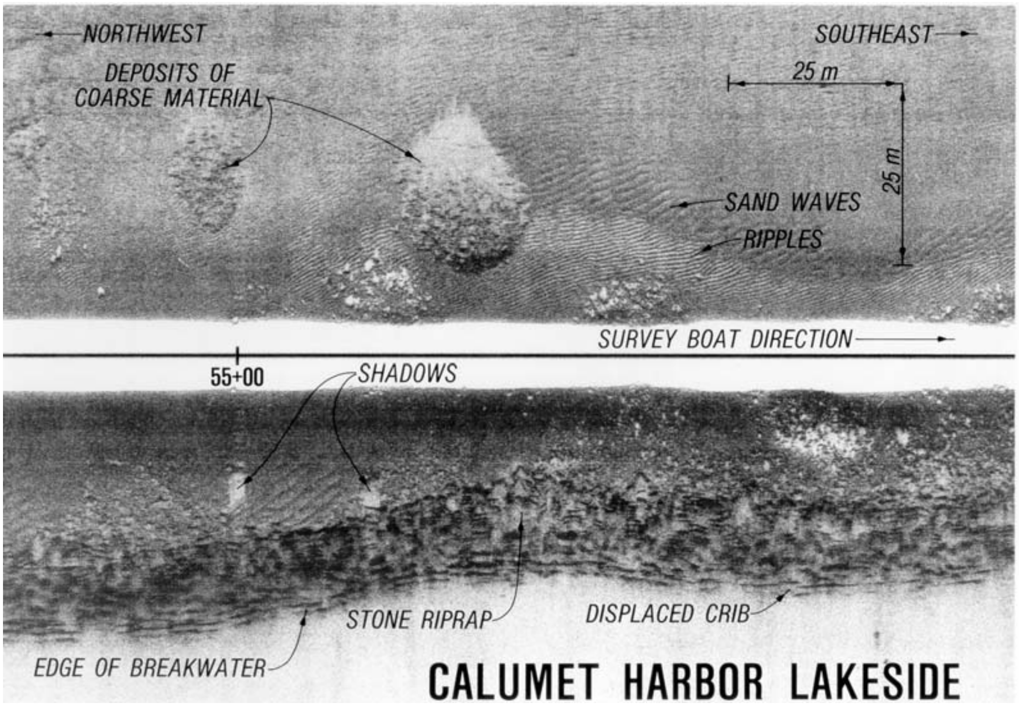

Figure M29 Annotated side-scan sonar record from Calumet harbor, southern Lake Michigan. The sonograph reveals a subtle displacement of some of the wood crib units and also shows how some construction material was deposited on the lake floor.

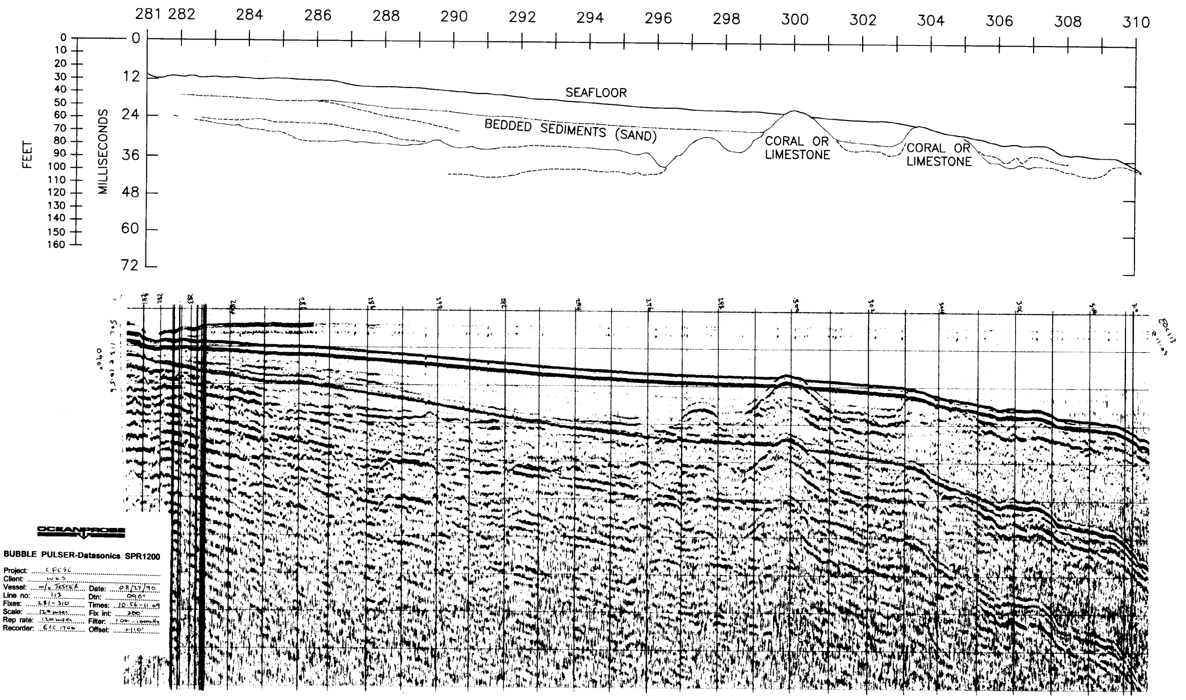

Figure M30 Analog subbottom profiler record from offshore Palm Beach County, Florida. Shore is to the left. The lump near Fix 300 is a coral or limestone outcrop. This is an example of data valuable for locating offshore sand resources to use for beach renourishment.

areas that may be subject to military operations (West *et al.*, 2001). Conventional survey methods require the deployment of small boats equipped with single- or multi-beam acoustic equipment along with terrestrial surveyors to perform beach profiles. These traditional methods are slow, are highly susceptible to weather, and expose the surveyors to hostile fire.

A similar technology is Airborne Topographic Mapper (ATM), an aircraft-based system that provides highly detailed topographic data of beaches. The National Aeronautics and Space Administration (NASA) and a group of partners are in the process of mapping the entire coast of the continental United States in unprecedented detail.

In situ technologies

The most common coastal applications of *in situ* systems are monitoring water flow and meteorological properties. Measuring waves and currents

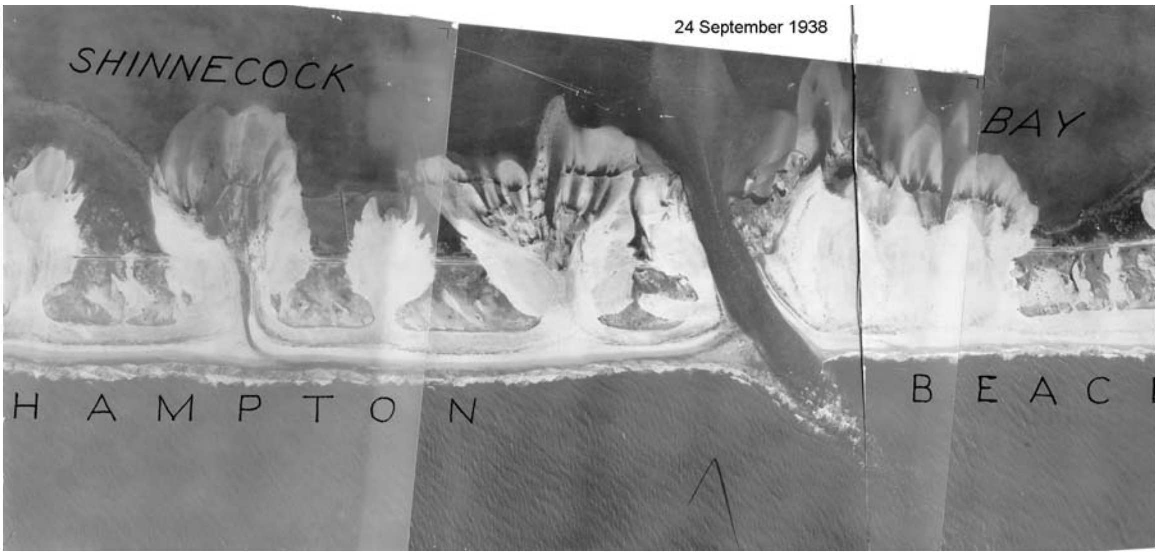

Figure M31 Vertical aerial photograph taken September 24, 1938 (three days after the Great New England Hurricane crossed the south shore of Long Island, New York). This image shows the new Shinnecock Inlet and numerous washover fans. Historical images like this are valuable in tracing the origin and behavior of coastal features (photographs from Beach Erosion Board Archives).

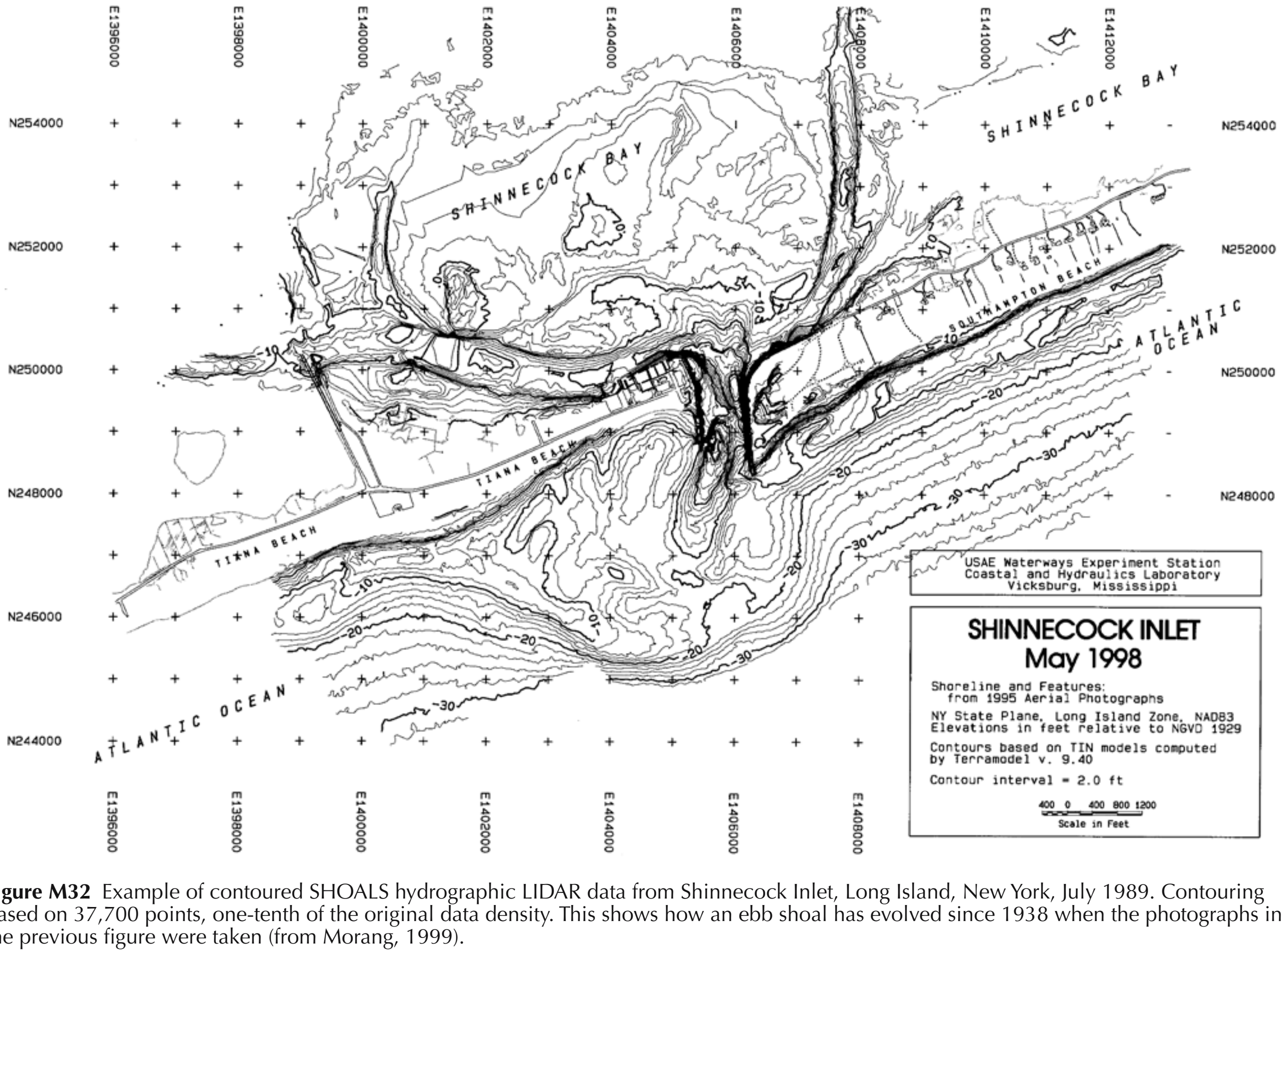

Figure M32 Example of contoured SHOALS hydrographic LIDAR data from Shinnecock Inlet, Long Island, New York, July 1989. Contouring based on 37,700 points, one-tenth of the original data density. This shows how an ebb shoal has evolved since 1938 when the photographs in the previous figure were taken (from Morang, 1999).

in the high-energy, hazardous nearshore zone is one of the more challenging endeavors of coastal engineering and research. Measurement programs must be thoroughly planned *before* any gauges are deployed to ensure that useful data are collected. A scientist must:

1. Determine what data units and analyzed products are needed to answer the critical engineering or scientific questions at the site.
2. Determine how long the gauges must be at the site (i.e., several years or just during the winter season).
3. Consider placing gauges in locations that are compatible with previous field programs.
4. Evaluate environmental constraints such as ice or trawler activity.
5. Be sure that enough funding is allocated for the analysis of the data.

Wave gauges

Two general types of wave gauges are available: nondirectional and directional. In general, directional gauges and gauge arrays are more expensive to build, deploy, and maintain than nondirectional gauges. Despite the greater cost and complexity, the former are preferred for most projects because the directional distribution of wave energy is an important parameter in many applications, such as sediment transport analysis and calculation of wave transformation. Wave gauges can be installed in buoys, placed directly on the sea or lake bottom, or mounted on existing structures, such as piers, jetties, or offshore platforms. Deployment of wave gauges is expensive and must be balanced against other project requirements. There are no hard-and-fast rules regarding how much wave or current data to collect—more is always better! Table M13 (from Morang *et al.*, 1997b) provides broad guidelines for wave gauging.

A wave-gauging program requires several steps:

- Planning (determine goals, allocate budget).
- Instrument deployment, servicing, and recovery.
- Data recovery (either real-time or periodic for internal-recording gauges).
- Data reduction, quality control, and generation of statistics.
- Display of statistics and summary results.

Wave data analysis is a complex topic in itself. To a casual observer on a boat, the sea surface usually appears as a chaotic jumble of waves of various heights and periods moving in many different directions. Most wave gauges measure and record a signal indicative of the changing elevation of the water surface. Unfortunately, when this signal is simply plotted against time, it provides little initial information about the characteristics of the individual waves that were present at the time the record was being made. Therefore, further processing is necessary to obtain wave statistics that can be used by coastal scientists or engineers to infer what wave forces have influenced their study area. Earle and Bishop (1984), Horikawa (1988), and Earle *et al.* (1995) provide background in the mathematics of wave analysis.

Another difficulty encountered in wave analysis is that different researchers are often inconsistent in their use of technical terms, and users are urged to be cautious of wave statistics from secondary sources and to be aware of how terms were defined and statistics calculated. For example, "significant wave height" (H_s) is defined as the average height of the highest one-third of the waves in a record. How long should this record be? Are the waves measured in the time domain by counting the wave upcrossings or downcrossings? Most automated processing programs *estimate* significant wave height by performing spectral analysis of a wave time series in the frequency domain and equating $H_s = H_{m0}$. The latter equivalency is usually considered valid in deep and intermediate water but may not be satisfactory in shallow water (Horikawa, 1988). To prevent collecting the wrong data when specifying or planning a wave measurement program, researchers are urged to consult a standard list of wave parameters such as the one prepared by the IAHR Working Group on Wave Generation and Analysis (1989).

Current meters

Currents can be measured by two general approaches. One of these, *Lagrangian*, follows the motion of an element of matter in its spatial and temporal evolution. The other, *Eulerian*, defines the motion of the water at a fixed point and determines its temporal evolution. Lagrangian current measuring devices are often used in sediment transport studies, in pollution monitoring, and for tracking ice drift. Eulerian, or fixed, current measurements are important for determining the variations in flow over time at a fixed location, such as in a tidal inlet or harbor entrance channel. Recently developed instruments combine aspects of both approaches.

Four general classes of current measuring technology have been tested or are in use (Appell and Curtin, 1990):

- Lagrangian methods: drifters and dye.
- Spatially integrating methods: experimental (not used often).
- Point source and related technology: moored current meters.
- Acoustic Doppler Current Profilers (ADCP) and related technology (fixed point and boat-mounted).

Table M13 Suggested wave gauge placement for coastal project monitoring

I. High-budget project (major harbor, highly populated area)

A. Recommended placement:
  1. One (or more) wave gauge(s) close to shore near the most critical features being monitored (e.g., near an inlet). Although nearshore, gauges should be in intermediate or deepwater based on expected most common wave period. Depth can be calculated from formulas in the *Coastal Engineering Manual* (USACE, 2002).
  2. In addition, one wave gauge in deepwater if needed for establishing boundary conditions of models.

B. Schedule:
  1. Minimum: 1 year. Monitor winter/summer wave patterns (critical for Indian Ocean projects).
  2. Optimum: 5 years or at least sufficient time to determine if there are noticeable changes in climatology over time. Try to include one El Niño season during coverage for North American projects.

C. Notes:
  1. Concurrent physical or numerical modeling: Placement of gauges may need to take into account modelers' requirements for input or model calibration. Placement in shallow water may be needed to test wave transformation models or wave hindcasts.
  2. Preexisting wave data may indicate that gauges should be placed in particular locations, or gauges may be placed in locations identical to the previous deployment to make the new data as compatible as possible with the older data. Long, continuous data sets are extremely valuable.
  3. Hazardous conditions: If there is a danger of gauges being damaged by anchors or fishing boats, the gauges must be protected, mounted on structures (if available), or deployed in a location that appears to be the least hazardous.

II. Medium-budget project

A. Recommended placement:
  1. One wave gauge close to shore near project site.
  2. Obtain data from nearest deepwater buoy (for US waters, NOAA, National Data Buoy Center (NDBC) buoys).

B. Schedule: minimum 1-year deployment; longer if possible.

C. Notes: same as IC above. Compatibility with existing data sets is very valuable.

III. Low budget, short-term project

A. Recommended placement: gauge close to project site.

B. Schedule: if 1-year deployment is not possible, try to monitor the season when the highest waves are expected (usually winter, although this may not be true in areas where ice pack occurs or in tropical storm areas).

C. Notes: same as IC above. It is critical to use any and all data from the vicinity, anything to provide additional information on the wave climatology of the region.

The large number of instruments and methods that have been tested underscores that detection and analysis of fluid motion in the oceans is exceedingly complex. The difficulty arises from the large continuous scales of motion in the water. "There is no single velocity in the water, but many, which are characterized by their temporal and spatial spectra. Implicit then in the concept of a fluid 'velocity' is knowledge of the temporal and spatial averaging processes used in measuring it" (McCullough, 1980, p. 106). In shallow water, particularly in the surf zone, additional difficulties are created by turbulence and air entrainment caused by breaking waves, by suspension of large concentrations of sediment, and by the physical violence of the environment. Trustworthy current measurement under these conditions becomes a daunting task.

Lagrangian methods: Dye, drogues, ship drift, bottles, temperature structures, oil slicks, radioactive materials, paper, wood chips, ice floes, trees, flora, fauna, and seabed drifters have all been used to study the motion of the oceans (McCullough, 1980). A disadvantage of all drifters is that they are only quasi-Lagrangian sensors because, regardless of their design or mass, they cannot exactly follow the movement of the water. Nevertheless, they are particularly effective at revealing surface flow patterns if they are photographed or video recorded on a time-lapse basis. Simple drifter experiments can also be helpful in developing a sampling strategy for more sophisticated subsequent field investigations. Floats, bottom drifters, drogues, and dye are used especially in the littoral zone where fixed current meters are adversely affected by turbulence (e.g., see Ingle, 1966). Resio and Hands (1994) examined the use of seabed drifters and commented on their value in conjunction with other instruments.

Point source (Eulerian) and related technology: In channels, bays, and offshore, direct measurements of the velocity and direction of current flow can be made by instruments deployed on the bottom or at various levels in the water column. Two general classes of current meters are available: mechanical (impeller-type) and electronic. Mechanical meters, based on rotors or propellers that turn in the water, have been largely phased out in favor of electronic instruments. These have the advantages of rapid response and self-contained design with no external moving parts to get fouled or corroded. They can be used in real-time systems and can be used to measure at least two velocity components, but only at a single depth. Vertical or horizontal arrays of meters can be deployed to measure the distribution of velocities vertically through the water column or across a specific area such as a channel.

Acoustic Doppler Current Profilers: These profilers (known as ADCPs) operate on the principle of Doppler shift in the backscattered acoustic energy caused by moving particles suspended in the water. Assuming that the particles have the same velocity as the ambient water, the Doppler shift is proportional to the velocity components of the water within the path of the instrument's acoustic pulse. The backscattered acoustic signal is divided into parts corresponding to specific depth cells, often termed "bins." The bins can be various sizes, depending upon the depth of water in which the instrument has been deployed, the frequency of the signal pulse, the time that each bin is sampled, and the acceptable accuracy of the estimated current velocity (Bos, 1990). ADCPs have revolutionized current measurement in all water depths, but a great advantage of using ADCPs in shallow water is that they provide profiles of the velocities in the entire water column, allowing more comprehensive views of water motions than do strings of multiple point source meters. An ADCP can be moored at a fixed point to monitor the change in water velocities over time, or it can be mounted on a boat to measure flow patterns over an area, such as across an inlet (Figure M33). ADCP data are inherently noisy, and signal processing and averaging are critical to successful performance.

Physical sampling methods

Despite the explosive development of remote sensing and geophysical technology during the last half of the 20th century, there continues to be a need to collect actual samples of the sediment or rock underlying a study area. There are several reasons for this continued reliance on what is sometimes regarded as a primitive desire to touch the sediment. First, any remote sensing technique is still "remote." It is an interpretation of what is down there and is hopefully an accurate picture, but this interpretation (or model) still needs field confirmation to provide ground-truthing. Hence, a seismic profiling study is often accompanied by a coring program. Second, many sediment characteristics can still be obtained only by analysis of the actual samples. For example, sieving is still the best way to determine the distribution of grain sizes in a sample. For geotechnical investigations, samples are needed to determine strength, organic content, compressibility, and permeability (USACE, 1996). Surficial sediments provide information about the energy of the environment as well as the long-term processes and movement of materials, such as sediment transport pathways, sources, and sinks.

Three types of devices are available for retrieving sediments in the marine environment: grab samplers, dredges, and corers. For soft surface

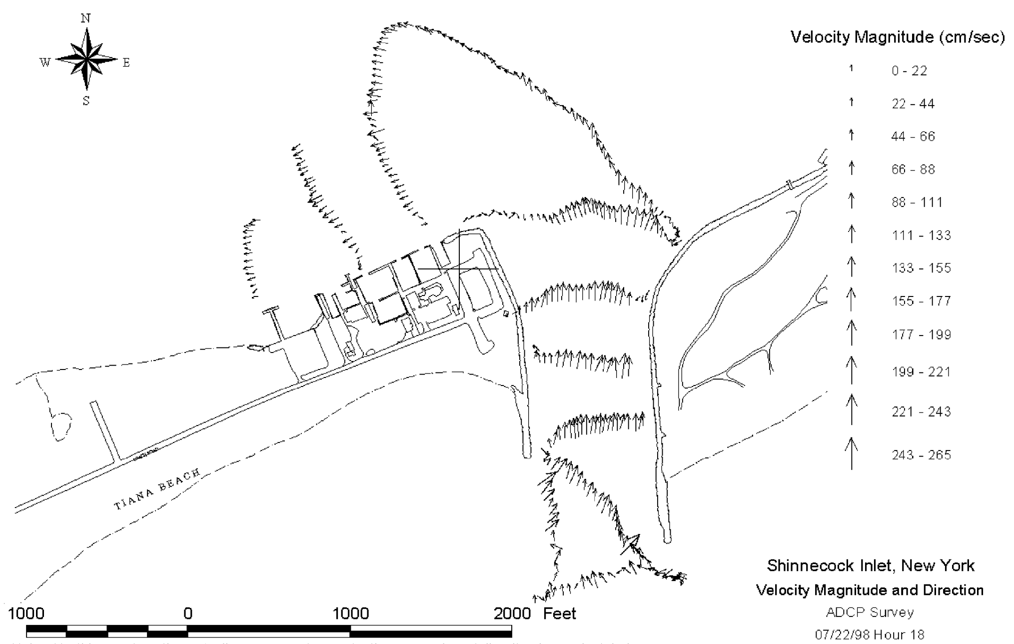

Figure M33 Analysis of ADCP current-meter surveys in Shinnecock Inlet, Long Island, New York. The instrument was mounted on a boat that made transects across the inlet. The arrows show the direction and magnitude of the flow during the flood tide. The tide enters the inlet from the Atlantic Ocean and diverges in the bay, with much of the flow moving to the west (from Pratt and Stauble, 2001).

materials, a variety of grab-type samplers of different sizes and design have been developed (Bouma, 1969; USACE, 1996). Most consist of a set of opposing, articulated scoop-shaped jaws that are lowered to the bottom in an open position and are then closed by various trip mechanisms to retrieve a sample. Some grab samplers are small enough to be deployed and retrieved by hand, but most require some type of lifting gear (Table M14). For hard seafloor areas, steel dredges can be dragged along the bottom from a boat, but dredges suffer from selective recovery (only loose boulders may be recovered), and positional information is poor.

For all sediment sampling, it is necessary to obtain a sufficient quantity of material to compute a statistically valid grain-size distribution, and if there is gravel in the sample, many liters of sample may be needed. For example, if the maximum particle size (<10% of the sample) is 2.4 mm, only 0.1 kg of sample is required, but if the sample includes cobble of 64 mm, 50 kg are needed. Required quantities are specified in manuals prepared by the standards organizations of various countries (e.g., British Standards Institution, 1990; American Society for Testing and Materials (ASTM), 2001).

Although surficial samples are helpful for assessing recent processes, they are typically of limited value in a stratigraphic study because grab devices usually recover less than 15 or 20 cm of material. To recover subbottom sediments, a type of coring system is needed. One of the simplest is the vibratory corer (vibracorer), commonly used by geologists to obtain samples in lacustrine, shallow marine, and coastal environments (Fuller and Meisberger, 1982a,b; USACE, 1996). Vibracoring is described in a companion entry in this volume. The core may be up to 4 or 5 m long, which is adequate for borrow site investigations, near-surface cross sections, and other coastal studies.

Cores can be invaluable because they allow a direct, detailed examination of the layering and sequences of the subsurface sediment. The

Table M14 Subaqueous sediment sampling without drill rigs and casing

Device	Application	Description	Penetration depth	Comments
Grab samplers				
Petersen grab[a]	Large, relatively intact "grab" samples of seafloor	Clam-shell type grab weighing about 450 kg with capacity about 0.4 ft^3 (0.1 m^3)	To about 10 cm	Effective in water depths to 600 m (or more with additional weight).
Corers (for subsurface sampling)				
Harpoon-type gravity corer	Cores 1.5–6-in., (3.8–15.2 cm) diameter in soft to firm sediments	Vaned weight connected to coring tube dropped directly from boat. Tube contains liners and core retainer	To about 10 m	Maximum water depth depends only on weight. Undisturbed (UD) sampling possible with short, large-diameter barrel
Free-fall gravity corer	(As above for harpoon type)	Device suspended on wire rope over vessel side at height above seafloor of about 5 m and then released	Soft sediment to about 5 m. Firm sediment to about 3 m	(As above for harpoon type)
Piston gravity corer (Ewing gravity corer)	2.5-in. (6.35 cm) sample in soft to firm sediments	Similar to free-fall corer except that coring tube contains a piston that remains stationary on the seafloor during sampling	Standard core barrel 10 ft (3.0 m); additional 10-ft sections can be added	Can obtain high-quality UD samples
Piggott explosive coring tube	Cores of soft to hard bottom sediments	Similar to gravity corer. Drive weight serves as gun barrel and coring tube as projectile. When tube meets resistance of seafloor, weighted gun barrel slides over trigger mechanism to fire a cartridge. The exploding gas drives tube into sediments	Cores to 1−7/8 in. (4.75 cm) and to 10-ft lengths have been recovered in stiff to hard materials	Has been used successfully in 6,000 m of water
Norwegian Geotechnical Institute gas-operated piston	Good-quality samples in soft clays	Similar to the Osterberg piston sampler except that the piston on the sampling tube is activated by gas pressure	About 10 m	
Vibracorer[b]	High-quality samples in soft to firm sediments. Dia. 3.0 in. (7.6 cm)	Apparatus is set on seafloor. Air pressure from the vessel activates an air-powered mechanical vibrator to cause penetration of the tube, which contains a plastic liner to retain the core	Length of 20 ft (6 m) Rate of penetration varies with material strength. Samples a 20-ft core in soft sediment in 2 min	Maximum water depth about 60 m
Box corer	Large, intact slice of seafloor	Weighted box with closure of bottom for benthic biological sampling or geological microstructure	To about 0.3 m	Central part of sample is undisturbed

Notes:
[a] Similar grab devices include the Ponar®, whose jaws close when the device strikes the seafloor, and the Ekman, whose jaws are activated by a messenger. A messenger is a metal plug that slides down the steel cable and strikes a spring-loaded jaw-control mechanism. Other types are the Van Veen and Smyth-Macintyre.
[b] Vibracorers vary greatly in size. Many are custom-made at universities or consulting companies. Some are electrically or mechanically powered, and many use 3.0-in. (7.6 cm) thin-walled aluminum irrigation pipe as a combination core barrel and liner.
Source: Adapted from HUNT (1984) and other sources.

sequences provide information regarding the history of the depositional environment and the physical processes during the time of sedimentation. Depending upon the information required, the types of analysis that can be performed on the core include grain size, sedimentary structures, identification of shells and minerals, organic content, microfaunal identification (pollen counts), X-ray radiographs, radiometric dating, and engineering tests. If only information regarding recent processes is necessary, then a box corer, which samples up to 0.6 m depths, can provide sufficient sediment. Because of its greater width, a box corer can recover undisturbed sediment from immediately below the seafloor, allowing the examination of bedding microstructure and lamination. These structures are usually destroyed by traditional vibratory or rotary coring.

If it is necessary to obtain deep cores, or if cemented or very hard sediments are present, the only alternative is rotary coring. Truck- or skid-mounted drilling rigs can be conveniently used on beaches or on barges in lagoons and shallow water. Offshore, rotary drilling becomes more complex and expensive, usually requiring jack-up drilling barges or four-point anchored drill ships. An experienced crew can drill and sample 100 m of the subsurface in about 24 h. Information on drilling and sampling practice is presented in Hunt (1984) and USACE (1996).

Mapping and shoreline change

Value of comparing historical with modern data

Collecting field data is just one phase of a coastal monitoring study. Analyzing, interpreting, and organizing the results are an equally important phase because this is how findings are displayed and communicated to engineers, coastal managers, and policy-makers. Several levels of analysis are possible. The simplest typically is the measurement of linear changes of coastal features over time. Historical charts, modern maps, aerial photographs, and LIDAR or topographic data can reveal details on:

- Long- and short-term advance or retreat of the shore. Shoreline change data are critical for coastal managers tasked with establishing setback lines and guiding growth in the coastal zone, especially in low areas subject to flooding.
- The impact of storms, including barrier island breaches, overwash, and changes in inlets, vegetation, and dunes.
- Human impacts caused by coastal construction, dune destruction, or dredging.
- Compliance with permits, illegal filling, and dumping.
- Biological condition of wetlands, estuaries, and barrier islands.
- Susceptibility of urban areas to storm flooding and catastrophic events (e.g., hurricanes) by means of storm surge models.

If historical 3D (bathymetric and topographic) data are available, volumetric comparisons between the old and modern surveys can provide quantitative information on:

- Longshore sediment movement.
- Shoaling or siltation associated with tidal inlets, river mouths, estuaries, and harbors.
- Sediment changes on ebb and flood shoals and in inlet channels.
- Nearshore bathymetry changes over time.
- Migrations of channel thalwegs.

Coastal engineers often make volumetric comparisons to compute amounts of sediment trapped by structures, examine the growth of shoals in navigation channels, determine dredging requirements, compute dredging contract payment, and evaluate post-dredging channel conditions. Volumetric analyses are also used to monitor the performance of beach renourishment projects.

Definitions and map datums

Many coastal zone features and subdivisions are difficult to define because temporal variability or gradational changes between features obscure precise boundaries. In addition, nomenclature is not standardized, and ambiguity is especially evident in the terminology and zonation of shore and littoral areas. If an ambiguous term is not precisely defined (for instance, the ever-controversial "shoreline"), the intended boundaries may differ greatly. Therefore, one of the most critical issues when combining historical and recent geographical data is to establish what datums have been used. A datum is "a fixed or assumed point, line, or surface, in relation to which others are determined; any quantity or value that serves as a base or reference for other quantities or values" (Bates and Jackson, 1984, p. 127). For coastal engineering and geologic studies, both horizontal (geographic location) and vertical (distance above sea level or other surface) datums must be established. Readers are referred to Umbach (1976), USACE (1994), Gorman *et al.* (1998), Moore (2000), and textbooks on geodetic surveying and photogrammetry for more background information on this complex topic.

Many possible datums can be used to monitor historical changes of the shoreline. The complexities around this term are discussed in a companion entry in this volume. Readers in the United States are also referred to the National Shoreline Data Standard, a draft standard prepared by NOAA, which defines shoreline as,

> The line of contact between the land and a body of water. On Coast and Geodetic Survey nautical charts and surveys, the shoreline approximates the mean high-water line. In Coast Survey usage, the term is considered synonymous with coastline (Shalowitz, 1962).

In many situations, the high water line (hwl) has been found to be the best indicator of the land–water interface, the coastline (Crowell *et al.*, 1991, 1993). The hwl is easily recognizable in the field and can sometimes be identified in aerial photographs by a line of seaweed and debris (wave run-up line). The wet-dry line, also visible on air photos, is more difficult to interpret because it is a function of water table, which in turn is a function of tide level, recent rainfall, and other factors. The datum printed on historical US National Ocean Service (NOS) T-sheets (topographic) is listed as mean high water. Fortunately, the early NOS topographers approximated hwl during their survey procedures (Shalowitz, 1962). Therefore, direct comparisons between historical T-sheets and modern aerial photograph interpretations are possible. However, even years ago, coastal scientists recognized that the hwl as mapped from aerial photographs was a dynamic feature and potentially a less reliable indicator of shoreline position than morphologic features on the shore that remain relatively constant from day to day. Some of these morphologic indicators are the berm crest, base of the dune, permanent vegetation line, crest of the overwash terrace, and shore protection structures, all of which are unaffected or only slightly altered by short-term changes in water levels (Morton, 1997). Therefore, many recent field surveys using Global Positioning System (GPS) instruments mounted on all-terrain vehicles are defining the shoreline based on these morphologic features. Whether these shorelines can be directly compared with older air photo interpretations is problematic.

A discussion of water level datums and shoreline definition is beyond the scope of this entry. An introduction to this complicated topic is presented in NOS (1988). The classic *Shore and Sea Boundaries* (Shalowitz, 1962, 1964; Reed, 2000) are exhaustive references on technical and legal issues relating to datums in the United States. USACE (1994) provides details on establishing tidal datums for coastal hydrographic surveys. In the Great Lakes of North America, water levels fluctuate on yearly and on longer-term cycles due to meteorologic and hydrologic conditions over the continent. In the lakes, charts and water depths are referenced to the International Great Lakes Datum of 1985 (Coordinating Committee, 1992).

Cross-shore profile surveys

Topographic and nearshore profile surveys provide one of the most direct and accurate means to assess geologic and geomorphic changes on the shoreface to water depths of 10 or 15 m. Beach profiles conducted over time can document erosion and accretion in the coastal zone, shoreline changes, sand bar movement, and dune volume changes. They provide the basic data for evaluating what happens to sand placed in beach nourishment projects (Weggel, 1995).

Permanent or semi-permanent benchmarks are required to reoccupy profile sites over successive months and years. These benchmarks should be located on a stable land feature at the landward end of the profile lines to minimize their likelihood of being damaged in storms. The locations of survey monuments must be carefully documented and referenced to other survey markers or to control points. Then, the profile data can be used to evaluate changes in sea level, changes in volume of sand on the beach, or other phenomena that require reference to established regional datums. The ability to accurately reestablish a survey monument is critical because it ensures that profile data collected over many years will be comparable. Locations that might experience dune erosion should be avoided, and care should also be taken to reduce the visibility of benchmarks to minimize vandalism. (Unfortunately, damage caused by vandals is an irritating and expensive problem at all coastal projects, even those far from urban areas.) With the increasing use of GPS receivers by surveyors, the rigorous need for duplicate survey monuments may be reduced. This is an evolving technology, and

Table M15 Example of Profile Survey Scheme for monitoring beach fill (after Stauble, 1994)

Time	Times/year	Number of profiles
Pre-fill	2	Collect within fill area and at control locations in summer and winter months to characterize seasonal profile envelope (beach and nearshore to closure depth).
Post-fill	1	Collect all profiles immediately after fill placement at each site (beach and offshore) to document fill volume. Collect control profiles immediately after project is completed.
Year 1	4	Four quarterly survey trips collecting all beach and offshore profiles out to depth of closure. Begin series during the quarter following the post-fill survey.
Continue Year 1 schedule to time of next renourishment (usually 4–6 years). If project is a single sand placement, taper surveys in subsequent years:		
Year 2	2	6- and 12-month survey of all beach and offshore profiles.
Year 3	2	6- and 12-month survey of all beach and offshore profiles.
Year 4	1	12-month survey of beach and offshore profiles.

Note: (1) If project is renourished, repeat survey schedule from post-fill immediately after each renourishment to document new fill quantity and behavior. (2) Monitoring fill after major storms is highly desirable to assess fill behavior and storm-protection ability. Include both profile and sediment sampling. Conduct less than one week after storm conditions abate to document the beach and offshore response.

for now we still recommend that two monuments per survey line be established. US Army Corps of Engineers standards for survey monuments are specified in USACE (1990).

When planning a beach profiling study, both the frequency of the sampling and the overall duration of a project must be considered. There are no definitive guidelines for the timing of profile lines, but for most sites, summer and winter surveys are recommended. Resurveying profiles over a period of more than one year can be of substantial help in understanding seasonal changes. In addition, supplemental surveys can be made after big storms to determine their effects and measure the rate of recovery of the local beach. Table M15 outlines a suggested survey schedule for monitoring beach fill projects.

The longshore spacing of profiles must be carefully planned. Profiles should be at close enough intervals to show any significant changes in lateral continuity. Reviewing locations of historical shorelines in the study area is one way to establish the gross limits of the area that should be examined in detail, particularly along rapidly changing coasts. Often, a spacing of 1,000 ft (300 m) is used in studies in the United States, but closer spacing may be needed near inlets, within project boundaries, or at the ends of spits or barriers that experience frequent changes, and fewer profiles may be needed in the more stable portions of barrierislands.

For proper coverage, profile lines should extend landward of the zone that can be inundated by storms, usually behind the frontal dunes. But, often it is not necessary to survey across an entire barrier island. For example, shore and dune deposits that are now inland from the modern shoreline may only be affected by marine or lacustrine processes during the most severe storms. Aerial photographs of these interior areas may be adequate to show morphologic changes. Seaward, the profiles should extend deep enough to include the portion of the shoreface where most sediment moves (i.e., to beyond closure—discussed in another entry in this volume). Areas subject to dune breaching and overwash require special efforts to establish a reusable benchmark system.

The land portion of a profile is typically surveyed with a stadia rod and a total station. The method is inexpensive and can extend offshore to about 1 m water depth (or deeper if the rodman is adventurous). The nearshore seafloor is often surveyed by a sled that is towed by boat out into the water from about +1.5 m to closure depth. This results in overlap between onshore rod surveys and sled surveys to assure that the two systems are recording the same elevations. With careful field technicians, vertical accuracy for sled surveys is in the range of ± 0.15 m (Clausner *et al*., 1986). If offshore surveys are conducted by boat-mounted echo sounder, overlap with rod surveys is often not possible because most boats cannot survey in water shallower than about 2 m. Also, acoustic surveys are difficult in the surf zone because bubbles in the water attenuate the acoustic pulses. Jet skis have proven to be a useful way to obtain data in the difficult surf zone or in tidal inlets when a towed sled is not available or is not practical due to logistical conditions (Dugan *et al*., 1999). With advances in remote sensing technology and data processing methods, remote sensing may replace field profile surveys in some circumstances (Judge and Overton, 2001).

Figure M34 shows an example of profile data collected at Westhampton Beach, Long Island, New York (facing southeast towards the Atlantic Ocean). In many areas around the world, beaches show a distinct pattern of summer growth and winter erosion. But along the south shore of Long Island, analysis of profiles has revealed that the seasonal effect is subtle (Morang *et al*., 1999). Storms occur during both the winter and the summer, and although the berm and dune crest often retreat and bars move offshore during each event, recovery typically is rapid as littoral material moves back onshore. For this study, the ability to detect subtle sand volume changes along the Long Island shore has underscored the value of a time series of topographic data spanning several years.

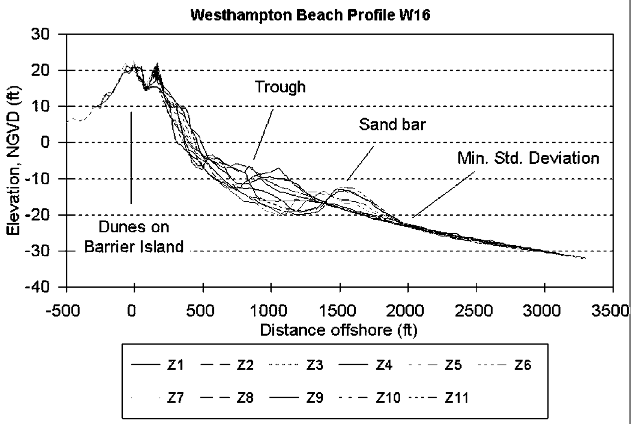

Figure M34 Example of cross-shore profile surveys from Westhampton Beach, Long Island. Surveys were made at six month intervals and demonstrate significant movement of the bar and trough. The location where the profiles converge, at the position of minimum standard deviation, is sometimes interpreted as the depth of closure.

Conclusions

Inexpensive computing and data storage technology and innovative sensors have brought about a revolution in marine data collection during the last two decades that shows no sign of ending. Advances have occurred in four areas: (1) sensors; (2) interactive or real-time data analysis of data; (3) data integration among different sensors and navigation systems; (4) data display and presentation, particularly with respect to Geographic Information System (GIS) organization and display. These new technologies have allowed marine scientists to examine phenomena in much greater detail than ever before and with much greater positional (navigation) accuracy. However, despite these advances, some areas of the coastal zone continue to be hazardous and difficult for any form of *in situ* data collection or monitoring. This is especially true of the breaker zone, where few instruments can survive during storms and where it is still difficult to obtain trustworthy bathymetry. As a result, some basic processes, such as the cross-shore distribution of longshore currents, are still little understood. Perversely, the more data we collect, the more we realize that we still know so little about marine processes in the coastal zone and the delicate interplay between hydrodynamics, geology, and biology.

MUDDY COASTS

Muddy coast is defined as a coastal depositional environment which exhibits muddy sediments as a major component of the sedimentary morphodynamic system. These morphodynamic deposits possess textural characteristics containing a high proportion of silt and clay, and exhibit identifiable sub-tidal, intertidal, and supra-tidal stratigraphy. Such deposits tend to form extensive low-gradient morphological surfaces, and are often manifest as broad intertidal flats, colloquially termed "mudflats."

The visually obvious muddy coastal sedimentary deposits and geomorphic forms occur mainly within the intertidal zone of coastal fringe waters, and are clearly evident as surficial deposits forming tidal flat and drainage channel deposits. Muddy coastal depositional environments also occur in nearshore sub-tidal locations characterized by relatively low energy hydrodynamic conditions, such as in shallow estuaries and embayments. But direct marine processes influencing muddy deposition extend inland as far as storm surge tides are effective, and especially in low-gradient coasts, some muddy coast deposits occur on land areas above the normal high-tide level.

In principle, silt and clay particles comprising the suspended sediment load in coastal waters will deposit (1) if there is sufficient particle concentration such that enhanced deposition takes place, (2) if the suspended load particles are advected into quiet waters where the fine particles gradually sink below wave agitation and turbulence levels and deposit on the bottom, and (3) where salt wedge and "estuarine circulation" mixing processes at the head of estuaries induce flocculation of the fine particles.

Definition of "mud"

In sedimentological terms "mud" is easily defined. Texturally "mud" is a detrital deposit composed of particle sizes smaller than 63 μm (i.e., 0.063 mm), and includes the textural classes of *silt*, 0.063–0.004 mm or 6φ–10φ in the sedimentological (phi) classification, and *clay*, which is generally accepted as being composed of particle sizes smaller than 0.004 mm (4 μm) or smaller than 10φ (Folk, 1968; Leeder, 1982).

However, muddy coastal deposits almost always contain a proportion of organic matter—typically ~3–5%-originating from the importation of fine suspended sediments into the coastal zone of the muddy sediment deposition. The organic matter includes both terrigenous (from fine vegetation detritus) and marine biogenic matter, as well as originating from *in situ* biogenic processes, such as mucus and feces from worms and other benthic organisms inhabiting the surficial muds. In many locations organic matter contributions include fine plant detritus originating from such diverse sources as mangrove stands, or adjacent "pastures" of sea grass, marsh grasses, and wetlands. Biogenic contribution to muddy sedimentary deposits may also include small shell fragments, minute sea urchin spines, and fragments of living and dead diatoms, foraminifera, ostracods, and coccoliths (Augustinus, 2002; Wang *et al*., 2002a).

Additional mineral matter occurs in the mud deposits, including fine sands, terrigenous matrix fragments, and shelly gravel fragments. Composition of the mineral matter is influenced by local supply and may consist of quartz, feldspar and mica, and small proportions of heavy minerals.

Typically, mud deposited in the intertidal zone is soft, pliable, of high plasticity, thixothrophic, and contains a large volume of water within its physical structure. Practically, a person may sink up to their knees in wading through intertidal muddy deposits. This thixotrophic property suggests that in geotechnical terms mud behaves either as a plastic or a fluid substance indicating that mud deposits exhibit properties rather different from noncohesive clasts in the sedimentary environment.

In mud-rich shallow waters of muddy coastal areas, the seafloor may be characterized by "fluid mud"—a state in which the particles occur partially as concentrated colloidal state, and the viscous substance possesses extremely high water content (Mehta and Hayter, 1989; Mathew and Baba, 1995).

Muddy coastal sediments also possess interesting geochemical characteristics, related to the chemical reactions associated with anoxic conditions and microorganism activity within the mud deposits. Below the oxic surface layers, usually only a few centimeters thick, the mud often looks blue-black and exhumes a pungent sulfurous smell.

Morphodynamic types of muddy coast

For expansive open ocean tidal flats, for example, of China, muddy deposits are an integral component. The muddy deposits may range from several hundred meters to more than 10 km in extent (Wang *et al.*, 2002b). But muddy coastal deposits may also exist in restricted lenses a few tens of meters wide. Wang *et al.* (2002a) identifies several morphodynamic categories of muddy coast:

Tidal flats: They are the typical geomorphic form of expansive muddy coasts and are characterized by intertidal surfaces with low slopes of order 0.5–1.0 : 1000. Distinct morphological and sedimentary zonation features can be identified (Wang *et al.*, 2002b). Generally, a low relief salt marsh zone is developed within the supra-tidal zone, which may be surmounted by shelly chenier beaches or ridges, or artificial stopbanks (dikes) on populated flat lowland coasts. Below high-tide level, true "mudflats" are located in the upper part of the intertidal flat. Clay and silt layers are often developed in the central parts of the tidal flats, and the lower-to-sub-tidal sectors become more sandy–silty or silty–sand, with wave ripple bedform features developed on the surface. Dendritic meandering tidal creeks are common on broad muddy tidal flats, formed by the scouring of ebb-tidal waters as they drain off the large areas of intertidal flat upon the falling tide. Erosion scour features, both tidal current and wave induced, are often observed on the central sectors (Wang *et al.*, 1990). For broad muddy tidal flats, spatially varying morpho-sedimentary zonation is evidently associated with different hydrodynamic forcing processes acting on the flat.

Inner deposits of barrier-enclosed lagoons: Within the landward side of barrier-enclosed lagoons, along the southeast coast of the United States, for example, a veneer of deposited mud is typically found. Such muddy deposits are typical of barrier lagoons, and may be associated variously with wetlands, oyster beds, and estuarine reentrant valley head deposits. Source of the muddy deposits is mainly from input from the surrounding land catchment, and the deposits are usually thin (0.5–2 m) but areally extensive in the available area, and overlie sands of the barrier lagoonal system.

Enclosed sheltered bay deposits: Muddy deposits of varying types may occur in sheltered embayments. Geomorphically, such embayments may be tectonically induced by block faulting, or form from drowned river valleys consequent upon the Holocene sea-level transgression. The deposits normally originate from the surrounding catchments and occur particularly in the tributary valley heads.

Estuarine drowned river valley deposits: Most funnel-shaped estuaries are drowned river valleys, which have significant freshwater input and within which there is strong mixing between the fresh and saline marine waters. The resulting "estuarine circulation" causes mud to be transported landwards on the bottom of the estuary, enhancing the tendency for deposits to become markedly more muddy toward the head of the estuary or bay. The freshwaters also carry suspended sediment loads of silt and clay, especially in river floods, and these tend to undergo flocculation and deposition upon mixing with the saline waters in the upper part of the estuary. The result is a concentration of muddy deposition at the heads of the estuaries.

Supra-tidal (storm surge) mud deposits: Lowland coasts with a broad shallow shelf, especially where they exist in the form of a large funnel, such as the German Friesland bight, the Bohai Bay in China, the Gulf of Thailand, or the Gulf of Bangladesh, may be subject to strong storm surges. Where there is abundant nearshore submarine muddy deposits, wave action during the storm surge event reagitates the silts and clays resulting in waters of high suspended load sediment concentration. These mud-laden waters can be swept onshore, mix with high suspended load river waters, and a mud layer deposited in the supra-tidal zone. Such supra-tidal deposits are found in China, and in Bangladesh as a result of storm surges and tropical cyclones. The material deposited tends to be mainly silt.

Chenier plains: Shelly chenier ridges can form plains as described by Schofield (1960) and Woodroffe *et al.* (1983) for the Firth of Thames in northern New Zealand. The shells comprise bivalves such as cockles, and during storm events become transported landwards, or otherwise move as wave-induced littoral drift along an active chenier beach face. The chenier ridges typically form shell spits overlying thick deposits of structureless mud, and the seaward-most chenier may comprise the active beach face surmounting a broad intertidal mudflat.

Swamp marsh and wetland deposits: This type of muddy coast deposit occurs in temperate coastal environments beyond the limit of mangroves. Good examples are found along the low terrain coasts which occur on a broadscale around the Dutch and German North Sea coasts, and in the Wash of England. Other well-known examples are found on the landward side of the extensive barrier enclosed lagoon system that is found around the southeast United States and the Gulf coast.

Mangrove forest and swamp deposits: Mangrove forests occur widely in the tropics and subtropics and are typically associated with muddy deposits. Their root mat assists in the trapping of fine suspended sediments. Mangrove stands also occur on the landward shores of coral platform reef and enclosed lagoons, and likewise may induce a veneer of muddy deposits to occur over the coral (Schaeffer-Novelli *et al.*, 2002; Wolanski *et al.*, 2002).

Mud veneer deposits on eroded shore platforms: In this type of muddy coast, an eroded shore platform has subsequently been layered with a veneer of muddy sediment. These types of muddy coast occur on a relatively small-scale and in sheltered harbor environments where there is a high source of muddy material either from adjacent catchments or from sublittoral deposits in the nearshore. Volumes of mud involved are relatively small. Examples occur in the harbors of northern New Zealand.

Ice deposited mud veneer: On Arctic shores, a muddy flat may be formed by ice rafts transporting mud and boulders, grounding and melting out in the thaw so that mud and boulders are jointly deposited on the tidal flats (Dionne, 2002).

Sub-littoral mud deposits: Along many coasts in sheltered and semi-enclosed bays where there is an abundant source of fine sediment supply and not particularly strong tidal currents, mud deposits occur in the sublittoral zone. These deposits may be of the fluid mud type, or occur as offshore mud banks, as off the coast of Kerala, India (Mathew and Baba, 1995). On occasions of strong wave agitation and shorewards wind-induced surface current, the agitated fine mud sediment particles may be eroded and suspended on the wave turbulence creating an estuarine "turbid fringe" and swept onshore and deposited as a mud layer either in the high tidal zone or the intertidal zone.

Beaches on muddy coasts

Although the dominant visual morphological feature of muddy coasts is often the broad intertidal flat, this is really just one component of a beach system. The extensive intertidal flat may also be part of a littoral drift system. In many estuarine beaches the following sequence can be observed: (1) a supra-tidal section with mainly storm surge silt and clay deposits active in storm surge events, and sometimes may have wind blown sand cappings; (2) a narrow, steep ($\sim 10°$), active beach face comprised of sand and shelly gravel sediment; (3) a broad intertidal flat containing muddy sediment and often *Zostera* beds; and (4) a subtidal zone containing mainly silts. Of course many variations exist, for example, the intertidal flat may be mainly sand and biogenic gravel with relatively small amounts of mud, and the subtidal sector can contain coarser sediments. But the important point is that the entire system is an active beach and sediment may be transported by wave and current processes over (diabathic transport) and along (parabathic transport) its components. Thus, shells and even terrigenous gravels originating in the subtidal zone may be transported onshore to accrete on the upper beach face. As tidal waters submerge and drain the intertidal flats, agitation of the surface sediments by waves creates a *turbid fringe* of high suspended load sediment—a typical feature of muddy coasts.

Stratigraphy and sedimentary structures of muddy coastal deposits

Wang *et al.* (2002a) identify that tidal flat muddy deposits are often stratified in fine laminae, the delicate bedding being caused by the interlamination of thin layers of very fine sand material in the more argillaceous basic substrate. The lamination of thin bedding is the result of varying hydrodynamic conditions, including the obvious flood and ebb oscillating tidal flows, but also reflecting neap and spring, storm, and seasonal changes. The bedding is seldom strictly parallel, but instead is generally streaky and lenticular. The alternating fine-sandy and clay layers wedge out rapidly in lateral extent and their thickness is not uniform. Such alternating bedding indicates frequent reworking of sediments under the influence of tidal currents of varying strength and direction, and the influence of meteorological factors, especially storm winds and associated waves.

Stratigraphically, modern coastal mud deposits tend to be thin relative to true deep-sea marine muds. This reflects the limited time—only some ~6,500 years—since the Holocene sea level reached its approximate present level, as well as the shallow depositional environment, which is typically energetic on a day-to-day Timescale. In some areas the deposits, especially clays, appear to be structureless and massive, but in other deposits there are often rare lenses of sand and shell—the result of episodic storm processes (Park and Choi, 2002).

In stratigraphic section, across broad tidal flats such as occur in China, shelly chenier deposits overlie the supratidal clay-rich muds. Typically, these muds laid down by storm surge processes, are clay-rich, massive, lensoid-shaped, and also contain relatively high organic matter, especially plant fragments. The supra-tidal clays overlie the silty muds of the upper tidal flats, which overlie the alternating fine sand and clay lenses of the mid-tidal area. These in turn overlie the very fine sand and coarse silt of the low tidal zone flat (Wang *et al*., 2002b).

Sedimentary structures found in muddy coastal deposits include ripple bedforms on the sandier sediments. Within the larger tidal creeks with high current speeds and transporting sandy bedload, bedforms of megaripples, and current-cross-bedding is typical. Upon the mudflats, bioturbation structures produced by organisms inhabiting the tidal flats are also evident, while polygon cracks are to be found on the supra-tidal deposits. These sedimentary structures reflect a range of dynamic processes on the muddy coast tidal flats.

Geographical spread of muddy coast

Muddy coasts are developed in a wide range of coastal climatic and oceanographic environments in the world, from Arctic oceanic coast to the tropics (Wang *et al*., 2002a). Their detailed geographic location and nature are presented in detail by Flemming (2002). Extensive well-formed, broad expansive intertidal muddy coasts are present around the Yellow River delta in the Bohai Sea of China, as well as the abandoned Yellow River delta in North Jiangsu Province along the Yellow Sea, and the southern embayments of the Changjiang River. Extensive sectors of muddy coast also occur along the east coast of the Americas, with the Amazon River mouth and the northern coasts of Guiana being of immediate note. Extensive muddy coast also occurs along the shores of Canada's Bay of Fundy, around the seasonal ice covered St. Laurence estuary, along the Atlantic east and southeast coasts of the United States, around the Mississippi delta and Vicinal coasts of the Gulf of Mexico, and inside several of the larger bays along the west coast of North America from California to Washington. In Europe, muddy coast deposits occur around the North Sea and Baltic coasts, such as Dollart, Lay and Jade Bays in Germany, the funnel-shaped mouths of large rivers (Elbe, Weser) in the east and north Friesian Bight, and in The Wash and other estuaries of east England. These exhibit many different examples and types of muddy coast. Muddy coast is widely evident in the tropical and monsoonal countries of Asia, including much of the coasts of India, Bangladesh, Thailand, Malaysia, Indonesia, and Vietnam. The north-east coasts of Australia, as well as the islands of the Pacific including New Zealand, New Guinea, and even the coral reef islands, contain areas of muddy coastal deposits. For the African continent, muddy coast occurs mainly within the tropical belt of both the east and west coasts.

It is evident that muddy coasts are characteristic of all continents (perhaps with the exception of Antarctica which typically exhibits a steep rocky profile for its minor coastal sectors of ice free coastline). They occur in a wide variety of the global coastal environments, but can vary widely in size and morphogenetic environment. However, muddy coasts tend to be particularly conspicuous in tropical zones, especially in the Asia region, and the muddy coastal deposits of largest extent are associated with major continental river discharges.

Factors leading to formation of muddy coast

A number of factors facilitate and enhance muddy coast formation (Wang *et al*., 2002a).

Abundant fine-grained sediment supply

This is the most important factor in influencing the formation of muddy coastal deposits of various types. Fundamentally, if a major source of fine sediments continuously provides muddy sediments at a faster rate than the hydrodynamic conditions can remove them, then muddy coastal deposits will form. Conversely, if muddy source material is not available in sufficient quantities within a coastal environment then muddy deposits do not form. Sources of sediment for concentration to form muddy coast are many and varied, but include:

Adjacent rivers. Adjacent rivers with high concentrations of fine suspended sediment loads. The classic example is the Huangho River of China, which drains a huge catchment including highly erodible loess regolith, which provides the bulk of the fine sediments to the Bohai Bay. Other examples include the Amazon (draining a huge and partly steep catchment of highly weathered tropical soils), the Fly River of New Guinea, the Mekong River of Vietnam/Laos (likewise draining large and partly steep catchments of highly weathered tropical soils), and the Waipaoa River of New Zealand (draining a steepland catchment of highly erodible montmorillonitic clay-rich Tertiary rocks). In the latter cases, the mountainous steepland catchments are also subject to episodic, intense, orographically induced rainfalls, factors which enhance the high volume of sediment load delivered to the littoral zone.

Supply of sediment from offshore. Often sediment that forms or contributes to coastal muddy deposits may be of "secondary origin" in the sense, that it is reworked from offshore. In this sense, the reworked mud deposits are "palimpsest." Examples include the onshore transfer of fine sediments from the ancient river deposits along the northern Jiangsu coast (Wang *et al*., 2002b), and the onshore transfer of eroded glacial till deposits from the North and Baltic seas.

Erosion of coastal sedimentary deposits and cliffs. In many enclosed and semienclosed seas, active erosion of the cliffs provides a limited source of fine material for muddy coastal deposits. In the Kiel Bay of the Western Baltic the surrounding coast is formed of glacial till containing a high proportion of fine sediment (Healy *et al*., 1987). Rapid erosion of the boulder clay cliffs (~0.3–1.0 m/a) provides considerable material for local muddy coastal deposits. Where there has been rapid cliff erosion and continuing supply of muddy sediment the shore platform may subsequently become veneered with mud. Likewise in sheltered steepland embayments containing an estuarine lagoon fronted by barrier spits (Healy *et al*., 1996) erosion of the cliffs produces mud deposits overlying the early Holocene marine sands.

Tidal range

A macro tidal range (>4 m) is often regarded a necessary factor in explaining extensive broad muddy-coast deposits. However, a general dearth of sediment supply or high wave energy may restrict tidal flat development (Davis, 1983). Certainly, the broad expansive intertidal flats and associated muddy deposits of the Jiangsu coast of China are very wide and have associated a macro tidal range. Other extensive muddy coastal deposits associated with large tidal ranges include the Bay of Fundy and The Wash of England (Amos, 1995). But in other locations of muddy coasts the tidal ranges may be meso (2–4 m) or micro (<2 m), and still extensive muddy deposits of various types occur, for example, around the coast of Indonesia, India, the southeast coast of the United States off the mouth of the Hwang-ho (Yellow River) of China, the Fly River of New Guinea, and around northern New Zealand.

A fundamental question is: why should a large tidal range be associated with broad intertidal muddy coastal deposits? Evidently, the answer lies in a different morpho-depositional mechanism from sandy and mixed sand gravel beaches, combined with the thixotrophic nature of the muddy deposits. While sandy beaches are characterized by non-cohesive grains, and thus undergo regular morphodynamic change in response to varying wave conditions, they typically assume some modal morphodynamic beach state. However, beaches on muddy coasts tend not so obviously to change their morphology, although the beach is active over time. This is because: the individual muddy sediment clasts possess cohesive qualities and thus the surface layer of sediments is not so easily moved around by the waves and currents as are noncohesive sandy sediments. Rather, in energetic wave conditions the surface layers of mud particles are reagitated and taken into suspension within the water column. Moreover, the sediments in purely muddy beaches tend to be deposited in episodic storm surge events with a net onshore movement of suspended sediment providing the material to become deposited on top of the existing muddy flat sediments. Finally, the muddy bulk sediment possesses little strength, and is subject to fluid and plastic flow, and this results in a low angle of natural repose within the intertidal zone.

Thus, "pure" muddy coast (i.e., without a landward surmounting narrow beach face of sand or shelly gravel or chenier beach) typically exhibits a muddy upper intertidal and supra-tidal zone of subdued relief, which undergoes relatively little morphodynamic change compared to a sandy beach. The essential point seems to be that the mode of formation of the intertidal muddy deposits is by net onshore sediment movement, and that the morphodynamics of deposition are such that an essentially flat topographic surface results. Providing there is abundant and continuing fine sediment supply then the extent or width of a muddy intertidal flat becomes a function of the tidal range (Wang *et al*., 2002b).

Conclusion

Muddy coast geomorphology and sedimentary depositional systems occur widely around the earths' coastlines, but compared to sandy coasts have been relatively little studied. Texturally, "mud" is defined based upon particle size, and comprises mineral material of silt and clay sizes. Muddy coasts are defined as possessing distinctive muddy deposits, typically but not exclusively manifest as broad intertidal muddy flats. Additional geomorphic features found on muddy coasts include chenier ridges and beaches, veneer muddy deposits, and shallow offshore muddy deposits, while associated biologic features may occur such as mangrove stands and salt marshes. Muddy coasts occur widely in geographic distribution from the tropics to the Arctic. Their fundamental *raison d'existence* is abundant mud-sized sediment particles in the coastal environment, but the existence of broad intertidal mudflats is often associated with a large tidal range.

NATURAL HAZARDS

Natural hazards are physical phenomena that expose the coastal zone to risk of property damage, loss of life, or environmental degradation. *Rapid-onset* hazards last over periods of minutes to several days. Examples include major cyclones, accompanied by high winds, waves, surges, and tsunamis—giant sea waves set off by earthquakes, volcanic eruptions, or submarine landslides. *Slow-onset* hazards develop incrementally over longer time periods. Examples include coastal erosion and sea-level rise.

The vulnerability of the world's coastlines to natural hazards varies considerably, because climate, tectonism, and other physical variables, such as bathymetry, shelf width, landform, lithology, and coastal configuration change from place to place. For example, although tropical cyclones may form wherever sea surface temperatures exceed 26°C, landfall occurs most commonly in particular regions such as southeast Asia, the Caribbean Sea, or southeastern United States (Figure N1). Tsunamis are most prevalent around the Pacific Ocean, due to the seismicity and volcanicity associated with convergent-plate boundaries along the circum-Pacific "Ring of Fire."

Rapid coastal development and urbanization expose increasing numbers of people to natural hazards in a dynamic and unstable environment. Globally, approximately 400 million people live within 20 m of sea level and within 20 km of a coast (Small *et al.*, 2000). In the United States, over 139 million people (53% of the population) live in coastal counties (Culliton, 1998). Anticipated climate changes will greatly amplify risks to coastal populations. By the end of this century, rise in sea level by 2–5 times present rates could lead to more frequent flooding and inundation of low-lying regions, worsening beach erosion, as well as loss of ecologically

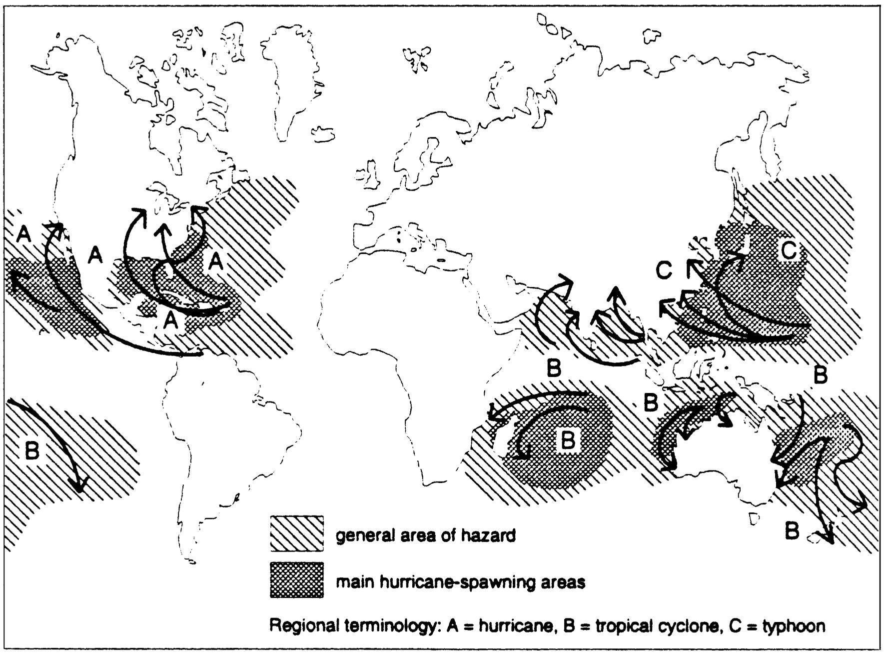

Figure N1 Location of tropical cyclone breeding areas (from Alexander, 1993).

productive coastal wetlands, and saltwater intrusion into coastal aquifers and estuaries (IPCC, 2001a,b).

Rapid-onset hazards

Tropical cyclones

Tropical cyclones (also called *hurricanes* in the Atlantic basin, *cyclones* in the Indian Ocean, and *typhoons* in the western Pacific) are major low-pressure systems that develop and intensify over the open ocean between $\pm 5°$ and 25° latitude (Figure N1). Hurricanes form where sea surface temperatures rise above 26°C, under conditions of high relative humidity, strong evaporation rates, weak vertical wind shear, and atmospheric instability (Henderson-Sellers *et al.*, 1998). In the Atlantic basin, the hurricane season lasts from June to November, peaking between August and early October.

A tropical cyclone consists of a rotating atmospheric low-pressure system, ranging from less than one hundred to several hundred kilometers in diameter. At the center is the "eye"—a zone of calm atmosphere and nearly clear sky. It is surrounded by the eyewall, where the strongest winds of the hurricane are concentrated (Figure N2). Spiraling around the eyewall are rainbands of high winds and torrential rains. In the Northern Hemisphere, the cyclonic system rotates counterclockwise around the eye, while simultaneously moving forward along a northwesterly track. Thus, winds are stronger on the cyclone's right side, due to the additive effect of the mean forward velocity of the storm and the rotational speed around the eye (Coch, 1995).

A number of factors contribute to hurricane damage. One of these is the damage produced by very high wind speeds (minimum 119 km/yr). In addition, hurricanes cause severe flooding due to the combination of heavy rainfall, waves, and storm surge. In coastal areas, a major hazard is flooding by the storm surge, which is a dome of water produced by the low barometric pressure and strong wind shear (see *Storm Surge*). The area at greatest risk lies to the right of the eyewall at landfall; the risk falls off with increasing distance. The hazard also depends on the mean forward velocity of the storm: a slowly moving storm can cause flooding over several tidal cycles. The angle at which the hurricane track crosses the coast also determines the hazard. A hurricane track which parallels the eastern coastline of a continent keeps the stronger right side of the cyclone seaward, thereby reducing the damage potential to land. On the other hand, a coast-normal track crossing land may cause serious damage on the right side of the storm (Coch, 1995).

The intensity of hurricanes is classified from 1 to 5 on the Saffir–Simpson scale, with 5 representing the most severe category (Table N1). This scale rates hurricanes on the basis of central air pressure (the lower the pressure, the more intense the storm), sustained wind velocity, storm surge potential, and potential for property damage. The three most powerful US hurricanes since 1900 includes a category 5 storm that struck the Florida Keys in 1935, Camille in 1969 (category 5; Louisiana-Mississippi), and Andrew in 1992 (category 5; south Florida, Louisiana) (NOAA, 2001).

The deadliest US hurricane (category 4) struck Galveston, Texas in September, 1900, killing over 8,000 people. The next most lethal hurricanes include several that swept over the Florida Keys in 1919, 1928, and 1935 (categories 4 and 5), and New England in 1938 (category 3). In the United States, deaths caused by hurricanes have decreased substantially in recent years, because of the advance warning provided by weather satellite tracking. In other parts of the world, however, tropical cyclones continue to exert a high toll. Between 1960 and 1981, tropical cyclones have killed 386,200 people in Bangladesh, 24,930 in India, and 7,480 in Vietnam (Alexander, 1993, p. 156).

Hurricane behavior in the Atlantic basin has not changed detectably over the last 60 years, although intense hurricanes (categories 3–5) were more frequent in the 1940–1960s and late 1990s (Landsea *et al.*, 1999). Yet the costliest hurricanes have occurred in recent years (i.e., Andrew in 1992 [category 5, Florida, Louisiana, $26.5 billion in damages], Hugo in 1989 [category 4, South Carolina, $7 billion], and Floyd in 1999 [category 2, mid-Atlantic & NE U.S., $4.5 billion]; NOAA, 2001). Extensive coastal development over the last few decades has increased the amount of property at risk to devastating storms (Van der Vink *et al.*, 1998; Chagnon and Chagnon, 1999).

Extratropical cyclones

Extratropical cyclones are the dominant type of storm responsible for major coastal flooding and beach erosion at mid-latitudes. These storms occur most frequently between October and April in the Northern Hemisphere, peaking in winter. Although wind speeds and surge heights are much lower than in hurricanes, extratropical cyclones inflict considerable damage because of their greater spatial extent (typically over 1,000 km versus 100–150 km for hurricanes), high waves, and duration spanning several tidal cycles at a given location (Davis and Dolan, 1993; Dolan and Davis, 1992). Areas at risk to flooding from extratropical cyclones include the Atlantic Coast of the United States north of 36°N, northwestern Europe, and northeastern Asia.

US Atlantic coast winter storms (*northeasters* or *nor'easters*) have been classified into five categories (5 is the most severe) based on significant wave height, $H_{1/3}$ (average of highest one-third of waves), duration,

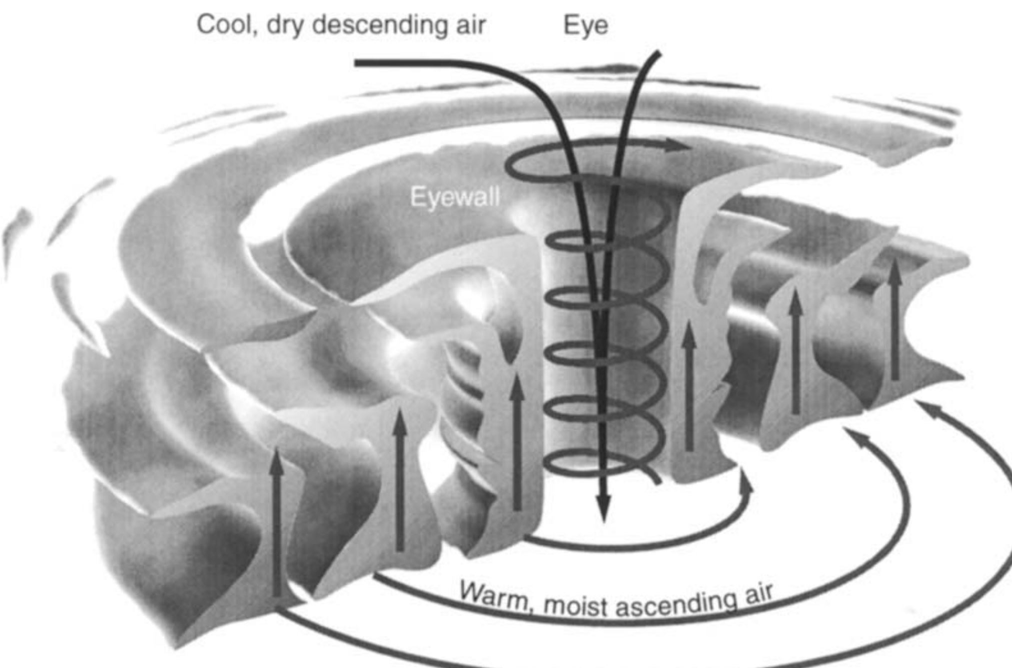

Figure N2 Structure of a hurricane.

Table N1 The Saffir–Simpson scale of hurricane intensity (after NOAA 1997)

Category	Central pressure (millibars)	Winds (km/h)	Surge (m)	Damage
The Saffir–Simpson scale				
1	⩾980	119–153	1.2–1.5	Minimal
2	965–979	154–177	1.8–2.4	Moderate
3	945–964	178–209	2.7–3.6	Extensive
4	920–944	210–249	3.9–5.5	Extreme
5	<920	>249	>5.5	Disaster

Effects
1 Minimal damage, mainly to unanchored mobile homes, trees, shrubs. Minor coastal flooding.
2 Some damage to roofs, windows, mobile homes, piers, vegetation. Coastal flooding; small boats break moorings.
3 Some structural damage to small buildings; mobile homes destroyed. Flooding destroys coastal small structures. Floodwaters may cover terrain below 1.5 m.
4 Major damage to lower floors of coastal buildings. Significant beach erosion. Potential flooding of terrain below 3 m inland as far as 9.6 km, requires mass evacuation.
5 Roofs blown off buildings. Many smaller buildings destroyed or blown away. Damage to flower floors of buildings below 4.5 m elevation, within 460 m of shoreline. Massive evacuation may be necessary.

Table N2 Dolan–Davis scale for the classification of Atlantic Coast nor'easters (after Dolan and Davis, 1994)

Storm class	Frequency (percent) (N = 1564)	Significant wave height (m)	Duration (h)	Power (m^2h)
The Dolan–Davis scale				
1 Weak	50.3	2.0	8	32
2 Moderate	25.1	2.5	19	107
3 Significant	21.6	3.2	35	384
4 Severe	2.5	5.0	62	1420
5 Extreme	0.5	6.8	97	4332

Effects
1 Minor beach erosion. No property damage.
2 Moderate beach erosion; minor dune erosion. No property damage.
3 Significant beach and dune erosion. Moderate property damage.
4 Severe beach and dune erosion. Overwash damage on low-profile beaches. Community-wide loss of structures.
5 Extreme beach erosion, dune destruction. Massive overwash in sheets and channels. Extensive regional-scale property losses in million of dollars.

D, and power, P, where $P = H_{1/3}^2 \times D$ (Dolan and Davis, 1992, 1994; Table N2). (The energy of a wave, hence its destructive capability, is proportional to $H_{1/3}^2$.) A qualitative assessment of the relation of storm class to coastal damage is also indicated in Table N2.

Nor'easters affecting the eastern United States have varied in number and severity over time, but do not show any long-term trends (Zhang *et al*., 2000). Severe storms peaked during the late 1970s and again in the early 1990s (Dolan and Davis, 1994). Significant nor'easters within the last 40 years include the "Ash Wednesday" storm (March 6–7, 1962), the Halloween storm (October 31, 1991), and two other powerful storms on December 11–12, 1992, and March 13–14, 1993. The "Ash Wednesday" storm generated 10-m-high waves in the open ocean and caused over US$300 million in property damage along 1,000 km of the Atlantic coast (Davis and Dolan, 1993). This storm was especially destructive because it lasted for five tidal cycles. The December 1992 nor'easter hit the mid-Atlantic and New England coasts with waves over 6 m in some locations (Davis and Dolan, 1993) and brought the entire transportation system of New York City to a virtual standstill (USACOE/ FEMA/NWS, 1995). Several months later, the March 1993 nor'easter (the so-called "storm of the century") created blizzard conditions over most of the East Coast and churned waves over 4.5 m along much of the East Coast. The Ash Wednesday storm of 1962 and the Halloween storm of 1991 rank as class 5 nor'easters (Davis and Dolan, 1993).

Northwestern Europe has also experienced severe winter storms. On February 1, 1953, a North Sea storm swept over the Netherlands, breaching dikes, inundating 150,000 ha, and killing over 1,800 people. That storm also caused major damage in eastern Great Britain (Alexander, 1993, p. 138). In 1990, a series of eight powerful gales, some with hurricane-force winds, hit western Europe between late January and early March (Munich Re, 1993).

Storm surges

A storm surge is the elevation of ocean water level above that expected from astronomical tides, caused by a passing storm. The surge results from the reduced atmospheric pressure, which causes sea water to rise by around 1 cm for each drop in pressure of 1 mb, and from the wind stress, which literally pushes water toward the coast. Factors contributing to the surge height include the storm intensity, width and slope of coastal shelf, and coastal configuration. The total flood height also depends on the tidal stage (see *Storm Surge*).

The flood surge is a major cause of coastal erosion (see below). On exposed barrier islands, sand washes from the beach and dunes, and redeposits bayward in overwash fans. The surge also cuts channels or tidal inlets across the barrier. As the surge ebbs, seaward-flowing water creates further erosion. The flood surge damages buildings and other structures by direct wave impact, hydraulic lift of waves and water beneath raised buildings, wave energy reflected from protruding structures such as groins and jetties, as well as battering from floating debris (Coch, 1995).

Regions of the world most vulnerable to surges from tropical cyclones include low-lying, deltaic coasts of southeast Asia, Bangladesh, China, the Philippines, the southeastern United States, the Caribbean, and northern Australia (Figures N1, N3). Surges from extratropical cyclones have also produced extensive flooding in the Netherlands, Germany, Italy, as well as the eastern United States (see on page 682).

Bangladesh is particularly vulnerable to storm surges because of its low topography, shallow continental shelf, high tidal range, tendency for coastal cyclones to converge near the apex of the Bay of Bengal, and high population density especially on low-lying islands (Murty and Flather, 1994). Storm surges caused over 220,000 deaths in 1970 and 150,000–200,000 more in 1991 (Alexander, 1993, p. 542). In the Netherlands, catastrophic storm surges killed 80,000 people in 1281, and 100,000 in 1421. The 1953 storm claimed around 1,900 lives (including England; Munich Re, 1993). The Netherlands has subsequently embarked on a massive program to strengthen its national sea defenses in the central Netherlands to be able to withstand the 1/10,000 year flood (De Ronde, 1991). In Venice, a storm flood of 1.94 m above the local datum inundated most of the historic city on November 3–4, 1966. A mean sea level rise of only 34 cm would reduce the return period of this flood from 165 to only 15 years (Pirazzoli, 1991).

Tsunamis

A tsunami is a series of waves caused by the vertical displacement of ocean water, triggered by an earthquake, volcanic eruption, landslide, or more rarely, the impact of a bolide. Most tsunamis occur on islands and shores around the Pacific Ocean. In contrast to ordinary water waves, tsunamis have long wavelengths (from 150 to 700 km), long periods (10–60 min), and low amplitudes (≤1 m). They propagate with enormous speeds (600–800 km/hr) over open ocean. The velocity of propagation is given by $v = \sqrt{(g \cdot h)}$, where v is velocity, g is the acceleration due to gravity, and h is water depth. The wavelength is $L = v \cdot T$, where L is wavelength and T is the period (Alexander, 1993; Bell, 1999).

The danger of tsunamis increases dramatically as the waves approach shallow water, where they slow down but increase tremendously in height. Water levels rise rapidly up to 20 m above normal sea level. Occasionally, a "bore" or wall of turbulent water moves up narrow bays or estuaries. The highest wave may occur hours after several lower ones have passed (Coch, 1995). The height of the wave as it arrives at the shore is related to the original amount of water displaced, distance from source, nearshore bathymetry, and coastal configuration (Bell, 1999). The destructiveness is linked to the run-up, or maximum vertical height (Table N3).

Tsunamis are usually caused by displacement of water due to vertical movement of the seafloor along faults, during major earthquakes associated with plate subduction or other tectonic events. Waves are formed as the displaced water mass attempts to return to an equilibrium state. However, major volcanic eruptions can also set off tsunamis. For example, the catastrophic tsunami produced by the Krakatau eruption in 1883 generated waves up to 30 m high in places that killed over 30,000 people in Java and Sumatra (Coch, 1995). Less commonly, submarine landslides can also cause tsunamis, as apparently happened in Papua New Guinea in 1998 (Tappin *et al*., 1999).

Around 90% of destructive tsunamis occur around the Pacific Basin at an average rate of 2 per year (Alexander, 1993). The Hawaiian Islands have suffered close to 160 such events in the past 200 years. Waves up to 8 m, generated by an earthquake in the Aleutian Islands in 1946 struck Hilo, Hawaii, killing 159 people and causing US$26 million ($1946) in damage. The tsunami caused by the 1960 Chilean earthquake produced waves up to 10.7 m at Hilo, killing 61 people. Crescent City, California, was struck by waves up to 6.3 m high from the 1964 Alaska earthquake, which caused 11 fatalities and US$7.5 million in property damage. A devastating tsunami in 1998 that killed around 2,200 people in Papua New Guinea may have been caused by an earthquake-induced underwater landslide (Tappin *et al*., 1999). A tsunami that battered various sites along the Pacific coast of Japan in January, 1700, has been traced to a massive earthquake (estimated magnitude 9) on the Cascadian subduction zone (Satake *et al*., 1996).

The Atlantic Coast of North America is also potentially at risk to destructive tsunamis, because of slope instabilities on the continental shelf. Discharge of natural gas along fractures along the outer continental shelf edge off southern Virginia-North Carolina could eventually destabilize the shelf edge, causing massive submarine landslides and tsunamis (Driscoll *et al*., 2000). Underconsolidated sediments on the New Jersey continental slope are also potentially susceptible to slumping (Dugan and Flemings, 2000).

Table N3 Tsunami intensity scale (after Bell, 1999; Soloviev, 1978)

Intensity	Wave height at run-up (m)	Frequency in Pacific Ocean
I	0.5	once per hour
II	1	once per month
III	1	once per eight months
IV	4	once per year
V	8	once in three years
≥VI	16	once in ten years

Effects

I *Very slight*. Weak waves detectable only on tide gauge records.

II *Slight*. Waves noticeable only on very flat shores.

III *Rather large*. Some flooding on low coasts; slight damage to small structures; light boats swept away; reversed flow up estuaries or rivers.

IV *Large*. Flooding of shore. Damage to coastal structures, embankments and dikes. Smaller ships and larger sailing vessels swept away. Floating debris.

V *Very large*. General flooding of shore to some depth. Considerable damage to quays, heavy structures near shore; extensive debris; vessels except for large ships swept away; large bores in estuaries; people drowned.

≥VI *Disastrous*. Partial to complete destruction of man-made structures along shore. Flooding of coasts to great depths. Large ships severely damaged. Trees uprooted or broken by waves; many casualties.

Slow-onset hazards

Coastal erosion

Around 70% of the world's sandy beaches are retreating at present (Bird, 1985). The prevalence of beach and cliff erosion (The NRC [1995] defines coastal erosion more narrowly as the volumetric loss of sand from a beach by waves, currents or other processes, whereas recession is the landward [linear] displacement of the coastline over time.) from many parts of the world, even where human impacts are minimal, implies an underlying global cause, such as the recent sea-level rise (IPCC, 2001; see below), which may have exacerbated other more localized processes. Among these are differences in rock resistance, coastal subsidence, diminution in sediment yield of rivers (because of reduced precipitation or upstream entrapment in artificial reservoirs), increase in wave attack due to greater number or severity of coastal storms, longshore drift, beach mining, or cliff quarrying, and presence of engineering structures that intercept sediment flow or enhance scour (Bird, 1996).

In the United States, the average erosion rate along the Gulf Coast is 1.8 m/yr, with 63% of the shoreline retreating (Dolan *et al*., 1985). Mean erosion rates in Louisiana are 4.2 m/yr— a consequence of the high relative sea-level rise due to land subsidence (Penland *et al*., 1989). Erosion rates along the Atlantic Coast average 0.8 m/yr; 79% of the coastline shows some degree of erosion (Dolan *et al*., 1985). The Atlantic side of the southern Delmarva Peninsula is an erosional "hotspot," possibly related to anomalously high subsidence rates near the mouth of Chesapeake Bay and jetties at Ocean City, Maryland, which have curbed southward littoral drift to Assateague Island (NRC, 1995). Widespread coastal erosion has also occurred as a result of major nor'easters (see above).

Coastal erosion is less severe on the Pacific Coast (Dolan *et al*., 1985). Nonetheless, 28.6% of the California coast is at "high risk" to natural hazards, with an additional 36.8% "requiring caution" (Griggs, 1994). California's most extensive coastal hazard comes from eroding cliffs and bluffs. Cliff failure arises from wave attack, subaerial erosion, mass movements, and earthquakes. Beaches and dunes are also prone to erosion, particularly following high waves and tides during El Niño events (Griggs, 1994; Storlazzi and Griggs, 2000; see also *El Niño–Southern Oscillation, ENSO*). Damming of many rivers has reduced the sediment supply to the sea, limiting beach recovery following episodic erosion events.

Beach nourishment and dune restoration are now a major means of shore protection against storm damage and long-term erosion (NRC, 1995). Beach nourishment or restoration consists of placing sand that has usually been dredged from offshore or other locations onto the upper part of the beach. The process must be repeated at intervals which depend on local factors such as beach profile, average sand grain size, and anticipated losses due to storms and other processes. An estimated US$2.4 billion (adjusted to $1996) has been spent renourishing Atlantic, Gulf Coasts, and Great Lakes beaches since the 1920s (Program for the Study of Developed Shorelines, 1999). Over US$480 million have been spent replenishing East Coast beaches between 1990 and 1996 alone (Valverde *et al.*, 1999).

Sea-level rise

Sea-level rise represents a slow-onset hazard whose main impacts will become apparent only decades from now. Mean global sea level has been increasing by around 1–2.0 mm/yr over the last 100–150 years. This is the most rapid rate within the last few thousand years and is probably linked to the 20th century warming trend of ~0.6°C (Gornitz, 1995; IPCC, 2001a). The recent sea-level rise comes mainly from melting of mountain glaciers and thermal expansion of the upper ocean layers, with less certain contributions from polar ice sheets. Anticipated global warming could increase rates of sea-level rise by factors of 2–5 by the end of this century, greatly amplifying risks to coastal populations (IPCC, 2001a,b). The major consequences of accelerated sea-level rise are permanent inundation of the shoreline, more frequent coastal flooding, increased erosion, and saltwater intrusion (IPCC, 2001b).

The impacts of sea-level rise will not be globally uniform, because of local variations in vertical crustal movements, topography, lithology, wave climatology, longshore currents, and storm frequencies. Low gradient coastal landforms most susceptible to inundation include deltas, estuaries, beaches and barrier islands, coral reefs and atolls. Regions at risk include the Low Countries of Europe, eastern England, the Nile Delta, Egypt, the Ganges–Brahmaputra, Irrawaddy, and Chao Phraya deltas of southeastern Asia, eastern Sumatra and Borneo (Figure N3). In the United States, the mid-Atlantic coastal plain, the Florida Everglades, and the Mississippi Delta will be especially vulnerable.

Coastal wetlands will be among the most severely affected ecosystems since they lie largely within the intertidal zone. The ability of a salt marsh (or mangrove) to keep pace with rising sea level depends on relative rates of submergence versus vertical accretion. In the United States, present rates of marsh accretion are generally keeping up with relative sea-level rise, except for parts of Louisiana and Chesapeake Bay (NRC, 1987). Louisiana, with a relative sea-level rise of ~10 mm/yr, is losing around 140 km^2 of wetlands annually (Boesch *et al.*, 1994).

Coral islands, with average elevations of only 1.5–2 m above present sea level are also at high risk. If projected rates of sea-level rise approach 10–12 mm/yr, near the upper limit of coral growth, some slow-growing species may drown, but a slight rise in sea surface temperatures may prove even more detrimental to coral reef survival (IPCC, 2001b). The additional stress of increasing sea-surface temperatures may inhibit the ability of corals to keep pace with sea-level rise. Increasingly frequent coral "bleaching" occurrences in recent years have been linked to warmer than normal sea surface temperatures, in part associated with El Niño events. Tropical ocean islands and reefs at risk include the Maldives, many Pacific and Caribbean islands, and Australia's Great Barrier Reef.

Coastal flooding due to storm surges will increase in frequency with sea-level rise, even if the number and strength of storms do not change (Zhang *et al.*, 1997). The flood return period is very sensitive to very minor increases in sea level. For example, by the end of this century, the return period of the 100-year flood in New York City would be reduced to around 33 years, even at present rates of sea-level rise (2.7 mm/yr; see *Storm Surge*).

Coastal erosion is likely to increase as sea-level rises. Waves will be able to cut into cliffs at a higher level, triggering mass movements and slumping in poorly consolidated sediments. Barrier islands respond to rising ocean levels by eroding on their ocean sides and depositing sand by overwash on the bay side, a process called "barrier rollover" (Figure N4).

The high-tide shoreline's response to sea-level rise is often estimated using the Bruun Rule, which states that a typical concave-upward beach profile erodes sand from the beachfront and deposit it offshore, so as to maintain constant water depth (see *Beach Erosion; Coastline Changes*). High-tide shoreline retreat depends on the average slope of the shore profile. A 1 m sea level rise could cause the beach to retreat by as much as 100–200 m, depending on the slope. The Bruun Rule has been generalized to account for landward migration and upward growth of the barrier. Other high-tide shoreline response models involve sediment budget analysis, dynamic approaches, or historical trend analysis (NRC, 1987; Douglas *et al.*, 1998).

As sea level rises, saltwater will generally penetrate further up estuaries and rivers, as well as infiltrate into coastal aquifers, which could contaminate urban water supplies. Excessive groundwater pumping has already induced an upward migration of the saltwater–freshwater interface in many coastal localities. Upstream migration of the salinity front due to sea-level rise is analogous to that occurring under present drought conditions.

NAVIGATION STRUCTURES

Nations with access to oceans or to large seas, rivers, and lakes utilize the resource of water-borne transport for defense, commerce, and recreation. Structures that protect and promote boat and ship traffic are among the oldest and largest engineered works along the coast. Masters (1996) discusses coastal harbors constructed in the Mediterranean from about 4,000 years ago, including a Phoenician harbor with almost continuous use for the past 3,000 years. Franco (1996) describes the engineering and functioning of pre-Roman harbors starting from the first harbor of Alexandria, Egypt, built by the Minoans some 3,800 years ago, and he gives examples of Roman and Italian design of harbor structures, including contributions by Leonardo da Vinci.

Safe passage through harbors, inlets, and river mouths requires (1) sheltering of vessels from breaking waves that form the surf zone, (2) a relatively straight and permanent channel, and (3) a channel that does not unexpectedly fill with sediment (called sediment shoaling or simply "shoaling"). Engineering works that promote reliable navigation are called coastal navigation structures. The two major coastal navigation structures are jetties and breakwaters. This entry discusses the functioning of jetties and breakwaters, and their interaction with the coast.

Jetties

Jetties are typically placed at inlets and river mouths to maintain and promote navigability. A jetty is an engineered structure extending from the shore into a body of water and is usually constructed to serve three purposes. First, jetties partially or fully block waves, sheltering vessels as they pass through shallower water and the breaking waves of the surf zone to reach deepwater. In this way, jetties act as a breakwater, described in the next section. Second, jetties stabilize the location of the inlet, river, or harbor entrance, and in doing so they direct and confine the tidal and river current. By stabilizing the entrance location and directing the current, the location of the navigation channel tends to remain fixed in location and at least partially scoured by the current. Third, jetties block the movement of sediment transported alongshore (the littoral or shore drift), keeping the channel clear. Channel location and removal of shoals that impede navigation is accomplished by dredging.

If a single jetty stabilizes the navigation channel, it is built updrift of the entrance to block the predominant waves and littoral drift. A single jetty stabilizes the location of an inlet or river mouth by preventing its migration through spit extension from the updrift side. Typically, however, jetties are built in pairs that flank the harbor, inlet, or river mouth. As much as possible, jetties are aligned such that vessels exit directly into the incident waves. On a long and open coast, jetties are aligned perpendicular to the shore, because wave refraction causes wave crests to be parallel to shore. If the jetties protect a harbor or entrance near a headland or other area where the crests of the incident waves are not parallel to the coast, then one or more jetties may be constructed at an angle to the shore or have a seaward segment aligned at an angle to better block the waves.

Jetty length is usually such as to extend across the surf zone that can be present under navigable wave conditions. As a rule of thumb, the jetties are extended to a depth approximately that of the designed navigable depth. The elevation of the landward ends of jetties is typically above sea level to prevent sand moving along the coast from passing over the structure. The seaward end may gradually taper below the water and become submerged to allow currents and waves to pass around the structure without direct impact. However, the seaward ends of most jetties are above water and armored with larger stone to withstand direct impacts by waves. In the Unites States, jetties are typically constructed of stone that is cut according to certain specifications and fit in place. These structures are referred to as rubble mound jetties.

Because jetties intercept sand moving along the coast, provision is usually made to bypass the beach-quality sand or sediment to the downdrift side (Seabergh and Kraus, 2003). Sediment that falls into the channel is dredged and can be pumped to the downdrift nearshore or beach to prevent or reduce erosion. At longer jetties or where the wave climate is severe, beach-quality sediment may be dumped in the nearshore if it is infeasible or extremely expensive to place the material on the beach.

Another means of bypassing sand is by construction of a weir jetty. A weir is a purposeful low section in a jetty located near the shore. A typical weir is about 300 m long and with elevation about mean sea level or lower. A weir section is always designed together with a deposition basin that collects sediment passing over the weir before it reaches the navigation channel (Seabergh, 1983; Weggel, 1983). Sand can then be pumped from the relatively sheltered area of the weir to the downdrift beach.

Many large jetties have been in place for more than a century. As a result, they may induce a regional coastal response, similar to the response of a beach to a natural headland, producing updrift accretion and progradation of the beach, and downdrift erosion and shore recession. Construction or extension of jetties will also tend to move ebb-tidal deltas further offshore from their natural position (Pope, 1991), with portions of the original shoal that is located to the side of the narrow ebb current tending to return to shore.

Breakwaters

A breakwater is an engineered offshore structure that protects a harbor, anchorage, beach, or shore area by creating a sheltered region of reduced wave height. Breakwaters are always sufficiently high to afford protection against storm waves, and they are typically constructed parallel to the shore. A general principle is to align them to create the greatest shadow zone for either the direction of the predominant waves or the direction of the larger incident waves. Breakwaters must withstand direct impact of waves and are constructed of large stone or pre-cast armor units. Because breakwaters tend to be long and high, sediment moving along the beach can collect behind the structure.

In the United States, breakwaters are typically constructed as rubble stone mounds or with pre-cast concrete armor units that come in various shapes. In some countries, especially those where large stone is unavailable, caisson breakwaters are common. Caissons are pre-cast hollow concrete containers that are towed on site and then sunk in place by filling them with sand and small stone.

In coastal terminology, a mole is a massive solid-fill protective structure extending from the shore into deeper water, formed of masonry and earth or large stones, and serving as a breakwater or a pier. A mole is not designed to stabilize an inlet or river mouth and typically functions as a breakwater and part of harbor infrastructure.

NEARSHORE GEOMORPHOLOGICAL MAPPING

Introduction

Widespread mapping of seabed topography was made possible through the introduction of seismic methods during World War II. Methods have improved dramatically since then and large surface areas of the deep-sea floor and continental shelf are now routinely mapped as, for example, in the Geological Long-Range Inclined Asdic (GLORIA) project based on long-range sidescan sonar surveys used by the US Geological Survey to map large segments of the Exclusive Economic Zone (EEZ) at depths generally greater than 400 m. The digital system, designed at the Institute of Oceanographic Sciences (now the Southampton Oceanography Center, Challenger Division, United Kingdom), was specifically designed to map the morphology and texture of seafloor features in the deep ocean. The GLORIA imagery, for example, displays a plethora of subsea geologic and geomorphological features such as volcanic edifices, fault scarps, channels, levees, slump scars, and crustal lineaments. Textural and tonal differences in the digital imagery show large sediment bedforms and varying sediment types. Ironically, more information has been collected from the outer continental shelf and deep-sea floor than from shallow water close to shore.

The nearshore zone is often neglected due to the difficulty of working in this technically hostile environment, which is characterized by spatially and temporally dynamic biophysical conditions of high-energy coastal ecosystems, irregular and shallow depths, variable and dangerous surf conditions, and strong currents. There are thus many dangers associated with marine survey in shallow waters, the surf zone being particularly notorious for both men and equipment. With the advent of modern high-resolution satellite imagery (e.g., SPOT, IKONOS), airborne sensor platforms such as LIDAR (Light Detection and Ranging), and development of digital aerial photography that can be georectified on the fly, mapping nearshore submarine topography becomes not only feasible but also practical for multipurpose applications. Passive satellite and photographic sensors that detect bottom reflected radiation restrict the method to clear, non-turbid Class II waters. Turbid nearshore waters along muddy coasts are unsuitable for classification of bottom types using satellite imagery and aerial photography. Muddy coasts, which are commonly associated with tropical mangrove systems and temperate salt marshes, are estimated to occupy about 75% of the world's coastline between 25°N and 25°S Latitudes (Fleming, 2002). These regions and other muddy coasts mainly associated with large deltaic environments (Wang and Healy, 2002) are generally excluded from satellite and airborne imagery. Coral reefs, sandy beach, and rock platform environments present more favorable settings where nearshore turbidity is minimal for at least part of the year. Under clear water conditions, maximum depth penetration is at least 30–40 m and so mapping can proceed in a shore-parallel swath of variable distance offshore, depending on the shoreface gradient.

Active remote sensing platforms such as airborne LIDAR are able to detect changes in bathymetry under a variety of conditions where the nearshore zone may be quite turbid. These developing methods, which allow rapid acquisition of topographic data, provide enormous amounts of information in the form of digital elevation points (laser repetition rates of 10,000 pulses per second can, for example, provide elevations of surface points with a nominal spacing of 2 m; RMS errors of less than 10 cm can be achieved for elevation points; overlapping lines can be flown to minimize non-scanned coastal segments and increase point density). These methods enable large-scale quantitative mapping of coastal features and are more cost effective than conventional surveying techniques. High-accuracy airborne LIDAR mapping, based on recent advances in Global Positioning System (GPS), Inertial Measurement Unit (IMU), laser ranging, and microcomputers has been applied to wave, beach, sea cliff, coastline position, and nearshore bathymetric surveys (e.g., Hwang *et al.*, 1998; Brock *et al.*, 1999; Krabill *et al.*, 2000; Stockdon *et al.*, 2002). The SHOALS system (a combined bathymetric/topographic LIDAR data source based on the acronym: Scanning Hydrographic Operational Airborne Lidar Survey) is another similar application of scanning laser mapping in the coastal zone that has found particular application in the vicinity of inlets and passes (e.g., Irish and Lillycrop, 1997, 1999). A 13-km^2-test area in Florida Bay, for example, was surveyed in just 12 h using SHOALS to demonstrate that airborne LIDAR bathymetric technology can be a valuable and cost effective tool for surveying large shallow water areas (Parson *et al.*, 1997). Complex morphologic features identified in Florida Bay included extensive shallow water networks of mud banks, cuts, and basins, among other features. Instead of using contours or isobaths to show terrain variability, modern computer displays associated with these laser-mapping systems often employ digital color ramps that gradationally distinguish one elevation from another by variation in colors. The result is a colorful map that shows transitional gradations in relief. Additionally, a technique of using false "sun illumination" can highlight artifacts, error sources, and features that are not always evident on color-coded bathymetry (e.g., Hogarth, 2002). These maps convey maximum information when they are combined with morphologic units that are interpreted and sea-truthed (i.e., based on information derived from visual observation, grab samples, jet probes, vibracores, etc.) from satellite or airborne imagery. Still other digital mapping procedures that are proving to be extremely useful in coastal areas are those that can now merge land-based topographic with marine-based bathymetric data into a seamless digital elevation model (DEM) (e.g., Milbert and Hess, 2001; Gesch and Wilson, 2002). The advantages of integrating USGS topographic data and NOAA hydrographic data in coastal DEM areas are

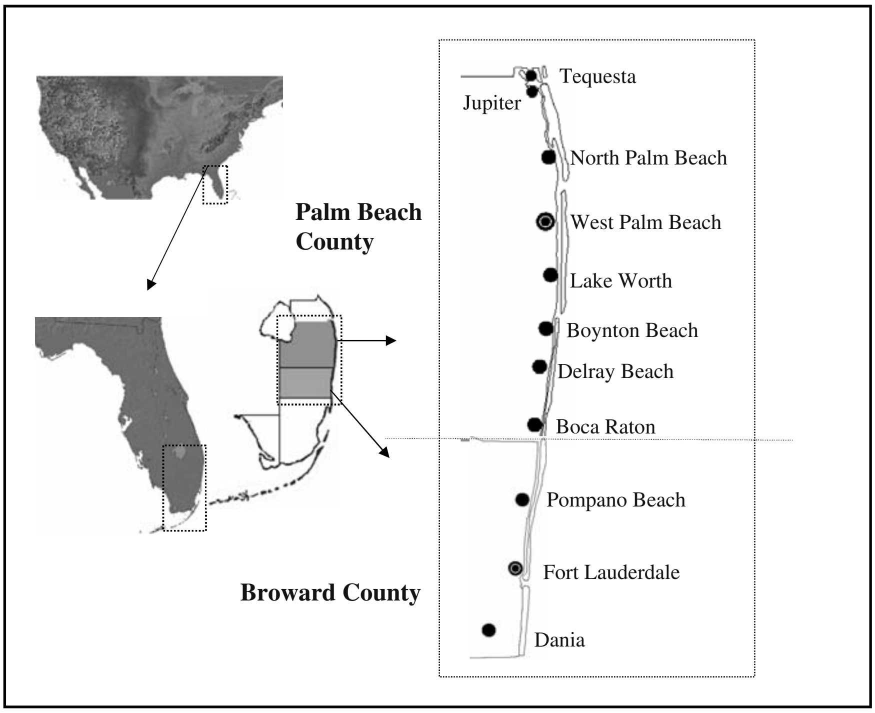

Figure N5 Location diagram showing the location of the Florida peninsula within the conterminous United States and the general Florida study area in Palm Beach and Broward counties along the southeast coast, as shown in the callout enlargements. The cities of West Palm Beach and Fort Lauderdale are near the center of their respective coastal counties. This 109-km stretch of subtropical coast is covered by 455 vertical, stereo-paired, digital, color, and georectified aerial photographs.

recognized as essential components of key baseline geospatial datasets for geologic, biologic, and hydrologic studies in the vicinities of tidal inlets and passes, lagoons, and estuaries. Highly accurate digital terrain models (DTMs), derived using high-accuracy photogrammetric techniques provide spatial richness that supports detailed study of coastal dune and beach processes (e.g., Judge and Overton, 2001).

Although high-resolution surveys in shallow waters are based on a wide range of sensor equipment and platforms (e.g., Gorman *et al.*, 1998; Byrne *et al.*, 2002), there is still a place for interpretation of aerial photography, especially for very detailed close order work in inshore areas. Aerial photography has a long history of application to document coastal features and of use in resolution of coastal problems such as flooding and erosion. Indeed, many coastal features are seen in some of the earliest commercially available aerial scenes as oblique images, as shown in this 1920s image of a long barrier spit in Broward County, Florida, near the present city of Fort Lauderdale (Figures N5 and N6). The early imagery in this case is extremely important to studies of coastal geomorphology because without this information, it is likely that the true coastal barriers along this coast would have been overlooked and ignored. Studies by Finkl (1993), for example, emphasized the crucial role of aerial photography for interpreting coastal morphology. Dietz (1947), for example, was among the first researchers to present a comprehensive analysis of the importance of aerial photographs in the study of shore features and processes. He pointed out the scientific value of aerial photographs in studying underwater features. A cogent and informative summary of aerial photography in the coastal zone is provided by El-Ashry (1977), who collected a range of examples covering multiple applications in different parts of the world. A more recent example of comprehensive use of aerial photographs may be found in Owens (1994) where aerial surveys covered over 40,000 km of Canadian coastline to assist in the compilation of oil spill response manuals. Oblique and vertical aerial photographs are used throughout the manual to illustrate different types of coastal environments, morphologic features, and shore processes. Other examples of new technologies, advanced techniques, and new applications (not limited to aerial photography) are found in a series of international conferences on remote sensing for marine and coastal environments sponsored by ERIM, a subsidiary of Veridian, Inc. (PO Box 134008, Ann Arbor, MI 48113). Vertical, stereo-paired aerial photographs find many applications, singly or in combination with other techniques, in coastal studies not only to relatively long-term shore variation in coastal planforms or coastline positions (e.g., Smith and Zarillo, 1990; Shoshany and Degani, 1992; Thieler and Danforth, 1994; Moore, 2000), but also in studies of short-term coastline changes that use fully automated techniques for determining the high-water line (e.g., Shoshany and Degani, 1992). Jiménez *et al.* (1997), for example, used temporally close order aerial photography (a series of seven aerial surveys over four months) to analyze highly dynamic coastal features in very flat, microtidal deltaic areas in Spain. Acquisition systems that collected temporal data to monitor the behavior of a dissipative multiple bar system in a nearshore zone near Terschelling, The Netherlands, were based on vertical aerial photogrammetry and echo sounding (Ruessink and Kroon, 1994) as were similar efforts that monitored nearshore submarine morphology at Duck, North Carolina (Guan-Hong Lee and Birkemeier, 1993), and along the Wanganui coast, New Zealand (Shand *et al.*, 1999). Alam *et al.* (1999), by way of another example, used high-resolution vertical black and white aerial photographs (1 : 20,000), using a zoom transferscope, to prepare a preliminary terrestrial geomorphological map of Cox's Bazar Coastal Plain, southeast Bangladesh.

Although the subject matter of nearshore geomorphological mapping is global in extent, this discussion necessarily focuses on the use of digital aerial photography for submarine geomorphological mapping along the nearshore zone of southeastern Florida. The example elucidated here is representative of many coastal areas that contain sandy beaches and rocky shores that front seabeds characterized by hardgrounds and unconsolidated sediments. The methodology is thus not restricted to tropical and subtropical carbonate environments, but applies to mid- and high-latitude coasts with low nearshore turbidity.

The nearshore environment of southeast Florida

Some of the more obvious topographic features of the inner continental shelf along the southeast coast of Florida were appreciated several decades ago when they were mapped by the US Army Corps of Engineers as hardgrounds and inter-reefal sand flats (Duane and Meisburger, 1969). The shore-parallel "reef" (comprised by rock and coral-algal components) system, composed of inshore exposure of the Pleistocene Anastasia Formation (a cemented, quartzitic, molluscan grainstone that formed in beach and shallow-water nearshore environments) (Stauble and McNeil, 1985; Davis, 1997) and coral-algal reef tracts (referred to as the Florida Reef Tract) (Lidz *et al.*, 1997),

Figure N6 Bay mouth bar and barrier spit near Fort Lauderdale, Florida, ca. 1925 (looking from east to west). The shallow open freshwater body on the right side of this oblique aerial photograph is Lake Mabel, now converted into the Port Everglades Turning Basin. A 9-km long barrier spit, situated approximately 100 m offshore, continued alongshore from Fort Lauderdale to Dania passing in front of the bay mouth bar. Inlet cutting in Fort Lauderdale beheaded the updrift part of the barrier spit turning it into a barrier island that migrated shoreward over a three to five year period. During the migratory phase or barrier island rollover, approximately 6–10 $\times$ 10^6 m^3 of sediment was moved shoreward (Finkl, 1993). Shown here is welding of the barrier spit to the bay mouth bar. The remaining southern (left side of photo) portion of New River Sound opens to a temporary natural inlet. By 1930, the entire barrier island (formerly a barrier spit) was welded to the mainland. When the Intracoastal Waterway (ICWW) was dredged through the tidal marsh (left center of photo), the ICWW—beach tract of land was mistaken for a barrier island and is still so designated today. (Partial scanned image from an original 1925 print by Fairchild Aerial Surveys, Inc., Long Island City, New York.)

increases in depth offshore as a giant staircase. These parabathic reef tracts extend southwards into the Florida Keys and represent approximate positions of paleocoastlines extensionally offshore and vertically within particular tracts as prior sea-level stands were revisited through time (Finkl, 1993, 1994). Sedimentary troughs that contain admixtures of clean, free-running sands, discontinuous lenses or stringers of silts and clays separate the reef tracts, or carbonate rubble accumulations deposited in association with paleo-inlets that cut through the reef tracts.

Most of the Holocene coast was characterized by extensive spits that extended downdrift and alongshore for tens of kilometers (cf. Figures N5, N6) (Finkl, 1993, 1994). The spits, which rose several meters above mean sea level, were stabilized by herbaceous and phanerophytic vegetation and protected shoreward sounds leading to coastal bays and estuaries. Inlet cutting and stabilization in the early 1900s initiated the demise of barrier spits (cf. Figures N5, N6) and islands by jetties and canalization of coastal wetlands, as described by Finkl (1993), to form the present shore. Bedrock of the Anastasia Formation is exposed onshore or buried at a shallow depth below present-day beaches (Figure N7). Most berms contain beach sands less than 2 m in thickness so that some beaches are stripped of sediment during storms to expose the underlying bedrock during part of the year (Finkl, 1994). Dunes fronting back beaches were commonly leveled for high-rise development so that today, incipient dunes only develop where buildings or infrastructure is setback from the shore. Seawalls that preclude dune formation back many beaches along this developed shore.

Morphologic features

The methodology employed in the identification of coastal geomorphic features was based on interpretation of digital, color aerial photographs at an acquisition scale of 1 : 3,900. In addition to on-screen digitizing of black and white images (derived from scanned color prints to a resolution of 300 dpi), the stereo-paired color prints were also utilized to enhance visual inspection of details and to resolve complicated photo patterns. Most photographs showed about 25% land and 75% ocean to provide dune-beach features and assist with location on the ground. Prior to mapping, two hundred and fifty-seven aerial photographs (23 $\times$ 23 cm color photographic prints) for the Palm Beach County shore were visually perused to determine the range of coastal features present in the study area. Compilation of a summary list of geomorphic features was organized as a general or organizational classification scheme with major categories for beach, bar and trough, dunes, rock outcrops, seabed morphosedimentary features, geologic structures, suspended sediments, and engineered structures. The morphologic forms and engineered structures that were noted are listed in Table N4.

Identification of the various morphologic features was based on direct recognition image interpretation strategy, but also employed field observations, information from grab samples and drill core, interpretation by inference, and probabilistic interpretation. Campbell (1996) provides a cogent summary of different image interpretation strategies and details disciplined procedures that enable the interpreter to relate geographic patterns on the ground (and under water) to their appearance in the image. Subaerial features such as dunes and infrastructure are identified by discretely different visual information. Because much of the native dune system has been destroyed by construction, many areas are interpreted through *a priori* knowledge. Visible dune sands and dune vegetation in other areas permitted application of a direct recognition strategy. Features in the backshore regions were identified by field observation and direct recognition. Beach berms and wrack lines were easily identified on the photographs due to distinct tonal variations. Interpretation of foreshore features was somewhat more difficult because this zone is partially submerged and acted upon by swash. The beachface is a predominant feature of the foreshore and can be conveniently divided into the upper (light-toned) and lower (dark-toned) beachface. Interpretation of geomorphic features of the inshore is sometimes hindered by complexity of spatial patterns. Sharp tonal contrasts facilitate interpretation of bars and troughs, which are the main sedimentary components of the inshore zones. Hardground features are identified by their dark tones, regular structural (lineament) patterns, and coarse texture of the rock surfaces. Many of the offshore features are identified using probabilistic interpretation as well as direct recognition. *A priori* knowledge of the existence of coral reefs (as mapped by Duane and Meisburger, 1969) in the offshore zone increases the probability of seeing reefs in the aerial photographs. Smooth tonal variations usually permitted differentiation of sandy bottom features from rock outcrops that are associated with disrupted blocky patterns and coarse textures.

Although a variety of interpretive techniques are available to assist in the identification of landforms in the coastal zone, it is necessary that the persons preparing the morphologic map have knowledge of coastal features prior to embarking on a project such as this. Preparation of a

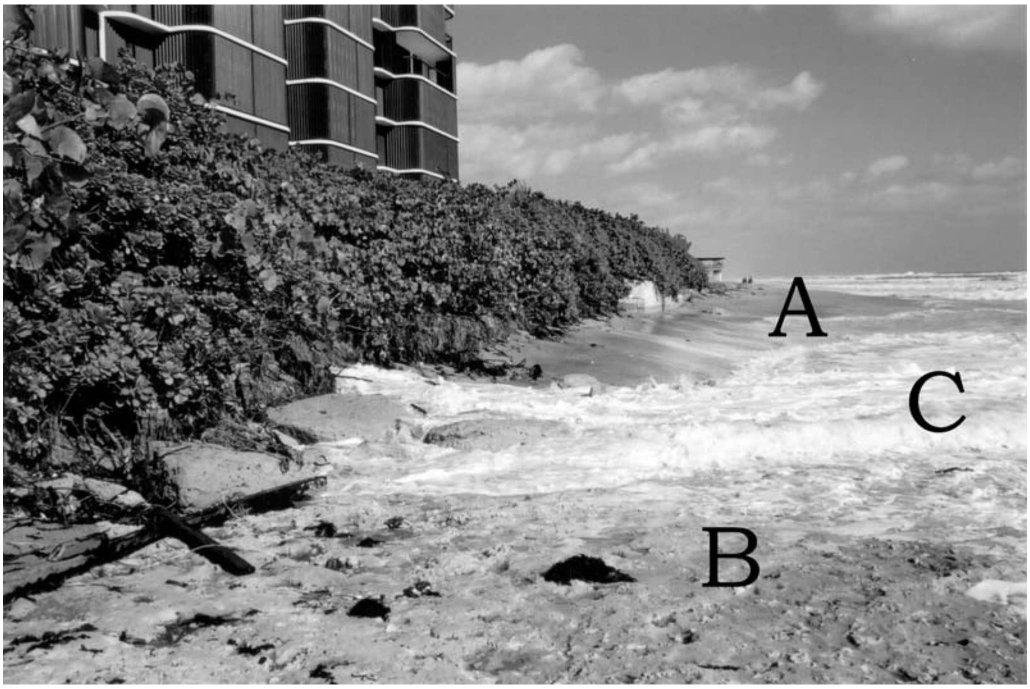

Figure N7 Erosion of perched beach and dunes in Boca Raton, central Palm Beach County, Florida, showing exposure of bedrock. (A) Remains of a subaerial beach that has been stripped off the underlying rock platform, cut into the Anastasia Formation, by an Atlantic Northeaster winter storm. Wave attack from the northeast tends to erode beaches and deposit the sediments offshore. (B) Rocky platform that underlies the perched beach shown in (A), upper part of photo center. (C) Reentrant surge channel that has cut across the berm and is shown here nipping foredune sediments. The surge channel, which follows a cross-shore fracture in the bedrock, brings turbulent water to the backshore. Note the salient environments along this eroded shore where perched beaches (A) with berm thicknesses generally less than 2 m are stripped away by storm surge to expose rocky platforms (B) that lie at about mean sea level and how ingression is facilitated by structural weakness in the bedrock (C). (Photo: Lindino Benedet, Florida Atlantic University, Boca Raton, Florida; photo taken in Winter 2001.)

comprehensive legend before mapping (cf. Table N4) assists in the rapid completion of the project. Modification of some morphologic units can take place as mapping proceeds, however.

The preceding paragraphs briefly outline some of the salient techniques for interpreting coastal morphologic features from vertical, stereo-paired aerial photography. Interpretation assumes familiarity with landscapes and seascapes, including polygenetic landform sequences that are so common along the world's coastline. There is no substitute for careful fieldwork, which must at some stage precede interpretive efforts that attempt to deduce what is on the ground from aerial imagery. Of the numerous reference works that show in pictorial or graphic formats physical features of the coast, the following are noteworthy for their wide scope of topical coverage, geographic focus, clarity of presentation, or detailed orientation to specific classes of morphologic features: Bird (1976), Bradley (1958), Emery and Kuhn (1982), Forbes and Syvitski (1994), Guilcher (1988), Hopley (1988), King (1959), McGill (1958), Nordstrom (1990), Nordstrom *et al.* (1990), Pethick (1984), Russell (1967), Schwartz (1982), Short (1993), Trenhaile (1987), Zenkovich (1967). In contrast to these general reference works are those that focus specifically on the southeast Florida coastal zone viz. White (1970), Duane and Meisburger (1969), Finkl and DaPrato (1993), Finkl (1993, 1994), Finkl and Esteves (1997), Finkl and Bruun (1998), Brown (1998), Khalil (1999), Warner (1999), Finkl and Khalil (2000), Finkl and Benedet (2002), etc. Prager and Halley (1997), while conducting a survey of bottom types in Florida Bay using sequential aerial photography, studied the distribution of sea grass and its influence on wave energy impacting mud banks. Bottom types in this shallow, low-energy embayment that are identified by Prager and Halley (1997) include: open sand, hard bottom, open mud, mud bank suite, mixed bottom suite, sparse sea grass, intermediate sea grass, and dense sea grass. The subtropical, open ocean coast of southeast Florida provides a wider range of morphologic types than might at first be anticipated for a coast that is commonly regarded as a sediment-rich, sandy beach shore. The frequent occurrence of rock forms, both subaerial and submarine, lends diversity to an otherwise potentially monotonous stretch of shore. Examples of morphologic units occurring in this subtropical zone of the western North Atlantic Ocean are first described in terms of the hard rock units comprised by coral and algal reef materials and lithified coquina and sandy deposits. These hard rock morpho-units are emphasized because antecedent topography influences present coastal configuration in Florida (e.g., Evans *et al.*, 1985; Kelletat, 1989; Finkl, 1993, 1994; Finkl and DaPrato, 1993; Lidz *et al.*, 1997), and as described for other areas, for example, by Sanlaville *et al.* (1997), Pilkey (1998) and Dillenburg *et al.* (2000). The occurrence and distribution of sedimentary geomorphic features is then considered, often in relation to the geologic framework of these coastal environments in southeast Florida.

Reef tract and hardground morphologic features

The term *hard shore* refers to the occurrence of sand, gravel, cobbles, boulders, or bedrock as opposed to the antonym *soft shore*, which identifies shore composed of peat, muck, mud, soft marl, or marsh vegetation (Bates and Jackson, 1979). *Hardground*, on the other hand, denotes a zone on the seafloor, usually a few centimeters thick, where the sediment is lithified to form a hardened surface that is often encrusted, casehardened, or solution-ridden. Colloquial usage in the Florida environment restricts hard shore and hardground to subaerial and submarine outcrops of bedrock or lithified sediments. The term hardground is further unrestricted in definition as it is used in reference to coral reefs, coral-algal reefs, and exposure of bedrock such as the Anastasia Formation. When corals or coral-algal reefs are known, explicit identifying terminology is applied but often, especially in remote sensing analyses, differentiation of specific units is not possible without ground-truthing and hence the general term is applied. The term *reef tract* specifically refers to coral and coral-algal reefs whereas hardground refers to any hard surface, regardless of composition or origin.

Because coral reefs and coral-algal reefs, which comprise the Florida Reef Tract, and hardgrounds appear as many distinct forms on the aerial photographs, they are divided into different map units as follows: abrasion platforms, fluted inshore/offshore rock reefs, parabathic hardground stringer, coral-algal rock reef, and sandy bottom with rock outcrop. Linear disjunctive segments that parallel the coast make up what are locally referred to as the first, second, and third reefs that collectively characterize this part of the Florida Reef Tract. Sandy deposits cover parts of the coral reef and inshore Anastasia Formation.

Table N4 Classification of salient coastal morphological forms and engineering structures identified from large-scale aerial photographs for the southeast coast of Florida, centered on Palm Beach and Broward counties (cf. Figure 1)

Level 1[a]	Level 2[b]	Level 3[c]
Beach	Berm	
	Cusp	
	Beachface	Lower beachface
		Upper beachface
		Sub-beach step
Bar-and-trough topography	Channels in bar	
	Crescentic bar, trough	
	Longshore bar	Welded
		Transverse
	Rip channel	
	Low tide terrace	
	Trough	Beachface trough
		Shoreface trough
		Crenulated trough
		Infilled nearshore trough
Dunes	Undifferentiated dunes	
Rock outcrop (intertidal and submarine)	Abrasion platform	
	Coral-algal reef (reef tract)—Hardground (rock reef) [Complex unit]	Beachface outcrop
		Outer coral-algal rock reef
		Fluted rock reef
		Fluted offshore rock reef
		Parabathic hardground stringer
Sedimentary morphological features	Sandy bottom	Light-toned running sand
		Dark-toned running sand
		With rock outcrop
		Featureless sandy bottom
		Structurally controlled sandflat
	Tidal delta (ebb, flood shoal)	
Suspended sediments	Turbidity plume	
Engineering structures	Dredged inlet	
	Seawall	
	Rock revetment	
	Groin	
	Pier	
	Submerged breakwater	
	Jetty	

[a] Level 1 groups the most general morphologic forms and engineering works.
[b] Level 2 categorizes the broad forms of Level 1 into specific types.
[c] Level 3 incorporates specific types of Level 2 that have distinguishing characteristics that permit further differentiation.

Fluted inshore/offshore rock reefs

Several morphologically distinctive types of hardground occur in southeast Florida. Some coastal segments are characterized by *patterned hardgrounds* (rock reefs) with somewhat regularly spaced distinct cross-shore channels, referred to here as *flutes* (Figure N8). The flutes average about 1–10 m in width and their length extends the width of the outcrops that can range upwards of 30–50 m. The flutes are clearly evident in the photograph (left) but the unit is mapped (right) without detailing the position of flutes. Some of the more prominent examples of fluted rock reefs are contiguous for more than 400 m in a shore-parallel direction. The flutes occurs in outcrops of the Anastasia Formation that are often cracked or fractured into large blocks that make up a general reticulate pattern due to increased differential erosion of these zones of weakness. The small diabathic channels or flutes follow the initial or pre-existing structural depressions that were later subaerially etched into the carbonate rock surface prior to drowning by the Flandrian sea-level rise.

Abrasion platforms

Abrasion platforms (Figure N8), a type of shore platform (e.g., Pethick, 1984; Trenhaile, 1987; Sunamura, 1992) that occur in the intertidal and inshore zone, are developed on outcrops of the Anastasia Formation, as described by Duane and Meisburger (1969) for the coast of southeast Florida. The platforms, which show signs of weathering, solution, and wave-induced erosion, are generally quite narrow (less than 50–100 m) and may extend intermittently alongshore for distances of 1,500 m or more. These calcareous platforms also occur as blocky, jagged outcrops arranged in sets along the shore and are separated by sandy flats, as shown in Figure N8. Structural patterns (left photograph) in the Pleistocene bedrock show clear shore- parallel lineations with sand partially filling chemically weathered depressions that lie below more resistant facies that have been abraded by wave action to produce concordance of ridge levels.

Parabathic hardground stringer

Another common type of hardground that occurs in this region is referred to as a parabathic hardground stringer (Figure N9). These narrowly elongate morphological features are referred to as *stringers* because they tend to occur as long, ridged rock outcrops surround by sandy seafloor. These inshore rock outcrops are narrow parabathic forms that are usually less then 7–10 m wide but may be more than 200 m long. These stringers usually occur in groups and are separated by sandy deposits. These topographically positive seabed features represent more chemically resistant and structurally competent facies of the Anastasia Formation or coral-algal reef. The stringer shown here (dark lines in center of the left photograph) trends in a general north–south direction along the axis of strike of the now-lithified banks (including coquina beds) of the Anastasia Formation and is partly overlain by coral-algal rock reef (bottom center of photograph, left, and geomorphological map, right). Extensions of buried hardground that are emergent above surrounding sand formations, such as bars, often form hardground stringers.

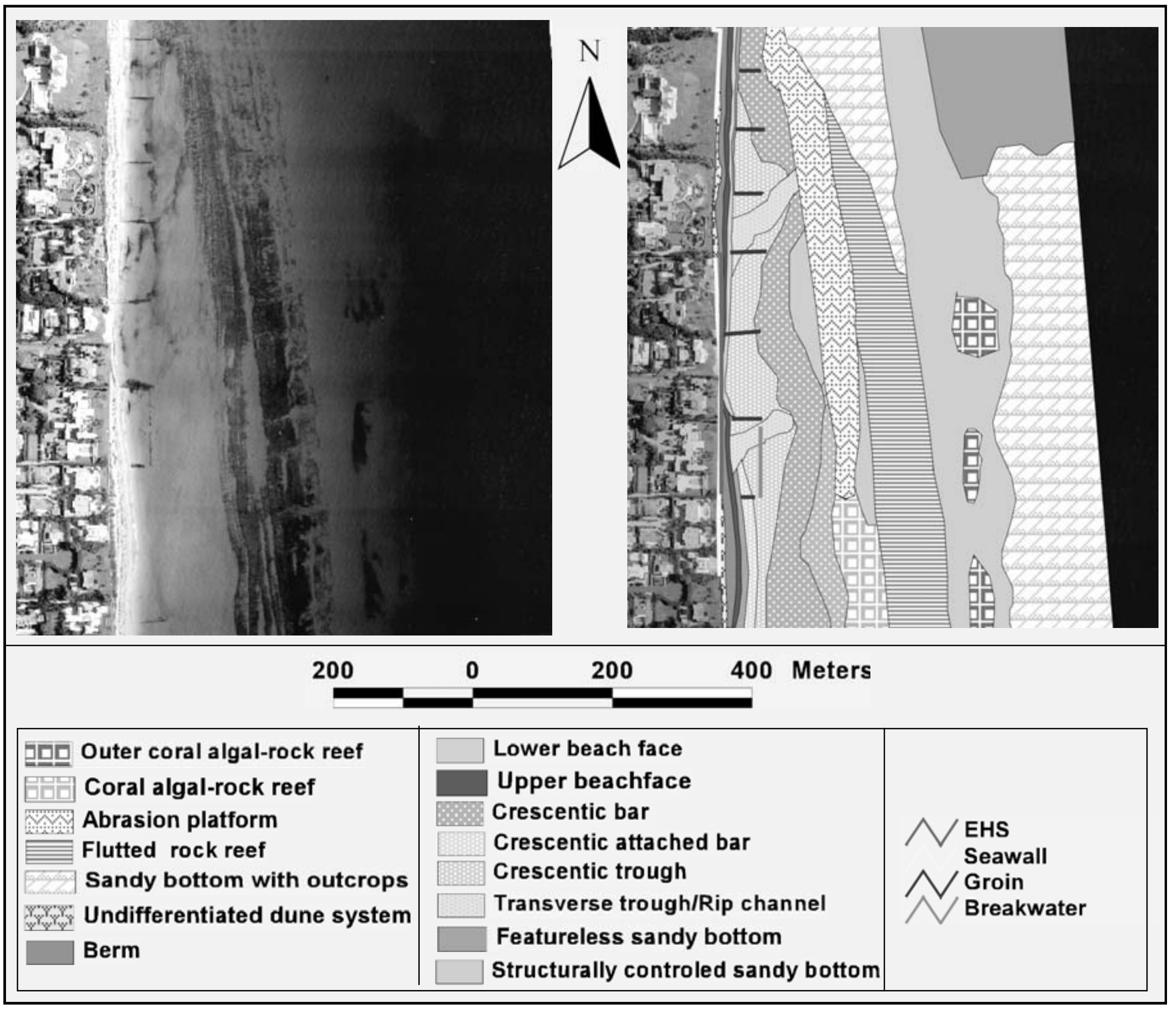

Figure N8 Rock outcrops and sandy bottoms along the southeast coast of Florida in the Town of Palm Beach, Palm Beach County. The complexity of geomorphic units is seen in parabathic and diabathic spatial distribution patterns, that is, differentiation of bottom types alongshore and across the shoreface. The occurrence of rock units on the seafloor is a most striking feature that is denoted by several categories of hardground: coral-algal reef, abrasion platforms, fluted rock reefs. The map of geomorphic units (right), interpreted from the aerial photograph (left), identifies complex features associated with the landward-most portions of the Florida Reef Tract, first and second reef systems. Isolated blocks of coral-algal rock associated with the 2nd reef system lie about 400 m offshore and poke through a thin veneer of sand that overlies slightly lower levels of the same rock unit (referred to as structurally controlled sandy bottom). The main features of the 1st reef are a beveled abrasion platform, rough carbonate rock reef of the Anastasia Formation, and a seaward portion identified as fluted rock reef that contains diabathic channels. Sedimentary features, composed of mixed siliciclastics and biogenic carbonate sands, include sandy bottoms and bar-and-trough topography. The rhythmic wave pattern of a large crescentic bar-and-trough system migrates alongshore, landward of the 1st reef. Rip current channels pass through the crescentic trough in a general NE direction. The beach is subdivided into berm, upper beachface, and lower beachface. A groin field and an erosional hot spot (zone of accelerated shore retreat) are additionally identified on the map.

Coral-algal rock reef

The northern extension of the Florida Reef Tract (see Lidz *et al.*, 1997), which extends northward from the Florida Keys, contains a seriously degraded coral reef environment that has been stressed by a variety of factors (Lidz and Hallock, 2000) to the point where many coral communities have died and their skeletons now serve as foundations for algal growth. The algal encrustations form a kind of biogenic carbonate rock that is mixed with surviving corals; the complex morphological structure (coral reef plus algal encrustations) is thus referred to as a *coral-algal rock reef* in an effort to identify its true status as a conditionally stable but degrading coral reef system. Bottom morphologies associated with this unit are thus complex intergrades that are undifferentiated due to interpretive difficulties to consistently separate true corals from coral-algal units. Outcrops of the Anastasia Formation sometimes occur in close proximity to these biogenic units (see Figures N8 and N9), further complicating the interpretive process. Varieties of these parabathic forms, which are mapped for simplicity as one unit, are visually contiguous as a distinct bottom type for distances ranging up to 4 or 5 km alongshore. Bottom sands separate successional coral reef systems (viz. the first, second, and third reefs) and also reefs from outcrops of the Anastasia Formation.

Sandy bottom with rock outcrop

This is a complex, intergraded bottom type (see Figures N8, N9, and N10) with spatial patterns that are too intricate or relationally detailed to warrant separation at the mapping scale. The unit is essentially a variety of hardground bottom type with a veneer of sand that ranges in thickness from a few millimeters to several tens of centimeters in thickness. The sandy veneer is so thin that structural features of the underlying rock are still visible, especially where slightly positive relief features emerge through the sand cover. Unconsolidated, free-running sands that overlie portions of the reef tract or intermittent rock outcrops characterize these bottom-type features. Because corals that have been buried by sediment are now dead, they are simply referred to as carbonate rock.

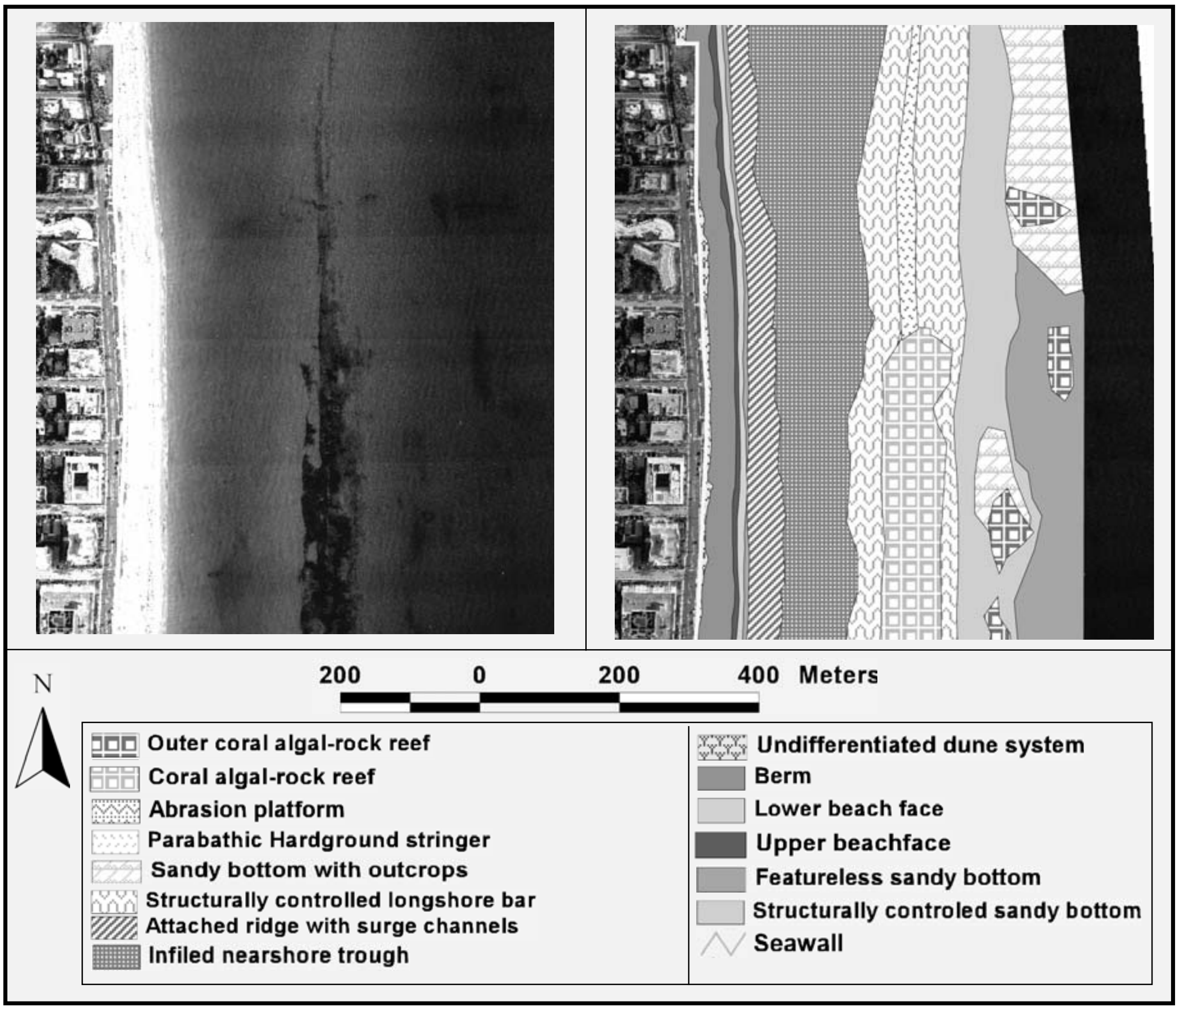

Figure N9 Sandy shore with submarine rock outcrops along the southeast coast of Florida a few kilometers south of the Town of Palm Beach, Palm Beach County. The aerial photograph (left) and interpreted geomorphological map (right) are companioned here to show salient characteristics of this shore. This sandy coastal segment is characterized by beach (berm, upper and lower beachface), bars and troughs, parabathic hardgrounds (coral-algal and rock reef), and sandy bottoms. Bedrock, which is close to the surface of the seabed here, is a component that is noted in composite units viz. sandy bottom with outcrops (which shallowly flanks coral-algal rock reefs) and structurally controlled sandy bottom (which shallowly overlies bedrock). The dominant parabathic geomorphic distribution patterns reflect shore-parallel rock outcrops on the seafloor. The parabathic attached ridge (welded to the lower beachface) with diabathic surge channels merges seaward with a partially infilled nearshore trough that together makes up the sandy nearshore environment. Structural control of sedimentary features and geomorphic patterns is evident in the vicinity of the coral-algal rock reef materials of the 1st Reef System in the Florida Reef Tract, the landward boundary of which lies about 300 m offshore. Note the northward extension of the hardground as a parabathic hardground stringer (about 500 m in length) in the upper central portion of the map (right). The black area on the seaward-most portion of the geomorphological map is uninterrupted due to depth constraints.

Rock outcrops occur primarily as parabathic features, but diabathic patterns with sediment between the outcrops can be found in some areas. Sedimentary infills immediately adjacent to the rock outcrops are relatively thin, usually less than 1 m thick. Sandy bottom with rock outcrop may occur in almost any geographic location along the shore as a reminder that bedrock or buried coral reef is never far away.

Sediment-composed morphologic features

A large part of the inner continental shelf, loosely analogous to what some researchers refer to as the shoreface (e.g., Wright, 1995), contains sedimentary covers that are surficially modified by currents to form distinct morphologic units. The various kinds of morphologic features, composed of silicilastic and carbonate sediments, occur in beach sands or as bars and troughs. Under conditions of relatively stable or slowly rising sea level, typical of the last 6,000 years, the shoreface may approach conditions of steady state equilibrium (as defined by Schumm, 1991). On shorter time frames, instantaneous or event timescales, the upper shoreface is subject to continual change with relaxation times on the order of days (Larson and Kraus, 1995). As Cowell *et al.* (1999) point out, the upper shoreface chases a dynamic equilibrium (Schumm, 1991) as boundary conditions vary stochastically, without ever quite making it. This section of the southeast Florida coast is no exception as beaches and inshore–offshore sedimentary features are seen to change over the long run, from winter to summer wave climates, to occurrences of winter northeasters and summer tropical storms. This morphologically dynamic zone features a range of sedimentary morphodynamic subaerial and submarine types that are identified from aerial photography in terms of coastal dunes, beaches, bar and trough systems, deltas, and sandy bottoms.

Coastal dunes

Dunes along this shore are generally compromised by construction for coastal infrastructure, recreational facilities, condominiums, or private estates. With the destruction of the primary dune system by development along this coast in the early part of the 20th century, there is little space left for contemporary dune building processes to operate.

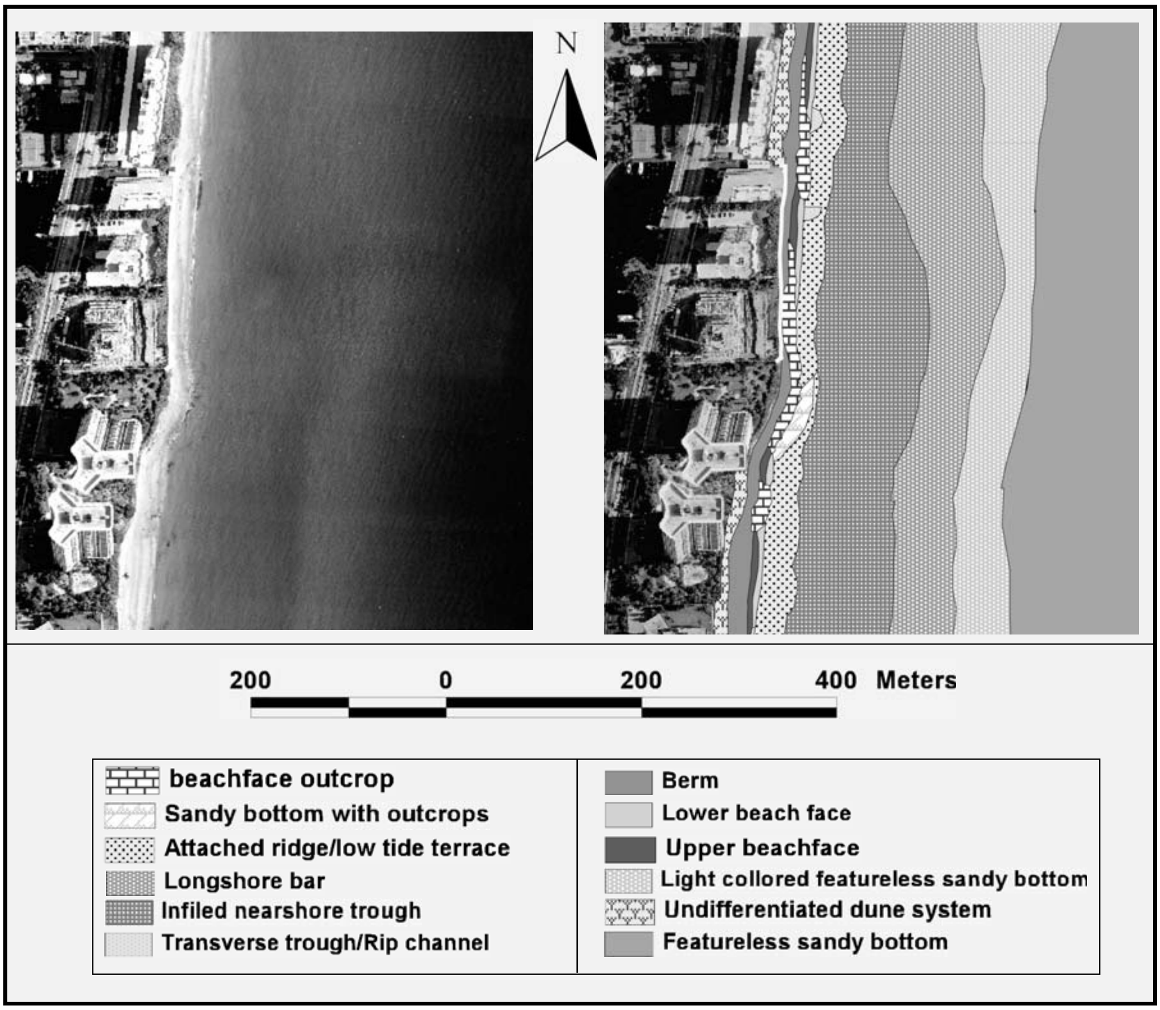

Figure N10 Example of beachface outcrops along the southeast coast near Boca Raton, Florida. This coastal segment shows beach sediments perched on top of bedrock (Anastasia Formation) that often helps to stabilize the shore and sometimes forms a natural salient, as seen in the lower left hand corner of the photograph (left) and in the interpreted map (right). Bedrock outcrops in parts of the low tide terrace where the sand cover is relatively thin and lineations in the rock structure are evident. Transverse troughs or rip channels transect the low tide terrace in the upper part of the photograph and are shown in the map. A bar and trough system up to 200 m in width grades seaward into flat lying featureless sandy bottom. Inshore rock outcrops are a prominent hard bottom feature along the shore and their presence is a clear influence on coastal configuration, when seen in plan view.

Nevertheless, some areas contain small foredunes that develop within a limited framework of environmental controls. Coastal dunes are found above the high water marks of sandy beaches and are formed by wind transport of predominantly loose, sand sized (2.0–0.05 mm) sediment of different origins, as described by Carter *et al*. (1990). Because of their limited developmental status and restricted geographic occurrence, no attempt is made here to differentiate types of coastal dunes. Dunes are mapped here, as shown in Figures N8–N12, as undifferentiated dune system. Severely restricted in geographic occurrence, the dunes may be somewhat wider (up to 40–50 m in width) (Figure N8, geomorphic map on right) to somewhat narrower (less than 20 m) (Figures N11 and N12; geomorphic maps on right).

Beach

As explained by Wright and Short (1984), there is considerable variability in concept, definition, and morphological properties of beaches. Although a common feature of many coasts, beaches can be deceptively complex systems that require careful attention to their biophysical characteristics and environments of formation. The term *beach* was originally used to designate the loose wave-worn shingle or pebbles found on English shores and is still used in this sense in some parts of England (Johnson, 1919, p. 163). In common parlance, the term is used locally for the seashore or lakeshore area. More closely defined usage refers to the temporary accumulation of loose water-borne material that is in active transport along, or deposited on, the shore between the limits of low and high water. From a geomorphological point of view, the beach is comprised by the unconsolidated material that covers a gently sloping zone, typically with a concave profile, and which extends landward from the low-water line to a place where there is a change in material or physiographic form (e.g., dune) or a line of permanent vegetation. Relying on these general concepts of beach as a morphodynamic unit, unconsolidated sandy material deposited along the shore zone between low and high water was mapped as beach (see units for berm and beachface in Figures N8–N12). Beaches in this area contain admixtures of siliciclastics and carbonates of biogenic origin from shells and calcareous algae. In the southern part of the southeast coast of Florida, beach sands are mostly carbonates and in the northern part they are mostly silicates. In the central part of this coastal segment, the beach sands are nearly equally differentiated into silica and carbonate components. All beach sands are shallowly underlain by the Anastasia Formation, which extends several kilometers inland (Finkl and Esteves, 1997) and continues as a shelf deposit along the southeast coast of the United States to at least the latitude of central North Carolina. Morphodynamically, these beaches key out as mostly intermediate types in the beach classification system developed by Short (1999) but the unit is not differentiated for mapping purposes. Based on beach width and planform configuration, it is evident that beaches are eroding, accreting, or stable. An example of an eroding beach, that is, one with a retreating coastline, is shown in Figure N11 where a condominium complex just out into the

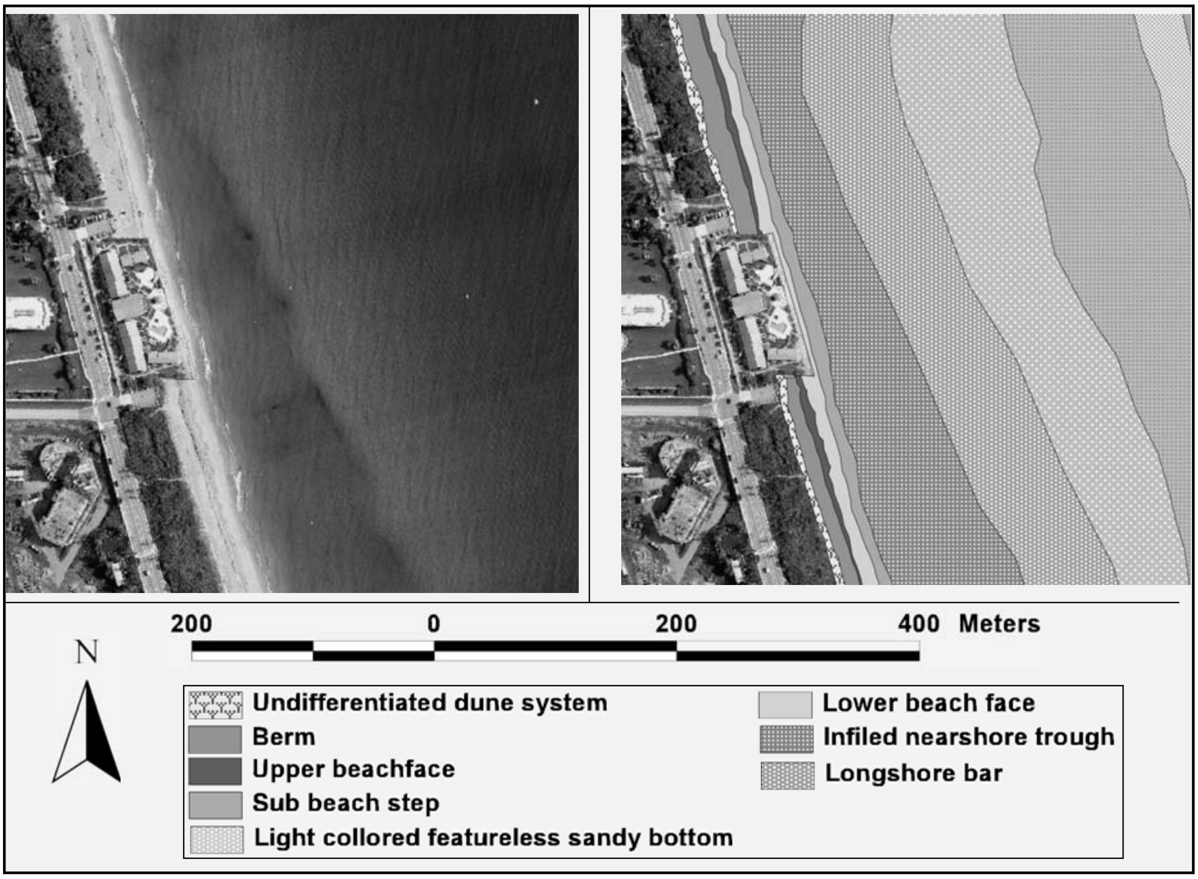

Figure N11 Example of a simple sandy shore with a series of shore-parallel sedimentary morphoforms viz. coastal dunes, beach, bar and trough, and featureless sandy bottom near Jupiter, Florida. The mapped polygons (right) correspond to major features interpreted from the aerial photograph (left) showing a truncated dune system restricted by the coastal highway (A1A), a wider berm on the northern updrift side of the recreational complex built on the beach, a sediment starved beach on the southern downdrift side of the structure, and the presence of a well-developed lower beach face and sub-beach step. The infilled nearshore trough flanks the seaward portion of the rectilinear beach face. Bars and troughs alternate in a seaward direction as depth increases. The Florida Reef Tract lies farther offshore and is not shown in this diagram. This coastal segment typifies a sediment-rich sequence of geomorphic forms and illustrates a gradation of bottom types that are commonly experienced along so-called soft coasts. The impression is, however, misplaced because the southeast coast of Florida is rock controlled (cf. Figures N8–N10).

sea. This facility sits astride the dune system, berm, and upper beachface; its seaward-most portion terminates on the lower beachface. The berm is widened on the northern updrift side of the complex and narrowed on the southern downdrift side that is now starved of sediment because this structure acts as a partial littoral drift blocker. Figure N9 shows a stable or accreting beach with a berm nearly 90 m in width.

Rhythmic features and berms were interpreted from the aerial photographs and mapped as separate units. The *beachface*, that section of the beach normally exposed to the action of wave uprush (i.e., the foreshore of the beach), was subdivided into two units, the *upper and lower beachface*. This distinction was interpreted from the aerials on the basis of geomorphic expression of the cross-shore profile, the *beach scarp* providing a consistently recognizable division, except along beaches where municipalities deliberately destroy the scarp by scraping. Beach scarps of 1–2 m can be hazardous barriers that block access to the water and they are thus destroyed, especially when they form in newly renourished beaches.

Cusps. These ephemeral features occur intermittently throughout the study area and belong to the class of "typical beach cusps," (versus storm cusps) as defined by Dolan and Ferm (1968). Cusp embayments average about 6 m wide (measured between horns) and have wavelengths of about 13–15 m. Beach cusps occur sporadically along the beach, usually in groups of rhythmic topography about 300 m long. These crescentic, concave-seaward features at the shoreline occur at different locations at different times of the year; in general, however, cuspate features seem to occur along coastal segments where reef tracts or hardgrounds outcrop in the inshore zone. Their morphometries (quasi-regular spacing alongshore) differ according to localized oceanographic processes that are influenced by bathymetry and bottom type. This rhythmic shoreline topography is associated with *intermediate beach systems*, as described by Hughes and Turner (1999). Beach cusps are not shown on any of the figures.

Berms. Berms are inter- to supratidal shore-parallel terraces or ridges that consist of a steeper seaward sloping beachface, topped by a shore-parallel crest. As explained by Hesp (1999), the term *berm* has come to be synonymous with the intertidal beach and backshore, as an asymmetric landform comprising a seaward swash slope (usually the steepest component; the "riser" in terrace morphological terminology), a crest, and a low, often linear, sometimes concave beach top slope (the "tread"). The term *berm* has often been taken to mean the nearly horizontal portion of the beach (i.e., the tread; see Davis, 1982). These low, impermanent, nearly horizontal or landward sloping benches, which occur as a backshore terrace on a beach, are formed by material deposited by storm waves. Some narrow native beaches (beaches that have not been renourished) have no berm while some of the wider, accreting beaches immediately updrift from jettied inlets may have several. Well-developed, wide berms are usually associated with renourished beaches that may extend more than 100 m seaward of frontal dunes. Eroded beaches may have narrow berms and along some critically eroded coastal segments there is no beach. Figure N10 (geomorphic map, right), for example, shows a rock outcrop immediately seaward of a seawall with no intervening beach. The seaward portion of the rock outcrop is partly overlain by a low-tide terrace. Berm crests define the seaward boundary of the dry beach. Some alongshore segments were mapped as a berm/upper beachface complex unit because it

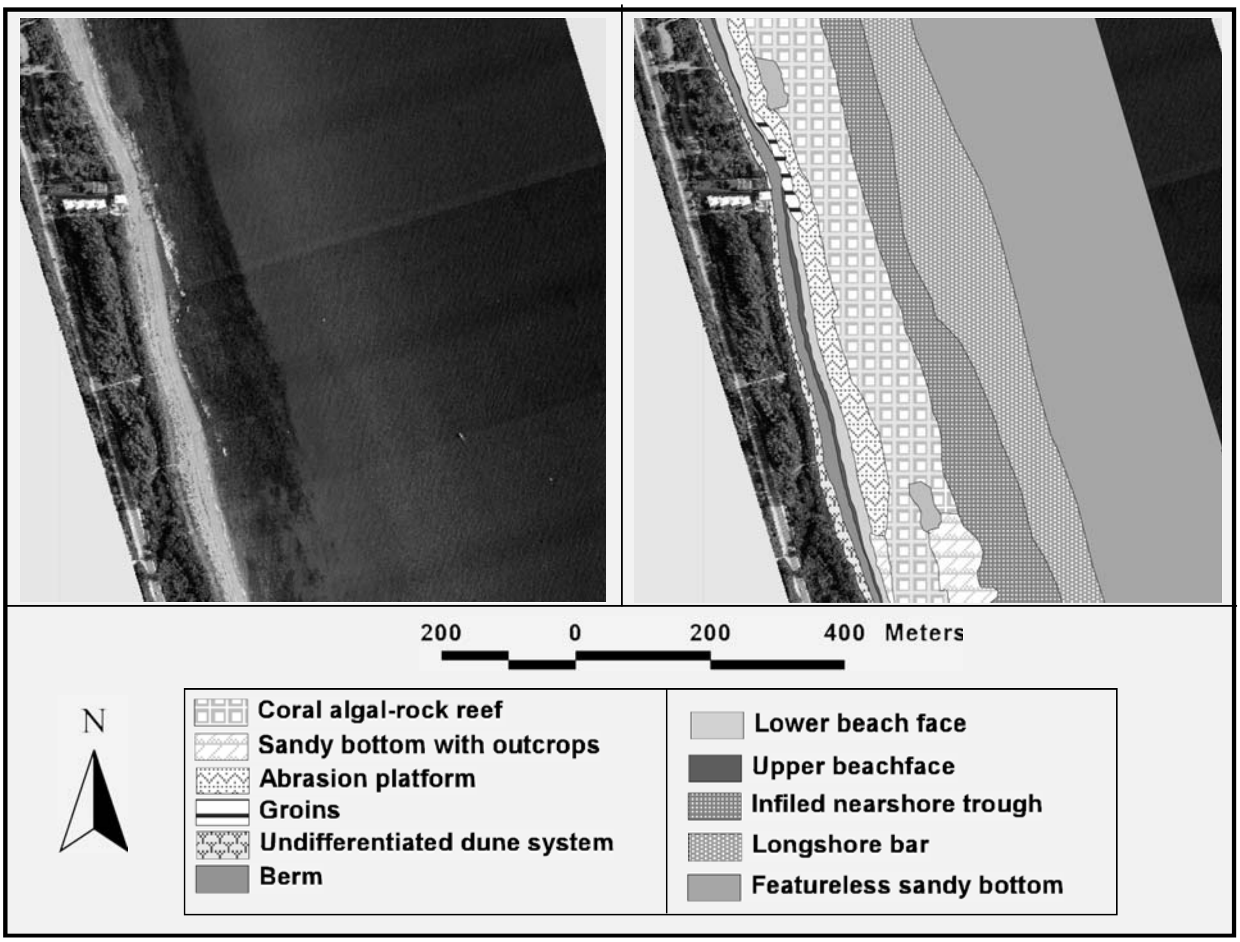

Figure N12 Example of alongshore rock outcrops on the southeast coast of Florida near Tequesta, Palm Beach County. Hardbottom types are clearly evident in the aerial photograph (left) by their dark tones, coarse texture, and linear patterns. The interpreted map (right), showing salient geomorphological units, delineates the presence of coral-algal rock reef seaward of the well developed abrasion platform that is about 100 m in width and 800 m in length. The beach is perched on top of the abrasion platform, which extends landward under the beach. A bar and trough system flanks the seaward side of the coral-algal reef, part of the 1st reef in the Florida Reef Tract. Undifferentiated sandy bottom extends at least 500 m offshore to about 30 m depth, below which photointerpretation is not possible. When hard bottoms occur this close inshore, sands from the perched beaches are often stripped away by storm waves and currents during northeasters leaving an extensive rock surface exposed to the base of coastal dunes.

was not possible to differentiate these two units on the aerial photographs. Small beach scarps separating the berm and upper beachface, which did not allow consistent identification on the aerials, compromised interpretation. On some beaches the scarp is mechanically swept, which combines the berm and upper beachface into a continuous unit, to make a user-friendlier beach. Beach morphology is extremely variable and the units mapped here (berm, upper/lower beachface) relate to the time of photo acquisition.

Upper/lower beachface. The *beachface* is that section of the beach that is normally exposed to the action of wave uprush, that is, the foreshore of the beach. The beachface is defined as being in a state of dynamic equilibrium when the net sediment transport, averaged over several swash cycles, is zero (Hughes and Turner, 1999). Thus, if offshore sediment transport is dominant, the beachface profile becomes flatter; and conversely, if onshore transport prevails, the profile becomes steeper. Beachface profiles rarely exhibit a uniform and planar gradient; the typical beachface is concave seaward but the beachface slope may vary alongshore. In this study, the *upper beachface* was distinguished form the *lower beachface* because they are morphologically distinct and are easily separated on aerial photographs due to different tone and pattern (cf. Figures N8–N12). The upper beachface extends from the landward limit of the lower beachface to the berm crest or foot of the beach scarp. The lower beachface is the seaward sloping portion of the foreshore where swash action begins to occur, that is, where waves break for the last time and swash moves up the beachface as a bore. The width and form of the beachface is significant because this is the feature that ultimately reflects or dissipates wave energy. In most cases, the lower beachface is less than 5 m wide.

Bar and trough systems

Study of cross-shore profiles has resulted in the notion of "winter" and "summer" profiles; winter storm waves removed sand from the berm forming a breakpoint bar, whereas calmer wave climates in summer induced landward migration of the bar with subsequent welding to the beachface to form a non-barred cross-shore profile (e.g., Fox and Davis, 1973; Aagaard and Masselink, 1999). Subsequent research suggested that beach response to wave climates was cyclic, rather than seasonal, and so the terms "barred" and "non-barred" appeared more appropriate (Greenwood and Davidson-Arnott, 1979). The separation between barred and non-barred profiles is now reported to relate to the direction of cross-shore sediment transport. Offshore sediment transport results in erosion of the beach and formation of barred profiles, whereas onshore sediment transport causes beach accretion and non-barred profiles (Aagaard and Masselink, 1999). Relationships between nearshore bar morphology and wave climates is complex and site specific, but periods of high or low wave energy impart distinctive bar types and sequences alongshore. Aagaard and Masselink (1999) report that in general, transverse bar morphology is found at the low energy end of the spectrum, whereas linear bar morphology characterizes high wave energy levels. Crescentic bars develop under intermediate wave energy conditions. All of these classical types of bar and trough systems are seen along the southeast Florida coast.

In addition to classical bar and trough forms, there are local or site-specific morphological variations and combinations that resulted in identification of the following main units: longshore bar, structurally controlled longshore bar, crescentic bar, crescentic attached bar, attached ridge with surge channels, crescentic trough, transverse trough/rip channel, and infilled nearshore trough. Longshore bars are low, elongate sand ridges that are built up mainly by wave action and which occur some distance from the shoreline. Longshore bars generally extend parallel to the shoreline and are submerged at least by high tides and are separated from the beach by an intervening trough (see Figures N8–N12). Several terms have been applied to these kinds of features (e.g., ball, offshore bar, submarine bar, barrier bar) as described here in their simplest situational occurrence. There is a wide range of morphological variation where bars and associated troughs occur as single linked units (e.g., Figure N12) or in multiple associations in rectilinear to strongly curved (wavy) planforms (e.g., Figures N8–N10). Bars and troughs may be continuous along the shore for many kilometers or they may occur as disjunctions continuously or sporadically along the shore (cf. Figures N8 and N12), parallel to shore or inclined at an angle (e.g., Figure N8). When longshore bars have migrated shoreward and become welded to the beachface as relatively high ridges of sand, they are termed welded bars or, as referred to here, as *attached ridges* (Figure N9).

Longshore bar. Along the southeast Florida coast, longshore bars occur in the inshore zone as single bars or as part of multiple bar and trough systems (Figures N10–N12). The bars are sediment ridges of running sand that generally parallel the shore. Some bars are rather narrow, for example, about 15 m wide, and continue without break for distances longer than 1.5 km. Occasionally, one end of transverse bars are welded to the shore either singly or in multiple sets (Figure N8).

Crescentic bars and crenulated troughs. Crescentic bars are rhythmic shore features that tend to have hyperbolic wavelengths on the order of 115–160 m and are usually located about 12–60 m from the shoreline (e.g., Figure N8). Crescentic bars are sometimes welded to the shore (Figure N8) but welded or not, they are associated with troughs that are either infilled nearshore or crenulated. The term *crenulated trough*, as applied here, describes certain inshore coastal segments where sedimentary troughs occur in the inshore zone adjacent to crescentic bars. The adjacent border of the crescentic bar forms their borders so that a convex seaward portion of a crescentic bar forms the concave seaward crenulated trough. Crenulated troughs may form on either the landward or seaward side of crescentic bars, and they may occur singularly (inside one cycle of the crescentic bar) or they may connect to form a crenulated trough that stretches 4 km or more alongshore.

Infilled nearshore trough. As defined here, infilled nearshore troughs are elongate sedimentary depressions that are associated with bars. Because the troughs tend to become partially infilled under subsequently calmer conditions than during their formation during storms, they are referred to as being infilled. These depressional features of the inshore zone range in width up to 150 m cross-shore and may extend for several kilometers alongshore (Figures N10–N12). As reported by Lippman and Holman (1990), longshore-bar-trough states are variable and the features may be highly mobile under certain wave conditions, whereas Wright *et al*. (1985) concluded that straight or rhythmic longshore bar and trough states could remain relatively stable under certain conditions. The bar and trough systems described here seem to remain positionally stable from year to year, based on observations of interannual photography. The presence of reefs and rock outcrops on the seafloor in the study area apparently complicates present comprehension of bar–trough positional stability.

Shoreface trough. These troughs, lying seaward of the lower beachface, contain variable water depths but all are several meters deeper compared with the longshore bars or hardground features to which they are adjacent. Shoreface troughs may extend uninterrupted for long distances, for example, up to several kilometers alongshore. Occupying areas of lower elevation compared with surrounding morphologic features, usually coral-algal rock reefs or structurally controlled sandflats, these troughs are commonly floored by hardbottom with thin sand veneers. Structural features of carbonate hardbottom are often evident in the aerial photographs, verifying the thin cover of overlying sand. The troughs more or less parallel landward variations in the Florida Reef Tract or follow inshore lineations in the Anastasia Formation.

Sandy bottom

Sandy sediments are a dominant feature of the seafloor on the inner continental shelf, occupying about 30–40% of the mapped areas (e.g., Brown, 1998; Warner, 1999), the remainder being coral-algal reef or exposure of bedrock as hardgrounds. The sandy deposits are mostly sheets overlying the karstified bedrock as basin infills. Corollary data from seismic survey shows that the sand lying between reefs in the Florida Reef Tract are shallow basinal-type deposits with stringers or lenses of fine grained (silt plus clay) sediments and occasional coarse rubble mounds in the vicinity of paleo-inlets (now submerged reef gaps) (e.g., see Finkl and Bruun, 1998; Khalil, 1999). Sedimentary infills here average several tens of meters in thickness, but present a generally monotonous flat topography at the surface between reefs. Because of the flat, rippled surface patterns seen on the aerial photographs, these features are referred to as sandflats or simply as sandy bottom. The sandy deposits are more or less of uniform grain size at the surface and thus appear similar and are easily recognized in the interpretive process. Some areas, however, are partially covered by anchored or bottom-drifting algal mats or less commonly with sea grass beds giving a dark-toned appearance in the imagery. Because these areas are so distinctive in appearance and thus mutually exclusive, they were separated as different mapping units and referred to simply as light- and dark-toned running sands. Areas of sand sheets appear similar to the inter-reefal sand flats but instead of occurring offshore they tend to occur more inshore and shallowly overlie karst limestone. The underlying limestone is evident in the imagery by its reticulate structural patterns that poke through the thin sedimentary cover. These sandy bottoms thus present complicated image patterns that are combinations of sedimentary cover over outcrops of rough bedrock surfaces. Although wide ranges of variable patterns are associated with this unit, they are grouped into one category of occurrence for mapping purposes.

Light- and dark-toned running sand. Unconsolidated running sands without vegetation or algal mats appear as smooth, fine textured, bright patterns on the aerial photographs. The "light-toned" photograph interpretation descriptor is used to differentiate this unit from the darker-toned seabed sands. These clean running sands occur mainly in the offshore zone (e.g., Figures N10 and N11), as rather wide (about 60–120 m in width) bars that parallel the shore or as sand sheets. Collateral data (e.g., side-scan sonar) indicates that these sandy bottoms may extend to several (6–7) meters in thickness and overlie carbonate substrates of the Florida Reef Tract. Dark-toned running sands are differentiated on the basis of the areal distribution and density of benthic algae or biological material that is integrated within the surface-most sediments. These dark-toned running sand sheets occupy large areas of seafloor and in contradistinction to the parabathic light colored bars and sheets, they display many different irregular shapes that are determined by the presence of organic matter at the sediment surface. These sands also infill depressions between reef tracts and occur as sheets of variable thinness over hardgrounds.

Structurally controlled sandflats. As defined here, these submarine sandy areas of flat lying sediments are bordered on both landward and seaward margins by hardground ledges. Figure N8, for example, shows marine sediments that have infilled solutional depressions in rock reefs. These sandy areas are laterally and vertically controlled by preexisting or antecedent topography that was previously subaerially exposed and then drowned by the Flandrian Transgression. The bounding ledges, which are clearly evident in aerial photographs, generally rise about 1–2 m above the seafloor to interiorly trap sediment. In some areas, the karst structures of the underling limestone show through the thin sedimentary veneer or are propagated upwards through the sedimentary cover to show the limestone's reticulate structural pattern. The structurally controlled sandflats tend to be irregular in overall shape, but their borders create zigzag or saw-tooth patterns. These sandy areas rarely contain algal mats and the sands are clean.

Tidal delta. Shoals associated with tidal inlets occur as flood-tidal deltas and ebb-tidal deltas along this microtidal (less than 2 m) coast with semi-diurnal tides. Tidal prism normally has a large influence on the size and shape of natural inlets, but inlets in the study area are cut through bedrock of the Anastasia Formation making them positionally stable (Finkl, 1993). Because the major ports have stabilized deep navigational entrances with cuts 15–18 m deep and jetties, which in turn results in practically no bypassing of sediments, only smaller inlets have well-developed deltas of the classical form in shallow water. These wave-dominated ebb-tidal deltas (Davis, 1997), always completely submerged along this coast, are sometimes deformed southwards due to structural impacts associated with the downdrift curvature of jetties and the net littoral drift from north to south. Bypass bars are often associated with the ebb-tidal deltas.

End products, applications and insight

Detailed coastal mapping, based on interpretation of aerial photographs, results in the preparation of special purpose morphologic maps along specified coastline segments. Mapping areas may be defined on the basis of coastal physiography or administrative units such as counties. Interpretation of georectified digital aerial photography has the advantage of being incorporated into spatial analysis programs such as ArcView®. Maps prepared in this manner can be compared with preexisting coverages for research and visual display. Mapping of coastal morphology provides new insight into the topologies of coasts that provides better understanding of process–form relationships. Classification of coastal morphologies elucidates associations of natural features and differentiates groups of related features. The delineation of coastal morphologies provides a basis to model coastal landform development and provides baseline data for subsequent change detection analysis.

Detailed coastal morphological maps (e.g., Brown, 1998; Khalil, 1999; Warner, 1999) are useful because they provide a record of coastal biophysical conditions that in turn may find application, for example, in: (1) searches for beach-quality sand that is required for beach renourishment, (2) studies of coastline stability where offshore morphology may determine onshore anchor points or erosional hot spots (localized zones of accelerated beach erosion), (3) in the development of computer models of coastal processes, (4) assessment of the structure and integrity of biological habitats, (5) background geological and geotechnical information for engineering works, (6) coastal hazards research related to surge flooding, overwash, sediment erosion and deposition, location of rip currents, and (7) investigations of coastal geomorphology, evolution of coastal configurations, and coastal/marine landform classification. The methodology is applicable to clear Class II waters where there is low turbidity in the water column during parts of the year when aerial photography can be acquired. Many rocky, sandy beach, and coral reef coasts are thus amenable to study using this technique. Muddy coasts and highly turbid waters are excluded from interpretation of bottom features using aerial photography.

These kinds of morphological studies emphasize the importance of underlying geomorphology to coastline configuration (in planform) and submarine beach profiles. With decreasing natural availability of littoral-drift sediment resulting from dredged inlet construction, the sand layer overlying the Anastasia Formation will continue to decrease in thickness. Consequently, an increased importance of underlying geology in describing profile variability and coastline configuration should be expected. It also follows that a greater portion of the beachface will be comprised of rock outcrops and a greater amount of littoral sediments may be permanently lost to the offshore. This positive feedback mechanism persists at the expense of artificial beach renourishment projects (Brown, 1998). As discussed by Finkl (1993), the limestone base will naturally inhibit shore erosion at points where exposed as submerged hardground in the nearshore zone (Figure N13) and thus control the alteration of beach profiles, shoreline configuration, as well as nearshore processes. Submarine headlands are thus seen as representing paleo-topographic highs in front of modern shores and modify the incoming wave climate (Pilkey *et al.*, 1993). Morphological mapping here clearly shows that rock-control of a sediment-starved beachface is a reality. As shown in Figures N3 and N13, perched beaches may be eroded away during storms and dunes threatened by waves but the rock platforms protect the shore. Sand eventually becomes reestablished on top of the bedrock and a new beach is again perched on top of the platform. These snapshots confirm on the ground what is interpreted from the aerial photographs and verifies the spatio-temporal importance of coastal materials that influence shoreline morphology.

It is the interpretation of aerial photography that makes this morphologic data crucial for coastal morphodynamic studies. Given more than one set of digital aerial photographs, multiple GIS coverages of the delineations of coastal geomorphology can be used in numerous overlay operations in order to gain insights into the planform coastal dynamics (e.g., Finkl and DaPrato, 1993; Brown, 1998). Essential to this topic is the development and implementation of methodologies by which to continually map and assess the coastal data acquired by present and future reconnaissance efforts.

Figure N13 Exposure of the Pleistocene Anastasia Formation in Boca Raton, Florida. This marine abrasion platform has truncated the coquinoid facies of the limestone bedrock base that occur along the Atlantic shore. The seaward margin of the platform along this rocky shore, which occurs as a pronounced ledge up to a meter or so in height, serves as a natural seawall. Note waves breaking offshore in the surf zone, tripped by hardgrounds, and the wave in the photo center that has crashed against the vertical wall of the ledge. There is a duality to this rock platform in that it helps to protect the shore from wave attack but at the same time inhibits onshore sediment, except under high-energy conditions. (Photo: Lindino Benedet, Florida Atlantic University, Boca Raton, Florida; photo taken in Winter 2001.)

Conclusions

In this example of detailed coastal mapping and classification, several important points emerge to illustrate the advantages of making morphological inventories based on interpretation of aerial photographs. That mapping based on georectified digital imagery is faster and more cost effective than conventional survey methods is hardly surprising. There are, however, many surprising elements to remotely sensed coastal surveys such as this one. Facts derived from visual and digital records are more reliable and informative than general impressions or suppositions that are often used in coastal planning, management, and engineering schemes. The southeast Florida shore is commonly referred to as a sandy beach coast with abundant sedimentary deposits offshore. Results of mapping here showed that beaches are shallowly perched over a limestone base, beach deposits are relatively thin at < 2 m in thickness (visible after large storms when beach sands are washed from buried shore platforms), there are many indicators of cross-shore processes (e.g., fluted rock reefs), there is a large expanse of hard bottom types in inshore and offshore zones, and that extremely narrow subaerial beaches occur inshore of reef gaps. Overall observations, based on analysis of the resulting morphological maps, indicate that this coastline morphology is lithologically controlled, the seabed is composed of drowned karst topography overlain locally by unconsolidated sedimentary bodies, and that coastal barriers such as the Florida Reef Tract modify coastline configuration.

Additional advantages that accrue from this kind of detailed mapping of coastal morphological features include the ability to define morphodynamic zones. Recognition of coastal process zones provides a rational basis for coastal management because certain topographic forms are morphodynamically significant, allowing interpretation of dominant processes. Although the technique is limited to clear Class II waters, significant stretches of the world's coastline warrant application of aerial photographic interpretation in conjunction with other methods of investigation.

NEARSHORE SEDIMENT TRANSPORT MEASUREMENT

Definitions and key parameters

Nearshore sediment transport is driven by the combined motions of water waves and currents. Due to the complications caused by orbital wave motion, methods developed for measuring sediment transport in largely unidirectional environments may not be applicable in measuring coastal sediment transport. To make matters even more complicated, the relatively orderly wave motion becomes disrupted by the extremely turbulent wave breaking at the transition between land and ocean, often referred to as the surf zone or breaker zone. In the following, the term nearshore is used in a general sense, representing a variety of coastal environments.

Generally, sediment transport rate is calculated as

$$Q = \frac{1}{t}\int_0^t \int_0^{x_n} \int_0^h C_s(x, z, t)\, U_s(x, z, t)\, dz\, dx\, dt, \qquad \text{(Eq. 1)}$$

where x_n is the width of a certain nearshore zone over which the transport is computed; h is the water depth; U_s is the particle velocity; C_s is the sediment concentration; x and z are the horizontal and vertical coordinates; and t is the time. The resultant Q is the total transport rate integrated over a water depth h across a horizontal scale x_n, and averaged over a time period of t. Sediment concentration C_s is a scalar quantity described only by its magnitude. Under most circumstances, C_s is greater near the bottom and decreases logarithmically upward. Therefore, it is important for sediment-concentration measurement to extend as close to the bottom as possible. In order to use equation 1 to calculate sediment transport, simultaneous current measurement is also important. It is worth emphasizing that sediment transport rate, the product of a scalar C_s and a vector U_s, is a vector in the same direction as U_s.

In coastal zones, especially in environments controlled strongly by wave motions, U_s and C_s vary rapidly with time and space. In a high-energy environment, such as the surf zone, sediment transport is extremely active. Measuring U_s and C_s simultaneously with satisfactory temporal and spatial resolutions is difficult. The product of U_s and C_s yields sediment flux

$$\overrightarrow{F_s(x, z)} = \overrightarrow{U_s(x, z)} \times C_s(x, z). \qquad \text{(Eq. 2)}$$

Under many circumstances, directly measuring the sediment flux is technically easier than measuring the U_s and C_s separately. However, precise measurements of U_s and C_s will not only yield transport rate, but also shed light on transport processes. In complicated coastal waters, the sediment concentration C_s and particle velocity U_s are influenced by many hydrodynamic and sedimentary factors. It is beyond the scope of this entry to examine the many factors that determine U_s and C_s. A comprehensive summary was provided by Van Rijn (1993).

Sediment transport is often described in three modes: bed load, suspended load, and wash load. As often as these terms are used, they are not as clearly defined, especially from a measurement perspective. The wash load describes the portion of very fine particles that are transported by the water but are not represented in the bed. Wash load is typically neglected or incorporated into suspended load during transport measurements. Conceptually, bed load is usually defined as the part of the total load that is in frequent contact with the bed during transport. It primarily includes grains that roll, slide, or jump along the bed. The suspended load is the part of the total load that moves without frequent contact with the bed controlled by the agitation of fluid turbulence.

The concepts of bed load and suspended load provide a visual representation of the modes of particle movement. But in practice, bed load and suspended load, as they are defined above, cannot be distinguished during field or laboratory measurements. From a measurement perspective, bed load is often simply defined as the part of the total load that travels below a certain level, which may be defined differently by different researchers, often on the basis of the measurement device. Therefore, bed load and suspended load measured during different studies may not be directly comparable due to different definitions. Caution should therefore be exercised in using these terms in nearshore sediment transport measurement and clear definition should be provided.

Fundamentals of nearshore sediment transport measurement

One of the first and rather critical decisions in planning a nearshore sediment transport measurement project is to determine the appropriate temporal and spatial scales. "Coastal zone" is a general term describing many different types of coastal environments, including tidal inlets, surf zones, estuaries, tidal deltas, etc. Sediment transport is dominated by different processes in these different environments. The spatial scale should be adequate to describe the characteristics of the specific coastal environment. Coastal sediment transport often demonstrates apparent periodicity controlled by the cycles of water motion and sediment supply, such as wave cycles, tidal cycles, seasonal wave conditions, seasonal cycles of riverine sediment supplies, etc. The temporal scale should be able to resolve the periodicity that is of interest to the specific study.

The most appropriate temporal and spatial scales are also influenced by the objectives of the sediment transport measurement, and different measurement methods are suitable for different scales. Generally speaking, finer temporal and spatial scales may provide more accurate measurement at the target location during the study period. However, fine scale studies tend to be short-term with limited regional coverage and may not entirely capture regional characteristics and yield a representative regional long-term transport rate. Therefore, fine scales tend to be used in studies where the main objective is to quantify transport physics. On the contrary, coarser temporal and spatial scales focus on providing regional and long-term measurement, although local details and short-term variations tend to be neglected. For studies with the objective of obtaining long-term regional transport rate, coarse scales may, therefore, be more suitable than fine scales. Determining proper temporal and spatial scales comprises an important portion of the nearshore sediment transport measurement. As mentioned earlier, coastal sediment transport demonstrates various periodicities, and although it is unlikely that a single study will be able to resolve all of them, it is important to incorporate certain periodicities, especially when average values are to be measured and calculated.

It is worth emphasizing that both current and sediment-concentration profiles typically demonstrate logarithmic trends with rapid changes in the vertical direction. The slight errors in determining elevations may be exaggerated during vertical interpolation and calculation of sediment flux. The logarithmic shape of the profile should be taken into consideration during the vertical interpolation and sum, and calculation of depth-averaged values.

Since sediment transport rate is a vector, determining its direction is as important as determining its magnitude. The direction of the sediment flux is equal to the direction of particle velocity, or current velocity in most cases. The majority of current sensors measure the velocity along two perpendicular axes, and the vector sum yields the magnitude and direction of the total current. A proper coordinate system provides many conveniences in describing the transport direction. One of the most commonly used coordinate systems aligns one axis parallel to the shore and one perpendicular. However, this longshore and cross-shore system may not be the most efficient for coasts with complicated features such as inlets and river mouths, where careful consideration of the dominant regional features may be necessary.

Methods for measuring nearshore sediment transport

From its definition, sediment transport rate can be obtained by simultaneously measuring sediment concentration and particle velocity, or by measuring sediment flux directly. However, in dynamic and complicated coastal zones, direct measurement of sediment flux is sometimes not possible due to technical difficulties, and as a result, alternative indirect methods are often used. In the following, nearshore sediment transport measurements are discussed in two categories: direct and indirect measurement. Direct measurements obtain the sediment flux or via the product of sediment concentration and particle velocity. Indirect measurements involve the measurements of other quantities, such as morphological changes, from which sediment flux can be deduced.

Direct measurement of sediment transport rate

Numerous methods are available for measuring sediment concentration and particle (or flow) velocity. Usually, the principle difficulty is measuring concentration and velocity simultaneously at the same location. The most straightforward measurement of sediment concentration is to determine the weight of sediment particles in a unit volume of water, obtained from the study area. A commonly used method consists of an array of sampling bottles with a trigger device to open and close the bottles (Kana, 1979). A considerable area can be covered by each sampling event. Temporal coverage of this kind of measurement is usually limited because of the manual-driven sampling. Also, sampling interval is generally short limited by the typically small amount (no more than several liters) of water sample. In a wave-dominated environment, this method may not be able to provide a representative average over an entire wave cycle due to its short sampling. The short sampling interval also makes the simultaneous velocity measurement difficult. However, in less dynamic environments with limited wave influence, such as semi-enclosed estuaries, where sediment concentration may not change quickly, the instantaneous sampling may provide reasonable representation of average value. Direct deployment of sampling bottles is often replaced by a pump-suction device. By regulating the rate of intake, the sampling duration can be increased to provide measurement of average value over several wave cycles (Nielsen, 1984).

A variety of turbidity sensors are available for measuring sediment concentration. Among them, the optical backscatter (OBS) is commercially available and is probably the most commonly used. The OBS can be deployed and synchronized with current sensors to provide measurement of sediment flux. The automated and self-recording concentration sensors are capable of sampling at high frequency to resolve sediment suspension events, such as those driven by wave motions (Beach and Sternberg, 1992; Osborne and Greenwood, 1993). A limitation of sensors like OBS is that the output is significantly influenced by sediment properties, and therefore, it requires calibration using *in situ* sediment. Bottom sediment from the study site is often used for the calibration. However, it is not uncommon that bottom sediment is substantially different from sediment in suspension (Wang *et al.*, 1998a). Therefore, calibration using bottom sediment may introduce uncertainties in computing the OBS concentration. Comparison with direct concentration measurement as described in the previous paragraph is always desirable. The self-recording sampling allows long-term measurements, however, biological fouling, especially during the summertime necessitates periodic cleaning of the sensors. The spatial coverage of the turbidity sensors is often limited by their relatively high cost, since at least three are required for the measurement of a concentration profile.

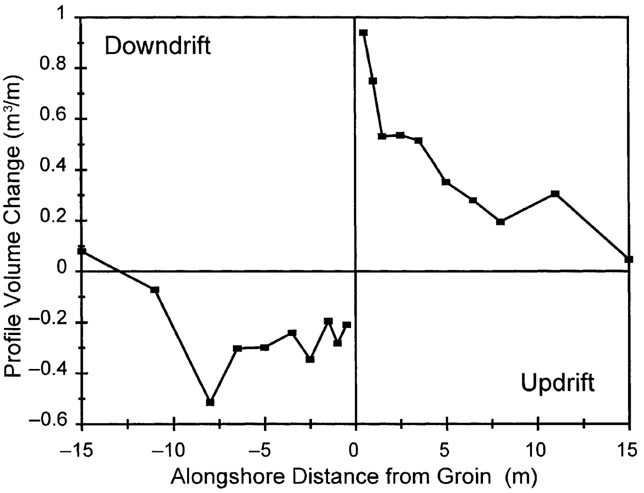

Figure N14 Sand accumulation at the updrift of a short-term impoundment, and erosion at the downdrift.

In order to obtain sediment flux, currents must be measured simultaneously with the concentration. Measuring current velocity is more complicated than measuring sediment concentration since velocity is a vector. Current measurement has been conducted for decades and the technology is fairly mature. The most commonly used current sensor is the electromagnetic current meter (EMCM), which measures currents along two perpendicular axes. Recently, the three-dimensional Acoustic Doppler Velocimeter (ADV), which measures particle velocity directly, has been used more and more frequently. The Acoustic Doppler Current Profiler (ADCP), which is capable of measuring three-dimensional current profiles throughout the water column, is becoming a promising technique in measuring coastal currents.

Sediment transport rate can be obtained by integrating sediment flux, which is commonly measured using sediment traps. Generally, there are two types of sediment traps, categorized by their functionality. Type 1 functions by reducing the intensity of the hydrodynamics to such an extent that the sediments that are moving with the fluid settle into the trap. Type 2 functions by providing a selective obstruction to sediment movement, for example, via the use of sieve cloth. The selective obstruction blocks the movement of the sediments and retains them in the trap, while allowing the majority of the fluid to pass through. Because it allows the passage of fluid, type 2 traps generally impose fewer disturbances to hydrodynamic conditions than type 1. Disturbance to hydrodynamic conditions may have a significant influence on the efficiency of sediment traps, as well as on the transport processes.

Due to the complexity of coastal hydrodynamics, no universal trap design functions well in all coastal environments. In the following paragraphs, sediment traps used to measure surf zone longshore sediment transport rate are discussed as examples. An example of the type 1 trap is described in Wang and Kraus (1999). A temporary shore-perpendicular structure was deployed as an obstruction to block longshore sediment transport, causing the sediment carried by the longshore current to be impounded updrift of the structure. The sediment flux was obtained by quantifying the volume of sediment accumulated at the updrift location during the period of experiment (Figure N14), which ranged from 2 to 6 h for the measurements conducted by Wang and Kraus (1999). Since the structure blocked longshore sediment supply, downdrift erosion occurred. According to mass conservation, the updrift accumulation should be equal to the down-drift erosion. The achievement of mass balance during the measurement provides a comprehensive check for data quality, which is valuable for non-repeatable and non-controllable field measurement. The disturbance the structure causes to hydrodynamics may introduce uncertainty in the measurement. Some permanent shore protection structures may function as total traps. Quantification of beach changes in the vicinity of these structures may provide reasonable estimates of regional sediment transport rate averaged over several months to a year (Dean, 1989).

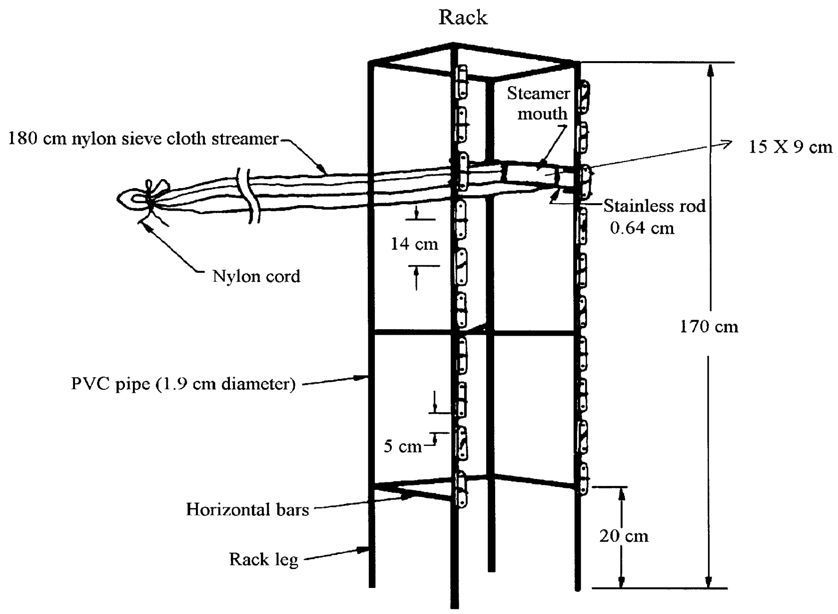

Figure N15 Design of the streamer sediment traps (modified from Wang *et al.*, 1998b).

The streamer sediment trap developed by Kraus (1987) and Wang *et al*. (1998b) provides an example of the type 2 trap (Figure N15). The streamer traps are made from sieve cloth of a mesh size dependent upon the size of the sediment in the study area. The traps not only allow water to flow through the sieve cloth but also move with the cross-shore wave motion, and therefore, impose minimal disturbance to hydrodynamics. The magnitude of the sediment flux is measured by the weight of sediment trapped in the streamer bag over the period of the experiment. The traps were operated manually, and the sampling interval ranged from 3 to 15 min, representing the value averaged over 60–200 waves. The longshore component of the sediment flux was measured by orienting the trap opening in the longshore direction. The streamer traps were mounted on a vertical rack, providing measurement of the vertical distribution of sediment flux. By deploying the trap array at different locations in the surf zone, cross-shore distribution of longshore sediment transport was also measured (Wang, 1998). Both the short-term impoundment and streamer sediment traps are fine-scale methods yielding nearly instantaneous measurements of longshore sediment transport, and are therefore more suitable for studying transport physics than obtaining regional long-term rates.

Indirect measurement of sediment transport

Generally, indirect methods can be classified into 2 categories. Method 1 provides an estimate of sediment transport rate via tracing the movement of a small amount of specially marked sediment particles (sediment tracers), from which the movement of all the grains is deduced. Method 2 estimates the rate of sediment transport by quantifying morphological changes resulting from net sediment transport.

Although an indirect method, sediment tracers were the primary method for measuring surf zone longshore sediment transport for over four decades (Ingle, 1966). The principal of the tracer method can be simplified as that a relatively thin layer of sand is assumed to move along shore at some average advection speed. The total longshore transport rate in the surf zone is then calculated as

$$Q = x_b Z \frac{P_2 - P_1}{t}, \qquad \text{(Eq. 3)}$$

where Z is the thickness of the moving layer, x_b is the surf zone width, P_1 and P_2 are locations of the tracer mass at the beginning and end of the experiment, and t is duration of the measurement. Accurately estimating Z through the vertical distribution of the tracer may be rather difficult (Kraus, 1985). Determination of location P_1 is straightforward, controlled by the initial tracer injection. Location P_2 can only be determined statistically and is influenced by many factors including the sampling scheme (White and Inman, 1989). The theoretical foundation and practical difficulties of the tracer method have been critically examined by Galvin (1987) and Madsen (1987).

Transport rate can also be estimated from morphological changes. The fundamental assumption is that morphological changes are caused by sediment accumulation or erosion, which are closely related to the rate of net sediment transport. For example, longshore transport rate can be estimated from the alongshore migration of barrier spits. From the volume change of ebb-tidal deltas, sediment transport in the vicinity of tidal inlets can be estimated (Davis and Gibeaut, 1990). These indirect methods are typically of coarse scales and tend to provide estimates of regional, long-term transport rate. Difficulties inherent in these indirect methods may include: (1) uncertainties in determining transport direction; (2) uncertainties involved in distinguishing the morphological changes caused by other processes such as tectonic subsidence and uplifting; and (3) uncertainties in estimating sediment bypassing. Also, morphological changes may be dominated by random extreme events.

Summary

Measuring nearshore sediment transport rate is a difficult task and no single method is universally applicable. A sound understanding of regional hydrodynamics and sediment-transport processes is important in adopting and executing the most suitable method for sediment-transport measurement. The first step in planning a transport measurement project is to determine the optimal temporal and spatial scales, which are partially controlled by the objective of the study. Some methods, such as sediment tracing or manual sediment trapping, are suitable for short-term measurement in a small region, while automated monitoring with self-recording instrumentation is more suitable for long-term study in a small, focused area. The few methods that are suitable for long-term, regional study are predominantly indirect techniques involving the examination of regional morphological changes. It is worth emphasizing that sediment transport rate is a vector and is described by not only a magnitude but also a direction. Sometimes, the directionality is simplified by studying the transport component in a pre-determined direction, such as transport in the longshore or cross-shore direction, respectively.

NEARSHORE WAVE MEASUREMENT

Definitions and key parameters

Generally, water waves are described by two length parameters, wave height and wavelength, and one temporal parameter, wave period. Wave height is the vertical distance between the wave crest and trough. Wavelength is the horizontal distance between two successive wave crests or alternatively, wave troughs. Wave period is the time needed for two successive crests or troughs to pass a spatial reference point. Direction of wave propagation is also an important parameter and critical when computing wave-induced sediment transport vectors. Scientific convention describes the wave direction as "direction to which it propagates" measured clockwise from the x-axis. In practice, however, wave direction is often reported as "direction from which the waves propagate," similar to the description of wind direction. It is necessary to specify the wave direction convention to avoid confusion. Depth over which the waves propagate is also important and is necessary in linking wave height and length to other parameters such as wave-induced water particle velocities and accelerations. Based on linear wave theory, wavelength and wave period are related through the dispersion relation as

$$L = \frac{g}{2\pi}T^2 \tanh\frac{2\pi h}{L}, \qquad \text{(Eq. 1)}$$

where L is the wavelength, g is the gravitational acceleration, T is the wave period, and h is the water depth. Although non-linear properties become increasingly more significant in shallow water than in deepwater, nonlinearities have rarely been considered during general wave measurements. Small amplitude (also referred to as Airy or Linear) wave theory has been used widely in coastal science and engineering research (Dean and Dalrymple, 1991).

A commonly used two-dimensional description of a small amplitude progressive wave is

$$\Phi(x, z, t) = -\frac{H}{2}\frac{gT}{2\pi}\frac{\cosh k(h+z)}{\cosh kh}\sin\left(kx - \frac{2\pi}{T}t\right), \qquad \text{(Eq. 2)}$$

where Φ is the velocity potential, k is the wave number defined as $2\pi/L$, x and z are the horizontal and vertical coordinates, respectively, and t is the time. The horizontal (u) and vertical (w) water particle velocities can be determined from the velocity potential as

$$u = -\frac{\partial\Phi}{\partial x}, \qquad \text{(Eq. 3)}$$

$$w = -\frac{\partial\Phi}{\partial z}. \qquad \text{(Eq. 4)}$$

Describing waves in the real world using one sinusoid, such as equation 2, is a significant simplification. A more realistic description would be a superposition of a large number of sinusoids, variable in direction. From a simplistic perspective, the objective of wave measurement can be generalized as an attempt to obtain the parameters of equation 2 to provide an optimal sinusoidal representation of real-world waves and their dominant direction of propagation. The purpose of this entry is to provide a summary of field methods used to measure these parameters, especially in nearshore regions. This review is prefaced, however, by an acknowledgment that the measurement of waves, and in particular their direction, has been one of the more difficult tasks in observational coastal engineering and oceanography.

Fundamentals of wave measurement

For the convenience of discussion, wave measurement is described in the following two categories: (1) measuring the sinusoidal parameters typically including wave height, period, and orbital velocities; and (2) measuring the direction of wave propagation. Measuring wave direction is more costly and instrumentation-intensive, and is more complicated with regard to data analysis, than measuring nondirectional waves.

Non-directional wave measurement

Generally, three approaches have been used to measure nondirectional waves and include measuring (1) the vertical acceleration of water particles; (2) orbital velocities of water particles; and (3) fluctuations in water surface. Approach (1) involves the use of wave-rider buoys, which are most commonly used in deep and intermediate depth wave measurement. Buoy use in coastal waters is limited by its relatively low sampling frequency and inability to measure water depth. Approach (2) requires complicated data processing procedures to obtain wave height. Approach (3) is most commonly used in coastal wave measurements and provides the most direct measurement of wave height and period. Most applications use wave height and period to describe waves, while orbital velocities are usually calculated based on a certain wave theory, for example, using equations 3 and 4 if linear wave theory is applied.

Directional wave measurements

In order to obtain wave direction, it is necessary to measure the nondirectional parameters simultaneously with one of the following: (1) the direction of water-surface slope; or (2) the direction of the water particle orbital velocity vector. Measuring the water-surface slope is accomplished using wave-rider buoys by recording the pitch and roll of the buoy. The water-surface slope can also be measured by deploying a specially arranged array of at least three water-surface variation sensors. Measuring the velocity vector is more frequently used to obtain directional nearshore waves by combining a velocity sensor with the water-surface variation sensors.

Wave direction can also be obtained through remote sensing techniques, such as radar and satellite imagery and has made considerable strides in large-scale ocean observing systems. A major advantage of this approach is that it provides a two-dimensional view, instead of a point measurement. Remote sensing methods remain to be innovative and promising for future wave measurements.

Wave sensors

For the convenience of discussion, wave sensors are divided into two categories, including (1) surface sensors and (2) subsurface sensors. There are two types of surface sensors, wave buoys, moving with the wave surface and recording the vertical acceleration of the wave motion, and surface piercing wave staffs which are generally attached to a fixed structure and measures the water-level fluctuations. The most commonly used subsurface sensors are the pressure transducers, measuring the pressure variations induced by water-level fluctuations. Water surface movement can also be measured with upward looking acoustic sensors mounted on the bottom, which measure the elevation of the air–sea interface.

Surface sensors

As discussed earlier, wave buoys are typically used in deepwater, where structures are not available to attach wave staffs and the water is too deep for bottom-mounted sensors. The application of buoys in coastal waters is seriously limited by its inability to measure water depth. Nevertheless, most ocean observing systems rely heavily on buoys for sea state measurement, and by and large, have provided unique data sets particularly during storms.

There are three main types of wave staff: resistance wire, capacitance, and electromagnetic transmission line staffs. The operating principle of this instrument is that the staff is a component of an electronic circuit which produces voltage changes proportional to the length of the staff that is either submerged or is not submerged. In turn this provides a measure of water-level fluctuation. Potential locations for wave-staff deployment are confined by mounting requirements. The mounting confinement also limits the options of incorporating directional measurements using wave-staff arrays. Biological fouling and electronic drifting limit the long-term applications of wave staffs.

Subsurface sensors

The most commonly used wave sensor in coastal waters is the bottom-mounted pressure transducer, which measures the pressure variation induced by water-level fluctuations. Directional waves can be measured by combining a pressure sensor and a velocity sensor. This combination comprises probably the most commonly used directional system for nearshore wave measurement, and is often called a PUV gage (Morang *et al*., 1997).

A primary limitation of bottom-mounted pressure and current sensors is the increased attenuation of signal strength with increased water depth, referred to as depth attenuation. This results in a decreasing signal-to-noise ratio with increasing water depth. The magnitude of depth attenuation is a function of frequency, with high-frequency signals attenuating more rapidly than low-frequency signals. Depth attenuation of signal strength can be quantified by comparing measurements taken near the water surface and near the bottom (Figure N16).

Similar energy spectral density was measured both near the surface and the bottom for low-frequency components, while for high-frequency components, greater energy spectral density was measured near the surface than that measured near the bottom.

Depth attenuation can be corrected during data analysis. A commonly used procedure, derived from linear wave theory, applies a frequency-dependent depth attenuation factor, $K(f)$

$$K(f) = \frac{\cosh[k(z_s + h)]}{\cosh(kh)}, \qquad \text{(Eq. 5)}$$

where z_s is the depth of the sensor below the water surface (negative downward). Wave number and wavelength cannot be directly measured by the pressure sensor, or other point sensors, but are calculated based on the dispersion relation equation 1. The measured power spectral density, $E_m(f)$, is corrected as

$$E_c(f) = \frac{E_m(f)}{K^2(f)}, \qquad \text{(Eq. 6)}$$

where $E_c(f)$ is the corrected power spectral density. The attenuation-correction factor $K(f)$ increases exponentially as the frequency increases (Figure N17).

When pressure spectra are corrected by the above methods (equations 5 and 6), increasing energy density is sometimes seen for frequencies significantly greater than the frequency of maximum wave energy. This is shown by the sharp increase toward the tail of the corrected power spectrum for the sensor that was 2.9 m below the surface (Figure N16). This is a result of the fact that the attenuation correction amplifies both the signal and noise. The high-frequency noise can be amplified significantly when divided by a very small $K^2(f)$, causing considerable error in computing wave height and sometimes, peak wave period. Therefore, the spectra should be truncated at a high-frequency cutoff, above which incorrect noise amplification has occurred. Noise amplification and the determination of a high-frequency cutoff depend on a variety of factors including the characteristics of the individual sensor and data collection system, the depth of the sensor, and the height and period of the waves.

Proper determination of the cutoff frequency has significant influence on the calculation of significant wave height and other statistical wave parameters in coastal waters, such as in estuaries, where local wind-generated short-period waves often dominate. It is common for these waves to have peak periods of 2–4 s (0.50–0.25 Hz). As shown in Figure N17, if the sensor is mounted 4 m below the surface, a correction of over 10^3 will be applied to signals that are higher than 0.5 Hz. In other words, the noise beyond 0.5 Hz will be amplified 1,000 times. For open-ocean waves, components shorter than 2-s period are negligible. High-frequency cutoffs ranging from 3 to 6 s are often applied for open ocean wave measurements. However, in coastal waters, especially in semi-enclosed coastal water bodies, wave components with a period less than 2 s may not be neglected. Determination of the proper high-frequency cutoff may be dictated by local conditions, and careful study is necessary. The use of a fraction of the peak wave period may not be appropriate for bi-modal spectra, which are common in coastal waters.

In recent years, Doppler technology (e.g., the Acoustic Doppler Current Profiler—ADCP) has been used broadly to measure current–velocity profiles throughout the water column. There has been considerable interest in exploring their efficacy as a wave sensor, and the use of upward-looking ADCPs to measure both waves and currents was pursued and

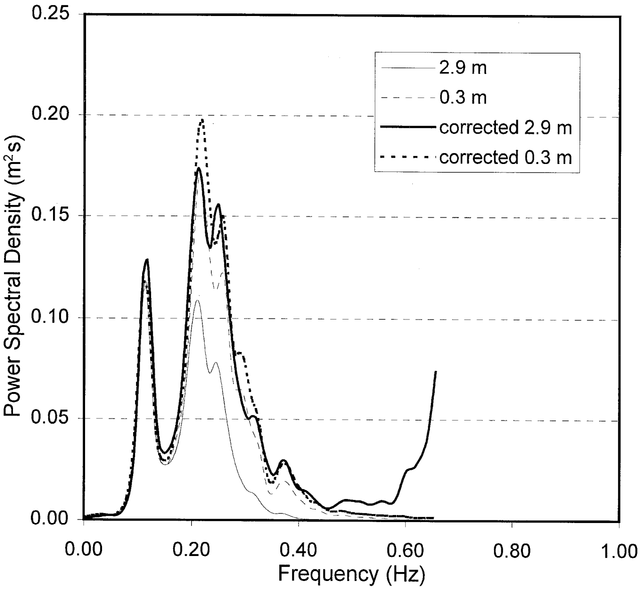

Figure N16 Wave spectral measured at different water depths, 2.9 and 0.3 m below surface, and depth-attenuation correction.

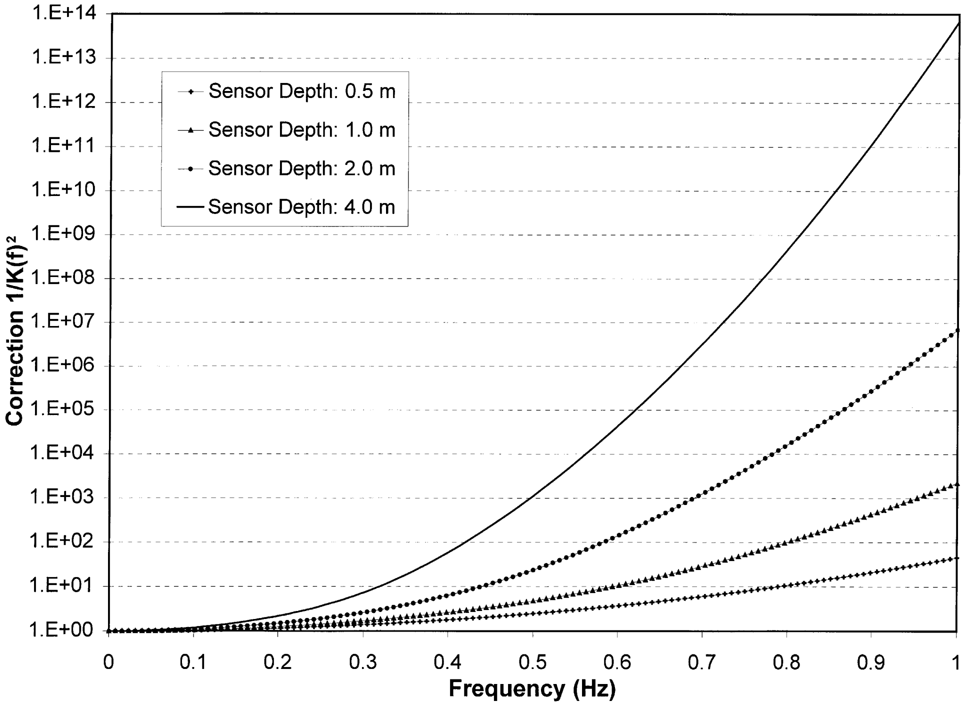

Figure N17 Increase of depth-attenuation correction with increase of frequency.

proved to be reasonably successful (Terray *et al.*, 1999). The spectrum of wave energy can be estimated from both the ADCP velocity measurements, and the direct echo-location of the surface along the four slant beams. It is worth noting that the ADCP is substantially more costly than the above wave sensors. The tremendous advantage is that a properly designed ADCP package is capable of yielding probably the most comprehensive point measurement of marine hydrodynamics including directional wave and the three-dimensional current profile.

Sampling schemes

Generally, a certain wave sampling scheme is composed of three aspects: (1) sampling rate of the sensor, often expressed in term of samples per second, or Hertz; (2) length of the sample; and (3) interval between each sampling events. The sampling rate and length are determined largely by the characteristics of the waves to be measured. The interval between samples is determined by several factors including the objectives of the research and capabilities of power supply and data storage.

The sampling rate should be rapid enough to capture the wave-induced water-level fluctuation. The minimum frequency that can be detected by a certain sampling rate, referred to as the Nyquist (f_N) or folding frequency, is

$$f_N = \frac{1}{2dt}, \qquad \text{(Eq. 7)}$$

where dt is the sampling rate. For example, if the sampling rate is 2 Hz, the minimum frequency that can be resolved is 1 Hz. However, it is worth mentioning that 2 Hz sampling may not capture the full magnitude of the 1 Hz signal, although the frequency is resolved. It is always desirable to sample at a faster rate than twice of the Nyquist frequency, and the latter should be determined with adequate knowledge of the shortest frequency that needs to be resolved, not the peak wave frequency. Each sampling event is typically called a wave burst. The duration, or length, of a wave burst is based on the peak wave period. As a rule of thumb, in order to obtain reliable statistical values of wave parameters, the length of a wave burst should be at least 150 times the peak period.

A general knowledge of the study area is important in determining the optimal sampling rate and wave-burst length. It is desirable to have a rapid sampling rate and long wave burst. However, these are often limited by the capacities of the power supply and data storage, especially for the bottom-mounted systems, which are typically powered by batteries and have a fixed amount of data storage. Optimal sampling balances the storage-consuming fast sampling and the power-consuming long wave burst with the most effective frequency coverage and reliable statistical properties.

The interval between wave bursts is an additional important parameter in planning a wave measurement program. Wave conditions in coastal waters can change quickly, thus it is preferable to have shorter intervals between wave bursts. However, more frequent wave bursts require more power and data storage. If the main goal of a wave measurement program is to obtain long-term averages of wave conditions, longer intervals between wave bursts, such as 3 or even 6 h, may be acceptable. If the main goal is to capture wave growth or development and dissipation of storm waves, shorter intervals, such as 1 h, are preferred. More than one sampling mode can be used, for example, a storm mode with 1 h interval and regular mode with a 3 h interval.

Wave data analysis

Nondirectional wave analysis

As discussed earlier, one sinusoidal form is not adequate to describe waves in the ocean. Waves are best presented in a statistical manner by means of spectral energy density and probability distribution. Numerous procedures exist for wave data analysis, largely based on concepts from time-series analysis and statistics. Details of wave analysis, especially that of directional waves, is complicated and beyond the scope of this entry. In the following, a procedure recommended by the Coastal and Hydraulic Laboratory of the US Army Corps of Engineers (Earle *et al.*, 1995), is discussed as an example. This procedure has been widely used in computing wave parameters, such as wave height, period, and direction. It is important to be consistent and to adopt a commonly used data processing procedure to ensure compatibility.

A key component of wave data processing is spectral analysis. Spectral analysis determines the distribution of wave variance as a function of frequency. Wave variance is proportional to the wave height squared, which in turn is proportional to wave energy. Thus, wave variance spectra are often referred to as wave-energy spectra. Spectral analysis is conducted using the Fourier Transformation. Wave spectra are typically calculated with units of variance/frequency so that integration over a frequency range provides the total variance of the wave components within the frequency range. Significant wave height (H_{mo}), which was originally defined as the average of the one-third highest waves in a wave record, can be calculated as

$$H_{mo} = 4 \times \sqrt{\sum_{1}^{m} E_c(f)\mathrm{d}f}, \qquad \text{(Eq. 8)}$$

where m is the number of discrete Fourier frequencies in the frequency band, and df is the small frequency interval over which the $E_c(f)$ is calculated. Another commonly used wave parameter is the peak wave period, which is defined as the reciprocal of the frequency of maximum wave variance. Other wave height parameters, such as the root-mean-square wave height (H_{rms}) and 1/10 maximum ($H_{1/10}$) wave height can be calculated assuming a Rayleigh probability distribution of wave heights:

$$H_{rms} = \frac{\sqrt{2}}{2} H_{mo}. \qquad \text{(Eq. 9)}$$

$$H_{1/10} = 1.80\, H_{rms} = 1.27 H_{mo}. \qquad \text{(Eq. 10)}$$

Directional wave analysis

Wave direction is important for applications such as harbor and structure design, wave refraction studies, and calculation of sediment transport rates (Massel, 1996). A directional spectrum, $E(f, \theta)$, is defined so that $E(f, \theta)\mathrm{d}f\mathrm{d}\theta$ is the wave variance in a small frequency range df, and direction range dθ. Integration over all directions provides the frequency spectrum $E(f)$:

$$E(f) = \int_0^{2\pi} E(f, \theta)\mathrm{d}\theta. \qquad \text{(Eq. 11)}$$

It is beyond the scope of this entry to examine in detail the measurement and determination of directional spectra (Earle and Bishop, 1984). Based on derivations of Longuet-Higgins *et al.* (1963), the directional spectrum can be simplified and represented by the first five Fourier coefficients

$$E(f, \theta) = \frac{a_0}{2} + \sum_{n=1}^{2} [a_n \cos(n\theta) + b_n \sin(n\theta)]. \qquad \text{(Eq. 12)}$$

The first five Fourier coefficients are calculated based on the cross spectrum analysis of two time series, such as water elevation and horizontal velocity vectors. A cross spectrum consists of a co-spectrum and a quadrature spectrum. The co-spectrum represents the variance of the in phase components of the two time series. The quadrature spectrum represents the variance of the out of phase components.

Since PUV gages are most commonly used in coastal water to obtain directional spectra, a simplified procedure of PUV data analysis is discussed in the following as an example. The five Fourier coefficients are calculated as

$$a_0(f) = \frac{C_{pp}(f)}{K_p^2(f)\pi}, \qquad \text{(Eq. 13)}$$

$$a_1(f) = \frac{C_{pu}(f)}{K_p(f)\, K_u(f)\, \pi(2\pi f)}, \qquad \text{(Eq. 14)}$$

$$b_1(f) = \frac{C_{pv}(f)}{K_p(f)\, K_u(f)\, \pi(2\pi f)}, \qquad \text{(Eq. 15)}$$

$$a_2(f) = \frac{C_{uu}(f) - C_{vv}(f)}{K_u^2(f)\, \pi(2f\pi)}, \qquad \text{(Eq. 16)}$$

$$b_2(f) = \frac{2C_{uv}(f)}{K_u^2(f)\, \pi(2f\pi)}, \qquad \text{(Eq. 17)}$$

where $C_{pp}(f)$ is the power spectral density of pressure at frequency f, $C_{pu}(f)$ and $C_{pv}(f)$ are the co-spectrum densities between pressure and velocities u and v, respectively, $C_{uv}(f)$ is the co-spectrum density between u and v, $C_{vv}(f)$ and $C_{uu}(f)$ are the power spectral densities of v and u, respectively, and $K_p(f)$ and $K_u(f)$ are the depth attenuation correction coefficients for pressure and velocity, respectively. There are two methods to calculate wave angle ϕ; using a_1 and b_1, or a_2 and b_2

$$\phi_m = \tan^{-1}\frac{b_1}{a_1} \qquad \text{(Eq. 18)}$$

or

$$\phi_p = \frac{1}{2}\tan^{-1}\frac{b_2}{a_2}. \qquad \text{(Eq. 19)}$$

Equation 18 is more frequently used, probably due to the relative ease in determining the quadrant. The result from using equation 19 is often referred to as the principal wave angle to differentiate it from the mean angle from equation 18. The quadrature spectrum is not used in the PUV data processing because the pressure and velocity sensors are typically at the same location and the signals are in phase. When an array of water-level sensors is used, the quadrature spectrum is necessary to examine the variance of the out of phase components.

Summary

Measuring waves in coastal zones is a complicated procedure and requires careful planning. Wave conditions in coastal zones can vary significantly from region to region. Coastal waves may also be substantially different from typical deep ocean waves in terms of spectral composition. Hardware and software developed for deep ocean swell measurement, such as large diameter disk buoys, may not be directly applicable to coastal wave measurements. Planning a coastal wave measurement project should include several considerations including objectives of the program, a general knowledge of the waves in the study area, types of instrumentation, sampling scheme, and data retrieval and analysis procedures. For wave measurements in semi-enclosed, high-frequency environments, it is important to have sensors close to the water surface to minimize the loss of important, high-frequency signals. A sound knowledge of the technical characteristics of different wave sensors and wave analysis procedures are also important in assembling an optimal system for a coastal wave measurement program.

NET TRANSPORT

Net transport refers to the difference between the total upcoast and the total downcoast movement of sand approximately parallel to the shore over a specified period, often one year (see entries on *Cross-Shore Sediment Transport* and *Longshore Sediment Transport*). Waves approaching the shore at an oblique angle, such that the crests of the breakers are at an angle to the shoreline, generate longshore currents that convey the mobilized sand along the shore (see entry on *Waves*). In many locales, the wave approach direction varies over time such that this transport can be in either direction relative to the shore. Consequently, sand may move downcoast (positive direction) for an interval and then, as wave conditions change or the lesser effects of tidal or wind-driven currents intervene, reverse and move upcoast (negative direction). Summing the volumes of sand transport over the period of interest and taking into account their signs yields net transport. The customary units of net transport are volumetric rates (cubic meters per year). The terms littoral drift and longshore drift are occasionally used to mean either net transport or gross transport (see entry on *Gross Transport*) so caution must be taken in their interpretation.

In some special locations, because of physical barriers or climatic anomalies, waves approach from only one direction. In this case, the net transport can be identical to the gross transport. In most instances, however, this is not the case. Studies of the potential for longshore transport, based upon directional measurements of nearshore waves at a large number of coastal locations, have shown that the net transport is often a very small difference between large values of positive and negative transport. For example, at Oceanside Harbor in California, during the entire year of 1980, the net transport potential observed was less than 1% of the gross transport (Castel and Seymour, 1986)

NEW ZEALAND, COASTAL ECOLOGY

Introduction

New Zealand has the fourth largest exclusive economic zone (EEZ) in the world (over 4 million km^2), and a long indented coast. The EEZ ranges from subtropical areas to subantarctic areas, though we confine our review to mainland New Zealand (i.e., North, South, and Stewart Islands). Our discussion considers areas from the upper limit of saltwater penetration to the edge of the continental shelf (mean depth 200 m), though we focus on coastal regions. Coastal regions supply New Zealanders with food, recreation, and a livelihood, with high-value near-shore capture fisheries and aquaculture being important contributors to the nation's economy.

The important features of the complex current patterns around New Zealand are becoming better known. The west coast is generally characterized by turbid, cold, productive seas, served in some areas by upwelling of nutrient-rich waters. Subtropical water impinges on northern New Zealand, and may reach down both coasts of the North Island in summer, influencing catches of pelagic gamefish. Interannual variation in the extent of those currents is large, and in recent years many previously unrecorded fishes and other taxa have been observed. The Subtropical Convergence (STC), a global oceanic front separating warmer subtropical waters to the north from cooler subantarctic waters to the south, intersects New Zealand's South Island. The STC passes around the southern end of the South Island, then follows the east coast of the South Island before moving offshore near Christchurch.

Intertidal habitats of New Zealand's coast include mangrove forests, sand and mudflats, salt marshes, surf beaches, and rocky platforms. Subtidally there are rocky reefs, harbor channels, sandy beaches, sounds, and fiords. Kelp forests occupy reefs, and solitary corals occur, and although there are no true coral reefs, reef-building corals do occur at the Kermadec Islands, 800 km northeast of Auckland. Over the 25 years after 1975, knowledge of coastal ecosystems has increased greatly, though Schiel (1991) was still able to suggest that very few processes structuring nearshore communities were understood.

Review of major ecosystems

Estuaries

The major biological habitats occupying intertidal areas in estuaries are mangroves, *Spartina* grass, and mud- and sand-flats. Mangroves occupy estuaries in the northern half of the North Island, and are thought to have important sediment-stabilizing and ecological roles there. Studies of mangrove populations have quantitatively and experimentally examined demography, litter production, and the inter-relationships between sediments and mangroves, but there are no comprehensive analyses of their effects on other fauna. Marsh grasses have been most intensively investigated in more southern areas, where attempts to control the introduced *Spartina* have had variable success. Sea grass (*Zostera* sp.) beds also form important habitat on intertidal areas throughout New Zealand. In recent years, some areas of sea grass are thought to have declined, perhaps due to various human activities, such as trampling on rocky intertidal platforms, or more subtle effects, perhaps related to water quality at the level of entire catchments. The other important plant of harbors is the green seaweed *Ulva lactuca*. Blooms of this species have occurred in several New Zealand estuaries, and are thought to indicate eutrophication. The seaweed also accumulates on shores of harbors after storms and rots, causing problems for local homes.

Throughout New Zealand the cockle *Austrovenus stutchburyi* is prominent in intertidal faunas of more sheltered shores, being harvested commercially throughout its latitudinal range. Several estuaries (e.g., Manukau, Firth of Thames; Figure N18) are important foraging areas for populations of birds that migrate to the Northern Hemisphere. The best-known faunal components of those areas are clams, and intensive studies of interactions between sedimentology and biology have been undertaken in the Manukau Harbour (e.g., Thrush *et al.*, 1997).

The dominant subtidal features of northern harbor channels are dense populations of pipi *Paphies australis*, often in association with abundant 11-armed starfish *Coscinasterias muricata*. The dense covers of shell associated with such areas probably modify sediment mobility, and the abundances of shellfish are possibly high enough to influence water quality. Harbors are thought to be important to stocks of commercially important fishes, and the fish fauna of harbors and estuaries in northern New Zealand is being investigated in a comprehensive program at present (2000). The fauna of Otago Harbour, near Dunedin and areas of Stewart Island have also been described, and feature broadly similar organisms to those in more northern areas. One important aspect of population biology that is not well understood is how the population biology of even common species varies along latitudinal gradients. Casual observations suggest large differences in the densities

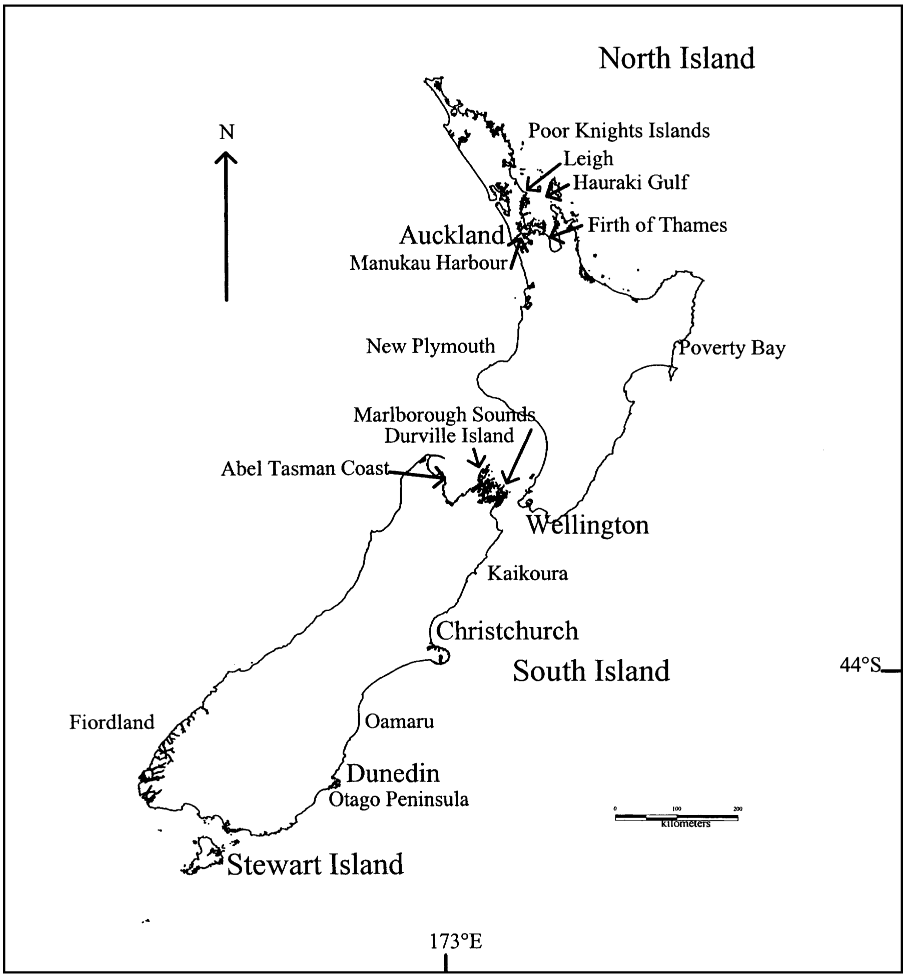

Figure N18 Map of New Zealand, showing localities mentioned in the text.

and sizes of seaweeds, intertidal bivalves, echinoderms, and fishes between northern and southern populations, but as yet there have been few focused studies on latitudinal patterns. One study has compared sites on the east and west coast of the South Island, but it is not clear whether such differences relate to broader-scale oceanographic processes or some other environmental difference between coasts.

Intertidal rocky shores

Considerable research investigating the rocky reef platforms in eastern South Island has been undertaken by University of Canterbury, with some additional comparative information available for the west coast. On the east coast, sea grass *Zostera* sp. and Neptune's necklace seaweed *Hormosira banksii* may occupy large areas of reef. Experimental investigations indicate complex patterns of demography of the sea grass that relate to position, and physical variables such as standing water and temperature. The seaweed is affected by trampling, but recovery is complex and influenced by season, location, and presence of corallines. Similar effects have been shown for trampling of coralline turfs in northeastern New Zealand.

Lower reaches of wave-exposed rocky shores of the southern half of the South Island are occupied by very large laminarians (Schiel, 1994). Earlier studies indicated geographic differences in the influence of grazers on the extent occupied by the bull kelp *Durvillaea antarctica*, and other patterns in morphology that were related to wave action. Research into the seaweed karengo at Durville Island is investigating the possibility of enhancing populations for iwi (local Maori).

Subtidal reefs

Most knowledge of subtidal reef ecology stems from work done in northeastern New Zealand, though additional information exists for New Plymouth, the Wellington coast, the Marlborough Sounds, the Abel Tasman coast, and Kaikoura (Figure N18). The northern studies have emphasized the role of seaweeds in structuring habitats, the importance of small mobile invertebrates such as amphipods in contributing to the productivity of those reefs, and the role of humans in modifying the populations of organisms on those reefs (see below).

Seaweed morphology has been shown to be important in several disparate ways in northeastern New Zealand. Surface area of seaweeds may be important to photosynthetic processes, as ammonium metabolism appears confined to surface layers of cells. A series of studies have shown that the secondary productivity of reefs in northeastern New Zealand is highest in stands of finely structured seaweeds, and that under certain circumstances the excretory products of the small animals might be of value as a nitrogen source to the seaweeds. Studies near Leigh documented large differences in life expectancy, morphology, and palatability to grazers for wave-exposed and wave-sheltered populations of the large fucalean *Carpophyllum flexuosum*. Investigations currently being undertaken near Dunedin examine the influence of wave action on large laminarian seaweeds directly by measuring wave forces.

The sea urchin *Evechinus chloroticus* forms prominent "barrens"—areas devoid of seaweeds—in northeastern New Zealand. Further south the extent of those barrens may be diminished, and in some areas, such as near New Plymouth, extensive barrens can occur in the presence of small abundances of *Evechinus*. In northern New Zealand, the large diadematid sea urchin *Centrostephanus rodgersii* may be abundant, and in deeper water the endemic diadematid *Diadema palmeri* may also be common. The other prominent grazers of New Zealand reefs are gastropods, which may be highly abundant both on the rocky seabed and on the fronds of seaweeds. Experimental investigations suggest that it is the grazing activities of *Evechinus* that structure seaweeds on reefs, and that gastropods mainly respond to the grazing of echinoids.

Seaweeds have also been shown to be important in structuring populations of fishes. Some fishes recruit into seaweed stands on reefs, others use detached seaweeds floating offshore as shelter (and may be moved onshore as a result of that association), still others feed mainly in areas where those seaweeds do not occur, and there is a growing base of knowledge regarding the biochemical pathways whereby herbivorous fishes process seaweeds. Small mobile crustaceans such as amphipods that contribute most of the secondary productivity on reefs, form an important an component of diet for nearly all reef fishes.

Open coast beaches and inner shelf

The dynamics of fauna occupying sediments of the inner shelf are relatively unknown, though much research attention has been focused on the effects of dredging of scallops and trawling. Again, dense populations of bivalves occur, some of which are implicated in structuring populations of other organisms. The best known of these is the horse mussel *Atrina zelandica*, dense beds of which occur throughout New Zealand. *Atrina* has a fragile shell, appears to have strong and weak year classes, is known to influence sedimentation and meiofauna, and to be influenced by physical disturbances such as dredging and anchoring. Other bivalves are important in other habitats; dense populations of the venerid *Tawera spissa* occur in northeastern New Zealand, and in Marlborough Sounds large areas are occupied by live and dead individuals of the dog-cockle *Glycymeris laticostata*. Beds of both *Tawera* and *Glycymeris* are sufficiently dense that they potentially structure the fauna of areas. Although large amounts of drift seaweed may occur on the seabed offshore, most investigations have examined its decay onshore, or its role in concentrating plankton at the sea surface.

Studies of sewage outfalls and dredge spoil disposal in offshore areas such as Tauranga and Gisborne generally suggest that the influence of those disturbances are localized and/or difficult to separate from natural variation. Biological investigations of coastal sediments have lagged behind physical oceanographic studies; in recent years the physical oceanography of the East Auckland Current, Manukau Harbour, Poverty Bay have all been described in some detail. The biological consequences of those processes are only well understood for the East Auckland Current, however, and there are few, if any, studies of the influences of such physical processes on organisms occupying sediments.

Fiords

The fiords of southwest South Island have an estuarine circulation system, which is maintained by the input of freshwater from the prodigious rainfall (>6 m per annum). Fiordland has a long complex coastline of inlets and islands, providing shelter from the prevailing westerly winds. Rainwater runoff from forests leach tannins from leaves and stains the surface fresh-water layer (up to 6 m thick) brown, limiting light penetration. Divers must pass through a murky freshwater layer in which visibility is poor, before bursting through into the clear saltwater below. In the low-light environment antipatharian corals may commonly be found as shallow as 10 m, and other deepwater emergent species also occur there. There are strong gradients in the distribution of several species along the length of the fiord (e.g., large brown seaweeds), and the freshwater layer influences grazing on mussels by starfishes. Starfishes are sensitive to salinity, whereas the mussels are able to resist freshwater incursions to some extent, so that mussels have a refuge in shallow water.

The Fiordland area is a renowned tourist destination, fishing area, source of hydro-electric power, and has been mooted for freshwater export. There is a readily accessible underwater observatory and a proposal for submarine tours. Visitors are concentrated in one readily accessible fiord, and other areas are subject to much lower visitor densities. However, some renowned dive destinations are under pressure from the large numbers of divers visiting. That effect is magnified as several of the species that are drawcards (such as red and black corals) are fragile and may be broken by careless divers. Such problems are likely to emerge with continuing diver pressure on areas such as Poor Knights Islands and Cape Rodney—Okakari Point Marine Reserve, near Leigh.

Marine birds and mammals

The best known New Zealand higher marine vertebrates are Hector's dolphin, seals, and penguins in southern New Zealand, and the huge flocks of wading birds in northern harbors. Hector's dolphin is endemic, permanently coastal, and thought to be endangered due partly to its susceptibility to set nets. Marine mammals and penguins are important tourist drawcards in southern New Zealand, particularly on the Otago Peninsula. Sperm whales are also abundant off the Kaikoura coast feeding in the productive waters overlying the Kaikoura Canyon. Conflicts between fisheries and Hooker's sea lion occur in some offshore fisheries, and modifications to fishing practices are used to minimize seal mortalities. In some areas of northeastern New Zealand feeding by birds in intertidal areas may be sufficiently intense to locally reduce abundances of clams.

Fisheries and aquaculture

New Zealand promotes a broad range of capture fisheries and aquaculture round its coast. Important coastal capture fisheries include spiny lobster *Jasus edwardsii* and snapper *Pagrus auratus*. Value of exports is increasing faster than the volume caught, reflecting at least partly improved handling techniques. Studies in several areas suggest that fisheries (both recreational and commercial) are a major influence on the marine environment and populations of marine animals. Environmental concerns are emerging regarding the environmental effects of some fisheries, and the role of commercial fishers is increasingly one of stewardship. The indigenous Maori people also have an important and growing stewardship role. Recreational fisheries can be important to populations of both the fish and the fishers, with snapper in the Hauraki Gulf, blue cod in the Marlborough Sounds, and kahawai throughout the country being among the most targeted species.

Studies of the benthic impact of trawl and dredge fisheries have revealed reductions in faunal richness and damage to other species. Some of those studies have revealed patterns at broad spatial scales that are consistent with fisheries being a dominant influence on benthic ecology. Concern regarding benthic impacts has led to closure of areas in northern New Zealand to scallop dredging. There are clear advantages for highly targeted, "clean" fisheries, which minimize bycatch. The benefits of such fisheries may extend into the overseas markets, where increasingly greater returns can be obtained for animals or plants that are captured in environmentally benign ways. Further, capture in such ways may have advantages in product quality and ultimately price, as greater shelf life follows from selective, highly controlled harvest.

The aquaculture of GreenShell™ mussels *Perna canaliculus* is a major industry, particularly in the Marlborough Sounds, but farms are found from the north of the North Island to Stewart Island. Mussels are grown on longlines, from which droppers bearing the mussels hang down (usually 10–12 m). Growers hope to harvest mussels within 14–17 months of seeding out, and aquaculture leases in productive areas are highly sought after. The environmental effects of such activities have been little investigated, and concerns regarding sustainability and benthic impacts are mounting. Localized depletion of phytoplankton within farms has been documented, but increasingly there are concerns of depletion at the level of entire embayments. Measurements of currents, phytoplankton abdundances, and computer models are being used to assess the viability of proposed farms. Environmental effects of salmon farming have been studied, but that activity occurs in only a few locations, mainly in southern New Zealand. Other cultured species include Pacific oysters, cockles *A. stutchburyi,* and developed paua (abalone) *Haliotis iris* ventures. As yet few pharmaceutical products are being harvested from aquaculture ventures. As yet few pharmaceutical products are being harvested from aquaculture ventures, though these have considerable potential for high returns.

Introduced species

Some of New Zealand's important coastal fisheries are for introduced species. The Pacific oyster was introduced in the late 1960s or early 1970s, and is now an important aquaculture industry. Sea-run trout and salmon provide valuable recreational fisheries in the South Island, with a trawl bycatch of salmon having been important in the past. However, not all such introductions have positive outcomes, and international experiences (some as close as Tasmania) indicate that introduced species can have major negative effects on many aspects of coastal ecology. Other introduced species will colonize New Zealand shores, and it appears that managing the inevitable arrivals is the focus of current efforts. Pamphlets detailing candidate invaders are circulated by NZ Ministry of Fisheries, with the aim of detecting exotic arrivals early.

A pest management plan has devised for the Asian kelp *Undaria pinnatifida*. However, that species is atypical of introduced species in many ways, in that it is commercially valuable, and that it has an extremely dispersive phase, linked to human activites. *Undaria* has spread throughout southern New Zealand, as far north as Gisborne in Poverty Bay, and in a wide range of environments from harbors to wave-exposed shores. Intense efforts are being made to prevent its spread at Stewart Island, although the success of the seaweed elsewhere has been variable. In Marlborough Sounds, *Undaria* has flourished in sheltered areas, persisted on shallow sills that are impacted by ferry wash, survived well on marine farms that it has recruited to, but failed to persist in subtidal areas adjacent to farms in several areas. It appears that human activities such as boating and aquaculture are the major vector, that grazers on natural shores are able to limit the abundance of *Undaria* in sheltered area but perhaps not in wave-exposed areas (e.g., Oamaru), and that the abundance and species composition of animals that occupy *Undaria* are distinct from natural seaweed stands on the same shores. There are conflicting opinions regarding whether the species should be exploited as a valuable resource or whether it should be extirpated.

Another invader, the Asian date mussel *Musculista senhousia*, is confined to northern harbors and appears to have limited capacity for long-term occupation of areas. It forms matlike localized beds, but the beds appear not to persist. In the Marlborough Sounds some marine farms have had serious problems with recruitment of a solitary ascidian *Ciona intestinalis*. It is thought to compete with mussels for food, and heavy recruitments are sufficient to diminish growth. Concerns regarding biosecurity are mounting, and an awareness of the threat posed by organisms in ballast water has prompted studies of the fauna of ballast tanks, and investigations of ways of treating it to ensure that foreign organisms would not survive. However, other species are able to survive externally on ship hulls (e.g., *Undaria*), and to protect the value of New Zealand's marine resources, great emphasis will have to be directed into surveillance of our borders, and studies of the biodiversity and susceptibility of natural populations. The experience with *Undaria* indicates that studies elsewhere are not able to be directly transferred to the New Zealand situation.

Marine reserves

New Zealand has been at the forefront of marine reserve creation since 1975, and as of October 2000 has 16 marine reserves in which all marine life is protected under the Marine Reserves Act 1971. One of the limitations of that legislation is that it permits marine reserves to be established solely for the purpose of scientific study, and public enthusiasm for marine reserves as a conservation method seems to have outstripped the need for scientific investigation. Several other areas are protected under different legislation, and designated as marine parks. There are also several taiapure and mataitai reserves, which are under the control of local Maori to varying degrees. Marine reserve legislation is currently under review to determine whether the current Marine Reserves Act 1971 is appropriate. It seems likely that it will be reshaped so as to give a broader range of reasons for protecting particular areas.

These protected areas have provided considerable information regarding ecological interactions in coastal habitats. The best-known marine reserve is the Cape Rodney to Okakari Point Marine Reserve, near Leigh, north of Auckland, which has been fully protected for almost 25 years (as of 2000). Partly because of its ready access, but also perhaps because of the duration of protection, it has provided considerable information regarding interactions among organisms on coastal reefs. Fish and spiny lobster populations have been investigated in great detail, and there is some indication that neighboring areas benefit from the existence of the reserve. The most interesting development has been the loss of sea urchin-dominated "barren grounds" (areas with no seaweed) at Leigh, and the reduction of their area in several other northern reserves. It has been suggested that the replacement of barren grounds by kelp forests in reserves reflects the high abundance of predators that consume sea urchins, though that conclusion is contentious. Those studies are of considerable importance internationally, since only in New Zealand have completely protected marine reserves been established for sufficient duration to determine long-term effects.

Scientific investigations targeting blue cod and spiny lobsters have recently been undertaken in more southern marine reserves, and have generally found evidence of increased abundances and/or size similar to those done in North Island marine reserves. As more studies are undertaken in reserves the generality of effects will emerge. It is not surprising that humans have important effects on populations of marine organisms, given the intensity of fishing effort, improved positioning capacity via GPS, and improved quality of access due to changes in both roading and vessel capabilities. Strong gradients of fish abundance and size in relation to access and/or protection status are obvious in many fisheries.

Summary

New Zealand's coast contains most physical environments and biological habitats common in temperate regions worldwide. Knowledge of physical and biological environments is increasing rapidly. Direct and indirect human activities are important influences on marine systems. Coastal developments, introduced species, aquaculture and marine reserves will be important influences on nearshore marine systems in the future.

NEW ZEALAND, COASTAL GEOMORPHOLOGY AND OCEANOGRAPHY

Historical background

New Zealand's coastal geomorphology exhibits a myriad of coastal landforms and sedimentary deposits, varying from estuarine types of fiords, rias, barrier enclosed estuarine lagoons, eroded calderas, and flooded grabens; to rocky cliffs and shore platforms, raised coastal terraces; to modern sandy Holocene barrier islands and spits, modern long sandy beaches and bayhead pocket beaches; and various types of nearshore sedimentary facies, to Pleistocene paleo-barriers; to various types of mixed sand-gravel beaches, boulder beaches and barriers; to muddy tidal flats and shelly gravel chenier ridges and beaches.

From the early 1900s, the classical geomorphology of New Zealand was widely expounded in the publications of Sir Charles Cotton, and especially in his book "*Geomorphology of New Zealand Part 1: Systematic*" first published in 1922 and revised as "*Geomorphology: An Introduction to the Study of Landforms*" (Cotton, 1942). About one-fifth of this classical text was devoted to coastal processes and landforms, including especially submerged and emerged coasts. Cotton (1974) later published the book "*Bold Coasts*" comprising a series of his papers on rias, cliffs, and rocky coasts and drawing widely on New Zealand examples. Cotton's pioneer work was focused primarily on deductive interpretation of erosional geomorphic features such as cliffs, headlands, and "old hat" platforms, from the Davisian geomorphic cycle perspective. Little emphasis was accorded coastal sedimentary deposits or investigation of coastal processes, although naturally at that time there was little technological capability to measure coastal geomorphic processes. Likewise some of the early New Zealand geologists and geographers, viz. P. Marshall, J. Bartrum, and G. Jobberns, wrote deductive papers on aspects of coastal geomorphology, for example, the origin of gravel in the Hawkes Bay beaches, and the origin of shore platform high level benches around the Auckland area. Jobberns was the first specialist "coastal geomorphologist," and researched the raised strandlines of North Canterbury (McLean, 1977). But at that time there was no fundamental research involving quantitative measurement of coastal sedimentary deposits or landforming processes. Healy and Kirk (1982) addressed this issue, and presented a more modern synthesis of New Zealand coastal geomorphology.

Figure N19 Professor Roger McLean, who may be regarded as the "father" of modern coastal geomorphology in New Zealand.

J.C. Schofield (1960) is credited with undertaking the first substantive surveys combined with shallow cores and dating to obtain quantitative data for New Zealand coastal evolution. His pioneering paper on the origin of a sequence of 13 progradational chenier ridges at the muddy head of the Firth of Thames attempted to relate progradational phases to oscillations of late Holocene sea levels. Later Schofield (1970) also published the first substantive regional beach sedimentological investigations based upon textural and mineralogical analysis of multiple samples from representative sand beaches of the northern half of the North Island.

The first modern systematic beach studies—involving quantitative measurement of form and process of Canterbury mixed sand-gravel beaches (McLean and Kirk, 1969)—were established at University of Canterbury in the 1960s by R.F. McLean, who may be regarded as the "father" of modern coastal geomorphology in New Zealand (Figure N19). McLean's student, R.M. Kirk, has continued coastal geomorphic studies at Canterbury since the 1970s. In 1973, sandy beach and estuarine sedimentary and process research was initiated at University of Waikato by T.R. Healy, where since 1980, and in collaboration with the pioneering developments in numerical simulation of two- and three-dimensional flows, waves, and sediment transport modeling of K.P. Black, the largest undergraduate and graduate school for coastal geomorphic and oceanographic studies in the country developed in the 1990s. Coastal geomorphic studies were also established at University of Auckland from the late 1970s, initially under the leadership of R.F. McLean and subsequently by K. Parnell. In the 1980s, a coastal unit with emphasis on numerical modeling was established within the then Ministry of Works and Development, but with restructuring of scientific research in the early 1990s, this group became part of the National Institute of Water and Atmosphere (NIWA), and under the leadership of T.M. Hume, has since grown into the largest group of coastal geomorphic and oceanographic researchers with strong national standing in New Zealand.

Environmental factors influencing New Zealand coastal geomorphology and processes

The distinctive diversity of coastal geomorphic types and sedimentary deposits characteristic of the extensive New Zealand coastline evolves from a combination of geological structure, tectonic and seismic history, lithology, a mid-latitude oceanic setting for wave and tidal processes, Pleistocene events, and climatic influences.

Geological structure and lithology. A series of lineal axial ranges comprise the essential structural backbone of New Zealand. In the North Island, these consist of lightly metamorphosed and intensely jointed Mesozoic greywacke, and in the South Island, of greywackes and metamorphosed Paleozoic schists of Otago and the alpine fault zone through to gneiss and granodiorites of south Westland. On-lapping the axial ranges are younger Tertiary rocks, predominantly soft clay-rich siltstones and some limestones, while ancient volcanic mounds punctuate the landscape. In the central North Island the active Taupo Volcanic Zone (TVZ), stretches from Lake Taupo to beyond the Bay of Plenty coast. The northern North Island exhibits evidence of back arc andesitic and acid volcanism, with basaltic volcanism around Auckland and Northland. This diversity of lithology provides a wide variety of topographic forms and sediment for distinctive beach types and coastal landscapes.

Influence of structure and Pleistocene events. New Zealand, like Japan and northern California, sits astride a plate margin where the coastal geomorphology closely reflects the adjacent lithology as well as historical geological events. Mesozoic and Tertiary orogenies created the basic axial ranges, the backbone of the country. Ongoing plate margin evolution saw the development of the transcurrent Alpine Fault stretching from the south of the South Island along the southern Alps and across Cook Strait to Wellington and through to Hawkes Bay. Along this transverse fault system the active earthquakes and tectonic dislocations have influenced the coastal geomorphology by creation of drowned transverse fault aligned valleys (rias) of the Marlborough Sounds and uplifted coastal terraces around Wellington.

An important element of structure is the alignment of the main islands comprising New Zealand along the plate margin and active subduction zone. Subduction of the Pacific plate under the central North Island results in a number of geologic processes including the active

TVZ, rapid tectonic uplift, folding, faulting, and stratal slumping with associated high seismic activity. These seismic and tectonic (uplift and downsinking) processes in the geological evolution, which are continuing at present, have occurred on both a regional and local scale. They enhance denudation of the hilly and highland catchments, providing high sediment loads to the coasts. Regional downsinking has helped create the rias of the Marlborough Sounds, while regional uplift in the central North Island has resulted in incised rivers without significant estuaries (e.g., Waitara River) cut into coastal terraces.

Events in the Pleistocene also played a major role in molding the modern coastal landscapes. Severe valley glaciation in the south Westland gneissic province produced glaciated U-shaped valleys, which upon drowning in the Holocene transgression have become classical fiords. The intense physical weathering of the fractured greywackes and schists, associated with the glaciations in the Southern Alps, provided outwash sands and gravels to build up alluvial fan deposits, the most striking example of which is the Canterbury Plains. These subsequently became blanketed in loess. Periglacial weathering action in the ranges of the North Island assisted in delivering a large volume of gravel sediment to the lowland plains and coast, notably in Hawkes Bay. Of course at that time the lowland plains extended 100–120 m below present sea level, so that many sand deposits were reworked over the inner continental shelf as sea level rose with the post-glacial transgression.

Influence of volcanism. Both modern and ancient volcanic influences are evident in the coastal geomorphic landscape. Eroded caldera in the ancient volcanic mound of Banks Peninsula today contain the harbors of Lyttelton and Akaroa. Volcanic deposits have also had an important influence in the central North Island west coast where erosion of lahar flows provides both cobbles and boulders for veneer beaches over eroding shore platforms, as well as the distinctive black titano-magnetite heavy mineral sand for the extensive sand littoral drift systems of the North Island west coast. Propylitized Miocene andesites and Pliocene rhyolites and ignimbrites comprising the Coromandel Ranges are back arc volcanics and have provided distinctive mineralogy for the beach sands of the embayed east Coromandel Peninsula.

Around the Auckland isthmus some of the numerous Pleistocene basalt volcanic cones are now eroded headlands, with the outstanding landscape feature being the recently formed island of Rangitoto, which erupted as Hawaiian-type fluid basalt flows, and is surmounted by a scoria cone crater active as recently as 600 years ago. Pleistocene and modern active volcanism from the TVZ has demonstrably influenced coastal evolution in the Bay of Plenty, where denudation of the acid volcanic tephras has provided large volumes of sand to the littoral zone. This has accumulated in the broad embayments to create extensive Holocene dune ridge progradations. The eruption of Mt. Tarawera (1886), which blanketed the surrounding landscape with pumicious deposits, provides detailed evidence of the impact of a large influx of sandy sediment into the coastal littoral system, and the air-fall ash deposit on the coastal dunes allows reliable dating of progradation rates (Pullar and Selby, 1971; Richmond *et al*., 1984). The ability to use the technique of tephrachronology has allowed reliable dating of Pleistocene and Holocene dune and barrier deposits and interpretation of rates of geomorphic evolution along both the west and east coasts of the North Island.

Wave and climate influences. The mid-latitude oceanic islands of New Zealand are dominated by southwesterly waves originating from the Southern Oceans, and driven by the prevailing southwesterly winds. These waves, typically of period ~8–11 s and height ~1–3 m, drive littoral drift systems within regional and local coastal compartments along the west coasts. On the east coast of the South Island and the southeast coast of the North Island the wave climate is likewise predominantly swell from the southern oceans. North of East Cape (North Island), the embayed coast—a "lee coast" from the prevailing westerly winds—is sheltered from the southerly swells and is subject to a mixture of distant Pacific swells and local storm and wind- generated waves, typically with periods of 7–9 s and heights of 0.5–1.5 m from variable onshore directions. Episodic storms, especially decaying tropical cyclones from the north, generate an important component of the wave climate which cause dune erosion problems.

The El Niño–Southern Oscillation (ENSO) plays a major role in the beach geomorphology and coastal oceanography. In El Niño conditions New Zealand experiences continual 15–20 knot winds from the southwest. This causes a surfeit of orographically induced rainfall and flooding particularly in Westland of the South Island, and enhancing sediment supply to the coast, while the constant onshore wind stress induces downwelling on the coast and inner shelf. But on the east coasts, particularly of the North Island, the continual offshore wind stress induces drought conditions, onshore transport of nearshore sands, and inner shelf oceanographic up-welling. As a result the east coast beaches become generally well accreted in El Niño conditions and the coastal upwelling brings nutrient-rich ocean waters to the inner shelf, which enhances conditions for algal and phytoplankton blooms in the nearshore coastal waters and harbors—a condition which severely impacts on fisheries and aquaculture industries. During the La Nina phase the opposite conditions occur, with more frequent, stronger northeasterly winds causing erosional tendencies for the northeast coast beaches, but upwelling induced algal blooms on the west coast. To date it is not clear whether the west coast beaches significantly accrete during La Nina conditions.

Tidal effects. Tides are of the semi-diurnal type. Walters *et al*. (2002) calculated the tidal amplitudes around the oceanic islands of New Zealand based upon the predominant M2 constituent, to produce an approximate mean tide range. Based upon the tidal gages at the "standard ports," the average tidal range is 1.8 m with spring means of 2.1 m and neap means of 1.4 m. The tidal ranges are predominantly micro (<2 m mean tide). Largest tidal ranges (>3.5 m mean tide) occur in Tasman and Golden bays in the northern South Island, and along the central west coast (e.g., Onehunga, Port Taranaki) and exhibit a mesotidal (>2 m to <4 m) mean range. However, spring tidal ranges in some areas approach 4 m. Lowest tidal ranges occur along the East Coast region. In most ports and harbors (e.g., Bluff, Lyttelton, Dunedin and Timaru ports and Manukau, Kaipara and Whangarei harbors) the tidal range is amplified relative to the open coast tidal range, indicating a hypersynchronous tidal condition, while two (Wellington, and Picton) are suppressed, indicating a hyposynchronous tidal condition. The difference in tidal phase between the west and east coast results in strong tidal currents through Cook Strait separating the main islands.

Regional coastal geomorphology

The New Zealand coastline can be classified into several distinctive geomorphic sectors (Figure N20).

High-energy North Island west coast. This sector is subjected to high wave energies with prevailing onshore winds, and a divergent littoral drift system, flowing northwards north of Cape Egmont and north of Wellington, and southwards south of Cape Egmont. The coastline is essentially curvilinear in alignment. Around Taranaki, the coastline exhibits low cliffs and rugged terrain, with gravel boulders littering the shore platforms cut into the lahar deposits which flowed from Mount Taranaki. The high wave energies and swell wave refraction around small promontories create numerous locations for good surfing waves, with renown "breaks" at Raglan and other locations. The distinctive fine "black ironsands" comprise titanomagnetite heavy mineral mainly eroded from the Taranaki lahars, which in some Pleistocene dune deposits is of sufficient concentration to mine (Waverly, Taharoa). There is a general reduction of heavy mineral concentrations away from Taranaki, both north and south. South of Cape Egmont, wave refraction induces a southeastward moving drift, but north of Cape Egmont there is a consistent northward drift to North Cape. Beaches along this sector typically exhibit a dissipative morphodynamic regime. Some of the littoral system is cliffed but the high-energy waves also move sand on the submarine cut platforms of the inner shelf. The coastal sector centered on Taranaki is also undergoing rapid tectonic uplift forming coastal terraces, so that rivers, such as the Waitara, are actively downcutting and no large estuaries occur. North of Kawhia Harbor a number of large shallow barrier enclosed estuarine lagoon harbors occur (Aotea, Raglan, Manukau, and Kaipara). Each is a tidal inlet type, but unusual in that the barriers enclosing the harbors comprise Pleistocene dunes up to 300 m high, and depending upon tidal discharge relative to wave exposure, these tidal inlets tend to have well formed fan shaped ebb-tidal deltas. Because of the high tidal ranges the currents in the inlet gorges tend to be strong—as much as 4 m/s.

Northeast embayed "lee" coast. Between North Cape and East Cape the coast is characteristically indented, including several large embayments with many islands (e.g., Bay of Islands, Hauraki Gulf). The embayments possess compartmentalized sandy littoral drift systems, some of which may be quite extensive (e.g., Bay of Plenty, Bream Bay, Doubtless Bay, Pakiri-Mangawhai), and contain extensive Holocene dune ridge sandy barrier progradation systems. The typically hilly catchments and active erosion of the soft Tertiary lithologies means that

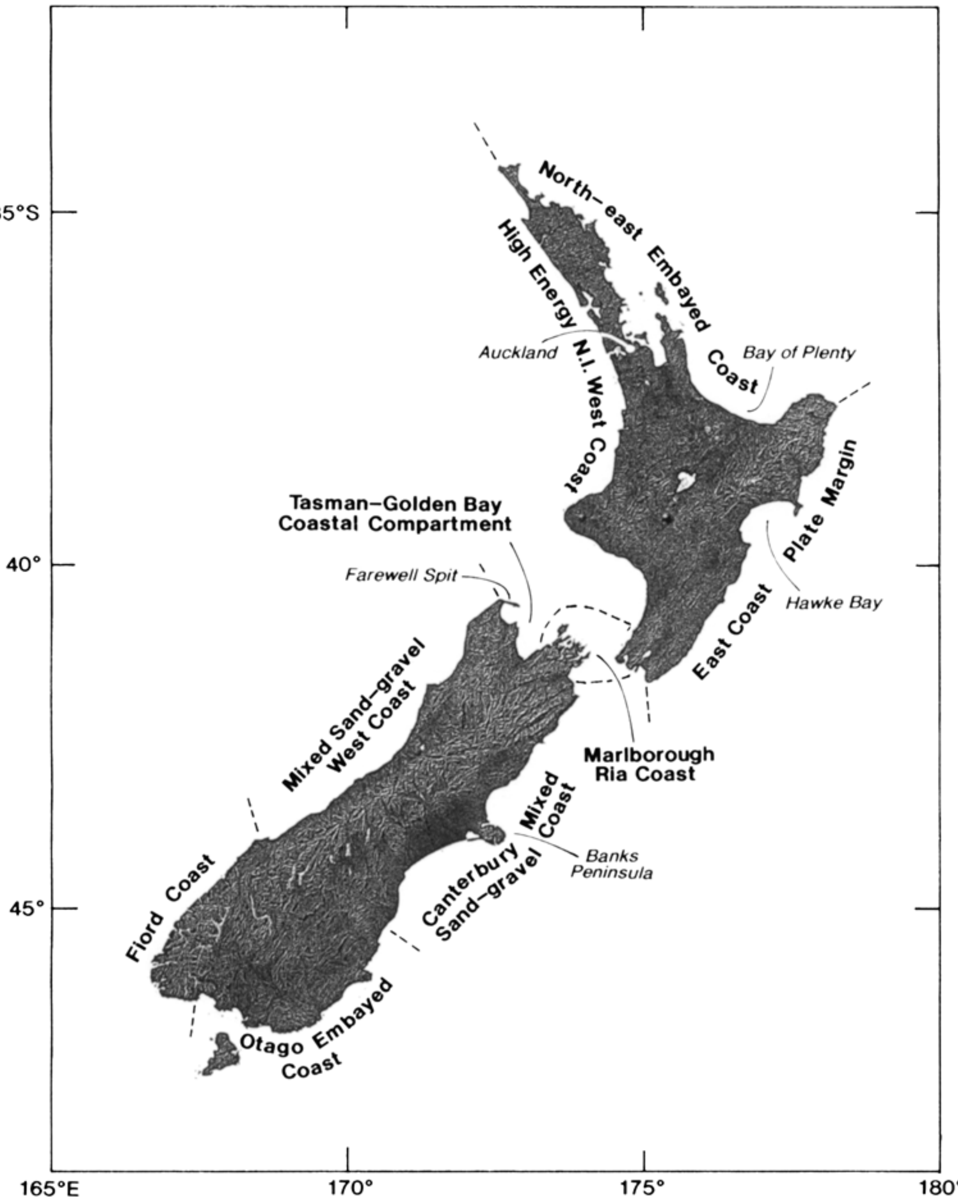

Figure N20 New Zealand coastal geomorphic provinces.

the drowned river valleys have to a large extent become infilled with sediment, so that the harbors are typically shallow and display extensive intertidal flats. At the mouth of many former drowned river valleys are Holocene sandy dune ridge barrier spits (e.g., Pauanui, Matarangi), which enclose shallow infilling estuarine lagoons. Within the Hauraki Gulf the soft Miocence alternating sandstone–siltstone flysch rocks have undergone rapid erosion in the Holocene and today display active cliffs and extensive shore platforms up to 400 m wide.

The Bay of Plenty contains the longest littoral system of the northeast region, and is dominated by low refracted swell waves of $T = 7$–9 s and $H = 0.5$–1.0 m. The bay is notable for containing the largest Holocene progradational extent of dune sands, 9 km in the Rangitaiki Plains, and also the largest barrier island (Matakana Island) in the country. The extensive Tauranga Harbor, geomorphically a barrier enclosed estuarine lagoon, is $\sim$70% exposed intertidal flats at low tide, and possesses a unique enclosing barrier system comprising Holocene barrier tombolos and an intervening barrier island. The surfeit of sand in the Bay of Plenty system is derived from the adjacent TVZ, having been brought to the coast during the Pleistocene, and reworked across the shelf during the Holocene post-glacial transgression, with continuous additions from some of the larger rivers.

The Firth of Thames graben is not typical of this "lee" coast, but is notable for containing a major area of muddy coast, with deep Holocene mud deposits, broad intertidal mud deposits, and a well-developed shelly chenier ridge plain (Healy, 2002).

East Coast Plate Margin coast. Extending from East Cape to the Wairarapa and Wellington is a rocky, eroding high-energy, mainly cliffed coast with extensive shore platforms cut into the Tertiary rocks. The coast is surmounted by veneer sandy pocket beaches in shallow embayments, and often backed by raised marine cut terraces. This coast is seismically active and undergoing rapid uplift due to subduction processes. The general NE–SW alignment is broken by two large embayments, Poverty Bay and Hawke Bay. Poverty Bay lowlands comprise intercollated dune ridges and alluvial deposits. The high discharges from the Waipaoa River eject considerable muddy suspended sediment from the soft Tertiary mudstone catchments into the nearshore and continental shelf. Thus paradoxically, this coast is high energy but possesses very muddy sediment at shallow depths due to the high mud supply. Hawke Bay is likewise subjected to high muddy river discharges to produce muddy sediment at shallow depths, but the rivers here also deliver greywacke from the central axial ranges, so that the beaches are predominantly composed of mixed sand

and angular greywacke gravel. Resulting from the Napier earthquake of 1931, a large area of shallow seafloor and harbor was uplifted ~2 m to create new coastal lowland backed by degraded cliffs where marine processes are no longer active.

Marlborough Sounds ria coast. Fault aligned valleys, transverse to the coastal alignment, result in classical rias (*sensu stricto*) known as the Marlborough Sounds. The structural alignment and transcurrent faulting have created long linear rias. The steep hillslopes dip below the waterline with only minimal interruption to the profile and there is relatively little infilling sedimentation except at the valley heads. Thus the rias remain deep. Wellington Harbor on the southern North Island is likewise part of the ria coast.

Canterbury mixed sand–gravel coast. This is a distinctive and unusual littoral drift coastal sector formed from high-energy storm and swell wave processes eroding the alluvial outwash gravel deposits comprising the Canterbury plains (Kirk, 1980). The result is a well-formed steep berm beach comprised of mixed sand–gravel sediments which are fed partly by direct erosion of the outwash gravel deposits and partly from episodic inputs from the several large braided gravel river systems. Along sectors of the coast the active synoptic beach berm is surmounted by higher storm berms which reach almost 20 m above sea level adjacent to Banks Peninsula. Erosion of the outwash gravel deposits has resulted in low coastal cliffs behind the beach along the southern sector. South of Banks Peninsula backing dunes are rare, but they do occur on the sector north of the Peninsula. Banks Peninsula itself comprises a Miocene andesitic volcanic mound with eroded calderas creating present-day harbors. Eroded loess deposits blanketing the hills have provided muddy infill sediments within the caldera harbors.

Southeast Otago cliffed and mildly embayed coast. Low hills of southeast Otago result in a mainly cliffed coast with pocket sand beaches and where rivers reach the sea. The region receives large swells from the southern oceans, and the beaches typically exhibit high-energy morphodynamic conditions. Otago Harbor is a ria that has become largely infilled.

Fiord Coast of South Westland. The southwest tip of New Zealand comprises a gneiss and granodiorite massif standing up to 3,000 m above sea level. At the coast precipitous slopes drop down to, and below, sea level. Some boulder beaches occur but the coastline is predominantly steep. Pleistocene valley glaciations have carved a spectacular landscape of classical U-shaped valleys, forming classical fiords where they have become flooded at the coast (e.g., Milford Sound, Doubtful Sound). The location in the zone of "roaring forties" and high topography means that the region receives very high precipitation, which provides fluxes of freshwater to drive a fiord-type estuarine salinity structure and circulation. As the area comprises national park the natural environment of this spectacular forested coastline remains in an essentially pristine condition.

Mixed sand–gravel sector of the South Island west coast. Waves from the southern oceans drive a northward littoral drift with sediment being fed to the littoral system by the numerous braided gravel rivers draining from the Southern Alps. The beaches in the southern sector are mixed sand–gravel type, and the wave climate is high energy. As in the North Island west coast littoral system, sand evidently bypasses rocky cliffs, and ultimately feeds the large sand deposits of the 30 km Farewell Spit at the northern tip of the South Island.

Golden and Tasman bays sandy compartment. Located between the Marlborough Sounds and Farewell Spit are sandy compartments. Two features are remarkable here, namely the existence of a low dune ridge Holocene barrier island (one of only two in New Zealand) and the 13 km long Nelson boulder barrier spit, which encloses a shallow muddy lagoon of Nelson Haven. About half of the enclosed area has been reclaimed, and the region possesses one of the highest tidal ranges in the country.

Major coastal geomorphic and oceanographic research achievements in the modern era (post-1970)

In the 1960s, the modern era of quantitative and process-based coastal research in the universities commenced. Research was initially centered on shore platforms, and beach morphology and sediments based upon the contemporary concepts of the sediment budget and process response model (McLean, 1977). Hume *et al*. (1992) outline the major achievements of coastal geomorphic and oceanographic research until about 1990.

Estuarine sedimentation. In the 1970s, there were rising concerns about the impact of changing land use practices—especially urbanization—on the water quality, biology, and sedimentation in estuaries. Early integrated interdisciplinary studies were initiated on the Avon–Heathcote estuary, the Pauatahanui Inlet, and the Waitemata Harbor. Numerous systematic sedimentological studies followed, often undertaken as thesis projects from the universities, especially from the Waikato University group (Healy *et al*., 1996). Most studies tended to concentrate on either the ecology or surficial sediments and only limited interdisciplinary investigations occurred.

Tidal inlets. New Zealand tidal inlets tend to have formed where Holocene barrier spits form across the embayment at the entrance to reentrant valley estuaries. They are found predominantly in the northeastern North Island where about 30 such features exist. They possess the typical morphological features of a narrow inlet gorge, and ebb and flood delta sand bodies, and are dynamic equilibrium systems. R.A. Heath investigated the tidal hydraulic equilibrium of the major inlets. The first quantitative hydrodynamics and sediment transport investigations were carried out by R.J. Davies-Colley around the entrance to Tauranga Harbor in 1976, where, prompted by port developments, the most comprehensive and detailed studies in a New Zealand inlet have since been carried out. Hume and Herdendorf (1990) provide a comprehensive compilation of morphological and empirical factors controlling New Zealand tidal inlet stability.

Numerical modeling of coastal hydrodynamics and sediment transport. Hydrodynamic numerical modeling of estuarine and inlet tidal flows was introduced to New Zealand relatively early by the pioneering work of K.P. Black when he developed his prototype one- and two-dimensional models for current flows and sediment transport in the tidal inlet at Whangarei Harbor (Black, 1983). For calibration and verification of the model, as well as wider understanding of the inlet physical system, an extensive field research program included hydrographic surveys, water level recorders, side-scan sonar mapping of the bottom sediments, a wide range of bottom photographs and sediment sampling taken by SCUBA diving, continuous recording current meters, drogue tracking of current flows, numerous tidal cycle vertical current profiles, and sediment traps, and underwater video records and sediment threshold experiments, and wave refraction studies. Subsequently modeling of estuarine and inlet hydrodynamics has been widely applied (Black *et al*., 1999), initially in Tauranga Harbor, but also in most of the ports, and across a wide range of applications. In more recent years, the models have become three-dimensional (Black *et al*., 2000) and applied to a range of EIA problems such as pollution dispersion associated with outfall effluents.

Tsunami modeling and research. New Zealand has experienced at least 32 identifiable tsunami events during its recorded history, but to date without the disastrous consequences experienced by Japan. The largest reported tsunami wave elevations were of order 10 m, originating primarily from local sources. The largest pan-Pacific tsunami recorded was the May 1960 Chilean tsunami which produced a wave elevation of 7 m at Whitianga in Mercury Bay. The most comprehensive tsunami research has been carried out by de Lange and Healy (1986) and their students. As part of disaster emergency planning and response, several tsunami scenarios have now been modeled for coastal sectors and harbors identified as potentially susceptible to significant tsunami impacts, for example, the Waitemata Harbor of Auckland city, the Bay of Plenty, Gisborne, Wellington Harbor, Port Lyttelton, and the Canterbury coast. Modern research is focusing on the ability of submarine slumping mechanisms to generate localized tsunami waves as occurred in March and May, 1947, centred around Tatapouri north of Gisborne.

Beach erosion and morphodynamics. As in many countries, severe beach erosion, especially when coastal property is placed at risk, spawns research programs on beach morphodynamics and beach budgets. The first integrated coastal erosion survey was along the Bay of Plenty coast in 1976–77, where episodes of erosion resulted in rapid duneline retreat, loss of houses, and construction of sea walls. The most spectacular example of erosion was along the embayed Holocene barrier spit of Omaha Beach, where in 1978 the seawall fronting a new subdivision was demolished at the height of a storm. This led to several studies seeking the cause and appropriate remediation, as well as litigation. Although the subject of much "expert" debate at the time, most would agree today that the cause was related to a long-term negative sand budget due to historical sand mining from the spit, consequent duneline retreat, and severe wave energy focusing in the storm. Other cases of erosion occurred locally as a result of interruptions to the littoral drift such as at inlets (e.g., Ohiwa Harbor) or downdrift of port developments (e.g., Port Napier and Port Taranaki), or due to sand mining from the beach (Papamoa in the Bay of Plenty). Concern for the sustainability and impact of long-term sand extraction from the nearshore zone along the 30 km Pakiri–Mangawhai coastal compartment resulted in a large and comprehensive study from 1996 to 1999. The study, lead by NIWA in collaboration with the universities of Waikato and Auckland, involved assessment of sand volumes onshore in the Holocene dune fields, investigation of the surficial sediment patterns from side-scan sonar mapping, bottom photographs and sedimentology, and shallow subsurface seismic profiling with calibrating vibrocore data. Historical beach profile data were analyzed for beach sediment budget. Oceanographic data were measured with recording current meters and wave gauges, and the wider Hauraki Gulf subjected to hydrodynamic and sediment transport modeling.

Beach–shore face–inner shelf sedimentation dynamics. It became evident from a number of studies that strict wave driven alongshore littoral drift is often difficult to ascertain for the compartmentalized New Zealand coast. The earliest studies linking the beach with the inner shelf sediments arose from investigations into severe beach erosion episodes at Omaha and Mangawhai beaches north of Auckland and the east Coromandel beaches, which had suffered during the "decade of erosion" from 1968 to 1978. The most detailed studies during the 1980s were on the east Coromandel "lee" shelf by B. Bradshaw and collaborators. These studies linked closely with the detailed research monitoring the dispersal of sandy dredged material on the inner shelf off Tauranga Harbor by the Waikato school. During the decade of the 1990s, NIWA undertook detailed research on inner shelf and beach sedimentary morphodynamic linkages offshore from the Katikati inlet to Tauranga Harbor.

Port developments and dredging issues. Requirements for port development EIAs have driven considerable research into the impact of dredging and spoil disposal. The most detailed work has been undertaken around the Port of Tauranga, a port which has expanded to become the largest export–import in the country during the last decade. The large Tauranga Harbor Study (1983–85), the most intensive harbor study to date, arose from the need to investigate whether dredging through the tidal delta inlet system had substantially affected the channel hydraulics and morphodynamic changes of the flood tidal delta and channels. Subsequent studies were undertaken on the dredge spoil dispersion on the inner shelf and shelf-beach interaction, as well as further studies on the impact of deepening the channels to take post-panamax sized vessels. Those physical and sedimentological impact studies were matched with ecological impact studies. Disposal of dredged material became a major environmental and litigation issue for the Port of Auckland, and resulted in an inquiry spawning numerous reports from the Dredging Options Advisory Group (DOAG).

Coastal hazard analysis and development setback planning. Assessment of coastal hazard and development setback has been a requirement for coastal local authorities since the 1970s. The first New Zealand application of quantifying the independent components of coastal hazard along a sandy duned coast was evolved by T.R. Healy for the setback of new subdivisions along the Bay of Plenty coast in 1976, and included quantitative assessment of the four independent parameters of long-term erosion (or accretion) trends, short (decadal) term "cut and fill" duneline fluctuations, assessment of expected sea-level rise effects, and the dune topographic stability factor. Summation of these four independent factors allows determination of an initial setback estimate, measured from the toe of the frontal dune, and based upon a planning time frame of 100 years (Healy and Dean, 2000). The methodology has been widely applied and is similar to that later proposed by J.G. Gibb (1981). Over recent years the methodology has been refined and the initial setback determination is now subjected to three tests, viz. (1) Is there sufficient reservoir of sand in the frontal dune to allow for the 1 : 100 year storm erosion episode? (2) Is the setback sufficient to allow for the 100 year storm surge? and (3) Is the setback sufficient to allow for tsunami washover? If the initial setback estimate is still subject to the above hazards, the setback is extended landwards beyond the zone of hazardous impact. The methodology may also be applied to existing subdivisions, in which the setback zone becomes a zone of non-further development.

Methodology for hazard analysis of development setback for cliffed coasts is given by Moon and Healy (1994) based upon identification of the mechanism of slope failure, and addition of a safety factor. For the cliffs cut into Miocene flysch deposits of the Waitemata Formation around the city of Auckland, the typical 100 year hazard setback is taken as ~16 m plus a safety factor of 7 m.

Innovative coastal environmental solutions and engineering applications. Early coastal engineering solutions to coastal erosion problems followed standard international practice of the early 20th century, and groins and seawalls were erected in many locations of localized coastal erosion. Most have subsequently failed or require expensive continuous maintenance. Since the 1970s, however, the environmental philosophy of allowing "nature to function in nature's way" has tended to hold sway, so that much scientific effort has been expended on understanding the coastal dynamic systems rather than resorting to "hard" engineering solutions. Many innovative applications have been demonstrated. Among the more notable are: (1) The application of *sediment transport modeling* at the design stage by K.P. Black in 1983 to determine the optimum length of bridge span relative to causeway length for the Tauranga Harbor bridge, which would minimize scour and shallow estuary morphodynamic impact. This resulted in a reduction of the steel bridge span and a saving of about $800,000 to the cost of the bridge construction. This application firmly demonstrated the value of numerical simulation as a major coastal processes tool. (2) The development of the concept of *artificial surfing reefs* by K.P. Black. This initiative originated during the late 1990s (Black *et al.*, 1997) with the dual purposes of coastal protection against beach erosion, and for enhancing breaking waves for surf board riders. The first arti-ficial reef so designed was constructed at Narrowneck on the Queensland Gold Coast in 1999. The reef units themselves are comprised of geotextile bags filled with dredged sand, a low cost construction system. Several such artificial surfing reefs are planned for New Zealand, including at Mt. Maunganui in the Bay of Plenty, New Plymouth and Opunake on the Taranaki coast, and at Summer Beach near Christchurch. (3) In the late 1990s, considerable work has been undertaken on the *re-design of Port Gisborne* to accommodate the large expansion of timber product for export coming on stream from 2005. An intensive field and modeling program has been undertaken and initial designs subjected to wave and sediment transport modeling (Healy *et al.*, 1998). This innovative application is to include substantial public amenity in the re-designed port-enclosing breakwater so that it acts as an artificial surfing reef to enhance a left hand break for the Pacific swells refracting into Poverty Bay. (4) *Artificial headlands for low-energy estuarine beach geomorphology* have been designed and implemented as a coastal erosion and coastal management option in the Waitemata Harbor, Auckland (2000). The artificial headlands use the principle that wave refraction into embayments at high tide will reduce sediment loss from the upper estuarine beach face by wave driven littoral drift, and induce retention of the sand and shelly gravel within the embayments. (5) The *use of dredge spoil for beach replenishment* has been applied at a few open coastal locations, including near Port Napier, Port of Tauranga, and Port Taranaki. These cases have used the concept of depositing the sandy dredge spoil as a berm in the shallow nearshore, with wave action taking the sediment on to the beach. The most detailed investigation has recently been for Port Taranaki (1997–99) where an extensive field program, including a large-scale tracer experiment, and supplemented by wave and current driven numerical simulation, has identified a suitable disposal site, which in conjunction with a planned artificial surfing reef, aims to re-establish the beaches of New Plymouth which had disappeared as a result of updrift port breakwater construction (McComb *et al.*, 2000).

Issues for the future

Research in the early years of the 2000 millennium is likely to concentrate on ongoing port developments and environmental impacts of dredging and disposal. Under development is investigation of the nature of mud deposition in ports and marinas, and attempts to induce its removal by "mud re-agitation" techniques, which requires ongoing field studies and numerical simulation of the results. Issues of the impact of sediment extraction from the littoral zone and the importance of closure depth and the links between diabathic and parabathic exchange will come under increasing scrutiny, and continuing developments can be expected in the frontier of morphodynamic numerical simulation of sedimentary bodies. Considerable effort is being undertaken to research beach and frontal dune behavior as part of "Dune-Care" programs in which local communities become stakeholders in the management and protection of the dunes. With the advent of modern data collection the application of marine GIS linked with dynamic modeling, presently unknown in the New Zealand context, will develop for wide application. Overall New Zealand has a sound basis of research achievements to tackle the coastal morphodynamic issues of the new millennium.

NORTH AMERICA, COASTAL ECOLOGY

The North American coastal ecosystems range in latitude from tropical Mexico to arctic Canada and have long been identified as among the most productive in the world (Odum, 1963). In reality, there is a broad range of annual productivities (ranging from several hundred to several thousand grams carbon) as well as species diversity. In the Arctic few species dominate the coastal ecosystems, while in the south along the Mexican coasts species diversity is especially rich (Lot *et al*., 1993). Widely varying in geomorphology and chemistry, they comprise: hypersaline lagoons, cheniers, coralline islands, temperate estuaries and barrier islands of the US Atlantic coast; as well as vast stretches of beach and permafrost coastlines of northern Canada and a myriad of rocky intertidal communities and embayments along the Pacific Coast to Mexico (Odum *et al*., 1974). As in most ecosystems, solar radiation exerts primary control on productivity and ultimately impacts distributions of the numerous species. Also critical in influencing the structure and function of these coastal systems are organic matter and nutrient exports from upland sources, as well as tidal energy. In contrast to terrestrial systems where precipitation is considered second in importance to input solar radiation, the force of astronomically driven tides is extremely important in structuring coastal systems which range along this coastline from below a centimeter in some marshes of Chesapeake Bay (Stevenson *et al*., 2001) to over 10 m in the Bay of Fundy (Chmura *et al*., 2001).

Water, critical in determining the productivity of terrestrial systems, is the key medium for exchange of energy and nutrients in coastal systems. Generally, inflows of freshwater from rivers are responsible for supplying organic materials and nutrients to coastal estuaries and lagoons as well as control of seasonal changes in salinity. Freshwater inflow plus tidal activity (along with bathymetric configuration of coastal water bodies) largely determine rates of mixing and flushing. Thus, the hydrological inputs at varying local and regional scales are critical in modulating responses to increasing nutrient loadings, which cause numerous changes in coastal ecosystems (Malone *et al*., 1993; Turner and Rabalais, 1994; Bricker and Stevenson, 1996; Vorosmarty and Petersen, 2000).

Drainage basin and river discharge

Although the magnitude of freshwater runoff is responsible for structuring estuaries (Pritchard, 1967), water quality is critical in determining their productivity. Increasing the flux of relatively few critical elements (e.g., nitrogen, phosphorus, and silica) in freshwater discharges to coastal waters can cause eutrophication (i.e., abundant nutrients promote high phytoplankton biomass which consumes large amounts of oxygen as it decomposes) negatively impacting submersed grasses and traditional fisheries (Twilley *et al*., 1985; Stevenson *et al*., 1993). Water balance/runoff models, geographic information systems (GIS), and remote sensing are tools increasingly used to relate changes in land use to fluxes of nitrogen, phosphorus, and organic carbon into coastal systems. The generalized watershed loading function (GWLF) is an example of a widely used model to estimate nitrogen and phosphorus loading from runoff and groundwater in northeastern watersheds of the United States (Haith and Shoemaker, 1987). In this model hydrologic fluxes are driven by daily weather data, including rainfall, evapotranspiration, and snowpack melting (the last two inferred from temperatures). Groundwater fluxes are estimated from considering both vadose (unsaturated) and phreatic (saturated) contributions in watershed soils. Suspended sediment inputs, important in coastal turbidity and as vectors for trace metals (and other particle-reactive pollutants), have traditionally been estimated from the Universal Soil Loss Equation (Gottschalk, 1964).

Once nitrogen, phosphorus, and other materials enter receiving waters they are subject to bioprocessing by various biochemical processes. Remineralization of organic material at the edges of coastal watersheds occurs when bacteria interact with dissolved and particulate phases, in wetlands and rivers. First-order streams, are perhaps the most important elements of coastal watersheds in bioprocessing as the time and volume of water in contact with wetland and the benthos is greater than in higher order streams (Peterson *et al*., 2001). Nitrogen, the most common element in fertilizer, transported as nitrate in streams or volatized to ammonium (NH_4^+), often ends up in coastal embayments (Pearl, 1985; Staver and Brinsfield, 1996). However, since biogeochemical buffering often occurs, actual nutrient delivery to coastal waters is not as great as watershed yield coefficients of particular land uses might suggest.

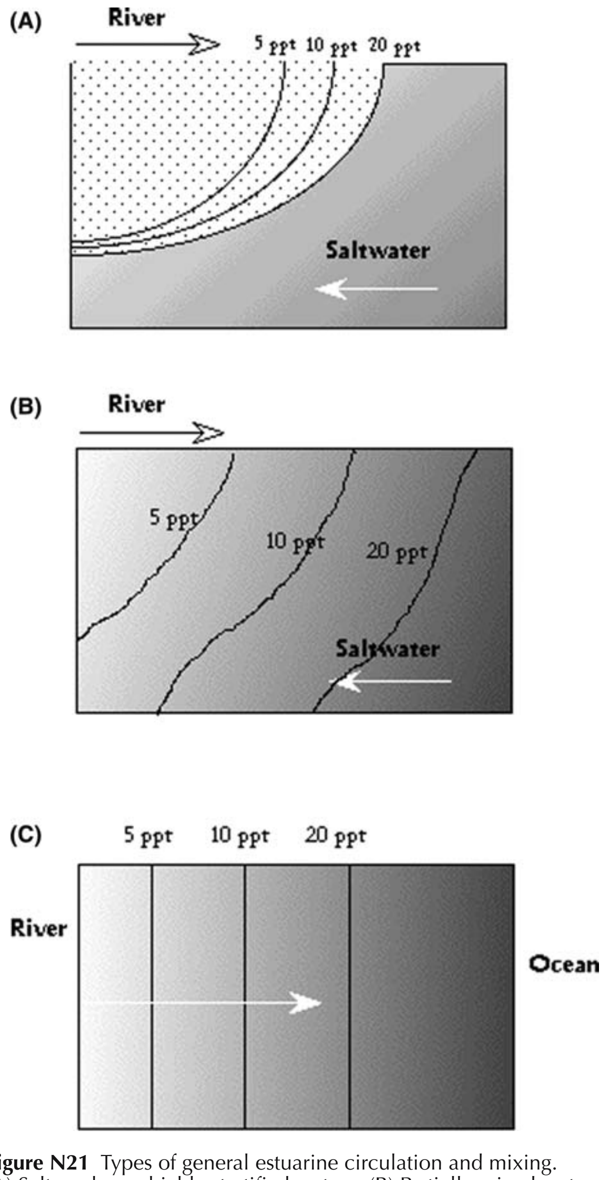

Figure N21 Types of general estuarine circulation and mixing. (A) Salt wedge or highly stratified system, (B) Partially mixed system, (C) Fully mixed system.

Sources of mixing

Waves, tides, and rivers control mixing in marginal environments. In estuaries, where major rivers meet the ocean, mixing is predominantly the result of tidal and river forces (Pritchard, 1967). Although there is a expansion of water surface area in estuaries with the incoming tide, particularly those of the low relief Atlantic coastal plain, the total net volume of water remains approximately the same throughout the tidal cycle; total estuarine volume rarely changes much (Berner and Berner, 1996). Essentially, incoming salty oceanic waters are transported landwards along the bottom balancing freshwater loss above the pycnocline in estuaries (Pritchard, 1954). Mixing occurs along the salinity gradient resulting in complex circulation patterns which are often estuary specific and impact the dispersion of sediment particles and other pollutants (Nichols and Biggs, 1985). These gradients generally depend on whether river discharge dominates the system, or tides (i.e., tidal currents).

A salt-wedge circulation occurs where inflowing river discharge greatly exceeds the volume of the incoming tide (expressed as the tidal prism) (Figure N21(A)). In situations where the river velocities are high, freshwater can over-ride the saltwater, yielding a sharp interface where mixing occurs by internal waves at the interface lifting parcels of saltwater into the inflowing river water (Nichols and Biggs, 1985). This distinct boundary is revealed by the tight clustering of isohalines (lines connecting water depths of equal salinity) where salinities can change from 5 to 30 ppt over vertical distance as little as 50 cm (Postma, 1980).

A partially mixed system occurs where stronger tidal currents diminish domination of the circulation by river flow, and the resulting greater tidal mixing produces a less sharply defined boundary between fresh and saltwater (Figure N21(B)). The stronger tidal currents produce both upward mixing of the river water and downward mixing of the saltwater. Partially mixed estuaries can be identified by a balance between river discharge and tidal prism. Fully or well-mixed circulation in an estuary occurs where the tidal prism is significantly larger than river discharge, and the tidal currents retard any tendency toward stratification of fresh and saltwater (Figure N21(C)). The result is that the estuary becomes well mixed with depth, and salinities vary only laterally, becoming more saline down estuary.

As critical to the fate of nutrients and pollutants in coastal waters is the flushing time, that is, the time it takes for the existing volume of freshwater to be replaced by river discharge (Aston, 1980), or

$$\tau = V_f / R,$$

where τ is the flushing time, V_f is the volume of freshwater in the estuary, and R is the river discharge into the estuary. Generally, the flushing times for less stratified and well-mixed estuaries tend to be longer than for more stratified, especially salt-wedge systems, where the fresh river water can flow out the estuary. Longer flushing times translate into longer periods for nutrients to be removed from estuary waters, with the visible evidence of such removal being an overall increase in phytoplankton biomass. In contrast, the faster flushing times for stratified estuaries, phytoplankton nutrient uptake is less, and phytoplankton debris is more likely to be exported from the estuary, slowing nutrient recycling (Berner and Berner, 1996). Moreover, stratified estuaries are more likely to become nutrient traps for remineralized nutrients in bottom waters (Redfield *et al*., 1963).

Waves are important mechanisms of mixing in coastal waters. In salt wedge and stratified estuaries, internal waves produce mixing along the boundary of river discharge and incoming flood waters. In shallow water areas, waves, especially during storms, can fully mix the entire water column. At the same time, such waves may resuspend fine-grained particulates from the bottom. Wave mixing and resuspension also predominate as agents of mixing in shallow coastal lagoons, although considerable mixing from tidal exchange occurs within the vicinity of inlets. A measure of the amount of exchange that occurs in coastal lagoons can be estimated by comparing the volume of the lagoon to the *tidal prism* of the inlet. This is in essence an index of the amount of inlet "water capture"—that is, what volume of the lagoon is exchanged by a particular inlet. In large coastal lagoons, serviced by several inlets, significant variations in inlet tidal prisms probably influence circulation within the lagoon. Net drift in the lagoon is controlled by the tidal prism of the largest inlet.

Biogeochemistry of estuaries

Spatial and temporal changes in the concentration of nutrients and other chemical constituents of the waters of Atlantic Coast estuaries have had considerable attention, especially as indicators of eutrophication. Studies have focused on sources of chemical constituents, vectors (if associated with particulates), cycling and transformations, and sinks.

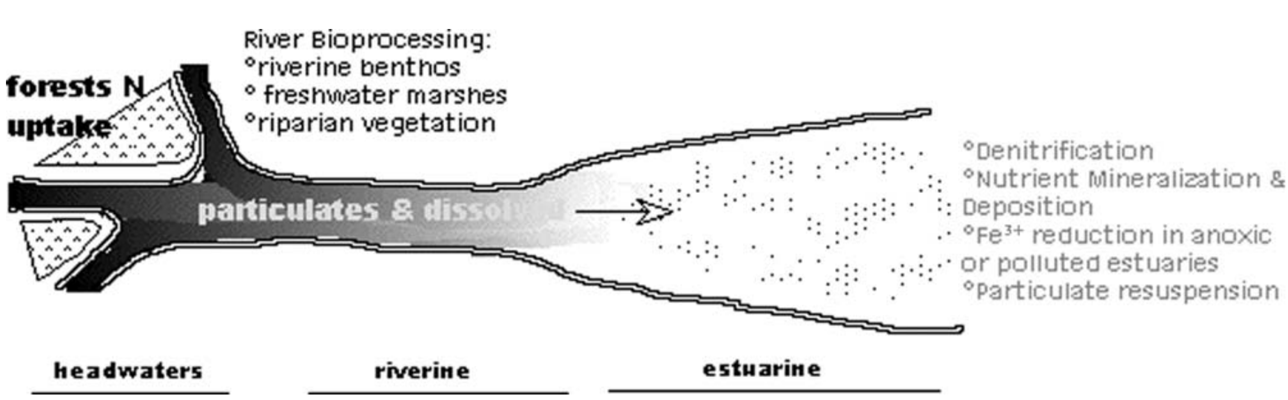

Figure N22 General biochemical interactions for a North American coastal plain estuary (based on Berner and Berner, 1996).

In simplest terms, the challenge of estuarine biogeochemistry is distinguished between terrestrial, marine and *autochonous* materials, and their fates (Figure N22 shows a general model of estuarine biochemical interactions).

Riverine constituents other than nutrients

Among the common chemical nonorganic constituents of coastal plain estuaries are Fe, Al, and Si. These constituents are commonly regarded as being of fluvial origin and indicative, when in high concentrations, of high rates of weathering within the drainage basin. Si, though naturally abundant in river water as dissolved silica, can also originate from groundwater sources. Various planktonic radiolarians and diatoms also contribute significant percentages. Dissolution of biogenic silica, however, is slowed by high concentrations of Fe^{3+} and Al^{3+} (Aston, 1980). Because much of the Al and Fe entering estuaries is often adsorbed on to fine clay particles, rapid flocculation of river clays between 5 and 15% salinity probably removes most of these metals (Aston, 1980). Moreover, this suggests that dissolution rates of biogenic silica are probably greater in the higher salinity (lower) parts of estuaries. Cations, such as Mg^{2+}, Ca^{2+}, K^{+}, and Na^{+}, estuarine waters are also largely derived riverine sources. In the rivers that flow through the highly weathered saprolitic rocks that compose much of the Piedmont of the Atlantic Seaboard's watersheds, concentrations of these ions tend to be high.

Dissolved organic matter (DOM) is also believed to be largely a function of riverine inputs. There is considerable seasonal as well as year-to-year variability in DOM, depending on river discharge and regional temperatures.

Nutrient constituents: phosphorus. The origin of phosphorus in estuarine waters largely reflects the influx of phosphate minerals in organic particulates and dissolved phosphate. Increasingly, the anthropogenic origin of phosphorus in sewage and other effluents has become a major concern in many North American estuaries. In Chesapeake Bay, Boynton *et al.* (1995) suggested that the total phosphorus load since European settlement had increased 16.5-fold, presently averaging about $0.065\,\mathrm{t\,km^{-2}\,yr^{-1}}$. In contrast to nitrogen, annual phosphorus loads largely reflect basin-wide runoff inputs, not groundwater inputs. Thus, the anthropogenic effects tied to land cover and land use changes (especially in regard to runoff efficiency as well as fertilizer application) are critical to understanding pathways for phosphorus (and nitrogen) export to coastal waters. The decline in forest cover, in particular, has been demonstrated to be a major factor in rising nutrient loads.

Once in coastal waters, particularly estuaries, phosphorus (as phosphate) is subjected to inorganic and biological controls. Phosphate "buffering" by being adsorbed on to mineral surfaces (Pomeroy *et al.*, 1965) is perhaps the major inorganic control. Depending on the phosphate concentration, adsorption surface available (i.e., mineral species and abundance) pH (lower salinities and more acidic pHs than seawater) and, possibly redox (higher oxidation states in estuarine sediments possibly releasing phosphates), phosphate buffering can be a principal means of moderating sewage outfalls in coastal plain estuaries (Aston, 1980).

The biological cycling of phosphorus in US Atlantic Coastal Plain estuaries has been shown to exhibit a seasonal cycle. Concentrations of dissolved phosphates in ambient waters are highest in summer (Taft and Taylor, 1976). Bacteria and, to a lesser extent, phytoplankton (depending on turbidity and its effects on light penetration and intensity) play the principal roles in uptake of phosphorus in the phosphorus cycle (Berner and Berner, 1996). However, the uptake of phosphorus by such organisms may be temporary since consumption by protozoans and other filter feeders with excretion and death can release back to the water column dissolved and particulate organic phosphate compounds (Aston, 1980). Ultimate removal may occur upon to adjacent ocean waters.

Nutrient constituents: nitrogen. The impact of increased loadings of nitrogen upon the ecology of coastal waters of North America has been perhaps even greater than that of phosphorus. The input of nitrogen (as nitrate) to Atlantic Coast rivers increased by 30% during the late 1970s (Smith *et al.*, 1987). Coastal waters are generally nitrogen limited due to denitrification by bacteria of nitrate (NO_3^-) under anaerobic conditions, low nitrogen fixing due to low light conditions (Howarth, 1988), and the toxicity of sulfides to nitrogen-fixing bacteria (Mitsch and Gosselink, 1995). Fluxes of nitrogen into coastal waters from rivers occur both as dissolved nitrate and particulate forms, though the latter probably only predominate during high precipitation events, particularly if these events coincide with the application of fertilizers within local drainage basins (Figure N23). Considerable research in Chesapeake Bay (Staver and Brinsfield, 1996) has underscored the importance of groundwater discharge as the major source of nitrogen loading of coastal estuaries either directly into coastal waters, or by discharges into tributaries as stream baseflow. Bachman and Phillips (1996) estimated that 40% of the total nitrogen load of Chesapeake Bay reflects groundwater discharge. The data on groundwater loadings of nitrogen from other areas in North America are limited, but this source is clearly potentially significant in areas with extensive marshes that are cut by numerous tidal creeks (Seagle *et al.*, 1999).

Direct input of nitrogen from the atmosphere has been demonstrated over the last two decades to be a major source of nitrogen to North American coastal waters (Paerl, 1985), as it is globally averaging 10–25% of the global atmospheric nitrogen input (Duce, 1991). Studies of atmospheric nitrogen loadings in the middle Atlantic coast show that wet deposition accounts for the atmospheric nitrogen, with nitrate being the most common form, though organic nitrogen can be important seasonally (Seagle *et al.*, 1999). Dry deposition, though accounting for less than half the atmospheric loading of nitrogen, nevertheless may yield as much 1.5–4.1 $\mathrm{kgN\,ha^{-1}\,yr^{-1}}$ in the Chesapeake Bay region (Gardner *et al.*, 1996).

Overall, as Seagle *et al.* (1999) point out, though figures for atmospheric deposition of nitrogen like those for groundwater loadings are limited, the phenomenon reinforces the importance of land use in not only controlling runoff and ground-water nutrient inputs into North American coastal waters, but the impact of land use in controlling the fate of atmospheric loadings. In particular, knowing the spatial distribution of upland and riparian forests/shrublands as nutrient buffers clearly holds the key to managing the effects of nutrients on North American Coasts. In this respect, databases like US National Oceanic and Atmospheric Administration's (NOAA), Coastal Change Analysis Program (CCAP; Klemas *et al.*, 1993), which portray changes in land cover and land use, comprise essential tools for wise coastal management.

Biological interactions

The populations of marine and brackish water organisms that characterize the coastal waters of North America constitute the fundamental

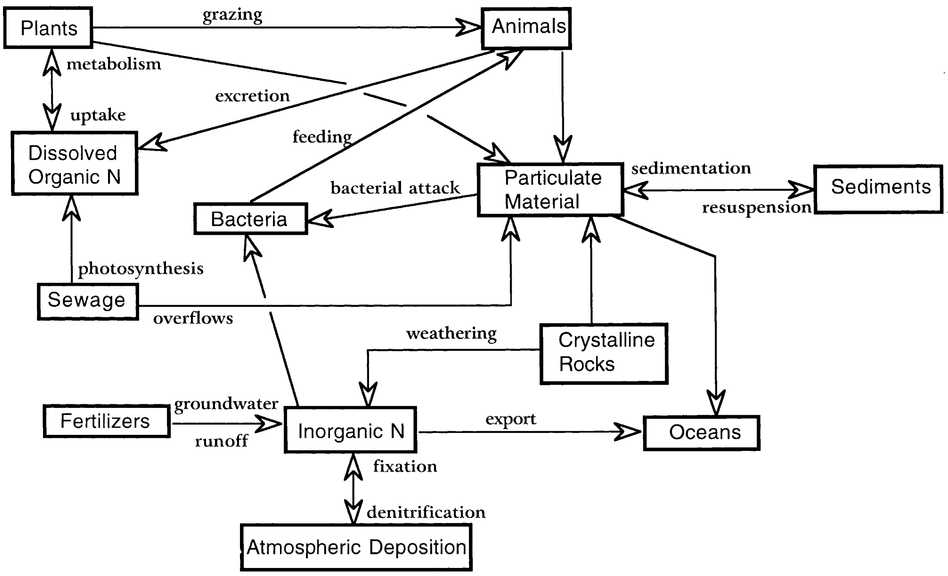

Figure N23 General nitrogen cycle for North America coasts (modified after Aston, 1980, with information from Boynton *et al.*, 1995).

components of a variety of ecosystems that range from the mangroves of south Florida to the high-latitude wetlands of Hudson Bay (Figure N23). The sheer variety of organisms, which vary broadly by latitude, and locally by salinity and season, is clearly beyond the scope of this entry. It is perhaps best to focus on examples of how these organisms comprise basic elements of North American coastal ecosystems, interact at various trophic levels, and influence overall ecosystem functioning.

Phytoplankton

Phytoplankton (diatoms, coccoliths, and dinoflagellates) populations in North American coastal waters, as along all coasts, depend on salinity, nutrient availability, and illumination. In estuaries, salinity plays an especially important role in the presence of species ranging from freshwater to brackish and fully marine species. Seasonal variations in salinity, particularly those associated with large spring runoff, may allow freshwater and lower salinity brackish species to migrate considerable distances down estuary. This down-estuary displacement, in highly stratified systems (e.g., salt-wedge systems), may ultimately prove disadvantageous, as internal wave mixing along salinity boundaries, may expose freshwater species in particular to osmotic stress. Euryhaline species are less likely to suffer such problems.

Nutrient influences on phytoplankton abundance reflect the similar riverine influxes that control nutrient dynamics. In Chesapeake Bay, low discharges of the Susquehanna River—the defining river of the estuary—and the other major tributaries, like the Potomac and James Rivers, in May through December probably underlie the nutrient limitations on phytoplankton productivity (Carpenter *et al.*, 1969). However, there is likely a greater year-round nutrient demand in most Atlantic Coast estuaries than inputs from external sources (absent significant sewage outfalls), and *in situ* processes in the estuaries must be supplying most of the remaining nutrient demand. These processes have been identified as: (1) remineralized nutrients excreted from herbivorous zooplankton and benthic organisms; (2) releases from sediment resuspension and interstitial sediment water; and (3) exchanges from nutrients in particulate forms and dissolved phases (Smayda, 1983).

In coastal lagoons and bays, which lack significant riverine inputs that produce changes in salinity and nutrient concentrations, light intensity in the euphotic zone above the compensation depth (where a balance occurs between rates of phytoplankton photosynthesis and respiration) is probably the major controlling factor. Resuspension of subtidal sediments is the principal mechanism by which turbidity and light attenuation occurs in lagoons, particularly in the open water lagoons that characterize the large, long thin barrier islands like Assateague Island and Atlantic City, New Jersey. Large-scale resuspension in these lagoons—many of which are quite shallow-occurs largely during storms. However, depending on tidal energies (and inlet tidal prisms) appreciable concentrations of subtidal materials may be entrained from the flanks of inlets and in the vicinity of shoals forming flood tidal deltas. Most of these materials probably settle out of suspension within a short distance of the inlets as tidal velocities rapidly slow. But in a lagoon with a large number of inlets, there could be significant diurnal variations in turbidity and illumination affecting phytoplankton. In the marshy lagoons behind drumstick barriers, outwelling of particulates from marshes during ebb is probably an additional source of suspended organic and mineral materials.

Lastly, though salinities in many coastal lagoons and bays do not vary as strongly seasonally as in estuaries, in areas away from inlets that may be blocked from ready tidal exchange by marshes, hypersaline conditions may prevail in late summer as evaporation rates increase, with concomitant effects on phytoplankton populations.

In estuaries of North America, plankton metabolism serves an important regulator of estuarine chemistry. Plankton photosynthesis is correlated with decreases in the concentration of carbon dioxide, ammonium, phosphate, nitrate, and silicate (Wolff, 1980). Moreover, oxygenation of local waters increases. In Long Island Sound, annual primary phtyoplankton productivity has been determined to be as much as 380 $\mathrm{gC\,m^{-2}\,yr^{-1}}$, which is similar to the value of 308 $\mathrm{gC\,m^{-2}\,yr^{-1}}$ determined for Narragansett Bay (Wolff, 1980; Smayda, 1983).

Benthic algae and macrophytes

The decline of sea grasses and parallel spread of benthic algae estuaries and coastal lagoons of North America have focused concern on the widespread phenomenon of coastal eutrophication. In coastal systems where high anthropogenic inputs of nutrients, coverage of benthic algae can be extensive, ranging form single cell species (like diatoms) to complex, multicellular species, forming mats. Studies of primary production of benthic in estuaries where nutrient concentrations are not yet excessive show comparatively low values, especially compared with phytoplankton (Wolff, 1980). Substrate characteristics have been suggested to be perhaps the most important limitation on benthic algae productivity. Single cell species prefer soft substrates like muds, whereas the complex multicellular species prefer hard substrates like shell debris, rocks, or shore construction, such as pilings or bulkheads.

The importance of benthic algae to the ecology of North America coasts has been underestimated, because often this component is measured as part of another system as in salt marshes where its productivity (but not biomass) sometimes rivals macrophytes. No such ambiguity relates to the role played by sea grasses, whose productivities exceed even phytoplankton. Sea grass biomass can reach 500 $\mathrm{gC\,m^{-2}\,yr^{-1}}$ (Wolff, 1980) and Barsdate *et al.* (1974) indicate that 90% of production in a lagoon in Alaska is due to *Zostera*. The high productivity of sea grasses ensures that they serve as a major food sources for organisms ranging from gastropods to fish, though direct consumption is probably limited and most of their importance to food chains appears to be as detritus (Barsdate *et al.*, 1974; Stevenson, 1988).

As plants rooted in the sea bottom, sea grasses cycle a number of compounds from subtidal sediments into ambient waters through their leaves and by decomposition after death. Phosphate, in particular, may be transported up roots and through leaves of *Zostera maritima* at a rate of $0.066\,g\,m^{-2}\,day^{-1}$ (McRoy *et al*., 1972).

Salinity, in lieu of anthropogenic influences, is the major control of the species distribution of sea grasses along North American coasts. *Zostera* and *Thalassia* can occur where salinities range through 35 ppt, whereas *Ruppia* and *Zanichellia* characterize brackish waters (Wolff, 1980).

Coastal wetlands: marshes and mangroves

The marshes—and the mangroves in south Florida—that characterize the North America coast occur in a variety of physiographic/depositional settings, but largely in areas protected from strong wave energies like lagoons and estuaries. In the United States southeast Atlantic Coast and Gulf Coast, coastal wetlands comprise a substantial part of the coastline, and individual marsh systems can easily range in size up to several thousand hectares or more. The contribution of large coastal wetlands to the ecology of coasts is clearly inescapable, but even the much smaller and more isolated marshes of New England up through the Canadian Maritimes are important to local ecosystems. Woodwell *et al*. (1979) demonstrated that significant interactions occurred between a salt marsh in Long Island Sound and local coastal waters.

Essentially, coastal wetlands serve several roles in North America coastal ecosystems: (1) as important components of several littoral biogeochemical cycles, especially nutrients and carbon; (2) as critical habitats for species ranging from invertebrates to birds; and (3) as sinks for mineral sediments. To these, may be their additional functions in coastline stabilization and erosion control, though rapidly eroding coastlines are seldom areas where marshes persist.

Coastal marshes are generally considered to be net sinks for inorganic nutrients and net exporters of organic materials (including associated nutrients) (Mitsch and Gosselink, 1995). Studies of nutrient exchanges in US Atlantic Coast marshes (e.g., Stevenson *et al*., 1977) leave the general question of whether marshes are net exporters or importer of nutrients unsettled. Nixon (1980) concluded, in his review of available evidence at the time, that marshes were, overall, exporters of dissolved organic nitrogen (DON) and dissolved phosphorus, but importers of nitrite and nitrate. Nonetheless, it is clear that high levels of denitrification can occur in marshes. Gross denitrification at Great Sippewissett Marsh in Massachusetts, particularly from June through October, was almost twice the import of nitrate into the marsh from groundwater (Kaplan *et al*., 1979).

The high net primary productivity has been cited as underscoring the importance of coastal wetlands as a source of organic detritus and dissolved organic carbon (DOC) in North American estuaries is clear. In eroding marshes the amount of organic detritus per hectare of marsh can be very large, particularly in brackish or estuarine marshes where the percentage of organic carbon by dry weight in marsh sediments is generally 50% (Stevenson *et al*., 1985). However, whether all of these materials eventually serve as food sources in estuaries is a matter of debate. The concept that "outwelling" of organic materials from marshes buffers nutrient demand in estuaries has been suggested to be one of the major functions of tidal marshes in estuarine productivity (Odum, 1961). Actual support for this hypothesis has proven inconclusive. Haines (1979), using carbon isotope data, showed that carbon from strictly terrestrial plants dominated the tissues of fish and other herbivorous species, suggesting that whatever the quantity of carbon exported from marshes, it was not preferred as a primary food source.

Similar problems surround the functions of marsh as sediment sinks. While it is clear from sedimentological studies (Stevenson *et al*., 1986) that marshes—and by extension, mangroves—comprise great stores of mineral sediment, the actual functions of coastal wetlands in littoral sediment budgets of North American coasts is not resolved. In Chesapeake Bay, Stevenson *et al*. (1988) suggested that suspended sediment deposition in marshes accounts for 11% of the total estuary sediment budget. Much of the effectiveness of coastal marshes lies in how tidal velocities vary between flood and ebb tides, with strong ebb domination of the tidal cycle promoting greater export of mineral than import. The few data on sediment fluxes in North American marshes implies that their functions as major sediment sinks are probably limited, with many marshes probably exporting more sediment than importing sediment during the tidal cycle (Stevenson *et al*., 1988).

The case for providing critical habitat, especially for water birds and commercially valuable species of finfish and shellfish, is much stronger. It has been estimated that 90% of commercially valuable finfish and shellfish spawn and spend their juvenile stages in coastal marshes (Mitsch and Gosselink, 1995). More directly important to coastal ecology is the contribution of coastal marshes to sustaining a host of organisms in the marsh food web, particularly larval stages of filter feeding organisms like the oyster (*Crassotera virginica*), which as adults, contribute significantly to maintenance of estuarine water quality.

Animals

The variety of animals that characterize the coastal waters of North America include organisms that spend their lives ranging more or less freely in the water column like zooplankton and complex vertebrates, organisms that largely inhabit the benthos (mainly invertebrates among the metazoans and many unicellular species like various bacteria), and those that move from the benthos to water column, often depending on life stage. These animals, whether herbivorous or predatory, are often part of complex trophic interactions in littoral food webs, above all in estuaries. The occurrence of both pelagic and benthic species is related to turbidity, salinity, dissolved oxygen, and availability of food sources. The last, not surprisingly, is exemplified by the fact that zooplankton are often found in greatest abundance in North American coastal waters (as elsewhere) where numbers of phytoplankton, their principal food source, are highest (Miller, 1983). However, in the general ecological functioning of North American coastal systems, the role of animals can be seen to relate to aspects of coastal biogeochemical cycles: (1) remineralization of nutrients from grazing on phytoplankton; (2) mixing and resuspension of subtidal sediments, affecting turbidity and reintroduction of biogenic debris, often fecal material; and (3) the filtering of largely organic particulates by filter feeders like oysters and clams.

Grazing on phytoplankton and organic detritus, with the ultimate release of remineralized nutrients in the excreta from death of animals, is a major element of nitrogen and phosphorus cycles in estuaries. Though filter-feeding benthic invertebrates clearly play a part in this, the major regenerators of nutrients are zooplankton. Ingestion of detritus as a source of remineralized nutrients by copepods appears to be seasonally important along the US Atlantic Coast, with the months between March and May being the time of year when algal food sources are insufficient (Heinle and Flemer, 1976).

Mixing and resuspension of subtidal sediments, particularly organic particles, mainly reflects the activities of burrowing invertebrates. Bioturbation of subtidal sediments in estuaries not only homogenizes sediments down to depths of often a meter (*Mytilus*), but increases the potential for resuspension of sediments, especially fecal pellets. In Atlantic Coast estuaries like Chesapeake Bay, the annual amount of fecal material excreted by oysters can be as high as 1–2 metric tons per hectare (Nichols and Biggs, 1985). The potential resuspension of these materials, as well as other organic particulates, for later heterotrophy or bacterial attack by bacteria is a significant source of inorganic nitrogen (e.g., NO_3^-) and orthophosphates (Aston, 1980) in ambient waters.

The decline in the populations of filter-feeding organisms like the oyster has been cited as one of the major reasons for the crises in water quality along North America coasts. In Chesapeake Bay, the population of oysters at the time of initial European contact in 1608 was probably sufficient to filter all the Bay's waters in two to three weeks, whereas by the late 20th century it needed several decades (Newell, 1988). This considerable contribution to the littoral waters of North American coasts should not diminish the importance of the removal of remineralized nitrogen passing through the guts of oysters as fecal material which binds the sediment, and makes it less vulnerable to resuspension.

Threats to the ecology of North American coasts

Eutrophication

Coastal eutrophication in North America during the latter half of the 20th century has yielded poorer water quality, diminishing catches of commercially valuable species of finfish and shellfish, loss of habitat for other creatures, and lower recreational values. A recent report by the National Oceans Service of the US NOAA found that 65% of the total estuarine surface area could be considered as exhibiting moderate to high levels of eutrophic conditions, marked by depleted dissolved oxygen levels, loss of submerged aquatic vegetation, growth of macroalgae, increasing frequency of toxic algal blooms, and increasing levels of chlorophyll *a* (Bricker *et al*., 1999). The middle Atlantic and Gulf Coasts, in particular, represent the most threatened coastal waters in North America.

Not the least of the many impacts of coastal eutrophication, are the mounting costs for saving what remains of rapidly vanishing coastal resources. The importance of the cost issue can be indicated by estimates of expenditures for controlling nutrients in the largest estuary in North America, Chesapeake Bay. Between 1985 and 1996, over US $3.5 billion were spent on nutrient control in the Bay's watershed (Butt and Brown, 2000). The cost of removing each kilogram of total nitrogen per year in the Chesapeake Bay alone probably ranges upwards of US $35 (Camacho, 1992). This cost, of course, does not reflect the large expenditures for the restoration of resources damaged by coastal eutrophication, encompassing funds for the monitoring and replanting of sea grasses, grants for improving the aquaculture of threatened species like the American oyster (*C. virginica*) in several Atlantic Coast estuaries, subsidies for the funding of alternative farming methods, and the like. But the dimensions of the threat posed by the eutrophication of North American coastal waters, epitomized by the rapidly enlarging "dead zone" in the Gulf of Mexico at the mouth of the Mississippi River (Turner and Rabalais, 1994), are such that delaying action may prove to incur costs well beyond the money needed for remediation.

Burgeoning human activities around coasts and in coastal watersheds underlie the phenomenon of coastal eutrophication. A major impediment to effective mitigation of the threat has been readily accessible, up-to-date information on the nature and extent of land cover changes and land use practices that contribute to loading of nutrients in coastal waters. The pace of change is such that growth of populations (regardless of the types of activities these people will be engaged in) could increase by 100% in many already heavily settled areas of the US Atlantic Coast (see Stevenson and Kearney, 1996).

Monitoring changes in land cover and land use is crucial to any assessment of the effects of human activities on coastal ecosystems. Satellite remote sensing has been particularly useful in this regard, and the C-CAP program in the United States (Klemas *et al.*, 1993) is a good example. This program produced the first, uniform information on land use and land cover changes in the US coastal zone using Landsat Thematic Mapper imagery. Application of remote sensing technologies in combination with Geographic Information Systems (GIS) and various spatial environmental models (e.g., Costanza *et al.*, 1990) are providing the broad synoptic tools for regional to coast-wide management of ecological impacts that attend population growth and development along North American coasts.

Providing information is not necessarily mitigation of ecological threats and damage, which require political action. Here, the progress has been more piecemeal, particularly in the United States with its combination of federal, state, and local jurisdictions, and overlapping and differing mandates between state and federal agencies. General water quality mandates, regulated by the US Environmental Protection Agency (EPA), are related to issues of direct or indirect risk to human health and seldom effectively address issues like coastal eutrophication that are usually loosely related to any specific human activity and tend to be regional to extra-regional in scope. Regional consortia of local and regional governments are perhaps best positioned to assume the various roles necessary for advocating (especially with local municipalities), enacting, and coordinating the measures for coastal mitigation. The Tri-State Commission—Maryland, Virginia, and Pennsylvania—for cleanup of the Chesapeake Bay is a good example of jurisdictional cooperation in a major effort to limit the influx of nutrients in a major coastal system of North America already burdened by extensive coastal eutrophication.

Land use policies aimed at controlling nutrient inputs span those advocating changes in regional agricultural practices to legislated controls on the types of land use permitted in critical areas of large watersheds feeding coastal systems. Controls on land use or density of development are not always popular, but are effective even where employed in only a limited fashion. In the 1980s, the State of Maryland enacted the Critical Areas Act mandating the creation of 1,000-foot (330 m) buffer zones around the Chesapeake Bay and its major tributaries. This buffer was largely intended to protect from encroaching development, upland forests and riparian zones that can attenuate nutrient runoff into coastal waters. In addition, the density of development in certain areas of the Bay coastline was further controlled, again to limit nutrient influx. To be sure, the Act met with mixed responses from various quarters, but subsequent studies did show that nutrient inputs were significantly diminished to the Bay (Marcus *et al.*, 1993).

Sea-level rise

The possibility of rapidly rising sea levels from global warming first became widely recognized almost 20 years ago, and was followed over the next two decades by numerous studies outlining what an acceleration in sea-level rise could mean for coastal systems. Though an accelerating sea-level rise could have a multitude of effects (both direct and indirect) on North American coastal ecosystems, at least two are likely: the potential extensive loss of coastal wetlands and increasing turbidity in Atlantic Coastal Plain estuaries from higher rates of shore erosion.

Estimates derived from historical surveys suggest that almost half of the coastal wetlands in the United States extant in 1900 had disappeared by the last quarter of the 20th century (Gosselink and Baumann, 1980). Many of these losses reflect development or other human activities, but overall it is safe to assume that a more generic cause, sea-level rise, was responsible. In recent years, regional studies ranging from the Mississippi Delta to the middle Atlantic Coast (cf. Stevenson *et al.*, 1986) indicate that marsh vertical accretion rates in many areas lag local rates of submergence. In areas where there are significant deficits in vertical accretion compared to sea-level rise, inventories using aerial photography and other techniques show high wetland losses. In the Mississippi Delta, annual losses of coastal marshes amount to almost 60 km^2 (Britsch and Kemp, 1990).

Projections for rates of global sea-level rise approaching 1 m per century would be catastrophic for the survival of coastal wetlands generally, in particular coastal marshes (Nicholls *et al.*, 1999). Admittedly, most research on the relations of coastal wetlands to sea-level rise has focused on middle latitude coastal marshes, but it is probably safe to assume high-latitude marshes in Hudson's Bay would fare the same. In addition, though the imminent widespread collapse of mangroves due to sea-level rise heralded almost a decade ago (cf. Ellison, 1993) was perhaps premature, the survival of mangroves in south Florida in such a scenario would be doubtful as well.

Despite some continuing disagreement concerning the overall ecological role of wetlands in estuaries and lagoons along North America's coasts, reviews by Nixon (1980), among others, make clear that loss of coastal wetlands would affect aspects of coastal ecology as various as nutrient cycling and fisheries. The economic costs of large-scale wetland decline and loss would be equally significant. Costanza *et al.* (1989) demonstrated that the size of shrimp harvests in Louisiana correlated well with marsh area in the Mississippi Delta.

The role of sea-level rise as the driver of long-term coastal erosion is well known. Nevertheless, the impact that an accelerated rate of sea-level rise would have on water turbidity in North American estuaries is just becoming evident. Detailed sediment budgets for many North America estuaries are generally not available, but it is clear that sediment inputs from shore erosion will increasingly loom larger as rates of sea-level rise increase. At present, shore erosion adds a volume of sediment into Chesapeake Bay every century equivalent to the District of Columbia (US Army Corps of Engineers, 1990). Much of the finer-grained eroded sediments will inevitably end up increasing the already high, suspended particulate load of estuaries, thereby further increasing water turbidity. With effects of high turbidity on estuarine biota that span damage to sea grasses to even the foraging success of predatory fish species like striped bass, mounting inputs of suspended sediments may offset any hard-won gains in water clarity from controls on upland erosion that have been emplaced in many areas in recent decades.

Baja California: a unique North American coast

In 1940, a year after the publication of *The Grapes of Wrath*, John Steinbeck with his friend, Edward Ricketts, spent five weeks exploring the Sea of Cortez. Exhausted and troubled by the controversy generated by his great novel, Steinbeck, connecting with his early undergraduate training as a marine biologist, surely could not have chosen a more unique coastal system in North America to visit. Surrounded by deserts, the Sea of Cortez contains some of the deepest basins (over 2,000 m) of any coastal region of the continent. About 4.5 million years old (Atwater, 1970), and formed by separation of the Baja Peninsula during the late Pliocene and Pleistocene, the area is seismically active, and characterized by occasional tsunamis, with volcanism occurring as recently as the Holocene (Gastil *et al.*, 1983). One of the most salient features of the Gulf, is its many islands (30–40) that fall into two general groups, northern and southern islands. The islands differ in origin, some being volcanic, others formed by uplift or submergence, and those next to the mainland created by narrow headlands separated by erosion (Gastil *et al.*, 1983).

The upper Gulf is an area characterized by some of the highest tides in the world, with spring tidal ranges in the vicinity of the Colorado River Delta reaching almost 10 m (Matthews, 1968). Tidal phase also changes from the delta to the middle Gulf, and though the tidal wave is modified by islands and, in particular, by shoals in the vicinity of the delta (Maluf, 1983). However, tidal phases for most of the Gulf appear to be largely semidiurnal in character, although they are regularly diurnal around Bahia Concepción and Guaymas during the month (Maluf, 1983).

The ecology of the Sea of Cortez is dominated by the seasonal climate variations and influence of the islands. Because the sea is too small to modify regional climates, water temperatures mirror seasonal changes in regional temperature, especially in the upper Gulf (Maluf, 1983). Together with the sometimes extreme range in salinities near the Colorado Delta, produced by changes in discharge of the Colorado, shallow-water biota show a greater interannual variations in composition (Maluf, 1983). The influence of the islands is reflected in bird, reptile, and mammal populations that change by location of the islands and their proximity to mainland coasts. Slight terrestrial faunal differences between the Baja Peninsula and the mainland Mexican Coast tend to characterize islands nearest either shore. Phytoplankton densities decline around islands clustered closest to mainland shores, where water turbidity is higher due to shore erosion and wave resuspension during storms (Thomson and Gilligan, 1983). Because water masses in the Sea of Cortez can be broadly partitioned into either being mainland-influenced or Pacific-influenced, there is said to be a pelagic species gradient within the upper and lower Gulf, but the actual gradient may run between the mainland shore and off-shore islands, reflecting the greater seasonal variation in sea surface temperature along mainland coasts (Thomson and Gilligan, 1983). Changes in benthic species also show mainland versus island differences, in this case largely due to the reefs that ring many of the islands, especially in the lower Gulf.

In the lower Gulf, a large, stable low oxygen zone, produced by decomposing phytoplankton, limits benthic species where it impinges upon shallower water areas (Maluf, 1983). At the mouth of the Gulf, ocean circulation disrupts, reinforcing the essentially confined-sea character of the Gulf of California.

NORTH AMERICA, COASTAL GEOMORPHOLOGY

The shores of the North American continent span approximately 55° of latitude and 100° of longitude. The continent is bounded by four major coastal regimes associated with the Atlantic, Arctic, and Pacific Oceans, and the Gulf of Mexico. The length of open ocean coast, excluding non-barrier islands, exceeds 110,000 km, and is much longer if the Great Lakes, embayments, *lagoons*, and islands are included. The coastal morphology includes all of the major coastal types described in Shepard's (1937) classification. There are *mangrove* and coral systems in the southern reaches of the continent, and *ice*-dominated systems in the north. The common occurrence of fjords and rias attests to the delayed response of most of the North American coast to glacial processes and *eustatic* and *isostatic sea-level* changes.

Geomorphic provinces

The coast of North America (Figure N24) comprises parts of at least seven of the geomorphic provinces described in Graf (1987). The designations for these provinces, and their characteristics, are taken from Graf (1987), unless otherwise noted, and they are used to organize and introduce the principal features of coastal regimes discussed herein. The North American distribution of *muddy coasts* and coarse clastic coasts are presented separately.

Pacific Rim Province

The west coast of the continent, from the Mexico-Guatemala border to the Alaska Peninsula is included in the Pacific Rim Province. It is a region that is tectonically active, lying along the convergent boundaries of the Pacific, Juan de Fuca, and Cocos Plates with the North American Plate, although the Golfo de California is a spreading center. Most of this coast, other than Baja California and southern California, is a collision coast using the terminology of Inman and Nordstrom (1971). The general morphology of the Province is characterized by a narrow continental shelf and narrow or absent coastal plains backed immediately by steep and high mountain ranges. Coastal *cliffs* are common and estuarine or *barrier* systems are limited to the vicinity of drowned river mouths. Notable exceptions are the barrier systems along the eastern shore of the Golfo de California. Spring *tide* ranges vary from about

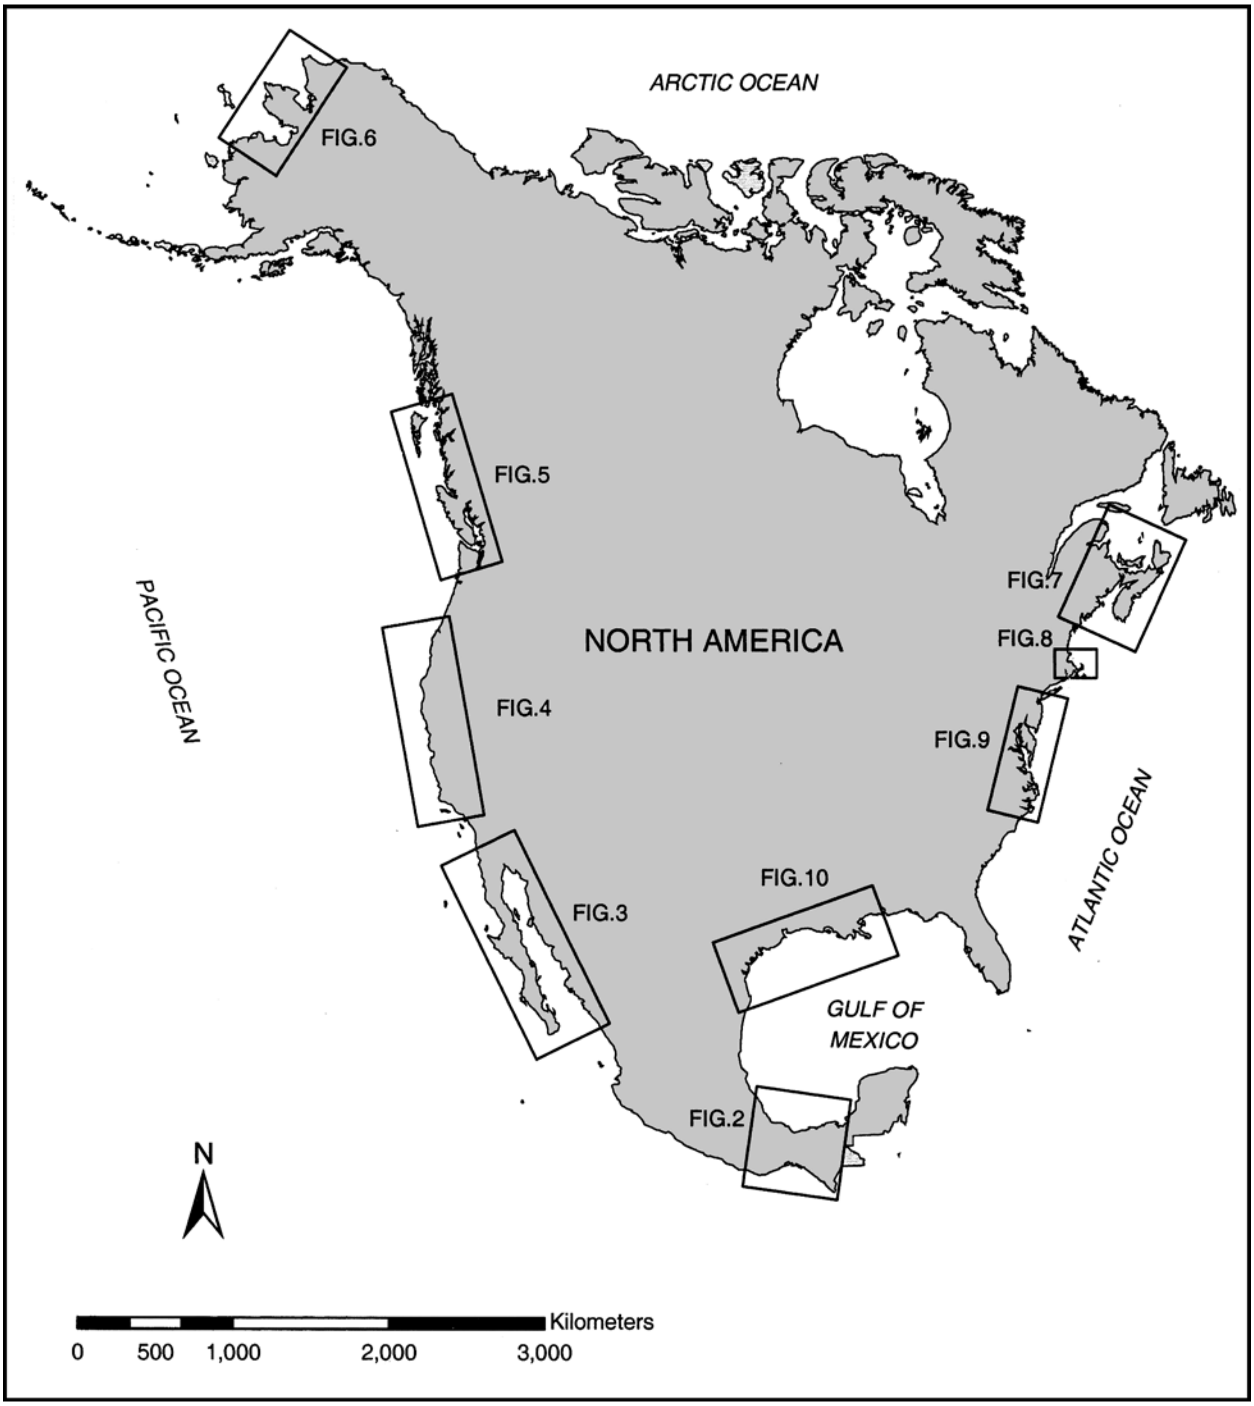

Figure N24 An outline of the North American continent. The insets mark regions represented in Figures N25–N33.

0.5 m along the Mexican coast near Acapulco, to 1.0–3.0 m along most of the rest of the Pacific coast to the US–Canada border. Ranges increase northward to more than 10 m in the vicinity of Anchorage, Alaska. Spring tide ranges reach 7 m in the northern reaches of the Golfo de California (Kelletat, 1995). The dominant source of wave energy along most of this coast is from ocean swell, although tropical-*storm*-induced *waves* are important in Mexico and (occasionally) southern California.

The Pacific coast of Mexico in the vicinity of Guatemala (Figure N25) is characterized by barrier/lagoon systems. *Dunes* are common on the barriers, and mangroves are present in many of the lagoons. *Coral reefs* occur sporadically along this coastline. Much of the coast north of the Golfo de Tehuantepec to Nayarit is cliffed where the Sierra Madre del Sur lies adjacent the coast. Along other reaches of this region, barrier/lagoon systems are extensive, especially east of Acapulco (Figure N25), in the vicinity of Zihuatenejo, and between Puerto Vallarta and Mazatlan.

There is another barrier/lagoon complex east of Los Mochis (Figure N26). The *sandy* barriers include coastal dune and *beach ridge* complexes. Many of the lagoons provide mangrove habitat (Kelletat, 1995). There are similar systems north from Los Mochis, but they become smaller and occur less frequently along the increasingly arid coastline of the Gulfo de California. Wave energy decreases northward into the Gulf, but the tide range increases to a maximum at the mouth of the Colorado River (Figure N26). The Colorado River *delta* comprises a

large network of distributaries, estuaries, marshes, and saline lagunas. Many of these coastal environments are threatened by reduced fluvial discharge and sediment supply caused by large *dams* on the river (Carriquiry and Sánchez, 1999). The location of the delta is controlled by the San Andreas *Fault* that separates the North American plate on the east, from the Pacific plate, with Baja California, on the west.

The east coast of Baja California (Figure N26) is shaped largely by recent *tectonic* activity, with the Sierra de San Pedro Martir and the Sierra de La Giganta (both part of the Peninsular Range that runs north to Los Angeles) abutting the coast in the northern and southern Gulf, respectively. The coast is irregular, and frequently cliffed with pocket beaches between headlands. The arid climate produces few perennial streams to deliver sediment to the shore and the entire coast is low energy, so beaches tend to be relatively narrow. There are only a few, small barrier systems, at Santa Rosalia, for example, or La Paz. Baja California's west coast is also quite rugged. However, drainage basins are larger than those found along the Gulf coast, and sediment supplies are larger. The most prominent coastal features are Bahia Magdalena and Vizcaino Bay. The former is the largest of a series of bays created by the presence of a chain of *barrier islands* and *spits*. Coastal dunes are common on the barriers and the lagoons are backed by marshes or sand and salt flats. In Vizcaino Bay, Laguna Ojo de Liebre (Scammon's Lagoon), results from structural control on coastal development. The Sierra Vizcaino parallel the Sierra de La Giganta to create a large trough that has been filled with sediments from the mountain ranges. The barrier and lagoon systems are formed in these sediments along the bay. Extensive dune fields and salt flats occur across this complex. Raised marine terraces are found at elevations up to 150 m (Orme, 1998).

Near the US–Mexico border, the Tijuana River created a substantial *estuary* marsh system, and has provided the sediments that were transported northward to form the barrier spit that protects San Diego Bay from the open ocean (Figure N26). Most of the coast in this region has cliffs fronted by narrow sand or cobble beaches. This configuration, often backed by sets of marine terraces, is common to the rest of the Pacific coast, except where structural controls have formed basins or where rivers have formed estuaries. The city of Los Angeles, for example, is built across the structurally controlled Los Angeles Basin that has been filled with thick deposits (locally in excess of 6,000 m) of marine sediments. It is the largest coastal plain in California, not coincidentally occupied by the largest city. Los Angeles beaches are backed by *Holocene* (and older) dunes, although most dune surfaces have been urbanized. The southern California coastline, with the exception of the military reservation at Camp Pendleton in San Diego County, is also extensively human altered through beach nourishment, cliff stabilization efforts, and seawalls and groin fields (Griggs, 1998), and the extent of alteration rivals that of the New Jersey shore.

The southern California coastline is also characterized by well-defined sets of raised marine terraces. The Palos Verde Peninsula divides the coast of the Los Angeles Basin. There are 13 terraces on the peninsula, at elevations up to 411 m, the marine limit (Orme, 1998). The marine limit rises to about 600 m, with 15 terraces, in the vicinity of Santa Barbara, and falls to about 200 m near the Big Sur coast of central California. The Big Sur coastline (Figure N27) is formed of high marine cliffs carved into the Santa Lucia Mountains. Pocket beaches, of sand or coarser materials, occur in sheltered locations along this coast.

Monterey Bay (Figure N27) marks the separation of the Santa Lucia and Santa Cruz Ranges. There is a coastal, deltaic plain created by the Salinas River flowing between the mountain ranges. Wave energies along this coast are high, and most of the coastline is backed by dune

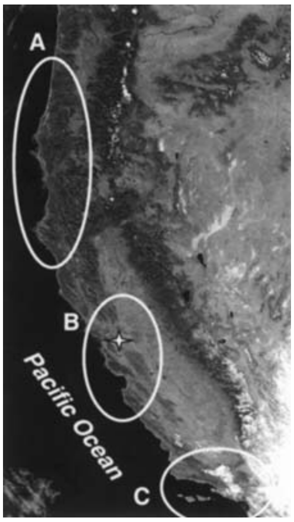

Figure N27 The coasts of Oregon and Cailfornia. This is a SeaWIFS image (courtesy of NASA) from 23/10/00. (A) The relatively straight coast of southern Oregon includes large barrier spit/estuary systems, and is backed by extensive coastal dunes. The major promontories are Cape Blanco in the north, and Cape Mendocino in California. (B) The central California coast from San Francisco (✧) to the Big Sur coast. San Francisco and the Bay are immediately west of the ✧. The large embayment to the south is Monterey Bay. (C) The west–east trending coast of southern California, including the Channel Islands. This coast is characterized by a series of small barrier/estuary systems separated by headlands and cliffs.

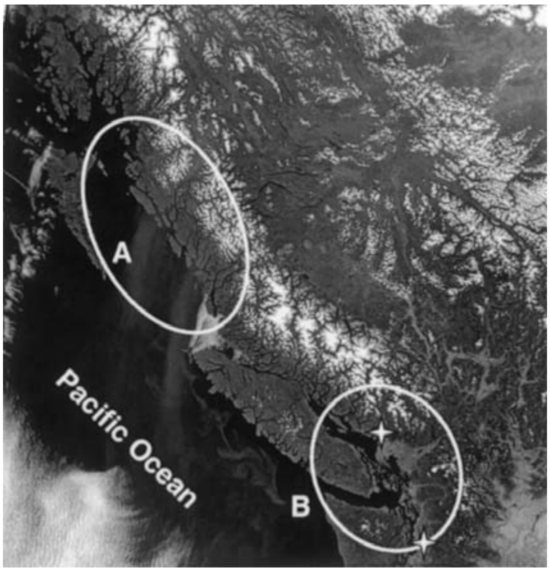

Figure N28 The west coast of Canada. This is a SeaWIFS image (courtesy of NASA) from 09/08/01. (A) The glaciated coast between Alaska and Vancouver Island. Rocky islands, fjords, and a paucity of sandy beaches are characteristic. (B) Vancouver, British Columbia (northern ✧) is on the northern edge of the Fraser River delta, on the Strait of Georgia. Seattle (✧) is on Puget Sound, connected to the Pacific through the Strait of Juan de Fuca. Fjords, rocky islands, and deltas are common.

complexes that extend inland, in locations, almost 10 km (Cooper, 1967). Coastal cliffs and low marine terraces back the coast from Santa Cruz, at the northern edge of Monterey Bay, north to San Francisco Bay. Noteworthy is the Devil's Slide coastline south of San Francisco, where steep, 250 m high cliffs have been eroded into the unstable Franciscan formation, and where, as the name implies, slope failures are common.

San Francisco Bay (Figure N27) is formed by the submergence of a Pliocene basin. The Sacramento River system flows into the bay, forming an inland delta and marsh complex. The distributaries are confined between levees and much of the delta surface is currently below sea level. During Pleistocene lowstands of sea level, the river debouched to the Pacific through the channel it had eroded between the Golden Gates. North of San Francisco is the Point Reyes peninsula, an outcrop of the Pacific Plate separated from the mainland by Tomales Bay, formed in a trough along the San Andreas fault line.

The California coast north to Cape Mendocino is extremely rugged, comprising high cliffs cut into the Coastal Range Mountains, and localized sand or gravel beaches. Numerous submarine canyons extend close to the shore. There are no large drainage systems reaching this coast and most of the reach remains inaccessible by land. North of the Cape, several large rivers, including the Eel, Mad, Klamath, and Smith, do reach the coast to form estuary and baymouth barrier systems such as the one that forms Humboldt Bay. Large coastal dune complexes have formed from the sediments blown off the beaches near these rivers.

The relatively straight coastlines of Oregon and Washington (Figure N27) lie adjacent to the subduction zones associated with the Juan de Fuca and Gorda Plates. As is common with collision coasts, rugged terrain and cliffs are characteristic along these shores. There are, however, numerous fluvial/estuarine systems with baymouth barrier spits. Good examples of these occur at Coos Bay, Newport, and Tillamook Bay in Oregon, and Willapa Bay, and Grays Harbor, Washington. There are also extensive dune systems along this coast (Cooper, 1958). Many of the dunes are confined to the barriers, but at several locations, such as near Florence, or Sand Lake, Oregon, they extend inland for kilometers.

The Pacific coasts of Canada and Alaska (Figure N28) show the marked influences of alpine glaciation. The coast of British Columbia shows a strong structural control on morphology, with the Georgia and Hecate depressions separating Vancouver Island and the Queen Charlotte Islands from the coastal mountain ranges on the mainland. The coast is deeply incised as a result of glacial erosion and the creation of numerous fjords. There are very few beaches along this entire coast, and they tend to be confined to the headwaters of the fjords where rivers deposit sands and gravels. There is a large delta system at the mouth of the Fraser River (Figure N28), creating a large coastal plain that is currently occupied by the city of Vancouver and its suburbs. Most of this coast, continuing into Alaska, is inaccessible by land.

The Pacific coast of Alaska (Figure N28) is similar to that of British Columbia, with three important distinctions. First, there is greater tectonic activity, especially along the Aleutian Megathrust, and this has spawned a chain of active *volcanoes* that have created the Aleutian Islands. Second, many of the Alaskan fjords retain tide-water glaciers that preclude any beach formation. Third, tidal ranges increase dramatically toward Anchorage, and this produces swift tidal *currents* that transport much of the fine sediment load from the coastal streams into deepwater. Most of this coastline is accessible only by water or air. About midway between Sitka and Cordova, Alaska, sits Lituya Bay, site of the largest "recorded" wave uprush or swash (just over 500 m) caused by an earthquake and resulting landslide, in 1958.

The Arctic coastline

The Arctic coasts of North America include portions of four geomorphic provinces: the Interior Mountains and Plateaus; the Rocky Mountains, the Arctic Lowlands; and the Canadian Shield. Over-arching characteristics of these coastal regimes are the effects of extensive sea ice, the effects of continental glaciation and isostatic adjustments, and the effects of permafrost. In addition to generating a suite of ice-related coastal landforms, such as ice foot, push ridges, thermokarst lagoons (Figure N29) or scour features, the presence of sea ice reduces or eliminates fetches, thereby reducing the wave energy available to reshape the coast (e.g., Trenhaile, 1990). Tide ranges are generally less than 1 m along the exposed arctic coasts, but increase to more than 4 m in parts of Hudson Bay and more than 6 m along parts of the Ungava Peninsula (Davies, 1980).

Interior Mountain Province

The coast between the Alaskan Peninsula and northern Kotzebue Sound (Figure N29) is part of the Interior Mountains and Plateaus Province. The regional morphology is dominated by a series of expansive, Quaternary coastal plains associated with a series of deltas. The

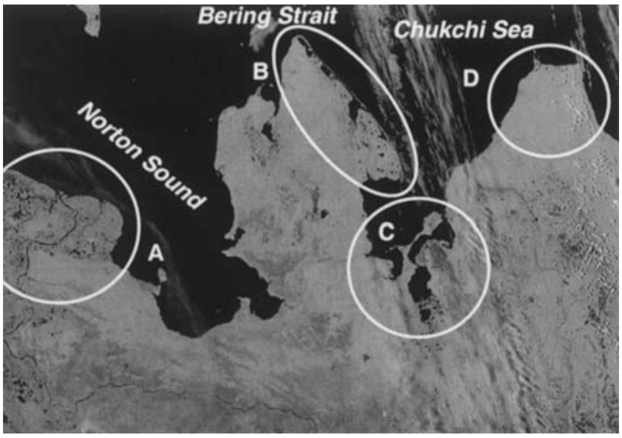

Figure N29 Alaska's Seward Peninsula (figure has west at the top). This is a MODIS image (courtesy of NASA) from 04/08/02. (A) The Yukon River delta, Characterized by fine sediments and thermokarst erosion. (B) North coast of the Seward Peninsula, with sandy barrier systems backed by lagoons and extensive marshes. Thermokarst erosion is common in the fine sediment deposits. (C) Kotzebue Sound and the Baldwin Peninsula. The southern shore has extensive coastal dunes. Most of the rest of the coast comprises deltaic mudflats with some thermokarst erosion. (D) Point Hope, at the western end of the Brooks Range.

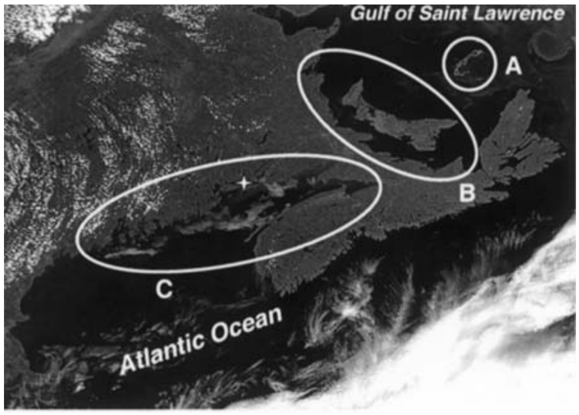

Figure N30 South eastern Canada. This is a SeaWIFS image (courtesy of NASA) from 20/07/01. (A) Îlesla Madeleine, Quebec. The islands are characterized by extensive sandy beaches and coastal dunes, with occasional rocky outcrops. (B) Prince Edward Island, Northumberland Strait, and the coastal plains of New Brunswick and Nova Scotia. The exposed coasts are characterized by barrier/estuary systems typically separated by cliffed headlands. (C) The Bay of Fundy and the glaciated coasts of New Brunswick and Maine. Muddy tidal flats are common in the Bay of Fundy east of Saint John (✧).

largest of these, the 3,000 km^2 Yukon delta, receives about 90% of the fluvial sediment yield in this Province (Walker, 1998). Coastal sediments are relatively fine-grained and mudflats (Flemming, 2002) and coastal dune fields (Walker, 1998) are common in the vicinity of the deltas.

Rocky Mountain Province

The Rocky Mountain Province is represented along a short distance of the Alaskan coast by the northern terminus of the Brooks Range. This coastline is characterized by permafrost cliffs with elevations between about 10 and 300 m (Walker, 1998), with the latter elevations occurring where the Brooks Range directly abuts the coast. Many of the cliffs are fronted by narrow, sandy beaches.

Arctic Lowlands Province

The Arctic Lowlands stretch from a point west of Point Barrow to the northern tip of the Boothia Peninsula, and includes a number of large, low relief islands. Banks, Victoria, Melville, and Prince of Wales Islands are the largest of these. Permafrost is ubiquitous in the Province, and many of the characteristic landscape elements of the coastal zone reflect this. Thermokarst depressions and pingos are common (Carter *et al.*, 1987). Coastal morphology reflects extensive control by glaciation and sea ice. This coast is ice-bound for much of the year, limiting wave-induced erosion. The eastern reaches of the lowlands are sheltered further by islands. Coastal sediments are typically derived from *bluff* erosion, glacial tills, or deltas, such as those of the Coleville and the MacKenzie Rivers. Much of the drainage of northern Canada debouches across the lowlands, creating extensive delta networks and delivering large sediment loads.

Canadian Shield Province

The Canadian Shield coast stretches from the relatively low relief of the Boothia Peninsula to the high relief coast of mainland Newfoundland (Labrador), and the northern coast of the Gulf of Saint Lawrence. It includes many islands, most notably Baffin Island. The landscape is dominated by the effects of Pleistocene glaciation (continental and alpine) and subsequent isostatic rebound. There is continuous permafrost along most of the low-lying coast, with sporadic permafrost found as far east (and south) as Labrador (Shilts *et al.*, 1987). Marine processes are minimized by short fetch distances caused by the presence of islands, and by the frequent presence of nearshore or shore-fast sea ice. The coasts of Baffin Island and much of Labrador are characterized by coastal cliff and fjord systems typical of high-relief *glaciated* coasts. The most distinctive large-scale morphological feature of the Shield coast is Hudson Bay, a flooded depression in the shield that has an east–west extent of about 800 km, and a north–south extent exceeding 1,000 km (including James Bay). The coast of southern and western Hudson Bay has emergent beach ridge systems that may extend inland up to 75 km (Martini *et al.*, 1980). Many of the beaches along eastern Hudson Bay through Ungava Bay are characterized by boulder strewn *tidal flats*. Rias are common along many reaches of the north coast of the Gulf of Saint Lawrence (Dubois, 1980).

Appalachian Mountains and Plateaus Province

The maritime provinces of Canada, and the coast of Maine are in the Appalachian Mountains and Plateaus Province. This includes the island of Newfoundland, Prince Edward Island, and Cape Breton Island. Most of the shores of this region display relict glacial landforms from the Pleistocene. The exposed northern coast of Newfoundland and the eastern coast of Nova Scotia are high wave-energy environments, characterized by *rocky* shores with till-derived, sand and gravel beaches in protected coves and estuaries. The coasts surrounding the southern reaches of the Gulf of Saint Lawrence are characterized by barrier bay systems. Sediments are derived mainly from the erosion of glacial tills or from offshore sources as a result of *transgression*.

The Bay of Fundy (Figure N30) is a low wave-energy environment that is dominated by tidal processes. Maximum spring tide ranges exceed 15 m in the southern arm of the bay, the Minas Basin, where large inter-tidal sand bodies are common. Wide, inter-tidal mudflats are common in the upper reaches of Chignecto Bay, Fundy's northern arm (e.g., Davidson-Arnott *et al.*, 2002).

Atlantic Coastal Plain Province

The Atlantic Coastal Plain Province reaches from Maine southward to the US–Mexico Border. Its morphological characteristics have been described by Walker and Coleman (1987). Tectonically, this is a passive, or trailing-edge coastline (Inman and Nordstrom, 1971) of low relief except where glacial or isostatic processes have created coastal cliffs in the northern parts of the Province. Most of the coastline in this Province is characterized by barrier island and estuary/bay systems, including many of the longest barrier islands on earth. Spring tide ranges on the open Atlantic coasts are typically less than 2 m, and less than 1 m along the coast of the Gulf of Mexico. Average annual wave energy decreases southward in this Province.

The coast from Maine south to New York (Figures N30–N32) displays the effects of continental glaciation during the Pleistocene, extensive submergence during the Holocene transgression, and a strong geological control on coastline features (Fitzgerald *et al.*, 2002). There are few sandy barriers north of Bigelow Bight (Figure N31). Drowned river mouths, moraines, and glacial outwash features are common. Examples of the former include Penobscot Bay, Maine, Boston Harbor

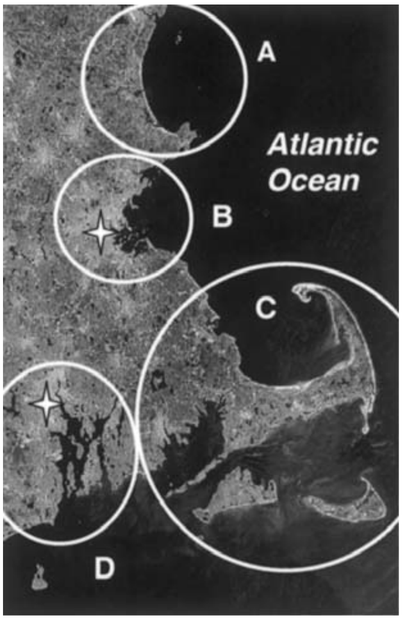

Figure N31 The southern New England coastline. This is a MISR image (courtesy of NASA) from 13/04/00. (A) Bigelow Bight, from Portsmouth, New Hampshire, past the Plum Island barrier, south to Cape Ann, Massachusetts. (B) Massachusetts Bay, including Boston Harbor and the City of Boston (✧). (C) The classic recurved spit of Cape Cod with sandy barrier systems common along the eastern shore, and the islands of Martha's Vineyard and Nantucket in the southwest and southeast. (D) The glaciated coastline in the vicinity of Narragansett Bay and Providence, Rhode Island (✧).

(that includes drumlins, Figure N31), Narragansett Bay, Rhode Island (Figure N31), and the New York Bight (Figure N32). The dominant glacial sedimentation features include Cape Cod and the islands of Martha's Vineyard and Nantucket (Figure N31), and Long Island (Figure N32). Western and northern Cape Cod has a spine of moraine deposits, but the most dramatic coastal features are the large, recurved spits formed from reworked outwash. Barrier systems are common along the Cape Cod shore, and extensive sand dunes occur in the northern reaches. Similarly, Long Island, New York, comprises a morainal spine along its northern coast and an outwash plain along its southern coast. Glacial sands, eroded from the eastern end of the island, have been transported westward by longshore currents to form several barrier islands, including Fire Island. The New York Bight (Figure N32) is the drowned valley of the Hudson River, bounded to the east by Breezy Point, a barrier spit, and to the south by Sandy Hook, another barrier spit. Staten Island is formed by a remnant moraine and is near the southern limit of glacially affected coastline in North America.

The rest of the coastline in this geomorphic Province is dominated by series of barrier and lagoon systems. Fisher (1982) identified four barrier island coastlines in the United States, and all are in this Province: the Middle Atlantic States from New York (south shore of Long Island) through North Carolina; South Carolina and Georgia Sea Islands; Florida's east coast; and the Texas and Mexico coasts. The groups are distinguished not only by geography, but also by characteristic form assemblages. All of the barrier islands include coastal dunes (although perhaps substantially human-altered), and many of the larger islands have extensive dune systems.

In the Middle Atlantic States, the shores of New Jersey and the Delmarva peninsula (Figure N32) are morphologically similar. Both are characterized by barrier island chains often separated from the mainland by wide bays. Both coasts are terminated by large estuaries, Delaware Bay to the north, and Chesapeake Bay to the south formed by the submergence of fluvial systems. Along the northern New Jersey coast the direction of net *alongshore transport* is toward the north, terminating at Sandy Hook. From central New Jersey to Chesapeake Bay, transport along the Atlantic coast is to the south. The configurations of Cape May and Cape Charles result in part from this process. Kraft (1985) notes that this reach typifies the response of coastal plains to marine transgressions with elongated and often overlapping islands. The extensive use of shore protection structures and beach nourishment projects make the barrier coast of New Jersey one of the most extensively, human-altered shorelines in North America (e.g., Nordstrom, 2000).

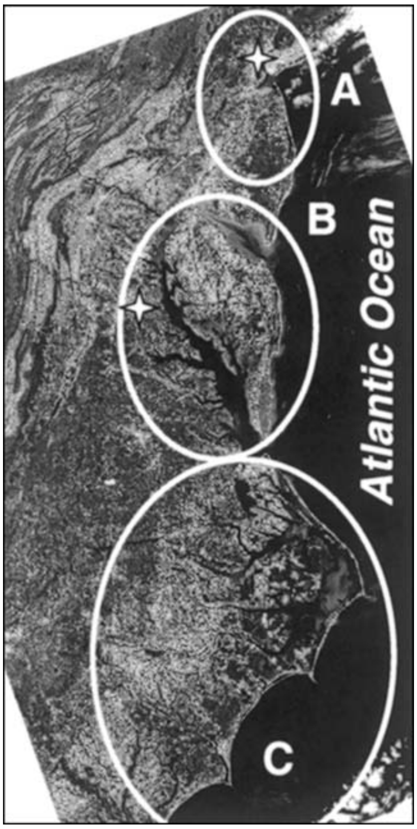

Figure N32 The mid-Atlantic seaboard of the United States. This is a MODIS image (courtesy of NASA) from 11/10/00. (A) New York Bight, western Long Island, New York City (✧), and the barrier systems of northern and central New Jersey. (B) Chesapeake Bay, a classic ria, and the Delmarva Peninsula. The ✧ indicates the approximate location of the Baltimore/Washington urban region. (C) The Carolina Capes—Hatteras, Lookout, and Fear (from north to south), with their long, sandy barriers, and Pamlico Sound.

The middle Atlantic coast of North Carolina also features nearly continuous barrier island chains (Figure N32). There are pronounced changes in orientation along this coast, with structural control across the boundary of the Chesapeake–Delaware Basin and the Cape Fear Arch (Walker and Coleman, 1987). The Holocene transgression submerged several large, low-relief drainage basins, leaving the elongated barrier chains configured as a set of capes, Capes Hatteras, Lookout, and Fear. The first two are well separated from the mainland by Albermarle and Pamlico Sounds. The larger barrier islands (e.g., Hatteras) have large, well-developed dune complexes.

The South Carolina and Georgia Sea Islands comprise a set of barriers with a distinctive morphology. Walker and Coleman (1987) describe three island types: Pleistocene remnants, Holocene barriers, and marsh islands (protected by the barriers). These barrier islands are much less elongated than their Middle Atlantic counterparts, with many more *inlets*.

The east coast of Florida between Jacksonville and Palm Beach is straight, other than the foreland caused by Cape Canaveral. There is no fluvial sediment delivery to the coast along this reach. Wave energies along this coast are moderate to low, but the region is subject to high-energy events caused by tropical storms. The barrier islands are elongated, and the bays behind them are also elongated with relatively few inlets. There are small dune systems on the barriers, sabellariid reefs in the inter-tidal zone (Kirtley and Tanner, 1968), and relict beach ridge plains on the mainland. Along the southern reaches of the Florida Peninsula, coral reefs replace the sabellariid colonies, there are low relief limestone cliffs, and calcium carbonate replaces silica as the dominant constituent of the beach sand. Mangroves occur in sheltered waters of the Florida *Keys*.

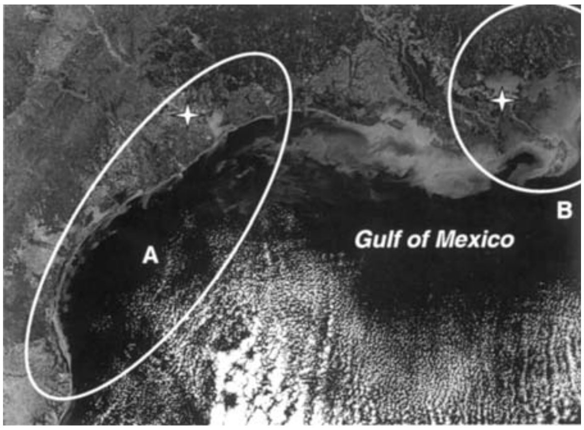

Figure N33 The Gulf of Mexico coasts of Texas and western Louisiana. This is a MODIS image (courtesy of NASA) from 13/11/02. (A) The coast of Texas from the Rio Grande River to the border with Louisiana. Long sandy barrier islands and extensive lagoon/marsh systems are characteristic of this low-lying coast. Houston (✧) is near the head of Galveston Bay. (B) The Mississippi River delta, characterized by extensive marshes and fine sediment deposition (note sediment plume from river mouth). New Orleans (✧) is located on the south shore of Lake Ponchartrain, with the latter created by the progradation of the delta.

The west coast of Florida is *micro-tidal* with very low wave energy. There are scattered barrier systems in the central sections of this reach, with mainly silica sands. Mangroves become locally important along the northern coasts, as wave energy north of Tampa Bay becomes trivial. In the Florida panhandle, wave energy increases westward, although tide ranges remain small. There are well-developed barrier, beach ridge, and coastal dune systems along this coast, especially from the Apalachicola River delta west to Pensacola.

The major morphological features of the US coast of the Gulf of Mexico are the Mississippi River delta and the barrier islands of Texas (Figure N33). There is minimal structural control along this coast, and the coastal plain is quite wide, 100 km or more in Texas and Louisiana (Walker and Coleman, 1987). Wave energy and tide ranges are low, although this region is also vulnerable to tropical storms. Beach sediments along the northwestern Gulf show strong influences of voluminous, fine sediment delivery by the Mississippi River and subsequent redistribution to the east by Gulf currents. The river drains more than 3×10^6 km^2, and discharges 580×10^9 m^3/yr of water and 330×10^9 kg/yr of suspended sediment (Meade, 1981). Delivery of this sediment load into the low-energy environment of the northern Gulf of Mexico has caused the progradation of the Mississippi River delta.

The Mississippi River delta is one of the largest, and most studied, deltas on earth (e.g., Walker and Coleman, 1987; Wells, 1996). Its classic birdfoot shape has grown more pronounced through historic times as the loss of *wetlands* has emphasized the configuration of the natural levees. Wetland loss, at rates averaging in excess of 50 km^2/yr for more than a half a century (Reed, 2002), represent the greatest rates of coastal land loss in North America. These losses are caused by oxidation of organic materials, subsidence of the delta deposits, and sea-level rise—the local, relative rate of sea-level rise exceeds 10 mm/yr (Reed, 2002). Coastal erosion contributes only slightly to the wetland loss rate, although it has contributed to the formation of several barrier island chains, such as the Timbaliers and Chandeleurs.

The coastline of Texas (Figure N33) is low energy and micro-tidal. There is a wide coastal plain of low relief, and the mainland coast is fronted by a series of long barrier islands and spits, including the longest undeveloped barrier in the world, Padre Island. The barriers are transgressive, being driven landward by sea-level rise. Beach sediments are also derived from the Mississippi River, and the four Texas streams that discharge through the barriers: the Brazos, San Bernard, and Colorado Rivers, and the Rio Grande (Aronow and Kaczorowski, 1985). The bays are also elongated, the Laguna Madre, for example, is about 200 km in length. Numerous small estuaries, from submerged drainage systems, form the landward perimeter of the bays. The entire coastal system is vulnerable to erosion, inundation, or washover, caused by tropical storms. Dune systems are common, especially along the southern coasts. Inlets are widely spaced, tend to have small ebb tidal deltas, and sediment *bypassing* is sporadic and event driven (Morton *et al.*, 1995). Galveston Island, once inundated by the most catastrophic hurricane in US history, is now the most human altered barrier in Texas, comprising groin fields, landfill, beach nourishment, and a seawall.

The Gulf coast of Mexico has several well-developed barrier/marsh/lagoon systems. South from the Rio Grande delta is the Laguna Madre and a long barrier spit and island system backed by a series of estuaries. This system extends from the Rio Grande south to the vicinity of La Pesca. The barriers and lagoons then become smaller and discontinuous until the large estuarine delta system of the Rio Panuco, near Tampico. Cabo Rojo is part of the Isla del Idolo barrier complex, including dunes and *beach ridges*, that protects the Laguna Tamiahua, and it is the only pronounced coastal feature in this reach. This coast is also in the range of tropical coral habitat.

Coral is also found off the Veracruz coast, and this reach is also characterized by large expanses of marshes, lagoons, and sandy barriers. Wave energy in this region is low, as is the tidal range. At about this location the coast begins a pronounced bend toward the northeast, and the large Laguna de Términos. Mangroves occur in sheltered locations within the lagoon systems, and dunes are common on the barriers. This coast changes largely in response to tropical storms and changes in water level. The western coast of the Yucatan Peninsula is dominated by sedimentation from large drainage systems, leading to the development of large beach ridge complexes associated with the deltas (Psuty, 1966). The eastern shore of the Yucatan is also a low-energy environment, with coral reef forming a barrier, and mangroves dominate in sheltered waters.

Distribution of muddy coasts

Few of the open ocean coasts of North America have extensive systems of muddy beaches. Their distribution is described by Flemming (2002), and the locations of the most extensive systems are summarized here. Muddy coasts are usually low-gradient, and often provide substrate for deltaic, lagoonal, or estuarine marsh systems. Typically, muddy coastal environments are found adjacent to large deltas, such as the Mississippi River delta (Figure N33) or where wave energy is low—in estuaries or embayments, such as the Bay of Fundy (Figure N30). Large, mud-dominated coasts are found in the lagoon systems of tropical Mexico (Figure N25), the Gulf of California, and the Baja California Peninsula (Figure N26) and are usually associated with marsh systems. There are few muddy-systems along the west coast of the United States, and those are confined to relatively small estuaries, except for the marshes around San Francisco Bay (Figure N27) and the Columbia River estuary. The muddy environments of the western Canadian coast are associated with the deltas of the Fraser and Skeena Rivers (Figure N28), and there are few substantial deposits along the Pacific coastline of Alaska. The rest of the Alaskan coast has muddy coastlines around Bristol Bay and in the vicinity of Norton Sound and the Yukon River delta (Figure N29).

Flemming (2002) notes that the major reaches of muddy coast in Arctic and Atlantic Canada are few, but include extensive mudflats in Hudson, James, and Ungava Bays, muddy marshes in the St. Lawrence estuary, and fringing mud deposits in the Bay of Fundy (Figure N30). The Atlantic coast of the United States is characterized by lengthy barrier systems that provide shelter for back barrier bays and marshes such as those in New Jersey and landward of the Carolina Capes (Figure N32). In all of these cases, the open Atlantic coasts are mainly sand. The estuaries of this coast, including Delaware and Chesapeake Bays (Figure N32), and Long Island Sound, provide sufficient protection from wave action to accumulate large muddy deposits, usually manifested in *salt marshes*. Similar systems are found around the Gulf of Mexico. Sandy barriers protecting muddy lagoons and marshes, with some estuaries, characterize the coasts of Mississippi, Alabama, and Texas (Figure N33), and much of the Mexican coast south to Belize. Notable for the extent of the deposits are Laguna Términos (Figure N25) and Laguna de Tamiahua. The Mississippi River delta (Figure N33) stands alone as the only significant reach of open coast to be characterized by muddy deposits. This reflects the river's extremely large, fine-sediment load, and the relatively low wave energy in the northern Gulf.

Distribution of coarse clastic coasts

Beaches composed of coarse clastic sediments, also referred to as shingle, gravel, pebble, cobble, or boulder beaches, are most common in *periglacial* or paraglacial environments, along cliffed coasts, or near the mouths of steep gradient coastal streams (Orford *et al.*, 2002). These beaches have steep profiles, and are relatively immobile compared to sand-dominated systems. Davies (1980) indicates that such deposits are of some degree of relative importance around most of the North American continent. Specifically, he categorizes these beaches as occasionally important along a reach of the Pacific coast roughly bounded by Acapulco (Figure N25) and San Diego (Figure N26), in Canada from northern Newfoundland to northern Nova Scotia (Figure N30), and along the reach from Maine (Figure N30) to New York (Figure N32). Davies classifies coarse clastic systems as important along the coasts of Canada and the United States north of Puget Sound on the west coast and north of Newfoundland on the east coast. They are also important along the coasts of Newfoundland and northern Maine.

NOTCHES

Littoral notches are more or less horizontal erosion features close to sea level into steeper coastal slopes. They prove that special processes of destruction around the surf level are much more intensive than in subtidal or supratidal positions. Their relation to tidal levels and their shape may differ from one type of notch to the other, because there are several genetic types of notches around the coastlines of the world (Kelletat, 1982; Pirazzoli, 1986).

Notches caused by melting

At ice cliffs of shelf ice, or even in driftng ice bergs, sharply incised notches can be detected at sea level, caused by melting processes of relatively warmer surficial waters, even in arctic or antarctic environments during summer. These forms may develop in a very short time (several days), but they are usually rapidly dislocated (mostly uplifted above sea level or tilted) by the moving of ice margins or tilting of ice bergs during the melting process, when the point of gravity will shift. Notches caused by melting processes may also occur in sediments of permafrost environments, if warmer seawater in the surf zone undermines steeper slopes. These forms are seldom stable for longer times; because by melting of the cliff, soft material will creep or slide into the surf zone and cover the notches.

Notches caused by chemical solution

In the scientific literature this kind of notch formation is very often described in carbonate rocks, because the sharp microforms resemble karstic features from terrestrial environments, and the seawater is believed to act as an aggressive agent upon limestones. This conclusion is incorrect, because seawater is always oversaturated (up to several 100%) by dissolved carbonates and is not able to destroy carbonates by solution. Solution may be responsible for notch formation in halites or gypsum rocks, but no descriptions from these environments exist.

Notches caused by salt weathering

In sedimentary or volcanic rocks with clasts of sandy or coarser grains salt weathering may act as a notch-forming process. It is often restricted to those levels above mean sea level, where salt water may rise through capillary action in the rock, transporting salts. By wetting and drying the grains in the rock may be loosened, producing honeycombs and tafoni of different sizes. Galleries of these smaller forms may decorate the rocky shores and, coalesced, form an irregular shaped kind of notch. The process dominates other littoral processes only in warm and arid regions with very limited surf action and tides, as in the eastern Mediterranean.

Notches caused by mechanical abrasion

This is a widespread (although only locally developed) notch type in hard rocks, where sand and pebbles or cobbles are present to be moved constantly in the surf zone. They polish the rock and abrade it. These notches show different profiles according to lithological characteristics, but are always very smooth, showing the rock's own color, because no algae or other organisms will survive the surf attack with abrading "weapons." The relation of this notch type to sea level or tidal levels may differ according to the availability of loose sediments: if only a limited amount is present, at a steep coast the polishing may only occur in the subtidal; and if a large amount is available, only the uppermost strata of the sediment can be moved against coastal rocks, so that the abrading and notching process is restricted to cliff parts in the upper surf zone. Therefore, a difference of the notch relative to mean sea level does not always mean relative sea-level variation. Abrasion notches are very often accompanied by smaller or larger coastal caves in parts of lesser resistant rocks. If rocky coasts dip into deeper water and no loose material is present in the surf zone, the extremely differing pressure of air and water under wave attack may destroy rocks with textural or structural weakness and break out larger portions of the cliff, but they will never form notches at plunging cliffs. In regions with drifting sea ice this effect (as well as frost action) may form notch-like features in less resistant rocks.

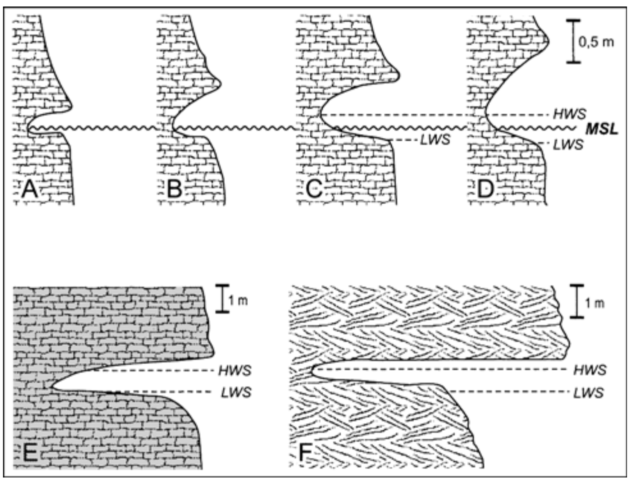

Figure N34 Shape of bioerosive notches and their relation to tidal levels (A–D from the Mediterranean): (A) tideless, sheltered; (B) tideless, exposed; (C) microtidal, sheltered; (D) microtidal, exposed; (E) microtidal, sheltered, in Neogene coral rocks of Palau, Micronesia; (F) microtidal, sheltered, in less resistant Pleistocene eolianites of the Bahamas.

Notches caused by bioerosion

This is by far the most widespread type of notch; but is restricted to carbonate rocks including carbonate sandstone (calcarenites) and sometimes dolomites, and to low latitudes (Kelletat, 1997). Its aspect is a horizontal back-carving of rocky shore faces, very often along extensive and continuous stretches of the coastline, with the smaller part under water and a wider above mean sea level. An important exception to this rule may be found at windward coasts in regions of strong and constant tradewinds, when bioerosion notches may be totally developed significantly above the high water mark. The shape of bioerosive notches differ according to tidal range and exposure (Figure N34). They are more open and wide with a tidal range larger than 1 m and more intensive surf, and more narrow with a nearly flat roof in very sheltered and almost tideless environments. These points are important if the relation of living and fossil notches to varying sea levels is discussed. In areas of large tidal ranges and extreme surf conditions bioerosional notches may be less developed or absent. Although bioerosive notches will undermine the cliff face rather rapidly (i.e., about 1–2 mm/year), collapse of cliffs by this process can only be detected in very less resistant rocks like eolianites. Looking closer to the shape of bioerosional notches, they always show a sharp microrelief in every part. The normal profile is asymmetrical and shows a rather flat bottom, an innermost knickpoint close to the bottom and a more (exposed) or less (sheltered) inclined notch-"roof" (Figure N34). The color of the rock in a notch is usually darker than in fresh cuts, ranging from greenish to dark grey and even black, the latter in levels above mean sea level. As a notch always indicates destructive processes near the surf horizon being more active than below and above, a special group of organisms forming notches should be living in these well-defined belts. In fact, we find here macroorganisms such as chitons or limpets (e.g., *Patella* sp.), used to living and grazing in permanently wetted but well-illuminated zones. Their grazing instrument is the so-called radula, their food being microscopic organisms like cyanophytes and chlorophytes (and sometimes fungi) (Schneider, 1976; Torunski, 1979). These are responsible for the rock colors: where wetting is guaranteed, these organisms live more epilithic, showing their green color; but in the tidal zone they escape from drying out and too much insolation by boring themselves into the rock, thus living as endoliths, their dried out parts showing darker colors. The specific penetration depth depends on the chance for photosynthesis and, therefore, is restricted to parts of a millimeter, the so-called light-compensation depth (which itself depends on the rock type with grain size and crystal forms). Under an scanning-electron microscope the boring patterns of the endoliths (bio-corrosion) can be detected as perforations of up to 800,000 per cm^2, and a three- to tenfold enlargement of the actively corroded surface, but no specific macroscopic geomorphological pattern is formed by this pro-cess. The latter is due totally to the limpets and other grazers, which wear down the surface in one grazing event by about 0.01–0.1 mm (bio-abrasion). Hence light can penetrate deeper into the rock, and the endoliths will bore deeper, as well, exhibiting a new sheet of food for the grazers. The restriction of the grazers to well-defined tidal (and wetting and drying) levels leads to the sharp horizontal bioerosive notches, visible after only some decades of grazing in the same level. All in all bioerosive notches, because of their good and rapid development and normally strong restriction to tidal levels, are among the best sea-level indicators at the coastlines of the world.

NUMERICAL MODELING

Originally, numerical modeling mainly referred to the techniques employed for numerically solving a set of equations (algebraic or differential equations). However, the meaning has evolved and is now often used to also denote the selection of the equations to be solved. In turn, this involves describing the physical processes of interest in mathematical terms, which is also referred to as mathematical modeling. Formulating a set of governing equations might be straightforward on a theoretical, fundamental level, but in practice such equations could be impossible to solve (*i.e.,* use), not only because of insufficient computational power, but also because initial and boundary conditions as well as various types of forcing are not known or understood at the required level of detail. This is normally the case when dealing with different phenomena in nature, including the physical processes which control the response and development of coastal areas. These areas are shaped by forcing factors which act and produce responses at a wide range of spatial and temporal scales, often in a complex, nonlinear manner with strong feedback between forcing and response. For example, the scale of fluid motion in coastal areas extends from small-scale turbulence at a fraction of a wave period to sea-level rise occurring over centuries, causing responses in sediment transport and coastal evolution at scales from *ripples* to *barrier islands* (De Vriend, 1991; Larson and Kraus, 1995).

The above-described features of the coastal zone imply that numerical models are developed to describe a specific set of processes (at a certain time and space scale) and that the equations employed represent aggregated formulations in time and space, typically including coefficients and parameters with values which ultimately have to be determined through comparison with data. These properties are especially characteristic for *sediment transport* and coastal evolution numerical models, which are the main types of models discussed here. Numerical models of coastal hydrodynamics, such as wave transformation and nearshore circulation models, are more readily derived from a set of basic equations than sediment transport related models. In this respect, it is less complicated to select the equations in coastal hydrodynamics, although there are still many phenomena which are difficult to model, for example, wave breaking and flows associated with rip currents and bottom boundary layers.

Basic concepts

Numerical modeling involves selecting an appropriate set of equations to simulate the behavior of the coastal system under study and then solving the equations using suitable numerical techniques. Other elements of numerical modeling are verification, validation, and calibration (see Figure N35 for a description of the main elements in numerical modeling and how they are connected). In its classical meaning verification of the model involves "solving the equations right," whereas validation implies "solving the right equations" (Roache, 1997, p. 124). Thus, in the verification it is demonstrated that the equations are solved

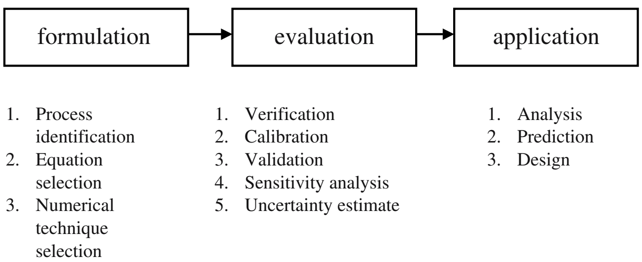

Figure N35 Schematized description of the main elements in numerical model development.

correctly yielding accurate results, which may be done by simulating an ideal case for which an analytical solution is available. The process of validation is typically more complicated since it involves establishing that the selected equations satisfactorily describe the system under consideration. In practice, this is done by employing measured data and showing that the numerical model can reproduce the measurements with some predefined accuracy. In general, numerical models include parameters and coefficients whose values have to be specified, which is done through calibration. In the calibration procedure, the model is used to simulate the coastal system using different sets of parameter values and the calculation result that is closest to the measurements (according to some criterion) defines the optimum parameter values, yielding a calibrated model. The available data set is normally split into two parts, where the first part is used for calibration and the second part for evaluation of how well the calibrated model can simulate the system. This evaluation of the calibrated model is often referred to as validation, although formally model validation should involve a more extensive confirmation that the model equations represent the coastal system.

A unique solution cannot be found to a set of equations unless proper initial and boundary conditions are provided. Specifying boundary conditions implies giving the value of the quantity to be solved for (or some derivative of the quantity) at the boundary of the solution domain at all times. Similarly, the initial conditions yield information on the state of the system at the start of the simulation (*i.e.,* a value is assigned to all points under study in the solution domain). The values provided for initial and boundary conditions as well as for parameters and coefficients are collectively denoted as model input. In contrast, the calculated results are known as model output.

An important aspect of numerical modeling that is often not given enough attention is the uncertainty in the calculation results. Techniques to assess the uncertainties related to numerical errors, for example, discretization of the solution domain and the governing equations, are available (Roache, 1997). However, these measures are associated with model verification more than model validation. In order to quantify the overall uncertainty in a calculation, one typically has to resort to comparison with measurements, where some statistical measure is computed to characterize the deviation between measurements and calculations. The uncertainty of a model forecast (alternatively denoted as predictive skill) poses additional problems since there are no data available for such quantifications. Thus, one typically has to assume that the uncertainty of the forecast is approximately the same as that in reproducing the measurements used in the calibration/validation process.

The stability of a numerical model normally refers to how errors grow or decay in the solution. In the case of linear equations, it is possible to mathematically derive criteria for the stability, whereas this is not possible for nonlinear equations. The related term robustness is typically given a wider interpretation, not only focusing on the numerical scheme employed but on the model as such. Evaluating model robustness includes assessing the effects of changes in, for example, model structure, input parameter values, and numerical solution schemes, on the calculation result. If small modifications in model formulation or parameter values produce large changes in the result, model robustness is low, and vice versa. The robustness may be examined using sensitivity analysis where calculations are performed for a selected range of input values (or different model configurations) and the resulting output is analyzed in statistical terms to quantify model behavior. Monte-Carlo methods, where the input values are randomly selected from specified probability distributions, may be employed in this type of sensitivity analysis. For a validated model, Monte-Carlo methods are also highly useful to quantify the variability in the response of the coastal system being modeled. In practical applications with numerical models it is desirable to produce forecasts which include some statistical measures of the variability.

Solving the model equations, which normally constitute a set of ordinary or partial differential equations, requires numerical methods. A wide range of such methods have been developed and each one has its strengths and weaknesses (Abbott, 1979). The most common numerical methods in coastal applications are based on finite differences or finite elements. Traditionally, finite difference methods have been utilized more frequently in coastal numerical models because they are fairly straightforward in the formulation of the equations to be numerically solved and they handle time-dependent problems in a direct way. In these methods derivatives are written in terms of differences resulting in a set of algebraic equations to be solved. If the approximations of the derivatives are formulated in such a way that the variable of interest can be directly calculated at the next time level (or adjacent space level), the solution scheme is explicit. In cases where the difference scheme involves several time (space) levels simultaneously, making it necessary to employ iterative techniques in solving for the desired variable, the scheme is implicit. Finite element methods use spatial discretization of the solution domain into elements of a selected shape, and the variable of interest is interpolated over the element through a given approximating function. This function is obtained based on values of the variable defined at the nodes located in the element corners. Finite element methods are convenient for solving steady-state problems over solution domains of complex geometry where the variable of interest exhibits large spatial variability. An example from coastal applications is diffraction around *structures* in the nearshore.

Classification of numerical models

The most common classification of numerical models is with respect to the spatial dimension of the model, that is, a model can be one-(1D), two-(2D), or three-dimensional (3D) depending on whether the leading variables vary in one, two, or three dimensions, respectively. Additionally, time often enters as another dimension giving rise to the distinction between time-dependent and steady state (*i.e.,* time-independent) models. Another type of classification with regard to the temporal variation, typically employed in wave modeling, is into phase-resolving and phase-averaged models, depending on whether the variation during a wave cycle is modeled or not, respectively. The labeling of numerical models for coastal systems is often not stringent and schematized approaches to describe variations in some spatial dimensions have given rise to, for example, multi-layer (contour), 1.5D, and 2.5D models.

Other common ways of classifying numerical models are related to the following properties:

Probabilistic versus deterministic behavior: In a probabilistic model a random element has been added so that repeated simulations with the same input yields different output. A deterministic model always produces the same output for a specific input. Hybrid modeling approaches are often employed where a deterministic set of equations are used in combination with input generated from some probability distributions in order to simulate the variability of the system response (*i.e.*, a Monte-Carlo simulation approach).

Linear versus nonlinear behavior: A linear model implies that the principles of proportionality and superposition are applicable. Thus, the sum of two different input data sets produces an output which is the sum of the individual outputs for respective inputs. A nonlinear model does not follow these principles and in general includes equations that are much more difficult to solve numerically. Furthermore, some particular nonlinear equations give rise to solutions which display chaotic behavior characterized by aperiodic bounded dynamics with marked sensitivity towards the initial conditions. Such solutions have a behavior similar to a random system, although the equations generating the solutions are purely deterministic.

Distributed versus lumped description: A model where the leading variables are continuous functions of some spatial coordinates are known as a distributed model. In contrast, employing a lumped description implies that specific spatial domains are assigned single values to characterize the variable of interest (and other physical properties) and, typically, the time evolution of this variable is modeled. In practice, lumped descriptions are often employed to parameterize the variation at scales below the one modeled. For example, in estimating the bottom friction in the presence of ripples a single friction coefficient is normally used instead of calculating the detailed flow around the individual ripples.

Physically based versus black-box description: In physically based modeling the objective is to describe the system under study using the laws of physics, whereas in a black-box model the only concern is to develop a set of equations that reproduces the output from the input in the best manner. Statistical models from the field of time series analysis are typical examples of black-box models.

Numerical models for coastal evolution

An informative way of classifying numerical models of coastal systems is with regard to the characteristic time and space scales of the process or phenomenon under study. Nowadays there is a general agreement that it is not feasible to develop one model which would describe the entire coastal system, but a wide range of models is needed that simulate processes at different scales. A certain process is typically a result of factors acting at the representative time and space scales for the process, where factors at other scales have little influence and are neglected, parameterized, or handled through a statistical description. For example, in modeling beach erosion due to severe storms wind-induced waves and water level change are the primary forcing factors to consider, whereas sea-level rise or intra-wave turbulence are factors that are not directly taken into account. Similarly, barrier island migration may be a function of sea-level rise and there is no need to include wind-generated waves in a model of this process. Figure N36 provides an overview of different types of numerical models for the coastal areas based on the characteristic time and space scales for the models. In the following, a

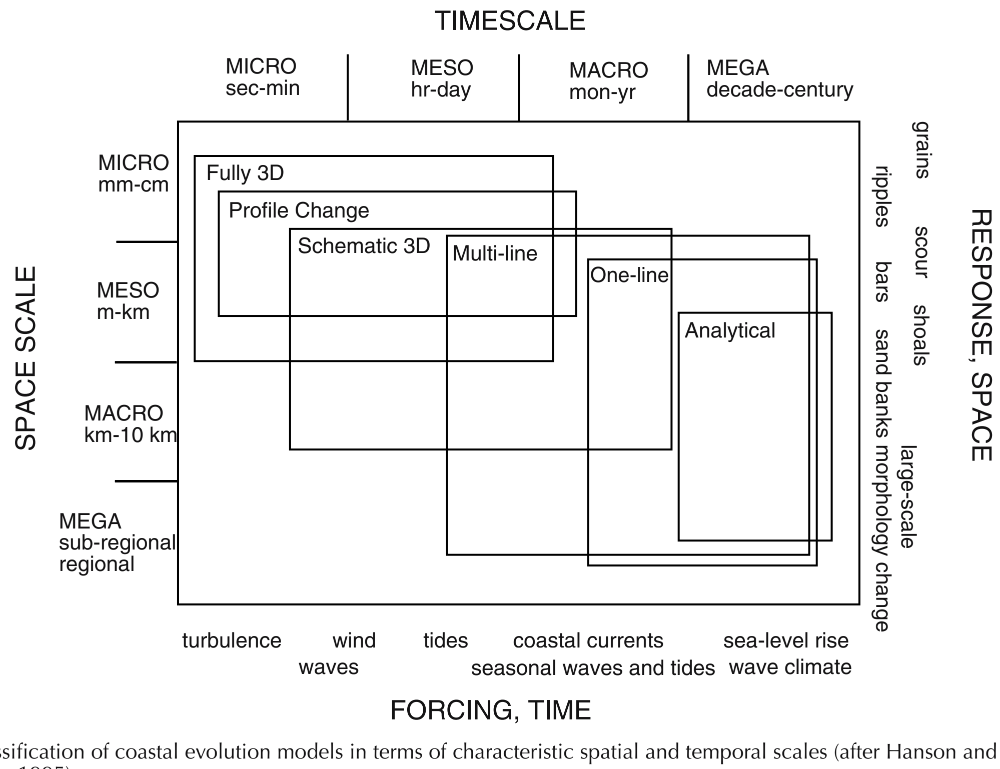

Figure N36 Classification of coastal evolution models in terms of characteristic spatial and temporal scales (after Hanson and Kraus, 1989; Larson and Kraus, 1995).

brief discussion is provided of the different types of models typically employed in simulating coastal evolution.

Historical development

Pelnard-Considère (1956) was the first to formulate a mathematical model to calculate the response of a beach to waves. His model only described the movement of the shoreline, assuming the beach profile to maintain a constant shape at all times. The theoretical work of Pelnard-Considère is the basis for many numerical models that have been successfully applied in calculating shoreline response to waves (Hanson, 1989). An extension of the one-line theory to include two contour lines was made by Bakker (1968), and Perlin and Dean (1978) further generalized this type of modeling to encompass an arbitrary number of contour lines. Watanabe (1982) made the first serious attempt to develop a complete three-dimensional numerical beach change model, which involved submodels to calculate nearshore waves, currents, sediment transport, and the resulting beach evolution. Initially, numerical modeling efforts aimed at simulating the main shape of the beach, whereas various types of morphological features overlaying this shape were considered secondary and not included in the modeling. However, later attempts were made to model such features, for example, longshore *bars* (Larson and Kraus, 1989) and different *rhythmic patterns* (Hino, 1974) including *offshore banks and linear ridges* (Falqués *et al.*, 1998).

Model overview

Analytical models of coastal evolution, as opposed to numerical models, are closed-form mathematical solutions of a simplified governing differential equation with the proper boundary and initial conditions. Analytical solutions have mainly been employed to determine shoreline change (e.g., Pelnard-Considère, 1956), although attempts have also been made to estimate *dune* erosion. Shoreline evolution is calculated under the assumption of steady wave conditions, idealized initial shoreline and structure positions, and simplified boundary conditions. A main assumption in the mathematical (either closed-form or numerical) shoreline change models is constancy of profile shape along the shore. Because of the many idealizations needed to obtain a closed-form solution, analytical models are typically too crude to use in planning and design, except possibly in the preliminary stage of project planning. Analytical solutions serve mainly as a means to make apparent trends in shoreline change through time and to investigate basic dependencies of shoreline change on waves and initial and boundary conditions. Larson *et al*. (1987) gave a comprehensive survey of new and previously derived analytical solutions of the shoreline change equation.

The *shoreline change numerical model* is a generalization of the analytical shoreline change model (Hanson, 1989; Price *et al*., 1978). It enables calculation of shoreline evolution under a wide range of beach, wave, initial, and boundary conditions, and these conditions can vary in space and time. Because the profile shape is assumed to remain constant, the shoreline can be used in the model to represent beach position change. Thus, this type of model is sometimes referred to as a one-line model. The length of the time interval for which the model should be used is in the range of one year to several decades (see Figure N36), depending on the wave and sand transport conditions, accuracy of the boundary conditions, characteristics of the project, and whether the beach is near or far from equilibrium. The spatial extent of the region to be simulated ranges from 1 to 100s of kilometers depending on the same factors.

Principal uses of *profile response models* are prediction of beach and dune erosion produced by severe storms or hurricanes, and initial adjustment of beach fills to wave action and fill loss during a storm (Kriebel and Dean, 1985; Larson and Kraus, 1989; Schooness and Theron, 1995). This type of model only considers *cross-shore sediment transport* and neglects any differentials in the *longshore sediment transport* processes, that is, one profile line is sufficient for describing the beach response. During a storm event such a simplification is normally of adequate accuracy for engineering applications. The typical timescale of profile response models is hours to days for a storm event, whereas if long-time beach recovery or fill adjustment is investigated a timescale of months is of interest (Figure N36).

Three-dimensional beach change models describe changes in bottom elevation which can vary in both horizontal (cross-shore and longshore) directions. Therefore, the fundamental assumptions of constant profile shape used in shoreline change models and constant longshore transport in profile erosion models are removed. Although 3D-beach change models represent the ultimate goal of calculating sediment transport and coastal evolution, achievement of this goal is limited by our capability to predict *wave climates* and sediment transport rates. Thus, simplifying assumptions are made in schematic 3D-models, for example, to restrict the shape of the profile or to calculate global rather than point transport rates. Including both longshore and cross-shore transport rates typically results in numerical models which cover a wider range of scales than shoreline evolution and profile response models only (see Figure N36). However, the development of 3D models (schematic or full) still requires careful consideration of the processes to be simulated and their characteristic scales.

A natural extension of the shoreline change numerical model is to introduce some kind of schematized profile so that cross-shore transport and associated beach change may be described. In an *n-line model* (or *multi-layer model*) the movement of additional contour lines besides the shoreline is simulated (Bakker, 1968; Perlin and Dean, 1978). In these models the cross-shore transport rate is determined from a specified cross-shore distribution (e.g., in terms of wave, sediment, and profile shape parameters) or simply from the average slope between the contour lines. Although n-line models provide information on the cross-shore beach response, the profile shape is still fairly restricted and such models cannot simulate the response of complex morphological features where the profile depths do not increase monotonically with distance offshore (e.g., longshore bars).

Another method for including both cross-shore and longshore transport in a simplified way is to decouple the cross-shore and longshore calculations in some of the modules in the numerical model. For example, instead of calculating on a complete 2D horizontal grid, waves, currents, and sediment transport are computed separately at individual profile lines with the main coupling occurring through the sediment conservation equation solved on a 2D grid. *Decoupled models* (*i.e.*, *schematic 3D models*) can describe bottom topographies that are more complex than n-line models, although alongshore gradients in the modeled quantities should be sufficiently small to allow for a decoupling.

Fully 3D coastal evolution models represent the state-of-art of research and are not widely available for application. Waves, currents, sediment transport, and changes in bottom elevation are calculated point by point in small areas defined by a horizontal grid placed over the region of interest (solution domain). Such models can employ averaged quantities over the water column, in part or throughout the calculations, or resolve the variation through the vertical. Use of these models requires special expertise, and only limited application have been made on large and well-funded projects (Watanabe, 1982). Because fully 3D coastal evolution models are used in attempts to simulate fine details of waves, currents, and sediment transport, they require extensive validation and sensitivity analysis, which in turn has implications for the data requirements.

Future developments

The trend towards developing numerical models describing coastal processes over selected space and timescales will probably continue, yielding a cascade of models for simulating the coastal system at different scales. It is expected that some types of models at adjacent scales will merge, although models at a higher or lower level in the model hierarchy will mainly provide boundary conditions, aggregated forcing, or general constraints for a numerical model at a certain scale. A general development of different numerical models towards increased robustness and reliability will facilitate their use as tools in engineering projects as well as in interpretation and sensitivity analysis of the coastal system. At present, shoreline change and profile response numerical models are the most commonly used types of models for forecasting coastal evolution, but in the near future it is expected that various types of schematized 3D models will reach a state where they can be applied with confidence.

The time (and space) scale of interest in *coastal engineering* and *coastal zone management* is increasing, making additional demands on being able to model the behavior of the coastal system at these scales. Most numerical modeling of coastal evolution has been carried out at timescales from hours to decades, and the experience of modeling at longer scales is limited. However, considerable research is underway concerning coastal evolution at longer timescales, including both decadal, century, and millennium timescales. Thus, it is expected that in the near future reliable predictions of coastal evolution at timescales from decades to centuries can be made.

Hybrid models with both deterministic and probabilistic elements have not been exploited enough for simulating coastal systems. All too often, forecasts of coastal evolution are made without any attempt to assess the uncertainty in the predictions. Monte-Carlo simulation techniques are highly useful in obtaining quantitative estimates of the uncertainty and such techniques should be employed more frequently in numerical modeling, especially in engineering projects. This technique yields a range of possible solutions/predictions rather than a unique, single answer.

OIL SPILLS

The term "oil spill" refers to the accidental release of liquid petroleum hydrocarbons to the environment. The visual nature of black oil coming ashore from a spill commonly attracts public interest on a national and even international scale, oftentimes falsely projecting damages far greater than actually occur. Of all areas, however, long-term damage from oil spillage is likely to be greatest within the ecologically rich coastal zone. Additionally, coastal tides and currents commonly increase damages as spilled oil is transported far from the site of the incident. The *Exxon Valdez* case provides a worst case example where over 2,000 km of Alaskan coastline was oiled from a single discharge location in Prince William Sound.

Principal reference material on oil spills can be found in the bi-annual proceedings of the International Oil Spill Conference available from the American Petroleum Institute (Washington, DC) and the annual proceedings of the Arctic Marine Oil Program sponsored by Environment Canada, Ottawa. Marine and coastal response guidance documents are available from the National Oceanic and Atmospheric Administration. National Research Council (1985) provides extensive reference material as well.

Quantity of oil entering the marine environment

In 1990, the level of petroleum hydrocarbons entering the marine environment was estimated by GESAMP (1993) as 2.35 million tons. (The common conversion factor is 1 ton = 7 barrels, 1 barrel = 42 US gallons.) Of this total, transportation-related activities accounted for 24% (564,000 tons) and included discharges from vessels as well as from terminals. In comparison, the estimated discharge from municipal and industrial sources is more than two times greater, 1.175 million tons or 50% of all oil entering the marine environment. The estimated quantities from other sources include atmospheric (305,500 tons, 13%), natural seeps (258,500 tons, 11%) and offshore exploration/production (47,000 tons, 2%). Note: 1 US gallon = 0.832 UK gallon.

Historically, there has been significant improvement in the prevention of accidental hydrocarbon discharges, particularly those related to marine transportation as well as those from offshore production. Figure O1 presents historic estimates for tons of oil spilled by tankers worldwide (Etkin, 2000). While a general decline in spillage is indicated, a single event during any year can highly influence the total spilled. For example, the loss of 223,000 tons from the *Amoco Cadiz* is larger than the total amounts spilled from 1992 to 1998. The number of tanker spills has also significantly declined, from a high of 3,153 spills in 1979 to an average of 1,200 from 1990 to 1998 (Etkin, 2000). Both spill size and frequency have declined in spite of the increase in the amount of oil shipped via tanker vessels.

Improvements to spill prevention are often associated with the aftermath of major spill events. After the *Exxon Valdez* incident in 1989, public scrutiny and international coverage of this event caused passage of US legislation and international agreements that strengthened requirements for spill-response equipment, training, and safety. In the United States, the passage of the Oil Pollution Act of 1990 will have national and international repercussions well into the future based on its requirement that all tankers be double-hulled by the year 2015 in order to enter US waters.

Hydrocarbon chemistry

Oil is composed of a complex mixture of hydrocarbons that varies highly by its source and subsequent refining. Once spilled, it is exposed to additional chemical and biological processes which further alters its composition.

The hydrocarbon component of oil is comprised of hundreds of organic compounds, principally divided into aliphatics and aromatics. In addition to hydrocarbons, oil may also contain small amounts of N, S, and O (termed NSO compounds), as well as widely varying concentrations of trace metals (e.g., V, Ni, Fe, Al, NA, Ca, Cu, and U). These metals and other unique components of the spilled oil are often used as a tracer to follow the distribution and long-term impacts of the spill.

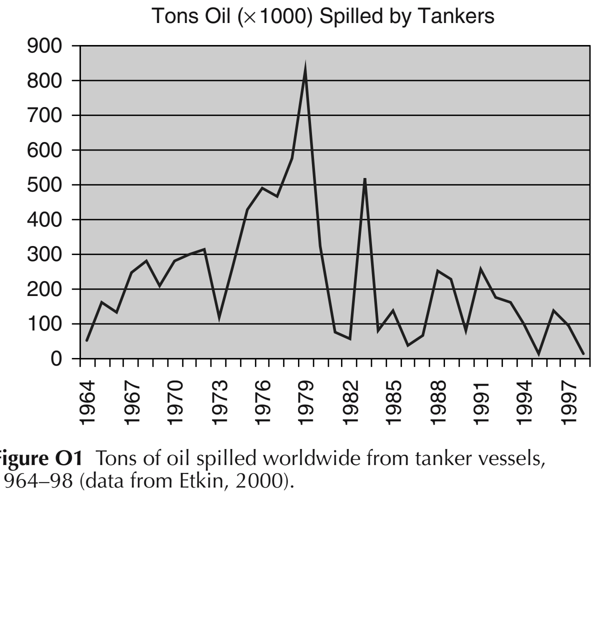

Figure O1 Tons of oil spilled worldwide from tanker vessels, 1964–98 (data from Etkin, 2000).

As crude oil is refined, the resulting product markedly changes in composition and physical properties (e.g., specific gravity, viscosity, pour point, and flash point), all of which influence the potential impact to the environment should it be released. The distillation process separates crude oil into refined products used for domestic and industrial purposes. These may be referred to as: light fractions (gasoline), middle distillates (kerosene, heating oil, jet fuel, and light gas oil), wide-cut gas oil (lube oil and heavy gas oil), and residuum or bunker oil.

For oil spill response planning, oils are commonly categorized into four groups (ITOPF, 1987). Group I has a specific gravity < 0.8, low viscosity (0.5–2.0 cSt at 15°C) and includes gasoline, naphtha, and kerosene. Group II has a specific gravity 0.80–0.85, average viscosity = 8 cSt at 15°C and contains light crude oils and gas oil. Group III has a specific gravity of 0.85–0.95, a higher viscosity averaging 275 cSt at 15°C and includes intermediate crude oils and medium fuel oils. Group IV are heavy crudes and fuel oils (e.g., bunker oils) that have a specific gravity of > 0.95 and high viscosities > 1500 cSt at 15°C. Group IV oils may include products that sink or have a buoyancy near that of water, greatly increasing the difficulty of recovery if spilled.

Spill weathering and fate

Once released to the environment, the spilled oil is exposed to a series of "weathering" processes that may alter its original chemistry and physical properties. These include spreading, advection, evaporation, emulsification, dissolution, dispersion, photo-oxidation, sedimentation, and biodegradation.

Spreading causes the formation of a relatively thin layer of oil on the water's surface after it is released. Affecting processes include gravity, friction, viscosity, and surface tension. The color of the oil on the water is related to thickness and has been used as a simple measure of the quantity of oil present. For example, a silver sheen has a thickness of approximately 0.0007 mm and represents approximately 100 L spread over 1 km^2. A brown sheen on the water's surface indicates a thicker layer (0.1–1 mm). When slicks are forced to the coastline by onshore winds, the slick may increase to a centimeter or more in thickness.

Advection is the movement of oil on the water's surface, influenced by currents and winds. Most predictions assume that oil will move in the direction and speed of the vector addition of current speed and direction plus 3% of wind velocity in the direction of the wind forcing. Shifting tides, eddies, and variable winds all add to the difficulty in predicting the real-time movement of the spill.

Evaporation is a major process influencing all aspects of oil chemistry and its physical properties. During evaporation, the light products (gasolines, kerosenes, etc.) escape to the atmosphere leaving a lesser amount of oil on the water, but increasing its specific gravity and viscosity. Evaporation can commonly remove 30–50% of light crude oils and refined products within a relatively short time period (hours to days).

While evaporation can substantially reduce the quantity of oil, the process of emulsification (a water-in-oil mixture) may significantly increase (double) the quantity of total oil mass by incorporating water within the oil structure. Emulsification commonly occurs by wave action and mixing. Oil weathering decreases as the oil emulsifies.

Dissolution is the transference of oil from the water's surface into solution within the water column. It is very minor accounting for 1% or less of the total oil spilled.

Dispersion is the process of forming oil particles or droplets in the water column as occurs during breaking wave conditions. The process of forming particles of ever smaller size enables the material to be biodegraded.

Photo-oxidation is the result of sunlight altering the composition of the oil. It accounts for only a small change (<1%) in the overall content of the spill. Direct effects of photo-oxidation on an actual spill have not been measured.

Sedimentation is the interaction of sedimentary particles and the spilled oil which may increase the density of the oil and carry it to the bottom. However, as most oils float, transport of substantial quantities to bottom sediments is relatively uncommon.

Biodegradation is based on the ability of bacteria and other organisms to degrade and convert the oil from a hydrocarbon to its fundamental elements. Biodegradation is able to act on small oil particles as the material is dispersed into the aquatic environment or when resident on shorelines. Oxygen and an adequate supply of nutrients are needed to sustain biodegradation.

Impact and reaction in coastal environments

Spilled oil can have a significant impact on the coastal environment, the level of which varies with physical processes (e.g., winds, tides, and currents) and with the geomorphology and ecology of the coast.

Coasts have been categorized and ranked in terms of sensitivity to oil spills by Gundlach and Hayes (1978). This system, called the Environmental Sensitivity Index (ESI) is widely used for spill contingency planning and to guide the response effort during spills. Common coastal types of the ESI are presented in Table O1.

The ESI shoreline ranking indicates that exposed rocky shores are the least sensitive to spilled oil, followed by beaches of varying sediment sizes (sands to gravels), and ending with the most spill-sensitive sheltered tidal flats, marshes, and mangroves.

Exposed rocky shores have the lowest sensitivity to oil spills. Where vertical, wave reflection tends to keep the oil offshore. In cases where the shore is terraced or wave cut, the sweep of the waves will remove most of the oil. The moderate to high wave activity present makes cleanup

Table O1 Characteristics of coastlines categorized in the Environmental Sensitivity Index (ESI). Coastlines are ranked 1–10, with 10 being the most sensitive (modified from NOAA, 1997)

ESI	Shoretype	Dominant sediment type and slope
1a	Exposed rocky shore or banks	Rocky = bedrock or boulders (>256 mm) of moderate-to-high slope Banks = marked by scarping, clays, and muds (<0.625 mm) are common
1b	Exposed seawalls and solid man-made structures	Vary from boulders and cobbles (>64 mm) to sand bags, solid concrete, sheet pile, or wood
2a	Eroding mud scarp on exposed beach	Silt and clay (< 0.0625 mm), very low-slope
2b	Exposed wave-cut platforms	Bedrock or boulders (>256 mm), low-slope backed by bluff or cliff
2c	Rocky shoals, bedrock ledges	Bedrock or boulders (>256 mm), low-slope
3a	Fine sand beach	Fine sand (0.0625–0.25 mm), low-slope (<5°)
3b	Scarps or steep slopes in sand	Sand = 0.0625–2.0 mm, marked by scarp or steep slope
4a	Medium-to-coarse sand beach	Grain size = 0.25–2.0mm, low-to-moderate slope (5–15°)
5	Mixed sand and gravel beach, bar or bank	Grain size = 1–64 mm, moderate slope (8–15°)
6a	Gravel beach or bar	Grain size > 2 mm, moderate–steep slope (10–20°)
6b	Riprap	Boulders (>256 mm), moderate–steep slope (>20°)
7	Exposed tidal flat	Coarse sand–mud (<2 mm), low slope (<3°)
8a	Sheltered rocky shore or scarp	Bedrock or boulders (>256 mm), moderate-to-steep slope (>15°)
8b	Sheltered riprap	Boulders (>256 mm), moderate–steep slope (>20°)
8c	Vegetated steeply sloping bluff	Soils (sand–mud) (<1 mm), moderate–steep slope (>15°)
9a	Sheltered tidal flat of sand or mud	Medium sand–mud (<0.5 mm), low slope (<3°)
9b	Vegetated low bank	Soils (sand–mud) (<1 mm), low–moderate slope (≥ 20°)
10a	Mangrove swamp	Mud (<0.625 mm), low slope (<3°)
10b	Salt marsh	(The type of vegetation type indicates the shoretype)
10c	Brackish/freshwater swamp	

difficult and in most cases unnecessary. However, these same areas may have high biological sensitivity, although the coast does not show long persistence of oil. For instance, the presence of bird colonies or seal haul-out areas on rocky shores will raise the sensitivity of the site. The ESI system uses symbols to designate these occurrences (NOAA, 1997).

On beaches, shore sensitivity increases with grain size. Coarser sediments commonly enable the deep penetration of oil and, because of greater changes in the form of the beach, burial is often deeper as well. In terms of cleanup, fine-grained sand beaches tend to be more compacted and flatter than coarse-sand and gravel beaches. This enables cleanup activities to be undertaken more easily, especially if the beach can be driven upon. As grain size increases and oil becomes more deeply buried, cleanup may become extremely difficult. At many spills, (e.g., *Exxon Valdez* (Alaska, USA) and *Amoco Cadiz* (Brittany, France)), pressure flushing was needed to remove oil from the gravelly sediments. Where oil was deeply buried (>1 m) in the upper berm, oiled sediments were physically relocated lower into the swash zone so that natural wave action would assist oil removal. As oil weathers, it becomes firmly adhered to the sediments, particularly gravels and cobbles. To remove oil, water may have to be heated which may cause additional damage to the intertidal plants and animals that survived the initial oiling. During spill events, cleanup operations are always reviewed in terms of potentially causing more harm than good. When more harmful than good, operations are stopped.

Tidal flats in the ESI ranking fall into two broad classifications depending on exposure. On exposed tidal flats, water saturates the sediments thereby inhibiting penetration into the flat. Oil tends to skim across the surface of the flat as the tide rises, eventually being deposited on the adjacent beach. However, clams, worms, and other organisms within the flat are likely to be exposed to high concentrations of hydrocarbons. During the *Amoco Cadiz*, hundreds of thousands of intertidal and shallow subtidal razor clams were killed by oil in the water column. In contrast to exposed flats, sheltered tidal flats have the potential for the long-term persistence of oil due to the lack of physical activity (waves and currents) to remove the oil and to the oil's affinity to bind with fine-grained materials.

Marshes are among the most sensitive of all temperate coastal habitats. Marshes are usually left to recover naturally unless oil quantities are thick and/or heavily mixed into the sediments. Heavy coatings (>3 cm) of oil at the *Metula* (1974) site in Patagonia, Chile, showed only minor recovery 25 years after the incident. Restoration of a damaged marsh can be greatly assisted by a replanting (as at *Amoco Cadiz*, Baca *et al.*, 1987). In cases where vegetation is coated but the sediments remain unoiled or only lightly oiled, recovery can be quite rapid depending on the season. The moderately oiled marsh at the *Julie N.* site in Maine (USA) during Autumn 1997 showed excellent recovery by Spring of the following year. The type of the oil spilled greatly influences the extent of damage and recovery. Lighter oils are generally more acutely toxic than heavier oils and crude.

Mangroves show sensitivity equal or greater than that of marshes. The *Peck Slip* (1979) site in Puerto Rico illustrated that tall mangrove trees and all associated life could be killed when the base of the tree and its sediments become heavily oiled. Recovery may be longer than that for marshes as years are necessary for the trees to regain their full height after oil concentrations have been sufficiently reduced to enable regrowth.

Response methods

Response activities to contain and recover spilled oil have not changed dramatically over the past 25 years. The principal methods of response in the United States is primarily a combination of mechanical and manual. Mechanical refers to the process of recovering oil by equipment such as skimmers or vacuum pumps. Manual recovery includes all aspects of physical labor, including shoveling, raking, hand-wiping, and collection using sorbent materials.

Alternative response methods are also available. In this category, dispersants are widely used outside the United States as a primary response tool. Most modern dispersants are essentially nontoxic and under appropriate conditions can enhance the dispersion of the slick into the water column, thereby making it available for biodegradation. Dispersant application is usually limited to offshore waters. Other agents are available for changing the oil's properties or "lifting" it from solid surfaces. Although rarely used, *in situ* burning, which burns oil at sea using igniters and a special fireproof boom, is gaining acceptance as a response tool. After the gross contamination has been removed by traditional means, the application of fertilizers to "biostimulate" existing bacteria may be used to augment naturally occurring bacterial populations which then degrade the remaining oil. Each alternative method has its place, and when combined with mechanical and manual recovery, provides a range of options to the spill responder.

OIL SPILLS, HIGH-ENERGY COASTS

Most oil spills at sea occur in relatively confined and sheltered localities, often from tankers in passage to or from oil terminals and ports. Natural processes, especially evaporation and other weathering effects quickly reduce the volume of oil at the surface but the more persistent residue requires expensive protection and clean-up procedures. Although normally less than is predicted at the time of the incident, substantial environmental and economic damage can occur along impacted coastlines and in nearshore zones. The Exxon Valdez oil spill in Alaska is the type-example of a large oil spill in a confined, low-energy location.

Some major oil spills occur in deep water more than 100 nautical miles from the nearest coastline. Normally weathering processes and, depending on wind and currents, the substantial time interval before the oil reaches a coastline minimize pollution damage. Chemical dispersants which are designed to breakdown the oil into tiny droplets for easier dilution, transport, and removal by microorganisms can be used but some nations prohibit their use nearshore or in confined sea and estuarine areas.

The *Braer* oil spill off Sumburgh Head in Shetland Islands, in 1993 epitomized a different type of oil spill when a large tanker ran aground on a high energy, rocky coastline (Figure O2). The *Sea Empress* oil spill off the coast of Wales, in 1996 also occurred in a moderately exposed coastline where strong tidal currents were also of considerable importance in the initial stage. In spite of the volume of oil involved and the initial "disaster" reaction to the grounding of the *Braer*, the true ecological and economic impacts were not substantial. The combination of gale-force winds, the incident energy of massive storm waves on the open Atlantic coastline and the strongly dissipative nature of the irregular cliff coastline led to rapid dispersal into a highly turbulent water column. Tidal and wave currents carried this oil, at depth, considerable distances offshore and alongshore. There was virtually no stranding of oil and the characteristic surface oil slick could not form due to the prevailing storm conditions. An exposed sand beach lies less than 1 km east of the position of grounding but, due to the power of backwash from the steep beach face, the oil and water mixture did not contaminate the intertidal zone. Although less than 1% of oil was involved, there were also local spray and aerosol effects due to the severity of wave action on the coastline.

Figure O2 Wreck of the oil tanker Braer on the south coast of the Shetland Islands in January 1993 (photograph kindly supplied by Mr. P. Fisher).

The *Braer* can be used to indicate that an oil spill on an exposed, high-energy coastline, especially a rocky and cliff coastline is unlikely to cause much environmental damage. Under such conditions, oil particles are likely to be transferred to the water column and, in time, lodged on the sea bed, perhaps at considerable distances offshore as a consequence of local and regional currents and water movements. Thus an oil spill on a high-energy coastline is more likely to create offshore, marine problems rather than to produce negative effects on the adjacent shore. In short, the critical difference is the presence or absence of a surface oil slick which is a consequence of local shelter and energy conditions at the time of the accident.

OFFSHORE SAND BANKS AND LINEAR SAND RIDGES

Shelf sand banks and linear sand ridges are found on numerous modern and ancient continental shelves where sufficient sand exists and currents are strong enough to transport sand-sized sediment (Off, 1963; Snedden and Dalrymple, 1999; Dyer and Huntley, 1999). Sand banks and linear sand ridges are defined as all elongate coastal to shelf sand bodies that form bathymetric highs on the seafloor and are characterized by a closed bathymetric contour (Figure O3). Other terms used to refer to these specific bathymetric features include *linear shoals*, *shoreface ridges*, *shoreface-attached* or *detached ridges*, *shoreface-connected* or *disconnected ridges*, *tidal current ridges*, and *banner banks*.

Typically, these linear sand bodies have heights that are more than 20% of the water depth, lengths that range from 5 to 120 km, relief up to 40 m, and side slopes that average <1°. They are 0.5–8 km wide, asymmetrical in profile, and consist of unconsolidated fine-to-coarse sand or even gravel. Axes of these sand bodies are generally oriented shore-parallel, shore-oblique (10–50°), or shore-normal when compared to the adjacent coastline, but any orientation is possible. Sand banks and linear sand ridges are present in a wide range of water depths and found in estuaries, at tidal entrances, adjacent to coastlines (offshore headlands, spits, and barrier islands), on the exposed shelf, and along the continental shelf edge. Moreover, these sand bodies usually occur in groups with spacing of individuals on the order of 250 times the water depth, but solitary ridges do occur (Snedden and Dalrymple, 1999). Two or more linear ridges grouped together are referred to as a *sand ridge field*, but other terms like *ridge and swale topography* are also used.

Initial investigations regarding bathymetric irregularities on continental shelves date as early as the 1930s (Van Veen, 1935; Veatch and Smith, 1939). Since that time, investigations into the origin, morphology, and geology of sand ridges may be organized into three groups: (1) morphology and surficial sediment studies (e.g., Off, 1963; Uchupi, 1968; Duane *et al*., 1972); (2) genesis and hydrodynamic regime (e.g., Swift and Field, 1981; Huthnance, 1982; Swift, 1985; McBride and Moslow, 1991; Snedden and Dalrymple, 1999), and (3) internal geology and stratigraphy (e.g., Penland *et al*., 1989; Snedden *et al*., 1994; Dalrymple and Hoogendoorn, 1997).

Classification

Many different classifications have been proposed for sand banks and linear sand ridges but the three most widely accepted are highlighted here. By the 1980s, leading investigators had classified linear sand bodies on continental shelves into two types—storm or tide built (Amos and King, 1984; Swift, 1985). In other words, either storm-generated or tide-generated currents were primarily responsible for ridge development and maintenance. Through time, however, researchers also recognized the importance of ridge precursors (i.e., sand body nuclei or initial irregularities, such as ebb-tidal deltas) and the subsequent hydrodynamic reworking of the nuclei (e.g., McBride and Moslow, 1991), which eventually led to two generic classifications (Dyer and Huntley, 1999; Snedden and Dalrymple, 1999).

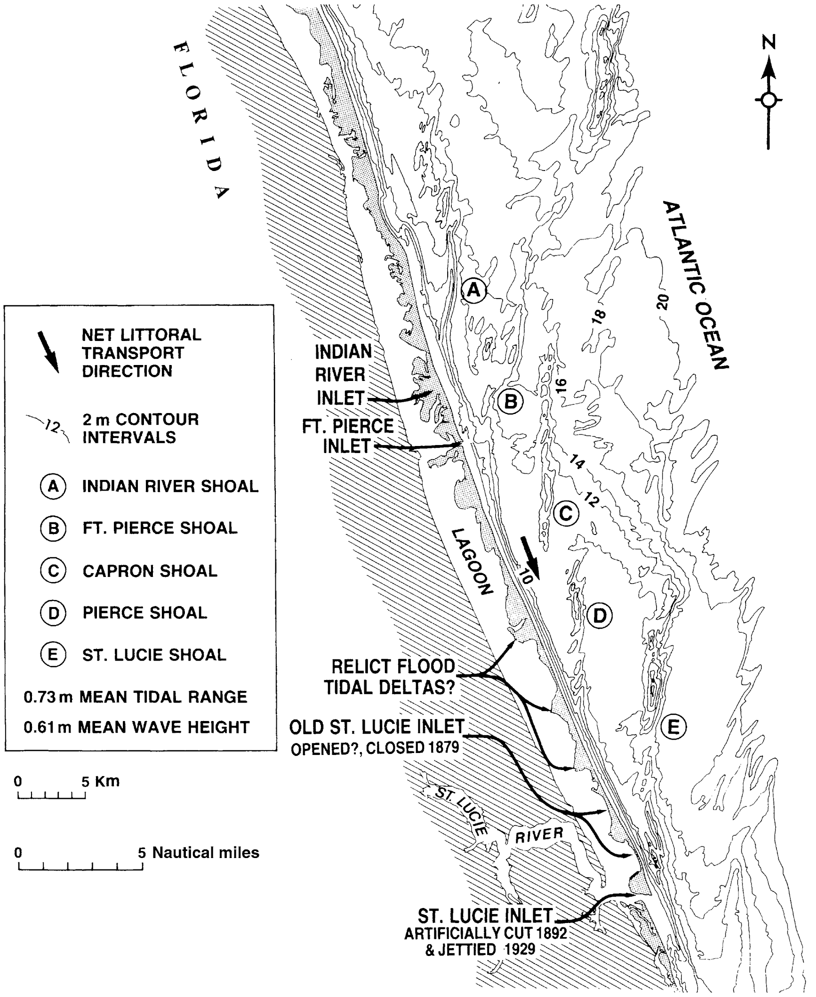

Figure O3 Example of shore-oblique shelf sand ridges, each characterized by a closed bathymetric contour. The Fort Pierce sand ridge field is located south of Cape Canaveral along the east coast of Florida, USA (from McBride and Moslow, 1991 with permission from Coastal Science). Orientations of other linear sand bodies may be shore-parallel or shore-normal.

Dyer and Huntley (1999) proposed a qualitative classification based on a generic relationship between different shelf sand bodies in light of their origin and development. They concluded that the morphodynamic stability models proposed by Huthnance (1982) were the most suitable at explaining the interaction between flow and sand body orientation. Their classification is composed of three primary ridge types and several subtypes as follows:

Type 1 Open shelf ridges
Type 2 Estuary mouth
 (a) Ridges (wide mouth)
 (b) Tidal delta (narrow mouth)
  (i) Without recession (ebb-tidal deltas)
  (ii) With recession (shoreface-connected ridges)
Type 3 Headland-associated banks
 (a) Banner banks (nonrecessional headland)
 (b) Alternating ridges (recessional headland)

Recognizing that the Huthnance stability model was applicable to both storm- and tide-built ridges, Snedden and Dalrymple (1999) proposed a unified model for ridge genesis and maintenance. They classified shelf sand ridges according to the amount of reworking of the original sand body (i.e., precursor irregularity) based on sedimentologic and stratigraphic evidence. As such, ridges were subdivided into three classes representing an evolutionary progression of increased ridge reworking and migration (Table O2). Class I ridges retain all of their original nucleus (i.e., precursor irregularity). Class II ridges are partially evolved sand bodies that have migrated less than their width and thus contain recognizable evidence of their original nucleus, whereas Class III ridges have migrated a distance equal to or more than their original width, thereby eroding virtually all evidence of their original nucleus.

Table O2 Classification and primary characteristics of shelf sand ridges and banks (modified from Snedden and Dalrymple, 1999)

	Class I	Class II	Class III
Type	Juvenile/static ridge	Partially evolved	Fully evolved
Precursor	Largely preserved	Partially preserved	Not preserved
Dynamics	Ridge stationary or rapidly buried	Ridge migrates $<$ original ridge width	Ridge migrates $\geq$ original ridge width

Depositional setting and global occurrence

Sand ridge genesis is most favorable during transgression on continental shelves that are characterized by the following four conditions: (1) initial irregularities most commonly developed in the nearshore zone, (2) sufficient supply of loose sand, (3) sand-transporting currents (tidal or storm-driven), and (4) sufficient time for the sand to be molded into a ridge or ridge field (Snedden and Dalrymple, 1999).

Some of the best developed, *storm-maintained* linear sand ridges and fields are located on continental shelves along North America, South America, and northern Europe. Linear sand ridges on the Atlantic shelf of the United States reside offshore Long Island, New York, New Jersey, Maryland, North Carolina, and the east coast of central Florida (Duane *et al.*, 1972; McBride and Moslow, 1991). Numerous linear shoals and banks are also found along the northern Gulf of Mexico of the United States offshore the Florida Panhandle (McBride *et al*., 1999), Louisiana (Penland *et al*., 1989), and east Texas (Rodriguez *et al*., 1999). Other classic localities include eastern Canada offshore Sable Island, Nova Scotia (Dalrymple and Hoogendoorn, 1997); northern Europe along the German Frisian Islands (Swift *et al*., 1978); and South America offshore northern Argentina, Uruguay, and Brazil (Swift *et al*., 1978). In contrast, well-developed, *tide-maintained* linear sand ridges or fields are located in the North Sea around England (Kenyon *et al.*, 1981; Belderson *et al.*, 1982) and other embayments characterized by >3 m tidal range (e.g., Gulf of Korea; Gulf of Cambay on Indian west coast; northern delta of Amazon River; northern end of Persian Gulf; Prince of Wales Strait just off Cape York, northernmost tip of Australia) as discussed by Off (1963).

OFFSHORE SAND SHEETS

Sands sheets are common features of modern-day, shallow seafloors. In addition, the ancient rock record contains numerous examples of sheet sandstones in both coastline and shallow marine open shelf associations (e.g., Goldring and Bridges, 1973). The Cretaceous epicontinental interior seaway of North America, for example, contains extensive sand sheet deposits and has been the focus of intense research due to their petroleum-bearing nature (Brenner, 1978; Walker, 1983; Shurr, 1984; Kreisa *et al*., 1986; Nummedal *et al*., 1989; Walker and Eyles, 1990; Winn, 1990). Modern sand sheets can also provide societal and economic benefits such as good quality beach nourishment sand, strategic minerals and ores, and productive marine habitat. On the other hand, the mobile sediments and bedforms associated with sand sheets can create navigation hazards and uncover buried cables and pipes. Despite their prevalence and importance, little is known about their geometry, bounding surfaces, dimensions, internal structure, origin, evolution, composition, and texture. In part, the diversity of sedimentary processes that operate in shallow marine environments accounts for the paucity of sand sheet classification schemes and models (e.g., process, facies, etc.). The disparate definitions and descriptions found in the coastal and marine literature attest to this reality.

What is a sand sheet?

Sand sheet definitions range from mass accumulations of sand to a veneer or sheet-like body of surficial sediment (Twichell *et al*., 1981; Stride *et al*., 1982; Belderson, 1986). They can range in thickness from a few centimeters to tens of meters and have a lateral persistence of a few meters to tens of kilometers. Some genetic definitions include the migration and stacking of large bedforms (i.e., sand waves), especially during transgressions (Nio, 1976; Stride *et al*., 1982; Walker, 1984; Belderson, 1986; Saito *et al*., 1989). Sand sheets have also been given:

- lithofacies descriptions such as glauconite facies and calcareous facies
- informal designations such as "facies A" and "A sand"
- descriptive designations such as coarse sand, cross-bedded facies and surficial sand sheet
- environmental interpretations such as tidally dominated sand sheet facies, storm-dominated sand sheet facies, or transgressive sand sheet, and
- combinations of the above such as shallow marine siliciclastic facies.

(Swift *et al*., 1971; Swift, 1976; Middleton, 1978; Knebel, 1981; Stride *et al*., 1982; Walker, 1983, 1984; Belderson, 1986; Johnson and Baldwin, 1986).

Some studies of sand sheets on the eastern North American continental shelf have used the term surficial sand sheet to include a variety of (hierarchical) bedform types and sizes. For example, Swift *et al.* (1973) and Field (1980) delineated three scales of superimposed sand "bodies" on a storm-dominated, epicontinental shelf surficial sand sheet. From largest to smallest by size, these sand bodies include shoal retreat massifs (cape and estuarine; first order features of Johnson and Baldwin, 1986); linear sand ridges (second order features of Johnson and Baldwin, 1986); and ripple, megaripple, and sand wave bedforms. Stubblefield *et al.* (1975) showed that, in some locations on the Atlantic shelf, the base of the sand sheet occurs above the topographic base of the ridges due to storm–current deepening of the swales. Since the various components of the surficial sand sheet form as a result of differences in flow regimes, dissimilarities in lithologic and paleontologic characteristics can be expected. Thus, although the massifs and linear ridges are components of the surficial sand sheet, they are discrete sedimentary facies from the sand sheet facies.

Sand sheet settings

Surficial "sheets" of sand veneer large portions of marginal (pericontinental) and epeiric (epicontinental) seafloors. In some regions, sand sheets are found in association with sand ridges, while in others the sheets constitute individual entities. In particular, the sheets have been shown to be interspersed between sand ridges, to underlie the ridges, or to exist some distance from a ridge field (e.g., Swift *et al.*, 1972; Stride *et al.*, 1982).

Four primary physical processes control sediment transport, deposition and erosion on epi- and peri-continental shelves: ocean currents, meteorological (storm) currents, density currents, and tidal currents (Swift *et al.*, 1971; Johnson and Baldwin, 1986). Globally, 3% of the shelves are ocean current-dominated, 80% are storm-dominated, and 17% are tide-dominated (Swift *et al.*, 1984). The most extensively studied sand sheets within the storm-, ocean current-, and tide- dominated settings are located on the middle-Atlantic Bight of the North America shelf, the southeast African shelf, and the epicontinental seaways rimming the British Isles, respectively.

Oceanic current-dominated sand sheets

The primary process controlling the surficial sand sheet characteristics on oceanic current-dominated shelves is the inherently unsteady geostrophic boundary current. The best studied example of an oceanic current-dominated sand sheet is located along the southeast African shelf (Flemming, 1978, 1980, 1981). On the narrow central region of the southeast African shelf, a wide variety of bedforms is molded onto a sand sheet that is maintained by the powerful, geostrophic Agulhas Current (surface velocities >2.5 m s^{-1}), a component of the major Indian Ocean circulation (Pearce *et al.*, 1978). Sediment dispersal along this shelf is also influenced by the morphology of the upper continental margin, the wave regime, wind-driven circulation, and sediment supply. Other oceanic current-dominated sand regimes include the outer Saharan shelf, the South American shelf, the Newfoundland shelf, the Osumi Strait, and the trough region of the Korean Strait (Newton *et al.*, 1973; Johnson and Baldwin, 1986; Park and Yoo, 1988; Barrie and Collins, 1989; Ikehara, 1989).

Storm-dominated sand sheets

Storm-dominated sand sheets are typified by their intra- and inter-sheet bathymetric, hydraulic, sedimentologic, and stratigraphic variability. The most comprehensive studies of storm-dominated sand sheets are of those situated along the North American Atlantic shelf between Cape Cod and South Carolina (Swift *et al.*, 1972; Knebel, 1981; Pilkey *et al.*, 1981; Swift *et al.*, 1981); the Pacific shelf off northwest United States (Clifton *et al.*, 1971; Sternberg and Larson, 1976); the Bering Sea (Cacchione and Drake, 1979; Field *et al.*, 1981; Nelson *et al.*, 1982); the Gulf of Mexico (Uchupi and Emery, 1968; Nelson and Bray, 1970; Hobday and Morton, 1984); the Bahama Bank (Mullins *et al.*, 1980; Hine *et al.*, 1981); the southern Brazilian inner continental shelf (Figueiredo *et al.*, 1982); and the Argentina inner shelf (Parker *et al.*, 1982).

The sand sheet located on the United States' east coast continental shelf is one of the largest storm-dominated sheets in existence: Over 85% of the sea floor from Georgia to New England is veneered by sand (Knebel, 1981; Swift *et al.*, 1981). In general, the spatial and temporal distribution of processes collectively have had a diverse and widespread effect on the attributes of the sand sheet. The central and southern Atlantic shelf sand sheet is the product of an autochthonous regime formed by erosional shoreface retreat during the Holocene transgression (Swift *et al.*, 1972; Swift, 1976). The primary erosional agents have been surf-zone wave action, wave-driven currents, and wind-driven currents seaward of the surf zone. This erosional transgression has resulted in the overprinting of the relict nearshore topography by a palimpsest sand sheet which, in turn, is molded with ridges and swales (Swift *et al.*, 1972; Knebel, 1981). The sand sheet is discontinuous, ranging in thickness from 1 m to 10 m. The importance of antecedent topography is indicated by the sand sheet thickness which increases in the vicinity of Pleistocene shelf river valleys, that is, Hudson River, Great Egg River, and Delaware River, and shoal retreat massifs (Swift *et al.*, 1972, 1981, Knebel, 1981) and decreases on the paleo-interfluves.

Tide-dominated sand sheets

One of the earliest studied tidally dominated modern sand sheets is located on the epicontinental seaway rimming the British Isles and on the northwest European shelf. Since the 1930s, a plethora of information has been compiled regarding the sand sheet and sand bank facies in the North Sea and Irish Sea. This information includes surface morphological, textural, and process data (e.g., Johnson and Belderson, 1969; Stride, 1970; McCave, 1971; Terwindt, 1971). From these data, theoretical (conceptual) models have been constructed regarding large- and small-scale bedform development, maintenance and internal structure (e.g., Houbolt, 1968; Allen, 1980; Johnson *et al.*, 1981) and sediment transport paths (e.g., Stride, 1963; Johnson *et al.*, 1982).

The thin sand sheet (<12 m) flanking the British Isles has formed from the unmixing of Pleistocene-age deposits during the Holocene transgression (Nio, 1976; Stride *et al.*, 1982). Materials move along transport paths associated with longitudinal and transverse tidal velocity gradients which produce bedload parting and convergence zones. The net result of tidally dominated sediment transport and deposition is to produce a well-sorted sandy deposit where fine-grained material accumulates at the ends of the bedload transport paths (i.e., grain size is in quasi-equilibrium with peak tidal current velocity; McCave, 1970, 1971; Stride *et al.*, 1982; Belderson, 1986). Superimposed on this sheet is a wide variety of bedform types ranging from small-scale ripples to large-scale sand waves (e.g., Johnson *et al.*, 1981; Belderson *et al.*, 1982). Johnson *et al.* (1981) hypothesized that the form, grain size distribution, and internal structure of the sand sheet are related directly to bedform dynamics.

Within the tide-dominated setting, sand sheets can be located in a variety of environments including marine influenced estuary- and bay-mouths, peri- and epi-continental shelf seas, and straits. A review of the sand sheet attributes of each environment reveals that the majority of information known about the tide-dominated sand sheet comes from studies of sand sheets within epicontinental seaways and upstream converging funnel estuaries. More recently, Fenster (1995) conducted a comprehensive study of the tide-dominated sand sheet in Eastern Long Island Sound. This study showed that the evolution of the sand sheet was linked closely to erosion of a marine delta, changes in the geometry and accumulation space of the basin, sea-level changes, attendant nonlinear tidal wave distortion, and common estuarine processes such as the development and migration of tidal channels.

Belderson (1986) postulated that a continuum of sand sheet facies exists between the tide- and storm-dominated sand sheet end members. The surficial and internal characteristics of the sand sheet depend on the degree of storm- versus tidal-influence. In general, tide-dominated sand sheets contain abundant sand waves which face in the direction of the stronger of the peak ebb or flood currents. Thus, the internal configuration of tide-dominated sand sheets primarily consists of pervasive cross-bedding, evidence of rhythmic periodicities, large dip angles, and reactivation surfaces. In contrast, storm-dominated sand sheets are devoid of sand waves as oscillatory currents act as a destructive force on sand waves (Langhorne, 1982; Belderson, 1986). In these regions, hummocky megaripples develop in response to along-coast geostrophic flows combined with wave orbitals of similar, or weaker intensity and result in hummocky cross-stratification (Swift *et al.*, 1983). Thus, on the tide-dominated sand sheet, storm-wave and storm-current activity sporadically increases transport rates while on the storm-dominated sand sheets, sediment transport is controlled primarily by wave- and wind-induced currents (Belderson, 1986).

Gaps in knowledge

The majority of work conducted to date on the sand sheet facies has focused on the depositional environment and geographical context (e.g., Park and Yoo, 1988; Saito *et al.*, 1989), modern processes (e.g., Knebel, 1981), surface sediment textural characteristics (e.g., Hollister, 1973; Schlee, 1973), thickness (e.g., Knebel and Spiker, 1977), surficial morphology (e.g., Swift *et al.*, 1972; Twichell, 1983), formation (e.g., Stahl *et al.*, 1974; Johnson *et al.*, 1981), and expected development (e.g., Johnson *et al.*, 1981). Much less work has focused on the geometry, boundary characteristics, and internal configuration of the sand sheet facies, especially in tide-dominated regimes. Although surficial information can be useful for delineating sediment transport paths, a paucity of information regarding the internal structure of the sand sheet facies partially has been responsible for limited (or incorrect) interpretations of the rock record.

Table O3 Classification and attribute list of the tide-dominated sand sheet facies (from Fenster, 1995)

	Sand sheet environments				
	Estuaries		Shelf seas		
Attributes	Coastal plain type (upstream converging funnel)	Semi-enclosed (constricted mouth) (drowned river*)	Epicontinental	Pericontinental	Straits
Examples	Oosterschelde Estuary Fraser River Estuary Gironde Estuary Ord River Estuary Bristol Channel Outer Thames Estuary Severn Estuary	Long Island Sound Chesapeake Bay* Delaware Bay*	North Sea Northeastern Bering Sea	Georges Bank Nantucket Shoals Irish Sea	Taiwan Strait Malaca Strait Bungo Strait Korean Strait Bass Strait
Tidal range (m)	3–15	0.4–1.1 1–1.3*	1–4	1–8	1.5–4
Tidal system	Progressive, rectilinear	Standing (resonant co-oscillating) with progressive component; progressive, rectilinear can extend 5–10 km onto shelf*	Complex due to interference of more than one amphidromic system; rectilinear to rotary	Rotary	Progressive, rectilinear
Currents ($m\ s-^1$)					
peak near-surface	0.6–1.3	0.4–2.2	0.5–1.0	0.3–0.8	0.3–1.0
peak near-bottom	0.5–0.9	0.3–0.6	0.3–0.6	0.55 times surface velocity	0.25 (ave.)
Dimensions (maximum):					
Length (km)	25	30	400	400	100
Width (km)	1–8	15	50	10–50	40
Area (km^2)	200	450	20,000	4,000–20,000	4,000
Thickness (m)		Variable, 1–24 m	12 (thickness has unknown relationship to original sand waves)	Variable, 1–20 m, up to 80 m	
Depth (m)	6–15 (can reach 35)	33–49	18–44	27–45	70–120
3D Geometry		Complex in three-dimensions due to lithofacies zonal variability	Complex in three-dimensions due to bed form sinuosity		
Grain size	Medium-to-coarse sands	0.56–1.07	Fine-to-coarse sand	Fine-to-very fine sand	Fine-to-coarse sand
Mean (mm)	0.32–0.65		0.15–0.40		0.13–0.50
Notes	Distribution influenced by mutual evasive ebb and flood channels, grain size gradient expected	Progressive decrease in mean grain size along velocity gradients (grain size in quasi-equilibrium with peak velocities)	Progressive decrease in mean grain size along velocity gradients (grain size in quasi-equilibrium with peak velocities)		

Table O3 (*Continued*)

Attributes	Sand sheet environments: Estuaries: Coastal plain type (upstream converging funnel)	Estuaries: Semi-enclosed (constricted mouth) (drowned river*)	Shelf seas: Epicontinental	Shelf seas: Pericontinental	Straits
Sorting	Moderate-to-well sorted	Moderate-to-well sorted	well sorted	well sorted	Volcaniclastic,
Composition		Quartzose minor amounts of rock fragments, heavy minerals	Quartzose minor amounts of calcareous material, heavy minerals	Quartzose to subarkosic minor amounts of heavy minerals, rock, and shell fragments	consolidated mud clasts, quartz
Biogenic		Within bedform spatial and temporal density changes	Increase in faunal density and diversity away from zone of large sand waves; within bed form changes		
Surficial elements	Ubiquitous presence of large and/or small bed forms; asymmetry governed by stronger peak ebb or flood current; sand wave $Ht \leq 8$ m 88–300 m	Ubiquitous presence of large and/or small bedforms-asymmetry governed by stronger peak ebb or flood current; sand wave Ht = 1–17 m, l = (most 5–15 m;	Ubiquitous presence of large and/or small bed forms; asymmetry governed by stronger peak ebb or flood current; sand wave Ht = 1–24 m, $l < 400$ m l = 150–750 m	Ubiquitous presence of large and/or small bed forms; asymmetry governed by stronger peak ebb or flood current; sand wave Ht = 1–10 m, most <3.4 m	Ubiquitous presence of large and/or small bed forms; asymmetry governed by stronger peak ebb or flood current; sand wave Ht = 0.5–15.3 m l = 100–300 m
Lower bounding surface	Erosional truncation due to migrating tidal channels	Erosional trunctation due to migrating tidal channels; erosional truncation due to migrating bed forms	Erosional truncation due to migrating bedforms	Erosional truncation due to ravinement surface	Erosional truncation due to ravinement surface
Lateral bounding surface	Controlled by: (1) sand availability (2) lower estuary physiography	Controlled by: (1) sand availability (2) lower estuary/bay geometry and physiography	Controlled by: (1) sand availability (2) current velocity (3) wave surge; sand/gravel boundary lies at near-surface mean spring peak tidal current = 1 ms^{-1}; outer limit of sand (sand/mud) lies at near-surface mean spring peak tidal current = 0.4 ms^{-1}; decrease in bedform size due to lack of sand	Controlled by: (1) sand availability (2) current velocity (3) wave surge (4) depth	Controlled by: (1) sand availability (2) current velocity (3) depth (4) antecedent geology
Internal structure	Erosional features and superposition of tidal channel sequences, megaripple structures,	Erosional features and superposition of tidal channel sequences, channel fill complex	Internal structure rel ated to location, 0°, basal surface of sheet; 1°, low angle		

	largescale cross bedding with reacti vation surfaces, mud couplets, tidal bundles and other rhythmic tidalites of various temporal and spatial scales	es ranging from complete (mature) to in complete (immature), erosional features associated with bed form trough migration including rising toepoint	basal surfaces of sand wave master bedding; 2°, generally pervasive low to moderately dipping sets of cross-strata with high-angle cross-bed dips; 3°, reactivation surfaces		
Vertical sequence	Pleistocene and Holocene sands unconformably overlie channel fill	Glaciolacustrine→ fluvial→low energy estuary→high energy estuary with varbility due to Holocene sediment supply, cut and fill processes	Successively formed sand wave complexes unconformably overlie Pleistocene gravel lags	Sand wave complexes unconformably overlie Pleistocene glacial diamict; separated by wave cut unconformity	
Secondary processes	Estuarine mixing and density gradients	Short-term enhancements due to estuarine circulation, storm forcing, flow divergence due to basin geometry and bathymetry	Geostrophic flows, storms, density gradients (water temperature)	Storms	Oceanic circulation
Partial reference list	Langhorne (1973); Nichols and Biggs (1985); Berné *et al.* (1988, 1993); Harris and Collins (1991); Stride and Belderson (1991)	Ludwick (1972); Bokuniewicz *et al.* (1977); Bokuniewicz (1980); Bokuniewicz and Gordon (1980); Knebel (1989); Fenster *et al.* (1990); Fenster (1995)	Harvey (1966); Belderson and Stride (1966, 1969); Johnson and Belderson (1969); Stride (1970); McCave (1971); Caston and Stride (1973); Belderson *et al.* (1982); Stride *et al.* (1982); Belderson (1986)	Twichell *et al.* (1981); Mann *et al.* (1981); Twichell (1983)	Keller and Richards (1967); Boggs (1974); Park and Yoo (1988); Arita *et al.* (1988); Malikides *et al.* (1989)

The lack of knowledge with respect to the surficial, subsurface, and facies characteristics of the sand sheets primarily has resulted from the difficulty involved in sampling the laterally extensive sand sheet. Consequently, most sand sheet analyses have relied on morphological and surficial sedimentological characteristics. Fenster (1995), however, did construct an evolutionary model and classification of tide-dominated sand sheets based, in part, on a regional assessment of modern-day surficial, internal, and boundary sand sheet characteristics (Table O3). More work is needed to define:

- the degree to which sand sheets incorporate relict units
- the three-dimensional distribution of subfacies within a sheet
- the controls on sheet shape (thickness and lateral continuity)
- lateral and bottom boundary characteristics, and
- within sheet characteristics (e.g., extent and continuity of unconformities).

Michael S. Fenster

P

PACIFIC OCEAN ISLANDS, COASTAL ECOLOGY

> The ecology of the tropics is an incredibly complex subject, probably far too complex to be grasped in its entirety by the human mind. Yet it is of the greatest urgency that it should be sufficiently understood so as to help man utilize tropical lands without utterly destroying the region eventually as a human habitat.

Adequate comprehension of the complexity of the vast number of relationships between organisms and their environment should be extended to both land and sea, especially where they are in relatively close proximity near the coastline.

Coastal ecology of isolated tropical Pacific islands offers many microcosmic examples of the forms and functions of species. It also focuses attention on the adaptation to a series of biogeochemical conditions presented by natural phenomena, and more recently by human activities. The ecosystems addressed in this selective review include coral reefs, marine, and freshwater wetlands, and coastal strand and forest. All of these can be found at, or relatively near tropical island coastlines within the world's largest single feature, the Pacific Ocean.

Ecological relationships along the coasts of Pacific Islands have been undergoing dynamic adjustment to tectonic and climatic changes at least throughout the last 1.8 million years (the Quaternary period). This synchronous and time-transgressive environmental change has continued into the Holocene Epoch, or recent postglacial warming period that began approximately 12,000 years BP. It is during this period that humans have had an increasing impact on the abiotic and biotic components of coastal ecosystems.

Here we focus on coastal ecology of Remote Oceania, which covers a vast area of the Pacific Ocean, and includes all those tropical Pacific Islands so isolated that humans were only able to find them within the past 4,000 years (see Figure P1). Within this huge region, the cultural impact of people locally, regionally, and perhaps globally must be, more or less, added to those natural factors which affect the changing nature of Pacific coastal ecology, such as volcanic eruptions, earthquakes, tsunami, and hurricanes (typhoons).

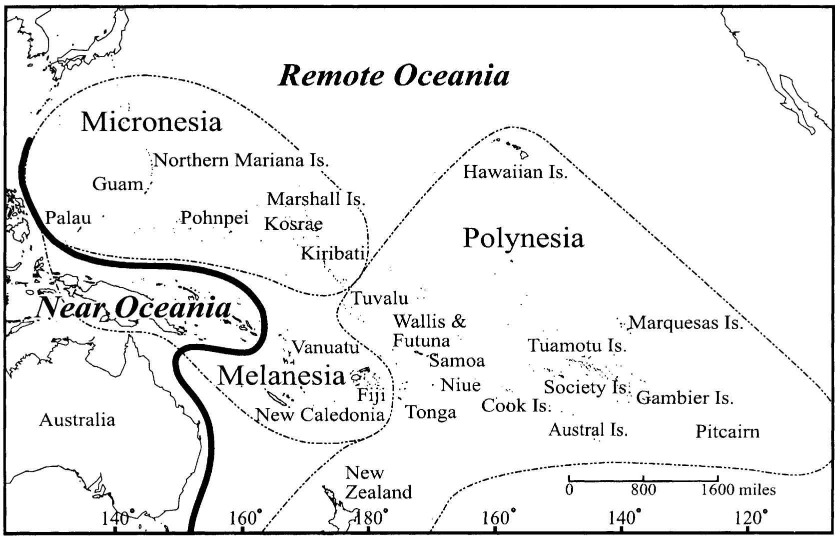

Figure P1 Map of Near and Remote Oceania (after Merlin, 2000).

The tropical Pacific Islands of Remote Oceania are basically the subaerial portions of hot-spot volcanoes (produced by melting anomalies), or limestone caps of reef development that are near or above the surface of the sea. The range of Remote Oceanic Islands include:

(1) High islands in various stages of volcanic development, geomorphological erosion, and subsidence or tectonic uplift (e.g., O'ahu, Nuku Hiva, Mo'orea, and Mangaia Islands);
(2) Atolls, which normally consist of an annular-shaped series of coral reefs with few to many low-lying islets comprised of wave-washed, unconsolidated reef, and other fauna or calcareous algal debris, more or less, surrounding a lagoon with all of the volcanic formation sunk below the sea level (e.g., Ulithi, Tarawa, and Takapoto Atolls);
(3) Raised Atolls or isolated reefs that have been uplifted or formed at higher stands of the sea, which are commonly referred to in the Pacific region as *makatea*, or raised reef islands (e.g., Fais, Nauru, Makatea, and Henderson Islands).

There are variants that, more or less, bridge the gaps between these islands categories (e.g., almost atolls such as Chuuk, Aitutaki, and Bora Bora Islands).

Thus the range of coastal ecosystems located near coastlines vary from those situated on the slopes of active volcanoes (e.g., some Hawaiian and Galapagos Islands), to those on older dormant or extinct volcanic high islands with well developed fringing and/or barrier reefs and few to many sandy beaches (e.g., Pohnpei, Kaua'i and Tahiti Islands), and those close to or along raised reefs (Atiu and Mitiaro Islands) and atoll shores (e.g., Ailinglaplap and Oeno Atolls).

Above and below the sea, a series of environments, or ecosystems, are distributed along tropical coastlines where inundation by sea water is continual, periodic, seasonal, or episodic in nature. These general environments include coral reefs, mangroves, freshwater wetlands, and strand communities. Their myriad inorganic and organic components interact with one another in wide variety of environmental relationships.

As volcanoes have subsided or been uplifted in concordance with climatically and/or tectonically controlled rising and lowering of the ocean level, those coastal species populations that have adapted to these environmental changes survived by effectively migrating in relationship to changing sea levels. In addition, environmental stresses produced by human use on land and in ocean have, more recently (during the past 1,000–4,000 years BP), also affected the distribution of species. It is generally assumed that these human impacts have accelerated in modern times; anthropogenic changes will be discussed below. Origins of the native species in the coastal ecosystems of the tropical islands in Remote Oceania are discussed first, followed by a description of the basic features of the ecosystems in which these species inhabit.

Origins of the species: biogeography and the filter effect

The ecosystem concept is a useful scientific form of reductionism designed to bring order to the diversity of life, including that found in the environments of the tropical coastal Pacific region. Whether or not ecosystems form and function in discrete, interrelated units is still an unresolved question for biologists. It has been argued that plants and animals in terrestrial ecosystems have independent ranges of distribution that often overlap in their adaptations to environmental parameters. This may also apply to marine species. Nevertheless, if only for systematic convenience, the ecosystem concept remains useful for scientific description and analysis.

It is clear that variable dispersal ability helps explain the distance-decay factor ("filter effect") determining which organisms can colonize remote geographic locations. Although many species adapted to tropical marine and nearshore land environments have long-distance dispersal mechanisms and are characteristically found over a vast region, there is consistent decline in the number of many species that become established in marine, and especially inland terrestrial environments over time in Remote Oceania (Carlquist, 1974; see Figure P2). For example, the total number of land birds on islands compared to the totals on neighboring islands and chains of islands in the South Pacific Region declines with distance east from the major source of immigrants in the New Guinea region, where there are 520 species, to 127 in the Solomons, 54 in Fiji, 33 in Samoa, and 17 in the Society Islands.

Indeed, a significant dropoff in the number of successful colonizing taxa can be verified for many groups of organisms found in tropical Pacific ecosystems, including those located at or near coastlines. For example, in the western tropical Pacific Islands of the Republic of Palau there are over 300 reef building coral species, while in remote Hawaii there are approximately 40 species (Grigg, 1983). And the distribution of damselfish (Pomacentridae) in the tropical Pacific drops off from 140 in the New Guinea region to 104 species in Fiji, 98 in Samoa, 81 in Tahiti, and 50 in Easter Island (Stoddart, 1992). Some of this oceanic barrier effect has been disrupted by humans who have brought many species (purposefully and unwittingly) with them over time, especially in the terrestrial island environments within the last two centuries (Mueller-Dombois and Fosberg, 1998; Kirch, 2000).

When distance from continents and other islands is combined with latitudinal proximity to the equator and rainfall distribution, the relative

Figure P2 Buoyant fruits of *Barringtonia asiatica* float long distances and eventually wash ashore viable in coastal areas such as shown here in the Solomon Islands (photograph by Mark Merlin).

biodiversity of coastal ecosystems in Remote Oceania can be explained. The further a coastal habitat is from the biological diverse continents and other islands, along with its relative distance from the equator in combination with declining annual rainfall, generally the fewer the number of naturally occurring species will be found. And this is much more pronounced for inland, high island environments (Stoddart, 1992).

Disturbance and succession

Environmental conditions in the ocean, atmosphere and on land, in themselves and in combination create periodic, sometimes catastrophic changes. Volcanic activity, including eruptions of both pyroclastics and lava, play a role in the periodic change of many ecosystems including those in the lowland coastal and nearshore environments. For example, basaltic lava flows erupting out of the active Kilauea volcano on the large island of Hawaii, often destroy coral reef formations as they enter the sea. However, the newly formed igneous surfaces provide the base for pioneer species to recolonize and initiate the successional processes. Over time and with limited disturbance, the ecosystem typically returns to a fully mature community of interacting organisms (Grigg and Maragos, 1974).

The erosional forces of mass wasting, along with stream, wind, and wave action, shape and reshape the coastal environments, both gradually and episodically. The relatively slow pace of disturbance and ecological recovery through biological succession, is occasionally punctuated by very intense environmental perturbations. Great waves of water generated in the Pacific Ocean can greatly alter the coral reefs and coastal lands over relatively short periods of time. These huge swells are often induced by high-energy land movements. Large earthquakes and/or giant landslides normally occur along subduction zones, and sometimes near or within archipelagoes of hot-spot volcanoes, particularly those in the youthful subaerial shield building stage (Moore *et al*., 1994). Given these determinants of biodiversity according to geographical and climatic distribution, as well as ecological disturbance and succession, we can now review the coastal ecosystems or environments of Remote Oceania. These include coral reefs, seagrass beds, mangrove forests, coastal freshwater wetlands, swamps and marshes, strand communities, and coastal lowland forest.

Coral reefs

Coral reefs are biologically diverse oases of high-energy flow and nutrient cycling. Major organism groups found on coral reefs include algae, seagrasses, corals, and other animals. Coralline algae are often equal or greater contributors to the calcium carbonate structure of the reefs than coral organisms. The zonation and profusion of life in coral reef communities is determined by environmental parameters such as distance and depth from the coastline. Wave exposure, gradients in sedimentation, degree of salinity, and temperature are the primary factors causing this variation in abundance and composition in coral reef communities in Remote Oceania. Corals can be viewed as organisms with specific behavior, physiology, and structure, as well as colonies that serve as habitat for a broad diversity of other organisms. Furthermore, coral reefs themselves may be seen as ecosystems with a great variety of interactions among the organic and inorganic components that function in these environments (see Figure P3).

Over much of the tropical Pacific Ocean, the composition of coral reefs is frequently similar, with the genus *Acropora* often the major component of the bottom cover (Gulko, 1998). Isolated and younger coral reefs in Remote Oceania such as those in the Hawaiian Islands, however, differ significantly from those in other tropical areas. In the case of the Hawaiian reefs, they are not as well developed because of their relatively youthful geological age. Therefore, most reefs in the younger islands are small fringing reefs. Wave exposure is also important. The leeward coasts of the Hawaiian islands, for example, which are generally more sheltered, have reefs with more coral cover than the wave-pounded windward coasts (Grigg, 1983; Jokiel, 1987).

The younger coral reefs, which lack barrier reefs (e.g., those in the windward Hawaiian Islands and some of the southern Cooks Islands) are normally less productive than other reefs associated with many other older high islands or atolls in Remote Oceania. Less reef area and the lack of lagoons that collect coastal and terrestrial runoff in the very remote, and younger, windward Hawaiian reefs results in relatively poor supplies of nutrients; this in turn helps explain the comparatively low numbers of soft corals, sponges, tunicates, bivalves, and other filter-feeding animals. Unlike many other reefs in Remote Oceania, especially those associated with older high islands or atolls, the reefs of Hawaii are noticeably dominated by corals, even though there are relatively few species of corals on these reefs.

As noted above, because of the remote location of the Hawaiian Islands the coral reefs have considerably less biodiversity than other reefs, particularly those located much closer to the Indo-Pacific region to which they belong. One effect of this lower diversity is reduced specialization of reef-building corals in the Hawaiian Islands, which as a result have more extensive distributions of individual species than in less-isolated regions. Although the biodiversity of marine species is much less in the more isolated coral reefs of Remote Oceania, these reefs, such as those in Hawaii have particularly high levels of endemic marine species.

Figure P3 Coral reef in Chuuk lagoon with reef islets in the background (photograph by Mark Merlin).

Seagrass beds

Seagrasses are flowering plants, and are dissimilar to algae in that they produce true roots, stems, leaves, flowers (often inconspicuous), and seeds. Seagrass beds or meadows are found in marine or estuarine waters continuously flooded by saltwater. Most seagrass species are rooted in silty or sandy sediments located in shallow water up to about 7 m deep. Below this depth there is not enough sunlight for the seagrasses to survive.

Worldwide there are approximately 49 species of seagrasses in 12 genera. They are classified as belonging to at least two monocotyledonous families, Hydrocharitaceae and Pota-mogetonaceae, which should not to be confused with members of Poaceae, the grass family. Sixteen species of seagrasses are found in the Pacific Island region. However, little research has been done on seagrasses in this region, and some scientists suspect that new species remain to be described in the tropical Pacific (den Hartog, 1970; Mathieson and Nienhuis, 1991). Many species of marine algae, as well as numerous animals, are also found in seagrass areas.

Seagrass beds are generally located in a mixed species zone running parallel to shore, but normally separated from the mangrove vegetation by a narrow band of nonvegetated sand or silt. In some areas, the seagrass beds extend out over large areas of the fringing reef flat and often cover interior areas such as embayments.

Like the mangrove forests (described below), the seagrasses, with their dense rhizome and root systems, serve as traps for silts and sediments washed into the sea from land areas. Seagrass beds are extremely productive, providing food as well as shelter for a number of animal species, including sea cucumbers, clams, some fish such as siganids, dugongs, and some reptiles such as the green sea turtle (*Chelonia mydas*). Throughout its huge geographical range in the tropical oceans of the world, the green sea turtle commonly consumes species of seagrasses in the genera of *Thalassia*, *Cymodocea*, and *Halophila*, all of which are found along many coastal areas of the tropical Pacific Ocean.

Seagrass beds are very significant in coastal food webs; in fact they typically sustain more invertebrates and fish than nearby areas lacking seagrasses. A multitude of epiphytic algae and associated small animals live on seagrasses, and several kinds of mollusks, and some fish obtain most of their nutrition by feeding on these epiphytes. Substantial amounts of detritus form as microorganisms colonize dying seagrass tissue; and because of this most animals found in seagrass beds are detritivores (Bortone, 2000).

Mangrove forests

Mangroves forests are unique and successful adaptations to harsh environmental restraints. They are found in saltwater-influenced swamps, and are composed of woody plants (trees and shrubs) adapted to areas affected by ocean tides (Chapman, 1976). These distinctive forest communities are located in many subtropical and tropical areas around the world, covering approximately 60–70% of all tropical coasts (Por and Dor, 1984). They are typically found on muddy reef flats of coastal areas.

Mangrove ecosystems are found between the latitudes of 32°N and 38°S, along the tropical coasts of Africa, Australia, Asia, the Americas, and many tropical oceanic islands. There are varying scientific classifications of what constitutes a mangrove plant depending upon how strictly the term "mangrove" is defined. The worldwide number of species classified as mangrove plants varies considerably (e.g., 54 according to Tomlinson, 1986, and 75 according to Field, 1995). The greatest diversity of mangrove species exists in Southeast Asia.

The biogeographic filter effect discussed above also applies to mangroves. For example, in the coastal saltwater environments of the Republic of Palau there are nine known species; further east in similar coastal environments of Yap there are only seven known species; in the Marshall Islands, much further to the east in the Pacific Ocean, there may be only three species, all of which are not very common; and much further east in the Hawaiian Islands there are no native species of mangroves.

The plants of the mangrove forests are very important for the environment (or ecosystem). They stabilize coastal areas by trapping and holding sediment washed down from inland areas. In some areas, where rainfall washes the thick mud from the interior down to the mangrove swamps, the mass of tangled roots of the woody plants prevent much of this sediment from washing out and smothering the coral reefs and seagrass beds. In those areas where the mangroves are located on the muddy reef flats, the plants of these forests also offer some coastal protection from normal wave action and strong storm surges (Lugo and Snedaker, 1974, see Figure P4).

As "producers," the mangrove plants convert energy from the sun, through the process of photosynthesis, into useful proteins and carbohydrates in their leaves and other parts of the plants. Eventually these plant parts drop off into the water and are carried out with the tides into nearshore waters forming a rich "nutrient soup." This supplies food for nearshore fisheries and the reef animals. Mangroves also provide an

Figure P4 Mangrove swamp bordered by fringing coral reef on the ocean side and coastal forest on the land side of Pohnpei Island (photograph by Mark Merlin).

important source of nourishment for many animal species that live within these marine swamps, including various types of shellfish, finfish, skinks, geckos, insects, and birds. In addition, several of these species use the mangroves as nurseries for their young.

All trees that live in the mangrove must have a means of obtaining oxygen since the tide comes in and water regularly covers the roots. Some woody mangrove plants have roots above the ground. These aerial prop roots have special air canals that allow the trees and shrubs to absorb oxygen, which is hard to get from the thick mud where the mangroves grow.

Rhizophora apiculata and *R. mucronata* are common mangrove trees in many tropical Pacific coastal areas; they can be identified quite easily by their hanging, aerial, prop roots. Other relatively common mangroves, such as *Sonneratia alba* and *Lumnitzera littorea* can be recognized by the exposed, cone (or pencil) shaped roots that stick up out of the muddy soil from extensive, cable-like roots. These exposed cone shaped roots, known as pneumatophores, serve as breathing organs in the swampy areas. Still other mangrove trees, such as *Xylocarpus granatum* can be identified by their very distinctive buttressed (or arched) roots that spread out like cables (or ribbons). The extraordinary wavy roots stretch out, allowing this large mangrove tree to grow in the loose soil or thick mud. Another plant often associated with the mangrove forest is *Nypa fruticans* (Nipa Palm), which has many uses (Merlin and Juvik, 1996).

The mangrove vegetation can be divided into zones from the edge of the land out into the lagoon, or from the shore out onto the muddy fringing reef flat. First, there is the intertidal, border zone where lowland forest and mangrove plants meet. It is a narrow zone along the high tide line with little or no vegetation. This zone usually has shallow mud deposits with patches of shrubs and trees. Some muddy areas in this zone emerge at low tide. This inner margin of the mangrove forest is usually quiet and protected (Teas, 1983). The mangrove forest vegetation at the edge of the intertidal border often has more species of mangrove plants than other zones in the mangrove forest.

On the outer seaward fringe or channels in the mangrove forest where mangrove plants meet the sea, there is often an overhang of branches above the water. The overhanging branches have two basic forms, depending upon the dominant mangrove tree species fronting the reef flat or lagoon waters. The more common form of overhanging branches is dominated by the *Rhizophora* species. These trees (5–10 m, 15–30 ft), with a green bushy canopy and reddish brown, interlocking, aerial prop roots, often form a dense wall of vegetation. Less common is the form of overhanging branches dominated by groves of *S. alba*, a mangrove tree with the single thick trunk, open understory, and conical-shaped, breathing roots (pneumatophores) sticking out of the mud. Some species of clams and finfish are also taken from the mangrove forest areas.

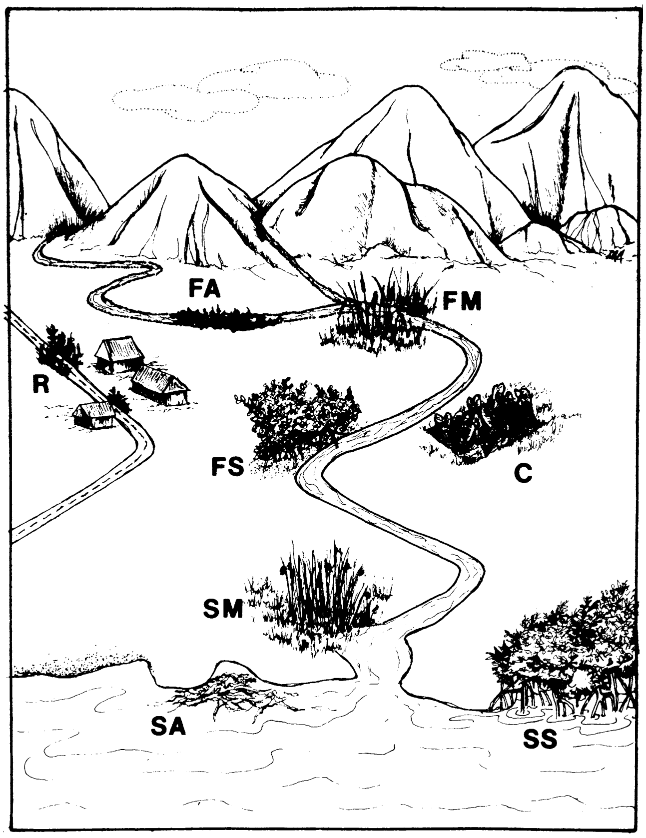

Figure P5 Schematic of wetland types: SA = seagrass beds; SM = coastal saltwater marsh; SS = mangrove swamp; FA = freshwater aquatic; FM = freshwater marsh; FS = freshwater swamp; C = cultivated wetlands; and R = ruderal wetlands (US Army Corps of Engineers).

Coastal freshwater wetlands, swamps, and marshes

Coastal freshwater wetlands, swamps, and marshes consist of those environments often flooded or saturated by ground or surface freshwater for periods of time long enough to support only plants that can grow in water-logged soils. Tropical freshwater wetland communities in Remote Oceania can be divided into five types: freshwater aquatic vegetation, freshwater marsh vegetation, freshwater swamp forest, cultivated wetland, and ruderal wetland (Stemmerman, 1981; Merlin *et al.*, 1992, 1993, see Figure P5).

Freshwater aquatic vegetation develops in areas permanently flooded with freshwater. This vegetation type is found in slowmoving streams, reservoirs, irrigation ditches, natural and artificial ponds, and open bodies of water surrounded by freshwater marshes. The plants in this aquatic vegetation grow submerged, partially submerged, or floating in the freshwater. They lack well-developed structural support provided by the more or less rigid trunks, stems and branches of plants growing in soil on land. Most of the species in this type of vegetation are annuals. Some of the species found in the freshwater aquatic vegetation can become troublesome weeds that multiply rapidly and choke waterways. Two examples of aquatic plants that may produce this kind of problem in Remote Oceania are "water lilies" (*Nymphaea* spp.) and "water hyacinth" (*Eichhornia crassipes*), both alien species introduced into Remote Oceania during the 20th century.

Freshwater marsh vegetation contains mostly nonwoody species, especially grasses and sedges that have roots in the water-logged soil, and are typically difficult to move through. Crops cannot be cultivated in the marshy areas without drainage. The vegetation of marshy areas is dominated by large sedges (Cyperaceae), grasses (Poaceae), and other herbs.

Freshwater swamp forests that have not been heavily exploited by people are mainly dominated by woody plants, such as *Terminalia* spp. and *Barringtonia racemosa*, which grow on soils that are often, if not always, water-logged. The swamp forests are found in depressions or other poorly drained places, usually behind the beach strand. In the past many freshwater swamp and marsh areas were cleared or severely altered in Remote Oceania for farming purposes. This often took place in areas with rich muddy soil where taro plants, such as *Colocasia esculenta* and *Cyrtosperma chamissonis* could be cultivated. Many of these former freshwater swamps are presently covered with secondary vegetation containing plants that recolonize this kind of wetland after the original vegetation has been heavily disturbed. In those wetlands where considerable disturbance has taken place, and no root crops are being cultivated, successional plants such as *Hibiscus tiliaceus* and *Phragmites karka* are commonly found. The environmental protection of those areas with remaining stands of swamp forests, such as those with *Terminalia carolinensis* found on Pohnpei and Kosrae Islands in the Eastern Caroline Islands of Micronesia, should be seriously considered because of their unique and interesting vegetation, as well as other aspects of resource conservation.

Cultivated wetland exists in areas where traditional "root crops" are grown. In many wetland areas, cultivated plants have replaced natural freshwater marsh and swamp plants. As noted above, traditional, edible taro species are planted in this largely artificial or man-made vegetation (see Figure P6).

Ruderal wetland vegetation is comprised mostly of weedy or successional species that are often aliens now common throughout the tropical Pacific. It occurs frequently in "waste" areas or terrain subject to flooding and interference by humans. This includes places such as rubbish dumps, roadside verges, and bombed sites.

Strand and lowland coastal forest

The flora and fauna of the coastal land ecosystems of Remote Oceania represent, more or less, an attenuated Indo-Malayan biota, containing relatively few plant and animal species, and even fewer endemics. The

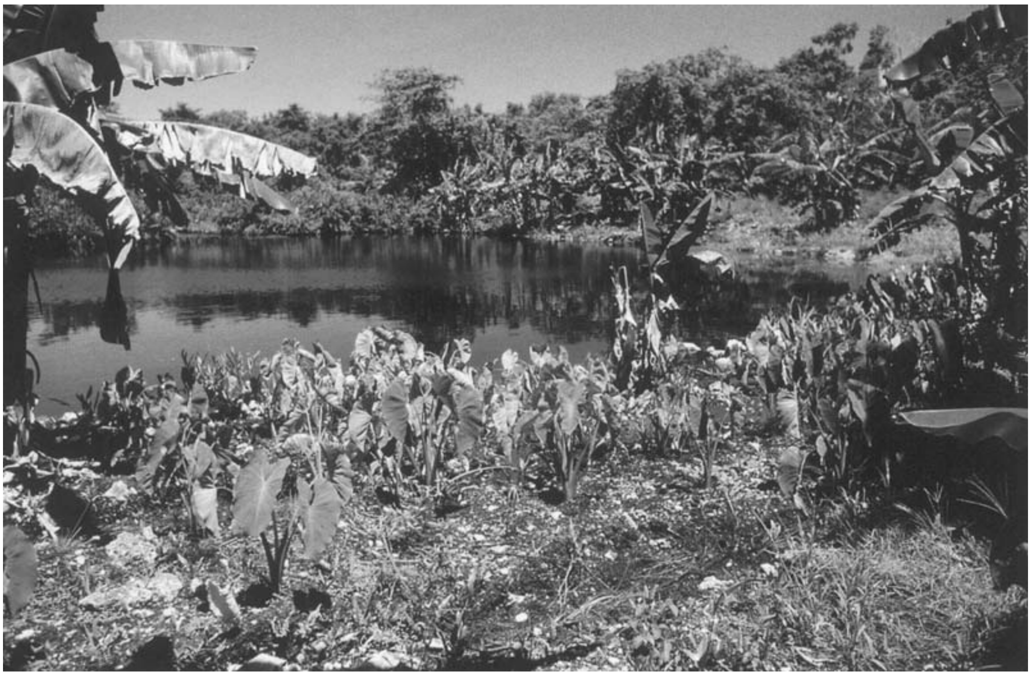

Figure P6 Cultivated wetland on Peleliu Island with *C. esculenta* taro (photograph by Mark Merlin).

size and composition of the biota in these ecosystems is largely a function of the distance from the Indo-Malayan region, size of the environment, hurricane (typhoon) frequency, droughts, salinity, native and introduced plants and animals, wars, and other human-induced disturbances (Manner, 1987). Strand and lowland coastal forest includes ecosystems comprised of terrestrial organisms occurring near the coastline. The coastal or littoral vegetation in the tropical region of Remote Oceania is found in a narrow zone near the edge of the sea on open, sandy, and rocky shores. It also typically includes all of the native vegetation on islets comprising atolls.

Plants with different life forms such as small trees, shrubs, vines, and herbs, are found in the coastal or littoral vegetation. Although they can be very different, in some ways, these plants share several things in common. Many produce seeds that float and are able to survive for long periods of time immersed in saltwater. The seeds of these plants are often moved long distances by ocean currents. The plants of the coastal vegetation also have to be able to survive under very sunny, often windy and salty conditions, near the seashore. At the edge of the sandy and rocky shores, the nonwoody plants commonly have fleshy leaves and sap that is salty. Most of these specially adapted coastal plants, as well as animals such as seabirds, are found along many, if not most, tropical Pacific shores (Merlin and Juvik, 1996; Merlin *et al*., 1997).

The plants that are found in and make up the coastal vegetation can be divided into more or less four separate types of littoral plant communities, including the herbaceous strand, littoral shrub land, pandanus scrub, and littoral forest (Whistler, 1994). Herbaceous strand or nonwoody vegetation is located above the high-tide mark of the ocean on both sandy and rocky or coral rubble shores (see Figure P7). Most strand species are perennials with deep taproots. Typical plants in the strand include creeping vines such as *Ipomoea pes-caprae* and *Vigna marina*. Littoral shrub land is typically located on windy coastal ridges and slopes, or on the seaward edges of coastal forests. Normally the dominant plant of this community is *Scaevola taccada*. Pandanus scrub is found usually on rocky, often exposed, windswept shores. As indicated in its name, this community is dominated by *Pandanus tectorius*, also known as "screwpine." *Pemphis acidula* shrubs or small trees are common on rocky, limestone coasts. Littoral forest is the most common kind of vegetation found along the tropical shores of Remote Oceania, typically just behind the strand vegetation. This forest is usually dense and is sometimes dominated by a single tree species. Common trees in this community include *Barringtonia asiatica*, *Hernandia sonora*, and *Callophyllum inophyllum*. The typical closed lowland wet forest is dominated by the widespread *Pisonia grandis*.

A variety of native animals reside in the coastal vegetation, especially where human disturbance has been low or non-existent and the less-remote islands. Among these animals are large numbers of breeding seabirds, some landbirds such as Pacific pigeons (*Ducula pacifica*) and fruit-doves (*Ptilinopus* spp.), some reptiles, and coconut crabs (*Birgus latro*).

Human impact

Human encroachment on marine coastal environments and adjacent areas, has produced some dramatic effects. The discussion that follows describes some of the more important ecological impacts that people have had on coral reefs, seagrass beds, mangrove forests, coastal wetlands, and coastal land communities.

Natural disturbances are certainly major, if not the most important factors affecting coral reefs (Grigg and Dollar, 1990). Nevertheless, the possible threats of human-induced global warming, including changes in sea level and increased frequency of intense low pressure system storms and El Niño Southern Oscillation events, are among many serious problems associated with human impact on coral reef ecosystems, including those in Remote Oceania. Among the more important problems are anchor damage, coral bleaching, coastal development, coral diseases, fish feeding, effects of fishing, tropical fish collecting, introduced species, marine tourism, sewage and eutrophication, effects of oil spills and heavy metals, effects of sedimentation, turtle tumors, effects of ultraviolet radiation on coral species, and effects of human divers (Richmond, 1993; Gulko, 1998).

The development and implementation of effective management plans to maintain the health and productivity of coral reefs requires a solid basis of scientific information and interpretation (Birkeland, 1997). Unfortunately, much of this information is still inadequate. For example, in the Hawaiian Islands, invasive alien algae and excessive fishing for food and the aquarium trade are present and dangerous threats to the nearshore coral reefs. However, a basic ecological understanding of how these pestiferous algae have become successfully established is still undetermined. In this case, more data is needed to understand the inherent factors such as growth parameters and reproductive strategies, as well as the anthropogenic impact on factors such as nutrient regimes and herbivore grazing pressure. These intrinsic and human-exacerbated factors interact ecologically to control the abundance of the alien algae (Hunter and Evans, 1995).

As noted above, alien invasions are further complicated if additional human-induced stresses are imposed on ecosystems. Vigorous coral reef ecosystems are normally dominated by reef-building corals and coralline algae, with macroalgae and algal turfs typically limited to places on the reefs that are comparatively more difficult for herbivores to reach. In the case of Hawaii, algal growth (native and non-native species) has been favored in some areas because of excessive fishing and

Figure P7 Coastal forest on Islet of Majuro Atoll with coral reef at low tide in the foreground (photograph by Mark Merlin).

eutrophication, and this has resulted in severe and perhaps permanent changes in reef community structure (Borowitzka, 1981; Steven and Larkum, 1993; Maragos *et al*., 1996; McClanahan, 1997).

Seagrass meadows form very productive ecosystems and provide nutrition and protection for many kinds of fish and invertebrates. They also help fasten the seafloor and maintain or improve water quality. Some natural disturbances have major effects on seagrasses. These include storms, floods, and droughts. For example, heavy rainfalls or extended droughts can severely affect the normal inflows of freshwater in the marine seagrass beds. Acute changes in salinity may result, and consequently have very adverse effects on the seagrasses. Intense storms may also redistribute coastal sediments through increased water current flows and larger influxes of fresh water. Increased turbidity may result, reducing the light available for seagrass photosynthesis. In addition, in extreme cases, huge quantities of sediment rearrangement can bury some seagrasses.

Anthropogenic disturbances on seagrasses can also be quite severe. Seagrass communities, especially those located in estuaries, are adapted to tolerate cyclic natural disturbances. Continuous heavy disturbances induced by human activities, however, may have severe impact on seagrasses. Water pollution, foreshore development, and recreational use of waterways are some of the major problems affecting the health of seagrass beds.

Intense terrestrial soil erosion can lead to excessive runoff that may limit the sunlight available to seagrasses. This tends to stunt their growth, or even kill the plants. Reductions in the area of seagrass growth can reduce number and extent of animals dependent upon these plant species. Nutrient inputs from agricultural runoff and urban areas can increase to the point that abnormal algal blooms develop. Such blooms decrease light penetration and limit the range and productivity of seagrasses. Reductions in available light may also result from dredging and fish trawling activities that increase turbidity through sediment resuspension. In several areas, inappropriate ship movement in shallow waters where seagrasses are found is another critical problem.

Extensive damage to marine and estuarine habitats due to the unintentional destruction of the seagrasses has been documented in several areas. Among the few animals that feed, more or less, exclusively on seagrasses, are green turtles and dugongs, and since these species are listed as threatened animals, their continued existence is dependent upon preservation of seagrass beds.

Mangroves, the "rainforests of the sea," dominate a large portion of the world's subtropical and tropical coastlines, covering an estimated area of 22 million hectares. People in tropical areas throughout the world, including Remote Oceania, utilize the raw materials of trees of the mangrove forests FOR numerous purposes (Baines, 1981). Unfortunately, during last several decades, the global area in mangroves has diminished at an increasing rate due to a variety of human activities. These disturbances include harvesting for firewood, charcoal, resins, and building materials, as well as freshwater diversion, dredging for land reclamation projects, and drainage to facilitate road construction. To some extent these impacts are also occurring in Remote Oceania (Hamilton and Snedaker 1991).

Mangrove habitat has a special role in maintaining the health of the marine environment and human industries that depend on its abundant life. The increasing removal of mangrove forests for a variety of reasons is having significant impact on fishing industries and tourism. The natural hatchery function of mangrove forest helps restock many marine populations, and mangrove forests have become popular attractions for ecotourism. Like other plants, mangrove trees and shrubs require oxygen. However, a coat of oil, even a thin one, can block the breathing pores on the aerial roots of mangroves and may kill them. Therefore, oil spills can be very dangerous for mangroves.

The introduction of alien species in some cases is also causing profound changes in the ecology of coastal environments in Remote Oceania. For example, as noted above, in the Hawaiian Islands, the introduction of invasive algal species (e.g., *Gracilaria salicornia*) has had significant impact in some coral reef regions. In these same islands, the introduction of mangroves trees (particularly *Rhizophora mangle*, see Figure P8) to the coastal zone of Hawaii, which previously had no native mangrove species, has created a series of alien mangrove forests, especially on O'ahu Island (Juvik and Juvik, 1998). Today, these mangroves intrude upon historical sites and critical habitat for a number of endangered shorebirds.

Low lying, freshwater swamp forests, just inland of mangroves and above tidal influence, are greatly disturbed in many areas of Remote Oceania. Most native vegetation of these freshwater swamp forests has been cleared or modified by human activity. Traditional and modern expansion of taro cultivation, as well as the commercial plantation development and the negative impacts of road development, have greatly affected the freshwater swamp forest habitat in many tropical Pacific Islands. There is an urgent need to protect the widely threatened, native freshwater swamp ecosystems in many areas of the tropical world, including those in Remote Oceania.

The majority of people in Remote Oceania have traditionally lived relatively close to the coastlines of the isolated islands of this region, and this settlement plan has continued into modern times. People have thus utilized the coastal zone for many purposes including the construction of housing. Therefore, the coastal flora and fauna in many areas has been modified significantly by human activity. Over the years, a great many native trees, including the often dominant trees of *P. grandis* and others,

Figure P8 Alien mangrove, *R. mangle* in coastal habitat on O'ahu, Hawai'i (photograph by Mark Merlin).

have been replaced with useful introduced, subsistence-oriented food species such trees of coconut (*Cocos nucifera*), breadfruit (*Artocarpus altilis*), and Tahitian chestnut (*Inocarpus fagifer*).

During the last two centuries or so, much of the area of the traditional cultivated coastal forests of Remote Oceania has been converted to, more or less, single stands of commercial coconut and other plantations. Traditionally, native peoples have left much of the native strand vegetation and forest immediately adjacent to the coastline for protection from strong winds and storm surge. However, modern urban, industrial, military, and tourist development has resulted in the removal of all or most of the natural components of the coastal land ecosystems in many areas of the islands of Remote Oceania. Even on remote atolls, because of traditional farming practices, little remains of the native forests, except on those that remain uninhabited.

PACIFIC OCEAN ISLANDS, COASTAL GEOMORPHOLOGY

Scattered across one-third of the earth's surface, Pacific Islands have some of the world's most fascinating landscapes (Menard, 1986; Nunn, 1994, 1998a). Yet notwithstanding their common attributes (comparatively small size, remoteness, young geology, topographic and structural simplicity, simple climate, and soil patterns) it would be wrong to suppose that Pacific Island coastal landforms are uniform within this vast area.

Much variation stems from latitude. Tropical Pacific Islands within the belt of tropical cyclones (hurricanes, typhoons) generally have coastal landforms which manifest the occasional impact of high-energy waves and winds while those outside this belt may not.

The primary cause of coastal variations in geomorphology lies with island type, of which three major kinds can be recognized in the Pacific;

(1) volcanic islands, often slowly subsiding, generally high, well vegetated with broad coastal plains around river mouths;
(2) high limestone islands, often rising, commonly cliffed, dense vegetation often only locally, with little lowland close to the shore; and
(3) atoll islands, usually rising no more than 3 m above mean sea level, made largely from unconsolidated materials accumulated on reef flats.

Most Pacific Islands are concentrated in the ocean's southwest quadrant because this is where the processes largely responsible for island formation dominate. Most Pacific Islands also occur within the tropics where coral reefs grow. Within this broad picture, volcanic islands generally occur either in arcs parallel to convergent plate boundaries or in chains in intraplate (midplate) locations. Most high limestone islands are either associated with (former) lines of plate convergence or places where flexure of the intraplate lithosphere has taken place. Most atolls occur in tropical intraplate locations marking the places where volcanic islands have sunk.

Coastal geomorphology

Owing to the approximately 120-m (postglacial) rise in sea level between the Last Glacial Maximum some 17,000–21,000 years ago and 5,000–4,000 years ago, all Pacific Island coasts exhibit signs of drowning. For many years, it was considered by some that the "Micronesia Curve" of sea-level rise, which supposed sea level to have been rising continuously since the Last Glacial Maximum (Bloom, 1970), was applicable to the Pacific Islands. More recent work has shown that instead, throughout this region, sea level reached a maximum around 5,000–4,000 years ago and has since fallen 1–2 m (Figure P9; Nunn, 1995). Thus, superimposed on

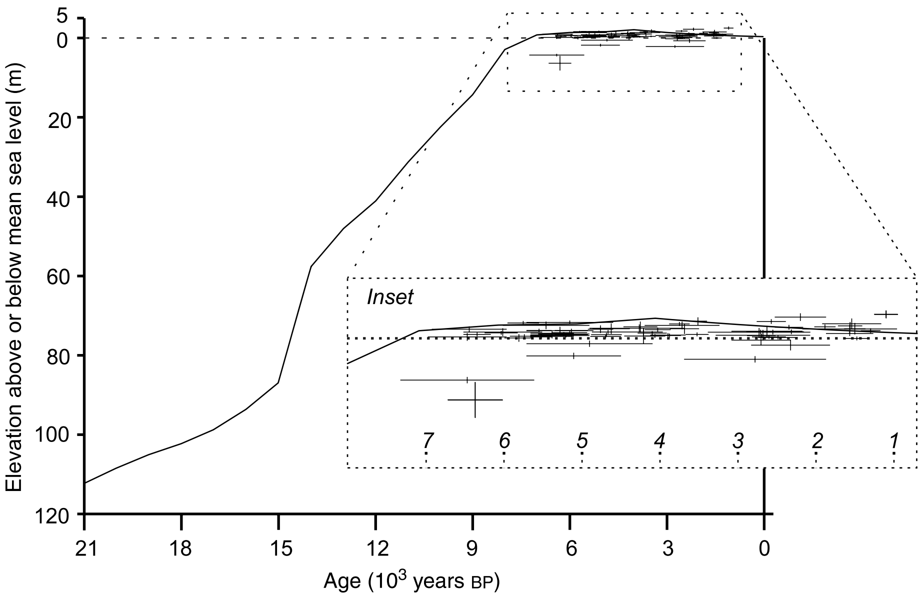

Figure P9 The course of postglacial sea-level changes in the Fiji Islands (after Nunn and Peltier, 2001). The solid line is the predicted sea-level change from the ICE-4G model. The data points are paleosea-level indicators from Fiji, enlarged in the inset to show the general concordance between empirical and predicted data.

the drowned nature of many coasts are the effects of a slight recent emergence. Superimposed on this in turn are the effects of tectonics (land-level changes) which affect many islands, particularly those along convergent plate boundaries.

Postglacial warming of ocean surface waters led to the recolonization of many nearshore and shallow areas by corals and associated reef organisms. As sea level continued to rise, corals grew upwards so that the reef surface remained within the photic zone. In some places, such as Tarawa in Kiribati and parts of French Polynesia, coral reefs apparently managed to "keep up" with rising sea level (Nunn, 1994). Elsewhere, as in most parts of the tropical southwest Pacific, for example, such reefs grew upwards at slower rates yet managed to "catch up" to sea level when its postglacial rise slowed around 6,000–5,000 years ago. In a few places, notably to the west of the islands of Samoa, reefs believed to have been established at sea level during the early postglacial were unable to grow upwards fast enough and are not visible at the surface today. These are characterized as "give up" reefs in the nomenclature of Neumann and McIntyre (1985).

The importance of coral reefs in the dynamics of modern coastlines in the tropical Pacific Islands cannot be overstated. Many beaches and sand islands are made solely from sediment created on reefs and, where those reefs become degraded and cease to be productive, beaches and sand islands can become severely eroded.

There has been a regrettable tendency to explain all environmental changes within the postsettlement history of Pacific Island coasts by human actions. While this may be true in large part of the last 100 years or so, there is clear evidence that at earlier times natural changes overwhelmed human endeavors. One of the most significant such occasions was the "AD 1300 event" in which a slight cooling, sea-level fall and increased El Niño frequency, caused widespread reef-surface death and infilling of coastal embayments, impeded lagoon-water circulation, and invoked major societal responses in Pacific Island societies (Nunn, 2000a; Nunn and Britton, 2001).

The following sections look at Pacific Island coastal geomorphology for each of the three major island types identified above.

Coastal geomorphology of volcanic islands

All oceanic islands in the Pacific began life as ocean-floor volcanoes but not all retain a recognizable volcanic form. Those which do are commonly young (<5 million years old) and/or in intraplate locations. Except around the mouths of large rivers, such islands typically have narrow coastal plains and, beneath their fringing reef platforms (where these exist), plunge steeply offshore. Most such coastal plains were formed only after the sea reached its present level 5,000–4,000 years ago and stabilized long enough (after its long postglacial rise) to erode platforms along island coasts. When sea level fell subsequently, these platforms emerged and became draped with sediment to form the coastal plains which have been the favored sites for human habitation in the Pacific Islands throughout the late Holocene (Figure P10).

Late Holocene sea-level fall also led to the outgrowth of both coral reefs and those coastlines composed of unconsolidated sediments, the infilling of coastal lagoons with sediment (both terrigenous and marine), and the subsequent establishment of characteristic ecosystems such as mangrove swamps (see below).

There is considerable controversy about the precise impact of early humans on Pacific Island landscapes, some regarding it as considerable (Kirch and Hunt, 1997), others as generally slight (Nunn, 1999a, 2001). Typical of the former is the scenario constructed for Aneityum Island in Vanuatu, where the earliest settlers are believed to have settled in upland areas (the valley floors then being too swampy), burned the forest which existed there, thus releasing large quantities of soil and sediment into the valleys which, after about 1,000 years of occupation, filled them up sufficiently for them to be settled by the people. The latter explanation sees humans as the passive agents in a landscape which was being changed solely by emergence of the land, in this case as a result of sea-level fall and tectonic uplift.

Coastal geomorphology of high limestone islands

High limestone islands are commonest in the Pacific along convergent plate boundaries where tectonic processes are generally most active and most variable in time and space. Typically such islands were formerly subsiding volcanic islands which developed a reefal capping before being uplifted. A good example are the Lau Islands of eastern Fiji which rise from a volcanic arc which became inactive and began subsiding some 5 million years ago. Subsequent uplift in the Plio–Pleistocene, perhaps due to the heating-up of a detached, partly subducted slab of lithosphere, elevated these islands as much as 315 m above sea level (Nunn, 1998b). Another example is the island Niue, which has been gradually rising up a flexure in the lithosphere east of the Tonga Trench for around 500,000 years, and is a fine example of an emerged atoll with the former ring reef and atoll lagoon well preserved 70 m above sea level (Hill, 1996).

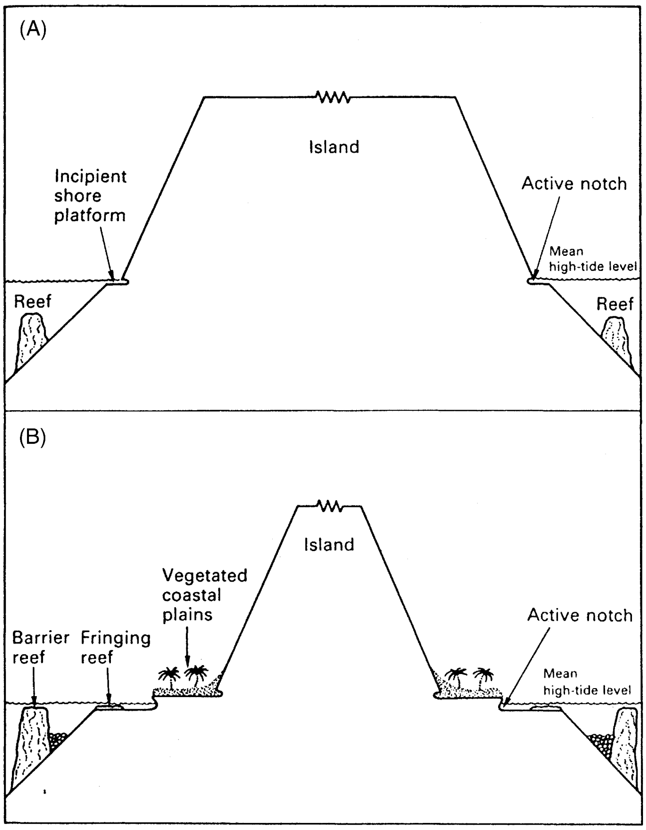

Figure P10 Formation of coastal plains around volcanic islands during the Holocene (from Nunn, 1994). (A) The time of the Holocene sea-level maximum. Sea level had been rising for the previous 11,000–13,000 years so little lateral erosion of the coastline had been accomplished. Reefs struggled to catch up with rising sea level; until they did so, a high-energy window was open. Potential settlers would have found this island type unattractive. (B) Following a fall of sea level in the late Holocene, the shore platforms cut at the higher sea level would have emerged and become covered with terrigenous and marine detritus. Barrier reefs would have caught up with sea level, the high-energy window would have been closed so that coastline erosion would have become relatively subdued. Fringing reefs would have developed and the lagoon become shallower. Potential settlers would have found this island type comparatively attractive.

Owing to a lack of running water and thus only comparatively little subaerial fluvial development, most high limestone island coasts are cliffed, often riddled with long sub-horizontal epiphreatic caves marking former stands of the water table (controlled by sea level). Coastal embayments on such islands tend to be few and formed from the drowning of karstic hollows or collpased caves.

A variant on high islands made solely from limestone is the *makatea* islands in which a volcanic island is fringed by high limestone, the products of fringing-reef uplift (Nunn, 1994). Examples abound in the southern Cook Islands. Their coasts are similar to those of other high islands, one difference being that because of the fertility of their inland areas, they tend to have been comparatively densely populated so that human modifications to their coasts are sometimes considerable.

Coastal geomorphology of atoll islands

Atoll (and barrier-reef) islands—narrow strips of land formed on broad atoll (or barrier) reef flats from the accumulation of associated sediments—are entirely coastal. Rarely rising more than 3 m above sea level, atoll islands generally develop on the windward sides of atoll reefs. In the tropical Pacific, most atolls lie in the belt of easterlies and thus have islands exclusively along their eastern sides; good examples are Kapingamarangi Atoll in Micronesia and Tarawa Atoll in Kiribati. Some atolls are occasionally affected by storm waves coming from the opposite direction to windward, and thus display islands of coarser sediment along their leeward sides than those to windward; examples include Nanumaga Atoll in Tuvalu (McLean and Hosking, 1991). Most atoll reefs enclose a shallow subcircular lagoon and in those cases where the lagoon is small relative to sediment supply, it may become infilled; such is the case with Nui and Vaitupu Atolls in Tuvalu (McLean and Hosking, 1991).

Atoll coasts are among the most vulnerable in the Pacific because of their often/largely unconsolidated character. Ephemeral atoll islands named cays can be distinguished from those which are more permanent named *motu* (Nunn, 1994). *Motu* are atoll islands which owe their durability to the formation of various rock armors such as beachrock, conglomerate platforms (*pakakota*), or phosphate rock (Figure P11). *Pakakota* occur widely in the Tuamotus. Even more enduring among such islands are those which have experienced a degree of emergence (uplift and/or sea-level fall) and thus have a core of fossil reef within the sediment pile. Many of the larger atoll islands, such as several in Kiribati and the Marshall Islands, may have such emerged-reef cores.

Tectonic controls on island coastal geomorphology

Islands which are sinking or rising comparatively rapidly exhibit distinctive coastal landforms. Subsiding islands generally show an unusual degree of coastal embayment, as recognized first by Dana (1872). Where such islands are composed of a single volcano, drained radially, a characteristic stellate island may form; the island Ono in the Kadavu group of southern Fiji is a classic example. Faulted coasts which are subsided may well be quite straight; they are particularly common along the sides of young high subaerial volcanic islands, as in parts of Samoa. Although large deltas are understandably rare on Pacific Islands, where they occur, they are usually associated with local subsidence. In such instances, sediment supply to the delta front usually exceeds the effects of subsidence, and characteristic delta forms result. Examples include the Rewa Delta on Vitilevu Island in Fiji.

Uplifting islands in the tropical Pacific are commonly marked by staircases of emerged coral reefs, comprising fossil reef surfaces separated by terrace risers. Dating of reef staircases on the Huon Peninsula in Papua New Guinea (Chappell, 1974) and elsewhere in the southwest Pacific have given rise to precise chronologies of sea-level and tectonic change during the Quaternary. Most coasts of uplifting islands are cliffed or have only very slightly developed coastal plains. Many of these appear to have been formed only during the period of comparative (land–sea) stability between bursts of uplift, commonly associated with large earthquakes and are thus termed coseismic. Coseismic uplift is known to affect many islands along convergent plate boundaries in the southwest and western Pacific. Coseismic uplifts with average magnitudes of 0.74 m affect Tongatapu Island in Tonga approximately every 870 years (Nunn and Finau, 1995). The Fiji island Vatulele is thought to experience coseismic uplift of some 1.8 m approximately every 1,400 years (Nunn, 1998a).

Figure P11 Beachrock exposed along the northern (leeward) coast of Eluvuka (Treasure) Island in the Mamanuca Group of western Fiji. Exposure of this beachrock is thought to be due to erosion of the beach in successive tropical cyclones during the 1990s followed by persistent northwesterly winds which have prevented the return of sand cover [digital photo 26—P. Nunn].

Challenges for the 21st century

Pacific Islands and the submarine ridges from which many rise are among the steepest structures on earth and, while the ocean contributes to their stability, it cannot prevent occasional structural failures. Owing to their infrequency, the nature and (potential) effects of such failures have become clear only recently. A groundbreaking study of the structural failure of Johnston Atoll (Keating, 1987) was followed by others, summarized by Keating and McGuire (2000). It has been estimated that a major oceanic island flank failure occurs once every 25 years (Siebert, 1992). Flank collapses along the Hawaiian Ridge have been studied and dated using deeply submerged fossil reefs (Moore and Moore, 1984; Moore *et al*., 1994). Such failures/ collapses are clearly capable of causing the disappearance of parts of islands, perhaps even whole islands, and producing giant waves which could wrought major changes to Pacific coasts. Their study is of considerable applied interest.

Pacific Island coasts composed of unconsolidated sediments are particularly vulnerable to change as sea level changes. While short-term changes, particularly during El Niño events, can have severe consequences for reef health, it is longer-term sea-level rise, particularly within the past 200 years or so, that has brought about significant changes to many Pacific Island coasts. Based on largely anecdotal evidence (more formal sources generally being absent from this region), it is clear that some coasts have been inundated and/or eroded laterally by as much as 200 m within the last 100 years. Recent warnings have been issued about the disappearing beaches of the Pacific Islands (Coyne *et al*., 1996; Nunn, 1999b).

Such problems have been compounded by the human inhabitants of Pacific Island coasts. Since humans came to occupy most Pacific Islands in larger numbers and to make more demands on their coasts, so their landscapes have been modified in consequence (Nunn *et al*., 1999). Much coastal vegetation has been removed and/or replaced by less suitable species. Mangroves in particular have been a major casualty of 20th century "development" in the Pacific Islands; the case studies of Ovalau and Moturiki Islands in Fiji show how those settlements which have removed their fringing mangrove forests now have severe problems of coastal erosion and inundation compared to those which preserved them (Nunn, 2000b).

PALEOCOASTLINES

As R.W. Fairbridge (1992) noted, "Paleogeography is an exercise in imaginative insight. One needs first to observe and understand the dynamic physical processes and landforms and then transfer and reapply these concepts to past landscapes." In essence, the study of paleocoastlines requires the application of fundamental concepts of geology. *Uniformitarianism* and its modern version *actualism* provide the conceptual basis for modern sedimentary environmental patterns to be used in analogous comparisons with older facies in the construction of paleogeographies. Equally Walther's dictum on *the correlation of sedimentary facies* provides the conceptual basis for differentiating *possible* conformable lateral and vertical facies patterns from the *improbable* in the delineation of ancient coastal landscapes. Climate, including glacial and other cycles, tectonics and eustasy are long-term forcing factors. Nevertheless, knowledge of local relative sea-level fluctuations are requisite to precise paleogeographic reconstruction.

Major advances in paleoenvironmental reconstructions in the mid to late 20th century were driven by the needs of the petroleum and coal industries for precision in sedimentary facies studies. For instance, Harlan Fisk, and later his students Hugh Bernard and Rufus LeBlanc, pioneered in intensive three-dimensional analysis of fluvial, deltaic, and coastal/nearshore marine facies. Emphasis was placed on sedimentary processes and depositional geometries of the various sedimentary environmental lithosomes, including lateral and vertical conformable and disconformable relationships. Studies of sedimentary environmental lineaments, geometries, internal sedimentary structures, and grain sizes and composition coupled with floral and faunal (fossil) analyses and ^{14}C dates therefrom allow precise definition of ancient landforms, physical processes, water salinities, and their lateral and vertical distributions. These factors are a requisite to the accurate reconstruction of ancient coastal landscapes. Kraft and Chrzastowski (1985); Belknap *et al*. (1994), and Kraft *et al*. (1987) as well as many other papers in the three referenced volumes of the Society for Sedimentary Geology (SEPM) provide many modern examples of sedimentary facies studies relevant to paleocoastline delineation.

Interdisciplinary study of paleocoastlines

Perhaps nowhere are paleocoastline morphologies of more interest than in the environs of historical and archaeological sites. Here, archaeology, history, and the Classics both complement and supplement each other in a synergistic manner clearly more effective than the sums of the disciplines applied separately. In the Aegean Sea, on the western coastline of Anatolia, sea level rose to its present position about 6,000 BP. Since then, sea level dropped 1–2 m relative to land, rising again to its present level. From the Würm glacial low stand to 6,000 BP fluvial and coastal environments were transgressed by nearshore marine environments, infilling valleys incised during Würm and earlier times. Since then, the Küçük Menderes (ancient Cayster River) has prograded 15 km seaward burying the marine sediments of the ancestral Gulf of Ephesus with a thin veneer of fluvial deltaic and barrier accretion plain sediments. The impact of this major change in coastal configuration had a profound effect on the peoples occupying the region from Neolithic time to present. Since the arrival of Ionian Greek colonists 3,000 years BP, the residents of the ancient city of Ephesus, its many harbors over 3 millennia of time, the Artemision (Temple of Diana of the Ephesians, one of the seven wonders of the ancient world), and the later Turkish peoples of the region have been continually adapting to major changes in coastal environmental morphologies (Kraft *et al*., 2000).

The floodplain and delta of the Küçük Menderes have been much altered by 20th century drainage and irrigation works. The coastal barriers form a damming effect that leads to widespread seasonal swamps and short-term floods in the wet season. Many palimsests of morphic features may be observed from air photo, satellite imagery, and correlated with a carefully documented Austrian survey in the late 19th century (Figure P12). Coastal barrier accretion ridges only occur in the lower 2.5 km of the delta-floodplain. Thus, in much of the earlier, relatively sheltered marine embayment from 6,000 BP to Late Byzantine time (ca. 1,300 AD) fluvial-deltaic progradation was into a shallow marine prodelta shelf, probably with birdfoot like distributaries and flanking swamps, ponds, and marshes.

Details of sedimentary environmental lithosome geometries, sediment characteristics, micro- and macro-faunal and ^{14}C dates were attained by an intensive coring program (over 120 drill cores, Kraft *et al*., 2000, 2001). Figure P13 is a schematic cross section based on 26 drill cores in the vicinity of the Artemision (Temple of Diana) constructed in the 7th century BC and finally destroyed by earthquake in the 3rd century AD. The Artemision was built on an alluvial fan of a flanking river and eventually, after destruction, buried therein. However, we can also show that the site of the Artemision was at one time, pre-3,000 BP, a coastline of the marine embayment. Therein lies an interplay with legend. *Callimachus: Hymn III to Artemis* tells us that "Amazons, lovers of battle set up a wooden image under an oak, in seaside Ephesos (II) and hippo offered a holy sacrifice to you; around the oak they danced you a war dance . . . Afterward around that wooden image, wide foundations were built . . . ." Our paleogeographic evidence confirms the coastline under the Artemision site in Bronze Age times. Further, we can position this "wonder of the ancient world" in a coastal setting overlooking the ancient Gulf of Ephesus, as late as Hellenistic time, ca. 200 BC. Eventually, two sets of alluvium inundated and buried the ruins of the Temple of Artemis (as shown in Figure P13).

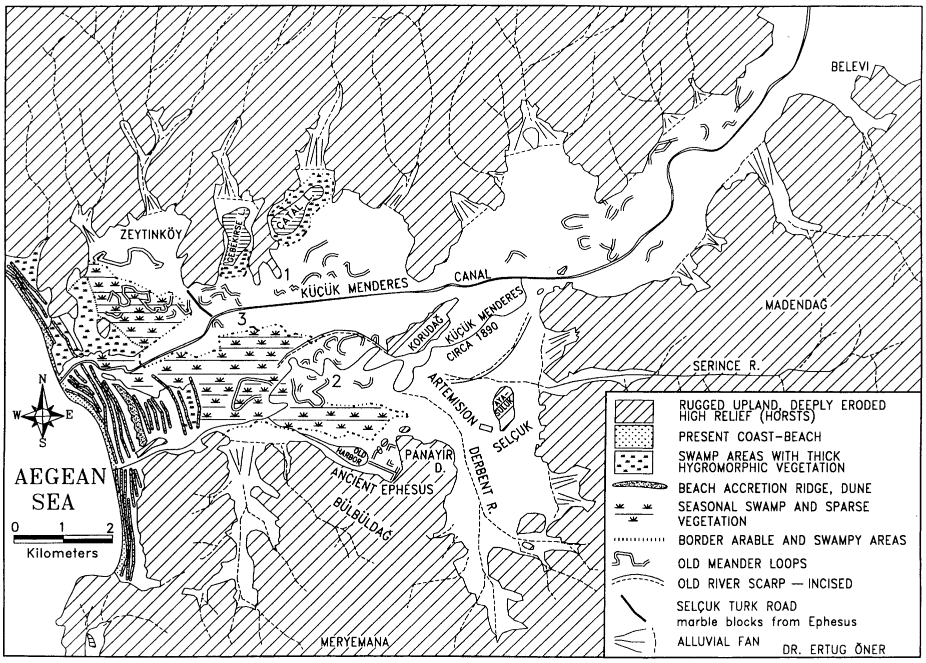

Figure P12 Holocene Epoch geomorphic elements of the Küçük Menderes (ancient Cayster River) in western Anatolia (from Kraft *et al.*, 2000. With permission, Österreichischen Archäologisches Institut.).

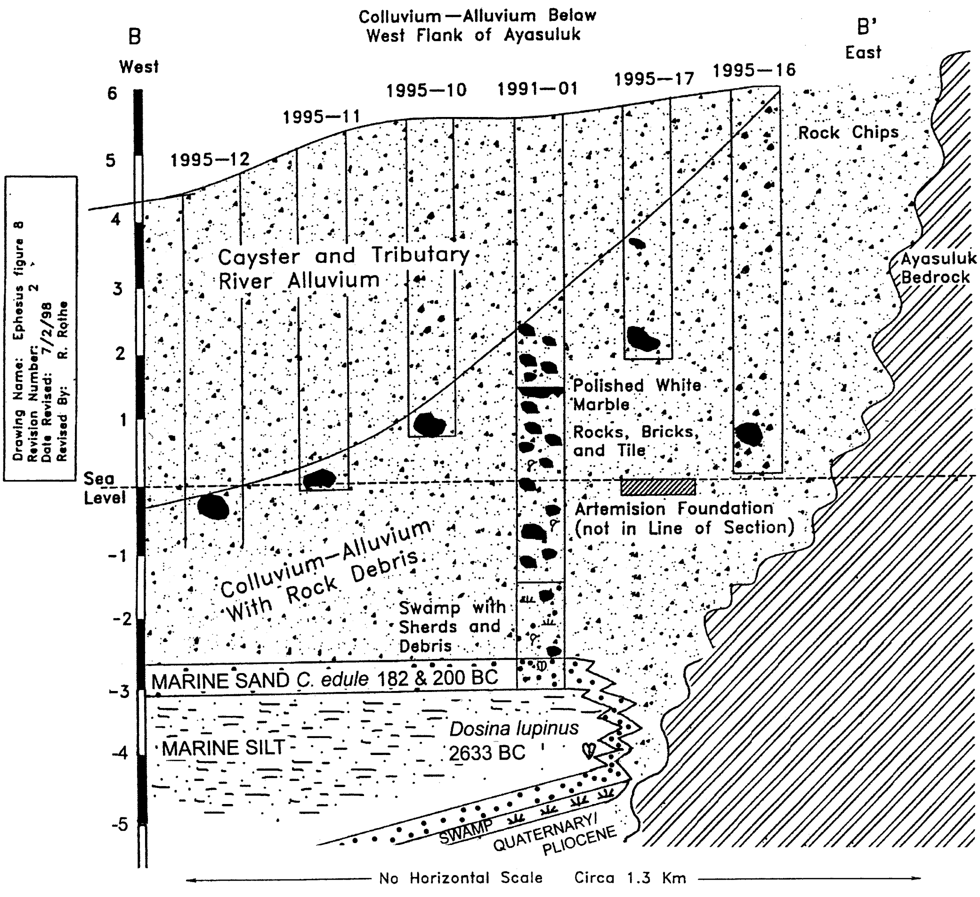

Figure P13 A schematic cross-section through the environs of the Artemision (Temple of Diana of the Ephesians, one of the Seven Wonders of the Ancient World). Constructed mid-7th Century BC, destroyed by earthquake 3rd Century AD, based on 26 drill cores (from Kraft *et al.*, 2000. With permission, Österreichischen Archäologisches Institut.).

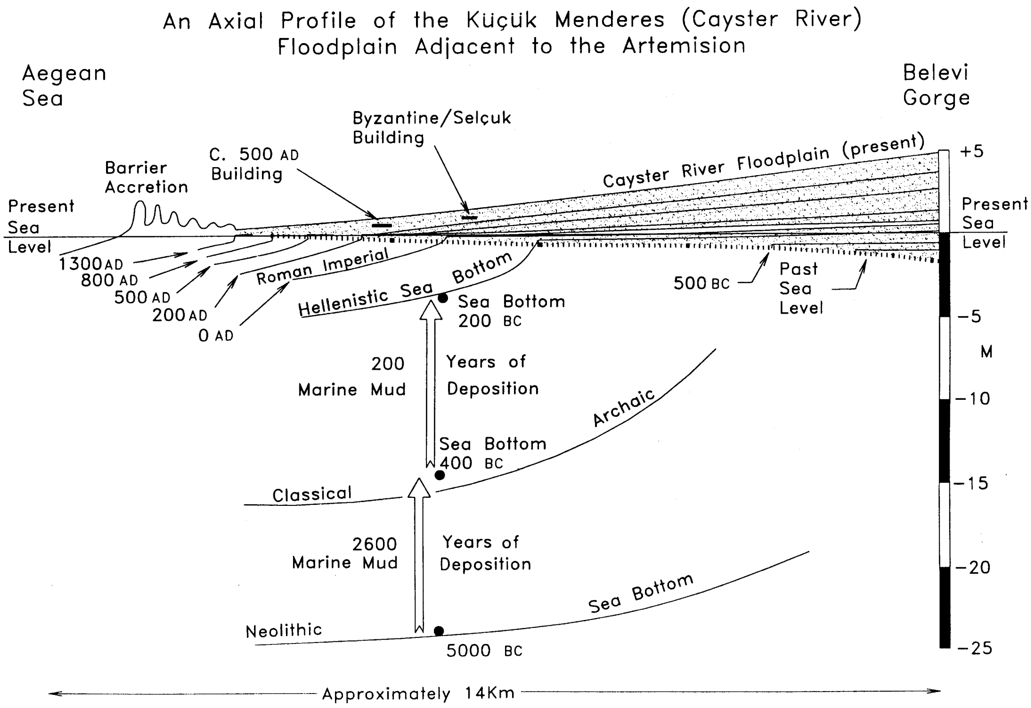

Figure P14 Cross-section of the lower Küçük Menderes (Cayster River) delta-floodplain. Seven thousand years of depositional valley infill, including 25 m of marine/estuarine sediments covered by a thin veneer of prograding floodplain alluvium and barrier accretion plain sands (from Kraft et al., 2000. With permission, Österreichischen Archäologisches Institut.).

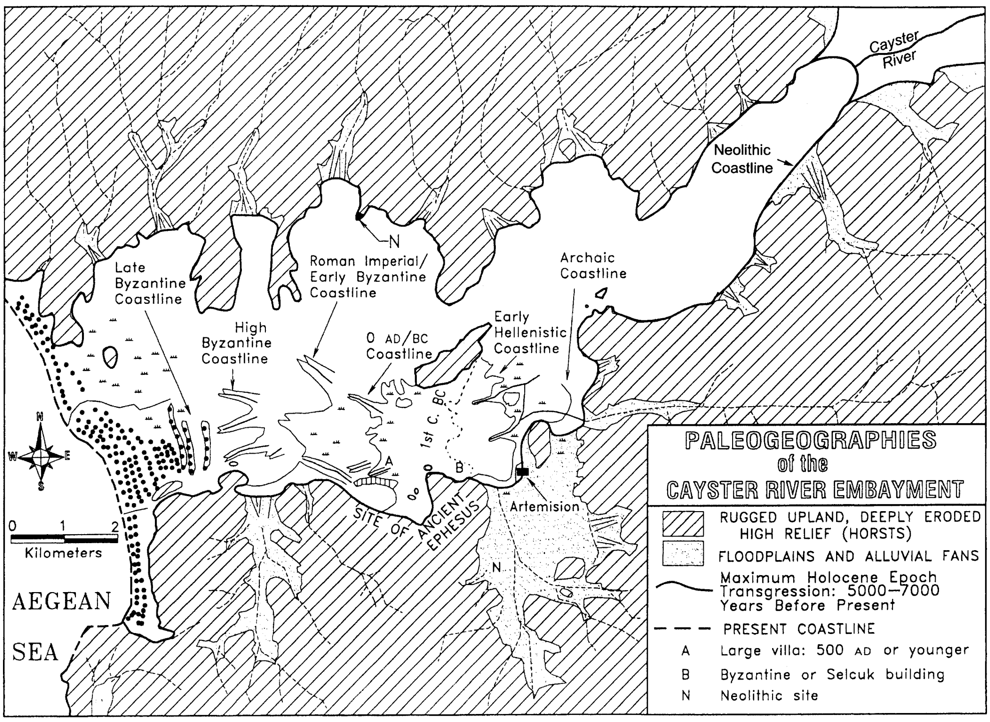

Figure P15 Paleocoastline progradation in the Küçük Menderes (Cayster River) embayment of the Aegean Sea in the vicinity of the ancient city of Ephesus and the Artemision (after Kraft *et al.*, 2001).

Using drill core evidence of sedimentary facies in their lateral and vertical distribution, we can show that the major portion of the Holocene strata that infilled the ancestral valley of the Küçük Menderes River was deposited in an open marine embayment, initially clear water, followed by distal and nearshore prodelta silts (Figure P14). Deposition was more rapid in the past 2,400 years, as the delta prograded and alluvium aggraded. A few archaeological sites in the floodplain provide minimal dates for the delta advances.

Figure P15 is a summary delineation of delta coastline progradation for the southern portion of the former marine embayment. The Neolithic coastline shows the maximum extent of the marine embayment of mid-Holocene time, ca. 6,000 BP, while, the Archaic coastline of 600 BC continues in an irregular configuration of distributaries, marsh, swamps, etc. until significant wave generated littoral transport of sands in barrier accretion started ca. AD 1,300. The city of Ephesus varied in location over 4 km along the southern flank of the embayment, eventually being built on portions of the delta including massive fill. Many documents attest to the "conflict or fight" with the river progradation over more than a millennium of time.

One of the clearest examples of negative environmental impact is a quote from Strabo (XIV 1, 24), "The city has both an arsenal and a harbor. The mouth of the harbor was made narrower by the engineers, but they, along with the King who ordered it, were deceived as to the result. I mean Attalus II Philadelphus (159–138 BC); for he thought that the entrance would be deep enough for large merchant vessels—as also the harbor itself, which formerly had shallow places because of silt deposited by the Cayster River—if a mole were thrown up at the mouth, which was very wide, and therefore ordered that the mole should be built. But the result was the opposite, for as the silt, thus hemmed in, made the whole of the harbor, as far as the mouth, more shallow. Before this time the ebb and flow of the tide would carry away the silt and draw it to the sea outside."

The literature abounds with writings of the problems that the ancient Ephesian peoples had with maintenance of their harbors over the millennia of existence of Ephesus, capital of the ancient Kingdom of Asia (Kraft *et al.*, 2000, 2001). Clearly interdisciplinary approaches to the study of paleocoastlines increases our abilities to precisely delineate ancient coastal configurations.

PARAGLACIAL COASTS

Definition

Paraglacial coasts are defined as those occurring on or close to glaciated terrain, where glacial erosion features or deposits have a recognizable effect on the nature and evolution of coastal morphology and sediments (Forbes and Syvitski, 1994). They thus encompass a range of coastal environments and landforms from proglacial fjord and outwash coastlines to sand- and gravel-dominated coasts deriving their sediment supply from glacigenic deposits, but where the glacial imprint is older and subdued. Such coastlines also occur in settings where other phenomena such as *periglacial* and related processes (including permafrost, ground ice, thaw subsidence, sea ice) or *human impact* (*q.v.*) may appear to dominate the coastal landscape. Essential features of paraglacial coastlines include a sediment source or physiographic setting in which the glacial origin exerts a continuing influence on the form and evolution of the coast.

Geographic extent

The geographic range of paraglacial coasts is broadly coincident with the maximum extent of the last major continental glaciation in the *Pleistocene Epoch* (*q.v.*), approximately 20,000 years ago (Figure P16). The most extensive paraglacial coasts (broadly defined by ellipses in Figure P16) are those of the Arctic circumpolar region, including parts of the North American Pacific and Atlantic coasts, Greenland, Iceland, northwest Europe including the Baltic, and many parts of the Arctic coasts of Canada, Norway, and Russia. Most of the Antarctic coast, where not presently glaciated, forms an equivalent southern circumpolar

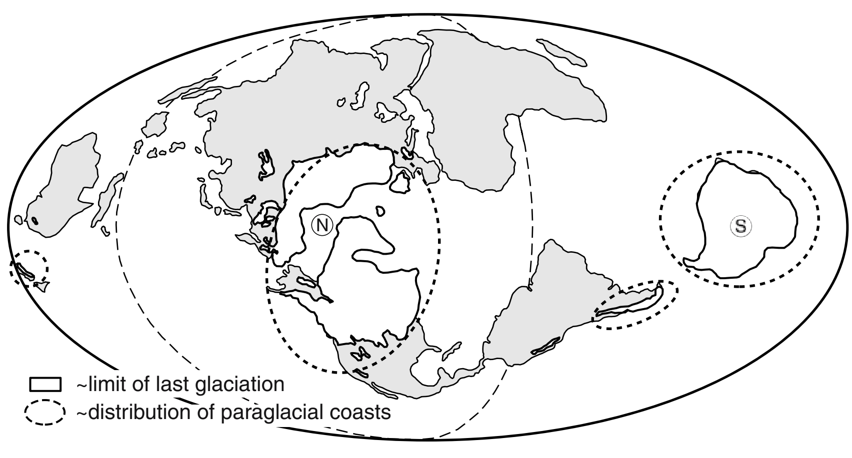

Figure P16 Approximate extent of last major glaciation and the geographic distribution of paraglacial coasts.

paraglacial region. Two other areas in the Southern Hemisphere showing extensive glacial influence on coastal development are the South Island of New Zealand and the west coast of South America in southern Chile, extending to Tierra del Fuego, where the southernmost coast of Argentina is also included.

Recognition and terminology

The term *paraglacial* was originally applied to river systems (Church and Ryder, 1972). In this context, it is used to describe the effects of disequilibrium excess sediment supply following deglaciation and the subsequent relaxation or decrease of sediment supply through surface reworking and downstream transport with time (cf. broken line in Figure P17B). While he did not use the term *paraglacial*, Johnson (1925) recognized the distinctive nature of coastal morphology directly arising from glacial erosion or indirectly sourced from glacial deposits such as moraines, drumlins, and outwash sediments. The term was adapted in the early 1980s for application to coasts where glacigenic sediment supply or morphology remain dominant controls (Forbes and Syvitski, 1994). Since that time, it has been most frequently employed in relation to coarse-clastic beaches and barriers sourced from glacial deposits (e.g., Forbes *et al*., 1995; Orford *et al*., 1996) but has also been applied to sediment sinks in coastal embayments (e.g., Carter *et al*., 1992; Shaw and Forbes, 1992) as well as to glaciated shelves.

Classification

Paraglacial coasts can be classified into nine broad categories:

- sediment-starved coasts dominated by glacial erosion—fjords, overdeepened basins, and coastal barrens;
- depositional systems in confined fjord-head and proximal basin settings;
- open outwash coasts (not embayed or confined);
- basin-margin or open coasts with abundant glacigenic sediment in coastal cliffs;
- drumlin coasts characterized by sediment source switching and time-varying supply;
- embayed coasts with sediment supply controlled by sea-level change;
- coasts with patchy glacial cover or terraced outwash sediments—supply limitation or restricted access;
- forced-regressive coasts with limited sediment supply; and
- boulder-rich coasts in otherwise sediment-starved settings.

It is obvious from this list that the geomorphic expression may be highly variable and that sediment supply can range from negligible to abundant. However, apart from cases of significant fluvial or glaciofluvial

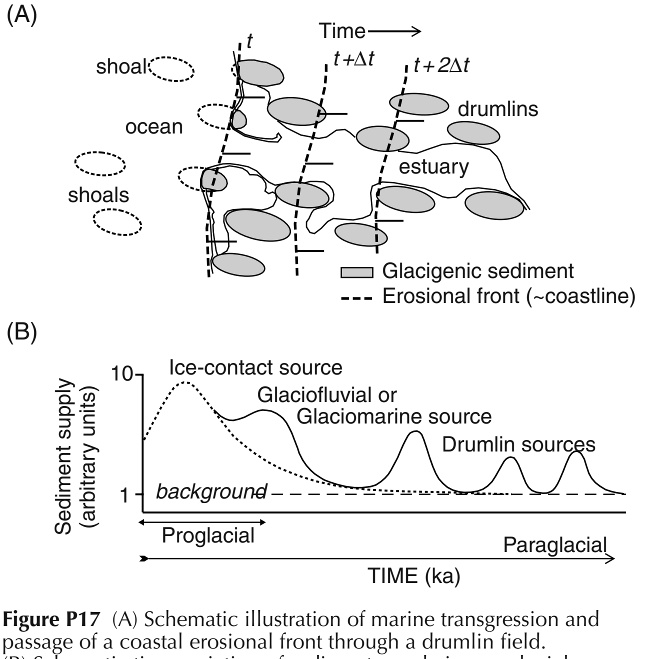

Figure P17 (A) Schematic illustration of marine transgression and passage of a coastal erosional front through a drumlin field. (B) Schematic time variation of sediment supply in paraglacial coastal systems (modified after Forbes and Taylor, 1987).

sediment input (fjord-head deltas and outwash coasts), previous work on paraglacial systems has emphasized the rationing of sediment supply from glacigenic sources as a major control (and often the dominant influence) on coastal evolution in paraglacial settings. In this entry, we consider two examples of time-varying sediment supply and its implications for morphosedimentary outcomes at the coast.

Sediment supply control

Coastal morphology and deposits are strongly dependent on the geological setting, climate, oceanographic environment, coastline orientation and exposure, and the rate and sign of relative sea-level change. Sediment supply is another critical variable, often in paraglacial settings the dominant factor defining the geomorphological response (Orford *et al*., 1996). If sufficiently large, sediment supply may counteract the transgressive effects of relative sea-level rise and produce a regressive sequence on a prograding coast (Forbes *et al*., 1995).

Persistent changes in relative sea level, related to postglacial *eustasy* (*q.v.*), *hydro-isostasy*, and *glacio-isostasy*, are near-ubiquitous on paraglacial coasts, where they exert a profound influence on coastal morphology and development, including control of delayed shore-zone access to glacigenic sediment sources. However sea-level change is neither fundamental nor unique to paraglacial environments and may occur on all types of coast throughout the world. The implications of these relative sea-level changes for coastal evolution in paraglacial systems include highly varying rates of landward retreat or seaward advance of the coastline, and significant variation in the rate of access to glacigenic sediment supplies.

On paraglacial coasts, sediment is predominantly derived from erosion of glacial deposits. In many cases these represent the only significant source. This has profound implications for the nature of coastal sedimentary facies and shore-zone morphology. Grain-size distributions in glacial deposits run the full gamut from clay to large blocks the size of houses. Glaciolacustrine and glaciomarine facies may contain a large proportion of clay and silt (glacial flour) with small proportions of sand and minor fractions of ice-rafted gravel. In other cases, the sediment source facies may include glaciofluvial outwash, till, or other ice-contact diamicts (Figure P17). The grain size in ice-contact sediments can range over more than six orders of magnitude (Forbes and Syvitski, 1994) and coarse clastic components (pebble and coarser) are often abundant. This leads to a preferential tendency for the development of gravel (including sand-pebble, cobble, and boulder) beaches on paraglacial coasts. Where the underlying bedrock is a soft sandstone or similarly friable lithology with a large proportion of sand, the ice-contact facies may be relatively sandy and large volumes of coastal sand derived from both bedrock and the overlying glacial units can feed extensive sandy beaches, barriers, nearshore bars, coastal dunes, and tidal inlet deposits, as in the southern Gulf of St. Lawrence.

The spatial disposition of source sediments on paraglacial coasts also exerts a major influence on patterns of coastal evolution. Landward movement of a coastal *erosional front* across a glaciated landscape (Figure P17A), as occurs with marine *transgression* under rising sea level, can lead to rapid mobilization of glacial deposits. The volume and spatial distribution of sediment may be discontinuous and vary widely, from a thin till veneer to larger volumes concentrated in distinctive glacial landforms such as eskers, kames, deltas, moraines, and drumlins. In such cases, the start of erosional incision (such as when barrier retreat exposes a back-barrier hillslope to wave action for the first time) can mark the beginning of significant sediment release. In the case of marine trangression through a drumlin field or multiple moraine complex, this process may involve repetitive injections of finite sediment volume into a coastal region (Figure P17B), spawning cyclic patterns of littoral-zone deposition with barrier growth, supply depletion, barrier breakdown, and landward transfer to begin the cycle over. This drumlin coast model has formed one of the dominant paradigms for understanding paraglacial coasts over the past 15 years (e.g., Boyd *et al*., 1987; Carter *et al*., 1990; Forbes *et al*., 1995; Orford *et al*., 1996).

Prograded bayhead barriers provide another example of time-varying sediment supply as a dominant control on coastal geomorphology. Experiments with numerical simulation of barrier growth in confined embayments with a thin till veneer provide useful insights on the role of relative sea-level change and sediment supply. Published examples (e.g., Forbes *et al*., 1995) are based on coastal embayments in southeast Newfoundland. The plan view (Figure P18A) shows a narrowing embayment with ocean wave approach up the axis of the bay to a barrier complex at the head. Breaking of refracted waves along the shore is assumed to mobilize all unlithified glacial cover within reach of the waves and transport it alongshore to the head of the bay. Assuming

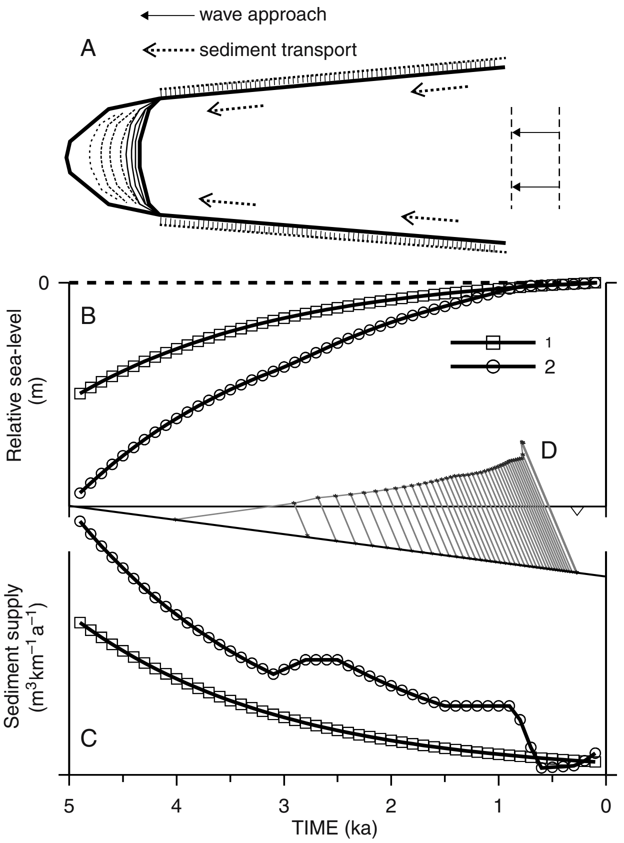

Figure P18 Numerical simulation of beach-ridge barrier growth in a bayhead setting. (A) Schematic plan view of embayment. (B) Arbitrarily selected relative sea-level histories. (C) Simulated sediment supply to bayhead barrier corresponding to the two sea-level histories shown above. (D) Model output showing schematic section through simulated beach ridges with high transgressive storm ridge at seaward margin.

simple geometry, the supply of sediment to the bayhead barrier is a function of access to erodible material, controlled by the rate of rise in relative sea level through time. The more rapid the rate of relative sea-level rise (Figure P18B), the greater the sediment supply; subtle variation in the rate of sea-level change can produce significant variation in the supply (Figure P18C). Progradation of the bayhead barrier (Figure P18D) is a function of sediment supply and accommodation space (increasing depth and bay width). Therefore, with diminishing relative sea-level rise, typical of the last few millennia in Newfoundland, the rate of simulated barrier progradation decelerates in response to reduced sediment input. As the progradation rate decreases, the potential for severe storm impact leading to overtopping and growth of the active beach ridge may increase. The morphological outcome is a seaward-rising sequence of barrier ridges, flooded at the back and reworked into a high transgressive storm ridge at the front.

These examples demonstrate the critical importance of sediment supply and the ways in which glacial inheritance may direct and ration the delivery of sediment to the coast. They also show the propensity for high spatial and temporal variation of sediment supply in some paraglacial settings. Some systems suffer from slow supply reduction, with distinctive morphological outcomes (Figure P18). Others experience highly fluctuating sediment budgets (Figure P17), resulting in abrupt coastal changes when supply from a given source is exhausted or other stability thresholds are exceeded (Forbes *et al.*, 1995). Delayed paraglacial sediment input to coastal systems, ultimately controlled by access through changing sea level, can prolong the paraglacial signal, extending the relaxation time through many thousands of years. Coastal morphology in glaciated regions of the mid- to high latitudes over a large part of the globe is thus affected to this day by the physiographic and sedimentary legacy of the last major glaciation.

PEAT

Peat forms from the accumulation of plant remains in waterlogged, anaerobic conditions that inhibit decomposition. In coastal situations peat forming environments occur within the intertidal zone, typically as *salt marsh* or *mangrove* peat, to the landward transition to freshwater environments, *wetlands* and *bog*. Accumulation requires a relatively low-energy environment, such as an *estuary* or behind *barriers* or *dunes*. Geographically the range is from the high latitudes to tropics, limited by water balance and the local conditions that constrain plant growth. If it is too dry, the plant material will decompose rapidly and peat will not accumulate.

Peat comprises authochthonous material, decomposed plant material deposited *in situ*, and allochthonous material, that which is transported to the site of deposition. The latter includes organic material, plants and fauna, and minerogenic material, usually clay, silt, and sand size fractions but occasionally coarser. The organic component includes the visible, or macrofossil, remains and a fine organic matrix. Separate constituents of this matrix that are indistinguishable with the naked eye include totally decomposed organic material and microfossils, such as pollen, spores, diatoms, thecamoebians, and foraminifera (see Troels-Smith, 1955, a classic work on the description of peat and other unconsolidated sediments, and recently summarized in chapter 11 of Jones *et al.*, 1999). The balance between organic and minerogenic sediment covers the full transition between the end members, with the intermediates described by terms such as sandy peat (predominance of organics) and organic sand (predominance of minerogenics). Peat-forming plant communities exhibit a spatial zonation in response to a series of environmental gradients; the most important of which in the coastal zone is usually ground surface elevation with respect to the tidal regime (Waller, 1994, chapters 3, 4, and 5). The spatial zonation changes through time, described as plant succession, as a result of autogenic and allogenic processes. Autogenic processes are those directional changes that operate within an ecosystem, trending toward equilibrium with the environment, the classical concept of climax vegetation. Allogenic processes are those operating externally to the vegetation. Examples include changes in sea level or sediment budget.

Where the balance of processes result in net accumulation, peat provides an excellent archive of environmental change. Successional changes that occur through time are recorded in the stratigraphic column. The physical, chemical, and biological properties of the sediment help to reconstruct the continuum from tidal flat, through marsh to wetland or bog. Although the classification into discrete units is difficult and somewhat arbitrary, it is relatively easy to reconstruct the trends or direction of change. This involves both the horizontal component of change (e.g., vegetation succession) and the vertical component (e.g., *sea-level change*). Early scientific studies, such as the geological surveys of coastal wetland areas carried out in the 19th century (or earlier) in northwest Europe, described the visible plant remains (macrofossils) within peat layers and from these inferred environmental change. With scientific advances during the 20th century, an increasing range of techniques has been used to analyze peat (van de Plassche, 1986). While macro-fossils, especially the roots and stems of the plants that were growing in the sediment, provide extremely good evidence of site conditions at the time of formation, their preservation is very variable and because only a small volume of sediment may be available (e.g., from a borehole) they may not give a reconstruction of the whole community or wider environment (Waller, 1994). From the microscopic sediment matrix the most widely studied element has been the microfossil content (especially pollen, spores, diatoms, and foraminifera).

Analysis of peat layers within a sediment sequence and the microfossils contained in the different layers can give reconstructions of a wide range of different environments, ranging from the coastal environments of previous interglacials, through the whole of the current interglacial to the present day. Peat can form quickly on the geological timescale. For example, the marshes around the Cook Inlet, Alaska subsided by up to 1.7 m during the great earthquake (M_w 9.2) of 1964 and were rapidly buried by tidal flat silt deposits (Figure P19). The 1964 marsh peat is now exposed along the banks of tidal creeks beneath minerogenic sediments, more than 1 m thick in some places, that grade upwards with an increasing organic content to the present marsh surface where there is already a centimeter or more of peat accumulating. While this example of recent marsh burial was the result of rapid coseismic change in land level, the gradual submergence of marsh peat beneath tidal flat minerogenic sediment records relative sea-level change due to nonseismic processes, especially the interaction of *eustasy* and *isostasy* (e.g., Allen, 2000).

Buried peats contain critical information on the long-term dynamics of coasts prior to the period of scientific observation and measurement. The threat of large earthquakes, comparable to the 1964 Alaska event, occurring in Washington, Oregon and British Columbia is clearly indicated by the multiple peat layers buried beneath many of the coastal marshes in these states (e.g., Shennan *et al*., 1996). Figure P20 shows a peat layer from the Johns River, Washington. The sequence from 105 to 69 cm shows the colonization of a marsh onto tidal flat. As the marsh peat accumulates, low-marsh plants, shown by the Chenopodiaceae and *Aster*-type pollen, are replaced by high- marsh plants (e.g., indicated by *Potentilla* pollen). At the same time, marine (polyhalobian) and brackish (mesohalobian) diatoms give way to increasingly freshwater (oligohalobian) and salt-intolerent (halophobes) diatom species. The top of the peat marks the rapid return to tidal flat sedimentation, interpreted as the result of an earthquake that caused about 1 m of ground subsidence. The radiocarbon age of the peat indicates this occurred about 300 years ago. Other peat layers from the estuary indicate a total of eight such events during the last 5,000 years. The earthquakes result from the collision of the Juan de Fuca and American plates.

Ian Shennan

Figure P19 Salt marsh and tidal flats at Girdwood, in the upper Turnagain Arm of the Cook Inlet, Alaska. The dead spruce trees are rooted in a peat layer that had developed over the tidal flat sediments visible in the exposure. Coseismic subsidence during the earthquake of 1964 dropped the forest to a level below high tides. Tidal inundation killed the trees and gray tidal silt accumulated over the peat and around the tree trunks. At this location the silt is approximately 50 cm thick. The present salt marsh, dominated by sedges, represents the first stage in the renewed growth of peat as gradual land uplift since 1964 allows saltmarsh, and eventually, freshwater environments to develop once more.

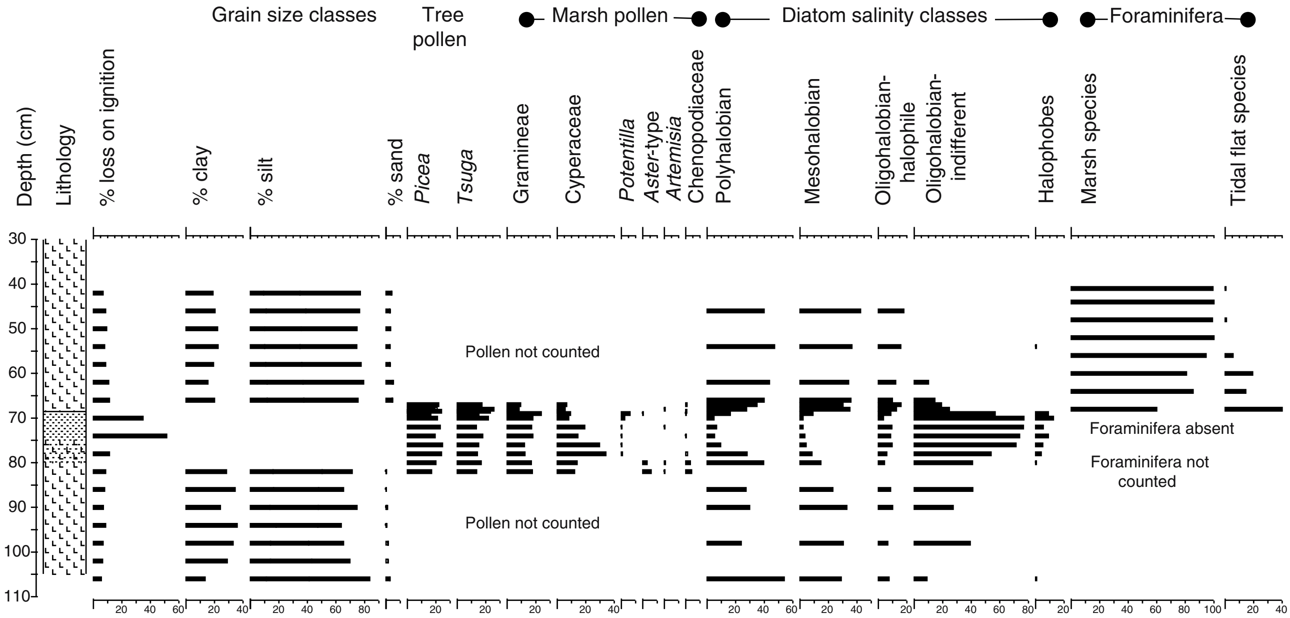

Figure P20 A buried peat layer from Johns River, Washington (after Shennan *et al.*, 1996). The peat, from 68 to 80 cm, lies between silt that represents tidal flat enviroments. The pollen, diatom, and foraminifera form the peat and the two silt layers record different stages of marsh development, then rapid burial caused by an earthquake ~300 years ago. The horizontal axes show percentage abundance for selected species for three microfossil types: pollen, diatoms, and foraminifera. The full data set comprises microfossils from over 100 different species.

PHOTOGRAMMETRY

Photogrammetry can be defined simply as the science of making reliable measurements from photographs. Unlike a map, however, a photograph contains a number of distortions that require correction before accurate measurements can be made. A number of photogrammetric techniques can be employed to remove these distortions and obtain useful measurements. In coastal studies, photogrammetric techniques are commonly employed to establish the positions of historical and modern features-of-interest (e.g., shorelines (defined as the high-water line or wet-dry boundary), cliff edges, dune positions, etc.). Historically, the focus of study has been overwhelmingly on the use of vertical aerial photography to derive accurate shoreline positions, although photogrammetric applications using ground-based photography, videography and integration with other types of remotely sensed data (e.g., lidar) are becoming widespread. Most often, a time series of feature positions is compiled for the purpose of studying coastal dynamics, such as the evolution of geomorphic features, or determining rates of coastal change (e.g., shore erosion and accretion). These time series have also been used to guide the delineation of coastal erosion or flood hazard areas and building setback lines.

Historical development

Early studies of coastal erosion (e.g., Stafford and Langfelder, 1971) used point measurements made on individual air photos to determine shoreline rates of change. The procedure is straightforward: stable reference points such as buildings and road intersections are selected on air photos taken in different years, and the distance between these points and the shoreline reference feature (typically the boundary between wet and dry beach sand, which approximates high water) is measured. These measurements are then multiplied by the nominal scale of the aerial photograph to obtain ground distances. The change in distance over time yields a rate of shoreline change at that location. Subsequent shoreline delineation methods expanded upon this basic approach, using techniques such as photo-enlargement or a Zoom Transfer Scope to match a base map (e.g., Dolan *et al.*, 1978, 1980; Smith and Zarillo, 1990). These methods permitted a continuous representation of the shoreline to be mapped from the photos, rather than discrete points, and were a significant improvement over point measurements in terms of the amount of information that could be extracted from aerial photography.

One of the primary limitations in early historical shoreline mapping studies was the inability to quickly and accurately correct aerial photographs for their inherent distortions. The first integrated coastal photogrammetry software package to address this need was the Metric Mapping System (MMS) (Leatherman, 1983; Clow and Leatherman, 1984). For aerial photographs, this package furnished the ability to correct individual photographs for image displacements and produce shoreline positions on a plotted map. The Digital Shoreline Mapping System (DSMS) (Thieler and Danforth, 1994a,b) expanded upon this approach to include a full photogrammetric adjustment of large groups of photographs and produce data suitable for plotting shoreline change maps in a Geographic Information System (GIS). Both the MMS and DSMS software packages utilized *x–y* tablet digitizers to obtain vector data from aerial photographs. While this approach kept the amount of data acquired from the photographs to a manageable size, much useful visual information was not used. More recently, however, advances in computer storage and processing capability allow photogrammetric techniques to be applied to digitally scanned photographs. This process, known as softcopy photogrammetry, has recently seen increased use in coastal studies. A comprehensive review of available shoreline mapping techniques is furnished by Moore (2000).

Characteristics of aerial photography

The basic principles involved in the extraction of geographic data from aerial photographs are derived from the geometric relationships between image space and object space. Image space refers to the world inside the camera (i.e., the photographic image and measurements obtained from it). Object space refers to real-world geographic coordinates outside the camera.

In distortion-free space, points in image space can be projected to points in object space. This relationship is based on the principle of collinearity: the perspective center of the camera lens (which is considered a point), an image point and its corresponding ground point all lie on the same straight line (Figure P21). Aerial photographs, however, are subject to a number of distortions introduced at various stages in the photographic process that perturb the collinearity condition. These perturbations affect both image space and object space.

The image space coordinate system is defined by the locations of the fiducial reference marks on a photograph, the calibrated focal length, and the geometric distortion characteristics of the lens system in the camera. Image space is described by a three-dimensional, rectangular Cartesian coordinate system with the origin located at the principal point (the center of an aerial photograph as defined by fiducial reference marks around the edge of the photograph). For aerial photographs, the *x*-axis is typically positive in the direction of flight. The *z*-axis corresponds to the optical axis of the camera.

The distortions affecting image space result from lens distortion and film deformation. All camera lenses have measurable distortions and optical defects that affect the representation of image points on film. Lens distortions can be radial or tangential. Radial distortion is symmetric around the principal point and is caused by optical defects in the lens.

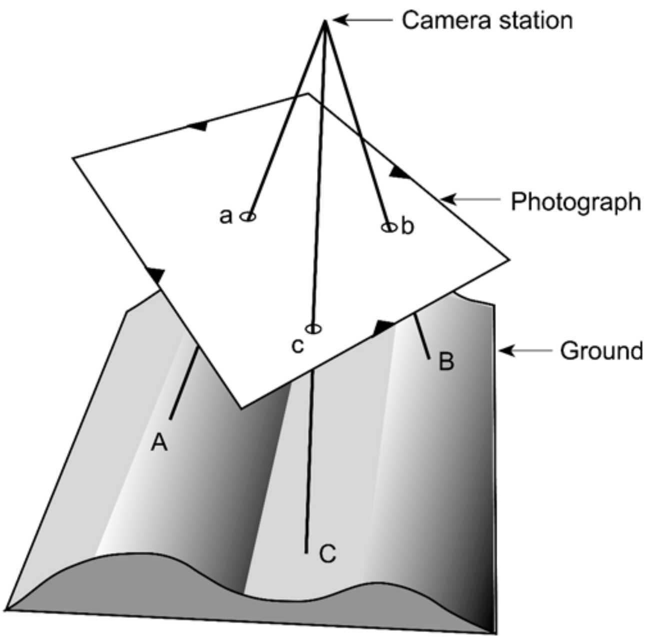

Figure P21 In distortion-free space, a projective relationship exists between image space (points on an aerial photograph) and object space (points on the ground). The camera station, an image point (a, b, c), and its corresponding ground point (A, B, C) all lie on the same straight line (after Thieler and Danforth, 1994b).

Tangential distortion is symmetric along a line through the principal point and results from the lens being slightly off-center in the camera. In a well-adjusted camera, however, only radial distortions are present.

The magnitude of lens distortion is highly variable. Some lenses used today have up to 0.110 mm radial distortion (American Society of Photogrammetry, 1980). Similar and sometimes greater amounts of lens distortion commonly are present in photographs taken prior to World War II, which brought an increased demand for accurate photography and improved lens manufacturing techniques. This is a particularly important consideration in using historical coastal photography. In most modern camera systems, however, lens distortion is negligible.

Two types of film deformation exist. Deformation can be introduced in the camera during the aerial survey or in subsequent processing. Film buckling, for example, may occur during the photographic survey due to irregularities in temperature, humidity or film spool tension in the camera. Further deformation is introduced not only in the development of the original negatives, but also in each generation of prints and transparencies (typically used by coastal researchers) made from the original negatives. The end result of these deformations is a photograph that no longer represents accurately the true geometric relationships between the fiducial reference marks and image points in the photo.

In addition to deformation occurring in the camera, the amount of film deformation present in a given photograph depends upon the age and type of material (glass, film, or paper), processing techniques used, and the temperature and humidity at the time measurements are made. Standard diapositive (transparency) film is generally stable within 0.005 mm. Photographic paper, however, is far less stable and may change in size up to 1% during processing alone (American Society of Photogrammetry, 1980).

The characteristics of object space cause image points on film to be displaced (as opposed to distorted) from their true position as a result of three factors: relief displacement, tilt displacement, and atmospheric refraction. Relief displacement is caused by changes in ground elevation within a photo that cause objects closer to the camera to be larger (i.e., at a larger scale) than those farther away. Relief displacement takes place radially from the nadir (Figure P22). Objects higher than the ground elevation at the point where the nadir intersects the ground (the ground nadir; Figure P22) are displaced outward; objects lower than the ground nadir point are displaced inward.

The determination and magnitude of relief and tilt displacements have been widely discussed in the context of coastal photogrammetry (e.g., Anders and Byrnes, 1991; Crowell *et al*., 1991). Tilt displacement occurs due to the inability to keep the aerial camera perfectly leveled during photography. Some degree of tilt is always present in an aerial photograph. On a tilted photograph, the sense of displacement depends on whether the image point is on the low or high side of the isometric parallel (Figure P22). Points on the low side of the isometric parallel are displaced outward from the isocenter; on the high side they are displaced inward. Points on the isometric parallel are not displaced.

Atmospheric refraction (the bending of light rays through the atmosphere) also causes photograph image points to be displaced. The displacement occurs radially outward from the nadir. The magnitude of the displacement depends on the aircraft flight height, direction of the optical axis relative to the ground, and the focal length of the camera. For most coastal applications, atmospheric refraction is negligible because low-altitude photography is used.

Extracting geographic data from aerial photographs

The traditional approach to analytical photogrammetry (American Society of Photogrammetry, 1980) is composed of three steps that remove the perturbations described above, and exploit geometric relationships between overlapping aerial photographs to extract geographic data: (1) preprocessing; (2) aerotriangulation; and (3) postprocessing. Preprocessing reduces measured image coordinates to the image space coordinate system described above, as well as removes systematic errors such as lens distortion and film deformation effects. The goal of preprocessing is to transform measured image data from a photograph to an idealized image space in which distortions do not exist. In other words, the measured coordinates are refined to remove image space distortions before the data are used in subsequent processing.

Aerotriangulation is used to solve simultaneously for the camera position of each photograph in a large group of overlapping photographs (a strip or a block), as well as the coordinates of unknown ground points. The absolute orientation performed in an aerotriangulation adjustment is basically an extension of the technique of space resection, which determines the six elements of exterior orientation for a photograph, including the position (latitude, longitude, and elevation), and attitude (roll, pitch, and yaw; designated ω, ϕ, and κ, respectively)

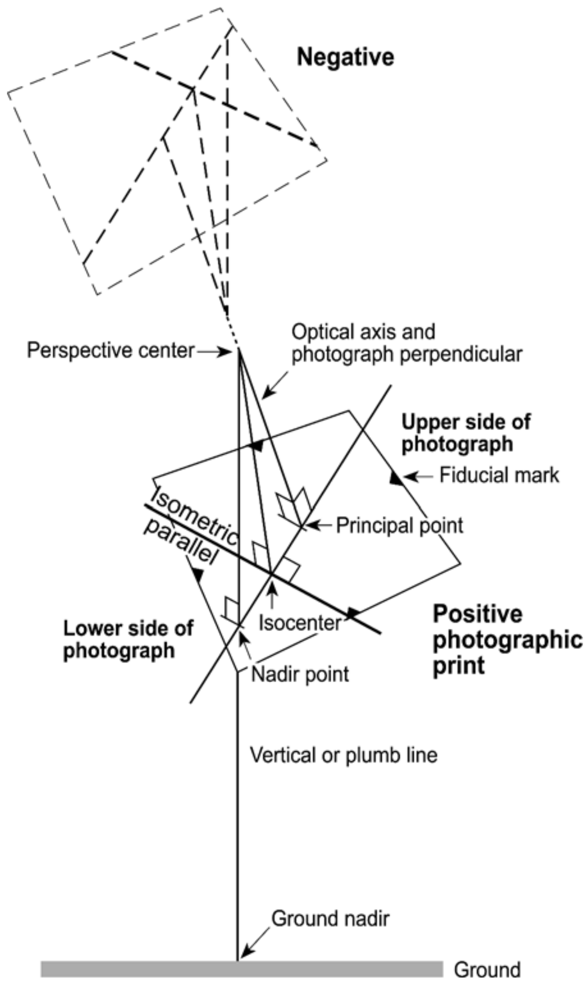

Figure P22 Definition sketch of terms used to describe the various elements of a tilted aerial photograph. Some degree of tilt is always present in an aerial photograph, which causes image points to be displaced from their true position (modified after American Society of Photogrammetry, 1980).

of the aerial camera. Atmospheric refraction effects can also be removed during space resection or aerotriangulation by applying a correction function each time the orientation of the camera is updated in the solution process.

Postprocessing typically involves transforming the camera position information into instrument settings used in stereoplotters or other photogrammetric equipment in order to compile basemaps or generate rectified photographs (also known as orthophotographs). In digital photogrammetry, camera information is input into computer software that performs orthorectification on scanned photographs. The result is a geographically corrected photograph that may be used directly in a GIS.

Ground control

The common requirement of all forms of photogrammetric manipulation is adequate ground control information so that quantitative, geographically accurate information can be extracted from the photographic data. Thus, establishing an adequate ground control network is critical. This is particularly true in studies using historical aerial photography, since points on the ground are the only source of position information.

A ground control network is a set of points that appears in one or more photographs, and provides the basic means of establishing a correspondence between the photographs and the ground. There are two types of points used in photogrammetry: ground control points and tie points. A point appearing in one or more photos for which information about its location is known (e.g., one or more of latitude, longitude, and elevation) is called a control point or ground control point. The image space coordinates of ground control points and their corresponding geographic coordinates are used to establish the collinear relationship between image space and object space (Figure P21).

There are a number of ground control data sources, including maps, field surveys and geodetic control tables. The locations of well-defined points shown on maps can be digitized, converted to geographic coordinates and used as ground control points. These points are termed "supplemental control points" because they are obtained from a map rather than by direct field survey. Supplemental control points, consisting primarily of buildings and road intersections, are the primary source of ground control for many historical shoreline mapping projects because other data are unavailable.

A tie point is defined as a point appearing in two or more photos, for which a corresponding ground position is not known. Tie points are used to "pass" or extend control between overlapping photos. These points are used in addition to ground control points to establish the relative orientation of photos to each other, such as is done when viewing a pair of overlapping photos through a stereoscope. Tie points commonly include features such as trees, buildings, and road intersections.

For most applications, at least four and preferably six to nine tie points are needed to provide adequate control for a given stereo-pair, and should be distributed throughout the photograph. Only a few control points are needed to establish the geographic orientation of a group of photographs in object space; most points used to control a photograph may simply be tie points.

Ideally, the exact planimetry (latitude, longitude, elevation) would be known for a large number of spatially and temporally well-distributed ground control points throughout all photographs. This is never the case, however, and ground control points of varying quantity and quality must be used when constructing the control network for a given mapping project.

In historical shoreline change studies, when several sets of photographs spanning several years of the same geographic area are used, the common ground control and tie points form a model that establishes correlations between images, in space and through time, that are readily exploited in aerotriangulation and error analysis.

It is often problematic, however, to furnish an adequate quantity and distribution of ground control and tie points due to the nature of photography along the shoreline and changes in coastal environments over time. Most photographs that include the shoreline, for example, are devoid of usable control points seaward of the shoreline. Coastal areas may also change rapidly over time, due to natural processes or human development, which reduces the number of stable points that can be used as ground control or tie points. In these situations, it is often necessary to use additional overlapping photos taken of more landward areas in order to augment the control network for the shoreline photographs.

Modern techniques and current investigations

Several different methods of digital rectification (Table P1) are available through the various softcopy photogrammetry software packages currently available. Not all rectification techniques, however, are equally accurate. The two most robust rectification methods are full orthorectification based on viewing and manipulating digital stereo-pairs, and pseudorectification, in which stereo-pairs are used but there is no ability to manipulate stereo-imagery. These two techniques both apply photogrammetric principles to produce orthophotographs, and involve the creation of a Digital Terrain Model (DTM) to remove relief displacement from the imagery. Generation of DTMs involves taking the user-input measurements (ground control and tie points) and deriving the DTM from a stereo model through interpolation (Ackerman, 1996). In many softcopy photogrammetry systems, DTM collection is automated but the user can edit the model. Editing a DTM (which is only possible with stereo-viewing photogrammetry) increases the accuracy of the ground surface model, allowing more complete removal of relief displacement in the orthophotograph. Using an unedited DTM may affect the spatial accuracy of the orthophotograph, and may not approximate rapid changes in topography. Another rectification technique, single frame resection, can be used to remove distortions associated with the camera system, but does not remove aircraft attitude or relief displacements. The final method available is warping (also known as "rubber sheeting"). In this case, no parameters are input to remove displacements; instead, ground control points are used to "stretch" the pixels of an individual image to a best georeferenced fit.

In comparing the various methods described above in coastal change applications, recent studies (Hapke and Richmond, 2000) have found that a shoreline position digitized on a stereo-based orthophotograph is

Table P1 Comparison of softcopy photogrammetry processing techniques

Technique	Process (result)	Products
Full orthorectification (stereo-viewing)	Input camera system parameters (remove camera distortions) Input tie points (remove aircraft attitude distortions) Add ground control points (georeference imagery) Create DTM (remove relief distortion) Edit DTM (correct for detailed topography) Aerotriangulate (tie all photos together, orthorectify)	Orthophotographs Stereo imagery High-accuracy DTMs
Pseudorectification	Input camera system parameters (remove camera distortions) Input tie points (remove aircraft attitude distortions) Add ground control points (georeference imagery) Create DTM (remove relief distortion) Aerotriangulate (tie all photos together, orthorectify)	Orthophotographs Uneditable DTMs
Single frame resection	Input camera system parameters (remove camera distortions) Add ground control points (georeference imagery) Least squares resample (statistical best-fit)	Pseudo-orthophotograph (relief distortion not removed)
Warping (rubber sheeting)	Add ground control points (georeference imagery) Stretch pixels to best fit approximation	Georeferenced image

the most reliable in terms of reproducing shoreline position. The technique of warping is the least reliable method and can be very inconsistent. In areas of high relief, or where high accuracy (submeter) is required, use of a stereo-edited DTM is recommended.

The recent proliferation of digital photogrammetry and GIS software has greatly increased the accessibility of aerial photograph analysis. Many software packages can be run on a standard desktop computer and do not require formal training in photogrammetry or GIS. Using such software requires scanning the aerial photographs to convert to digital format. There are several options as to the media of the aerial photography and the choice of scanners, all of which may have noticeable impact on the spatial accuracy of the final orthophotograph.

The first step in digital aerial photograph analysis is to convert the photograph into a digital format using a scanner. The most accurate choice, a geometrically correct photogrammetric scanner, will produce minimal distortion. This ensures that the spatial distribution of objects in the original photography is reproduced accurately in the digital version. Photogrammetric scanners provide the most accurate digital imagery, but these scanners and/or the contracting of photogrammetric scanning may be too costly for smaller-scale coastal mapping projects. As a less-expensive (and less-accurate) substitute, high-quality graphic design scanners or desktop scanners are available. Graphic and desktop scanners are not designed to assure geometrically accurate data conversions, and thus may introduce distortion to the digital imagery, which results in nonsystematic positional errors in the resulting orthophotograph (Hapke *et al*., 2000). A further limitation of desktop scanners is that the scanning resolutions rarely exceed 800 dpi (dots per inch), whereas most photogrammetric workflows recommend 1,200 dpi or higher.

Standard aerial photography is typically available from the original negatives in two different media: contact (paper) prints and diapositives (positive film transparencies). Although contact prints cost less and are readily available, as noted above photographic paper may undergo stretching, shrinkage, and warping, resulting in positional errors. Diapositives are a much more stable media, since film is much less likely to undergo distortion.

Most digital softcopy photogrammetry software packages provide an overall RMS (root mean square) value as an indication of error associated with rectification. US National Map Accuracy Standards (NMAS) (Falkner, 1995) state that in order to conform to the accuracy standards, 90% of identifiable stationary objects should be accurate to within a specified RMS error. In a study comparing media types and scanners, Hapke *et al*. (2000) found that at a scale of 1 : 12,000, the only combination of scanner and media type that conforms to NMAS is a diapositive scanned on a photogrammetric scanner. The RMS error increases with the lower precision scanner and with the use of contact prints versus diapositives. The NMAS standards also require that the maximum error at any given point, either horizontal or vertical, does not exceed three times the magnitude of the RMS. For images scanned on a nonphotogrammetric scanner (either graphic design or desktop), this value is almost always exceeded in the X and Y, and in every case in the Z direction. If a coastal mapping application involves delineation of absolute position (e.g., establishing setback lines, determining hazard zones at the scale of individual property boundaries, etc.), or if the resulting data could be used for such applications, then it is especially important to use a technique that adheres to the NMAS.

Table P2 Suggested scanner and media types for coastal research

Project scope and examples	Recommended scanner and media
Absolute position: setbacks, hazard zones, elevation changes, short-term changes	Photogrammetric scanner, diapositives
Long-term erosion rates: bluff or shoreline change	Graphic arts scanner, diapositives
Thematic mapping: vegetation, land use, watershed mapping	Desktop scanner, diapositives

For other types of coastal applications, larger errors may be quite acceptable (e.g., rate calculations, especially over long periods of time), such that using contact prints and/or nonphotogrammetric scanners is appropriate to the study design. These methods, however, may introduce large nonsystematic errors into the final orthophotograph. These nonsystematic errors are most likely due to stretching or shrinking of the contact prints. Table P2 provides an overview of the recommended scanner and media choices for a variety of coastal research activities utilizing aerial photography. The image quality of scanned contact prints is significantly degraded as compared to scanned diapositives, regardless of the quality of the scanner. This may result in the inability to measure ground control and tie accurately.

The full stereo-orthorectification process requires the generation of a DTM that defines topography within the stereo-overlap region of images using a series of points and is required if the distortion from terrain relief is to be removed from the orthorectified images. Two formats of DTMs may be generated from stereo-images: grid or TIN (triangulated irregular network). The grid is a regularly spaced network of points where the elevation of individual points can be edited but the network spacing must remain constant, and thus the horizontal position of each point cannot change. In a TIN model, however, not only the elevation of points may be edited, but they may also be added in areas where a greater density is desired, or deleted in problematic areas. Another advantage of TIN models is the ability to add breaklines, which allows for more accurate definition of subtle topographic changes. Breaklines are crucial to accurately define the topographic signal of narrow or sharp features such as beach scarps, cliff edges, or dune ridges in the surface model. A breakline is a manually entered line composed of a series of points that are incorporated into the DTM. Breaklines can only be added to the model while viewing in stereo, as the operator must be able to identify the elevation change in order to correctly place the line.

DTMs generated from stereo-models can be used to derive volume, and hence volumetric changes. However, the automated process of DTM generation has distinct, nonsystematic errors that must be corrected if DTMs are to be used for accurate surface modeling and volumetric change analyses. Automated collection with no editing is problematic in images of coastal regions due to typical low-contrast beach conditions and high visual interference areas like the swash zone, where the water has moved and thus varies in position from one image

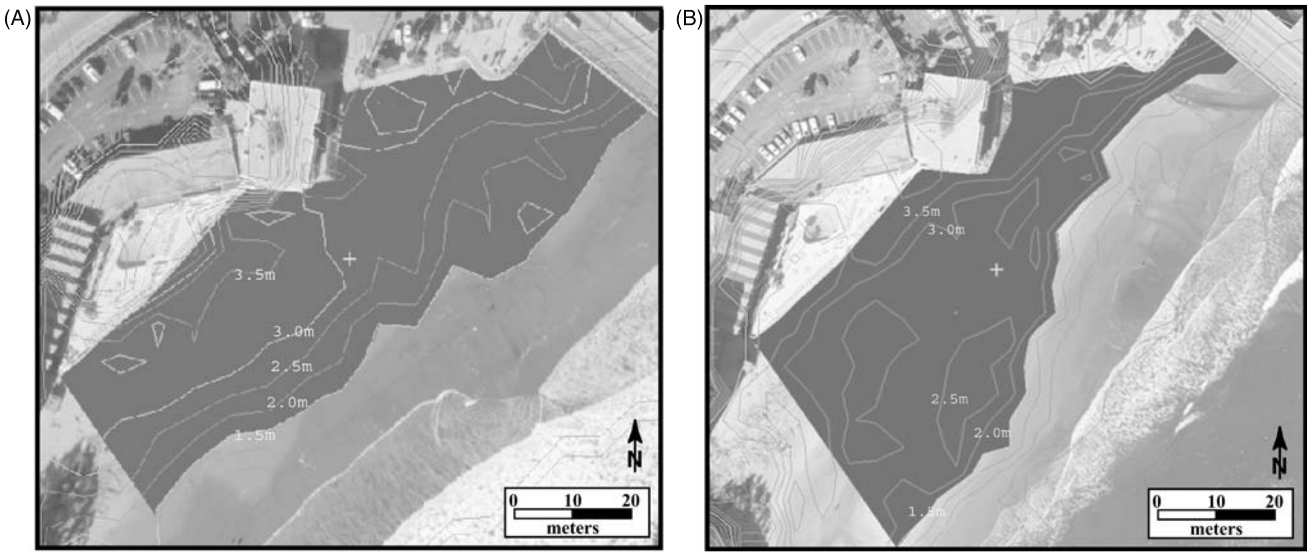

Figure P23 Topographic contours generated from an edited grid DTM of Cowell Beach, Santa Cruz, California, for two time periods: (A) January 27, 1998 and (B) March 6, 1998. The seaward extension of the area under which the volume is calculated is the 1.5-m contour. The volume of sand above a zero datum on January 27 is 49,740 m^3, as calculated from the topographic model. Almost one half the volume of sand on this beach was lost during the 1998 El Niño winter. By March 6, the volume of sand above a zero datum is 24,380 m^3. Note how the position of the 1.5-m contour has changed between January 27 and March 6.

to the next. In order to utilize the DTMs for time-series volumetric studies, careful editing is crucial.

Beach volume (Hapke and Richmond, 2000) and/or dune volume (Brown and Arbogast, 1999) can be calculated using an edited TIN format DTM derived from each date of photography (Figure P23). For the volume calculations, a base elevation must be defined, and 0 m (MSL) is typically used. However, surface elevations below the 0.5 to1.5-m zone contour on a subaerial beach are commonly in, or very near, the swash zone that creates severe interference when viewing in stereo and thus greatly reduces the accuracy of the contours. Merging other topographic data in high interference areas or areas prone to shadow (e.g., base of seacliff, scarp, or dune) is highly desirable if such data is available. In addition, once ground control points are measured within a block or strip of air photos, other sources of DTM data can be used for final orthorectification. These sources include lidar as well as existing contour maps.

Technological advances in surveying techniques and digital data collection are rapidly influencing the field of photogrammetry, and will eventually result in reducing the currently required processing time by several orders of magnitude. As described above, orthorectification and DTM generation both require a network of accurate ground control points that are visually identifiable on imagery. In order to remove displacements associated with aircraft attitude and topographic relief, a network of tie points are used to connect the images and then the ground control points must be digitally located in order to successfully aerotriangulate and rectify imagery. Airborne kinematic GPS used in conjunction with the collection of the photographic data eliminates the need to collect ground control points as well as measure tie points on the imagery. Changes in aircraft position from frame to frame can be recorded using an inertial measurement system as the photography is being collected; the attitude values (ω, ϕ, κ) can be entered into processing software. Airborne kinematic GPS can be used to record simultaneously the exact location of the center of the camera lens as the instant exposure occurs, thus eliminating the requirement of locating photo-identifiable ground control points in a strip or block of images (Lucas and Lapine, 1996).

For use in traditional softcopy photogrammetry, photographs are presently converted from film to digital format using a photogrammetric scanner. With continued advances in the resolution of sensor arrays in digital cameras, it is inevitable that photographic collection will eventually be dominated by digital systems.

Summary

The use of photogrammetric techniques in coastal studies has progressed in concert with technological advances over the past several decades. Early studies of coastal change used simple point measurements at control point locations on individual photographs. This was a time-consuming process and did not yield a great amount of information relative to the effort involved. In most cases, a simple rate of shoreline change at discrete locations was produced. Modern applications of photogrammetry, although computerized and somewhat automated, are similarly time-consuming. The data produced from this process, however, enables the delineation and measurement of a variety of parameters, such as morphology, position and volume changes in coastal environments that are of use to a wide audience including coastal managers and scientists.

PHYSICAL MODELS

In the context of coastal science and engineering, the term physical model can be defined as the physical reproduction of the environment of interest in the laboratory, normally at reduced scale. To many readers, the use of physical models in an age of increasingly sophisticated numerical, or computer models must appear antiquated. Indeed, Leonardo da Vinci employed the technique to examine a variety of hydraulic problems in the 1500s (American Museum of Natural History, 1996)! Physical models retain their usefulness in the study of coastal processes and design for a variety of reasons, including:

1. When scaled correctly, physical models can simulate complex turbulent phenomena to a degree of accuracy that is not possible with analytical and numerical models.
2. The inherent control that laboratory experiments afford allows for the careful investigation of dominant physics, and the evaluation of cause-and-effect relationships among the various forcings of interest. These advantages are not attainable via field experiments because of the prohibitive expense of long-term coastal measurements having the requisite spatial coverage and resolution.
3. Physical models facilitate the development of visual-based, “hands on” knowledge of the environment and problem being investigated. This advantage can be particularly important when dealing with complex dynamics, and/or when examining the impact of coastal engineering design alternatives.

Physical models are however, not without disadvantages. These include:

1. Scale effects, which are present in virtually any reduced-scale physical model. These are associated with the improper scaling of one or more relevant forces or flow features. The degree of influence of scale effects depends on the relative importance of the poorly scaled variable(s) to the problem of interest. The optimization of model accuracy in the presence of scale effects remains part of the “art” of physical modeling.
2. The possibility that the natural environment cannot be fully reproduced because of (e.g.) incomplete representation of all natural forcings, or inadequate model dimensions leading to boundary effects.
3. The high expense associated with the construction and implementation of physical models. When comparing the costs of physical and numerical models, however, one should consider the full range of costs associated with each, including, for example, the developmental costs associated with a numerical model, and the field data acquisition necessary to calibrate and validate both types of models.

Similitude

Similitude between a reduced-scale physical model and the full-scale prototype is simply defined as the condition when the reduced-scale model is an exact reproduction of the full-scale system, or prototype, being examined. There are three basic forms of similitude, including:

- Geometric—wherein the ratios of corresponding lengths in the model and prototype are identical, for example, $(L_{\text{model}}/L_{\text{prototype}}) = (d_{\text{model}}/d_{\text{prototype}})$. In other words, the model and prototype have the same shape.
- Kinematic—wherein the ratios of corresponding flow velocities and accelerations in the model and prototype are identical, for example, $(V1_{\text{model}}/V1_{\text{prototype}}) = (V2_{\text{model}}/V2_{\text{prototype}})$, where $V1$ and $V2$ represent velocities at corresponding locations in the model and prototype.
- Dynamic—wherein the ratios of corresponding forces in the model and prototype are identical, for example, $F1_{\text{model}}/\ F1_{\text{prototype}}) = (F2_{\text{model}}/F2_{\text{prototype}})$, where $F1$ and $F2$ represent forces acting on corresponding locations in the model and prototype.

Assurance of geometric similarity is relatively straightforward, and requires knowledge only of the linear dimensions of the physical system to be modeled. These dimensions must then be reduced in equal proportion in all directions—vertical, lateral, and longitudinal. This assures that the reduced-scale model accurately reproduces both the scale and the shape of the prototype. In the case of reduced-scale models of coastal systems, the large spatial extent of the domain of interest and/or the restricted size of the laboratory facility, will at times require the use of a “distorted” model, in which the vertical and horizontal scales are reduced by different ratios. The use of distorted models is normally avoided because of the problems assuring kinematic and dynamic similarity in such models.

Assurance of kinematic and dynamic similarity requires knowledge, if not of the detailed physics of the full-scale system being modeled, then at a minimum knowledge of the important variables that describe the system. These variables include forces such as gravity and pressure, fluid characteristics such as density and viscosity, and flow characteristics such as velocity. One must first determine which among the various variables are important to the problem at hand. Proper representation of these variables can then assure that both kinematic and dynamic similarity are achieved. If, as is often the case in coastal systems, the number of variables is large, the proper scaling of each individual variable can become problematic. As an alternative, one can group the various variables into dimensionless parameters, which, if properly reproduced in the physical model, can assure similarity. Of course, the challenge lies in the selection of the dimensionless parameters. This process is known as *dimensional analysis*, and is accomplished either by inspection, using experience and/or knowledge of the physical system, or through a more formal process such as the Buckingham-π theorem (e.g., see Fischer *et al*., 1979). For an excellent treatment of scaling considerations for a variety of practical coastal problems, the reader is referred to Hughes (1993).

The construction of physical models for coastal systems is usually accomplished through the use of one or both of the following dimensionless parameters: the Froude number: $\mathrm{Fr} = V/(gL)^{1/2}$, where V is the velocity of interest, L is the length of interest, and g is the acceleration due to gravity; and the Reynolds number: $\mathrm{Re} = VL/\nu$, where ν is the kinematic viscosity of the fluid. Both of these dimensionless parameters are constructed via the ratio of the force of interest—the force due to gravity in the case of the Froude number and the force due to viscosity in the case of the Reynolds number—to the inertial force. We discuss each parameter below.

Froude number similarity

The Froude number is employed in virtually every physical model study dealing with coastal processes, because of the importance of free surface (gravity) effects. Using our definition, $\mathrm{Fr} = V/(gL)^{1/2}$, Froude number similarity is achieved by assuring that:

$$\frac{V_{\mathrm{m}}}{(g\,L_{\mathrm{m}})^{1/2}} = \frac{V_{\mathrm{p}}}{(g\,L_{\mathrm{p}})^{1/2}}$$

where the subscripts "m" and "p" denote model and prototype values, respectively. Since gravity remains constant at model scale, this relation can be rewritten as:

$$\frac{V_\mathrm{m}}{V_\mathrm{p}} = \frac{L_\mathrm{m}^{1/2}}{L_\mathrm{p}^{1/2}}$$

which indicates that the scale reduction for the velocity is equal to the square root of the length scale reduction. Alternatively, since velocity is (length/time), we can restate this by saying that the scale reduction for time is equal to the square root of the length scale reduction. In other words, using geometric similarity and Froude number similarity, and employing a model that has (undistorted) length scale reduction of 9, the corresponding timescale reduction is equal to 3. If one was to use this model to simulate a full-scale 12-h flow event, for example, one would employ a 4-h event in the model.

Reynolds number similarity

The Reynolds number was originally employed to predict the onset of turbulence in flow through pipes. It is commonly used in physical model studies that address problems where viscous forces are expected to play an important role. Examples of such problems in the fields of coastal science and engineering include fluid flow within porous media such as sand or a stone structure, and boundary layer flows. Using our definition, $\mathrm{Re} = VL/\nu$, Reynolds number similarity is achieved by assuring that:

$$\frac{V_\mathrm{m} L_\mathrm{m}}{\nu_\mathrm{m}} = \frac{V_\mathrm{p} L_\mathrm{p}}{\nu_\mathrm{p}}$$

This relation can be rewritten as:

$$\frac{V_\mathrm{m}}{V_\mathrm{p}} = \frac{L_\mathrm{p}\, \nu_\mathrm{m}}{L_\mathrm{m} \nu_\mathrm{p}}$$

which indicates that the scale reduction for the velocity is in this case equal to the *inverse* of the length scale reduction, multiplied by the viscosity scale reduction. If we assume that the same fluid is employed in the model as exists in the prototype, we can restate this by saying that the scale reduction for time is equal to the *square* of the length scale reduction. In other words, using geometric similarity and Reynolds number similarity, and employing a model that has (undistorted) length scale reduction of 9, the corresponding timescale reduction is equal to 81.

Clearly from this discussion, both Froude number similarity and Reynolds number similarity cannot be achieved for a given flow regime without much difficulty (e.g., using a model fluid having a different viscosity than that of fresh or salt water). It is therefore left to the coastal physical modeler to ascertain whether viscous or gravity forces dominate the system being examined. Once this decision is made, the physical model is developed using geometric similarity and either Froude or Reynolds number similarity. In most cases involving coastal systems, Froude number similarity is chosen, because of the dominance of free surface (gravity) effects. However, care must be taken to assure that viscous forces—which in such cases have been assumed to be relatively small in the prototype—are not large (relative to gravity forces) in the model. This most often requires avoiding large length scale reductions, which give rise to small Reynolds number flows at model scale, leading to potentially large viscosity effects. One example of such a dilemma is the small interstitial spaces in a model stone breakwater structure that has been reduced in scale to the point of creating very low Reynolds number flows within the spaces, and therefore unrealistic behavior of both the water motion and the stone response. An example of overcoming this problem can be found in the use of small models for slow-moving surface vessels such as sailing yachts. When such models are scaled according to geometric and Froude number similarity, the Reynolds number is too low to assure that a natural, turbulent boundary layer exists along the hull of the vessel. "Turbulence stimulators," in the form of a roughened bow of the vessel or small roughness elements placed along the leading edge of the vessel, serve to artificially stimulate the generation of turbulence at model scale.

Challenges in coastal physical modeling

Scale effects

The inherent difficulties associated with assuring both Froude number and Reynolds number similarity represent a formidable challenge to modelers seeking to simulate the behavior of the coastal environment over large prototype scales. Typically, such models are employed in the simulation of coastal wave processes, such as wave diffraction around a proposed breakwater, or wave refraction and shoaling in the nearshore region. In these cases, as in virtually every coastal physical model, the proper representation of surface wave dynamics is critical to success, and so Froude number scaling is employed along with geometric scaling.

The largest three-dimensional physical model facilities, or wave basins, have horizontal dimensions of the order 100 m. Even so, if one desires to model a coastal system over horizontal scales of 10 km or greater (e.g., to examine the high-tide shoreline impact of a coastal structure, geometric similitude requires a length scale reduction of the order 100). This presents immediate difficulties related to scale effects, the most obvious being the requirement that the water depth must likewise be reduced at model scale by the scale reduction factor of order 100. If, for example, the offshore depths at full scale vary over a range of 1–10 m, the model depths must range from 0.01 to 0.1 m, or 1–10 cm. These shallow water depths give rise to viscous dissipation in the model which is not present at full scale.

Although the modeler may be tempted to employ larger water depths in the physical model so as to avoid the unwanted wave attenuation at model scale, this is strongly discouraged. The use of vertical scale distortion alters the wave kinematics by altering the vertical distribution of velocity and pressure. This in turn alters the wave transformation processes, including refraction, diffraction, and shoaling. Rather than employ scale distortion, the modeler should first investigate whether the viscous effects are appreciable—particularly in terms of the problem being examined. This can be accomplished, for example, by comparing the reduced-scale wave behavior with that expected from either field data or analytical or model results. Such comparisons are in fact advisable regardless of whether scale effects are suspected. If the modeler concludes that scale effects may impact the study results, a decision must be made between proceeding—perhaps accepting that the model results are only qualitative representations of the full-scale system—or reconstructing the model at closer to full scale so as to reduce the relative importance of the model-scale viscous effects.

An additional concern regarding scale effects arises in cases when wave–structure interactions are being examined (e.g., in the model analysis of the influence of a breakwater on wave propagation). The examination of these interactions requires accurate representation of wave transmission and reflection at the structure face. This requires accurate representation of the wave–structure interaction and wave-induced flows. Since this localized behavior is not likely to be well reproduced at model scale because of the lack of Reynolds number similarity and the importance of viscous effects in such behavior (particularly for porous structures such as stone breakwaters), it is probable that the large-scale, three-dimensional model discussed here will not be adequate to address the problem. This situation is one example of a scenario in which a two-dimensional (cross-shore and vertical) physical model can be effective. Two-dimensional physical model facilities, that is "traditional" wave tanks, allow for modeling cross-shore processes and wave–structure interaction at scales larger than those normally utilized in three-dimensional facilities. The use of closer-to-full-scale models assures that even if Froude number scaling is used in the construction of the model, the model-scale Reynolds number is sufficiently high to assure that realistic turbulent flow exists (e.g., in the gaps within a model stone structure). It is in fact not uncommon for a coastal engineering physical model study to be composed of two separate components: (1) a two-dimensional study to examine wave–structure interaction (wave run-up, transmission, reflection, etc.), and (2) a three-dimensional study of wave transformation and other processes, which uses the results of the two-dimensional study in model design and interpretation.

Moveable bed models

The proper simulation of sediment transport dynamics remains one of the most challenging problems facing physical modelers. And yet, the simulation of sediment transport is essential if one is to examine the coastal environment in a complete manner, since we know that bottom topography is dynamic, changing over timescales of many wave periods in response to bottom shear stresses and currents associated with surface waves. In fact, knowledge of the "equilibrium" beach geometry and bottom topography (or nearshore profile) is often a desired output of coastal physical model studies. Since the scope and cost of field observations required to achieve the same results are prohibitive, and since numerical model algorithms to address the problem must still be considered an area of active research, physical model studies remain an important tool in addressing the problem.

For an excellent discussion regarding moveable bed modeling, the reader is referred to Kamphuis (1985) and Kamphuis (2000). A fundamental problem with moveable bed models is that the model sediment grain size obtained via the same geometric scale ratio used for the hydraulic model development will in all likelihood be so small as to introduce scale effects (e.g., cohesive forces, that are not present in the prototype).

For many problems of interest, the selection of the sediment grain size scale reduction factor begins with the assessment of whether bedload or suspended load sediment transport dominates the coastal system being examined. For example, we might expect that suspended sediment transport dominates the environment in the breaking wave region, or surf zone while bedload transport dominates moveable bed dynamics in deeper, less energetic regions of the coast.

In the case of bedload-dominated systems, a reasonable approach appears to be to select the length scale reduction factor based on the ratio of the prototype and model sand grain diameter, with the model sand grain diameter being chosen as to avoid cohesive forces, or roughly speaking, greater than 0.06 mm. Additionally, the model sand must have the same density as that of the prototype sand. In practice, this requires either a large model facility in order to accommodate scale reduction factors of order 10, or the good fortune of dealing with prototype sand having grain diameters measuring several millimeters.

In the case of suspended load-dominated systems, one must correctly scale the sandfall velocity, as this becomes a critically important parameter. Dean (1973) proposed the use of a dimensionless parameter that includes a measure of the erosion capability of the wave and the bias toward deposition represented by the fall velocity of the sand. This parameter, now commonly referred to as the Dean number, can be written:

$$\frac{H}{w\,T}$$

where H is the wave height, T is the wave period, and w is the sediment fall velocity.

The fall velocity of the model sediment can be selected by forcing similarity of the Dean number between model and prototype, using geometric similarity for the wave height and Froude number similarity for the wave period. Since sediment fall velocity is a strong function of grain diameter, this provides the scale reduction factor for the model sediment grain size, which is expected to differ from the length scale reduction factor.

Concluding remarks

Numerical models continue to become more sophisticated in their handling of the complex, turbulent coastal environment. Improved instrumentation allows for the collection of high-resolution data that are being used to both improve our understanding of coastal dynamics, and to provide essential data for numerical model calibration and verification. However, our knowledge of the complex interactions of waves, currents, and (moveable) bottom bathymetry across scales ranging from wave period to several years, has not progressed to the point where accurate simulations of coastal processes can be made solely with the use of numerical models. It would appear therefore, that physical models will remain an important tool for coastal scientists and engineers for the foreseeable future. It is likely in fact that for many problems (e.g., the influence of structures on the coastal environment), the future holds promise of stronger-than-ever collaboration between the physical and numerical modeling community, with physical models being used to provide valuable insights and verification data to the developers of numerical model algorithms.

PLACER DEPOSITS

A placer is any waterborne deposit of sand or gravel that contains concentrated grains of valuable minerals such as gold or magnetite, grains that had originally been eroded from bedrock but were then transported and concentrated by the flowing water. Placers can be found in rivers (alluvial placers) and on the coast, particularly in beaches (beach placers). In some locations, the ore minerals that initially were concentrated into a beach placer have been blown inland by coastal winds to form mineral-rich dune sands. Beach placers also have been submerged by the rising level of the sea, and are now found as relict placers within sediments on the continental shelf. However, some placer deposits found in continental shelf sands may have originated in that environment, formed by waves and currents that transported the shelf sands and concentrated the ore minerals.

Coastal placers, including those in beaches, dunes, and on the continental shelf, have been mined for gold, platinum, diamonds, the titanium-bearing minerals rutile, monazite and ilmenite, cassiterite (containing tin), magnetite (iron), zircon (zirconium), and garnet (used for making sand paper). Coastal placers are found throughout the world, with the economically most significant deposits being in Alaska (gold), India (magnetite), New Zealand (magnetite), Australia (rutile, monazite, and zircon), Indonesia (cassiterite), and South Africa (diamonds).

Placers are formed under the action of flowing water, by a current or the to-and-fro movement of water beneath waves, which transport the sand and gravel, leading to the concentration of the placer minerals due to their high densities. The range of mineral densities is shown in Figure P24, illustrating that platinum and gold have extremely high densities, while cassiterite, magnetite, etc. (generally referred to as heavy minerals) range in densities from about 3.5 to 7.0 g/cm^3. Of importance, these densities are greater than those of quartz and feldspar (the light minerals), which have a density on the order of 2.65 g/cm^3. Included in Figure P24 is the density of water, 1.00 g/cm^3 for fresh water and slightly greater for sea water.

Most deposits of sand on the continents are composed mainly of quartz and feldspar, with only small percentages of heavy minerals. When transported by currents and waves, the processes of selective grain sorting can occur where the quartz and feldspar are transported more easily and at higher rates, leaving behind a concentrated deposit of heavy minerals (Komar, 1989). In that the heavy minerals are generally dark in color, the result is the formation of a "black sand" deposit; if it contains a valuable ore mineral, the deposit then also qualifies as a placer.

The process of formation of black sand and placer deposits can be readily observed on beaches, especially during a storm that erodes back the beachface and berm, transporting the eroded sand to offshore bars. The tan-colored grains of quartz and feldspar are easily picked up by the swash of the waves at the shore, and are quickly transported offshore, leaving behind the heavy minerals as a concentrated black-sand layer on the eroded beach. In that the different heavy minerals have a range of densities and colors (e.g., pink garnet versus black magnetite), some selective grain sorting between the heavy minerals may also be seen (Komar, 1989). With the return of smaller waves following the storm, the quartz and feldspar sand moves back onshore, burying the black-sand layer. The search for beach placers, therefore, often necessitates digging trenches through the beach sand in order to reach the black-sand deposit at depth.

Having initially formed within the active swash zone of the beach, the placer minerals may be washed inland by still stronger storms, or blown there by the wind to form dunes. If the area of coast is accreting due to an abundant supply of sand, with the beach environment slowly shifting seaward, beach placer deposits dating hundreds to thousands of years old may be found well inland. This is the case on the southeast coast of Australia, where research has focused on the formation of such deposits

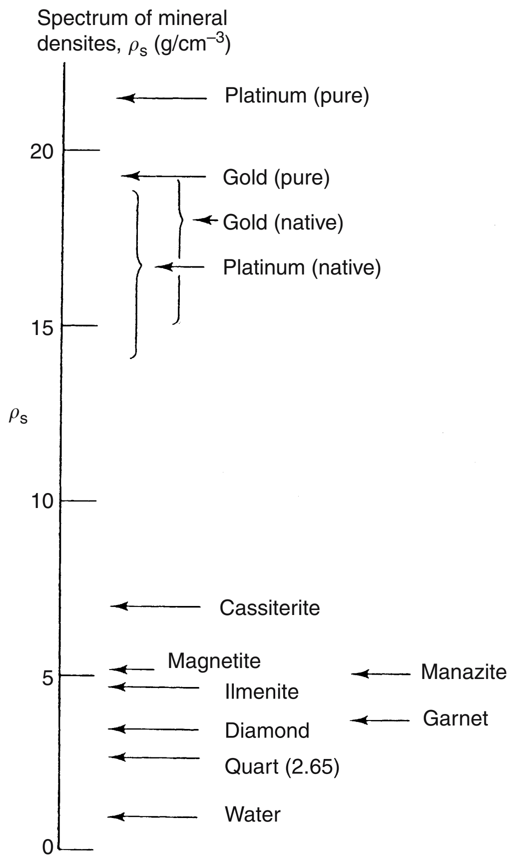

Figure P24 The range of densities of quartz grains and representative minerals found in placers (from Komar, 1989). With permission of CRC Press.

(Roy, 1999), which are also the deposits most actively mined at present, the mineral resource on the modern beach having been exhausted by mining in the past. The search for placer deposits also has extended out onto the continental shelf off the southeast coast of Australia, but generally with disappointing results. Research suggests that ocean waves may preferentially transport the heavy minerals and placer minerals onshore from the shelf sands, contributing to their concentration in the beaches, but depleting the shelf sands (Cronan, 2000). The principal minerals that are being mined from continental shelf placers are gold (Alaska), cassiterite (Indonesia), and diamonds (South Africa).

PLEISTOCENE EPOCH

The Pleistocene comprises most of the geological epoch of the Quaternary. It started at the end of the Tertiary 1.8–2.3 million years ago with a remarkable cooling of the earth's climate. The beginning of the Pleistocene is set when the first "cold guests," such as the mollusk *Cyprina islandica* or the foraminifer *Hyalinea balthica*, appeared in the Mediterranean (1.6 million years ago), or at the boundary of the Gauss-Normal paleomagnetic period to the Matuyama-Reverse paleomagnetic epoch 2.3–2.4 million years ago (Figure P25). It ended with the establishment of a warmer climate similar to modern conditions about 10,000–11,000 years ago, called the Holocene. Most characteristic of the Pleistocene was not only cooling, but a multitemporal change between cold and warm periods, established by oxygen isotope measurements (ratio of $^{16}O/^{18}O$ in foraminifera of the tropical Pacific). There were more than 20 of these cool and warm periods, the cold ones becoming real ice ages during the younger part of the Old Pleistocene less than 1 million years ago, but inland ice was present for a much longer time on the Antarctic continent. The terrestrial records, however, are much more incomplete than those from deep sea sediments, and the number and exact dating of cold and warm phases is under debate for all periods older than about 200,000 years (see also *Geochronology*).

Mostly the Pleistocene is set synonymous with the ice ages. During the cold periods, glaciers formed in arctic and antarctic latitudes moving equatorwards to about 50°N in Europe and even 40°N in North America. High mountain areas have been glaciated even along the equator. The cooling was much more intensive in higher latitudes, reaching 10–15° compared to equatorial regions, where about 4° lower temperatures than today occurred, so that smaller belts of coral reefs as well as tropical rain forest could survive. The ice ages also were epochs of dryer climate and a significant shifting of all vegetation belts toward lower latitudes, while forests were extinct in higher and most of the middle latitudes. The tundra-like grasslands were characterized by large mammals like the mammoth and mastodon, long-horned bison, cave bear or sable-toothed tiger as well as camels and horses, most of them extinct at the end of the Pleistocene epoch, perhaps accelerated by hunting man. The many and intensive climatic changes during the Pleistocene epoch certainly have had impacts on the evolution of plants and animals including man, and the Pleistocene is the period of human development from early hominids to *Homo sapiens sapiens* and its distribution over all continents.

With the rhythm of cold and warm periods (the first lasting many thousand to tens of thousands of years, the latter several to many thousand of years) the balance of liquid and frozen water on the globe changed significantly, leading to a lowering of the oceans in the amount of 100 m to more than 150 m during the ice ages and sea levels not far from today's during the peak of the warmer periods. This evidently has had a remarkable influence on coastal-forming processes, but we have little information on coastal phenomena of the sea-level lowstands. Much more evidence could be gained, including dating of the sea-level oscillations, in areas of ongoing uplift, where marine or littoral terraces have been developed by abrasion (such as in southern Italy) or by reef construction with high staircases of coral reef terraces found on the island of Barbados or on the Huon Peninsula of Papua, New Guinea. From this evidence, and from paleotemperature curves gained from foraminifera of tropical deep sea cores, we have learned that sea level was highest during the last interglacial period around 100,000–125,000 years ago, reaching about +6 m. Its remnants are widespread around the coastlines of the world. The last lowstand during the peak of the last glaciation (called Würm, Weichsel, Vistulian, Wisconsin or just LGM = Last Glacial Maximum) was around −100 to −120 m about 23,000–18,000 years ago. This was the last phase with wide exposed shelf areas and landbridges, enabling mankind to spread and bridge distances which now are covered by the ocean again.

PLUVIAL LAKE SHORE DEPOSITS

Pluvial lakes are lakes that existed in enclosed basins in the interior of continents during times of enhanced rainfall, reduced evaporation, or a combination of both. These lakes in many cases left a valuable record of paleoclimates in the form of lake sediments, of erosional shore features, and of gravelly to sandy shore deposits. Pluvial lake shore features have been recognized in many parts of the world, but are particularly well known from North America. Here, they were first described, identified, and interpreted in classical studies by geological pioneers I.C Russel (1885), and G.K. Gilbert (1890) who worked on the shore deposits of Lake Bonneville ("the proto Great Salt Lake"), a pluvial lake that existed during the Wisconsinan/ Weichselian Ice Age.

In the last few years, Lake Bonneville shore deposits have received renewed attention. Many of the internal structures of these deposits remained unknown because of slumping or other types of outcrop deterioration. Only where gravel pits, road building, or fluvial dissection afforded access, could internal sedimentary structures be defined and interpreted (Oviatt and Miller, 1997). Now, however, the advent of Ground Penetrating Radar (GPR) permits identification of previously unknown sedimentary structures. For instance, Smith *et al.* (1997) described gravelly shore deposits from Lake Bonneville, and identified a sequence of sedimentary processes that led to the deposition of gravelly shore features.

Other gravelly shores exist further west, in California and Nevada. One of the pluvial lakes that existed here was Lake Lahontan (Figure P26) which left a variety of shore features. This is illustrated for the Jessup embayment, Nevada, by Adams and Wesnousky (1998, and references therein). The reader is referred to this excellent description of shore features and shore processes. The authors were successful in separating shore features formed during both transgressive and regressive as well as highstand phases of lake-level changes. Examples of other pluvial lakes that existed are Lake Russel (the "proto-Mono Lake") and Lake Manly (Figure P27) that filled the central part of Death Valley.

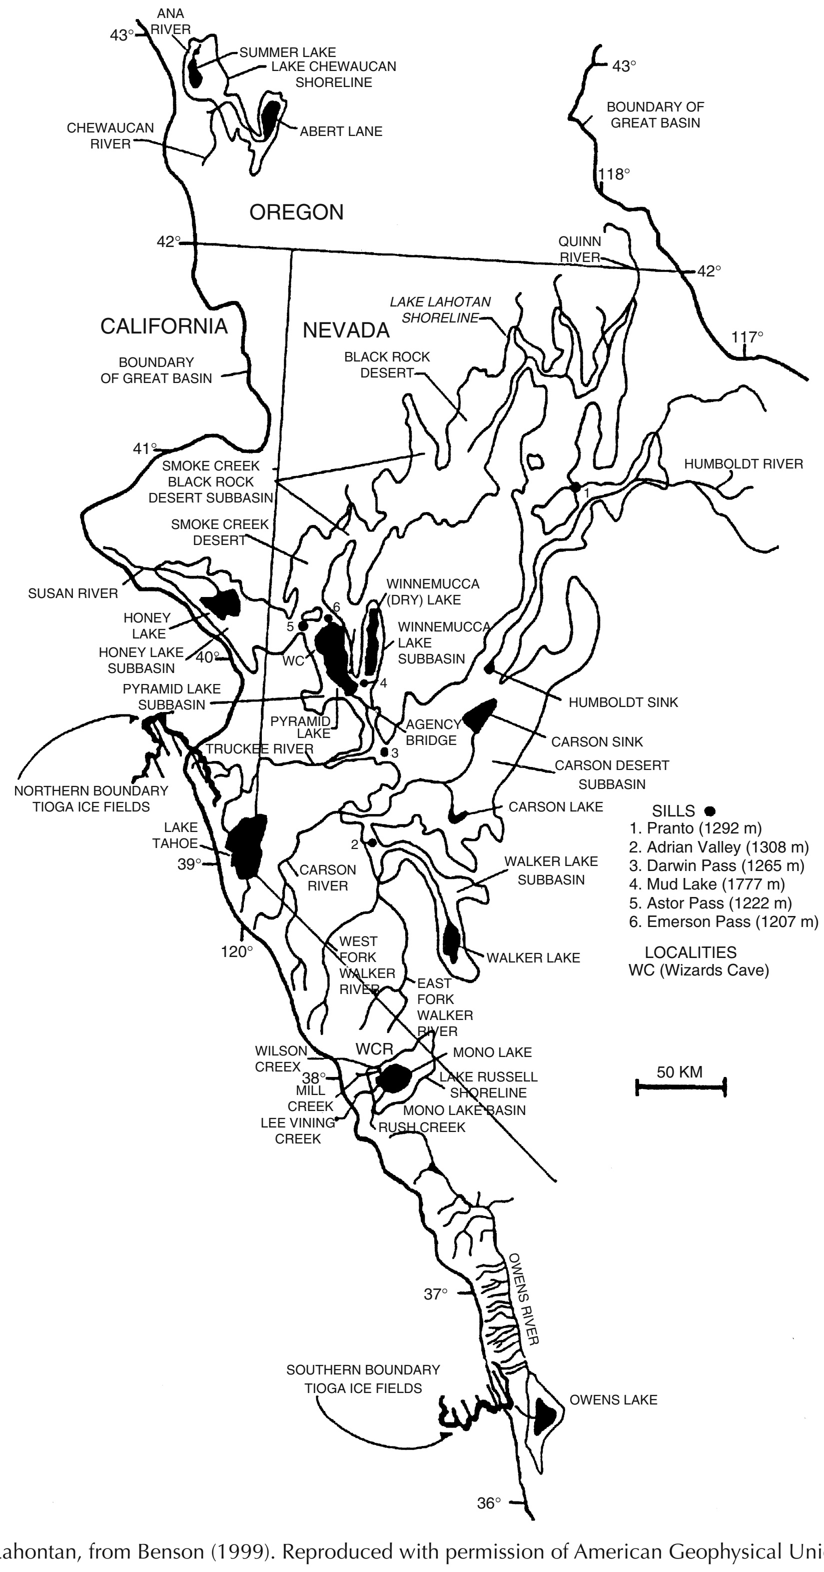

Figure P26 Map of Lake Lahontan, from Benson (1999). Reproduced with permission of American Geophysical Union.

Although these pluvial lakes left a legacy of both erosional and depositional features, this entry is primarily concerned with depositional features, consisting mainly of beach gravel. After a general description of beach gravel, we will illustrate these deposits, based on a study of a deposit from Lake Manly by Ibbeken and Warnke (2000).

Beach gravel consists of clasts which "tend to be well rounded, well stratified, and well sorted within strata" (Adams and Wesnousky, 1998, p. 1319). Clast sizes range from pebbles to cobbles or larger. In most cases beach-gravel deposits are clast supported, but may have a matrix of coarse sand to granules (Adams and Wesnousky, 1998). Depositional features are various types of barriers, spits, etc., similar to equivalent features on marine coastlines, and produced by washover processes during storm events, longshore transport, and simple aggradation on the beachface. However, the rapid lake-level changes can produce lakeshore deposits with a history and internal architecture "notably more complex than their marine counterparts" (Blair, 1999, p. 217). Blair (1999) studied the Churchill Butte shore deposit in western Nevada, about 52 km east-southeast of Reno. The age of the deposit is about 14.5 ka. The shore remnant is easily accessible because it is bisected by US Hwy Alt. 95, leading from Fallon, Nevada to Carson City, Nevada. The locality affords an excellent introduction to gravelly lakeshore deposits, based upon the analysis of the deposit provided by Blair (1999). The following description is extracted from Blair (1999) to which the reader is deferred for more detailed information. "The beach deposit consists of a lakeshore barrier spit and a lake lower-shoreface spit platform. The lakeward side of the barrier consist of beachface deposits (1–10-cm-thick beds of granules and pebbles) sloping 10–15°. These interfinger downslope with thicker and less steep lakeward-dipping beds of pebble gravel of the lake upper shoreface. Interstratified with these beds are high-angle cross-beds that dip southward, alongshore. Landward-dipping (15–20°) sets form the proximal backshore of the barrier, deposited by overwash processes during storms. Fossiliferous sand and mud exist landward of the barrier in what was a lagoon, separated from the lake by the barrier. The lake lower shoreface consists of a southward prograding spit platform constructed by longshore drift, and is characterized by 'Gilbert' foresets of pebble gravel dipping southward 16°." The various facies identified by Blair (1999) are described in Table P3.

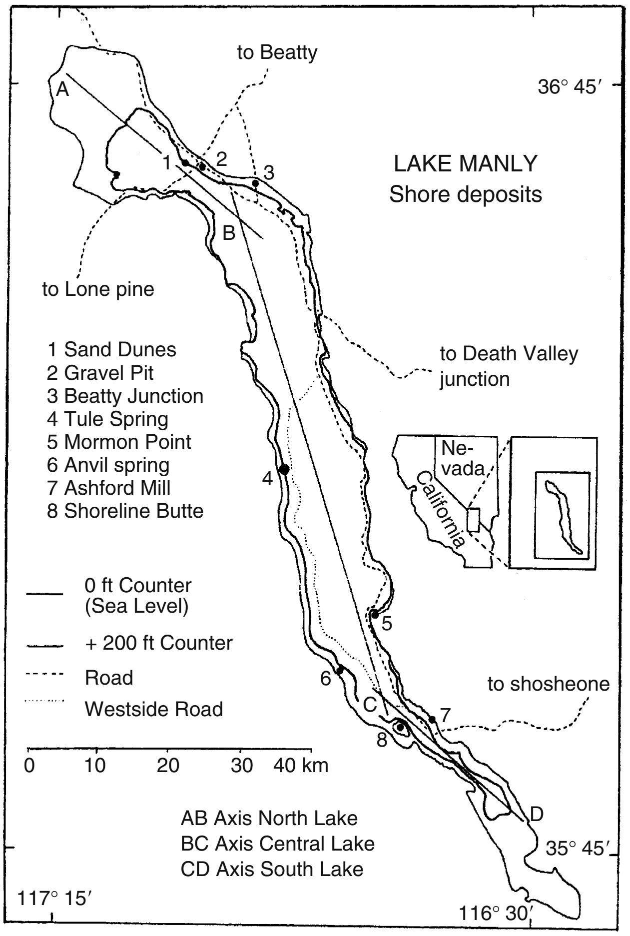

Figure P27 Sketch map of several, major known localities of shore features in Death Valley National Park. Zero feet (0 m) and 200 ft (61 m) contour lines indicated. From Ibbeken and Warnke, 2000. Reprinted with permission from Kluwer Academic Publishers.

The Hanaupah-Fan shore deposit at Tule Spring, Death Valley National Park, California

During the Pleistocene, a series of lakes existed in the enclosed basin of Death Valley, collectively referred to as Lake Manly. Higher lake levels existed during pre-Wisconsinan/Weichselian ice ages. For instance, the higher Beatty Junction bar complex (Figure P28) was deposited during the Illinoian (?) according to Orme and Orme (1991) although Klinger (2001) favors a younger age, based on soil development on the main spit. The reason(s) for higher lake levels in pre-Wisconsinan times are still in debate. A comprehensive description of shoreline elevations is provided by Meek (1997). During the Wisconsinan, the lake level oscillated about the 0 m contour line in the valley, and left a series of shore features that have been and continue to be, the subject of investigations. (Note added in proof: Machette *et al.*, 2003, how consider the deposit described below, to be 128–145 ka, correletive with oxygen-isotope stage 6).

Here, we describe a remarkable, gravelly shore deposit that exists west of Tule Spring (Figure P27). It can be seen from the Westside Road in Death Valley National Park, and can be reached by a short hike across the lower fan surface. The deposit consists of a gently sloping, WSW-ENE elongated ridge, about 600 m long, 165 m wide, and 8 m high (Figure P29). Its surface extends from −12 to +28 m in elevation. The sedimentary inventory consists of cross-stratified gravel beds (Figure P30) of various size ranges dipping in all directions (beachface and overwash sets), of horizontal berm gravel beds, and horizontal silt layers, probably lagoonal overwash deposits landward of a barrier. The deposit is the erosional remnant of a once much larger deposit that extended from the lakeshore east into the lake. Waves from both the north and the south eroded fan materials, and produced a sediment body with a complex architecture. Although at first we favored the idea that the deposit was formed during lake-level rise, albeit with major oscillations (Ibbeken and Warnke, 2000), subsequent ground-penetrating radar GPR profiles (unpublished data) show that the gravel beds have a predominant offlap architecture. As a working hypothesis we suggest that the deposit started to form during a highstand of Lake Manly, but at an unknown elevation since the uppermost part has been lost by erosion. Falling lake level caused the deposit to be extended eastward, and produced the sloping surface that exists today, albeit modified by faulting. In a final phase, a discordant gravel layer was deposited over the entire surface of the deposit. This uniform gravel layer is quite distinct from the surrounding fan surfaces. It is relatively fine grained, better sorted, and densely packed. Rock varnish is very well developed (Figure P31), resulting in a dark surface color that makes the deposit recognizable on aerial photographs. The exact depositional history and facies architecture still remains to be worked out, but the deposit has the potential of yielding valuable information on wave approaches and wave strength during the existence of Late Wisconsinan Lake Manly.

Detlef A. Warnke and Hillert Ibbeken

Table P3 A list of sedimentary facies identified by Blair (1999) from a beach deposit of Lake Lahontan. Note the attitude of the beds with respect to the paleoshore (modified after Blair, 1999)

Facies	Sedimentary features	Depositional environments
A	Unsorted, unstratified, angular, muddy bouldery pebble cobble gravel	Subaerial bedrock-fringing colluvium
B	Thickly bedded, matrix-supported, muddy cobble pebble gravel	Subaerial alluvial-fan debris flows
C	Lakeward-dipping low-angle (5–15°) beds of granular fine to medium pebble gravel	Lake beachface and upper shoreface
D	Landward-dipping (10–20°) foresets of sandy granule fine to medium pebble gravel	Proximal washover in a back-barrier pond
E	Irregular pebbly granule gravel, fossiliferous sand, mud, and diatom beds	Distal back-barrier pond
F	Poorly sorted, sandy granule pebble gravel in south-dipping (10–16°) foresets	Spit-front foresets, lower lake shoreface
G	Burrowed and oscillation ripples, granular sand in south-dipping (1–6°) toesets	Spit-front toesets, lower lake shoreface
H	Horizontally laminated silt and thickly bedded mud and clay	Lake bottom, below storm wave base

POLDERS

Poldering is practiced for reclaiming arable land in many countries of the world in lacustrine, riverine, and coastal lowlands in areas with impeded drainage.

The art of poldering will be exemplified for the Flemish-Dutch-Northern German lowlands around the eastern shores of the North Sea. Poldering essentially consists of isolating a certain area by diking and improving the drainage of this area by expelling the surplus water. So poldering requires three major abilities: the art of diking, of drainage and of the discharge of surplus water.

The art of poldering in medieval times

The earliest diking and reclamation of peat areas was reported from around 800 AD. Monasteries and cloisters, being centers of knowledge, played an important role in the development of techniques and abilities for diking, poldering, and river training. The dikes were preferentially located on the natural levees of the creeks and rivers. Land reclamation required detailed local knowledge of the topography and hydrography of the area.

In early times dewatering was accomplished by digging of ditches according to the (small) slopes of the terrain. A major technical invention was the so-called "ebb-valve" which opened when the outside water level was lower and closed by the water pressure while the outer level was higher. It was only since 1200 AD that larger channels were dug to connect the major drainage creeks and small channels in order to facilitate the discharge of surplus water. But it was still a drainage under natural gradients, thus on the supratidal areas. Similar practices were employed in the riverine areas by digging of ditches, almost parallel to the main river courses, thus using the natural downslope gradient of the terrain.

It was in the 14th century that the sluice was developed, which made it possible to have different levels in and outside the polder. The sluice allows ships to pass the obstruction.

Poldering and land reclamation not only had beneficial effects by increasing the extension of arable lands. On the negative side, poldering decreases the area of the supratidal and higher intertidal lands. This reduced the tidal storage capacity. The drainage was more concentrated in the channels, which eroded. As a result the tidal wave could penetrate further inland and because of the funnel shape of estuaries and tidal basins the tidal range increased too. Not only the HW levels were heightened but also the storm surge levels. This is especially problematic in coastal lowlands experiencing a sea-level rise.

Dewatering resulted in bio-oxidation and compaction of the peat and clay layers, which obstructed the drainage. In addition, the lowering of the land surface by compaction was increased by the excavation of peat for domestic use and for salt extraction by an ever-increasing population. Many disastrous floods have been reported, and considerable acreage of land was lost.

The art of poldering in the 15th to 18th century

The problem of the drainage of the ever-sinking polders was solved effectively in the beginning of the 15th century by the introduction of the windmill as a pumping device. Much more water from lower levels could be pumped up and discharged and greater areas (combined polders) could be handled. From then on, the way of poldering showed a new setup (Figure P32) consisting of diked areas with ditches draining into internal drainage channels, which in turn drain into natural waters. Also in the riverine areas, the development of the windmills offered tremendous opportunities for improvement of the drainage. A large number of windmills were built here too. These developments resulted in new, larger reclamations, a well-balanced and organized hydrological drainage system and better water management.

However, windmills were not applied everywhere in the coastal and riverin areas. Windmills were costly (equivalent of US $500,000 at present) and have a low capacity. In addition, they could only function effectively at a wind speed above some 4 Beaufort, effectively only some 25% of the time (Van der Ven, 1993). Other areas were too low to be handled by windmills or required too high a discharge capacity. This was especially the case in Flanders and the northern part of the Netherlands and Germany. These areas could only be poldered after better techniques became available.

Poldering in the 19th and 20th century

Steam-powered pumping stations took over the function of the numerous windmills, because they were more powerful and cheaper. Again because of their greater capacity they made the reclamation of larger lakes possible (Figure P33). In addition, this resulted in an increase in scale of the polder units and a rationalization of the system of drainage channels. In the 20th century motor and electric power increased the capacity of the drainage devices and the size of the polders further. After completion in 1932 of the Closure Dike, which separated the former Zuiderzee from the Wadden Sea (Figure P33) three new modern polders were constructed in Lake IJssel between 1937 and 1968, totally covering some 145,000 ha.

Recent developments

In the last decade a discussion was started about depoldering some polders by opening dikes or substantially reduce the drainage. Two arguments are at stake. The first is the expected consequences of an increased sea-level rise viz. a heightening of the HW levels along the coast and the increase in precipitation in the drainage areas of the major rivers, which will negatively affect the safety of the dikes and drainage of the polders areas.

The second argument is that because of the developments of agriculture in the European Community (EC) the need for arable land has reduced considerably and more and more land becomes available for other purposes, including housing, recreation, and landscape restoration and nature conservation. So there is a shift in priorities in rural planning. Several plans are under consideration viz. the use, as in former times, of overflow dikes, to temporarily store water in the polders during peak river floods to reduce the top water levels. Another plan is to reduce the drainage of some higher polders, creating lakes in which housing, floating, or on heightened lands, recreation and nature conservation are foreseen. A third type of plan is to depolder areas in the upper parts of estuaries in order to increase the tidal volume and the tidal currents to reduce the necessary dredging in the shipping routes.

Conclusion

Poldering requires special techniques and abilities: precision leveling and positioning, adequate information of water levels, current velocities, drainage systems and facilities, diking, discharge techniques, and water management policies and organization. In past time these challenges

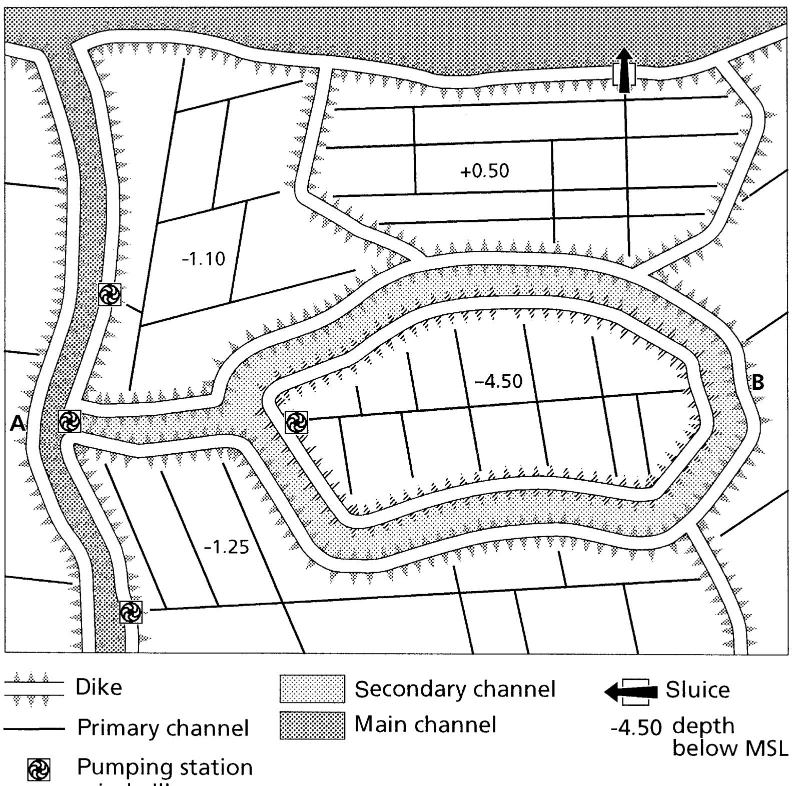

Figure P32 Drainage system in larger polders (from: A compact Geography of the Netherlands. With Permission of the Royal Dutch Geographical Society).

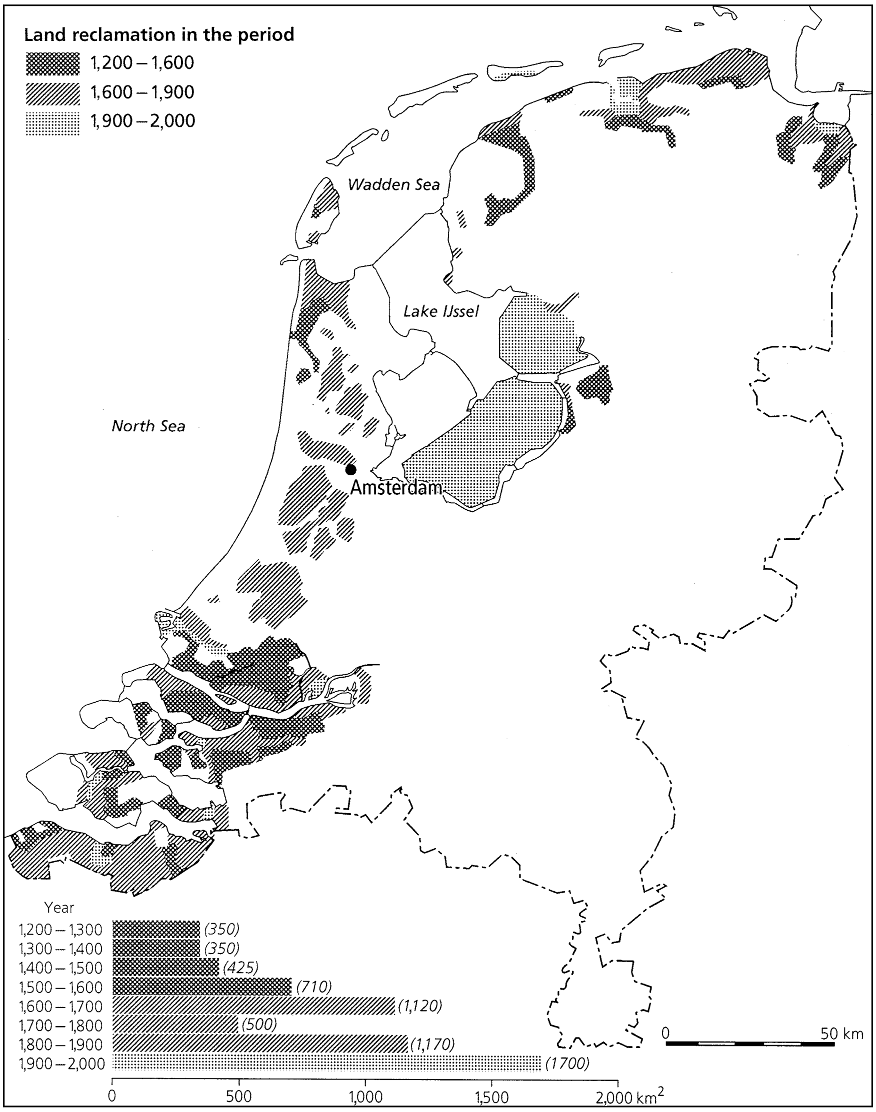

Figure P33 Land reclamation in the Netherlands (from: A compact Geography of the Netherlands. With Permission of the Royal Dutch Geographical Society)

forced the ever-increasing population to solve these problems. In recent times, facing problems of climatic change, there is a need for more space for water management and depoldering of some areas is a serious option.

PRESSURE GRADIENT FORCE

Horizontal and vertical forces called pressure gradient forces drive fluids. In vector equations this is symbolically represented by $\vec{\nabla}p$, which is shorthand for "grad p." A pressure gradient force is a spatial expression of Newton's Second Law, $F = ma$, as applied to the ocean or the atmosphere.

Figure P34 shows a Cartesian coordinate system with the x-axis pointing eastward, the y-axis pointing northward, the z-axis pointing upward in the opposite direction of the gravity vector $\vec{g}$. The x–y plane is parallel to a level surface and may be defined as coincident with the equipotential surface, known as the marine geoid, situated approximately a meter or so below sea level. An equipotential surface is everywhere orthogonal to the local gravity vector where the geopotential $\phi = gz$ is a constant, and pressure (p) is a function of x, y, z.

The largest oceanic pressure difference, $\partial p = p_{z_2} - p_{z_1}$, occurs in the vertical over a distance $\partial z = z_2 - z_1$. The ratio $\partial p/\partial z$ is defined as the vertical pressure gradient and is given by the hydrostatic equation $\partial p = -\rho g \partial z$ where ρ is the density of seawater ($\rho_{\text{seawater}} \approx 1025\,\text{kg m}^{-3}$). If written in the form $(1/\rho)(\partial p/\partial z) = -g$, the hydrostatic equation defines a balance between the vertical Pressure gradient force per unit mass and the acceleration due to gravity. In m.k.s. units $(1/\rho)(\partial p/\partial z)$ is dimensionally $[m^3/kg]\,[N\,m{-}^2/m] = N/kg$, which is force (newtons) per unit mass (kilograms), when pressure difference is expressed in newtons per square meter (N m^{-2}) and vertical distance is expressed in meters (m).

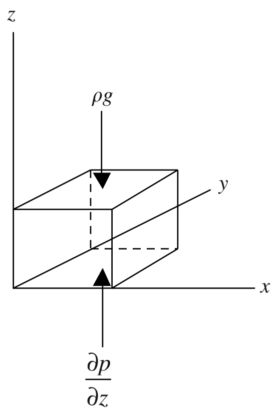

Figure P34 A cubic meter of sea water in hydrostatic balance where the upward pressure gradient force per unit volume $\partial p/\partial z$ is equal to the downward gravity force per unit volume ρg.

In terms of ocean currents, the most important pressure gradient force per unit mass is in the horizontal, $(1/\rho)(\partial p/\partial x)$ or $(1/\rho)(\partial p/\partial y)$ in the east–west direction and the north–south direction, respectively. Recalling that the partial derivative ∂p is taken with respect to a level surface ∂x or ∂y, the horizontal pressure gradient force may be expressed as height departures of a constant pressure surface. From the hydrostatic equation $p_2 = -\int_{Z_2}^{D=0} \rho g \partial z = \rho \partial g h_2$ and similarly for p_1, the pressure difference on a level surface is just $\partial p = p_2 - p_1$. Thus the east–west pressure gradient force per unit mass $(1/\rho)(\partial p/\partial x) = g(\partial h/\partial x)$, and likewise for the north–south direction $(1/\rho)(\partial p/\partial y) = g(\partial h/\partial y)$, where h is the height of the sea surface above the level surface.

In a similar fashion, the pressure gradient force may be expressed in terms of the gradient of geopotential ϕ. Since $\phi = gz$, and $(\partial \phi/\partial x) = g(\partial h/\partial x)$, the horizontal pressure gradient force per unit mass is just $\partial \phi/\partial x$ in the east–west direction, and $\partial \phi/\partial y$ in the north–south. Oceanographers commonly calculate the geopotential anomaly (also called the dynamic height anomaly) from measurements of temperature and salinity versus depth, and compute horizontal currents with respect to a deep reference surface (which is assumed to be a level surface), using the geostrophic equation.

Geostrophy further illustrates the role of horizontal pressure gradients in the sea. Consider the geostrophic equation $fv_g = (1/\rho)(\partial p/\partial x)$, where f is the Coriolis parameter $(1.459 \times 10^{-4} \sin \phi)$, $\partial p/\partial x$ is the east–west direction pressure gradient force per unit volume, and v_g is the north–south geostrophic current. Recall that pressure is an integral $p = \int_h^D \rho g dz$ from the sea surface ($z = h$) to some deep layer where $z = D$. Derivatives of an integral require application of Leibnitz's Rule, which yields:

$$\rho f v_g = \rho g \frac{\partial h}{\partial x} + \int_h^D g \frac{\partial \rho}{\partial x} dz$$

The term on the left-hand side is the force per unit volume due to earth's rotation creating a geostrophic current, v_g. On the right-hand side, the first term is proportional to the slope of the sea surface with respect to a level surface, and the second term is that due to the internal horizontal gradient of the density field. The term $\rho g(\partial h/\partial x)$ is the barotropic pressure gradient force per unit volume, from which the surface geostrophic current $v_g(z = 0)$ is calculated, and $\int_h^D g(\partial \rho/\partial x)\, dz$ is the baroclinic pressure gradient force per unit volume.

To illustrate these terms, consider a crossing of the Gulf Stream from Charleston, South Carolina to Bermuda. The sea surface slopes upward to the east a total of about 1 m and thus the barotropic term is positive. The subsurface horizontal density gradient $\partial p/\partial x$ however is negative, and at some depth $z = D_0$ the integral of the baroclinic term will be equal in magnitude but opposite in sign to the barotropic term. Thus at this horizon $v_g(z = D_0) = 0$, a depth called the level of no motion. In the offing of Charleston, D_0 typically is assumed to occur at about $z = 2000$ m.

PROFILING, BEACH

Surveys of the beach profile are conducted to locate the high-tide shoreline or land and sea boundary, to determine the shape or morphology of the beach, to evaluate the performance of shore-protection projects, and to monitor the volume of sediment in the beach. Legal or regulatory marine boundaries are usually determined as the location of a certain elevation related to a tidal datum such as mean high water, requiring a survey of the upper beach profile to the foreshore (see *Beach Profile* entry for terminology). Marine boundary issues and surveys are described by Shalowitz (1962, 1964) and Flushman (2001) and are not discussed here. This section describes surveys made to determine beach morphology and measure beach volume.

Beach profile surveys include considerations that are not part of traditional land surveying procedures or of bathymetric or hydrographic surveys. Knowledge of coastal processes is necessary to understand operations in surf zone waves, longshore current, and rip currents, as well as in the beach morphology itself. For example, the surveyor can "go off line" in strong currents, and survey points should be closely spaced in areas of the profile having steep gradients such as at the dune toe, scarp, and longshore bars. Surveyors who are familiar with the morphology of the beach profile will pay attention to its detail.

The length and spacing of survey lines (often called transects) alongshore depends on the purpose of the survey. A beach profile survey extends seaward from an established control point on land along a predetermined heading, typically along a line normal to the local trend in the high-tide shoreline. The starting point might be placed at or landward of the cliff, dune, or seawall at the coast. The survey proceeds seaward to the depth of closure (Kraus *et al*., 1999), where the profile does not change for "long lines" and to wading depth for "short lines." If long lines are surveyed, the area of active sediment movement by waves on the nearshore beach profile is encompassed, and change in beach volume can be measured by taking the difference of two surveys performed at different times.

Methods of beach profile surveying

Land (inshore) survey

An early method for making an inshore survey that requires only a stadia or survey rod was devised by Emery (1961). An observer records levels on the survey rod by sighting parallel across to the horizon as the rod holder moves along the beach profile. This method is still employed to make inexpensive and adhoc inshore surveys. The standard rod-and-transit method of surveying has been replaced by readily available "total survey stations," which register data electronically and provide distance and elevation through setting of an angle to the baseline and measurement of the distance of the instrument to a survey monument. A total station measures time of flight of a beam transmitted from a light-emitting diode to and reflected from the survey prism. Such surveys provide the highest accuracy (subcentimeter) in horizontal and vertical position. Differential Global Positioning Systems (DGPS) can also be used. These typically give 1–2-cm accuracy in the horizontal and 2–4-cm accuracy in the vertical, and are most suited for reconnaissance or wide-area surveys or if measurement of beach volume is not the survey purpose.

The reproducibility or precision of the elevation measurement obtained from a total survey station was investigated in a beach environment with heat waves reflecting from the water and high humidity, which is typical (Kraus and Heilman, 1998). The standard deviation in the fixed height of a survey rod is plotted in Figure P35. For up to a kilometer from the survey station, precision is less than 1 cm. Depending humidity and glare, a total station has a range of 1–3 km, involving atmospheric conditions and presence of reflections of sunlight from the sea surface. Sled surveys are more labor intensive and require more time than boat surveys.

Marine (offshore) survey

Traditionally, offshore surveys have been done by boat serving as a platform for an acoustic echo sounder. Such a survey brings great potential inaccuracy because of motion of a vessel in waves and requirement for a tidal correction to be made for the water level throughout the survey period. Tide corrections are difficult to define for great longshore and offshore distances from a tide gauge. In addition to being inaccurate, echo sounder surveys by boat have the difficulty of joining to the inshore survey. Gibeaut *et al.* (1998) discuss procedures and improvements that can be made for echo sounder surveys.

For greatest accuracy of beach profile measurement, a sea survey sled is recommended (Grosskopf and Kraus, 1994). A total station (or a transit) can sight on survey prisms mounted on a mast of a sled that is towed to sea by boat. Figure P36 shows a sea sled with a mast containing a halo of survey prism targets that can be reached from a wide angle to minimize relocation of the survey station alongshore. A survey sled can be winched to shore or towed from shore to measure the entire subaqueous beach profile, eliminating a wading-depth inshore survey. Sled accuracy in the vertical is on order of ± 1 cm. Recently, kinematic differential GPS receivers have been placed on personal watercraft (jet skis) that enables near-decimeter vertical accuracy (Wamsley and Edge, 2001).

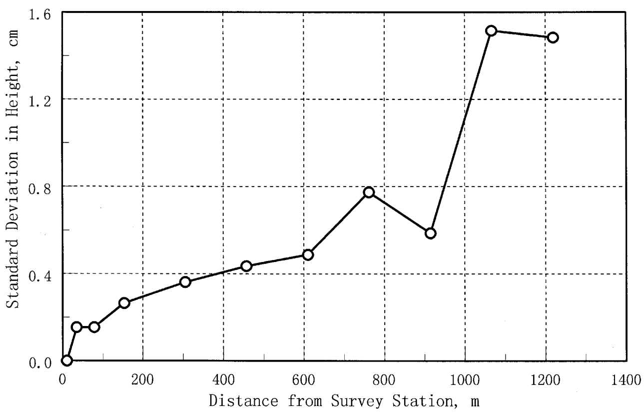

Figure P35 Standard deviation in measured height of prism at fixed elevation for 10 measurements taken at each specified distance from total survey station.

Overlapping of inshore and offshore surveys

A necessary and nonomittable aspect of a beach profile survey is to assure that there is adequate overlap between the inshore and offshore surveys. Assuming that the inshore survey is most reliable, overlap of the two surveys on each transect serves as quality control for the offshore survey and provides an adjustment for it, if necessary. An overlap distance of about 30 m and at least five survey points is recommended.

Sources of error

Highest accuracy is necessary to measure the beach profile if beach fill volume is to be tracked through time. An apparent small error in elevation (say, 10 cm) of the profile over several kilometers of beach can introduce uncertainty larger than the volume of sand originally placed. High accuracy, taken to be at centimeter level in elevation, is not necessary if profile morphology alone is being investigated.

A beach profile survey produces a set of distance-elevation datapoint pairs on specified shore-normal transects established along the shore, usually at fixed intervals, but sometimes becoming more dense in areas of interest and telescoping to a greater interval if located far from an area of interest. These transects are typically reoccupied to perform surveys through time. Such transects may not be reoccupied exactly in successive surveys, and slightly different location of the survey point and angle of the survey over a profile morphologic feature may produce slight variations between surveys that do not represent actual change.

The greatest source of inaccuracy in a beach profile survey is use of an inaccurate measurement method for the offshore survey, such as a boat-mounted echo sounder. Unless the water is calm and the water level relatively unchanging, such as in the Great Lakes, accuracy may be ± 30 cm and not systematic between the transects of the same survey and between surveys at different times for the same transect. Overlapping of the inshore and offshore surveys will give a measure of this inaccuracy.

Consistency in operation of the survey station is desirable. Operators will sight somewhat differently on a target. To avoid possible operator

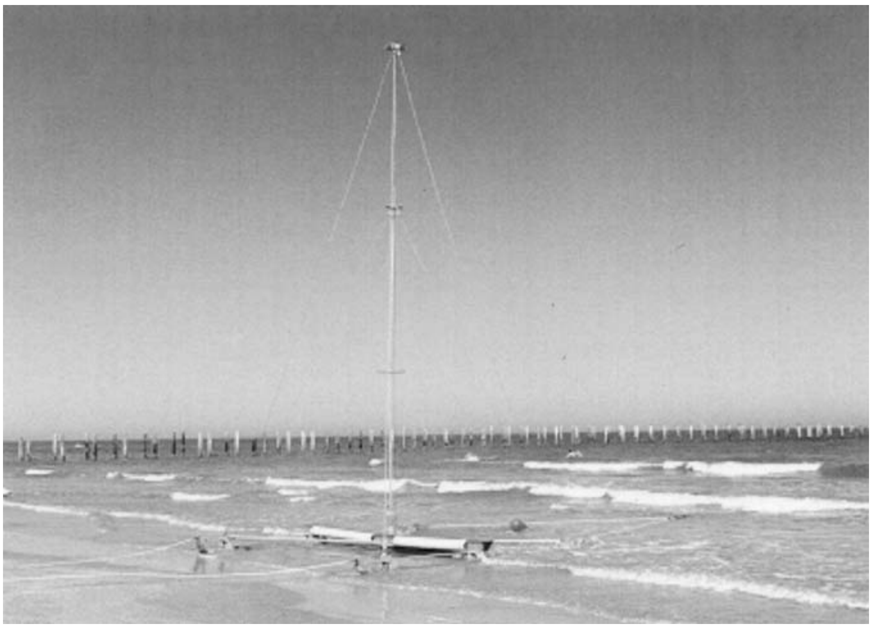

Figure P36 Sea sled on foreshore, North Padre Island, Texas.

bias between surveys, the same person should sight the survey station. In this way, any bias by a given operator will tend to cancel if taking a difference between surveys to document volume change and change in profile morphology. Errors due to beach and sea bottom properties fall partially in the category of operator error, in that different people holding a survey rod will place the rod on the beach or bottom with slightly different pressure. Affixing a small horizontal plate (typically about 5 cm in diameter) to the bottom end of the survey rod will minimize this error. Sea sled runners are made wide so as not to penetrate the seafloor.

Monumentation and documentation errors must be avoided if different organizations are involved in separate surveys at the same site. Different organizations tend to place transects in different locations and assign different names to the same transects; as much as possible, this confusion should be avoided through planning and communication. Monuments should be well controlled and tied to a permanent baseline with recovery feasible if a few monuments are lost. As much as possible, permanent (deep-driven) monuments should be placed on fixed land or landward of the dunes to reduce possibility of erosion.

Survey planning

Well-developed survey plans improve data quality. Data should be examined in the field by, for example, comparing previous surveys done at the same transect. Specialized profile survey analysis software such as the Beach Morphology Analysis Package (BMAP) (Sommerfeld *et al.*, 1993; US Army Corps of Engineers, 1995) makes data checking, editing, and archiving convenient. Field examination can identify datum errors, errors in spacing across shore such as not containing enough detail, and overlap mismatches.

Only experience at a given coast and comparison of profile surveys on adjacent transects can assure proper alongshore spacing. On an open coast with little curvature and no coastal structures, a spacing of 300 m between transects has proven satisfactory for measurement of beach volume. Long-term monitoring surveys might use 1-km spacing for documenting long-term trends. Near inlets and structures, the spacing may be reduced in step fashion to 500, 250, 100, and even 50 m. Local design, permitting, and construction requirements may also dictate the appropriate spacing.

Beach profile surveys are normally considered as a synoptic representation of the beach at a given time. Therefore, the full survey or logical subsets of the survey should be completed in the shortest possible time. Attention to the weather forecast will reduce interruptions by adverse seas and precipitation. Prior to a survey, the local authorities should be notified and permissions obtained, as necessary, both to access the beach and to avoid delays in obtaining permissions. Coordination with the city manager, city engineer, park ranger, police, lifeguards, and others may be necessary. It is recommended that a brochure be prepared to distribute to bystanders so that the attention of the surveyors is not interrupted.

All necessary equipment and backups, such as batteries, should be prepared to avoid delays in the survey. Pairs of highly visible temporary markers placed on each transect aid in aligning the inshore and land survey operators. Two-way radios, flags, gloves, tools, and first aid kit are part of the standard equipment needed for any kind of survey. A camera for taking pictures at each profile is also recommended. Further information on performing beach profile surveys can be found in Grosskopf and Kraus (1994).

RADARSAT-2

RADARSAT-2, the second in a series of Canadian spaceborne Synthetic Aperture Radar (SAR) satellites, was built by MacDonald Dettwiler, Richmond, Canada. RADARSAT-2, jointly funded by the Canadian Space Agency and MacDonald Dettwiler, represents a good example of public–private partnerships. RADARSAT-2 builds on the heritage of the RADARSAT-1 SAR satellite, which was launched in 1995. RADARSAT-2 will be a single-sensor polarimetric C-band SAR (5.405 GHz).

RADARSAT-2 retains the same capability as RADARSAT-1. Morena et al., 2004 For example, the RADARSAT-2 has the same imaging modes as RADARSAT-1, and as well, the orbit parameters will be the same thus allowing co-registration of RADARSAT-1 and RADARSAT-2 images. Furthermore, radiometric and geometric calibration is maintained thus permitting correlation of time series data for applications such as long-term change detection (Luscombe and Thomson, 2001).

The following features of the RADARSAT-2 system are thought to be the most significant in terms of their impact on existing and new applications.

Polarization modes. Three polarization modes: Selective, Polarimetry, Selective Single.
Resolution. 3 m ultra-fine mode and a 10-m Multi-Look Fine mode.
Programming lead time. Programming is defined as the minimum time between receiving a request to program the satellite and the actual image acquisition. Routine image acquisition planning is base-lined at 12–24 h, and emergency acquisition planning is base-lined at 4–12 h.
Processing. Routine processing is base-lined at 4 h; emergency processing is base-lined at 3 h; and 20 min for processing a single scene.
Re-visit. Re-visit is defined as the capability of the satellite to image the same geographic region. Re-visit is improved through the use of left- and right-looking capability.
Georeference. Image location knowledge of <300 m at down-link and <100 m post-processing.

RADARSAT-2 polarimetry modes

The RADARSAT-2 polarimetric capability is considered to be the most significant in terms of increasing the information content of the SAR imagery, and is subsequently discussed in more detail. To date, SAR data have been widely available from single channel (single frequency and polarization) spaceborne radars including ERS-1 and 2, JERS-1, and RADARSAT-1. RADARSAT-2 provides polarized data, and is the first spaceborne commercial SAR to offer polarimetry data.

The intent here is not to outline polarimetry theory, but to present the concepts in an intuitive manner so that those not familiar with polarimetry can understand the benefits of polarimetry and the information available in polarimetry data. Many articles are available that discuss polarimetry theory, applications, and provide excellent background information (Ulaby and Elachi, 1990; Touzi *et al*. 2004). Notwithstanding the inherent complexity of polarimetry, polarimetry in its simplest terms refers to the orientation of the radar wave relative to the earth's surface and the phase information between polarization configurations.

RADARSAT-1 is horizontally polarized meaning the radar wave (the electric component of the radar wave) is horizontal to the earth's surface (Figure R1). In contrast, the ERS SAR sensor was vertically polarized, implying the radar wave was vertical to the earth's surface. Spaceborne SAR sensors such as RADARSAT-2, ENVISAT, and the Shuttle Imaging Radar have the capability to send and receive data in both horizontal (HH) and vertical (VV) polarizations. Both the HH and VV polarization configurations are referred to as co-polarized modes. A second mode, the cross-polarized mode, combines horizontal send with vertical receive (HV) or vice versa (VH). As a rule, the law of reciprocity applies and HV ≅ VH (Ulaby and Elachi, 1990).

A unique feature of RADARSAT-2 is the availability of polarimetry data, meaning that both the amplitude and the phase information are available. The amplitude information is familiar to SAR users, but the phase information is likely new and rather nonintuitive. In its simplest term, phase can be thought of as the travel time for the SAR signal: the travel time is the two-way time between the sensor and the earth, and includes any propagation delays as a result of surface or volume scattering. It is the propagation delays and the scattering properties of the HH and VV polarization configurations that make polarimetry data so powerful.

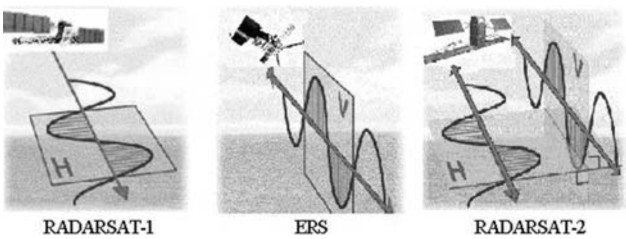

Figure R1 Orientation of horizontal (H) and vertical (V) polarization. Typical transmit and receive polarizations are HH, VV, and HV (adapted from the CCRS website).

Table R1 RADARSAT-2 modes. Beam mode name, swath width, swath coverage, and nominal resolution

	Beam mode	Nominal swath width (km)	Swath coverage to left or right of ground track (km)	Approximate resolution Rng × Az (m^2)
Selective Polarization	Standard	100	250–750	25 × 28
	Wide	150	250–650	25 × 28
Transmit H or V	Low incidence	170	125–300	40 × 28
Receive H or V or (H and V)	High incidence	70	750–1000	20 × 28
	Fine	50	525–750	10 × 9
	ScanSAR wide	500	250–750	100 × 100
	ScanSAR narrow	300	300–720	50 × 50
Polarimetry				
Transmit H and V on alternate pulses	Standard QP	25	250–600	25 × 28
Receive H and V on every pulse	Fine QP	25	400–600	11 × 9
Selective Single Polarization				
Transmit H or V	Multiple fine	50	400–750	11 × 9
Receive H or V	Ultra-fine wide	20	400–550	3 × 3

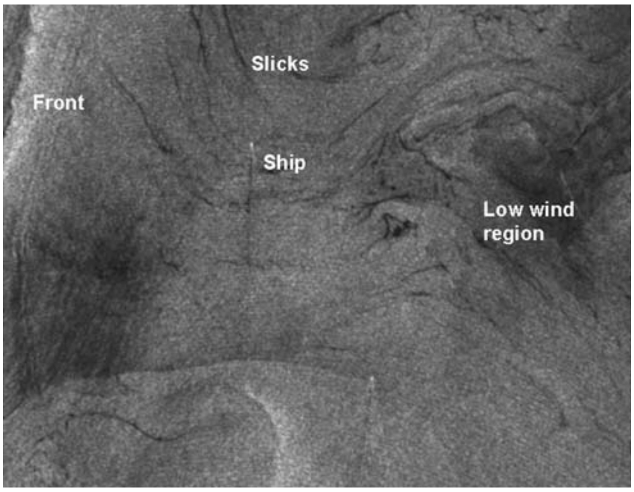

Figure R2 RADARSAT-1 SAR image acquired September, 1998 off the coast of Alaska. Typical ocean features and targets are shown. (Canadian Space Agency, 1998).

The RADARSAT-2 program has adopted the following terms to define the polarization modes (Table R1): Selective Polarization, Polarimetry, and Selective Single Polarization. Selective Polarization and Selective Single Polarization modes imply the availability of amplitude data, but no interchannel phase data. For example, amplitude data may be HH, VV, or HV imagery. In contrast, the polarimetry mode (also called quad-polarized) implies the availability of both amplitude and interchannel phase information. The amplitude information is the same as the Selective Polarization and Selective Single Polarization modes, but adds phase information, such as the co-polarized phase difference.

Marine applications

Marine applications of SAR data can be divided into three main categories: atmospheric phenomena, ship detection, and ocean features (Figure R2).

Atmospheric phenomena include the effect of large-scale atmospheric features such as hurricanes on the ocean surface. Although SAR images through the hurricane cloud-structure, the variability of the hurricane wind speed produces changes in the ocean surface-roughness that the radar detects. For example, the low-wind regime at the eye of the hurricane looks very different than the outer high-wind edges. The radar sensitivity to wind-induced roughness can also be used to map ocean-surface wind speed and direction. The use of VV polarization will be the preferred polarization configuration, largely due to a better radar response relative to HH or HV configurations.

Ship detection is optimal under low wind conditions, HH polarization, and large incidence angles. When co-polarized data and small incidence angles are used, there is increased radar return from the ocean surface, thus reducing the contrast between the ocean and the ship. The use of cross-polarized data (e.g., HV), however, enhances ship detection at small incidence angles due to the weaker return from the ocean surface, but similar return from the ship. Through the application of target decomposition algorithms, quad-polarized data can be used for ship detection and classification (Yeremy *et al*., 2001).

Ocean features include the detection of eddies, fronts, slicks, currents, surface waves, and internal waves. Radar return from the ocean surface is due to Bragg scattering. Bragg scattering is stronger for VV polarization, thus VV polarization is predominantly used versus HH or HV. The use of quad-polarized data will add significantly to the information content of the SAR imagery.

RATING BEACHES

Introduction

Beaches are the number one recreational destination for Americans and Europeans, and a beach culture has developed worldwide. Nothing restores the body and soul like a stay at the beach. We are naturally drawn to the rhythmic pounding of the waves as if returning to our primordial beginnings. Recreational opportunities abound, and everyone, but perhaps children most of all, loves sand.

People are flocking to the shore in ever-increasing numbers for sun and fun. But most want much more from a beach experience—people are searching for real getaway places where they can escape from urban confinement and everyday pressures. The shore offers freedom from the "hemmed-in" feeling as we gaze out from the beach at the seemingly endless sea. The fresh, salty air invigorates the body as the sheer beauty and dynamic interplay between the waves and beach captures our imagination and refreshes our psyche.

So what do people look for in a beach? Water quality is probably the first concern. Polluted water can ruin any beach; the washing ashore of medical wastes along northern New Jersey beaches a decade ago nearly wrecked the local coastal economy as tourism plummeted. Coastal waters are the recipient of much of the nation's wastewater. Already stressed by pollution from upland sources, coastal environments are also adversely affected by the onslaught of contaminants from coastal development and wastes dumped at sea. Sewage-associated wastes are an eyesore, particularly along parts of the US urbanized northeast coast, where inadequate treatment systems still exist. The Gulf coast states, especially Louisiana, have the greatest accumulation of ship galley wastes on their beaches. All of these materials degrade nearshore coastal waters and foul beaches (Center for Marine Conservation, 1990). While concern about pollution is mounting as coastal development continues, some areas are addressing long-standing problems (e.g., construction of the massive Boston Harbor sewerage system). Actually, US beaches are generally quite clean compared to those in many countries, where pollution concerns receive far less attention and funding.

There is a worldwide coastward migration of the population, which itself is burgeoning at over 6 billion at present. What some oceanographers refer to as the ring around the bathtub is some of the most expensive real estate in the world. These areas are rapidly urbanizing, and there is much public concern about the quality of coastal areas. For example, it is estimated that by the year 2010, the coastal population will increase almost 60% in the United States. (NOAA, 1990). As the population trend continues, many of the qualities that attracted people initially are diminishing.

Crowded beaches such as Jones Beach, New York, where the sunbathing towels run together like a gigantic patchwork quilt, accommodate a huge number of people, but few would rate this as the best beach. If coastal communities are too successful in encouraging development, as Ocean City, Maryland has been in the last few decades, then overall quality also drops.

Beach weather and water temperature can greatly limit planned activities. The rugged beauty and sereneness of Oregon's beaches appeal to the wilderness enthusiasts, but the water is much too cold for swimming, and frequent rainy days can spoil any plans for sunbathing. While the picturesque Northwest Pacific coast may be described as the most beautiful, others prefer the palm-treed beachscapes of Hawaii. Which is the most beautiful beach? Shakespeare correctly noted that "Beauty lies in the eyes of the beholder." But all of us can probably agree on a few basic characteristics, which include the physical condition, biological quality, and human use and development of beaches.

Beach awards and ratings

Beach awards and evaluation systems in Europe have been identified as a valuable tool for promotion of beach tourism (Williams and Morgan, 1995). The proliferation of awards and awarding bodies in the United Kingdom, however, has led to low public awareness and distrust of their validity. Those currently in use in the United Kingdom include the European Blue Flag Award (administered by the Foundation for Environmental Education in Europe; FEEE, 1997), the Seaside Award given by the Tidy Britain Group, and the Good Beach Guide, a book published annually by the Marine Conservation Society (MCS, 1997). All of these awards are based on a limited number of factors and do not approach coverage of all measurable aspects of the beach environment (Williams and Morgan, 1995).

Over 2,000 beaches in 18 countries presently participate in the European Blue Flag Award with the numbers growing through time. Only one-third of beach users have a reasonable understanding of the award criteria, which are largely based on water quality; 11% recognized the Blue Flag itself and 7% actually thought the symbol represented danger (Williams and Morgan, 1995).

The Seaside Award was introduced in the United Kingdom in 1992 and is administered by the Tidy Britain Group (a NGO with some government funding). The award criteria are similar to the Blue Flag (e.g., water quality, beach cleanliness, and high standards of facilities and management). While the Blue Flag Award requires strict water quality standards, the Seaside Award system is less rigid so that more UK beaches qualify for this recognition (Williams and Morgan, 1995).

The Good Beach Award is published annually by the MCS and available for sale to the general public at bookstores. Beaches must exhibit a high standard of water quality and a low probability of sewage contamination (which is a major problem for many European beaches). Over 1,000 UK beaches were assessed, and 136 were recommended in 1997. There must be no sewage outfalls adjacent to the beach, bathing must be safe, and there must be no excessive marine litter or sewage—related debris (Williams and Morgan, 1995).

During the past decade, researchers in the United States (Leatherman, 1991, 1997) and Williams and Morgan (1995) in the United Kingdom have devised beach rating systems that attempt to take into account all measurable beach aspects. The two rating surveys are quite similar; beaches are scored for 50 parameters on a scale from one to five (Table R2). In the United States, 650 public recreational beaches were evaluated by Leatherman (1991) and 182 UK beaches were rated by Williams and Morgan (1995). Kapalua on Maui, Hawaii was the first National Winner in 1991 with a score of 92%, and Porthmeir along the English Cornwell coast was listed as the top UK beach in 1995 (at 86%).

For a number of the criteria, a beach user's preference was assumed (e.g., wide beaches are preferable to narrow ones). Quantitative values were attributed to all categories to the extent possible, but some were judged on a purely subjective basis (e.g., vistas far and near). No weighting was attached to the 50 parameters relative to each other in either scheme (Leatherman, 1991; Williams and Morgan, 1995).

US beaches ratings

A beach rating survey was designed to provide an objective appraisal of the major public recreational beaches along the US Atlantic, Gulf, and Pacific coasts. About 650 beaches were evaluated nationwide on the basis of 50 criteria with a sliding scale to quantify the elusive quality factor. In-state coastal experts provided information and assisted Leatherman (1991) in this evaluation. Only the open ocean and Gulf coast beaches were rated. Therefore, seashores along Long Island Sound in New York and Connecticut were not considered nor were the many small beaches in major bays such as the Chesapeake and San Francisco. Puget Sound is perhaps the most desirable coastal property in the State of Washington, but here again it is an inland marine water body. In addition, Alaska's long coastline with many sandy to cobbly beaches was not evaluated, although the Valdez oil spill spotlighted this area's scenic beauty and the small pocket beaches where the oil tended to accumulate and pool.

A battery of factors were arrayed in order to allow for a quantitative comparison of the various beaches. The relevant criteria are those which influence beach quality as broadly defined. The factors considered in this analysis are of three types: physical, biological, and human use and impacts (Table R2). These ranged from 1 (poor) to 5 (excellent). This approach follows that developed by Leopold (1969) in her quantitative comparison of aesthetic factors for rivers.

The survey was designed to reflect general beach usage with swimming water (see especially factors 5–14) being of primary importance. A water temperature scale for optimal and tolerable conditions for swimming and bathing (Figure R3) was also designed to aid in quantifying factor 5 of the questionnaire (see Table R2). In general, pristine beaches with limited development scored much better than the overdeveloped and overcrowded urban resort areas. A profile can be developed for each beach based on the 50 factors evaluated; Figure R4 illustrates this graphical representation for Kapalua on Maui, Hawaii—the top-rated beach nationally in 1991. For visual comparison, one of the nation's worst beaches (Pike's Beach in the New York City area) is presented (Figure R5). This rating of America's best beaches has been conducted for the past 10 years, and the results have appeared in the popular media. Specialty categories were determined by using a subset of the data. Figure R6 illustrates the ranking for the US northeast region as presented in America's Best Beaches (Leatherman, 1998).

Some coastal specialists have questioned the objectiveness of the beach rating scale. For example, white and pink sand are the most highly rated, while gray sand is assigned the lowest rating. While pure white sand does cause much glare, the sugar-white beaches of the Florida panhandle are considered the most beautiful by sunglass-wearing tourists. Also, the pink sand beaches of Bermuda are something to behold. Others have pointed out that the 50 parameters are all equally weighted and that some factors are more important than others. This consideration was partly dealt with by using a suite of factors that are all related to one variable such as pollution (Table R2, factors 21, 23, 27, 29–31, 43, 44, and 48) or beach safety (Table R2, factors 10–14, 21, 23, 28, 40, 41, and 49). Therefore, multiple factors are used to delineate important criteria in rating beaches.

Table R2 Beach rating questionnaire

	1	2	3	4	5
Physical factors					
1. Beach width at low tide	narrow <10 m	10–30 m	30–60 m	60–100 m	100+ m wide
2. Beach material	cobbles	sand/cobbles	coarse sand		fine sand
3. Beach condition or variation	erosional		stable		depositional
4. Sand softness	hard				soft
5. Water temperature	cold/hot				warm (70–85°F)
6. Air temprature (midday)	<60°F >100°F				80–90°F
7. Number of sunny days	few				many
8. Amount of rain	large			little	
9. Wind speeds	high				low
10. Size of breaking waves	high/dangerous				low/safe
11. Number of waves/ width of breaker zone	none	1	2	3	4+
12. Beach slope (underwater)	steeply sloping bottom				gently sloping bottom
13. Longshore current	strong				weak
14. Rip currents present	often				never
15. Color of sand	gray	black	brown	light tan	white/pink
16. Tidal range	large (>4 m)	3–4 m	2–3 m	1–2 m	small (<1 m)
17. Beach shape	straight				pocket
18. Bathing area bottom conditions	rocky, cobbles, mud				fine sand
Biological factors					
19. Turbidity	turbid				clear
20. Water color	gray				aquablue/turquoise
21. Floating/suspended human material (sewerage, scum)	plentiful				none
22. Algae in water	infested				absent
23. Red tide	common				none
24. Smell (seaweed, rotting fish)	bad odors				fresh salty air
25. Wildlife (e.g., shore birds)	none				plentiful
26. Pests (biting files, ticks, mosquitos)	common				no problem
27. Presence of sewerage/runoff outfall lines on/across the beach	several				none
28. Seaweed/jellyfish on the beach	many				none
Human use and impacts					
29. Trash and litter (paper, plastics, nets, ropes, planks)	common				rare
30. Oil and tar balls	common				none
31. Glass and rubble	common				rare
32. Views and vistas local scene	obstructed				unobstructed
33. View and vistas far vista	confined				unconfined
34. Buildings/urbanism	overdeveloped				pristine/wild
35. Access	limited				good

Table R2 (*Continued*)

	1	2	3	4	5
36. Misfits (nuclear power station; offshore dumping)	☐ present	☐	☐	☐	☐ none
37. Vegetation (nearby) trees, dunes	☐ none	☐	☐	☐	☐ many
38. Well-kept grounds/ promenades or natural environment	☐ no	☐	☐	☐	☐ yes
39. Amenities (showers, chairs, bars, etc.)	☐ none	☐	☐	☐	☐ some

50. Competition for free use of beach (e.g., fishermen, boaters, waterskiers)	☐ many	☐	☐	☐	☐ few

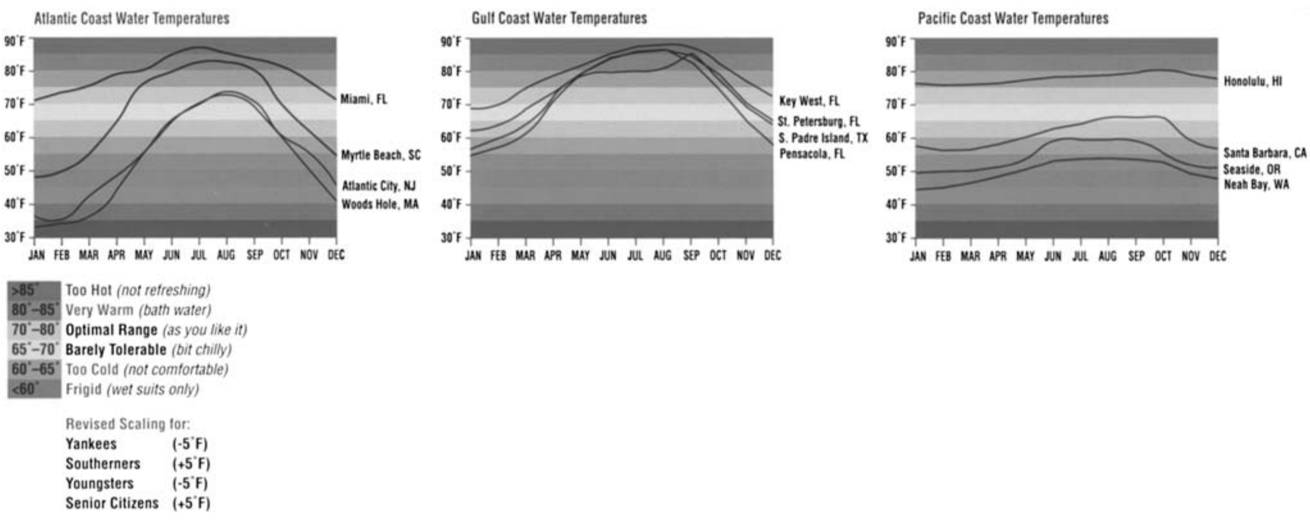

Figure R3 Water temperature scale for bathing and swimming.

America's most famous beaches were rarely rated the best ones for overall quality. For instance, the beaches at world famous Waikiki Beach in Honolulu, Hawaii have experienced progressive erosion to the point that the beach simply does not exist in some sections. Coney Island in New York city was a very popular beach in the 1960s, but crime and other problems have taken their toll.

Beach users survey

Morgan (1999) developed a questionnaire to query recreational beach users in Wales, UK. Overall, scenic quality was rated as the most important factor in the beach environment, but it must be remembered that Welsh beaches are "cold water" and not that conducive to swimming. Sand and water quality were also highly rated in this innovative study.

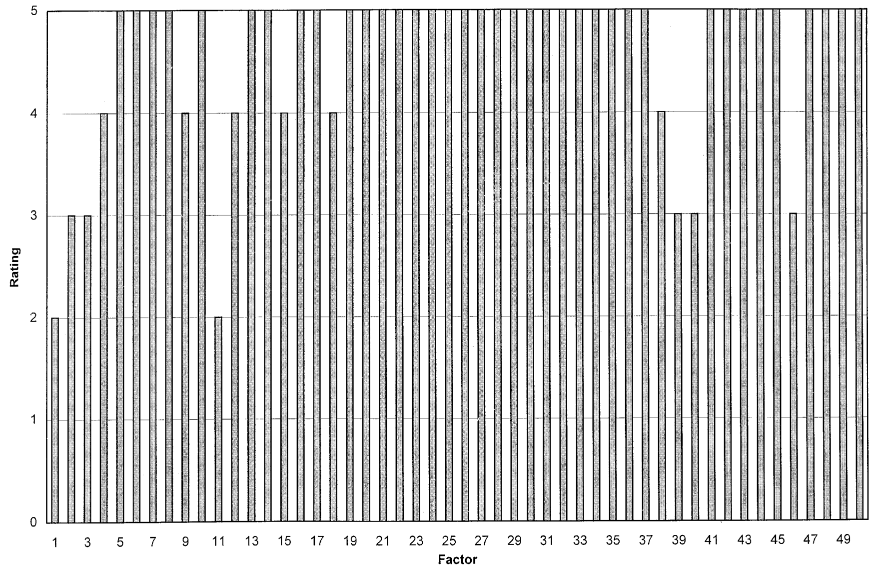

Figure R4 Beach profile for top-rated Kapalua Bay Beach, Maui, Hawaii.

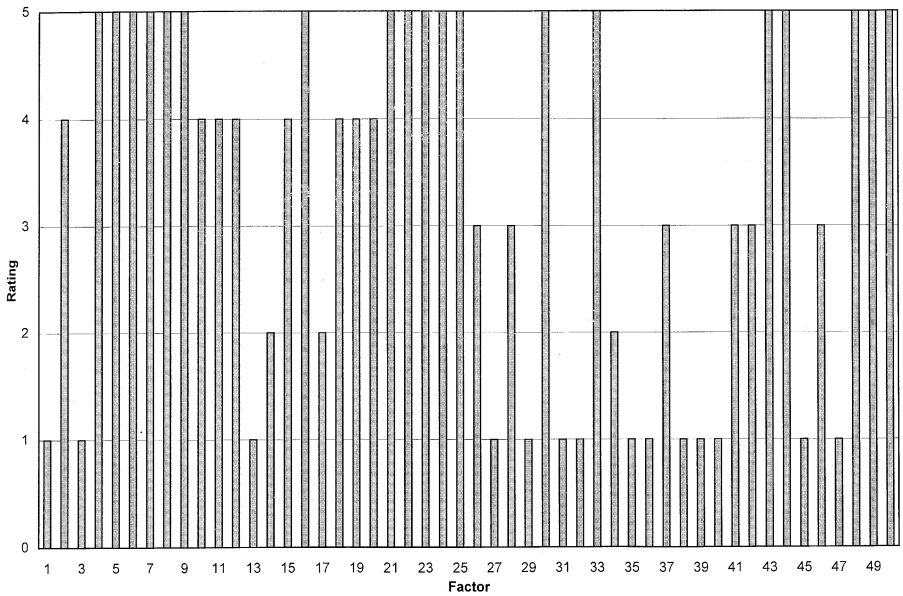

Figure R5 Beach rating profile for Pikes Beach, New York. Note that the "sawtooth" graph indicates a less aesthetically pleasing and overall lower quality beach.

There were many observed differences in beach user preferences, depending upon the type of beach (e.g., urban to rural) that the user preferred to visit. Some vacationers wanted all the amenities and "creature comforts" of a beach resort (e.g., good hotels and restaurants, many water-based activities, and nightlife) compared to others who preferred the natural characteristics of a beach (e.g., fauna and flora, scenery, and camping). Morgan (1999) found that high environmental quality was a prerequisite for all beach users, emphasizing the high level of public concern for this aspect.

Summary

Various beach awards have been ongoing in Europe for decades, but the use of scientific criteria and ratings have evolved subsequently to the efforts begun in the US beaches are always changing because of storm impact, beach nourishment, pollution problems, etc. so the rankings vary year to year.

Stephen P. Leatherman

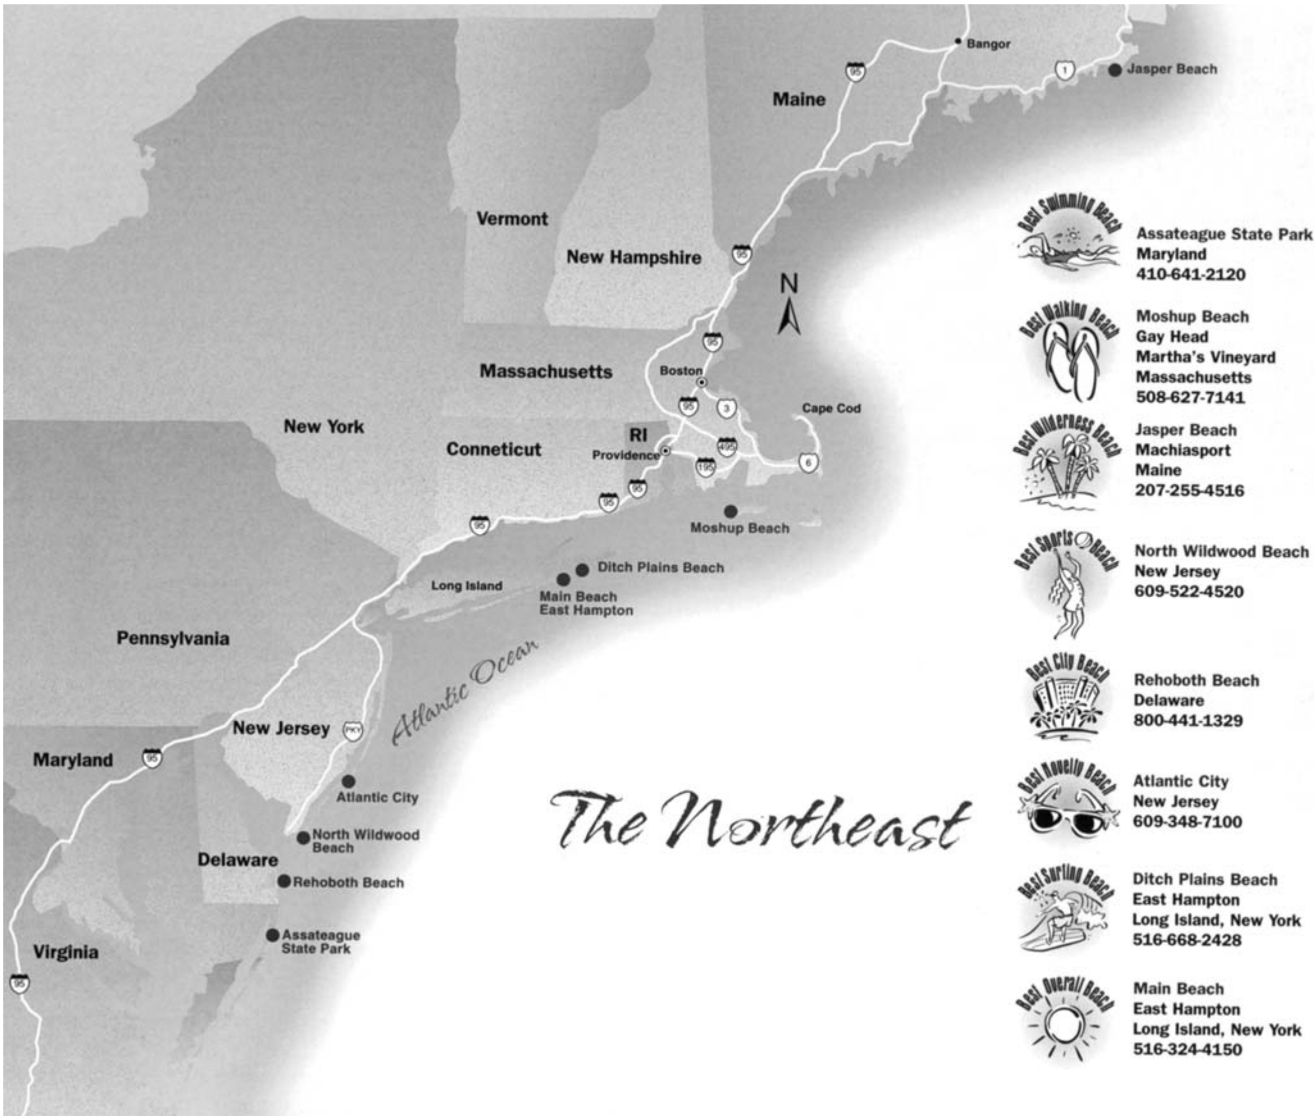

Figure R6 US beaches have been evaluated by region and category (Leatherman, 1998). Each region offers a different venue and recreational advantage. While swimming is the favorite activity of most beachgoers, many people just enjoy walking along beaches for the exercise or to enjoy the scenery. Purists prefer wilderness beaches, but many vacationers are looking for creature comforts; the top city beaches offer all the amenities.

RECLAMATION

Although normally associated with the rehabilitation of land, reclamation in the coastal context refers to the exclusion of marine or estuarine water from formerly submerged land. The basic idea of reclamation is to win land from the sea, to displace water and to create new land (Plant *et al.*, 1998, p. 563). The resulting land surface normally extends from the existing coastline and should be well above the level reached by the sea. Reclamation differs from the building up of shallow offshore grounds to form *artificial islands* (*q.v.*) (Kondo, 1995). It also differs from *polders* (*q.v.*) (CUR, 1993, p. 230, 244) in which the level of land subject to seasonal or permanent high water level is protected by dikes, and flood control and water management are important aspects.

Historical and geographical brief

The origins of reclamation probably date back to humankind's efforts in reclaiming land from estuaries and along coasts for their homes, livestock, and crops. For example, in the first few centuries, artificial clay mounds ("terps") were constructed by people in the lower parts of the Netherlands (Pilarczyk, 2000). It is likely that reclamation initially involved the draining of low-lying land and marshes. A survey of reclamation in temperate countries shows reclamation was primarily for agricultural purposes. Later, expanding population and increasing needs for industrial expansion and dock development led to a more focused objective of gaining land from the sea. It started with small-scale reclamation in almost all of the larger cities and ports situated on estuaries and coast throughout the world (Cole and Knights, 1979) (Figure R7). In fact, the reclamation of estuaries was better addressed, especially in the second-half of the 19th century to provide dock and harbor facilities to meet world trade expansion during the period of rapid industrialization in Europe and the United States (Kendrick, 1994).

Any mention of gaining land from the sea cannot avoid the Netherlands because of the massive scale of reclamation in a country where the battle against the sea has become an integral part of the way of life. Reclamation was carried out in conjunction with poldering and the construction of sea defense works. Many lessons were learnt not only in engineering aspects but also in the physical and economic planning of reclaimed land. Another country in which reclamation of its estuaries and low-lying coastal areas has been carried extensively is Japan, which has at least 400 years of reclamation history. It has considerable experience in the consolidation and settlement of fill material, particularly in the treatment of soft foundations, such as the wide application of the sand drain method and the sand compaction method (Watari *et al.*, 1994).

The need for reclaimed land for various developments varies worldwide and becomes particularly crucial around existing ports and cities and in countries where land scarcity is a factor, for example, in Singapore and Hong Kong (Walker, 1988) (Figure R7). Faced with land scarcity, Singapore has resorted to large-scale reclamation from the 1960s although reclamation dated back to the 19th century. Through various projects, it has reclaimed about 10% of its area, which totaled 647 km^2 in 1998. Under the Concept Plan to accommodate a population of 4 million from the present 3.2 million, another 100 km^2 have to be reclaimed. This would amount to 25% in land area since the 1960s (Figure R8). With current technology, it is not cost-effective to reclaim in waters deeper than 15 m. Another limitation is that reclamation encroaches into the sea space for shipping lanes and anchorage.

Reclamation methods

Land won from the sea is normally carried out by raising the level of previously submerged land above sea level using materials dredged from the sea or excavated from the land. The reclaimed site is where reclamation is to take place and eventually forms the platform for required land use. The borrow area is where such material is obtained for reclamation and the disposal area is where material, unsuitable for fill, is to be disposed.

Depending on the type of landfill, there are two major types of reclamation and each has its advantages and disadvantages (Plant *et al.*, 1998, p. 197, 561; CUR, 1993, p. 244).

1. In the "drained" reclamation, fill is placed on the reclaimed site. The advantage is that existing soft marine material can be left in place, reducing the amount of fill required. The disadvantage is the longer time required for settlement and a greater uncertainty in the duration and rate of consolidation. This could increase the costs in follow-up structures to accommodate a larger settlement. Artificial drainage is required to reduce drainage paths and accelerate settlement (Plant *et al.*, 1998, p. 561).
2. In the "dredged" reclamation, landfill by is by replacement, in which soft marine material is removed and replaced by imported fill. This means a larger volume of fill but the advantage of faster consolidation. The Hong Kong International Airport at Chek Lap Kok is an example of "dredged" reclamation in which three-quarters of the airport platform was reclaimed from the sea using a combination of dredging mud from the seabed, borrowing marine sand, excavation of islands, and construction of seawalls.

Site conditions have a strong influence on reclamation and factors such as climate, site access and site geology are important (Plant *et al.*, 1998, p. 15). Inaccurate information on these factors has led to delays, disruptions, disputes, and operational failures. For example, heavy

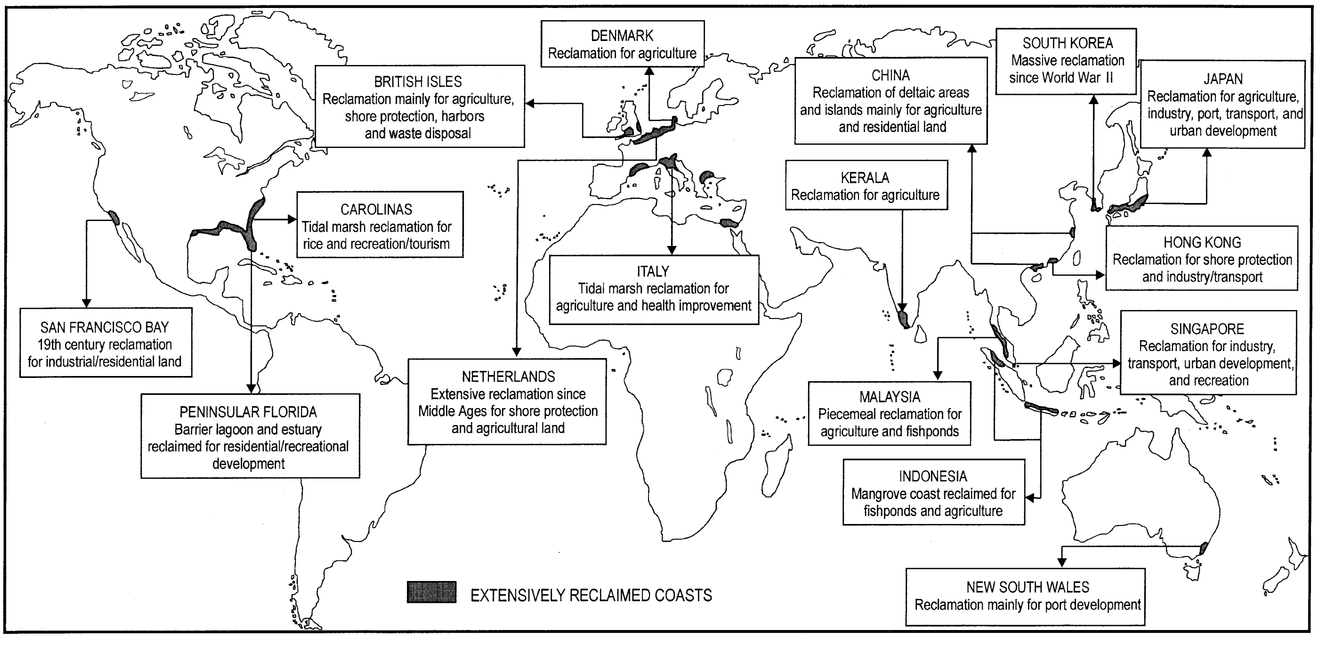

Figure R7 Major reclaimed coasts in the world.

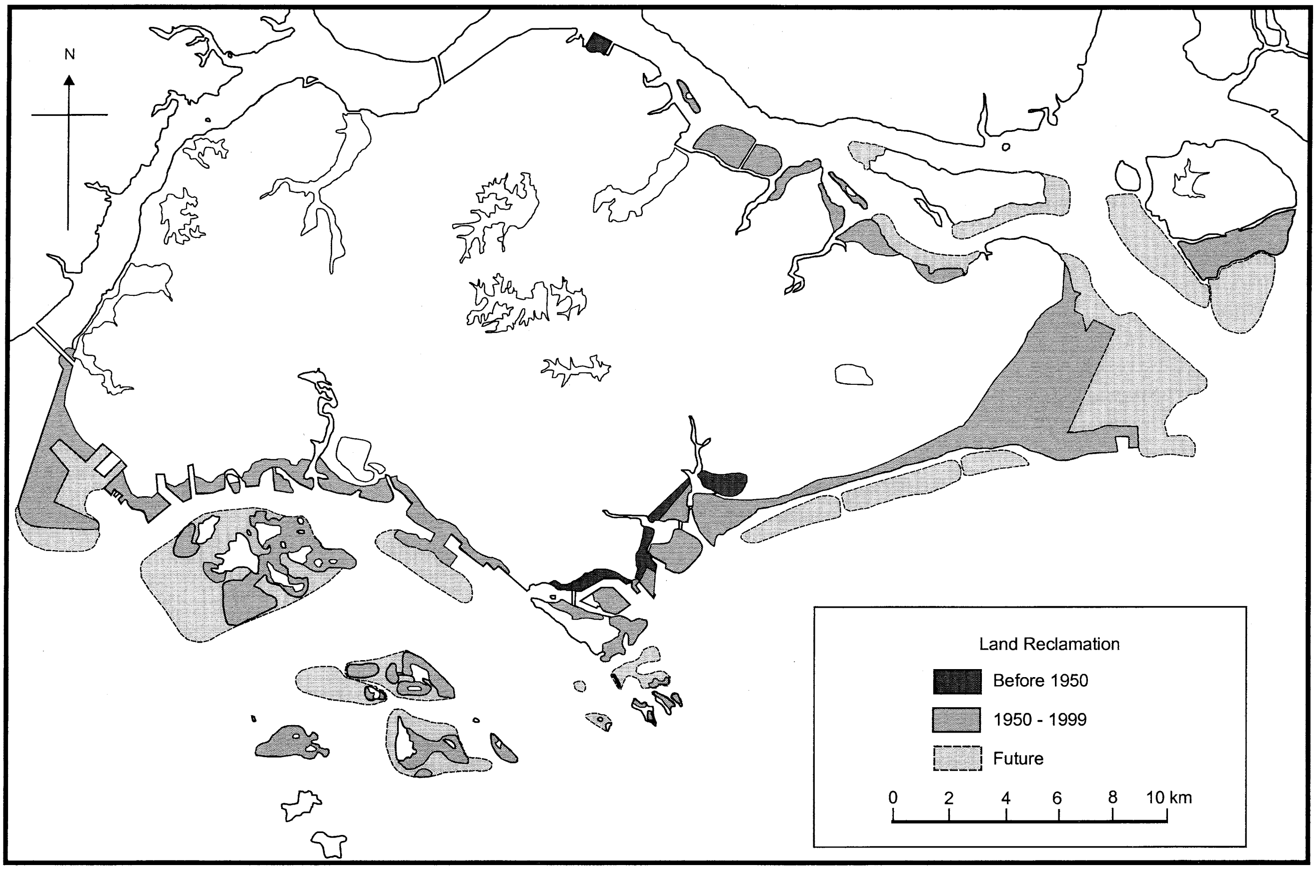

Figure R8 Reclaimed land in Singapore.

rainstorms can halt reclamation operation. Marine conditions as influenced by climate can be equally significant, for example, water depth and wave conditions influence the operation of dredgers. Seabed conditions can vary widely and water depth and type of materials influence both settlement and stability. A low-energy environment is advantageous as fill material can be placed on the seabed and not easily scoured by wave action. The availability of power, water, and communication services at the site can influence the design of reclamation.

Much of the early reclamation efforts often capitalized on the availability of fills such as quarry waste, urban refuse, excavation spoil, building demolition spoil, dredged material from ports and navigation channels, or the byproduct of some dredging operation. It was also carried out in connection with shallow tidal, marshy, or mangrove areas. Usually, for specific reclamation projects, materials cut from hills or seabed sand have been the most common fill. But with increasing scarcity of such fill materials, alternative sources, such as marine clays were dredged from the seabed. Marine aggregates, primarily sand and gravel from offshore-submerged sources, are also used in reclamation projects. In 1989, 7.7 million m^3 and more than 9 million m^3 were used for reclamation works in Denmark and Netherlands, respectively (Bokuniewicz, 2000).

Various techniques have been in use to deal with the reclamation of coastal areas with soft foundations. For example, in Japan, the removal of the soft material and replacement by sand was the common method. The lack of sand and environmental problems, such as increased turbidity of water and the problem of disposal of dredged material, saw the end of this method for large-scale reclamation in 1975. This was replaced by the sand drain, which first came into use in 1952. From 1970–83 some 230,000 sand drains, each about 20 m long, were used for seabed foundation improvement in Japan. Driving-type sand compaction was used in 1966 in offshore construction and supplemented by the deep mixing method (DMM) from the mid-1970s (Watari *et al.*, 1994).

For its earlier phases of reclamation, Singapore obtained landfill from the cutting of hills in the construction of public housing where extensive platforms were required. In the east coast reclamation, the fill was excavated by bucket wheel excavators and transported by belt conveyors to a loading jetty for loading to barges and dumped directly into the reclaimed site. Where water depth limited the movement of barges, the fill was unloaded by a reclaimer and conveyor system. Bulldozers and dump trucks then spread, graded, and compacted the reclaimed land (Yong *et al.*, 1991). The reclaimed land required little settlement after compaction.

As materials from land become less readily available, Singapore has to import from neighboring countries or obtain them from marine resources. The typical procedure in large-scale coastal reclamation is as follows (Yong *et al.*, 1991; Chuah and Tan, 1995).

1. Seabed stabilization is first carried out in several ways by the excavation of soft material from the seabed, dredging to form a sandkey trench or the installation of sand compaction piles or vertical drains. Sand compaction piles were first used in 1989. A hollow pipe casing is driven into soft material, filled with sand, then compacted, and the casing is withdrawn. Sand piles were placed at close intervals. This method strengthens the clay seabed, obviated dredging, and thus avoids the costs of disposal.
2. A sandkey is formed from transported sand towed in by hopper barges. In some cases, where conditions are suitable, a sand wall is also constructed along the coast to be reclaimed. Sand barges build up a stockpile outside the sand wall.
3. Reclamation is carried out by direct dumping or hydraulic filling using cutter suction dredgers and pumps or trailer hopper suction dredgers. Where sand is sucked from the stockpile, it is spread into the fill area by a floating spreader. If the depth is too shallow, sand is pumped through overland pipes.
4. After filling, compaction is carried out by rollers. Shore trimming and shore protection works (geotextile placing, stone placing, and hand-pitching) complete the reclamation. The reclaimed land is usually ready for development after 1–5 years.

The above procedure has been applied to the reclamation of a group of islands located about 1 km south of Jurong Industrial Estate to form a single island zoned for petrochemical and chemical industries. The shape of the reclaimed island is to give a maximum land area that could be possibly reclaimed and a coastline with harbor basins that have no adverse conditions on water currents, sedimentation, and navigation (Chuah and Tan, 1995).

Ground treatment

The magnitude and rate of settlement of *in situ* soils and fills is a major concern in reclamation. The settlement depends on the type of fill, method of placement, and use of reclaimed area (Plant *et al*., 1998, p. 131). Ground treatment is any process in which the properties of the ground are improved or changed. Various methods are used to speedup settlement, each has its own merits.

Surcharging or preloading is the process in which the ground surface is loaded with additional mass. A stockpile of material is required and the material is moved from location to location until the process is completed (rolling surcharge). This procedure avoids importing vast quantities of additional material. Where rockfill is used, surcharging is an effective means of reducing future settlement in rockfilled areas (Plant *et al*., 1998, p. 417) and less disruptive to the geotextile over rockfill. Fine-grained dredged materials take up to 2–3 years or more to consolidate under self-weight before surcharging is used. Although surcharging avoids the costs of handling large quantities of surcharge fill material and its eventual disposal, the whole process can take up to a decade or more for a 200-acre site (Thevanayagam *et al*., 1994).

Vibrocompaction refers to ground treatment in which heavy vibrators are inserted into loose granular soils and then withdrawn leaving a column of compacted soil in the ground. This reduces creep and vibration-induced settlement of the ground surface during follow-up construction activities. It is a fast method of achieving a high degree of compaction for a specific material. In dynamic compaction, the ground is compacted by high-energy impacts using a tampering weight. It can be used for all fill types but its effective depth is limited to about 10 m.

To facilitate rapid settlement associated with very soft clayey material, water conduits have to be installed for easy dissipation of water. In the past, this was achieved by vertical columns of sand drains installed at a grid of about 1–3 m. In recent years, sand drains are being replaced by wick drains or band-shaped drains, which make installing faster and easier. In the reclamation of a seabed underlain by thick deposits of soft clay, soil improvement is required. One of the most popular procedures is to combine prefabricated band-shaped drains with preloading.

In the reclamation for Hong Kong International Airport at Chek Lap Kok, seabed conditions varied widely in terms of water depth, thickness of marine mud to be dredged, and underlying compressible strata. These had a strong influence on both settlement and stability of the reclaimed land. The time taken for settlement was difficult to determine as the settlement of fill after construction depends on the type of fill, method of placement, and use of filled area. Instruments monitored settlement and allowed analytical settlement models to be calibrated and updated as reclamation and follow-up works progressed. An extra 0.5 m was provided for future settlement. For ground treatment, surcharge, vibrocompaction, and dynamic compaction were used (Plant *et al*., 1998).

Coastal protection

Land gained from sea has to be protected from erosion by waves and currents. Depending on coastal conditions, various types of halophytes can be used to protect reclaimed land. For example, marram grass (*Ammophila*) is used in Europe (Cole and Knights, 1979). In Singapore, idle reclaimed land along Changi Coast Road has been effectively colonized by beach vegetation, such as *Ipomoea pes-caprae* and trees such as *Casuarina equisetifolia*.

More often, reclaimed land is protected by shore protection works. In accordance with current international practice, seawall construction allows for some risk of damage under extreme conditions. A high factor of safety will result in a disproportionate effect on costs. As the philosophy on coastal protection changes, this is also reflected in the protection of reclaimed land. For example, in Japan, coastal protection began with seawalls, followed by groins and then detached breakwaters (Hsu *et al*., 2000).

Although Singapore is not in a high wave-energy environment, various types of coastal protection works were required for the reclaimed land depending on several variables, such as the usage of reclaimed land, ease and speed of construction, site constraints, cost of construction, and predominant wave approach. Three major groups of shore protection works for reclaimed land in Singapore can be identified.

1. Reclaimed land with beaches. Initially, a seawall was used but this was superceded by a series of breakwaters acting as headlands between which beaches can be developed. These were used in the east coast because of the low wave energy, predominant wave approach from the southeast, and net littoral drift to the west. Beaches were formed in J-shaped bays with their upcoast curves in the east and downcoast straight sectors in the west.
2. Reclaimed land for port purposes. A sand key provides the broad base for the seawall to be constructed and withstand loads, for example, in Jurong. Sheet piles are used for deep-water frontage where wharf construction is required.
3. Reclaimed land retained behind a marine retaining wall. Various types of structures are used. Generally, stone bunds are constructed with stones large enough to withstand dynamic lifting and to absorb forces of waves on their outer face. Stone bunds were constructed around some islands with gaps for beaches to form (Wong, 1985). Various prefabricated structures were also used. Caissons or huge reinforced concrete boxes were towed to sea by tugboats, then filled with sand and positioned on the seabed. These are costly and used where a rocky seabed is available. Depending on their size to be used, L-blocks of 30–70 tons require a compacted rubble foundation and are positioned by cranes. These were used in the reclamation of Marina Bay and Tanjung Rhu.

Depending on the size of area to be reclaimed, the condition of the seabed which may require stabilization, and the necessity of shore protection to protect reclaimed land from erosion, the following approaches can be identified for reclamation in Singapore. For small areas, such as offshore islands, site preparation is followed by seabed stabilization for the construction of breakwaters to prevent erosion from currents and waves and followed by the filling of sand. For large areas extending from the mainland, site preparation is followed by seabed stabilization, filling of sand, and shore protection works. For large swampy areas, settlement is a problem and additional time and costs are required for shore protection measures. Site preparation is thus followed by sand filling and shore protection works.

New developments

Reclamation often involves work on land and sea, which is collectively referred to as land operations and marine operations, respectively. The land operation is basically civil engineering and quarrying operations and the scale of earthworks is typical of large mining operations. The marine operation usually involves dredging and coastal protection. Dredging is defined as "underwater excavation of seabed material, transportation of the materials to a discharge area, and subsequent discharging of dredged material" (Plant *et al*., 1998, p. 266). In recent years, reclamation has seen new developments in both land and marine operations.

Modern reclamation relies on some heavy specialist equipment to recover (dredge) from the burrow area, transport, and place the material over the reclaimed site. Cutter-suction dredgers and trailing-suction hopper dredgers (also called trailer dredgers) have been developed to dredge a greater volume of materials in a short time and at lower costs, often in deeper waters. A trailing-suction hopper dredger is a self-proposed ocean-going vessel fitted with special dredging equipment. The hopper capacity of these dredgers has doubled from 10,000 m^3 in the 1980s to 23,000 m^3 and set to treble to 33,000 m^3 in 2000 (Riddell, 2000). A cutter-suction dredger differs from a trailing-suction hopper dredger in that the former is effectively stationary during dredging, has more control over the dredging process and is also capable of dredging harder material. Depending on water depth, a cutter-suction dredger trails as dredging progresses. The dredged material is projected through a nozzle at its bow in a process called "rainbowing" as land is reclaimed. Hopper barges are for direct dumping of material and are confined to sheltered waters.

The increasing use of geosynthetics in coastal and harbor engineering has also found its place in reclamation. Geosynthetics is a generic name given to various materials that are synthesized for use with geological materials to improve or modify their behavior. One major success was the construction of storm-resistant structures over soft soils at the coast in the Netherlands (Rao and Sarkar, 1998). In Japan, geosynthetics have been commonly used for more than three decades in land reclamation involving a soft clay foundation. They are mainly used for surface stabilization to increase bearing capacity and to reinforce the base of fill and for foundation improvement to replace sand drains in facilitating drainage (Akagi, 1998). Probably the world's largest sewn single sheet of geotextile used for reclamation took place in Singapore in one phase of the reclamation for Changi Airport. A 180-ha pond, 2,000 m in length and 750 m and 1,050 m in width at both ends, created earlier by the borrowing of sand contained slurry-like material 3 to 20 m thick. The initial spreading of sand over the pond failed as mud burst through the sand cap. Remedial measures started with the removal of some of the exposed slurry. Then, the geotextile sheet of 1,060,000 m^2 sewn from 5×90 m^2 rolls was laid across the silt pond to strengthen the foundation soil. This was supplemented by prefabricated band-shaped vertical drains to accelerate the consolidation time by shortening the drainage path (Na *et al.*, 1998). This example shows that high-strength geotextile can strengthen foundation soil that is extremely soft.

The technique of vacuum consolidation is being used in reclamation. This is a process in which a vacuum is applied to a soil mass to produce a negative pore pressure, leading to increased effective stress that leads to consolidation. Although the technique was known in the early 1950s, it was not widely used until the 1980s because of high costs and implementation difficulties. Its application was made possible by recent technological advances in geotextiles and efficient and cost-effective prefabricated vertical drains (wick drains) (Shang *et al.*, 1998). The technique has been field-tested for on-land vacuum consolidation in countries such as the Netherlands, France, Malaysia, Sweden, Japan, and China. It shows considerable promise as an economically viable method to replace or supplement surcharge fill and the potential to strengthen weak sediments on the seabed adjacent to or beneath water, or consolidate fine-grained hydraulic fills during construction. The technique can also be used with prefabricated horizontal drains and selective placement of dredged materials for new land reclamation (Thevanayagam *et al.*, 1994). It was applied to 480,000 m^2 of reclaimed land in Tianjin Harbor, China, where individual sites treated with vacuum ranged from 5,000 to 30,000 m^2, illustrating that it was especially attractive for hydraulic fills and in reclamation sites with a shortage of surcharge fills but that have an easy access to a power supply. Currently, research on the method is on numerical modeling of the consolidation process, the application of geotextiles over larger areas, and the development of high-efficiency vacuum equipment (Shang *et al.*, 1998).

During earthquakes, especially in Japan, some reclaimed land can undergo a complex phenomenon called liquefaction in which loose sandy deposits change into a liquid state. The liquefaction sites are related to the age of reclamation, the methods used, and type of material. The remediation methods depend on large-scale or localized remediation and are implemented during or after completion of land reclamation. With wide experience in this area, Japan has produced a handbook on remediation measures (Port and Harbor Research Institute, 1997) that can be used in other seismically active regions where reclamation has been carried out.

Compared with the past, environmental considerations are given serious attention in modern reclamation and associated works (Bates, 1994). The main areas of impact are at the dredging site, the transportation route, and the reclamation site. The potential adverse effects of dredging include the release of contaminants into the water, increased turbidity, disturbance to the seabed, erosion, noise, oil spillage, blanket cover, and consequent loss of habitat. To some extent, the impacts resulting from dredging and dumping may be overcome by changing the type of dredger and method of dumping. With the concern on the impacts on water quality and ecology, there is a need to develop methods to minimize environmental impact, such as modeling to examine environmental impacts of reclamation projects.

Conclusion

Reclamation continues to be a significant means in providing land to meet the needs of expanding population and economic development, especially in small countries and coastal cities where land is scarce. It brings about a complete change in the coastal environment. Its implementation involves the input of various disciplines, for example, physical geography, geology, soil mechanics, loose boundary hydraulics, land drainage, coastal engineering in the planning and design of reclamation, and ecology, with the increasing concern on loss of natural habitats. New developments have to try to overcome the technical constraints, make reclamation low cost, take advantage of available soft material and other fills, such as incinerator ash, and to reclaim further into increasing depths.

REEFS, NON-CORAL

Although most modern reefs are communities of coral and coralline algae that live in clear, well-lit tropical and subtropical waters, there are many different groups of reef-forming organisms that are found on living and ancient reefs. The modern non-coral reefs thrive in a wide range of environments extending from sponge reefs in the arctic to non-photosymbiotic algae and Halimeda reefs found near methane seeping faults at depths of 600 m (Wood, 1999).

Definitions of reefs

The word, reef, is derived from the Norwegian word, rif, which means rib. In nautical terms, reef refers to a narrow chain of rocks, shingle or sand lying at or near to the surface of the water. When early sailing ships explored the tropical waters of the South Pacific, they encountered ring-like reefs of coral that enclosed a lagoon which they called "atoll" after "atolu," the Malayalam name for the Maldives Islands. In the more restrictive modern use of the word, reef denotes a rigid, wave-resistant framework constructed by large skeletal organisms (Ladd, 1944). While living coral reefs on atolls are wave resistant and contain a framework of corals and algae, boreholes drilled beneath the reefs consist of rubble, sediment, and voids (Hubbard *et al*., 1990). Many ancient carbonate buildups, that are referred to as reefs, show that the original coral framework is almost completely destroyed by deep burial and diagenesis. A broader definition of reef, which would encompass both modern and ancient non-coral reefs, has been proposed by Rachel Wood: "a reef is a discrete carbonate structure formed by in-situ organic components that develops topographic relief upon the Seafloor" (Wood, 1999, p. 5).

Reef-forming organism on non-coral reefs

The earliest recognized reefs are composed of stromatolites which were found on Phanerozoic carbonate platforms dating back to 2.5 Ga. Stromatolites are finely laminated microbialites produced by photosynthetic blue-green algae (cyanobacteria) that form a range of morphologies including domes, columns, and mounds (Reitner, 1993). Ancient stromatolite reefs were constructed on preexisting carbonate ramps and rimmed shelves (Grotzinger, 1989). Living stromatolites are found in intertidal zones on Lizard Island in the Great Barrier Reef, in Shark Bay, Australia, and in submerged tidal channels on Lee Stocking Island in the Bahamas. Thrombolites, which also form reefs, are non-laminated microbial structures which often have a mottled or bioturbated appearance.

Archeocyathids were the first metazoan reef-forming organisms and are found in Lower Cambrian limestones. The archeocyathids are large sponges with double-walled inverted conical calcareous skeletons (Debrenne and Zhuravleb, 1994). The first bryozoan reefs appeared in deep cold waters perhaps related to the presence of microbial mounds in the Lower Ordovician (Pratt, 1989). Stenolaemate bryozoa colonies of clonally calcified chambers, which formed reefs in the Lower Ordovician and died out during the Permian, reappeared as gymnolaemate bryozoans in the Jurassic and expanded during the Cretaceous and Eocene. Phylloid algae are calcified algae of platy, cup, and encrusting leaf-like forms that inhabited many late Paleozoic reefs.

Rudistid reefs are common in the Jurassic to Cretaceous limestones. Rudists are heavily calcified, heterodont bivalves in which the hinge and ligament have been modified forming a complete uncoiling of both valves (Skelton, 1991). The large lower (right) valve is conical, cylindrical, or coiled and the upper (left) valve is flattened. Most rudists were semi-infauna, soft sediment dwellers, but they often colonized storm-generated debris forming large rudistid reefs.

Large colonies of the common oyster, *Crassostera virginica*, are found in intertidal to subtidal environments including sounds and estuaries where the salinity is between 5 and 30 ppt. The oyster spat becomes cemented to old oyster shells and forms mounds of oysters which are commonly known as oyster reefs. When the buried oyster beds are exposed as fossils, they take on a reef-like form, but do not resemble the modern coral reefs.

Conclusions

Most living reefs are composed of coral and coralline algae and consist of a wave-resistant framework constructed by large skeletal organisms. A broader definition of a reef is "a discrete carbonate structure formed by in-situ organic components that develops topographic relief upon the sea floor" (Wood, 1999, p. 5). A wide variety of non-coral organisms including coralline algae, stromatolites, archeocyathids, bryozoans, rudists, and oysters formed reefs in the geologic past and many are still forming reefs today.

REFLECTIVE BEACHES

Definition and classification

Reflective beaches are systems where there is minimal wave-energy dissipation by breaking and therefore most energy is reflected by the nearshore morphology. In cases of strong reflection, individual reflected waves can be seen propagating away from the foreshore. Guza (1974), in his study of beach cusp formation, was apparently the first to use the term reflective beach. He distinguished between reflective and dissipative beaches (*q.v.*) using the surf-scaling parameter, ε:

$$\varepsilon = \frac{\alpha\omega^2}{g\tan^2\beta},$$

where α is the wave amplitude at breaking, ω is the wave radian frequency ($\omega = 2\pi/L$, where L is wave length), g is the gravity constant, and β is the beach slope in degrees. The proportion of incident wave energy that is reflected from the beach increases as ε decreases. For beaches where ε is larger than 20, most energy is dissipated by the turbulence associated with wave breaking. Where ε is less than about 2.5, most wave energy is reflected off the foreshore, and such beaches are designated as reflective. Thus, Guza (1974) used the relative degree of reflection or dissipation of incident waves as a rationale for the classification

Figure R9 A reflective gravel beach near Malin Head, Co. Donegal, Ireland. Note steep foreshore and cusps. Maximum height of the collapsing breakers is less than 0.5 m, with a period of about 6 s.

of beaches. This approach was subsequently subsumed under the rubric of nearshore morphodynamics.

Nearshore morphodynamics

The concept of nearshore morphodynamics was developed to characterize systems where form and process are closely coupled through feedback mechanisms. On beaches, waves (*q.v.*) interact strongly with sediments and morphology, and the form of wave breaking is one manifestation of these interactions. For a given wave steepness, H/L (where H is wave height), the breaker type will change as the nearshore slope changes. On a very low gradient slope, spilling breakers should occur. As the gradient increases, there should be a progression through plunging and collapsing breakers. Finally, on very steep beaches, surging breakers should occur (Galvin, 1968). For a constant nearshore slope, the same sequence of breaker types will occur as wave steepness decreases. Breaker type is closely associated with the expenditure of wave energy in the nearshore (e.g., reflection or dissipation) and the development of nearshore morphology. The morphology, in turn, controls breaker type. These relationships are the underlying bases for the concept of nearshore morphodynamics (see summary by Wright and Short, 1984). The recognition of characteristic sets of dynamic relationships provides the basis for using morphodynamic regimes (or states) as a means for classifying beach types. For example, collapsing or surging breakers occur on reflective beaches. This contrasts with dissipative beaches (*q.v.*), where spilling breakers are common. Plunging waves tend to occur on the intermediate beach states of the morphodynamic model (i.e., systems where $20 \geq \varepsilon \geq 2.5$), where neither reflection nor dissipation dominates the nearshore energy response.

Characteristics of reflective beaches

In cross section, morphodynamically reflective beaches display the classic form of “swell” or “summer” beach profiles (e.g., Sonu and Van Beek, 1971). According to Wright and Short (1984), other distinguishing characteristics include steep nearshore and beach slopes ($\tan \beta$ between about 0.10 and 0.20), and, typically, relatively coarse sediment sizes. Coarse clastic beaches, therefore, tend to be reflective. The subaerial beach tends to be narrow with a pronounced step at the foot of the foreshore. Low-energy reflective beaches are approximately two-dimensional alongshore. Higher-energy systems frequently include well-developed beach cusps on the foreshore. These cusp systems are presumed to be caused by low-mode, subharmonic edge waves. Incident wave energy is a maximum at or near the beach face. The classic reflective system displays only one coincident set of breakers (Figure R9), and substantial energy remains at the landward extremity of uprush. On meso- and macrotidal beaches, the nearshore system may be reflective only at higher tidal stages and dissipative at low tide (Short, 1991; Masselink and Hegge, 1995). Short and Hesp (1982) have linked the reflective beach state to the formation of small foredunes that are eroded frequently. This linkage is a key concept in the development of beach-dune interaction models (e.g., Sherman and Bauer, 1993).

REMOTE SENSING OF COASTAL ENVIRONMENTS

Coastal ecosystems are transitional environments that are sensitively balanced between open water and upland landscapes. Worldwide, they exhibit extreme variations in areal extent, spatial complexity, and temporal variability. Sustaining these ecosystems requires the ability to monitor their biophysical features and controlling processes at high spatial and temporal resolutions but within a holistic context. Remote sensing is the only tool that can economically measure these features and processes over large areas at appropriate resolutions. Consequently, it offers the only holistic approach to understanding the variable forces shaping the dynamic coastal landscape. Remote sensing must be able to adjust to these spatially and temporally changing conditions and also be able to discriminate subtle differences in these systems. As a result, remote sensing of coastal ecosystems is a complex undertaking that needs to incorporate not only the ability to define the observable hydrologic and vegetation features, but also the scale of measurement.

Historical development

Since the 1960s, remote sensing has been used to describe a new field of information collection that includes aircraft and satellite platforms carrying cameras to electro-optical and antenna sensor systems (Jensen, 2000). Up to that time, camera systems dominated image collection and photographic media dominated the storage of the spatially varying visible (VIS) and near-infrared (NIR) radiation spectral intensities reflected from the earth to aircraft platforms. Beginning in the 1960s, electronic sensor systems were increasingly used for collection and storage of earth's reflected radiation, and satellites were posed as an alternative to aircraft platforms. Advances in electronic sensors and satellite platforms were accompanied by an increased interest and use of radiant energy not only from the VIS and NIR wavelength regions but also from the thermal and microwave regions. In 1983, the American Society of Photogrammetry and Remote Sensing adopted a formal definition of remote sensing as "the measurement or acquisition of information of some property of an object or phenomenon, by a recording device that is not in physical or intimate contact with the object or phenomenon under study" (Jensen, 2000, p. 3). Although, others extended this definition to encompass the new technologies established for data collection, all definitions implicitly suggest that the property measured should describe a feature occupying a finite volume at a certain spatial and temporal position.

Remote sensing can include mapping of the earth's magnetic and gravitational fields and monitoring activities based on mechanical vibrations such as marine profiling by sonar and seismic exploration (Slater, 1980; Horler and Barber, 1981), or it can be applied to fields as diverse as cosmology to medical imaging. Historically, however, remote sensing has been used primarily to describe the collection of information transmitted in the form of electromagnetic radiant energy from an aircraft or satellite that is relevant to the earth's natural resources. Following this description, most remote sensing applications can be generally described by considering, (1) the nature of the probing signal, (2) the characteristics of the sensor and sensor platform, and (3) the interaction of the signal with the target.

Electromagnetic spectrum

The electromagnetic spectrum describes the distribution of energy per wavelength (λ) or within an interval of consecutive wavelengths referred to as spectral bands ($\Delta\lambda$). Standardized to the speed of light in a vacuum, the electromagnetic spectrum is used to categorize general similarities of electromagnetic radiation in terms of changes in wavelength. The spectrum begins at the short wavelength cosmic rays and extends to the long wavelength radio waves (Figure R10). Ultraviolet radiation below 0.3 μm is removed by atmospheric ozone absorption, and between 0.3 and 0.4 μm atmospheric scattering reduces image contrast to levels generally unacceptable for satellite remote sensing applications (Slater, 1980). From about 0.4 μm to about 0.7 μm (VIS) little absorption occurs in clear and unpolluted atmosphere, although scattering is higher in this region than at longer wavelengths. In practice, the VIS is subdivided into the blue, green, and red regions. Above 0.7 μm, remote sensing applications are concentrated in atmospheric transmitting regions or windows bridging strong absorption bands primarily related to water vapor, ozone, and carbon dioxide. The region from 0.7 to 1.3 μm defines the NIR region, and the combined VIS and NIR regions are commonly referred to as the VNIR. The middle infrared (MIR) region from 1.3 to 8.0 μm is sometimes partitioned into a shortwave infrared (SWIR) region from 1.3 to 2.5 μm dominated by reflectance and a region from 2.5 to 8.0 μm dominated by emission. The MIR contains high atmospheric water vapor and carbon dioxide absorption bands and includes an atmospheric window from about 3 to 4 μm and a region of strong absorption between 5 and 8 μm. Ozone absorption between 9 and 10 μm interrupts the thermal region extending from 8 to 14 μm. Poor atmospheric transmission and the lack of sensitive detectors and instrumentation prohibit remote sensing applications between around 14 μm and 1 mm. Starting at 1 mm and extending up to 1 m, the microwave region is subdivided into regions from the shortest (*K*) to the longest (*P*) wavelength. Beyond the microwave region begins the region of television and radio frequencies. The electromagnetic spectrum does not end abruptly, but frequencies less than 3 kHz corresponding to

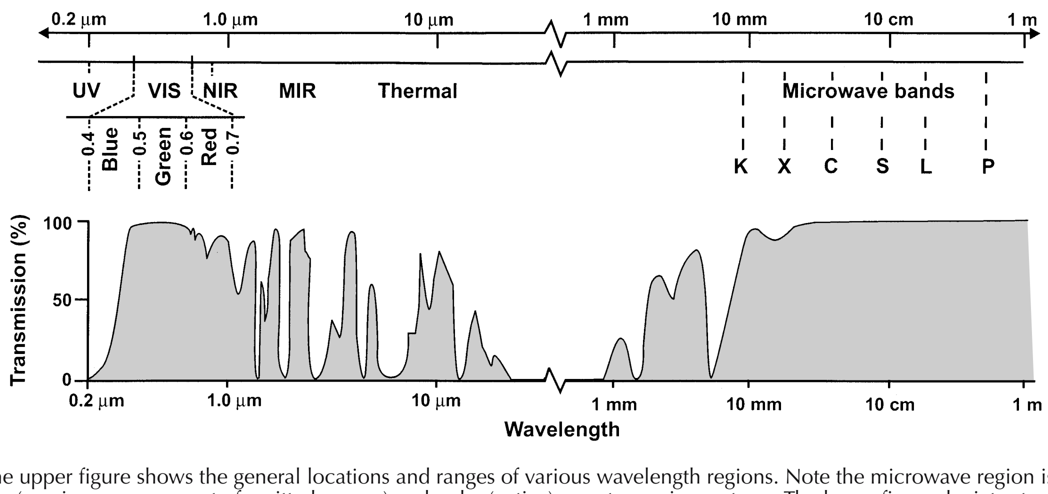

Figure R10 The upper figure shows the general locations and ranges of various wavelength regions. Note the microwave region is used by passive microwave (passive measurement of emitted energy) and radar (active) remote sensing systems. The lower figure depicts atmospheric transmission. Satellite remote sensing applications are normally carried out in spectral regions of high transmission (shaded) and avoid regions of high blockage.

wavelengths longer than 10^5 m are not used. Mechanical vibrations including sound and seismic waves begin at frequencies below 20 kHz. Marine profiling by sonar, the audio analog to radar, is in the 200-Hz range (Slater, 1980).

Platforms and sensors

Aircraft color infrared photography is useful in providing detailed biophysical, high-quality information about coastal ecosystems; unfortunately, turnaround for new map production is relatively slow. Satellite remote sensing provides holistic but detailed information on a regional as well as repetitive basis, and it is the only feasible approach to successfully overcome many intractable problems related to mapping and monitoring of coastal ecosystems. Satellite remote sensors are increasing in number, in type, and in operational usefulness, and will provide the basis for integrated remote sensing applications (Lillesand and Kiefer, 1994; Jensen, 2000). Visible to thermal sensors have the longest history and have shown promise in mapping and monitoring coastal wetland type, health, biomass, and water quality. Since the late 1970s, microwave has gained importance in wetland mapping (Lewis *et al.*, 1998). Microwave sensors extend the past capabilities of visible to thermal sensors in mapping coastal ecosystems by adding the potential for higher canopy penetration, more detailed canopy orientation and density information, and 24-hr-a-day collections nearly independent of weather conditions. Aircraft data will continue to provide calibration surveys, algorithm verification, testing of new sensor systems, specialized sensor collections, and in some cases local disaster response.

Remote sensing sensors measure radiant flux over bands defined by a range of wavelengths (e.g., VIS). A radiometer is a remote sensing instrument that measures radiant flux at any distance over a single band and a spectroradiometer measures over multiple bands. The specification of the instrument determines the spectral coverage, spectral, angular (or spatial or ground resolution), and radiometric resolutions. These factors clearly control the type and value of the data obtained.

Imaging and nonimaging sensors used in remote sensing use either electro-optical (VIS to thermal) or antenna detectors (microwave). Normally, nonimaging sensors are radiometers that collect accurate data over wide spectral regions where the spatial and spectral aspects are less important (Elachi, 1987). The signals returned to the sensor represent the scene spatial characteristics as rows and columns of pixels (discrete picture elements) within an image. Resampling is sometimes necessary to construct a continuous image representation of the scene (orbital and sensor characteristics), and almost always necessary to georeference the image to an earth coordinate system (e.g., latitude/longitude). Resampling tends to reduce confidence in the pixel location and blur the information contained in spatially adjacent pixels by adding a component of within-image spatial covariation. The pixel dimensions and location on the image represent an estimate of the spatial dimensions (spatially averaged ground area) and scene location that contributed to the pixel value.

Sensors commonly used can be separated into two types, active and passive. Active sensor systems both transmit and receive reflected or scattered radiant flux. The light detection and ranging (LIDAR) and radio detection and ranging (RADAR) are common active sensor systems. These systems track the time difference between the transmission of the emitted pulses of energy and the arrival of the scattered return at the sensor. The distance to or range of the target is then directly obtained from the time difference. Active systems can also control the nature of the radiation used to probe the target. For instance, the wavelength placement, bandwidth ($\Delta\lambda$), polarization, and the angle of incidence can be controlled by the sensor and sensor platform. And because the energy source is part of the system, active systems can operate day and night and in the case of radar during most weather conditions. These features allow a greater control over the application of remote sensing techniques, and their use in monitoring earth's resources is increasing.

Passive remote sensing primarily uses the sun as the source of electromagnetic energy. Planck's blackbody law describes the sun's energy distribution with respect to frequency and wavelength. A perfect blackbody absorbs and re-emits all electromagnetic radiation impingement upon it, while a partial emitter (gray body, e.g., water) is spectrally similar but of lower amplitude, and a selective emitter (e.g., quartz) is spectrally selective compared to the general shape of a blackbody. The sun's emitted radiation closely approximates a blackbody at 6,000 K where energy emissions are mostly contained between 0.3 and 2.5 μm, peaking near 0.55 μm. Solar radiation transferred through the earth's atmosphere and scattered and reflected by its surface is generally referred to as *solar reflected radiant flux* (Slater, 1980). In addition, solar heating of the earth's atmosphere and surface produces a secondary source of energy that has a distribution similar to radiation emitted from a blackbody at approximately 300 K. Energy emitted by the earth starts around 2.5 μm and peaks near 10 μm. Radiation emitted by the earth's atmosphere and surface is referred to as *self-emitted thermal radiant flux* (Slater, 1980). Radiant flux below about 2.5 μm represents solar-reflected radiant flux while above 6.0 μm it represents self-emitted thermal radiant flux. Between 2.5 and 6.0 μm, the relative amounts of each flux depend on the target reflectance, emissivity, temperature, and atmospheric transmittance. Lowered atmospheric transmittance between 2.5 and 5.5 μm normally results in the self-emitted flux dominating this region even when the surface has a high reflectance. Even though the self-emitted thermal radiant flux is very low at microwave wavelengths, the atmosphere is nearly transparent permitting successful application of passive microwave remote sensing.

Target interactions

Surface irradiance ($I_{T\lambda}$) (e.g., solar in passive, instrument in active) interactions with earth's features can be partitioned following Kirchhoff's law (a restatement of the conservation of energy) as the proportion of $I_{T\lambda}$ reflected ($\rho(\lambda)$), transmitted ($\tau(\lambda)$) and absorbed ($\alpha(\lambda)$), that is, $\rho(\lambda) + \tau(\lambda) + \alpha(\lambda) = 1$. These interactions are commonly described as finite volume or surface averages of discrete elements, such as algal cells in water, leaves in a canopy, pebbles on the soil surface, and aerosol particles in the atmosphere. If the aggregate properties associated with these elements are independent of changes in $I_{T\lambda}$ and the method of measurement, they are referred to as inherent, the desired quantity to extract from the target radiance ($L_{T\lambda}$) (Bukata *et al.*, 1995). Other definitions include the specific conditions, particularly the view (θ_v) and local incident (θ_i) angles (Figure R11), within the definition of inherent optical properties. Under such measurement conditions, inherent optical properties whether describing discrete scatters or averages, reflect, transmit, and absorb the same fraction of $I_{T\lambda}$ unless the material's inherent properties change. Unless the sensor is within the target volume (transmittance), a remote sensing sensor only measures the net result of the reflectance, transmittance, and absorption summed over the target (pixel) (including depth) and generalized to a single source and view (normally θ_v and θ_i) as r_λ. The resultant target reflectance (r_λ) represents the measured fraction of $I_{T\lambda}$ reflected ($I_{R\lambda}$) ($r_\lambda = I_{R\lambda}/I_{T\lambda}$, range = 0–1). The source of r_λ (and ultimately $L_{T\lambda}$) is surface and volume scattering, partitioned based on the transmittance depth (Whitt *et al.*, 1990).

VNIR and MIR

If the conditions of the measurement and $I_{T\lambda}$ are clearly specified, r_λ is related to the averaged target properties through the averaged inherent optical properties ($\rho(\lambda)$, $\tau(\lambda)$, and $\alpha(\lambda)$) throughout the surface or volume. However, the $L_{T\lambda}$ is commonly recorded but not irradiance ($I_{T\lambda}$), thus, a factor similar to r_λ and tied to $I_{T\lambda}$ by a geometric distribution related to $L_{T\lambda}$ is needed. In VNIR and MIR, the bidirectional (θ_v and θ_i, bistatic) reflectance distribution function ($BRDF_\lambda$) describes the fraction of $I_{T\lambda}$ reflected over a solid angle (Ω) at θ_v, or the surface distribution of $L_{T\lambda}$ ($BRDF_\lambda = L_{T\lambda}/I_{T\lambda}$). $BRDF_\lambda$ is a function of the incident

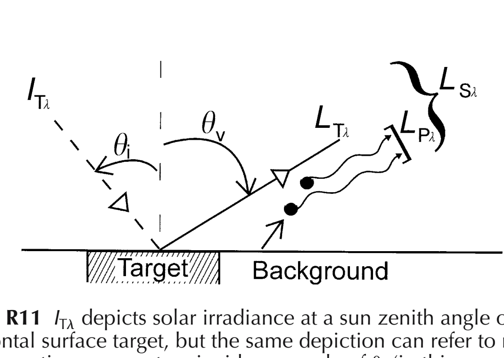

Figure R11 $I_{T\lambda}$ depicts solar irradiance at a sun zenith angle of θ_i on a horizontal surface target, but the same depiction can refer to radiance from an active source at an incidence angle of θ_i (in this case θ_i and θ_v may be equal although the direction of the incident and reflected (backscattered) fluxes would be opposite). $L_{T\lambda}$ depicts the reflected or scattered radiance from the target at θ_v, the sensor view zenith angle. $L_{P\lambda}$ depicts nontarget radiance added to $L_{T\lambda}$ from atmospheric scattering (● being the scatter center) and from areas surrounding the target (background). $L_{S\lambda}$ is the radiance at the sensor.

(ϕ_i) and view (ϕ_v) azimuths, θ_i, θ_v, and Ω_s subtended by the source at a point on the surface, and Ω_v subtended by the entrance pupil of the sensor at the surface, that is, $\mathrm{BRDF}_\lambda(\theta_I, \phi_i, \theta_v, \phi_v, \Omega_s, \Omega_v)$ (Jensen, 2000).

Emitted energy

In thermal radiometry, the target or source emissions depend on the target contact kinetic temperature (KT) and the emissivity ($\varepsilon(\lambda)$). The $\varepsilon(\lambda)$ of a target equals $1 - \rho(\lambda)$ (when $\varepsilon(\lambda) = \alpha(\lambda)$, all transmitted incident Φ_λ is absorbed) and is the ratio of the emission spectral characteristics to a blackbody at the same temperature. The $\varepsilon(\lambda)$ relates KT to the self-emitted Φ_λ ($T_R(\lambda)$) from the target (i.e., $T_R(\lambda) = \varepsilon(\lambda)^{1/4} \cdot \mathrm{KT}$). Because of this relationship, materials with equal KTs but different $\varepsilon(\lambda)$s will have different $T_R(\lambda)$s or in terms of the sensor, $L_{T\lambda}$s. Passive microwave intensity is the product of $\varepsilon(\lambda)$ and KT and is usually reported as brightness temperature. The $\varepsilon(\lambda)$ determines the energy from the effective emitting layer that is transferred across the soil surface, and it is dominated by surface soil moisture, and soil moisture dampens thermal and microwave emissions. In nonvegetated areas (e.g., deserts, oceans), atmospheric influences (including clouds) pose a problem to retrieval of the $T_R(\lambda)$ and therefore KT based on thermal radiometry. In vegetated areas, the vegetation adds to and attenuates the soil emissions; thus, $T_R(\lambda)$ detected at the sensor as $L_{T\lambda}$ contains emitted information proportional to both the vegetation and the soil layer. In passive microwave, the single scattering albedo and the optical depth describe microwave interactions and emissions from the overlying vegetation layer. In most cases, the effects of the single scattering albedo appear small and can be incorporated into the optical depth or set to a constant value.

Radar

The scattering properties of discrete targets (in isolation) are described by the radar cross-section (RCS, m^{-2}). As in optical cross-sections, the RCS symbolizes the interaction cross-section or the target backscatter reflectivity, not the actual target area (Raney, 1998). Flux reflected or scattered to the sensor is the product of the incident radiant flux and RCS normalized by propagation losses and the area of the receiving antenna (Zebker *et al.*, 1990). In typical resource applications, the radar signal recorded per pixel is the coherent summation of reflected (backscattered) energy from all scatterers (relative to the wavelength) in the distributed or diffuse target back to the sensor (Massonnet and Feigl, 1998). As such, the recorded flux depends on the target or pixel area. The backscatter coefficient ($\sigma°(R, A)$ at a specific range (R) and azimuth (A) location) generated from the calibrated return and normalized by the target area (corrected for the local incidence angle) (where, $\sigma°(R, A) \cdot \Delta R \cdot \Delta A / \sin \theta_i(R)$ is equivalent to RCS) represents the measured fraction of incident Φ_λ backscattered ($\Phi_{b\lambda}$) from the target, $\sigma° = \Phi_{b\lambda}/\Phi_\lambda$ (Raney, 1998). As in reporting BRDF (albeit at one angle, monostatic), $\sigma°$, at a specific wavelength, incident direction and polarization, is most closely related to the size, shape, orientation, and composition (primarily water content) properties of the diffuse target. Changes in $\sigma°$ reflect the variability of these diffuse targets to send the incident energy back to the sensor (Massonnet and Feigl, 1998). A positive $\log(\sigma°)$ in decibels implies focusing energy toward the sensor, while a negative number implies focusing energy away from the sensor (Elachi, 1987).

Synthetic aperture processing (focusing) creating synthetic aperture radar (SAR) (NASA, 1989) is used to improve the radar's spatial resolution. Within the processing, signal return variability is related to successive observations of the same area but from slightly different positions and somewhat different fine details in neighboring pixels with the same RCS (grainy appearance of image) (Elachi, 1987). Increasing the number of looks (statistical averages of the radar returns) reduces these effects but decreases the effective spatial resolution. Contrary to the total solar irradiance, polarimetric radar is capable of synthesizing well-defined polarization states represented in the linear case by horizontal and vertical orientations. After standard processing and image construction, phase information related to the distance between the sensor and the target can be linked to the polarimetric return (Elachi, 1987; Zebker *et al.*, 1990). An interferogram is the resulting phase difference between two SAR images collected either from two antennae (bistatic) from a single platform or one antenna (monostatic) at two different times (Massonnet and Feigl, 1998). In the latter case, the direction of observation and wavelengths must be identical, and in practice, the input images are collected from the same satellite in the same orbital configuration and focusing or synthetic aperture processing (SAR) of the original image data are identical.

Both imaging and non-imaging radar sensors are commonly used in today's remote sensing applications. Altimeters use radar's ranging capabilities to measure the surface topography profile to centimeter-level precision at relatively high pixel spatial resolutions. This level of precision requires precise measurement of time and information extracted from the shape and slope of the returned pulse. Scatterometers assess the average scattering properties over large areas and within narrow spectral bands and provide directional capability by including more than one antenna (Elachi, 1987). They provide high precision backscatter measurements that cover large areas but at low pixel spatial resolutions (Cavanie and Gohin, 1995). Imaging SAR sensors are most often used for resource mapping because of their ability to provide high pixel spatial resolution data at multiple wavelengths, polarizations, and incident angles.

In all cases, objects of comparable size to the microwave wavelengths (mainly 2–30 cm in satellite imaging of earth's resources) most strongly influence the microwave scatter. At a constant incidence angle, canopy components such as leaves and stems normally interact with microwave wavelengths from about 2 to 6 cm, and trunks and limbs at longer wavelengths (10–30 cm). Longer wavelengths (>30 cm) provide more information about the surface properties but little about the canopy volume. Use of cross polarizations (e.g., horizontal send and vertical return, HV) and higher incidence angles, however, enhance volume scattering relative to lower (more vertical) incidence angles and like polarizations (e.g., VV, HH).

Applications of remote sensing in coastal ecosystems

Polarization, angles of incidence and view, proportions of direct and scattered irradiance, and surface roughness all work to modify and build a directional reflectance character that becomes the target radiance ($L_{T\lambda}$). $L_{T\lambda}$ can be further altered from the surface to the satellite ($L_{S\lambda}$) by attenuation and addition of path radiance ($L_{P\lambda}$) (Figure R11), especially in the VIS but also in the NIR, MIR, and thermal regions and further modulated from the sensor to its representation on the image. In short, uncovering the relationship between $L_{S\lambda}$ output as a pixel in a grid-based image representation and the inherent properties of the target is often highly complex, and many times may be impossible to fully determine. Accountability can be built into the analysis by linking the image data to site-specific measurements through physical-based models. Greater accountability can diminish the reliance on gathering site-specific data and ultimately advance the operational and accurate representation of the temporal and spatial distributions of biophysical features in the scene.

The generation of the bidirectional reflectance distribution function (BRDF_λ) or radar backscatter coefficient ($\sigma°$) is required when target inherent properties are sought or when the spectral contrast between the target ($L_{T\lambda}$) and its surroundings at the sensor prevents successful classification of the target. Classifications can be improved by generation of BRDF_λ or $\sigma°$; for example, biomass estimates are improved when generated from $L_{T\lambda}$ (top of canopy after atmospheric correction) versus $L_{S\lambda}$ (top of the atmosphere). Inferential relationships have more promise of extension over space and over time and the detection and mapping of subtle scene features when based on BRDF_λ or $\sigma°$. The consistent success of these detection and monitoring methods based on remote sensing data requires a rudimentary estimation of the relative extent the target material reflects, transmits, and absorbs surface irradiance ($I_{T\lambda}$) under various geometric and $I_{T\lambda}$ conditions.

Classification

Most often, classification has relied on the differential interactions and responses of VNIR and MIR (e.g., spectral signature or $L_{T\lambda}$) to changes within the coastal scene to provide spectral classes uniquely linked to the type and state of coastal features. These classifications generally use simple image-based parametric statistical models (e.g., clustering techniques, principal component analysis, canonical correlation, discriminant analysis) that do not require detailed information about the plant, canopy, or water optical properties. The developed relationships are commonly limited to conditions existent only during the data collection, and are not necessarily extendable temporally or spatially. Integrating data from multiple remote sensors (VIS to microwave, hybrid models) has successfully improved the spatial detail of coastal vegetation classifications (Ramsey *et al.*, 1998), as have newer classifications based on nonparametric statistical models (e.g., neural network analysis) that allow greater control in linking the classification to the biophysical characteristics.

Classification of the radar images can follow the commonly used procedures of VNIR and MIR classifications (Ramsey *et al*., 1998), while also enhancing the use of neighborhood information or image texture in the classification. Radar image texture is a combination of the system and scene features. System texture (speckle) can be diminished by increasing the number of looks or can be estimated and removed by averaging the radar return over undisturbed water bodies. The improved or corrected measure is a more accurate representation of scene texture and a more pertinent input into the classification process. A more direct method is developed on rule-based logic (van Zyl, 1989; Dobson *et al*., 1995). In one method, returns associated with single or combinations of SAR sensors of different wavelengths and polarizations from sites with known structural characteristics are used to generate a progressive classification hierarchy. In another, rules based on predicted polarimetric return signatures from different features are used to classify targets within the scene.

Biophysical features

Vegetation type classifications are not always the primary objective of the remote sensing application. Often the objective is to directly link the remote sensing data to biophysical variables that describe the coastal ecosystem. Of the biophysical variables, leaf area index (LAI) is probably the most sought, and it can be related to wetted or total biomass and in certain instances primary productivity and even CO_2 exchange.

In the VNIR, the ability to map canopy LAI and productivity is based on two facts (Horler and Barber, 1981; Smith and Morgan, 1981). First, although biomass and yield depend ultimately on light absorption, the usually close correlation between leaf reflectance and transmittance provides a basis for remote sensing reflectance measurements to be successfully applied in agronomic applications. Second, there is a striking attenuation difference between the red and NIR. NIR is not significantly absorbed and is nearly equivalent to above-canopy flux while the red is strongly absorbed and is therefore nearly equivalent to flux transmitted between the canopy leaves. Thus, the degree of canopy shading is related to both the LAI and the differential interactions of red and NIR as described numerically by a vegetation index (VI). In the VNIR, two types of VI are commonly used to transform remote sensing data into estimates of LAI: those based on ratio transforms and those based on orthogonal transforms. These VIs can be modified and possibly improved by altering the required input bands, or by precorrecting the image data to account for atmospheric influence, but variability remains related to the canopy $BRDF_\lambda$, or primarily to canopy structure.

Because the three-dimensional (3-D) distribution of water within the canopy has the greatest influence on microwave interactions, and because wetted biomass is related to vegetation water content, passive microwave and radar remote sensing are sensitive to LAI, and in turn, biomass variations. Similar to VNIR to MIR ratios and differences, biophysical variables such as LAI can be related to radar copolarized (e.g., HH, VV) and cross-polarized (e.g., VH) ratios and differences (Wegmuller and Werner, 1997). The vegetation biomass distribution (canopy structure) and quantity (water content) are also related to canopy optical depth that in turn is related to emission variability at microwave wavelengths (Wigneron *et al*., 1995).

Vertical canopy profiling

Vertical canopy profiling is an indirect result of using multispectral remote sensing systems. Canopy profiling can be used to estimate canopy architecture, an indicator of species variety, phenological stage, and present and past vigor (Malet, 1996). In general, the longer wavelengths transmit further into fully formed vegetation canopies relative to shorter wavelengths. Canopy structure, or the spatial distribution and orientation of the canopy elements, however, also influences canopy penetration and must be removed or accounted for before the variable return can be used to describe the canopy architecture. Typically, NIR to MIR wavelengths transmit from 8 to 10 leaf layers (equivalent LAIs) into the canopy and VIS wavelengths from 2 to 3 LAIs. Although there are notable exceptions, active sensors offer a greater ability to profile the response from various depths within the vegetation canopy as compared to passive sensors. The use of shorter to longer radar wavelengths, multiple incident angles probing with a single band, and multiple polarizations can offer variable depths of transmittance although the analogy becomes less straightforward in canopies with convoluted branching (Ramsey, 1998). LIDAR offers the most direct canopy profiling. By using the allometric relationship between tree height and diameter-at-breast-height, LIDAR can provide volumetric representation of the canopy structure.

Vegetation stress

One of the greatest challenges to coastal remote sensing is detecting plant stress before irreversible losses occur due to changes in inundation, flushing water salinity, and other external forces as a result of sea-level rise and shoreline alteration and protection. Although broadband VNIR to MIR remote sensing applications have detected broad indicators of vegetation stress, hyperspectral systems have identified specific spectral features related to stress from metal contamination to deficient foliar water content (Card *et al*., 1988). Radar is sensitive to vegetation stress through changes in water content, and because optical depth is linked to water content, passive microwave and thermal radiometry are closely related to plant stress. Chlorophyll_a fluorescence can also be used to assess vegetation stress by providing estimates of photosynthetic capacity (Carter *et al*., 1996). A passive technique using Fraunhofer line radiometers (FLR) detects the absorbed photosynthetic radiant flux (about 3%) re-emitted as fluorescence by taking advantage of the relatively strong Fraunhofer absorption lines in the solar irradiance (Horler and Barber, 1981; Carter *et al*., 1996). One of the strongest Fraunhofer lines is located in the chlorophyll fluorescence peak providing a convenient method for identifying plants suffering from metal toxicity and water stress. Active laser-induced fluorescence (LIF) sensors also provide the ability to assess the fluorescent properties of the leaf pigments (e.g., chlorophyll). Both passive FLR and active LIF offer new capabilities to isolate the alteration or change in dominance of specific pigments as an early indicator of vegetation stress.

Thermal radiometry

In dry environments (e.g., nearly constant emissivity (ε_λ)), the rate of temperature change in response to variable surface solar irradiance (I_T) can be used to uniquely identify the target material (e.g., soil composition, mineral) (Lillesand and Kiefer, 1994). To characterize the rate materials respond to temperature changes (thermal inertia), radiant temperature ($T_R(\lambda)$) measurements are collected in the early morning and the afternoon. This temperature difference indicates the variable heat capacity of the different materials and can be used to map landcover variation. Heat capacity mapping has been applied mostly in nonvegetated regions for identifying geologic materials. Intense heat sources, however, can often be directly observed. Fires can exhibit self-emitted thermal fluxes down to about 3.0 μm, and some volcanic lava flows as low as the NIR (0.7–1.3 μm).

Area mixtures

In any remote sensing application, all pixels are weighted mixtures of different scene features, even when the pixel nearly matches the target feature's mean spatial extent (e.g., adjacency effects, boundary pixel landcover mixtures). Mixture models are used to extract the occurrence of specific scene features from composite mixtures (e.g., trees, water, bare ground). In a linear mixture model, weighted combinations of specific scene features (e.g., spectral endmembers) are combined to completely reconstruct every spectral signature ($L_{S\lambda}$ or $L_{T\lambda}$) as represented on the image. This reconstruction allows target features to be detected and the percent occurrence in each image pixel to be determined. In nonlinear endmember analysis, the interaction between target features is included. Mixture models can be based on broadband sensor data; but most successful applications are based on hyperspectral sensor data (Adams *et al*., 1986).

Soil moisture content

The NIR to MIR regions are used to estimate soil moisture where the increase in soil moisture (as in the presence of standing water) dampens the return to the sensor. Successful studies have relied more on direct determinations with thermal radiometry and passive microwave and radar (Idso *et al*., 1978; Ulaby *et al*., 1983; Shutko, 1992; Kostov and Jackson, 1993; Chanzy *et al*., 1995; van de Griend *et al*., 1996). As noted, decreases in moisture content are associated normally with decreases in the radiant temperature ($T_R(\lambda)$). In the thermal region, emissions are constrained to within 50 μm of the surface and this shallow depth can exhibit rapid temperature variations. Even though monitoring diurnal temperature variations in the thermal region may improve the moisture content estimation, microwave is the only remote sensing platform and technique that can provide soil moisture with reasonable precision and consistency.

Both radar and passive microwave sensors are sensitive to non-bound water, and in general, sandy soils hold less bound water than clays. Normally, microwave is sensitive to soil moisture content within the top 2–5 cm of the soil depth (Chanzy *et al*., 1995). In exceptional conditions, radar can detect changes in moisture content at depths greater than 1 m, and passive microwave returns have been related to moisture content and groundwater at depths exceeding 1 m (Reutov and Shutko, 1992). Up to saturation, soil moisture acts to enhance the radar return at any given soil surface roughness height; in some cases, surface roughness variability can severely hamper the ability of radar to estimate changes in soil moisture (Ramsey, 1998). Radar is sensitive to soil moisture under short vegetation canopies; however, where moderately dense, the detection of soil moisture depends on the relative strength of the vegetation canopy and the incident flux interaction (Dobson *et al*., 1995). Surface roughness increases also enhance passive microwave emissions and can enhance soil emissivity differences between wavelengths. For most natural surfaces, however, roughness is not a serious limitation, and in wet soils, emissivity differences may be minor (Wang *et al*., 1987; Engman and Chauhan, 1995). In most soils, passive microwave emissions are practically independent of soil type, salinity, bulk density, and temperature variability (Shutko, 1992; Engman and Chauhan, 1995), but overlying vegetation attenuation increases as water content increases (van de Griend *et al*., 1996). In both passive microwave and radar, in general, the transmission through the vegetation canopy increases with increasing wavelength. Thus, longer wavelengths, HH polarization, and steeper incident angles are preferred for sensing soil moisture through a vegetation canopy.

Shoreline placement

The delineation of land and water is important in coastal classifications, land loss, and shoreline displacement. Accurate mapping of coastal shoreline (defined as the high water line or wet–dry boundary) placement requires not only high spatial resolution sensors but also the spectral ability to provide contrast between open water and the regional nearshore material. Historically, optical sensors (especially photographic) have provided image data used for shoreline mapping, but more recently, radar image data have been used to construct shorelines (Lee, 1990; Ramsey, 1995). Coastline detection and automated tracing algorithms are being developed to provide dynamic shoreline construction. In the case of radar, scatter from roughened open water at times can limit the ability to differentiate land and water areas. In addition, a shoreline position is dynamic, especially in coastal regions experiencing high tidal ranges. Consequently, to truly represent the shoreline position, the variation in the tidal height relative to mean high tide and the occurrence of influencing forces such as wind set-up or set-down or abnormal river runoff must be accounted for at the time of the measurement.

Flood monitoring

Remote sensing can detect flooding under vegetation. VNIR to MIR have been used, but microwave remote sensing offers the greatest potential for the instantaneous and consistent determination of flood extent. Within the microwave region, the most extensive history of flood detection under vegetation has been associated with radar (Ramsey, 1998). The radar return from flooded forest is usually enhanced compared to returns from nonflooded forests. The enhancement is related to the double bounce mechanism where the signal penetrating the canopy is reflected off the water surface and subsequently reflected back toward the sensor by a second reflection off a tree trunk (Hess *et al*., 1990). In contrast, diminished returns from flooded relative to nonflooded coastal marshes have been observed (e.g., Ramsey, 1995). The marsh grasses may calm the water surface accentuating specular reflection but without the grasses providing the double bounce (Ormsby *et al*., 1985). As in soil moisture mapping, flood detection can occur only if transmitted through the canopy; thus, longer wavelengths, HH polarization, and steeper incident angles are preferred.

Topography

Coastal topography controls the hydrology of the coastal wetlands, and thereby the distribution and health of the coastal vegetation. Offshore coastal bathymetry is a result of the dynamic forces of local erosion and sedimentation and littoral drift. Mapping and monitoring the onshore topography and offshore bathymetry is of vital importance to the coastal engineer and resource manager. Historically and currently, indirect methods based on the simultaneous viewing of overlapping images (parallax) are commonly used to generate topographic information. Methods based on passive optical remote sensing also have been used to map coastal bathymetry, but these methods are limited by severe and variable attenuation by the water column materials (Ji *et al*., 1992; Lyon *et al*., 1992). Besides audio-mechanical systems (sonar), radar and LIDAR systems offer a direct and more consistent approach to surveying coastal topography and bathymetry.

After processing and most orbital contributions have been eliminated from the interferogram (radar phase difference image), slight remaining differences in the point of view of the radar sensor yield fringes that follow the topography (Massonnet and Feigl, 1998). These topographic contours can be used to generate a digital elevation model (DEM). Additionally corrected for elevation and local elevation gradient (slope) spatial variances, the interferogram can be related to finer resolution topographic changes from deformation (e.g., coastal volcanoes, surface subsidence, erosion, rebound, or deposition). In monostatic systems, success of this technique requires all scatters comprising the target (e.g., overlying vegetation, moisture content, inundation) remain unchanged between the time of the two radar image collections (Massonnet and Feigl, 1998). While successful application is problematic in vegetated environments, absolute stability, and thereby success, in dynamic and highly vegetated coastal environments is less probable. Frequent and variable flooding and the associated changes in soil and vegetation moisture contents add complexities that appear as random speckles in the interferogram. In coastal areas, these complexities may limit the absolute elevation and elevation change resolutions attainable with interferograms generated from monostatic systems.

Airborne laser altimetry (ALS) is the simplest application of LIDAR remote sensing. ALS surveys are primarily performed at 700–1,000 m above ground level in order to eliminate most atmospheric attenuation of the signal. As in radar systems, when properly calibrated to a stable platform, the time between the emitted and detected pulses is directly related to the range, and thereby to changes in the surface elevation. Vegetation interferes with the laser pulse and complicates conversion of the ALS image into a topographic surface. Reflectance of solar illumination into the sensor field of view within the laser operational bandwidth also corrupts the ALS signal. A correction for vegetation interference and contamination uses data collected near in time along multiple transects to develop a topographic precision estimate.

Bathymetry

ALS is also used to develop coastal bathymetry maps. Most current ALS systems use two wavelengths: a green band for high water penetration to the bottom and a NIR band with little to no water penetration and almost total reflectance from the surface. Use of the two-band system helps diminish errors resulting from platform altitude variation so that the time delay difference between the two return pulses is a direct bathymetric measure. Increased turbidity, however, results in lower spatial resolutions and increased water volume backscattering of the emitted pulse creates false echoes in the record. The low altitude and fairly narrow coverage of current ALS systems hamper the operational feasibility of these systems in regional assessments. Even with these limitations, of all the electromagnetic systems, the ALS systems may provide the only feasible mechanism for rapid and consistent detailed mapping of coastal bathymetry and wetland topography.

Water quality and submerged aquatic vegetation

Remote sensing of estuarine and coastal waters is primarily concerned with mapping the type, concentration, distribution, and dispersion of materials suspended and dissolved in the water (water quality) (Morel and Gordon, 1980; Ramsey and Jensen, 1990), and the type and distribution of submerged aquatic vegetation and bottom cover (e.g., rock, mud, sand, shell). To accurately map the water quality and bottom type, the radiant flux depth-intensity and spectral distribution must be estimated (Kirk, 1980). In a well-mixed water column, the underwater radiation environment is determined by reflection and refraction at the water–air interface (surface), absorption and scattering within the water body, and reflection from the bottom. Surface reflections of $I_{T\lambda}$, upwelling restrictions (due to refraction at the surface), added atmospheric path and background fluxes, and atmospheric attenuation result in the upwelling water volume flux (below the water surface) transferred through the surface ($L_{T\lambda}$) normally comprising only 3–5% of the sensor signal ($L_{S\lambda}$). Corrected for water surface reflection, transmission, and atmospheric influences, $L_{T\lambda}$ can be related to the inherent bulk absorption and scattering properties of the water and water materials and bottom reflectance in the shallow waters (Morel and Gordon, 1980; Carder and Steward, 1985).

Excluding bottom reflections, the inherent bulk absorption ($\alpha(\lambda)$) and backscatter ($b_b(\lambda)$) coefficients can be related to $L_{T\lambda}$ as $L_{T\lambda}/I_{T\lambda} = \mathrm{BRDF}_\lambda = C_F \cdot b_b(\lambda)/\alpha(\lambda)$, where backscattering is scattering into the hemisphere trailing the incident flux, and C_F incorporates the ratio of two subsurface upwelling fluxes and the water refractive index (Carder and Steward, 1985; Bukata *et al.*, 1995). In optically complex coastal waters, bulk $b_b(\lambda)$ and $\alpha(\lambda)$ are commonly related to bulk descriptors of biomass (e.g., chlorophyll-a [Chl]), suspended materials (SMs) (e.g., detritus, suspended inorganic particles), and dissolved organic carbon (DOC) (Bukata *et al.*, 1995). Use of these bulk descriptors normally provides a good and stable estimation of water quality with respect to location and time in coastal environments. The inherent bulk properties are related to the specific optical coefficients (i) as $b_b(\lambda) = \Sigma C_i(b_b)_i(\lambda)$ and $\alpha(\lambda) = \Sigma C_i\alpha_i(\lambda)$, where the subscript ($i$) represents one water component and C_i refers to the components concentration (e.g., $\alpha(\lambda) = a_w + C_{Chl}\alpha_{Chl}(\lambda) + C_{SM}\alpha_{SM}(\lambda) + C_{DOC}\alpha_{DOC}(\lambda)$, where a_w is absorption due to the water).

LIDAR systems can be used to stimulate fluorescence in chlorophyll pigments associated with phytoplankton, plants and corals, and fluorescent DOC (i.e., Gelbstoff) (Measures, 1984). As in passive optical remote sensing of water quality, the signal returned to the sensor can be corrupted by the atmosphere and by addition of reflectance from the bottom. The selection of the excitation (send) and emission (return) wavelengths is either fixed by the LIDAR system or optimized by laboratory measurements. Chlorophyll is normally determined by excitation in the low red and measuring the emission in the high red wavelength regions. Gelbstoff is linearly related to natural fluorescence (Otto, 1967) that has been used as a conservative tracer of riverine and ocean waters mixing. Natural fluorescence is normally determined by excitation in the ultraviolet and by measuring the fluorescence in the blue. As in canopy profiling, the fluorescent return can be scattered or self-absorbed before reaching the water surface, causing ambiguity in mapping the concentration of the fluorescent material. Raman intensity variability can be measured simultaneously with the fluorescent return and used to remove the effect of self-absorption, thereby creating spatially comparable fluorescent images (Bristow *et al.*, 1981).

Bottom reflectance

Seagrasses and bottom type (mud, sand, shell) mapping is an important aspect of coastal monitoring. In this case, the overlying water column attenuates the signal to and from the bottom. In both passive VNIR and LIDAR mapping, the same problems apply as in water quality monitoring; however, in this case, the overlying water column signal must be removed from or de-emphasized in the return signal (Ji *et al.*, 1992; Lyon *et al.*, 1992). Increasing water turbidity and absorption can severely restrict the ability of either method (passive VNIR and LIDAR) to accurately map bottom reflectance variations as does low contrast between the different bottom materials.

Surface films and salinity

Observation of surface water features, especially surface films, has long been recognized as an indirect method of mapping convergence zones, mixing zones, and internal wave fields in optical oceanography (Klemas, 1980). The natural and extracted oils and similar substances also can be observed by SAR systems because they tend to dampen the creation of surface waves, smoothing the water surface, and attenuating the SAR returns. This differential dampening enables SAR sensors to map and monitor surface spills, and because of its nearly all weather capabilities, SAR provides capabilities many times superior to VNIR and MIR. Laser Induced Flouresence (ultraviolet excitation, visible emission) has also been used to detect and classify oil slicks and oil film thickness (Measures, 1984).

Of the possible conservative tracers of water mass mixing, salinity is the most notable. Salinity is not directly measurable with VIS to thermal systems (ignoring extremely slight dependencies), although salinity changes have been inferred from changes in other water properties, such as fluorescence and suspended particle concentrations. A more direct measure is based on the definition of salinity as the concentration of dissolved cations and anions. Changes in these concentrations change the water's ionic strength, leading to changes in the dielectric properties of the water that are most apparent at microwave wavelengths. These changes are best observed as changes in the emissivity, although to accurately observed changes, microwave emissions must be corrected for water temperature and surface roughness variations. To accomplish this correction, microwave measurements are collected at two wavelengths, obtaining a direct method to map changes in water salinity (Shutko, 1985).

Sea surface temperature

One of the earliest uses of radiometry was to map the sea surface temperature (SST) and thereby map different water masses and physical dynamics (e.g., frontal convergence, upwelling). Along the same line, water temperature mapping of heated effluents into rivers, estuaries, and coastal oceans is used to monitor compliance of discharges. In each of these radiometric applications, the radiant temperature ($T_{R\lambda}$) is related to the 3–5 μm thick surface skin by converting via emissivity ($\varepsilon(\lambda$, water)) to the skin kinetic temperature (KT). On average, surface skin temperatures are about 0.3 K cooler than bulk temperatures, but differences can range from about +1 to −1 K (Emery *et al.*, 1995). Depending on the water stability or the amount of mixing, the bulk temperature can represent the well-mixed surface layer or the temperature gradient depth. Often the skin $T_{R\lambda}$ (radiometer measurements) is related to the bulk KT or SST by breaking the surface skin with buckets of water (i.e., bucket temperature). Ship intakes and moored buoys offer bulk temperature measurements at variable depths. These measurements are used to correct atmospheric influences (especially water vapor) and consequently directly relate the sensor signal ($L_{S\lambda}$) to the SST, aggregating skin effects into atmospheric correction (Minnett, 1995). A separate type of atmospheric correction relates $L_{S\lambda}$ to atmospheric attenuation and thereby to the skin KT. Atmospheric effects are inferred from spectral relationships based on multiple band measurements (e.g., $\mathrm{SST} = a_0 + a_\lambda \mathrm{KT}_\lambda$, where λ refers to one or a combination of bands) (Emery *et al.*, 1995; Minnet, 1995). Alternatively, measurements of the same target but at different sensor view angles provide a direct measurement of atmospheric influences ($\mathrm{SST} = b_0 + b_{\lambda,N}\mathrm{KT}_N + b_{\lambda,S}\mathrm{KT}_S$, where N is nadir, S is oblique views, and λ refers to one band or a band combination). Based on current correction techniques, skin and bulk surface water temperatures can be estimated to less than 0.5°C. Even though less influenced by atmospheric conditions, the coarse spatial resolution associated with passive microwave systems makes them less preferred than thermal radiometry. Further, even at longer wavelengths, passive microwave measurements have shown dependence on surface roughness as a function of wind speed (Shutko, 1985; Trokhimovski *et al.*, 1995).

Sea ice

Detection and monitoring the distribution and type (first year and multiyear ice) of coastal (Arctic) sea ice is important in marine mammal ecology, climate processes, and early detection of global warming (Piwowar and LeDrew, 1996). Operational methods until recently have been applicable only to broadscale spatial inventories. More recently, optical, passive microwave, and radar sensors have provided higher spatial resolutions; however, increasing spatial resolution beyond 1 km constrains the ability to operationally monitor global or hemispheric regions. The primary factor controlling the remote sensing of sea ice is emissivity ($\varepsilon(\lambda)$), and the major factor controlling emissivity is salinity (Comiso, 1995). In thermal radiometry and passive microwave, the effective emissivity decreases from the cold saline first-year to the cold desalinated multiyear ice. Emissivity also decreases from first-year to multiyear ice due to the decreased density and increased surface roughness resulting in increased surface scatter. Added to this overall change, emissivity varies with wavelength and polarization. First-year ice is nearly independent of wavelength and polarization while emissivities of both VV and HH polarizations associated with multiyear ice increase with wavelength (Comiso, 1995). SAR returns tend to increase from first-year to multiyear ice (Drinkwater, 1995). In radar imaging, shorter wavelengths scattered from the ice surface primarily respond to dielectric differences (salinity) and roughness, while longer wavelengths (>5 cm) penetrate the ice (multiyear >> first-year) and are returned via volume scattering. Use of longer wavelengths normally results in a higher return from the relatively lower salinity and density multiyear ice than other ice types (Drinkwater, 1995). Of the three sensors, optical sensors are constrained by persistent clouds and darkness in Arctic regions, and radar returns from roughened multiyear ice surfaces are more prone to confusion with other types of sea ice than are emissions sensed by passive microwave sensors (Hall, 1998). Integrated approaches seem to provide the best results and the added benefit of comparison and validation.

Wind speed and surface waves

Short gravity (>1.7 cm) and small capillary (<1.7 cm) waves are the surface water features observed with operational radar systems (2–30 cm wavelengths) (Elachi, 1987). Increasing near-surface wind speed increases the amplitude of these waves, intensifying surface roughness that in turn promotes increasing slope (specular or facet) reflections and point scatter (or Bragg). As wind speed is related to surface roughness, altimeter and scatterometer sensors can provide estimates of wind speed (U). Scatterometers provide regional coverage, but at coarse pixel resolutions, while altimeter measurements cover narrow swaths. In the case of altimeters, σ^0 is a result of near nadir specular reflections (facet) that decrease as surface roughness increases ($\sigma^0 \propto U^{-x}$) (Elachi, 1987; Dobson, 1995). Although designed for measuring open ocean winds, scatterometers have also been found useful in measuring winds in coastal and enclosed seas. σ^0 derived from scatterometer measurements increases with wind speed increases (at >25° incident angle) as $\sigma^0 \propto U^x$ (x is dependent on wavelength) and are principally a result of Bragg scattering (Topliss and Guymer, 1995). Scatterometers also include multiple azimuths, providing the ability to estimate the wind direction. Wind speed accuracies derived from scatterometers are about 2 m/s with a directional tolerance of 20° (Topliss and Guymer, 1995). Compared to open ocean measurements, altimeter and scatterometer coastal measurements are more difficult to explain based on dynamic processes and are generally plagued by three types of problems: (1) contamination from land–water mixing, (2) varying wind–radar relationships, and (3) substantial influences of temporal and spatial variations in SST resulting in incorrect estimates of σ^0.

Currents and waves

Indirect observation of convergence and divergence zones associated with currents and possibly internal waves through varying surface features is used in optical remote sensing of ocean features (Klemas, 1980). Radar systems, however, offer a nearly unimpeded source of mapping surface features related to ocean dynamics. Short gravity and capillary waves created by wind stress and mechanically (independent of wind stress) are modified (local slope and growth) by long-period gravity or internal waves and variable currents (fronts, eddies, upwelling, tidal circulation) and bottom topography (Topliss and Guymer, 1995). These spatially and periodic modulated small wave fields (bands of roughness) are detectable with altimeters, scatterometers, and SAR imaging. Dependent on the angle of incidence and wavelength, SAR returns can be dominated by either a mixture of Bragg scattering or specular reflections. SAR images are used to define wave direction and length and to map the location of convergence zones and currents.

Water surface topography

Instantaneous sea surface height (S_0) observed by an altimeter is the sum of the geoid (N, a level surface of the earth's gravity field associated with a motionless ocean surface regarded as time invariant), the permanent dynamic topography (ξ_0, related to ocean circulation, $N + \xi_0$ = mean sea level), the variable topography (ξ_v, e.g., ocean tides and waves and swells), orbital and propagation errors (e.g., sensor attitude corrections, barometric correction), and sensor noise ($S_0 = N + \xi_0 + \xi_v$ + error + noise) (Le Traon, 1995). Wave heights from altimeter measurements are related to the shape or rise time of the returned pulse (Dobson and Monaldo, 1995). Increasing wave heights increase the slope or rise time. Large surface-wave heights or swell heights are estimated by differencing wave energy ($\propto$ (wave height)^2) and wave energy associated with wave heights estimated from altimeter wind speeds. In principle, skewness of the generated wave height probability distribution can also be used to estimate the dominant wavelength in unimodal seas (Dobson and Monaldo, 1995).

The low-frequency harmonic rise and fall of the coastal tides can be observed with satellite altimetry with a precision of about 3–5 cm (Han, 1995). Limited sampling frequency associated with altimeter data, however, leads to aliasing shorter tidal periods into longer tidal periods causing ambiguities in tidal period evaluations. Conversely, extraction of tidal fluctuations from the surface height variability is necessary to recover long-term height variability (e.g., annual cycles). As in other coastal applications, increased problems are created by the high temporal and spatial variability in the surface height due to basin morphology (shape and shallow depths ($\approx$100 m)), variable river runoff (buoyancy), solar heating (e.g., SST), wind stress (e.g., Eckman drift), and the surface expression of subsurface features (e.g., sea mounds or submarines).

REMOTE SENSING: WETLANDS CLASSIFICATION

Coastal wetlands are a highly productive and critical habitat for a number of plants, fish, shellfish, waterfowl, and other wildlife. Wetlands also provide flood damage protection, protection from storm and wave damage, water quality improvement through filtering of agricultural and industrial waste, and recharge of aquifers. After years of degradation due to dredge and fill operations, impoundments, urban development subsidence/erosion, toxic pollutants, entrophication, and sea-level rise, wetlands have finally begun to receive public attention and protection (Daiber, 1986). Heightened awareness of the value of wetlands has resulted in the need to better understand their function and importance and find ways to manage them more effectively. To accomplish this, at least two types of data are required: (1) information on the present distribution and abundance of wetlands; and (2) information on the trends of wetland losses and gains.

Coastal wetlands can be conveniently divided into four major types: salt marshes, coastal fresh marshes, coastal forested and scrub–shrub wetlands, and tidal flats (Field *et al*., 1991). Each of these wetland types has different hydrologic requirements and is dominated by a different type of vegetative cover. As a result, their spectral signatures and detectability by remote sensors differ significantly. For instance, salt marshes are widely distributed along the Atlantic and Gulf coasts and are dominated by smooth cordgrass (*Spartina alterniflora*) and frequently include other grasses, such as salt hay (*Spartina patens*) and big cordgrass (*Spartina cynosuroides*). The relative purity and size of salt marshes makes it possible to map them from aircraft and satellites.

Freshwater marshes are relatively diverse and have a more mixed vegetative cover producing a more complex, composite spectral signature. Forested and scrub–shrub wetlands, characterized as woody communities, are regularly inundated and saturated during the growing season. Wooded wetlands resemble spectrally wooded uplands and are therefore difficult to distinguish from wooded upland areas. Combining RADAR data with Landsat TM helps to distinguish wooded uplands from wetlands by providing soil moisture conditions beneath the tree canopy.

Wetlands mapping

Most of the major wetlands mapping programs, conducted by the United States Geological Survey (USGS), the National Oceanic and Atmospheric Administration (NOAA), and the Environmental Protection Agency (EPA), and other agencies, are described in Kiraly *et al*. (1990). Traditionally the US Fish and Wildlife Service (FWS) has played a key role, conducting its first nationwide wetlands inventory in 1954, which focused on waterfowl wetlands. In 1974, the FWS established the National Wetlands Inventory Project (NWI) to generate scientific information on the characteristics of US wetlands, including detailed maps and status/trend reports. The maps are available as 7.5 min quads at a scale of 1 : 24,000. Most have been digitized, converting them from paper maps to a GIS (Geographic Information System)-compatible digital line graph (DLG) format (Tiner, 1985).

The NWI program produced a new classification system and a more rigorous definition of wetlands: wetlands are transitional areas between terrestrial and aquatic systems where the water table is usually at or near the surface or the land is covered by shallow water. Wetlands must also have one or more of the following attributes: (1) at least periodically, the land supports predominantly hydrophytes; (2) the substrate is predominately hydric soil; and (3) the substrate is non-soil and is saturated with water or covered by shallow water at some time during the growing season each year (Cowardin *et al*. 1979). The classification system developed for the NWI by Cowardin *et al*. (1979) is hierarchical, progressing from systems (Marine, Estuarine, Riverine, Lacustrine, and Palustrine) and subsystems (Tidal, Subtidal, Intertidal, etc.), at the most general levels, to classes, subclasses, and dominance types (Figure R12). While suitable for use with field data and aerial photography, this classification system proved too complex for satellite remote sensors, which lacked the spatial, spectral, and temporal resolution required by such detailed mapping efforts. More recently, satellite techniques are being tested for updating the NWI maps and publishing status and trend reports every 10 years. Most coastal states have used aerial photography to map their wetlands in great detail (e.g., scales of 1 : 2,400) in order to satisfy legal or planning requirements.

Remote sensing

Satellite remote sensing of wetlands was attempted, with limited success, as soon as the first Landsat MSS was launched. SPOT with its 20/10 m resolution and Landsat Thematic Mapper (TM) with its six reflected bands and 30 m spatial resolution significantly improved our ability to map large coastal marshes. Using Landsat TM data, NOAA has initiated the Coastal Change Analysis Program (C-CAP) in order to develop a nationally standardized database on land-cover and habitat change in the coastal regions of the United States C-CAP inventories coastal submersed habitats, wetland habitats, and adjacent uplands and monitors changes in these habitats on a one-to five-year cycle with a minimum mapping unit of several hectares. This type of information and frequency of detection are required to improve scientific understanding of the linkages of coastal and submersed wetland habitats with adjacent uplands and with the distribution, abundance, and health of living marine resources. Using a rigorous protocol, satellite imagery, aerial photography, and field data are interpreted, classified, analyzed, and integrated with other digital data in a GIS. The resulting land-cover change databases are disseminated in digital form to users (Dobson *et al*., 1995).

C-CAP developed a classification system, shown in Table R3 to facilitate the use of satellite imagery (Klemas *et al*., 1993). Two study areas in South Carolina were used to evaluate a modified C-CAP classification scheme, image classification procedures, change detection algorithm alternatives, and the impact of tidal stage on coastal change detection. The modified C-CAP Classification Scheme worked well and can be adapted for other coastal regions (Jensen *et al*., 1993). Unsupervised "cluster-busting" techniques coupled with "threshold 3 majority filtering" yielded the most accurate individual date classification maps (86.7–92.3% overall accuracy; Kappa coefficients of 0.85–0.90). The best change detection accuracy was obtained when individual classification maps were majority filtered and subjected to "post-classification comparison" change detection (85.2% overall accuracy; Kappa coefficient of 0.82). The multiple date images selected for coastal change detection had to meet stringent tidal stage and seasonal guidelines (Jensen *et al*., 1993; Jensen, 1996).

Henderson *et al*. (1999) performed a detailed accuracy assessment of coastal land-cover mapping results obtained for Long Island using Landsat TM data and the C-CAP protocol. Table R4 displays two columns of user accuracies for C-CAP classification categories obtained by Henderson *et al*. (1999). The first column shows the user accuracies for the classification based on the raw spectral data, while the second column shows the accuracies after the data was recoded and filtered using ancillary verification data sets. Table R4 indicates that originally there were considerable errors in some categories, such as the Palustrine Wooded and Cultivated. However, as shown in Table R4, incorporation of ancillary data layers (e.g., aerial photographs, NWI wetland maps, etc.) increased the user accuracies of most categories into the upper 90% range, with the lowest, "Cultivated," attaining 86% (Henderson *et al*., 1999).

Table R3 C-CAP coastal land-cover classification system[a]

Upland	Wetland	Water and submerged land
Developed land	Marine/estuarine rocky shore	Water
Cultivated land	Marine/estuarine unconsolidated shore	Marine/estuarine reef
Grassland	Estuarine emergent wetland	Marine/estuarine aquatic bed
Woody land	Estuarine woody wetland	Riverine aquatic bed
Bare land	Riverine unconsolidated shore	Lacustrine aquatic bed (basin ≥20 acres)
Tundra	Lacustrine unconsolidated shore	Palustrine aquatic bed basin ≤20 acres)
Snow/ice	Palustrine unconsolidated shore	
	Palustrine emergent wetland	
	Palustrine woody wetland	

[a] Only the upper two levels are shown in this table. The third, more detailed level has been omitted.

Table R4 Comparison of user's accuracy by classification category for combined raw spectral images and composite (including ancillary data) imagery

Category	Raw spectral (%)	Composite imagery (%)
Bare	92.67	93.00
Cultivated	70.00	86.00
Developed	96.67	98.00
Grassland	84.47	95.00
Water	100.00	99.00
Palustrine wooded	46.67	97.00
Palustrine emergent	85.33	97.00
Estuarine emergent	81.13	100.00
Wooded	87.33	89.00

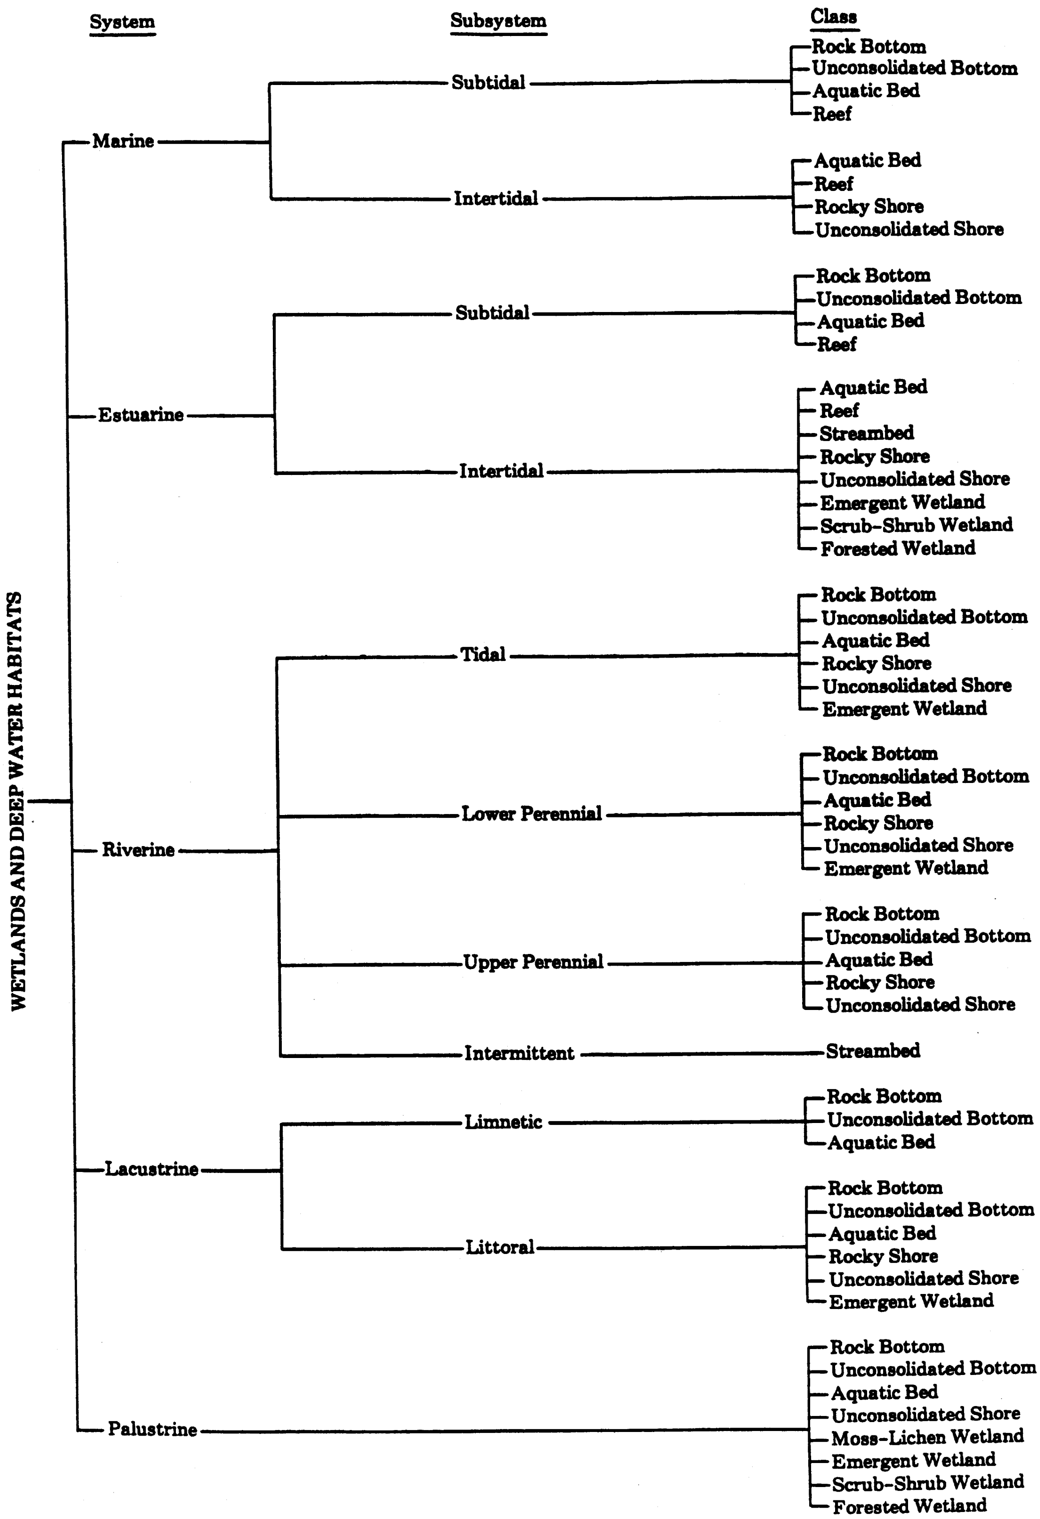

Figure R12 Classification hierarchy of wetlands and deepwater habitats showing systems, subsystems, and classes. The Palustrine System does not include deepwater habitats (Cowardin *et al.*, 1979, Fish and Wildlife Service).

Another way to improve the accuracy of wetland classifications derived from satellite imagery is to use multiple-date (multiple season) imagery. Multi-temporal Landsat TM imagery was evaluated for the identification and monitoring of potential jurisdictional wetlands located in the states of Maryland and Delaware (Lunetta and Balogh, 1999). A wetland map prepared from single-date TM imagery was compared to a hybrid map developed using two dates of imagery. The basic approach was to identify land-cover vegetation types using spring leaf-on imagery, and identify the location and extent of the seasonally saturated soil conditions and areas exhibiting wetland hydrology using spring leaf-off imagery. The accuracy of the wetland maps produced from both single- and multiple-date TM imagery were assessed using reference data derived from aerial photographic interpretations and field observations. Subsequent to the merging of wetland forest and shrub categories, the overall accuracy of the wetland map produced from two dates of imagery was 88% compared to the 69% result from single-date imagery. A Kappa test Z statistic of 5.8 indicated a significant increase in accuracy was achieved using multiple-date TM images. Wetland maps developed from multi-temporal Landsat TM imagery may potentially provide a valuable tool to supplement existing NWI maps for identifying the location and extent of wetlands in northern temperate regions.

Summary and conclusions

Coastal wetlands are valuable natural assets and must be protected and managed more effectively. To accomplish this, timely information on wetlands distribution, abundance, and trends are required. This information can be provided efficiently by remote sensors on aircraft and satellites. Since many wetlands occur in narrow, elongated patches and have complex spectral signatures, satellite sensors on Landsat and SPOT can provide accurate wetland maps only if multi-temporal images are used or significant amounts of ancillary data employed. Fortunately, technology, cost, and need are converging in ways that are making remote sensing and GIS techniques practical and attractive for wetlands mapping and coastal resource management (Lyon and McCarthy, 1995). With the launch of Landsat 7, the cost of TM imagery has dropped by nearly a factor of 10, decreasing the cost of mapping large coastal areas. New satellites, carrying sensors with much finer spatial (1–5 m) and spectral (200 bands) resolutions are being launched and may more accurately map and detect changes in coastal habitat. Advances in the application of GIS are helping to incorporate ancillary data layers to further improve the accuracy of satellite classification of coastal wetlands and land-cover.

RHYTHMIC PATTERNS

Beaches are seldom straight or smoothly curved in the longshore direction. Instead, they commonly include seaward projections of sediment, termed cusps, or embayments locally cut into the shore. Such features may be isolated, but more often occur in groups of alternating cusps and embayments that have a fairly regular spacing; they are then referred to as rhythmic patterns. There are several recognized types of rhythmic patterns, including beach cusps, sand waves, and giant cusps (Komar, 1998).

A wide range of spacings of rhythmic patterns can be found on beaches. Along the shores of ponds and small lakes the spacings between adjacent cusps may vary from less than 10 cm to 1 m. On ocean beaches with small waves, the spacing may be on the order of 2 m, while those built by large storm waves may be 50 m or more. Other rhythmic patterns, sand waves and giant cusps, have still larger spacings, typically ranging from 150 to 1,500 m, but with most being between 500 and 750 m, with the cusps projecting on average some 15–25 m seaward from the embayments.

The classification of rhythmic patterns

In the past, the classification of different types of rhythmic patterns has been based on the lengths of their spacings. Beach cusps were considered to have the smallest spacings, less than 25 m, while sand waves and giant cusps have larger spacings. These latter terms can be considered to be nearly synonymous, different names for the same or very similar features. Research in recent years has led to a better understanding of the formation of the various types of rhythmic patterns, and this now makes it possible to develop a genetic classification that depends on the processes of waves and currents that are responsible for their formation, rather than depending simply on their spacings (Komar, 1998). Furthermore, it is clear that rhythmic patterns having a wide range of spacings can be generated by a single mechanism, and more than one mechanism may be capable of producing rhythmic patterns having the same spacing. It is clear therefore that a genetic classification is needed, one that reflects the processes of formation. Such a genetic classification is depicted in Figure R13 (Komar, 1983), one that distinguishes between beach cusps, systems of rip-current embayments and cusps, series of transverse bars that produce cusps along the shore, and crescentic bars that are chiefly an underwater feature but can produce a rhythmic pattern that extends onto the dry part of the beach. In general, this order represents an increase in cusp spacings, with the latter three mechanisms yielding what had formerly been referred to as sand waves or giant cusps.

Beach cusps as a type of rhythmic pattern

The most easily recognized rhythmic pattern seen on beaches are the cuspate deposits of sand and gravel built by waves and known as beach cusps. Because of their marked regularity with nearly uniform spacings, beach cusps have attracted many observers and much speculation as to

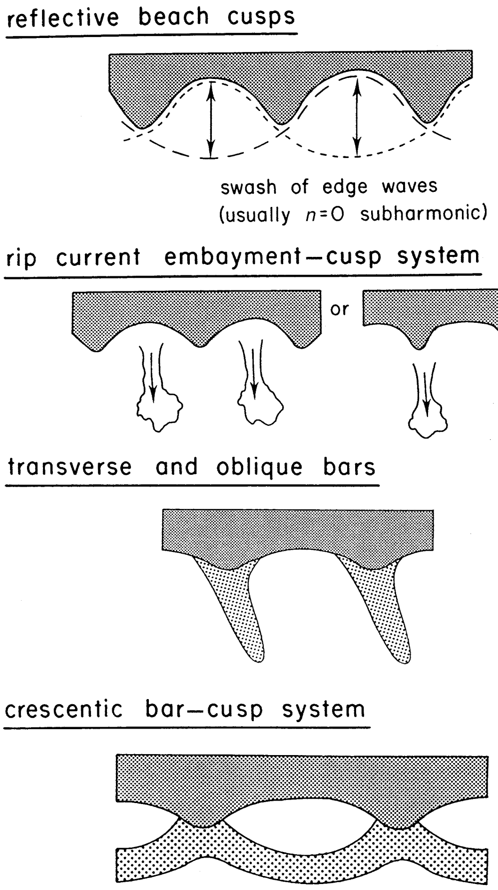

Figure R13 A genetic classification of rhythmic patterns where the origin of the series of cusps and embayments can be attributed to different processes of waves and currents (after Komar, 1983).

their origin. Arguments still persist with regard to the processes of wave motions and sediment transport that control their formation and determine the lengths of their spacings.

Beach-cusp formation is most favorable when the waves approach normal to the beach, that is, with their crests parallel to the longshore trend of the beach. This may explain why pocket beaches are particularly favorable sites for beach cusp formation. Furthermore, regular waves having long crest lengths are particularly conducive to cusp formation; beach cusps generally are not formed by irregular, confused seas.

Various investigators have described contrasting patterns of water circulation induced by the swash of waves around the cusps and within their embayments. In some cases there is an alternating surge inward and out of the embayments. Water flows from one embayment where the wave-swash runup has been a maximum, around the nearest cusp, and into a neighboring bay where it rushes up the beach face with the next wave. Thus, the maximum runup alternates in its timing between adjacent embayments. In other cases, the arriving waves break evenly along the beach, but the wave surge then piles up against the steep cusps and is divided into divergent streams that flow into the adjoining embayments. These streams head off the wave surge that had flowed directly up into the embayment. The two side streams from the cusps on either side meet at the center of the bay, and together form a seaward flow of considerable strength. This return flow can resemble a rip current, but unlike true rip currents, the flow is discontinuous and the mechanisms of formation are quite different. These contrasting patterns of water circulation observed around beach cusps suggests that more than one mechanism may give rise to their formation.

A number of hypotheses have been proposed to account for the formation of beach cusps. For a theory to be acceptable, it must account for the uniformity of spacing within an observed series of cusps, and the way in which this spacing is related to the wave parameters. The hypothesis that has been most successful in explaining the formation of beach cusps and accounting for their spacings is one based on the presence of edge waves in the surf zone (Guza and Inman, 1975). An edge wave is a type of wave that is trapped in the surf by refraction across the slope of the beach, moving in the longshore direction as it alternately refracts while moving offshore, then bends entirely around to return to the shore, reflects from the beach, and repeats the pattern of movement. The important result is that the presence of the edge wave affects the intensity and distance of swash runup on the beach, producing a regular runup spacing along the length of shore. This hypothesis explains the formation of beach cusps as the rearrangement of the sediment into a regular pattern of alternating cusps and embayments, corresponding to the longshore wave length of the edge waves and spacing of their maximum runup on the beach. The validity of this hypothesis has been demonstrated in the controlled conditions of laboratory wave basins, and by a few studies on ocean beaches that happened to be measuring edge waves at the same time beach cusps formed (see review in Komar, 1998). In that the longshore length of edge waves is determined by the wave period and slope of the beach, this hypothesis yields a mathematical equation that predicts the beach-cusp spacing (Guza and Inman, 1975). Measured beach-cusp spacings ranging from 0.1 to nearly 100 m have been shown to agree with this mathematical relationship (Komar, 1998). Thus, there is strong supporting evidence for the edge wave hypothesis of beach cusp formation.

There is, however, an alternative hypothesis that has been proposed to account for the formation of beach cusps, the so-called "self organization" hypothesis of Werner and Fink (1993). It envisions an initially smooth, straight beach, lacking cusps, but with waves arriving and swashing up the beach face with some degree of irregularity. According to the hypothesis, this irregularity in the wave swash produces variable amounts of beach sand movement along the shore, with a tendency for the sand to preferentially accumulate in a few isolated areas. The critical aspect of this hypothesis is that the zones of accumulated sand then affect the subsequent patterns of wave runup, thereby increasing the sizes of the accumulated sand and causing them to evolve into a pattern of beach cusps having regular spacings. It is this trend toward increasing regularity to which the name "self organization" refers. The main supporting evidence for this hypothesis comes in the form of computer simulation models that demonstrate the possibility of such an evolution. While not actually having mathematical relationships that predict the eventual beach cusp spacing, the computer models demonstrate that the spacing depends on the wave period and height, and on the beach slope, and in fact the model yields cusp spacings that are similar to those predicted by the edge-wave hypothesis. This similarity in prediction has made it difficult to distinguish which mechanism is responsible for the formation of beach cusps on ocean shores. It is possible that both hypotheses can, in different situations, account for the formation of beach cusps, and in some cases may actually work together.

As noted above, the early definition of "beach cusps" restricted them to spacings of 25 m or less, but provided no explanation for their formation. Although we are still uncertain as to the specific generation mechanism, the proposed hypotheses appear to offer satisfactory explanations, so the term "beach cusps" is now used in genetic classifications like that in Figure R13. For the most part the old and new uses of the term refer to the same rhythmic pattern, but we now recognize that edge waves and perhaps self-organization can generate beach cusps that have spacings up to 100 m.

Rip current embayments and cuspate shores

Within the series of rhythmic patterns diagrammed in Figure R13, generally the next larger form beyond beach cusps is the system of erosional embayments and intervening cusps formed by nearshore current systems that include seaward-flowing rip currents. In most instances the rip currents erode sand from the beach and transport it offshore, forming embayments at the rip-current positions, with cusps midway between. In rarer instances, particularly on steep beaches, coarse sand and gravel may accumulate at the shoreward ends of the rips, developing cusps at those positions. Rip currents, and hence the embayments and cusps, typically have spacings that range from tens to hundreds of meters. As such, the resulting rhythmic pattern corresponds to what has been referred to variously as sand waves or giant cusps.

The effect of the nearshore currents on the shore, forming series of embayments and cusps, is the surface expression of the underwater topography that is molded by the currents acting together with the waves. The seaward-flowing rip currents tend to erode channels across the full width of the beach within the embayments, segmenting the offshore bar. This leaves a system of cusps midway between rip currents, but each cusp seen on the shore is part of a shoal that extends out to the remaining segment of offshore bar.

This form of rhythmic pattern with embayments cut by rip currents is often important to property erosion in that the embayments narrow the beach width and remove most of the buffer protection offered to properties backing the beach. Although the rip embayments themselves do not usually produce much erosion of dunes and sea cliffs, they provide an area of deeper water where storm waves can approach close to shore before breaking against the coastal properties.

Rhythmic patterns produced by welded and transverse bars

A variety of sand bars have been observed in the nearshore that run obliquely to the longshore trend of the beach. These have been termed "welded" or "transverse" bars (Figure R13). An example is shown in Figure R14 on the ocean shore of Cape Cod, Massachusetts, consisting of a series of bars and a cuspate shore that has a distinctive longshore rhythmicity of several hundred meters. Therefore, the presence of welded or transverse bars can also give rise to a rhythmic pattern.

A number of suggestions have been made for the origin of bars that trend obliquely to the shore, and for the corresponding rhythmic pattern. It has been observed that when waves break at pronounced angles to the beach, the offshore bars that were originally parallel to the shore and segmented by evenly spaced rip currents, rotate to align themselves with the incoming wave crests. This may be the origin of the welded bars and rhythmic pattern seen in Figure R14.

Another type of oblique bar is found on coasts of low wave energy, for example in lakes or along the shore of the Gulf of Mexico. Referred to as transverse bars, they tend to occur in families that run parallel to one another, directed toward the offshore. At each point where a transverse bar joins the shore, a large cusp develops on the dry beach. Transverse bars can be fairly permanent features—examples on the shores of the Gulf of Mexico have been observed to persist in aerial photographs that span 25 years, showing little or no tendency to migrate alongshore during that time. Investigations have demonstrated that this type of transverse bar affects the paths of nearshore currents, with the current being concentrated over the bar and flowing offshore along its length, thereby perpetuating the bar's existence and extending it's length.

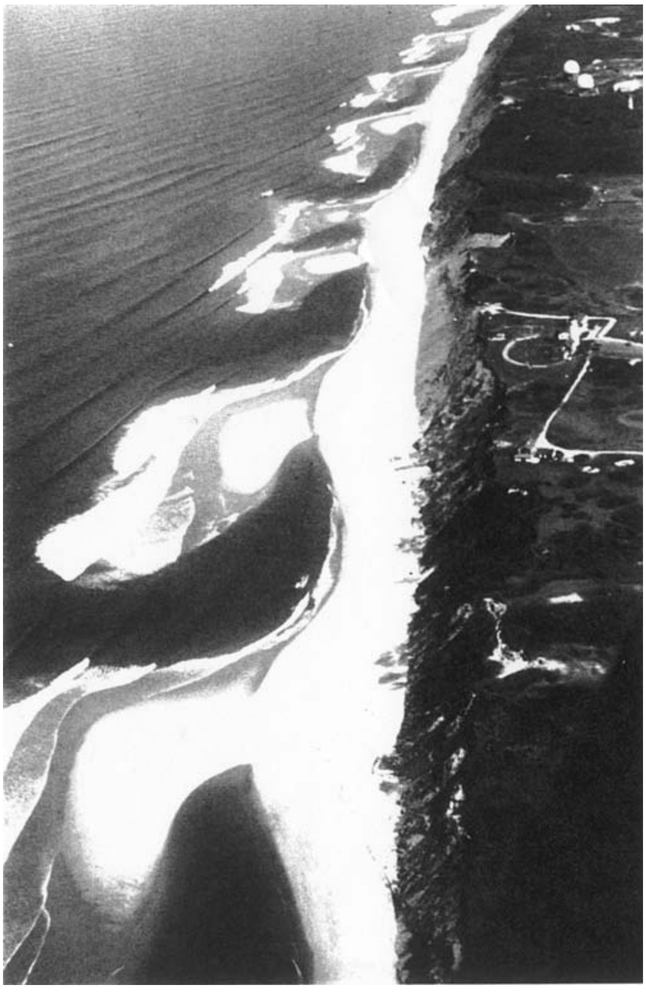

Figure R14 A series of welded bars and associated rhythmic pattern on Cape Cod, Massachusetts (photo courtesy of David S. Aubrey, Woods Hole Oceanographic Institution).

Crescentic bars and large-scale rhythmic patterns

Crescentic bars are one form of submerged offshore bars where rather than being linear, they have a regular lunate or crescentic shape (Figure R13), together with a uniform repetition along the length of beach. This regularity generally cannot be appreciated by observers on the dry beach, since most of the feature is underwater. However, there may be an associated series of cusps on the beach if the landward ends of the crescentic bars attach to the shore. In this instance, the presence of offshore crescentic bars leads to the development of another form of rhythmic pattern.

Crescentic bars are much larger features than beach cusps, and generally are somewhat larger than the rhythmic patterns due to rip currents or welded bars. In some instances, large crescentic bars form the outer-bar system of a beach, while the inner bar is linear and segmented by the more closely spaced rip currents. The range in lengths of crescentic bars is difficult to establish, since for many reported occurrences it is not possible to determine conclusively whether crescentic bars or some other form of rhythmic pattern is being described. Crescentic bars appear to range up to 2,000 m in length (Komar, 1998). At times there can be multiple crescentic bars on a beach, the further offshore the bars the larger their spacings. The corresponding rhythmic pattern on the beach would similarly have very large spacings between successive cusps.

Like beach cusps, the regularity in shapes and the even spacings of crescentic bars have inspired a number of suggestions as to their formation. The mechanism proposed by Bowen and Inman (1971), again by the movement of edge waves, provides the most reasonable explanation. In this case, however, important is the velocity of water movements associated with the edge waves, not their swash runup on the sloping beach which may be responsible for beach cusps. According to this mode of formation, beach sediment in the outer surf zone drifts about under the currents of the edge waves, until the sand reaches zones where the water velocity is low and the sand can accumulate. According to computer models of edge wave motions, this rearrangement of the sand would yield lunate-shaped bars that are remarkably similar to those observed on ocean beaches, a result that argues in favor of this hypothesis. Bowen and Inman (1971) conducted a series of laboratory wave-basin experiments that further confirmed this predicted sand accretion pattern, leading to the formation of crescentic bars. At this time, there is no reasonable alternative hypothesis for crescent-bar formation that satisfactorily accounts for their regularity in shapes and spacings, and for the formation of the associated rhythmic pattern.

Rhythmic patterns, irregular shores, and coastal erosion

Depending on the mechanism, rhythmic patterns may consist of alternating cusps and embayments whose spacings range from a few meters (beach cusps), to on the order of 100 m (rip-current embayments or welded bars), and on up to 500–1,500 m (crescentic bars). If one includes series of cuspate forelands or capes like those that exist along the southeast coast of the United States, the series can be extended up to tens of kilometers. When only one type of rhythmic pattern is present on the beach, it gives rise to a fairly regular spacing of alternating cusps and embayments. However, it is common for more than one type of pattern to occur simultaneously on a beach, and the summation of what are otherwise regularly spaced patterns can lead to an irregular beach and shore. An example is shown in Figure R15, the Cape Hatteras coast of North Carolina, photographed in 1970 before the lighthouse was moved (Dolan, 1971). Apparent are the series of large cusps and embayments, with a fair degree of regularity along the length of coast covered by the photograph. However, there is a level of irregularity, with some embayments being larger than others. Although the cause in this example is uncertain, it is probable that the irregularity of the rhythmicity is produced by the summation of two rhythmic patterns, that due to a rip-current cusps/embayment system, together with a larger-scale variation due to offshore crescentic bars. Of interest in this example, the respective embayments produced by rip currents and the crescentic bars appear to have combined in the area of the Cape

Figure R15 A rhythmic pattern of alternating cusps and embayments on the Cape Hatteras coast of North Carolina, photographed in 1970, with the largest embayment producing beach erosion and threatening the lighthouse (from Dolan, 1971).

Hatteras Lighthouse, resulting in the total loss of the beach and erosion of the dunes to the extent that the lighthouse was in danger. Therefore, an understanding of the origin and types of rhythmic patterns can be important to interpretations of the causes of coastal erosion problems.

RIA

A ria is a long, narrow, often branching inlet formed by marine submergence of the lower parts of a river valley that had previously been incised below present sea level. Rias are the drowned mouths of unglaciated valleys, usually bordered by steep slopes rising to mountains, hills, or plateaux (Figure R16). The term is of Spanish origin, derived from large inlets on the coasts of Galicia such as the Ria de Arosa and the Ria de Muros y Noya, fingering far inland. They are known as abers in Brittany and Wales.

Von Richthofen (1886) defined a ria as a drowned valley cut transverse to the geological strike, but the Rias of Galicia do not meet this strict definition (Cotton, 1956). Perusal of coastal textbooks indicates that the term has come to be used as a synonym for a drowned valley mouth without any structural constraint. Rias generally have a dendritic (tree-like) outline, remaining open to the sea, as in Carrick Roads (Figure R17) in southwest England, Chesapeake Bay in the United States and Port Jackson (Sydney Harbor) in Australia. The long, straight valley-mouth gulfs on the southwest coast of Ireland, such as Bantry Bay, are examples of rias, even though they follow a geological strike that runs transverse to the general coastline. Where rivers have cut valleys across geological structures there may be tributaries that follow the geological strike, submerged to form a trellised pattern, as in Cork Harbor in southern Ireland. On the Dalmatian coast of the Adriatic Sea rias are elongated straits along valleys that follow the geological strike, linked to the sea by transverse channels.

Existing rias were formed by marine submergence during the Late Quaternary (Flandrian) marine transgression, but in southwest England there is evidence of several phases of valley incision during Pleistocene low sea-level phases, alternating with earlier ria formation

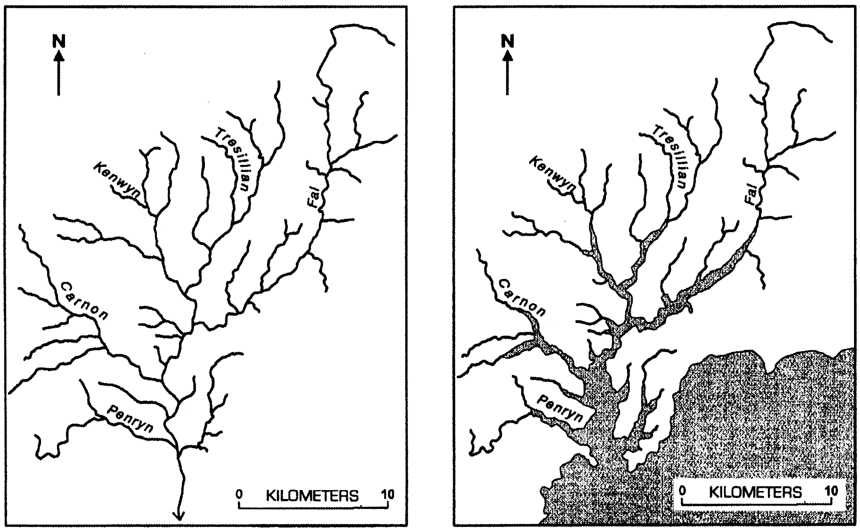

Figure R17 The Carrick Roads ria on the south coast of Cornwall, England. (Left) the river systems as they were 20,000 years ago, during the Late Pleistocene low sealevel phase. (Right) the present outlines, after partial submergence by the Late Quaternary marine transgression. (©Geostudies).

during interglacial marine transgressions and at least one Late Pleistocene higher sea-level phase indicated by an emerged beach (Kidson, 1977).

The Galician rias are generally wide and deep (up to 30 m) marine inlets in valleys which may have been shaped partly by tectonic subsidence and the recession of bordering scarps. Subsidence has probably contributed to the persistence of the ria at the mouth of Johore River in southeastern Malaysia, which remains a wide and deep inlet, whereas other Malaysian valley mouths have been infilled as alluvial plains, some with protruding deltas. Other rias persist because they were initially deep and sedimentary filling has been slow, as on the New South Wales coast (Roy, 1984).

Rias show varying degrees of sedimentary filling, partly from inflowing rivers and partly inwashed from the sea. There are marshy deltas at the heads of the several branches of Carrick Roads in Cornwall, while other rias in southwest England have banks of inwashed marine sand, particularly on the Atlantic coast, as in the Padstow ria, where at low tide the Camel River is narrow, flowing between broad exposed sandbanks that are submerged when the tide rises. Muddy sediment has been derived from periglacial deposits on bordering slopes.

Slopes bordering rias generally show only limited cliffing on sectors exposed to strong wave action, yielding sand and gravel to local beaches. Typically' there are sandy, gravelly, and rocky embayed shores, some spits, muddy sediment and salt marshes at their heads, and sandy shoals at their entrances (Castaing and Guilcher, 1995). The Rade de Brest is noteworthy for its several bordering sand and gravel spits (Guilcher *et al.*, 1957). Finer sediment is deposited in fringing tidal marshes and mudflats, and on the adjacent sea floor.

There is no clear distinction between a ria and an estuary, most rias being estuarine in the sense that inflowing rivers provide freshwater that meets and mixes with seawater moved in and out by the tide. Rias on high limestone coasts in the Mediterranean are known as calas or calanques, while those on arid coasts are termed sharms or sherms. In Chile' there is a transition southward from rias to fiords with increasing influence of glaciation on valleys.

RIP CURRENTS

Definition, types, and early studies

Many of the world's beaches are characterized by the presence of strong, concentrated seaward flows called *rip currents*. Rips are an integral component of nearshore cell circulation and ideally consist of two converging longshore *feeder* currents which meet and turn seawards into a narrow, fast-flowing *rip-neck* that extends through the surf zone, decelerating and expanding into a *rip-head* past the line of breakers. The circulation cell is completed by net onshore flow due to *mass transport* between adjacent rip systems. Rip flows are often, but not always, contained within distinct topographic channels (Figure R18) and can be visually identified by darker streaks through the surf zone due to greater water depths, offshore moving foam/sediment patches, and surface turbulence created by the wave–current interactions. Rips are of great significance to coastal nearshore studies since they provide a major mechanism for the seaward transport of water and sediments, have a pronounced effect on nearshore morphology, aid in the dispersal of pollutants, and represent a major hazard to recreational beach users. It is therefore of some concern that many aspects of rip behavior, generation, and occurrence remain poorly understood. In fact, the term was first used by Shepard (1936) in order to distinguish rip currents from the misnomers *rip tide* and *undertow*, which are unfortunately still commonly used to describe rips today.

Rips are generally absent on pure dissipative and reflective beaches, but are a key component of sandy intermediate beach states as described by various microtidal beach models (e.g., Wright and Short,

Figure R18 Enhanced time-exposure image of topographically arrested accretion rips at Palm Beach, NSW, Australia. Rip channels appear as dark areas between bars (white regions) and are approximately 150–200 m apart. Note the absence of pronounced longshore feeder channels (image courtesy of G. Symonds, R. Holman, and R. Ranasinghe).

1984) and also occur, but are not as predominant, on macrotidal beaches. Short (1985) identified three types of rip currents: (1) *accretion rips* occur during decreasing or stable wave-energy conditions and are often topographically arrested in position (Figure R18) having mean velocities typically on the order of 0.5 m/s, but exceeding 1 m/s in high-energy surf zones (Brander and Short, 2000); (2) hydrodynamically controlled *erosion rips*, which occur under rising wave-energy conditions and are transient in location, having mean flows in excess of 1 m/s; and (3) *mega-rips*, which occur in embayments under high waves (>3 m) and can extend offshore for distances of more than 1 km, attaining velocities greater than 2 m/s. All are associated with localized erosion of the shoreline and often create rhythmic *rip embayments* termed *mega-cusps*. Relatively, permanent rips located adjacent to headlands, reefs, and coastal structures such as groins have been referred to as *topographically controlled rips*.

The primary limitation to our understanding of rips has been the logistical difficulty in obtaining quantitative field measurements. The first serious scientific attempts at describing rips (Shepard *et al.*, 1941; McKenzie, 1958) were largely qualitative and suggested that rips: (1) exist as a response to an excess of water built up on shore by breaking waves; (2) often display a periodic longshore spacing; (3) increase in intensity and decrease in number as wave height increases; (4) vary in location and intensity over time; and (5) flow fastest at low tide. Subsequent theoretical, laboratory, and field studies have attempted to explain these characteristics with varying degrees of success.

Rip generation and spacing

It is generally accepted that the primary mechanism behind the formation of rip currents is the presence of longshore variations in wave height which act to produce *wave set-up* gradients that drive water alongshore from regions of high water level to regions of lower water level. Bowen (1969) showed that these gradients are intrinsically related to variations in the longshore component of *radiation stress* (Longuet-Higgins and Stewart, 1964)

$$S_{yy} = \frac{E}{2} = \frac{1}{16}\rho g H^2,$$

where E is the energy, ρ is the water density, g is the gravitational constant, and H the wave height. Bowen (1969) demonstrated that within the surf zone, the longshore gradients in set-up and radiation stress act in the same direction to produce longshore feeder currents, whereas outside the surf zone, the S_{yy} gradient is balanced by a longshore variation in wave set-down and no longshore flow is produced.

Existing models for the generation of rip cell circulation have thus incorporated various mechanisms to account for the existence of longshore gradients in wave height/set-up and can be grouped into three main categories. The wave–boundary interaction model involves the modification of the wave field by non-uniform topography and/or coastal structures. The resulting convergence and divergence of wave rays due to wave refraction can produce regions of high and low waves such that rips can occur in the lee of offshore submarine canyons (Shepard and Inman, 1950), but more commonly adjacent to headlands and groins.

Wave–wave interaction models have been used to explain both longshore variations in wave height and regular longshore rip spacing. Bowen (1969) and Bowen and Inman (1969) showed both theoretically and in the laboratory that incident waves can generate synchronous edge waves which produce alternating patterns of high and low wave heights along the shore. Rips are produced at every other antinode with a rip spacing (L_r) equal to the edge wavelength given by

$$L_r = L_o \sin(2n + 1)\beta,$$

where L_o is the deep-water incident wave length, n is the edge wave mode, and β the beach slope. Dalrymple (1975) provided a model for long, straight beaches showing that the intersection of synchronous wave trains from different incident angles can also produce longshore set-up gradients and a regular rip spacing. The third type of mechanism, an instability model, was proposed by Hino (1974) who suggested that a longshore uniformity in set-up on plane beaches is unstable to any small disturbance caused by hydrodynamic or topographic factors and that predicted rip spacing was equal to four times the surf zone width. Subsequent studies based on direct field observations have shown that this ratio can range from 1.5 to 8.

It should be emphasized that validation of the above models has primarily been restricted to laboratory experiments. Using a long-term field dataset of rip spacing obtained by remote video images, Ranasinghe *et al.* (1999) showed that the models of Bowen (1969) and Dalrymple (1975) under-predicted observed rip spacing and that there was no evidence to support instability mechanisms as being responsible for rip spacing. Furthermore, the common acceptance of the edge wave model as an explanation for rip generation and spacing should be treated with caution since synchronous edge waves have not been measured in the field and the required interaction between edge waves and incident waves of the same period is believed to be restricted to steep, reflective beaches, an environment where rips are usually absent.

Based on field observations from Narrabeen Beach, NSW, Australia, Huntley and Short (1992) found that rip spacing increases with increasing wave height and surf zone width and with decreasing sediment size and beach gradient. Short and Brander (1999) used a global dataset to show that rip spacing is related to regional wave environments. Patterns of rip spacing were consistent within west coast swell ($L_r \cong 500$ m), east coast swell ($L_r \cong 200$ m), and Fetch-limited environments ($L_r \cong$ 50–100 m). Distinct scaling factors between the environments also applied to planimetric dimensions of the rip systems and were directly correlated to wave energy. Prediction of rip spacing and location remains problematic however, and it should perhaps be acknowledged that rip spacing is often irregular.

Topographic control and flow characteristics

The theoretical models for rip generation described previously are based on longshore variations in wave height, but on a beach consisting of alternating bars and offshore channels, Sonu (1972) found that under conditions of uniform longshore wave height, constant and extensive wave-energy dissipation across the bars, and local and intense wave breaking over the channels created a set-up gradient toward the channels. Set-up gradients generated in this manner support field data confirmation (Aagaard *et al.*, 1997; Brander, 1999) that rip flows are tidally modulated (Figure R19), since stronger flows at low tide would be expected with increased wave dissipation associated with shallower water depths over the bars.

Aagaard *et al.* (1997) used field measurements to show that rip velocity (u_r) can be predicted by

$$u_r = \frac{QL_r}{A_r},$$

where Q is onshore mass transport and A_r is the cross-sectional area of the rip channel. Based on computations for Q, rip velocity will increase with H^2 and decrease with longer wave periods, and will also increase with greater distances between rips and smaller channel areas. The latter is supported by field data by Brander (1999) who found a strong relationship between increasing rip velocity and decreasing channel area. However, the degree to which rip circulation is either controlled by antecedent topography or creates this topographic feedback effect through sediment transport processes remains unclear and it should be remembered that rips do occur on beaches without irregular topography.

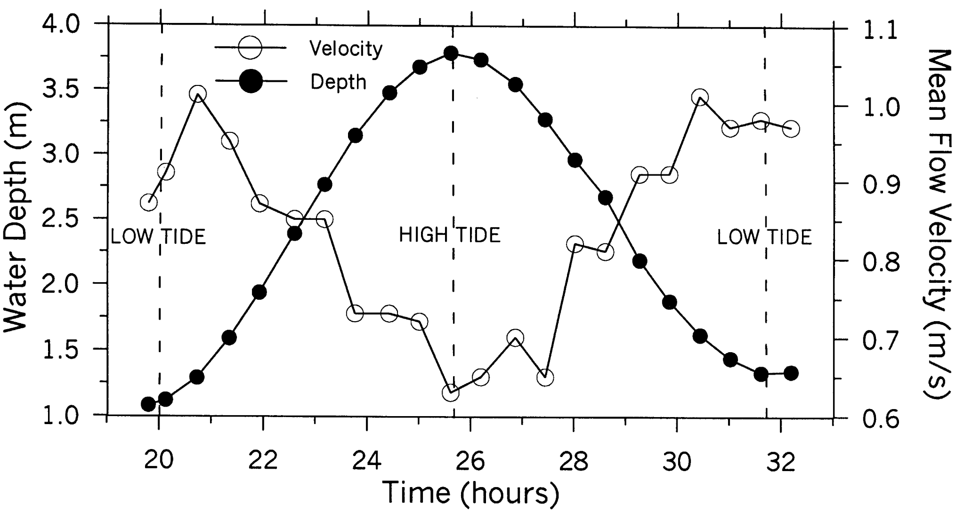

Figure R19 Tidal modulation of rip velocity at Muriwai Beach, New Zealand showing maximum and minimum flow strengths around low and high tide, respectively. Data points represent 34-min time averages recorded 0.9 m above the bed.

Field studies have also shown that rip velocities increase steadily from the feeders to the middle of the rip-neck, with strongest flows toward the middle of the water column, decreasing away from the bed and toward the surface (Sonu, 1972). Rip flows also experience low-frequency velocity pulses on the order of several minutes, but the forcing of this behavior in response to *infragravity waves, wave groups,* or *shear waves* has yet to be determined.

RIPPLE MARKS

General definition and description

Allen (1978) defined ripple marks as "… regular, ridge-like structures, transverse to current, which arise and are maintained at the interface between a moving, viscous fluid (water, air) and a moveable, non-cohesive sediment (usually sand) by interaction between fluid and transported sediment." Ripple marks fall principally into two classes: aeolian ripples and water-formed ripples. Fundamental work on aeolian ripples was undertaken by Bagnold (1941) as an army officer in the Lybian desert; he considered *ripples* to be constant in size with time once formed, whereas larger types grew with time, almost without limit. Aeolian ripples are influenced by saltation bombardment of sand creating ballistic ripples which lack internal structure, and have wavelengths related to saltation length. Water-formed ripples are created by lee eddy avalanches in the direction of sediment transport, possess well-defined internal structure, and have wavelengths controlled by grain size. Thus, despite outward similarities in form, there is little overlap in the mechanisms of genesis between subaqueous and aeolian forms.

Essential concepts and applications

Definitions based solely on morphology do not discriminate between what we "understand" to be ripple marks (small-scale bedforms) and genetically similar bedforms such as dunes, giant ripples, sand waves, or megaripples (large-scale bedforms). There appears to be a continuum in bedform morphology and sizes in both aeolian and subaqueous ripples, from the smallest forms found in silt to "giant" forms kilometers in length (Wilson, 1972; Ellwood *et al.*, 1975; Amos and King, 1984;

Ashley, 1990). So what are ripple marks, and how do they form? Darwin (1883) linked subaqueous ripples to vortices in the near-bed flow and subsequent sand transport. Exner (1925, from Allen, 1982) showed that they initiated from bottom irregularities, and were self-maintaining and self-organizing due to perturbations in the horizontal pressure gradient and sediment transport rate. They are considered to be the physical manifestations of bedload transport and the grain-to-grain interaction of the material in transport (Bagnold, 1963; Harms *et al*., 1982; Middleton and Southard, 1984) and, as such, demonstrate the emergence of order out of the chaotic movement of individual sand grains within a viscous sub-layer at the bed. This order, according to Leopold *et al*. (1964), results from the creation of a *kinetic wave* in sediment flux not unlike traffic movement on a congested highway. Early classifications were based on the shape and size of bedforms (height, wavelength, asymmetry, planform, cord coherence) which resulted in the discrimination of: small-scale ripples, large-scale ripples (superimposed by smaller forms; Allen, 1968), short-crested ripples, intermediate-crested ripples, and long-crested ripples (Inman, 1957). Each ripple type was further classified on the basis of sinuosity, bifurcation, and continuity of the crestline into: straight, sinuous, linguoid, caternary, or lunate types (Allen, 1968). Classifications of ripples based purely on metrics do not consider genesis, and hence were considered deficient in two fundamental ways: (1) they could not be predicted, and (2) they could not be used to hindcast the conditions that formed them. Fundamental observations by H.C. Sorbey, and later Gilbert (1914) showed that current-formed ripples varied with flow type and flow intensity; the product of either oscillatory near-bed currents produced by waves, by unidirectional, turbulent currents; or by a combination of oscillatory and steady currents. The majority of these forms were found to be "*flow-transverse*"; that is, the crestline oriented normal to the direction of flow. Thus, from a genetic standpoint, ripple marks were primary classified as: wave (oscillation) ripples; current ripples; or combined-form ripples (Harms, 1975). In general, wave ripples are symmetrical, sharp-crested, and two-dimensional (2-D) in planform (or brick-pattern); current ripples, by contrast are generally asymmetrical showing a continuum on planform geometry from straight, through sinuous, to linguoid (Tanner, 1967); combined-flow ripples show a complex super-imposition of forms forming three-dimensional (3-D) ripples (Amos *et al*., 1988; Arnott and Southard, 1990; Southard *et al*., 1990). Bagnold (1956) and others suggested that small-scale and large-scale ripples were genetically different; referring to the latter as "dunes." The subsequent classification of large-scale bedforms and their distinction from ripples was presented by Allen (1985).

The classic work of Allen (1968), published in a book titled simply "*Current Ripples*," links clearly and elegantly the morphology, dynamics, and internal structure of current ripples with the near-bed unidirectional flows that created them. Current ripples occur in turbulent flows between the threshold for the traction and saltation/suspension of the rippled material at Froude numbers between 0.2 and 0.6 and flow Reynolds numbers between 5×10^{-3} and 10^{-5} (Tanner, 1978) and at mean grain sizes less than 600 μm. Allen (1985) reviewed the fundamental hydrodynamic research into the near-bed physical processes responsible for unidirectional bedform generation. A variety of phase-diagrams of bedform stability have resulted from this work largely expressed in 2-D: flow strength (power, pressure, or speed); and grain size (diameter, dimensionless diameter, or grain Reynolds number). Each scheme, according to Allen (1985) is "*restricted in applicability by the limitations of the database*," and are poorly understood for silt- and gravel-sized materials. Furthermore, most proposed 2-D phase relationships ignore the solid-transmitted (ballistic) part of the shear stress caused by the sand in motion (Bagnold, 1941). This ballistic contribution, important to the evolution of aeolian ripples, also appears important in the evolution of subaqueous ripples. As well, the possible feedback of ripple bed morphology into flow turbulence, and hence bed shear stress, has primary and secondary effects over that created by grain (skin) friction of an initial flat bed (Bagnold, 1963).

The classical work on the hydrodynamics of wave ripple formation, migration, and evolution was undertaken in the laboratory by Bagnold (1946) and Manohar (1955) and in the field by Inman (1957). Bagnold (1946) observed a complex interaction between the movement of sand grains, the structure of the benthic boundary layer (and in particular, the evolution of attached vortices), and ripple morphology. From these observations, rolling grain ripples, vortex ripples, and post-vortex ripples were defined; each form stable within a range of grain sizes and near-bed conditions of oscillatory flow. Later, Komar (1974) and Clifton and Dingler (1984) showed that the cord length of the wave ripples was linearly correlated to (and predictable by) either wave orbital diameter (orbital ripples), or grain size (anorbital ripples), or were transitional between the two (suborbital ripples). More importantly, the type of ripple and its orientation and cord length could be predicted from knowledge of (1) grain size, (2) water depth, (3) wave orbital diameter, and (4) wave orbital velocity (Sleath, 1984). The importance of this work lies in the power to discriminate wave conditions, and thus paleoenvironment (water depth, wave heights, etc.) in the geological past (Allen, 1981). However, one vital piece of information still remains to be introduced to understand the significance and behavior of ripple marks: the internal structure.

The link between ripple marks and internal structure came from early work on current ripples undertaken by van Straaten (1954) and later Reineck and Singh (1966) on tidal flats of the Waaden Sea. They showed conclusively that the internal structure of ripples, and the relationship to ripple form, provides a record of the evolution and migration of the ripple, and equally important, the direction and magnitude of net sediment transport. This attribute of bedforms has been explored and exploited by Harms *et al*. (1982) and later by Rubin (1987) who showed a complex suite of internal structures resulting from invariable or variable ripples. These ripples may be either transverse to the mean sand transport direction, longitudinal (parallel) to it, or oblique and may produce either 2-D or 3-D cross-bedding. Internal structures reveal that bedform superimposition is common. The cause of superimposition has been assigned to either a fluctuating flow in time (Allen, 1978), or to a multiple-boundary layer (Rubin and Hunter, 1987). However, field observation shows complex superimposed ripple patterns in nature resulting from wave–steady current interactions under storms (Amos *et al*., 1988; Arnott and Southard, 1990). These patterns are further complicated by rotation of the flows leading to complex polygonal transitional patterns in the wave-formed ripple field (Allen, 1982), which merge or diverge dependent on the angle between the two flow types. At high angles of incidence, wave ripples and current ripples coexist in a steady state defined by the partitioned (wave or current) component of the bed shear stress; each ripple type responding to the flow as if oblivious of the superimposing stress (Young and Sleath, 1990). At low angles of incidence however, the bedforms coalesce into asymmetrical wave ripples, or multifrequency ripples with parallel crests (Allen, 1982).

Future research

Future studies on the interaction of combined flows on ripple genesis is required, particularly in relation to the net sediment transport direction and at the saltation/suspension threshold: the ripple "break-off region" (Grant and Madsen, 1982). The role of ballistic impacts to bedform evolution in subaqueous flows, also needs exploring, particularly for poorly sorted sand.

The feedback of ripple form on bed shear stress deserves attention: The late J. Ludwick once said that the world of sediment dynamics is divided into "*lumpers*" those who consider that bedforms influence the movement of sand, and "*splitters*" those who do not (assigning the frictional drag entirely to skin friction of the composite sediment grains). The literature on the relationship between form drag, turbulence, and ripple shape and size is inconsistent (Soulsby, 1997). Future work is needed on the feedback mechanism between bedform genesis and turbulence generation/dissipation within the benthic boundary layer. Only then will we know if the "*lumpers*" or "*splitters*" were right.

ROCK COAST PROCESSES

Our ability to identify and measure the effect of rock coast processes has improved with the application of modern analytical techniques, geochronometric dating, and physical and mathematical modeling, but we are still largely ignorant of their precise nature (Trenhaile, 1987; Sunamura, 1992). The relative importance of rock erosional processes is often determined on the basis of ambiguous morphological evidence. Although the processes responsible for the slow lowering of rock surfaces have been inferred from micro-erosion meter data, the technique is unable to measure the dislodgement of large rock fragments by waves and frost.

It is difficult to obtain quantitative process data because of the imperceptible changes that generally occur on rock coasts within human lifetimes, the importance of storms and other high intensity—low frequency events, the lack of access to high and frequently precipitous cliffs, and the occurrence of exposed and often dangerous environments for wave measurement and subaqueous exploration. Changes in relative sea level and climate have also caused the nature and intensity of marine and subaerial processes to fluctuate through time, and because of slow rates of erosion, rock coasts often retain vestiges of environmental conditions that were quite different from today.

Mechanical wave erosion

Wave quarrying appears to be the dominant erosional mechanism in the vigorous storm wave environments of the middle latitudes, based on the frequent occurrence of fresh rock scars and coarse, angular debris consisting of joint blocks and other rock fragments on shore platforms and at the foot of cliffs. Weaker waves in polar and tropical regions also play important roles, however, in eroding weathered rocks and removing loose debris.

The forces exerted by waves on coastal structures depend upon their deep water characteristics, tidal elevation, and submarine topography. A broken wave may be a less effective erosional agent than a wave that breaks directly against a cliff or other steep, natural structure, but broken waves occur much more frequently. Therefore, the compression of air in joints and other structural discontinuities by broken waves is probably of much greater importance than the direct impact of waves on rocks (water hammer) and the generation of high shock pressures against near-vertical structures by breaking waves. Rock fragments and sand can be effective abrasional agents in the intertidal and shallow subtidal zones, although even large waves may be unable to agitate material sufficiently at the base of thick accumulations (Robinson, 1977). Gently sloping abrasional surfaces are generally much smoother than wave quarried surfaces, but deep grooves can develop where abrasion is concentrated along joint planes and other structural weaknesses. Potholes are approximately cylindrical depressions that form where sand or large clasts are rotated by swirling water in the surf or breaker zones. They are particularly common in the upper intertidal zone where abrasives are trapped at the foot of scarps, and in structural or erosional depressions, and they also inherit, and subsequently modify, corrosional hollows in calcareous rocks.

Air compression, water hammer, and other processes responsible for wave quarrying require the alternate presence of air and water, and they therefore operate most effectively in a narrow zone extending from the wave crest to just below the still-water level. Most mathematical models also suggest that standing, broken, and breaking waves exert the greatest pressures on vertical structures at, or slightly above, the water surface. Wave erosion on a rock coast must therefore be greatest at the elevation that is most frequently occupied by the water surface. Over long periods of time, the tidally controlled water surface is most frequently at, or close to, the neap high and low tidal levels, and wave action is increasingly concentrated within the neap tidal levels as the tidal range decreases (Trenhaile, 1987, 1997) (Figure R20).Therefore, in

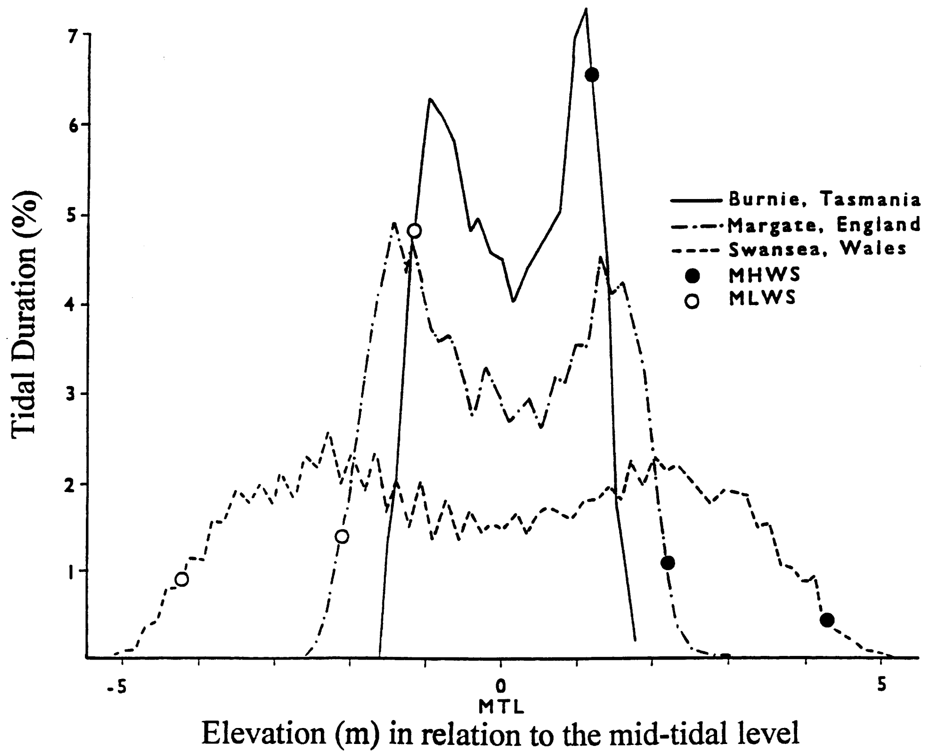

Figure R20 Tidal duration distributions—the amount of time that the water surface is at each intertidal elevation. MHWS and MLWS are the means of the high and low water spring tidal levels, and MTL is the mid-tidal level. (After Carr and Graff, 1982.)

controlling the elevation of the water surface, tides allocate the expenditure of wave energy and direct the work of mechanical wave erosional processes within the intertidal zone.

Although mechanical wave erosion is vertically distributed according to the tidal distribution of the water surface, it may be skewed toward the upper portions of the tidal range because of the occurrence of deeper water, and therefore higher waves, at high tide, and because large storm waves operate when sea level is meteorologically raised above the tidal level. In areas with low tidal ranges, this latter effect could elevate the zone of maximum erosion above the level of the high spring tides. Furthermore, as only vigorous storm waves, which operate at higher elevations than weak waves, are able to erode resistant rocks, whereas weaker waves, operating at lower elevations, are able to erode less resistant rocks, the difference between the level of greatest erosion and the most frequent tidal level may increase with the resistance of the rock (Trenhaile, 1987).

Weathering

Coasts are particularly suitable environments for physical and chemical weathering owing to alternate wetting and drying in the spray and intertidal zones, and the presence of salts. It is normally assumed that physical weathering is most important in high latitudes and chemical and biological weathering in low latitudes, in part because of the occurrence of suitable climates, but also because of fairly weak waves in these areas. Weathering also weakens rocks in the vigorous storm–wave environments of the middle latitudes, however, and it may be an essential precursor for the dislodgement and removal of rocks by weak waves in sheltered areas.

Physical weathering mechanisms include the alternate expansion and contraction of clay minerals under cycles of wetting and drying, temperature-dependent adsorption of water, thermally induced changes in volume, and frost action. The alternate expansion and contraction of clay minerals experiencing tidal- and weather-induced cycles of wetting and drying causes discontinuities to develop in shales and other argillaceous rocks, and also in the rocks that are adjacent to them. Clay minerals within small rock capillaries have negative charges that attract the positively charged ends of water molecules. This can breakup fine-grained, clay-rich rocks, which adsorb water and expand as temperatures rise, and desorb and contract as temperatures fall (Hudec, 1973). Temperature-dependent wetting and drying may be responsible for much of the field evidence that has traditionally been attributed to frost action, although several theories suggest that the two mechanisms could act together to generate more deleterious pressures within rocks than are generated by either mechanism acting alone. Thermally induced changes in volume also reduce the strength of some rocks. In southern Wales, for example, the expansion of limestones and the contraction of mudrocks under dry, hot conditions are responsible for diurnal variations in joint widths of up to 0.5 mm (Williams and Davies, 1987).

Although much remains to be determined about the mechanisms involved in frost action, we do have a general sense of the conditions that are most suitable for their operation. Coastal regions may be almost optimum environments. High levels of saturation can be attained in the supratidal and intertidal zones, and because intertidal rocks can freeze in air during low tide, and thaw in water during high tide, they experience many more frost cycles than in areas further inland. Intertidal frost action may also be particularly effective because of rapid changes in temperature caused by the sudden emergence and submergence of the rocks. Whereas rock temperatures rapidly increase when they are inundated in seawater, however, at least 5–6 h are needed for rocks to dissipate released latent heat and to cool to the freezing point of air. It is questionable whether critical levels of saturation can be maintained in the rocks over this period in the upper portion of the intertidal zone, and effective frost action in the lower portion of the intertidal zone may be inhibited by limited exposure to low air temperatures (Robinson and Jerwood, 1987). Although the presence of salts in solution can inhibit frost action, several studies have suggested that the greatest rock deterioration occurs in solutions that contain between 2 and 6% of their weight in salt; this suggests that frost action may be particularly effective in rocks that are saturated with seawater.

Frost- and temperature-dependent wetting and drying can only be effective erosional agents where there are suitable rocks, and waves that are strong enough to remove the coarse debris and prevent progressive burial of the cliff. Tidally induced frost action is inhibited at high latitudes by low water temperatures, but water and air temperatures suggest that it may occur at various times of the year in cool temperate regions (Trenhaile, 1987). Normal frost action, resulting from changes in air temperature, may also be more effective in the midlatitudes than in higher latitudes, where there are less frequent fluctuations about the freezing point. Atmospheric and tidally induced frost cycles are therefore probably most effective in cool, storm wave environments, and waves and frost also tend to be most effective on the same types of rock; strong wave action may therefore obscure or inhibit the effects of frost action in exposed areas.

Chemical and salt weathering are most important in warm temperate and tropical regions. Chemical weathering requires a good supply of water to promote chemical reactions, and more crucially, to remove the soluble products. Chemical reactions are accelerated by high temperatures in the tropics, but the lack of liquid water rather than low temperatures is probably primarily responsible for the fairly low rates of chemical weathering in high latitudes. Mechanical salt weathering occurs through the growth of crystals from solutions in rock capillaries, and crystal hydration and temperature-induced expansion. Chemical and salt weathering contribute to the formation of tafoni and honeycombs, the smoothing and lowering of shore platforms by the suite of processes collectively referred to as water layer levelling, case hardening, and the impregnation of joint planes by dissolved ions to form frame- or box-like structures, and the formation of various types of weathering pits (Trenhaile, 1987). The existence of a permanent level of saturation in the intertidal zone, separating a weak, weathered oxidation zone from a strong and largely unweathered saturated zone below, has been a basic tenet of Australasian workers for almost a century. Present evidence suggests that rocks can only be permanently saturated below the low tidal level, however, where they are constantly submerged.

There is continuing debate over the processes responsible for the sharp pinnacles, ridges, grooves, and circular basins that are characteristic of coastal limestones in the spray and splash zones. Although these features are similar to karren formed by freshwater on land, surface seawater is usually saturated or supersaturated with calcium carbonate. It has been suggested that solution could occur in rock pools at night, when the carbon dioxide produced by faunal respiration is not removed by algae. Lower pH then causes calcium carbonate to be transformed into more soluble bicarbonate. Solution can be inhibited or prevented by other biochemical processes, however, including dissolved organic substances coating rock surfaces and building complexes with calcium ions. Although chemical solution does appear to be possible in seawater, recent studies have provided support for the contention that marine karren and other characteristic features of limestone coasts are primarily bioerosional in origin.

Bioerosion

Bioerosion is the removal of the substrate by direct organic activity. It is probably most important in tropical regions, where there are fairly weak waves and an enormously varied marine biota living on coral, aeolianite, and other calcareous substrates. A wide range of techniques are used to breakdown rocks. Microflora and fauna that lack hard parts may use only chemical mechanisms, but other fauna secrete fluids that chemically weaken the rock, before mechanically abrading them with teeth, valvular edges, and other hard parts.

Microflora bore into rock and they change the chemistry of the water that is in contact with it—indeed cyanophyta (blue-green) and other algae may be the most important biological agents on rock coasts. Algae, lichen, and fungi are pioneer colonizers in the intertidal and supratidal zones and they allow subsequent occupation by gastropods, echinoids, chitons, and other grazing organisms that effectively abrade rock surfaces as they feed on epilithic and the ends of endolithic microflora. Grazing organisms are of enormous importance in some environments. For example, it has been estimated that they are responsible for about one-third of the surface erosion in the mid-tidal zone on Aldabra Atoll where sand is available for abrasion, and as much as two-thirds where sand is absent (Trudgill, 1976). At least 12 faunal phyla contain members that bore into rocks, especially in the lower parts of the intertidal zone. They include *Lithotrya* and other boring barnacles, sipunculoid and polychaete worms, gastropods, echinoids, *Lithophaga* and other bivalve molluscs, and Clionid sponges. Borers directly remove rock material, and they also weaken the remaining rock, making it more vulnerable to mechanical wave erosion and weathering. In the tropics, carbonate rocks favor chemical borers, but mechanical borers are active on a variety of substrates in temperate and cool seawater environments. There is a great deal of published data on bioerosional rates of erosion (Trenhaile, 1987), but they are of variable reliability and relevance. Nevertheless, most reported rates of erosion on vertical and horizontal limestone surfaces are between about 0.5 and $1\,\mathrm{mm\,yr^{-1}}$, which may reflect the maximum boring rate of endolithic microflora.

Ice

Until recently, it was generally believed that coastal ice is an ineffective erosional agent in the coastal zone, but its potential contribution to the development of rock coasts in cold environments is now being reassessed. The formation of subhorizontal shore platforms in the South Shetland Islands has been attributed to fast ice freezing to the underlying bedrock, quarrying by grounded ice and stranded ice rocked by the tides, and abrasion by rocks frozen into the ice base (Hansom and Kirk, 1989). Ice-push, by wind-driven floating ice loaded with rock fragments, also assists gelifraction and frost wedging in quarrying gneissic joint blocks in macrotidal Ungava Bay. Much of the ice-foot melts in place and does not contribute to debris removal, but it may facilitate deep frost penetration by providing a thermal barrier to sporadic warming by tidal water. Frost weathering and the effects of ice abrasion, dislodgement, and quarrying are also considered to be the main processes responsible for the formation of wide, subhorizontal platforms in the upper St. Lawrence Estuary (Dionne and Brodeur, 1988). Although there is clear evidence of the erosive efficacy of shore ice in this area, weak slates and shales, high tidal range, strong currents, and large erratic blocks provide particularly suitable conditions for frost and ice action, and it remains to be determined whether these cold region mechanisms assume similar roles in less favorable places.

Mass movement

Active marine cliffs possess short rather than long-term stability because of undercutting, oversteepening, and the removal of basal debris by wave action. Mass movements therefore play an important role in the development of cliffed coasts, and there is a close relationship between the morphology of cliffs and the type of mass movement that takes place on them. Mass movements range, according to local circumstances, from the quasi-continuous fall of small debris to infrequent but extensive landsliding. Although rock falls are more frequent than deep-seated slides, they are generally much smaller. Falls occur in well-fractured rocks, especially where notches are cut into the cliff foot by waves, or, as in the tropics, by solution or bioerosion. Rock columns defined by joints or bedding planes also topple or overturn by forward tilting. Rock and slab falls, sags, and topples are essentially surficial failures induced by frost and other types of weathering, basal erosion, hydrostatic pressures exerted by water in rock clefts, and the reduction in confining pressures resulting from cliff erosion and retreat.

Deep-seated mass movements are triggered by groundwater build-up and basal undercutting. Translational slides usually occur where there are seaward dipping rocks, alternations of permeable and impermeable strata, massive rocks overlying incompetent materials, or argillaceous and other easily sheared rocks with low bearing strength. Slumps or rotational slides are common in thick, fairly homogeneous deposits of clay, shale, or marl. Sliding takes place in rocks that have been weakened by alternate wetting and drying, clay mineral swelling, or deep chemical weathering. Slides tend to occur during or shortly after snowmelt, or prolonged and/or intense precipitation. Water from septic systems, irrigation, runoff disruption, beach depletion through the building of coastal structures, and other human activities are playing increasing roles in some areas (Griggs and Trenhaile, 1994). The damming of rivers has also reduced the bed load reaching the coast, depleting beaches and exposing cliffs to more vigorous wave action.

SALT MARSH

Salt marshes or saline wetlands are vegetated intertidal flats dominated by low-growing halophytic (salt-tolerant) shrubs and herbaceous plants, particularly grasses. Typically, salt marsh borders freshwater or brackish environments. Largely confined to temperate coastlines, they occupy a similar niche to tropical mangrove forests; that is, the upper intertidal zone of inlets, estuaries, lagoons, and embayments, or fronting the open sea where low-energy conditions persist (Frey and Basan, 1985). In warm temperate, subtropical, and some tropical regions, salt marsh and mangrove communities sometimes intermingle, but can be separated by definition on the basis of floristics or intertidal position.

Salt marsh originates with the spread of vegetation onto an accreting intertidal mudflat. Fine suspended sediments (silts and clays) and organic material washed in by tides, and subsequently trapped by roots of salt marsh vegetation, generate a gently sloping depositional terrace or platform between the high spring tide level and the mid-tide line (Bird, 2000). At a smaller scale, characteristic features of salt marsh include tidal creeks, levees, cliffs, and salt pans. The patterns and morphology of these features are collectively dictated by a number of factors: the extent of vegetative cover; the climatic, hydrographic, and edaphic influences on this vegetation; the availability, composition, deposition, and compaction of sediments; organism–substrate relationships; topography; tidal range; wave and current energy and stability of the coastal area (Frey and Basan, 1985).

The salt marsh platform is typically dissected by a system of meandering creeks and levees that channel the ebb and flow of tidal waters. Wide shallow creeks are common where the salt marsh is in an early developmental phase or where sediments have high sand content, but as the marsh platform rises or expands with continued accretion, well-defined steep-edged channels become more commonplace. The seaward edge of a marsh may grade smoothly into adjacent tidal flats, or it may end abruptly in a small vertical cliff up to several meters high, or the transition may be marked by an irregular series of channels separated by ridges (Haslett, 2000; Ke and Collins, 2002).

The wide variety of sediments underlying coastal marsh systems reflect the range of adjacent terrestrial and marine habitats from whence these originate. The shallow waters and low-velocity currents characteristic of marsh surfaces promote deposition of fine-grained inorganic sediments such as mud, clay, silt, and fine sands, and rarely gravels. Most are reworked and modified by roots of plants and the action of animals, leading to the deposition of organic components, including peats which are formed from the degradation of roots, stems, and leaves of marsh plants and animal skeletons including shells and carbonate tests (Chapman, 1977; Dawes, 1998).

Salt marshes support an abundance of organisms of both terrestrial and marine origin. They are highly productive ecosystems, but the extreme physiological and ecological stresses of the intertidal environment maintain characteristically low species diversities. Clear zonation patterns of vegetation and associated fauna are generally evident, influenced by factors such as salinity (which ranges from near ocean strength to near fresh in most systems), frequency and duration of tidal exposure, and climate (Haslett, 2000). Low-marsh communities toward the seaward edge normally comprise pioneering halophytes such as sea grasses (e.g., *Zostera*) and glassworts (e.g., *Salicornia*) through to those tolerant of brackish conditions (e.g., *Spartina*). High-marsh communities, being relatively more stable and terrestrially influenced, include more diverse assemblages of less salt-tolerant species such as rushes (e.g., *Juncus* spp.), grasses (e.g., *Puccinellia, Sporobolus*), and herbs (e.g., *Aster, Plantago*).

Vegetation cover of a salt marsh surface does not usually follow a continuous sequence from sea-edge to land. In addition to creeks and channels, highly saline, dry, or water-filled shallow depressions often feature in the surface of the marsh. They form where vegetation has either failed to establish, or where it has died back, or where drainage channels have slumped and blocked. Strong evaporation from the resulting pools of water or bare substrate surfaces advances the accumulation of salts, inhibiting seed germination and further establishment of plants, and giving rise to the conspicuous vegetation-free areas known as salt pans (Bird, 2000).

SAND RIGHTS

Introduction

Sand Rights is a concept that merges the physical laws of sediment transport with societal laws of public trust. The basis doctrine is that human actions will not interfere, diminish, modify, or impede sand and other sediments from being transported to and along rivers, beaches, shores, or any flowing or windblown paths or bodies without proper restitution. Under this doctrine, projects should be designed or reevaluated to mitigate any interference that the project may have with sand transport.

As early as Justinian, cultures have understood that certain natural resources are incapable of private ownership. "By the law of nature these things are common to mankind—the air, running water, the sea and consequently the shores of the sea." (Institutes of Justinian 2.1.1, quoted in *National Audubon Society v. Superior Court* (1983) 33 Cal.3d 419, 433–34.) Traditionally water, navigation, fisheries, and tidelands had been covered by the public trust doctrine. In certain cases, states have extended the public trust doctrine to marine resources. The basis doctrine of Sand Rights would establish the application of public trust to inland and coastal sand resources.

Physical principles

The coast is a dynamic area—the junction of the land, the air, and the sea. The coastline can be divided into a series of littoral cells or segments to contain one or more sources of sand, mechanisms for moving sand along the coast, and a sink from which the sand cannot be carried back onshore by wave action. On the western US coast, headlands, rivers, and submarine canyons can often delineate the cell boundaries. On the eastern US coast, the littoral cells are defined differently, often as reaches between inlets, but the same processes apply. Similarly, littoral cells can be defined on the Gulf of Mexico and the Great Lakes. Sand is supplied to the coast from coastal streams, erosion of coastal cliffs, erosion of offshore reefs, or transport of offshore sediments onshore. Transport of sand up and down the coast is usually by waves and currents. Sediment sinks include submarine canyons, harbors, lagoons, sand dunes, and deep-water bars and shoals.

Coastal erosion is a major concern for many areas and sea-level rise will compound this problem. While coastlines have receded and advanced over the past centuries, human activities can interrupt or modify the supplies and delivery of this material to and along the coast. Dams and other flood control structures can block sediment and trap it in reservoirs or prevent channel erosion and reduce sediment supply. It has been estimated that hundreds of millions of cubic meters of sand are trapped behind dams in the Los Angeles, CA region and similar amounts are trapped by all the flood control structures on the Mississippi. The worldwide estimates for the amount of material trapped in reservoirs would be in trillions of cubic meters. In addition to trapping sediment, flood control structures reduce the carrying capacity of streams and thus the amount of sediment delivered to the coast. Finally, in-stream sand and gravel mining removes material that was being transported to the coast and reduces the overall amount of beach sediment that reaches the coast.

Coastal cliffs are a second source of beach material. Many coastal cliffs are composed of sandstone or contain a large percentage of sand-sized sediment. As these cliffs erode, they can supply significant amounts of beach quality material to the coast. When roads or railroads are built at the base of a coastal cliff, these structures can interfere with cliff erosion and reduce sediment delivery to the coast through road-clearing efforts. Supplies of sediment from coastal cliffs also can be reduced by the construction of seawalls or other armoring that prevents cliff erosion.

Waves can carry sand from offshore sources to the nearshore and onto the dry beach. These offshore sources, such as deep-water bars or ebb-tidal shoals, are often used for beach nourishment. Human activities of dredging from these offshore sources and depositing it on beaches has augmented the natural transport of offshore sediment to the coast, or made more sources of offshore sediments available as littoral material. However, if areas within the zone of on- and offshore transport are deepened, these areas will refill with littoral material that will be lost temporarily as beach material. Also, offshore structures can block the onshore transport of sediment.

Once sand is on the beach and in the nearshore area, waves and currents move it up and down the coast regularly. Structures, such as groins and jetties interrupt longshore transport of sediment and relocate areas of erosion and deposition. If there is no effort to place sediment downcoast of these structures or to by-pass sediment around the structures there will be accretion on the upcoast side and erosion on the downcoast side. The effect may be compounded by the construction of an entire series of structures. Offshore structures like breakwaters and reefs block or reduce wave energy shoreward of the structure. This modification of wave energy will alter the sediment carrying capacity in the nearshore and also the erosion and accretion areas.

Submarine canyons, deep-water bars, and sand dunes are natural sinks for coastal sediment. In general, once sediment is carried into one of these areas, it is no longer readily available as beach material. Harbors, inlets, and deepened navigation channels can also be temporary sinks. These features can function just like natural sediment sinks unless they are regularly maintained and the trapped material is reintroduced to the littoral system.

Finally, sand mining accounts for significant losses of beach material. Large-scale commercial sand mining has taken place on various beaches (e.g., Monterey, CA) and in various streams (e.g., San Juan Creek, Orange County, CA). This sand mostly goes for construction purposes, but it is also used in less familiar ways such as for making glass or pottery. Noncommercial sand mining also occurs. Every summer truckloads of sand are removed daily when seaweed, flotsam, and trash are raked from the beach. All these activities result in a net deficit of sand moving to and along the coast.

Societal significance of coastal sand

Coastlines have had importance throughout history. Fishermen built their homes and shops by the coast and gained access to the great food supply of the ocean. Oceans provided some of the earliest and most lasting modes of transportation and commerce routes. The coast has always had an important recreational value. The coast has also played an important role as a place of solace and spiritual renewal. It has become clear that everyone benefits from the coast.

Sand serves valuable purposes. It is a commercial resource, as is attested by the extensive sand-mining operations worldwide. Beaches are major recreational resources and tourist attractions for most coastal states and nations. Sandy beaches are also a major buffer and zone of protection for inland areas from coastal storms and hurricanes.

Beach erosion is a major problem in many areas. The coastline has never been static, yet, the problem of erosion has been exacerbated by those human activities that either have reduced supplies of sediment to the coast, or have changed its transport along the coast. As civilization demanded more from the coast, activities such as construction of cities and harbors interrupted natural supplies of coastal sediments. However, until recently, the connections between development far from the coast, changes to coastal sediment supplies and coastal erosion were not well-recognized.

Doctrine of public trust and sand rights

The doctrine of public trust traces it lineage to ancient Roman law that established certain types of property to be common to all people and incapable of private ownership. These common properties, *res communes*, include running water in the sea and the land beneath them. The sovereign or government is under obligation to manage these *res communes* lands for the public interest, in perpetuity. A private owner can have a bare legal title to the lands, the *jus publicum*, but this interest is subject to and restricted by the superior public interest.

The public trust doctrine was lost during the Middle Ages and was reinstated in England in the middle of the 16th century. Under this interpretation, the restraint was placed only upon the sovereign and only for tidelands, not for navigable waters. However, Parliament retained the power to enlarge or diminish the rights of the public over the tidelands, provided some legitimate public purpose was asserted.

The Roman and English versions of public trust have been carried over into American law where it is now firmly established. Since most land use law has been assigned to state and local governments, the development of public trust varies from state to state. Traditionally, public trust was reserved for navigation, commerce, and fisheries. Many states have expanded the use of public trust to water resources, protection of the environment, and recreational values.

In Florida, and states such as Oregon and Hawaii, the customary rights doctrine has been invoked to protect the public use of beaches. The Florida Supreme Court has observed:

> The beaches of Florida are of such a character as to use and potential development as to require separate consideration from other lands with respect to the elements and consequences of title. The sandy portion of the beaches are of no use for farming, grazing, timber production, or residency—the traditional uses of land—but has served as a thoroughfare and haven for fishermen and bathers, as well as a place of recreation for the public. The interest and rights of the public to the full use of the beaches should be protected. (*City of Daytona Beach v. Tona-Rama, Inc.* (1974) 294 So. 2d 73,77)

In California, the California Coastal Commission has used existing statutory authority to require mitigation of quantifiable sand losses. Both the losses from the construction of seawalls along coastal bluffs and the reductions to inland sediment supplies have been addressed through financial compensation into regional nourishment programs. Public agencies can use existing authorities to fund many nourishment projects.

Conclusion

The coast is one of the nations' most valuable areas and sand beaches are critical parts of the coast. The Sand Rights doctrine extends public trust to coastal beaches and those sand resources that are essential to perpetuation of coastal beaches. This doctrine requires that all decision-makers give careful consideration to proposed or existing projects that interfere with the delivery of sand to, or transport of sand along the beach. The basis doctrine is that human actions will not interfere, diminish, modify, or impede sand and other sediments from being transported to and along beaches, shores, or any flowing or windblown paths or bodies without proper restitution. Under this doctrine, projects should be designed or evaluated to mitigate any interference that the project may have with sand transport.

SANDY COASTS

Introduction

Sandy coasts are those coasts dominated by an abundance of sand-size sediments (0.063–2 mm). The location of these coasts is a function of both sand sources and coastal processes. As a consequence, they are more abundant in certain climate and geological or plate settings. They are most prevalent in humid climates supplying abundant terrigenous sand to passive margin coasts and where exposed to more energetic wave and tidal environments that can both winnow out the finer mud and concentrate and deposit the abundant sands in a range of wave-tide features. In addition, sandy coasts are also influenced by secondary regional features such as geology of the hinterland and shore, geological inheritance, sources of shelf siliclastic and carbonate sands, and littoral drift.

Terrigenous sources

Sand is the most abundant sediment of the world's open coasts. It occurs from the poles to the tropics, but with latitudinal and regional maxima. Sand is globally abundant for two reasons. First, the ultimate source rock of most terrigenous sand is granite, which makes up the cores of all continents. As granite erodes the less resilient weaker minerals (feldspars) chemically weather to fines, leaving behind the harder sand-size quartz (or silica) grains together with minor percentages of sand-size heavy minerals, all of which are resilient to abrasion. Secondary sources are sedimentary and metasedimentary rocks, all of which contain variable percentages of sand-size material. The erosion and weathering of all these rocks potentially supplies boulders through mud. However, erosion and transport processes selectively erode and transport the fines most readily in suspension, then the sands as traction and bedload, while the coarser gravel, cobbles, and boulders become increasingly intransigent. Table S1 highlights the transportability of different size fractions.

Transport

Fines are readily transported in suspension by rivers and streams to the coast. At the coast their continued suspension and transport by waves and tidal currents result in their deposition being restricted to quieter estuarine, deltaic, or shelf locations. Sand on the other hand once it reaches the coast is deposited rapidly as bedload, building river mouth bars and deltas. It can then be reworked on- and longshore by waves into bars and beaches, and by tides into tidal sand waves and ridges, all shallow water and shore features. The size of gravel and boulders

Table S1 Sediment size and settling rates (from Short, 1999, © John Wiley & Sons Limited, reprinted with permission)

Size	Grain diameter	Time to settle 1 m	Distance traveled per hour in 1 m/s current
Clay	0.001–0.008 mm	Hours to days	3.6 km
Silt	0.008–0.063 mm	5 min–2 h	3.6 km
Sand	0.063–2.000 mm	5 s–5 min	10's m
Cobble	2 mm–6.4 cm	1–5 s	<<1 m
Boulder	>6.4 cm	<1 s	0

restricts their erosion, transport, and availability. They will only reach the coast at the mouth of short, steep rivers, along eroding rocky coasts and when delivered by glaciers.

Accumulation and recycling

For the above reasons, even though fines dominate many of the world's river sediment discharges their deposition is precluded from energetic shores. Sands however, are not only deposited right at the coast, but once deposited are ideally suited to reside there. Gravel and boulders will also remain at the shore once deposited, however, they are more restricted in extent to usually high relief and high latitude coasts. Quartz sand and particularly heavy minerals are extremely resistant to physical abrasions and can be reworked time and time again by rivers, waves, tides, and winds, and are termed polycyclic. Consequently, many sedimentary shores are composed of quartz sand because it is globally abundant in source rocks (20–40% of crust); it is the major bedload product of denudation; it is relatively easily transported during high river discharge events; it can reside in the most energetic coastal environments; it is resilient and over time and can accumulate along coasts, and can be reworked during rising sea levels, leading in places to massive polycyclic accumulations of Quaternary (shelf) sand deposits.

Carbonate sands

The second major source of coastal sand is marine carbonates that live from shallow intertidal waters to the inner shelf. While carbonate detritus is more easily broken and abraded by physical processes, their *in situ* and shore linear sources, can act as a continual supply, with waves and tidal currents eroding, abrading, and transporting the sand size and coarser material shoreward. Carbonate sand coasts in fact dominate large areas of the world's tropical and arid temperate coasts (Short, 2002) (Figure S1). The source of these sands are both the shallow coral algae and reefs in the tropics, while in more temperate latitudes shelf carbonates (molluscs, red algae, encrusting bryozoans, and echinoids) are delivered both during and subsequent to sea-level transgressions from depth as great as 100 m (Boreen and James, 1993).

Climate

Climate plays a major role in the occurrence of sand coasts. Most terrigenous sand is derived from denudation of the hinterland and transported by rivers to the coast. Regions of greatest chemical and physical weathering will potentially supply the greatest volumes of sediment including sand to the coast. Figure S2 shows the global distribution of mechanical erosion, the world's major rivers and their solid discharge. Using this as an indicator of bedload sand discharge, the greatest supply of sediment to the coast is associated with low to lower mid-latitude river systems (40°N–40°S). All the rivers and their headwaters are associated with humid tropical and mid-latitude climates that supply the higher rainfall and warmer temperatures to physically and chemically erode and transport the sediments. While there are some major rivers in the higher latitudes (>40°N), the smaller discharges and dominance of physical weathering supplies generally low quantities of predominantly coarser sediments (sand through boulders). The impact of both climate and latitude on shelf sediment supply is highlighted by Figure S3, which shows the latitudinal distribution of shell, coral, rock and gravel, sand and mud. Sand dominates the subtropics and lower mid-latitudes (20–40°), and while sand volumes are still large in the tropics, mud still dominates owing to the intense chemical weathering and lower-energy coasts.

Hinterland geology also plays an important secondary role, as sand-rich source rocks (granites, sandstone, metasedimentary) will supply more sand and less suspended sediment, than finer grained rocks (e.g., basalt, shale, limestone).

Plate setting

Location of a coast relative to its tectonic plate setting is also a major contributing factor in the location of sand coasts. Inman and Nordstrom (1971) classified the world's coast according to their tectonic setting, and noted the dominance of coastal plains and deltaic coasts, usually associated with sand coast, on passive margin coasts (Table S2). The reasons for this are highlighted in Table S3. The passive margin coasts are supplied with abundant sand and finer sediments by larger river systems, draining distant mountains. At the coast they supply abundant, mature, stable sand, and fines, which build extensive sand-rich coastal strand plains composed of deltas and barriers, as along the east coast of the Americas and India. In contrast, convergent coasts have high relief and short rivers which tend to supply, along with mass movement, a limited amount of coarse, poorly sorted unstable sediments, as along the west coast of the Americas.

Landforms

Deltas

Sand supplied by river to the coast is initially deposited in deltaic systems. The proportion of sand in a delta and the overall morphology of the delta is a function of both the fluvial sediment supply, the geological inheritance that influences the shape and size of depositional basin or accommodation space, and the contribution of the river flow, waves, tides, littoral currents, and winds to the reworking, redistribution, and

construction of the deltaic and adjacent depositional systems (see e.g., Davis, 1983). River-dominated deltas tend to deposit the sand as digitate river channel, levee, and river mouth bar deposits, as in the Mississippi, with limited shoreline sand deposits. Tide-dominated deltas accumulate the sand in subaqueous shore perpendicular to linear tidal sand waves and ridges, again with little sand at the shore. Only along wave-dominated deltas do extensive shore parallel beaches, barriers, and strand plains occur, which if exposed to strong winds may be capped by coastal sand dunes.

Beaches

Beach systems are the most common and visual expression of sand coasts. They form the shore of all sand coasts whether backed by deltas, barriers, and sand dunes or even fronted by sand flats. Beaches can however, be formed from fine sand through boulders, and like sand supply itself the sediment type is a function of tectonic setting (Table S3) and latitude/climate (Table S4). As Table S4 indicates sand beaches are more likely to occur in the low- to mid-latitudes, with beach type also a function of sediment size, and through climate, wave environment. Some of the world's longest beach systems occur along the east and Gulf coast of the United States and the central Brazilian coast of South America, with beaches up to several hundred kilometers in length in south Brazil. While the visible beach usually forms a narrow strip along the shore, most beaches also extend offshore to the limit of modal wave base. On high-energy coasts this may be as deep as 30 m and as far as 2–3 km offshore.

Dunes

All beaches composed of fine to medium sand and exposed to onshore winds, particularly strong winds, will be backed by coastal sand dunes, composed of fine well-sorted sand. The location and occurrence of dunes is also a function of latitude/climate (Table S4) with the world's largest coastal sand dunes occurring on passive margin coasts exposed to moderate to strong onshore winds, as along the Brazilian trade wind coast and the south to west-facing coasts of South Africa, southern Australia, South America, west coast United States, and parts of western Europe. Most coastal sand dunes extend up to a few tens to hundreds of meters inland reaching elevations of a few tens of meters. They can in very exposed locations migrate up to tens of kilometers inland and to elevations of over 100 m and up to 200–300 m in extreme locations. In these locations the coastal sand dunes become a very dominant and prominent feature of the coastal landscape.

Tidal sand deposits

Coastal sand deposits can also include tidal sand deposits, which are by definition located in the inter to subtidal. Tidal inlets and their ebb and flood deltas are a component of all barrier islands, and all barriers and beaches bounded by an inlet. They can also accumulate extensive sand deposits in estuaries, in the tidal deltas and some tidal flats. Tidal sand deposits occur at occasional inlets along wave-dominated barrier systems. They become more dominant with decreasing wave height and increasing tide range as inlets increase in number and size, while along tide-dominated shores intertidal sand flats and subtidal sand ridges dominate the coast and nearshore zones.

Table S2 Tectonic coastal types and shoreline types (from Short, 1999, © John Wiley & Sons Limited, reprinted with permission; modified from Inman and Nordstrom, 1971)

Tectonic setting and shoreline type	Mountainous	Hilly, narrow shelf	Plains, narrow shelf	Plains, wide shelf	Hilly, wide shelf	Deltaic	Reef	Glaciated	World's coast
Convergent	96.2							23.9	39.1
Passive-neo	1.0	69.5	15.5			3.8			4.3
Passive-Afro		21.3	73.3	1.0		20.7	16.7	47.8	6.8

Table S3 Coastal characteristics of convergent and passive margin coasts

	Convergent margin	Passive margin
Age	Young (1–10s of millions of years)	Old (100s of million of years)
Relief	Steep, mountainous	Low-gradient plains
Landforms	High mountains and volcanoes	Coastal aggradation plains
	Narrow continental shelf	Wide, low continental shelf
	Deep-sea trough	Continental slope
Tectonics	Active, earthquakes	Quiescent, stable
Weathering	Physical, mass movement	Chemical, fluvial, rivers
Drainage	Short steep streams	Long, meandering rivers
Sediments		
Quantity	Low	High
Size	Fine–coarse (mud-boulder)	Fine (mud-sand)
Sorting	Poor	Well
Color	Dark	Light
Composition	Unstable minerals	Stable minerals (quartz)
Coastal landforms	Rocky, few beaches	Extensive barriers and deltas
Examples	West coast Americas	East coast Americas
	New Zealand	Southern Africa
	Iceland	Southern Australia
	Japan	North Alaska
		India

Table S4 Sediment and beach-dune characteristics on high-, mid-, and low-latitude coast (modified from Short, 1999, © John Wiley & Sons Limited, reprinted with permission)

Latitude	High	Mid	Low
Climate type	Polar	Temperate	Tropical
Latitudinal range	50°/60°–90°	30°/40°–50°/60°	0°–30°/40°
Sediments	Coarse (cobbles, shingle) dark, unstable minerals	Terrigenous and shelf quartz sand, temperate shelf carbonates	Fine terrigenous quartz sand, coral and algae reefs
Beach type	Reflective beach face Possible multi bar	Reflective to dissipative	Reflective
Other climatic impacts	Permafrost in barriers	Dune calcarenite in arid regions lithifies beaches and dunes	Beachrock lithifies intertidal beach
Dunes	Low and poorly developed owing to: coarse sand, light winds, short season, frozen winter surface, poor vegetation cover, prone to overwash	Largest on west-facing coasts in 40°S latitude, Well-developed: full range of dune types (foredunes through massive transgressive dunes)	Low to minimal owing to low waves and sediment supply and low winds Predominantly foredunes, some dune transgression on trade wind coasts

Barriers

All of the above, beaches, dunes, and tidal inlets are usually components of a larger sand barrier system. The barriers represent longer-term accumulations of wave-, wind-, and tide-deposited sand and other sediments. The barrier may be narrow transgressive barrier islands, wide regressive strand plains capped by beach and/or foredune ridges, or backed by larger coastal dune systems. Some of the world's most extensive sand barrier coasts include the barrier islands along the east and Gulf coast of the United States, the prograding attached barriers or embayed barriers as in much of southern Australia, and large barriers capped by dune systems as in parts of Brazil, South Africa, and Australia. Barriers can also contain tidal sand deposits and where not capped by dunes they are commonly backed by washover fans and aprons.

Large-scale sand coasts and landforms

As indicated in Tables S2 and S3, the largest accumulations of sand at the coast are associated with humid climates on passive margin coasts, in the lower mid to low latitudes. The most extensive sand coasts on each continent are:

North America: the southeast and Gulf coasts, both low-gradient passive margin coasts supplied by numerous rivers including the Mississippi, with the sand reworked onshore by a high-energy wave environment. Coastal dunes are however, poorly developed. Also parts of the west coast exposed to high shelf sediment supply and winds to build dunes.

South America: massive long-term sand supply to entire east coast, leading to an essentially sand barrier–dune coast from the Amazon south to Argentina. Long beach–barrier–dune systems for much of the coast.

Africa: beach, barrier and dune systems ring most of the continent, with sand supplies by local rivers, including the Nile, Niger, and Orange, and on the most exposed coasts by shelf supply of quartz, and in the south also carbonate sands.

Asia: sand dominates most exposed western (Europe—Mediterranean), southern (India), and eastern shores (Southeast Asia—China), with some substantial river systems and deltas and extensive sand barriers in south India and Sri Lanka.

Australia: 50% of passive margin coast consists of sand deposits, with low-energy beaches in north through high-energy beaches and dune systems across south. Supply from rivers and shelf in north, and from shelf quartz in southeast and carbonate in the south and west.

The largest single accumulation of coastal sand in the world is *Fraser Island* on Australia's east coast. The massive sand island is 125 km long and up to 25 km wide. It averages 100 m in elevation reaching 244 m and has an area of 1,840 km^2 and a conservative volume (above sea level) of 185 km^3. It is the largest and last of five near continuous sand islands which extend for 320 km along on a passive margin coast backed by a humid hinterland. The long-term (Pleistocene) accumulation of sand on the islands has been favored by numerous rivers supplying quartz sand to the updrift coast, predominately northern littoral drift toward the islands, coastal orientation to receive the southerly waves, and coastal inflection north of the island which places the island at the terminus of the littoral transport, bedrock headlands to tie the island, moderate to occasionally high-wave energy to move sand long and onshore, and moderate south-east trades to build successive layers of massive dunes up to 244 m high and 20 km wide.

SCOUR AND BURIAL OF OBJECTS IN SHALLOW WATER

Scour around objects on or near a sediment bed are caused by flow modification due to the object. The presence of the object generates vortices that locally change the bottom stress inducing changes in the sediment transport rate. The presence of an obstacle on a sediment bed where the stress is below the threshold (onset) of motion may induce local intensification and sediment transport, while an obstacle on a bed surface where the stress exceeds the threshold will alter the stress field, producing local depressions and ridges in the bed. The scour phenomenon occurs in unidirectional and oscillatory flow and in types of fluid ranging from air to water to sediment-laden turbidity currents and pyroclastic flows. Obstacles producing scour range from millimeter size grains to topographic features many meters high and kilometers in length. The resulting bedforms range from sand streaks and ripples to large desert dunes and scour moats and sediment drifts around seamounts in the deep ocean.

Here we are primarily concerned with scour in nearshore waters and on beaches where the flow is both unidirectional and oscillatory. Scour naturally occurs wherever a larger object occurs on an otherwise smaller grained bed. For example, a seashell or a kelp-rafted rock on the seabed will form scour features ranging in size from rhomboid marks around small objects to crater-like crescentic depressions twice the size of the shell or rock. On larger scales, rip currents scour large channels over and through longshore bars. Above the waterline, wind-blown scour features form around kelp clumps and rocks on the beach, while accretionary dunes and sand shadows form around hardrock outcrops on the coastal desert floor. In recent decades, the importance of scour in the burial of mines has led to increased interest in scour phenomena.

Introduction

Scour and scour marks are the erosional and accretionary bedform patterns that occur in the vicinity of obstacles that are on or near a sediment bed. Scour always involves some degree of perturbation in the flow system that changes the local pattern of erosion and deposition relative to that of the general flow. The primary scour pattern may be erosion as in the formation of crescentic scour around a rock on the beach (Figure S4) or depositional as in the dune deposits in the stagnation area of flow around an outcrop (Figure S5).

Any form that locally concentrates vorticity near the bed can elevate bed shear stress and initiate onset of grain motion, leading to local bed scour including bumps and depressions on the bed itself (Figure S6). Once initiated, a pattern of scour may spread down current in the form of a growing field of current ripples (Figures S6(B)–(D)), while vortex ripples under wave action may spread both against and with wave propagation from a single initiating irregularity in the bed (Inman and Bowen, 1962; Tunstall and Inman, 1975).

The most commonly studied scour patterns are those associated with single bluff (blunt) bodies placed on or protruding from the bed. There is an extensive engineering literature of the scour around the piles of bridges and piers (e.g., Collins, 1980; Chiew and Melville, 1987). Engineers refer to scour as *local* when it results from the effects of a structure on the flow pattern and *general* when it would occur irrespective of the presence of a structure; it is termed *clear water scour* when the bed upstream of a structure is at rest (e.g., Raudkivi, 1990).

In sedimentology, the interest has usually been in the scour pattern around individual objects, referred to as *scour marks* (e.g., Pettijohn and Potter, 1964; Reineck and Singh, 1975) or as *obstacle marks* (Allen, 1984, 1985). Allen further subdivides obstacle marks into *current crescents, current shadows*, and *scour-remnant ridges*. It appears, from the extensive literature on the subject, that current crescent and *crescentic scour mark* are the most general terms for the crescentic feature formed around an object on the bed, and that the feature may be either erosional as in Figure S4 or accretional as in Figure S5. The appearance of other associated features such as current shadow, scour-remnant ridges, and ripples are wake phenomena that depend upon the height to width aspects of the object, the nature of the flow system, and the type of sediment.

Bagnold (1941) introduced *sand shadow* for the various shapes of sand accumulation in the shelter of an obstacle. Allen's (1984) current shadow is based on Bagnold's sand shadow. Allen defines scour-remnant ridges as the small ridges of sand, snow, or mud preserved in place on the lee side of resistant objects after the surrounding material has been eroded away. Thus scour-remnant ridges are residual leeward

Figure S4 Wind-formed crescentic scour pattern around a rock (~30 cm diameter) on the beach berm, Coronado, CA. Wind blows from left to right (D.L. Inman photograph).

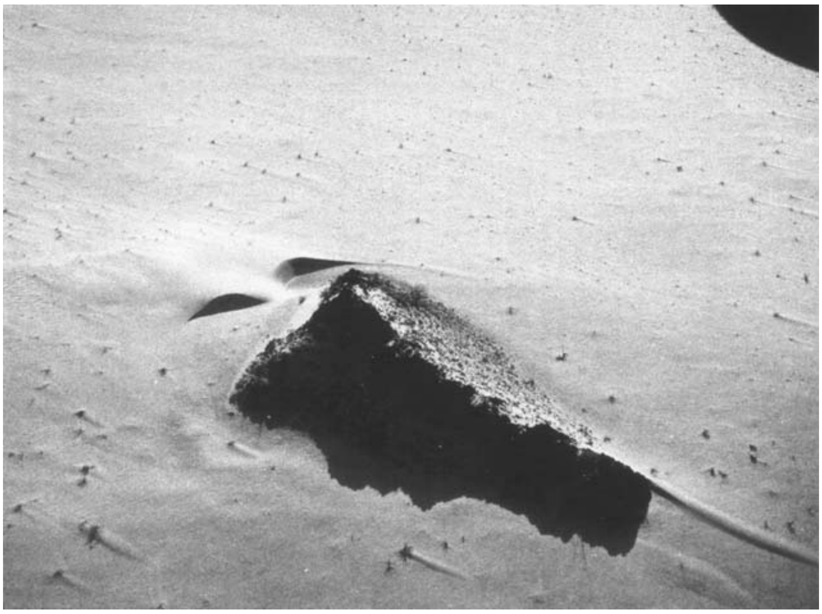

Figure S5 Wind-deposited crescentic pattern consisting of two barchan dunes formed around an outcropping ridge (~8 m high, 40 m long) on the desert floor, northwestern Gulf of California. Wind blows from upper left to lower right as indicated by sand shadows in the lee of bushes and by the double shadow from the sand drift passing along the sides of the ridge (D.L. Inman photograph).

phenomena while current (or sand) shadows are depositional and/or erosional leeward bedforms.

Characteristics of the flow around a vertical cylinder, such as a bridge pile in steady currents, have been investigated extensively (e.g., Shen *et al*., 1969; Breusers *et al*., 1977). It has been found that a horseshoe vortex above the scoured bed is a dominant factor in the scour process, and that the vortex has a close relationship with the bed profile near the cylinder. The vortex behavior caused by the object is thus a very important factor to consider in the estimation of bed scour as described under Scour Mechanics.

Relatively few studies have been conducted on scour induced by waves and currents. Nishizawa and Sawamoto (1988) and Sumer *et al.* (1992) have studied the flow around a slender vertical cylinder under waves using flow visualization techniques. They have reported relationships

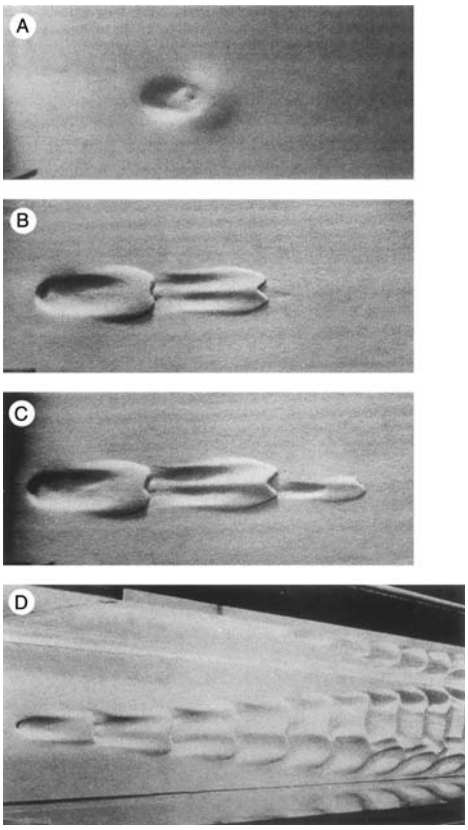

Figure S6 Progressive downstream propagation and lateral widening of a single perturbation (A) on a fine sand bed. Flume is 17 cm wide (sidewalls visible in panel as in (D) and bottom stress is near the threshold of grain motion (photographs by permission of John Dingler).

between the flow characteristics and nondimensional parameters of flow similitude such as the Strouhal number (acceleration forces/inertial forces) based on experimental results for a flat bottom. There is less literature for a scoured seabed, probably because these flows often show a highly complex three-dimensional rippled pattern owing to the complicated shape of natural obstacles and the unsteadiness of the main flow. Even for simple shapes such as a cylinder, unsteady three-dimensional flow over the bed generates vortices that govern the local scour process.

Continued scour around objects on a sand bed usually leads to complete burial of the object. Shells and rafted objects dropped to the seafloor eventually bury and disappear if the sand bed has sufficient thickness (e.g., Inman, 1957, Figures 20, 21). A study of mine scour and burial was conducted for the Office of Naval Research during 1953–56 on the sandy shelf off the Scripps Institution of Oceanography in La Jolla, CA, in water depths extending from the surf zone to 23 m (Inman and Jenkins, 1996). The mines were 1.6 m long cylinders, 60 cm in diameter. It was found that the burial process began with scour depressions around the mine and continued with rollover into the depressions (Figure S7). This process repeated itself until the mine was completely buried. Burial time ranged from hours and days in the surf zone to almost one year at 17 m depth.

Scour mechanics

The scour phenomenon around objects differs from other types of sediment flux in that the presence of an object on or near the bed induces local changes in an otherwise uniform pattern of bed stress, thereby causing local patterns of erosion and/or accretion that may differ from the general bedform pattern. The object may be either blunt or streamlined and the resulting scour pattern may be erosional, depositional, or both. Scour develops from a variety of mechanisms whose relative importance depends upon the scale and intensity of the flow and the relative size and shape of the obstacle. The most common and largest bedforms result from scour around bluff bodies where the formation of a horseshoe vortex generates a scour hole that begins on the upstream side and wraps around the object (Figure S4) as described below.

The mechanics of the scour around a body are inherent in the vorticity field generated when a fluid moves over a bed or solid surface. For example, consider the velocity profile above the bed and up current from an object on the bed (Figure S8). The shear near the bed in the bottom boundary layer generates vorticity between the layers of differing flow velocity creating a vorticity sheet. *Vorticity* is the angular momentum of a fluid element, while a *vortex* is the arrangement of many of these fluid elements into a pattern of angular motion.

The presence of an obstacle on the bed rearranges the sheet of vorticity in the boundary layer, and creates new vorticity by the shear flow around the obstacle. The flow disturbance of the obstacle creates a stagnation point (s′) at the bed interface upstream of the obstacle. The bed vorticity in the approaching flow collects at the stagnation point forming a local excess of vorticity that organizes into a *forward bound vortex* (Figure S8) that moves the stagnation point (s) upstream of the vortex. The forward bound vortex initiates the scour process by causing intense velocity shear stress at the base of the obstacle. The incoming vorticity from the flow builds up in the bound vortex and the excess leaks around the base of the cylinder forming a pair of *trailing vortex filaments* on either side of the obstacle. The bound vortex with its pair of trailing filaments form a vortex system known as a *horseshoe vortex*. The trailing vortex filaments extend the region of scour from the upstream base of the obstacle, around the sides, and downstream. As the trailing filaments extend downstream, the vorticity of the filaments diffuse into the interior of the fluid, thereby slowing the filament rotation and weakening the shear stress on the bed. Consequently, the scour diminishes downstream of the obstacle forming a scour pattern around the obstacle known as *current crescent* or *crescentic scour mark*.

The horseshoe vortex and its associated crescent scour are nearfield bedform responses that occur over distances of about two obstacle diameters. Further downstream in the farfield the trailing filaments of the horseshoe vortex begin to entwine into a helical vortex system. At each crossover of the helical pairs, the induced velocities of the vortex system approach a null on the bed, allowing for complimentary depositional features such as ripple marks in the current shadow downstream of the crescentic scour. Initially, both the near and farfield scour and its shadow system are referred to as *forced* forms because these erosional and depositional responses are controlled by the length scales of the flow field around the obstacle. However, once the scour process erodes deeply into the bed, the crescentic scour features will modify the flow field around the obstacle. In turn, the modified flow field further modifies the form of the scour and the associated bedforms in the current shadow. The fully developed horseshoe vortex is a consequence of the scour depression. Therefore, once this feedback takes place, the scour depression becomes an *interactive* part of a fluid-bedform system where the bedform interacts with and extensively modifies the flow field above it.

Other scour mechanisms

Other scour mechanisms become important in very shallow water typical of the swash and backwash motion of wave runup on the beach face. These mechanisms are associated with thin flows where water velocity often exceeds the critical limit for wave propagation and where capillary waves become important. Also, in thin flows, common "V"-shaped ship waves are formed by small objects and induce stress perturbations on the sediment bed. As a consequence, the beach face often shows rhomboid marks caused by one or more of the mechanisms associated with thin flow (Figure S9). Large rhomboid marks 3–10 m across are known to occur on beaches following the backwash from tsunami waves (i.e., Shepard, 1963, figure 100(B)).

The flow regime over the beach face may be either subcritical ($u < \sqrt{gh}$) or supercritical ($u > \sqrt{gh}$) depending on the speed of the water u relative to the shallow water wave speed $\sqrt{gh}$, where g is the acceleration of gravity and h is the thickness of the flow. In either case, the height of small obstacles such as shells, pebbles, and the feathery antennae of filter feeding organisms that protrude above the bed are of the order of the flow thickness. Supercritical flow is readily perturbed by an obstacle on the bed and locally slowed to subcritical flow by small oblique hydraulic jumps (Henderson, 1966) upstream of and extending downstream from the obstacle in a V-shaped pattern. The turbulence of the hydraulic jump scours a corresponding V-shaped erosion pattern around the obstacle, often made strikingly visible by exposure of dark minerals in the laminated beach sand similar to that shown in Figure S9. Intersections of adjacent V-shaped jumps form the characteristic diamond pattern of the rhomboid ripple. These marks are distinguished by their long scour trail and because the vertex of the V-shape is always upstream of the obstacle, much like the crescentic scour of larger obstacles under subcritical flow conditions. However, the large supercritical

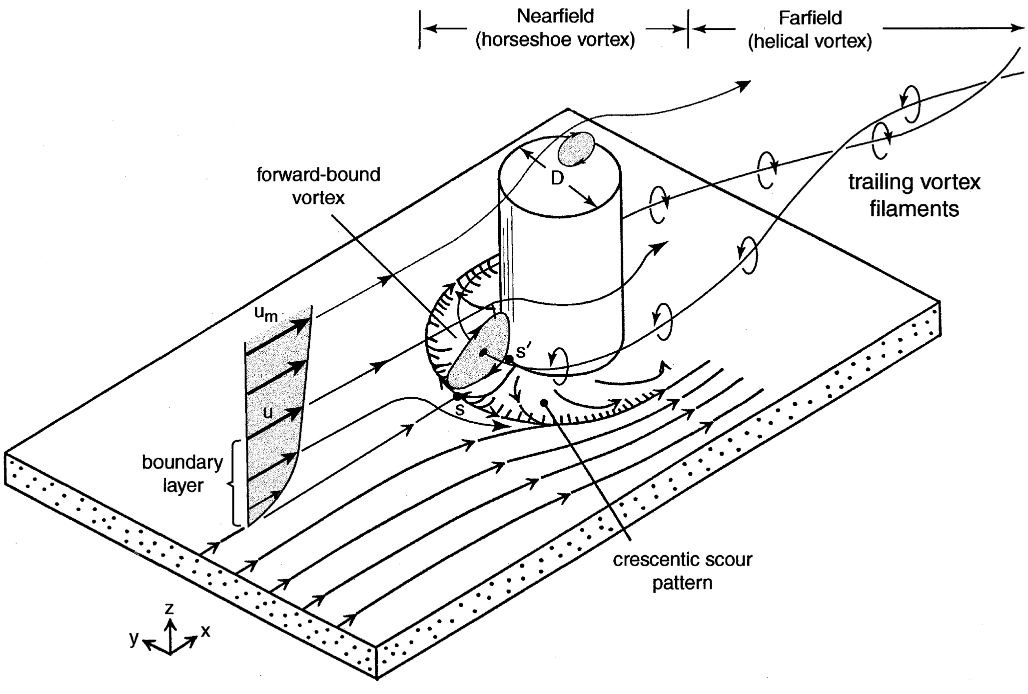

Figure S8 Definition sketch of fluid motion and scour features around an upright cylinder extending through the surface of a sediment bed under unidirectional flow (after Schlichting, 1979; Allen, 1984); compare with Figure S4.

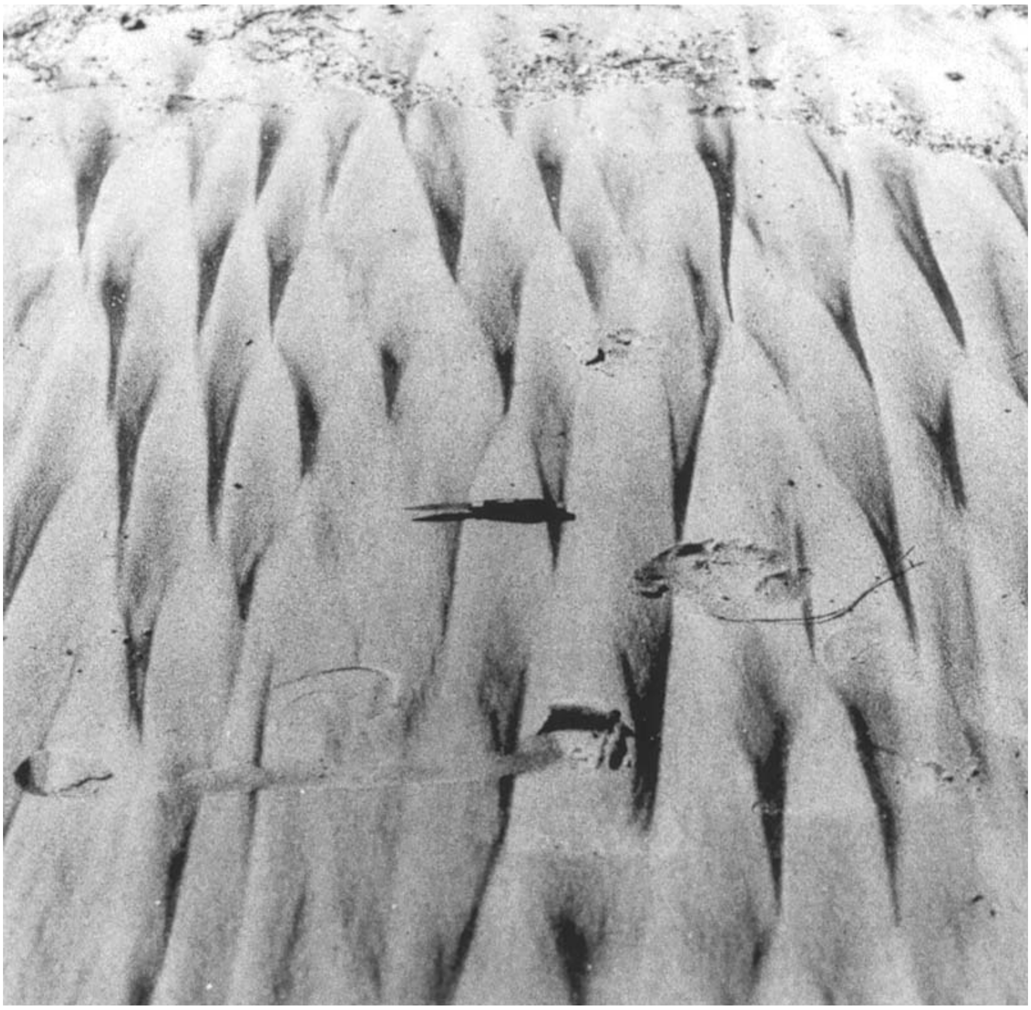

Figure S9 Rhomboid ripple marks on beach face at La Jolla, CA. Diamond pattern associated with flow divergence around antennae of a field of sand crabs (*Emerita analoga*). Photo looking seaward, knife (including blade) 12 cm, swash mark at top (D.L. Inman photograph).

rhomboid marks are less common than would be expected because supercritical flow over sand beaches rapidly develop *backwash ripples*, small-scale sand waves that parallel the beach contours and obliterate the large, extensive rhomboid marks that are found on the otherwise flat beach face.

There are at least three thin-flow mechanisms that may lead to the formation of rhomboidal patterns in subcritical backwash flow. These include the bow and stern wave mechanisms of ordinary ship waves (e.g., Stoker, 1957; Whitham, 1974), and the formation of capillary waves. Bow waves may form at the stagnation point upstream of an obstacle on the beach, and travel outward with the traditional Kelvin angle of the classical ship wave pattern. In contrast, thinning flow over the obstacle may become supercritical, then revert to subcritical flow with the accompanying small hydraulic jump downstream of the object. The wakes from both bow and stern waves form V-shapes that trail downstream of the object, with the vertex of the V on the upstream side of the obstacle for the bow-wave case and just downstream for the stern wave. The rhomboid ripple marks shown in Figure S9 were observed to have formed from the bow waves of the filter feeding beach crab *Emerita*. Sand crabs together with other beach-dwelling organisms, such as the bean clam *Donax gouldii* (Ricketts *et al*., 1985), play a far more active part in shaping bedforms on sandy beaches than is generally recognized.

Often, the system of ship waves formed by small obstacles on the beach have short-length scales where surface tension forces become important. In this case, the gravity–capillary waves (Whitham, 1974) can propagate upstream as well as downstream of the object and produce a more parabolic-shaped wave and scour pattern near the object than for typical rhomboid marks.

SEA-LEVEL CHANGE—See CHANGING SEA LEVELS

SEA-LEVEL CHANGES DURING THE LAST MILLENNIUM

Introduction

The last millennium includes well-known periods of marked, possibly global, climatic change, such as the Medieval Warm Period (MWP) and the Little Ice Age (LIA), as well as the period of global industrialization, often referred to in climatic terms as the period of Modern Warming (MW). Some important questions, relating to these periods, are key to understanding the relationship between climate change and *changing sea levels* (*q.v.*). What was the pattern and amplitude of sea-level change during the LIA and the MWP? Can the MWP serve as an analog for present and future sea-level conditions? When did the rapid rise of sea level, as registered by tide-gauge measurements, commence? Has sea-level rise accelerated during the 20th century? Because sea-level records spanning the last millennium are recent from a geological point of view, they have particular relevance to issues of *global warming* (*q.v.*) and future climate. Given the historical timescale, the answers to the four questions rely on the interpretation of instrumental as well as geologic records.

In view of the importance of a good understanding of the most recent sea-level history, it is perhaps somewhat surprising that detailed records are rare. This can be ascribed to three causes. First, the length of observational records is relatively short. The oldest direct measurements of sea level started in Amsterdam in 1682. The Permanent Service for Mean Sea Level (PSMSL) database contains only eight records that start before 1850, the oldest being Brest in western France (1807). Second, conventional geological methods of *Holocene* (*q.v.*) sea-level reconstruction have inherent limitations. Diagrams of radiocarbon-dated sea-level indicators plotted in a time-depth diagram reveal underlying trends but usually do not yield sufficient precision to resolve oscillations of sea-level over the past 1,000 years, which are on the order of decimeters. Geomorphologic evidence, in the form of beach ridges, marine platforms, and rock notches, also has its limits in terms of resolving power. Accurate dating of sea-level positions is limited by statistical uncertainties of the radiocarbon method. Finally, human development has in many locations around the world impacted on sedimentary environments. In northwest Europe, for example, many salt marshes have been reclaimed or embanked and the once extensive coastal fen peatlands have become a rare feature.

This entry will review published records of sea-level change during the past millennium, with a primary focus on the salt marsh records from the northeast coast of the United States. It will highlight some of the common features in these records. The main aim of this review, however, is to discuss the pitfalls and problems that need to be resolved before any wider climatic interpretations can be made from the sea-level data.

Northeastern United States

In recent years, detailed analyses of the litho- and biostratigraphy of *salt marshes* (*q.v.*) along the northeast coast of the United States have yielded relatively complete and continuous records of sea-level changes spanning the last millennium. The vegetated surfaces of the salt marshes have remained close to the high tide mark throughout the middle and late Holocene while sea level has been rising, forming accumulations of highly organic sediment from which sea-level information can be extracted. Some of the sea-level records from the northeastern United States are depicted in Figure S10.

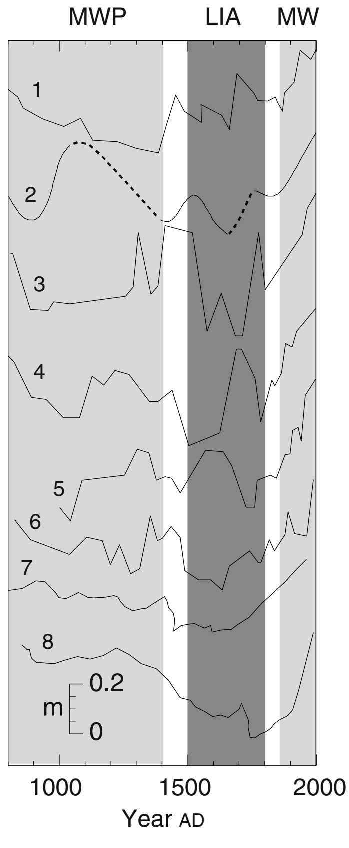

Figure S10 Sea-level records from Connecticut (1–6; compiled by van de Plassche, 2000) and Maine (7, 8), USA. (1, 2) Hammock River marsh. (3) Farm River marsh. (4, 5) East River marsh. (6) West River marsh. (7) Machiasport, eastern Maine (Gehrels, 1999). (8) Wells, southwestern Maine (Gehrels *et al.*, 2000). Millennial scale trends reflecting isostatic subsidence (1.0 m per 1,000 yr for Connecticut, 0.43 m per 1,000 yr for Machiasport, 0.30 m per 1,000 yr for Wells) have been removed from the relative sea-level curves. MWP, Medieval Warm Period; LIA, Little Ice Age; MW, Modern Warming.

Salt marsh sediments as recorders of sea-level change

The ability of salt marsh sediments to record sea-level rise is controlled by the balance between sediment accretion and sea-level rise. When sedimentation outpaces sea-level rise, a regression is recorded. Alternatively, when sea-level rise is faster than accretion, a transgressive overlap occurs. These landward and seaward environmental shifts are manifested in the lithostratigraphy of the marshes. For example, a regressive shift can be recognized by an organic-rich high marsh facies overlying a clay-rich low marsh facies, both containing identifiable remains of plant roots and rhizomes. Biostratigraphy is often more useful in that it can detect changes within a distinct lithostratigraphical unit, offering greater resolution. In the marshes of northeastern North America, foraminifera have proven to be the most useful biological sea-level indicators (Scott and Medioli, 1978). Different species of these single-celled organisms possess different tolerances to air and therefore live in distinct zones on the salt marshes, much like the vascular plants. Their high abundance and good preservation enable a quantitative assessment of former marsh heights from fossil foraminifera in cores. The most accurate way to calculate sea-level changes from reconstructed paleo-marsh surfaces is through the use of transfer functions based on modern foraminiferal distributions (Gehrels, 1999, 2000).

Besides the upward motion of sea level, the process of autocompaction provides accommodation space for sediments to accumulate (Gehrels, 1999; Allen, 2000). Autocompaction is defined as compression of a sedimentary package under its own weight (Kaye and Barghoorn, 1964; Allen, 1999). While the degree of autocompaction is sometimes difficult to assess, the process ensures that sea-level stillstands and even small sea-level falls are registered when sediment fills the accommodation space created by compression of the sediment package. In theory, a relative sea-level signal can be isolated when rates of sediment accretion and rates of autocompaction are determined. Sediment accretion is measured through detailed dating, while autocompaction can be determined from dating basal peat (Gehrels, 1999) or by a geotechnically based modeling approach.

Medieval Warm Period

The period from AD 800 to 1400 is often referred to as the MWP. Although warming may not have occurred synchronously on a global scale, the MWP offers the nearest reasonable historical analog to future global warming conditions. In Connecticut, van de Plassche *et al.* (1998) and van de Plassche (2000) recorded a sea-level rise of 0.25 m (corrected for isostatic subsidence) between AD 950 and 1000 and estimated that, during the MWP, sea level stood between 0 and 0.5 m higher than during the LIA. In an earlier study of the same salt marsh, however, Varekamp *et al.* (1992) could not find evidence for high rates of sea-level rise during the MWP. Nydick *et al.* (1995) documented slightly higher sea levels in one of two study sites a few kilometers further west. In eastern Maine, sea levels during the MWP were about 0.2 m lower than present-day levels, and 0.2 m higher than during the LIA (Gehrels, 1999). The error margins on these sea-level positions were determined statistically to be about $\pm$0.25 m. The record from southwestern Maine (Gehrels *et al.*, 2000) is better dated and shows a sea level close to the present height during the MWP.

Little Ice Age

Like the MWP, the duration and intensity of the LIA varies from place to place, but may be taken as the period from AD 1500 to 1800 in the northern hemisphere, although in Scandinavia AD 1900 is often considered as the end of the cooling. In Connecticut, Varekamp and Thomas (1998) recorded a slow rate of relative sea-level rise of 0.3 mm per year from AD 1300 to 1650, compared to a rise of 1.6 mm/yr averaged over the past 1,000 years. This finding was confirmed by van de Plassche *et al.* (1998) in a nearby marsh. In eastern Maine, sea level fell slightly between AD 1500 and 1700 (Gehrels, 1999), while in southwestern Maine, sea level fell after AD 1200 to reach a lowstand of 0.5 ± 0.25 m below present sea level between AD 1700 and 1800 (Gehrels *et al.*, 2000).

Past 300 years

Sea-level records from Connecticut and Maine are consistent in that they all show a rapid sea-level rise during the past several centuries. In southwestern Maine, a relative sea-level rise of 0.5 m has occurred since AD 1800 (Gehrels *et al.*, 2000). A similar rise occurred in eastern Maine (Gehrels, 1999) but the chronology is not well constrained. Records from Connecticut show a sea-level rise of 0.3–0.6 m since ~1700 AD superimposed on a long-term trend of 1 mm/yr (van de Plassche, 2000). In Dennis Creek, New Jersey, Varekamp, and Thomas (1998) documented a relative sea-level rise of 7 mm/yr since AD 1650, a rate which appears anomalously high. The rates of sea-level rise in the salt marshes of Connecticut and Maine for the past 300 years are comparable with *tide-gauge* (*q.v.*) observations during the past 100 years. The salt marsh records do not clearly resolve any acceleration of sea level in the past 150 years.

Other regions

Detailed high-resolution records from coastlines outside eastern North America do not exist, but several studies have shown fluctuations of sea level during the last 1,000 years. The studies discussed below are reviewed by Long (2000) and corresponding references can be found therein. In the South Pacific, sea levels were possibly up to 1 m higher than present levels during the MWP and up to 0.9 m lower than present levels during the LIA. Data from this region must be treated with caution as the sea-level index points come from many different islands thousands of miles apart and error margins were not considered. In a salt marsh on the south coast of Britain, increased sedimentation rates during the past 200 years might be related to accelerated sea-level rise. In the coastal plain of Belgium and northern France sea level did not reach a clear highstand during the MWP. Sea-level index points from the Frisian Islands in the Netherlands are imprecise, but a rapid sea-level rise may have occurred at some time during the past 800 years while sea-level rise possibly slowed down during the LIA.

Long instrumental records of sea-level change

Tide-gauge records long enough to span the climatic transition between the LIA and MW are sparse. Of the eight sea-level records commencing before 1850 that are held in the PSMSL database, seven are from Europe. The other one is from Bermuda and started in 1833. Woodworth (1990) analyzed the oldest European mean sea-level records, some of which are not officially part of the PSMSL database. Combining observations from Brest (starting in 1807), Sheerness (1834), Amsterdam (1700), and Stockholm (1774), he found an acceleration of 0.4 mm/yr per century. The Liverpool record, starting in 1768, shows an acceleration of 0.33 ± 0.10 mm per year per century, with a mean rise of 0.39 ± 0.17 mm/yr between 1768 and 1880 and 1.22 ± 0.25 mm/yr for the 20th century (Woodworth, 1999). Ekman (1999) estimated that sea-level rise, corrected for isostasy, increased at Stockholm from 0.0 ± 0.4 mm/yr between 1774 and 1884 to 1.05 ± 0.25 mm/yr between 1892 and 1991. In an earlier study, Mörner (1973) reconstructed from tide-gauge data at Amsterdam, Stockholm, and Warnemünde a stable "eustatic" sea level from 1682 to 1740, a fall of 0.25 mm/yr between 1740 and 1820 and a stable sea level from 1820 to 1840, followed by a rapid sea-level rise of 1.1 mm/yr around 1840 which lasted until 1950. The evidence from Florida for an acceleration since 1846 is weak (Maul and Martin, 1993), while Douglas (1992) found no statistical evidence to support a global sea-level acceleration after 1850. The feasibility of assessing a global rate and potential acceleration of sea-level rise from tide-gauge data may be questioned on the grounds that large parts of ocean basins are not represented by long records. For that reason, it may be argued that temporal variability of sea level should only be assessed on a regional scale.

Problems

Precision

The main problem in accurately reconstructing sea-level oscillations during the past 1,000 years is that the amplitude of fluctuations is on the same order as the precision of the sea-level indicators. The signal-to-noise ratio is often very low. Statistical analyses of the errors associated with the indicative meaning of microfauna in salt marshes, for example, show that they are on the order of $\pm$0.15 m at best (e.g., Gehrels, 2000). Surveying errors and other uncertainties add to the imprecision. Scott and Medioli's (1978) claim that the foraminifer *Trochammina macrescens* can indicate sea levels with a precision of $\pm$0.05 m is not statistically supported.

Salt marsh records of sea-level change are reliable only if sedimentation has been continuous. Variations in sedimentation rate should be adequately resolved by the dating of the sequence. Given the complex stratigraphy of many salt marshes, it is crucial that the site from which sea-level change is reconstructed is carefully selected.

Suitable sites for sea-level reconstruction may be found very near the highest tide level in broad, undisturbed areas of high marsh, away from tidal creeks and channels. In lower marsh areas and tidal flats, the precision of sea-level indicators is usually too low to resolve changes in height caused by accretion while sedimentation is often episodic. Clayey tidal flat and low-marsh facies are therefore best avoided, also because suitable material for dating is sparse. Some contradictions between sea-level records from the same salt marshes in Connecticut may be due to core site selection.

Near the highest tide level, accommodation space is minimal and its creation is controlled by a rising sea level and autocompaction (Allen, 2000). The stratigraphic record is hence (mostly) a reflection of sea-level change, rather than the static infilling of available accommodation space. Even during stillstands and sea-level reversals sedimentation and peat growth may continue, as the compression of the salt marsh sediments under their accumulating weight provides the accommodation space.

Dating

Radiocarbon measurement is the method commonly used for dating sea-level changes in the last 1,000 years. However, this method is limited in its precision due to the associated statistical counting errors. The radiocarbon ages, including their errors, need to be expressed into calendar years when rates of sea-level rise are calculated. The wiggles in the radiocarbon calibration curve provide particular problems for dating sediments that were deposited in the past 300 years. In Table S5, calibration results are given for two ^{14}C ages to illustrate radiocarbon age uncertainties. The ages represent, with 95% certainty (2σ), time spans of 74 and 131 years, respectively.

Pollen markers are often useful for dating sediments younger than 300 years, provided they are accurately matched with historical events. Lead and cesium radioisotopes provide means to date the last 100 years and enable comparisons with observational records.

Conclusions

Sea-level records for the past millennium come primarily from the northeast coast of the United States. In this region, there is sparse evidence for a significant highstand during the MWP. It appears that there has been a widespread sea-level low- or stillstand during the LIA, which has, to some extent, also been documented in other regions. Another common element in the US records is the rapid rise of sea level since about AD 1800. The longest European instrumental sea-level records have recorded an acceleration of sea-level rise into the 20th century. Records that start after AD 1850 are too short to detect any, possibly anthropogenic, acceleration in the rise of sea level.

The finding that sea-level rise was well underway before ca. 1850 would suggest that contemporary sea-level rise is, at least, partly the result of natural warming following the LIA. An acceleration in industrial times points to anthropogenic sea-level rise as an additional factor. Clearly, these results are not conclusive until they can be replicated in other localities and chronological control is improved.

An intriguing question is why the MWP did not produce any clear sea-level signal, even though temperatures were as high as they are today. Apparently, warmth does not necessarily produce higher sea levels through increased melting and thermal expansion of the ocean surface layer. The relationship between temperature and sea level is complicated by additional oceanographic factors. A hypothesis that needs to be tested is whether the velocity of the Gulf Stream can lower sea levels during warm spells. It has been shown from tide-gauge records that, along the east coast of North America, increase in Gulf Stream velocity produces low coastal sea levels (Ezer *et al*., 1995) while transporting heat northwards at a higher rate thereby warming up the northern Atlantic (Kushnir, 1994). Bianchi and McCave (1999) produced the first record of deep-current strength south of Iceland showing high rates of flow around AD 1000, similar to today. More such records are needed to investigate the link between ocean current velocity and sea-level change along the east coast of North America.

Table S5 Two examples of calibration of radiocarbon ages into calendar years produced by the program Calib4

^{14}C age	1σ Calendar age (AD)	2σ Calendar age (AD)
500 ± 40	1408–39	1331–41, 1396–1450
200 ± 20	1661–70, 1674–80, 1741–42, 1766–70, 1779–87, 1788–98, 1940–54	1650–84, 1731–33, 1735–46, 1748–57, 1761–1809, 1927–54

While replication of sea-level records is important to substantiate any proposed link between rates of sea-level change and climate, it must be kept in mind that the response of sea level to a climatic change cannot be expected to be uniform across the globe. This is due to geoidal, steric, and oceanographic effects, which all act on regional scales. The search for global correlations of decadal-scale sea-level changes is therefore a futile exercise. Similarly, future sea-level rise will not be uniform, a point that is not taken into account by current Intergovernmental Panel on Climate Change (IPCC) predictions (Long, 2000).

The precision of sea-level reconstruction is limited by the vertical precision of sea-level indicators as well as by suitable chronological control. Reducing counting errors on radiocarbon measurements, ^{14}C wiggle-matching, the application of ^{210}Pb-dating and pollen markers, and development of new dating techniques, for example, aspartic acid racemization, will all contribute to decreasing dating uncertainties. It is possible that testate amoebae, which are found in narrow zones in the upper parts of salt marshes, can help increase the precision of sea-level reconstructions (Charman *et al*., 1998). Statistical techniques, such as the use of transfer functions, offer a way to obtain objective quantitative assessments of the precision of sea-level reconstructions. Indeed, statistical techniques have been widely applied in many studies of paleoenvironmental reconstruction, while sea-level research arguably lags behind in embracing a more quantitative approach.

Developments in sea-level research during the past decades have clearly shown that, in addition to the growth and decay of land-based ice, a multitude of factors contribute to sea-level change. Oceanographic factors, such as sea-surface dynamical and steric changes, become increasingly important when sea-level changes are investigated on centennial and decadal timescales. The role of sea-level change in decadal climatic variability, for example, its link with the North Atlantic Oscillation, is poorly understood. A major task for future sea-level research is to couple the changes of the surface of the ocean to other elements of the global climate system described by ocean-atmosphere models, in particular the thermohaline circulation.

SEA-LEVEL INDICATORS, BIOLOGIC

Use of subfossil fixed biological remains as Biological Mean Sea-level Indicators (BMSIs), (Laborel and Laborel-Deguen, 1994) or Fixed Biological Indicators (FBI) (Baker and Haworth, 1999) were initiated about 40 years ago (Donner, 1959; Van Andel and Laborel, 1964; Fevret and Sanlaville, 1966) and have gained recent impetus as the study of sea-level variations developed and took into account pluridisciplinary criteria. Use of FBI allowed reliable monitoring of recent sea-level variations along rocky coasts, stable or seismically active (Brazil, West Africa, Mediterranean, Japan, Australia).

Principle

On rocky shores, littoral fauna and vegetation currently develop in horizontal belts parallel to the water surface (Stephenson and Stephenson, 1949; Peres and Picard, 1964) which define several zones, where various eroding and building biological factors are at work (Figure S11). These zones are:

A *littoral fringe* (Stephenson and Stephenson, 1949) or *supralittoral* zone (Peres and Picard, 1964), wetted by surf where endolithic Cyanobacteria are dominating.

A *midlittoral zone* (Peres and Picard, 1964), submersed at regular intervals by waves or tides, where parallel vegetational belts are more developed. Eroding Cyanobacteria, patellaceous gastropods (limpets), and chitons (lower zone) are abundant. Rock-building agents (coralline rhodophytes) also occur.

An *infralittoral (sublittoral) zone*, from mean sea level (MSL) down to 25–35 m whose upper part bears brown algae, coralline rhodophytes, vermetid gastropods, oysters, annelids, cirripeds, and eroding agents such as clionid sponges, sea-urchins and rock-boring pelecypods (*Lithophaga*). A few species are restricted to the upper margin of that zone, but many display a clear-cut population limit at that level. Some organisms build various reef or reef-like structures (bioherms, biostromes), or develop as an erosion-protecting cover.

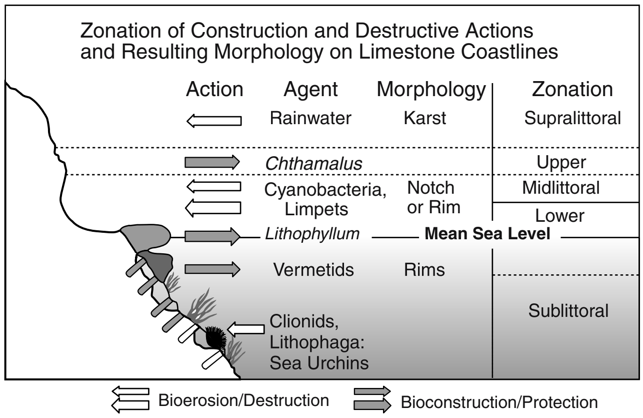

Figure S11 Division of erosion and construction on a vertical profile on limestones in temperate seas (modified from Laborel and Laborel-Deguen, 1994).

On limestone coasts, the balance of bioerosion versus bioconstruction leads to various types of vertical profiles (Guilcher, 1953) such as "tidal" notches and horizontal "benches" or "tidal platforms" on soft rocks .

Definition of a Biological Mean Sea Level (BMSL)

The limit between the midlittoral and infralittoral zones defines a (BMSL) marked by a large and sudden increase in species diversity (Boudouresque, 1971). It also corresponds to such morphological features as the vertex of "tidal" notches or the inner edge of erosion "tidal" platforms (Focke, 1978; Pirazzoli, 1986).

Principal groups of plants and animals used as FBI

A small group of fixed plant and animal species such as the corallines *Lithophyllum lynoides* and *Lithophyllum onkodes*, vermetid gastropods of genus *Dendropoma* and *Spiroglyphus* (Laborel, 1986) and annelids such as *Idanthyrsus* and *Galeolaria* (Baker and Haworth, 1999) enjoy very narrow depth ranges located at that limit (or a little above or below) so they are currently used as FBI and considered to be among the most reliable indicators. They are all the more interesting since they often develop into algal rims, cornices, and other reef-like bioherms whose erosion-resistant remains are easy to spot and sample. Most other species have a wider vertical range but may be successfully used as FBI taking into account the upper limit of their populations (for infralittoral cirrhipeds, like *Balanus*, largely used in the archaeological study of ancient harbors (Morhange *et al*., 1996), and *Lithophaga* holes). Scleractinian corals which develop in the infralittoral (sublittoral) zone belong to this category and the upper limit of coral construction is widely used as FBI in tropical waters (Hopley, 1986). The use of coral indicators, generally sampled by coring or drilling methods, has generated a large specific bibliography of its own that we shall not develop here.

For midlittoral species such as the small barnacles *Chthamalus* or *Elminius*, or some coralline rhodophytes, it is the lower limit of the population which is taken into account.

Population limits inside both midlittoral and sublittoral zones are considered as stable when MSL is constant. Aperiodic or seasonal short variations of sea level have little or no influence since most species have a long life and integrate sea-level variations on a yearly scale.

Field use of FBI

The FBI must provide information upon the direction and rapidity of past displacements of MSL and allow easy and accurate radiometric dating.

The elevation or submersion of a displaced coastline is defined as the altitudinal difference between the upper limit of the displaced remains and that of their present homologs, measured with the local BMSL as datum (Figure S12). No special reference (observed or calculated) to the actual water level is therefore necessary.

For species with a wide vertical range, best results are obtained when the uppermost limits of both fossil and living populations are well delineated. It must also be noted that biological sea-level marks are not

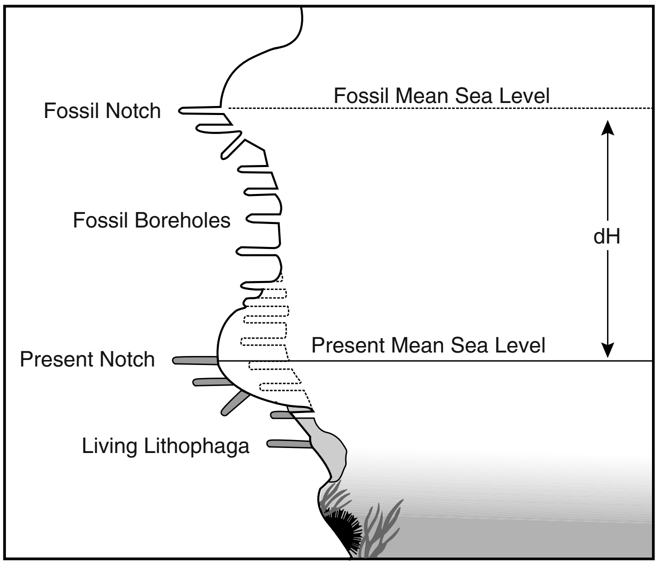

Figure S12 Measurement for the elevation of an ancient sea level (modified from Laborel and Laborel-Deguen, 1994).

perfect horizontal lines but may be warped, even on short distances, by local variations of hydrodynamism (Laborel and Laborel-Deguen, 1994). Measurements must then be done on a single vertical profile including both the fossil specimen and its present equivalent. Selecting a unique temporary bench mark for several measurements (Jardine, 1986), even at a horizontal distance of a few meters is therefore not recommended.

Discussion

An accuracy of ±5 cm was obtained in Crete (Thommeret *et al.*, 1981) for vermetid rims. In the western Mediterranean, a vertical accuracy of about ±10 to 20 cm is common on submerged lines of *L. lichenoides* (Laborel *et al.*, 1994). Lower accuracies (about ±50 cm or less) were obtained for Brazilian vermetids (Delibrias and Laborel, 1971) or for *Chthamalus* in surf-beaten crevices.

When sea level is falling slowly (about a few millimeters per year), the frailer sublittoral FBI species are killed, and their skeletons are eroded after a few years in the midlittoral zone. Reeflike structures, being stronger, may still be used as sea-level markers after long periods of midlittoral erosion. Preservation of frail details indicates rapid (even very rapid!) uplift (Thommeret *et al.*, 1981).

Determination of the velocity of a submergence movement is sometimes difficult but submersed *Lithophyllum* or vermetid rims may be preserved underwater for long periods of time.

The limits of the FBI method have been tested by comparison of field observation and direct sea-level measurement in an area of high volcanic activity (Morhange *et al.*, 1998). They proved to be reliable and sensitive in most cases, with the exception of short-lived oscillations of sea level (less than a few years) which are too rapid to be registered by biological growth.

Radiocarbon dating of aragonitic shells living in agitated surface sea water, is generally accurate. Calcareous algal bioherms can also be dated notwithstanding inner matrix and micritic cements. Direct isotopic counting methods make dating possible for small limestone fragments provided samples have suffered no contamination by alien carbon and the regional reservoir effect correction for sea water is known. Careful selection and cleaning of samples is always necessary.

SEA-LEVEL INDICATORS—BIOLOGICAL IN DEPOSITIONAL SEQUENCES

Introduction

Biological sea-level indicators have been discussed for *rocky intertidal coasts* but this section deals with biologic remains in a depositional sequence such as a marsh or *estuarine* (*q.v.*) deposit. Often the lithology will not provide sufficient information to delineate an accurate sea level from within a depositional sequence but biological remains in the form of fossils will greatly enhance the accuracy. Any good sea-level indicator must provide three essential elements: (1) accuracy, (2) preservability, and (3) be datable. Fossils within depositional sequences have the highest probability to provide all three of these elements. The type of fossil is very important because not all fossils will provide an accurate relocation of a former *sea level* (*q.v.*). The accuracy of a given fossil type depends mostly on the range of water depths that the organism occupies when living and it must be *in situ* when found in a sequence. However, even fossils with a large range may be useful to determine marine/freshwater transitions which may in turn sometimes be used as a sea-level indicator. There is a large range of organisms that serve as indicators; probably the most commonly used historically are "miscellaneous shells" which are not very accurate because they often are not in place and contain a large array of species with a broad band of water depth ranges. Some specific macro invertebrates such as mussels or oysters provide a range within ± 2 m but this is not adequate for determining the smaller movements of the late *Holocene* (*q.v.*). By far, the most useful are microfossils because they occur in large numbers in small diameter cores which are often where the sea-level records come from in Holocene *submerged coastlines* (*q.v.*). In the following sections the various groups will be detailed in terms of where and how to use the various groups as well as a brief assessment of the accuracy possible with each group.

Plant groups

Marsh vegetation generally

There are many cases in the literature where sea levels have been reported based on either "undifferentiated *peat*" (*q.v.*), meaning the authors did not know if it was freshwater or marine (Emery and Garrison, 1967); in this case the only information that can be derived is that sea level was at about the depth (± 5 m) of the deposit at the time of formation or lower if it was freshwater. This determination is useful in the absence of any other data but not useful for the problems of measuring late Holocene movements which are well within the error bars mentioned above. Sometimes it is known that the peat is a salt marsh deposit in which case it narrows the range to the upper half of the *tidal cycle* (Chapman, 1960, 1976). When one steps on a salt marsh it is visually obvious that there is a distinct plant zonation but the plants respond to more than just tidal exposure and often will have differing ranges even in adjacent marshes (Scott *et al*., 1981, 1988) so the macro-vegetation alone is not a reliable indicator for subdividing salt marsh deposits in terms of sea level, especially in fossil peats.

On a broader scale macro-plant remains have been used to suggest trends of salinity change and hence *transgression* or *regression* (*q.v.*) but there are many factors that have to be considered since plants respond to many variables (Behre, 1986).

Many have also used buried forests as indicators of submergence (Heyworth, 1986) and again this gives only the indication of the sea level being below the forest at the time it was living. This is a very powerful tool, however, when looking at rapid changes in sea level such as earthquakes (Atwater, 1987) where the repeated submergence of a series of forests provides a sense of the periodicity of these events.

Microfossil plant remains

Apart from the variability of vegetation assemblages across the marsh, there is the problem of identifying macro-plant remains in a peat deposit since they tend to breakdown rapidly in the subsurface. However, some attempts have been made to use pollen which of course is the microscopic part of the sexual reproductive organs of all angiosperm plants. This meets with some success (Shennan *et al*., 1998) but pollen is inherently reworked. Probably, more successful is the use of diatoms which are one-celled algae which leave a siliceous shell in the sediments (Shennan *et al*., 1998, 1999). These fossils appear to leave a record that can partially subdivide the marsh into zones with varying accuracies (± 20–50 cm at best).

The most useful technique involving microfossil plants is determining sea levels in an indirect way where *coastal ponds* either become submerged or emerged (Palmer and Abbott, 1986; Shennan *et al*., 1996). If they are emerged they go from marine to freshwater and *vice versa* for submergence; the key is to be able to determine the sill depth of the basin and then relate that to the radiocarbon-dated transition. This method is usually accurate to within ± 1 m depending on the depth and size of the basin (Laidler and Scott, 1996). Either diatoms (Palmer and Abbott, 1986) or dinoflagellates (Miller *et al*., 1982) can be used in this manner. Dinoflagellates are also microscopic algae but they are organic-walled as opposed to the siliceous shells of diatoms. Both of these groups occur in large numbers such that 1 cm^3 of wet sediment is often sufficient to obtain a valid result (Haq and Boersma, 1978).

Animal groups

Macro-animal fossils

As discussed briefly above invertebrate macrofossils are limited in their value as sea-level indicators by their vertical range in the water column. Some groups such as *corals* (*q.v.*) or attached biological indicators have extremely narrow ranges and have been used to produce some of the best and longest sea-level curves (Fairbanks, 1989). However, these are limited in occurrence and rocky intertidal forms are often not well preserved, especially in a submergent regime. Other macro-invertebrate groups have been used in depositional sequences but their vertical ranges are usually quite high and hence accuracy is not good, especially the above-mentioned "miscellaneous shells." Peterson (1986) details the use of marine molluscs which are by far the most widely used macrofossil in Quaternary studies of raised marine deposits. He emphasizes the use of communities rather than single species to relocate sea level which is generally true for all organisms. Of all the species of molluscs perhaps *Mytilus* (the blue mussel) provides the highest accuracy (5 m) but even that range is high. However, in the raised deposits of northern Europe it is still very useful. However, as is the case with macro-vegetation, there is often insufficient material in small diameter cores that are often the basis for building sea-level curves, especially Late Holocene curves on submergent coastlines.

Micro-animal fossils

There are two principal groups of animal microfossils that have been used extensively in sea-level studies, ostracodes (van Harten, 1986) and foraminifera (Scott and Medioli, 1986). Ostracodes leave a calcareous shell as a fossil and that in itself presents a problem because many of the best deposits for sea-level studies are not conducive to the preservation of $CaCO_3$ hence the fossils are not present. van Harten (1986) suggests the resolution with ostracodes to be within 100 m which is not useful at all for modern sea-level studies but they can be used as accurate salinity tracers and hence suggest transgression and regression (Haq and Boersma, 1978).

On the other hand, foraminifera have both calcareous and agglutinated shells, agglutinated shells are resistant to dissolution in low pH, highly organic sediments, and often are very abundant in some highly organic deposits such as marshes ($>5{,}000/10\,cm^3$, Scott and Medioli, 1980). Unlike plants foraminifera have been shown to be consistent in their vertical range in relation to tidal levels within a marsh sequence (Scott and Medioli, 1978, 1980, 1986) such that the same 8–10 species inhabit the world's marshes and specific assemblages can always locate the upper one-fourth of the tidal range. In some cases the higher high level can be accurately located to provide an incredible accuracy of ± 5 cm (Scott and Medioli, 1978, 1980, 1986; Hayward *et al*., 1999); this is by far the most accurate indicator now available but it is limited to coastal marsh areas and isolated peat deposits that are sometimes found offshore in marine surveys (e.g., Scott and Medioli, 1982). At the very least "undifferentiated peats" can now at least be determined to be either marine or freshwater which significantly increases their value as a sea-level indicator.

Archaeological remains

Although many assumptions must be made to use paleo-human occupation sites as sea-level indicators they have been used by many workers, especially on emergent coasts (Colquhoun and Brookes, 1986; Martin *et al*., 1986). The main assumption is that paleo-humans did not carry their food that they gathered from coastal *estuaries* and *lagoons* (*q.v.*) far from the coastline. The most commonly used remains are shell middens or dumps of usually molluscs that are exposed in many areas but are probably the most spectacular on the South American east coasts of Brazil and Argentina (Martin *et al.*, 1986). Colquhoun and Brookes (1986) used a combination of shell middens and peats to reconstruct sea levels on the South Carolina (USA) coast.

Summary

The above is a small sampling of the most commonly used biological remains in depositonal sequences for determining sea levels. It is clear that some areas will provide a higher probability of determining an accurate and extended sea-level record than others and in some areas it may be impossible to obtain a sea-level record of any kind. Biological remains provide the best means of determining former sea levels because they are usually in a depositional sequence and they usually can supply the carbon required to obtain a ^{14}C date, without which you have a level but no way of knowing when the sea level was at that point. The key to determining accurate sea levels is being versatile in the approach taken to take advantage of what the record provides.

SEA-LEVEL INDICATORS, GEOMORPHIC

Introduction

Several geomorphic features, erosional or depositional, develop near sea level. Some of them may be preserved after a change in sea level and can be used, therefore, as indicators of former sea-level positions. Erosional indicators can be preserved only in hard rock, and occur in a vertical range which depends on site exposure. They include notches, benches, trottoirs, platforms, abrasional marine terraces, strandflats, pools, potholes, sea caves, honeycomb features, and tafoni. For accurate sea-level reconstructions (Pirazzoli, 1996), it is essential therefore to refer the elevation of a former indicator to that of the active counterpart in the same place rather than to that of the present sea level. Depositional indicators include tidal flats, marine-built shore platforms and terraces, beaches, beachrocks, reef flats, and submerged speleothems. Erosional features are generally inadequate to date former sea levels, whereas marine deposits may include guide fossils or organic material liable to be dated radiometrically.

Erosional indicators

Several types of notches can be distinguished (Van de Plassche, 1986). Abrasion notches are often found near high-tide level at the boundary between a cliff and a shore platform, but they may develop at any level reached by wave action and give therefore only approximate indications of sea-level position. Much more precise are tidal notches, which are typical midlittoral erosional features, especially on limestone coasts. In sheltered conditions tidal notches occupy all the intertidal range, showing a vertex at about mean sea level (MSL) (Figure S13).

The formation of erosional benches and shore platforms is usually ascribed to the removal by waves of the weathered parts of cliffs. The lowest level of possible weathering corresponds to that of constant soakage by sea water, probably in the intertidal zone. Wide benches of abrasional origin are called platforms or terraces; they usually develop in the intertidal range, sloping gently seawards.

Not to be confused with tidal notches are surf notches, which may occur at higher elevations on limestone coasts exposed to persistent winds and strong surf and spray action; surf notches delimit the boundary between a surf bench and a cliff. On exposed coasts, organic accretions often develop near the outer edge of a bench, protecting the substrate rock, while erosion can proceed higher than the accretion level, widening a surf bench and undercutting a surf notch on the cliff. The elevation of surf benches depends upon site exposure; elevation as high as 2 m above high tide-level has been reported locally, but it may decline rapidly with decreasing wave exposure. On the Levant coasts, in the eastern Mediterranean, surf benches (called trottoirs) are quite common at elevations of 0.2–0.4 m above MSL.

In high latitude, strandflats are low shore platforms where the rock material, disintegrated by freeze–thaw alternation, has been washed away by wave action. The reliability of erosional coastal benches, platforms and strandflats as sea-level indicators depends on the identification and understanding of the processes by which these features were produced.

Coastal pools are flat-bottomed depressions resulting from local lowering of limestone benches. On sheltered shores they correspond to intertidal levels, whereas on exposed coasts they may occur in any supralittoral area in the reach of waves. Potholes are rounded depressions, usually deeper than wide, worn into solid rock by sand, gravel, pebbles, or boulders spun round by the force of waves. As they may be formed at various elevations, above or below sea level, they are not accurate sea-level indicators.

Sea caves are cavities excavated by erosion into a cliff in the range of wave action. They generally develop into weaker parts of the rock formation or are often of karstic origin. A sea cave open on both sides of a promontory is called a sea arch. Sea caves and arches are generally inaccurate sea-level indicators; however, in limestone formations, their floor, if regular and flat, may be related to a former low-tide position.

Honeycombs are small cavernous features, showing a cell-like structure, which may form on the surface of several granular rocks in the spray zone above high tide. Their development may be ascribed to temperature variations, chemical weathering, and wind corrasion. Honeycomb structures indicate the proximity of sea level below them, but with poor accuracy. Tafoni are cavernous weathering features of greater size (from a decimeter to several meters). Because they may occur also far away from the shore, tafoni should be avoided as sea-level indicators.

In uplifted areas of former ice sheets, low-tide positions corresponding to the marine limit (maximum recorded sea-level elevation) can be identified at the elevation where channels disappear from the surface of former glacio-marine deltas.

Depositional indicators

The grain size of marine deposits depends mainly on the energy of the water environment, which varies with exposure to waves and currents. Marine muds and clays can be deposited only in very calm water, either offshore at depth, or in very sheltered coastal basins. Tidal flats are marshy or muddy land areas which are covered and uncovered by the rise and fall of the tide. They are usually studied by analyzing samples collected using boring techniques. The upper part of tidal flats, which may reach but not exceed the elevation of extreme high tides, is usually very flat and colonized by halophytic vegetation. Flora and fauna still in growing position, and the local tidal range and topographic configuration, will often help to indicate the kind of environment in which they formed and the depth of their deposition. Well-chosen foraminiferal assemblages from coastal paleomarsh deposits may permit very precise (up to ± 10 cm) determinations of former sea level even in macrotidal areas. Botanical remains can also contribute to sea-level reconstructions, by determining the degree of salinity and therefore the position relative to mean high-water level. Assemblages of freshwater, brackish, and marine microflora (diatoms) can be used to infer marine transgressions and regressions (Van de Plassche, 1986).

The main difficulties in reconstructing former sea-level histories from tidal-flat deposits are given by the estimation of sediment compaction and tidal changes. Wet sediments have a low density. After their deposition, compaction is rapid during the first centuries, then decreases gradually. In the Mississippi Delta, for example, contemporary silty muds contain water to 70% of their volume. At a burial depth of 24 m there is about 15% loss by compaction and at about 1,000 m apparent subsidence may approach 70%. The highest rates of compaction correspond

Figure S13 Emerged tidal notches cut into a mushroom rock and, in the background, an emerged beachrock capped by green living algae, are consistent with the present-day low-tide situation and indicate recent stability in the relative sea level. Miyako Island (the Ryukyus, Japan). Local mean spring tidal range is 1.5 m; water level is 0.4 m below MSL (photo 6149, Feb. 1981).

to peat layers, which can reduce in volume as much as 90%. To survive, a tidal flat needs therefore rates of sedimentation high enough to compensate compaction phenomena. If sedimentation is inadequate, the tidal flat will be submerged; if it is excessive, its marginal, sheltered basin will be rapidly infilled. Tide characteristics depend narrowly upon the basin morphology, which is continually modified by sedimentation and compaction and eventually by sea-level changes. For example, in the Bay of Fundy, during the last 4,000 years, the high-tide level has increased 1.5 mm/yr faster than MSL.

Sand deposits are common where wave energy is moderate and are found on beaches and intertidal shores near lagoon entrances. Pebbles are generally found only in high-energy shores, usually on exposed beaches. Raised or submerged beaches are however, seldom used as sea-level indicators because of the wide uncertainties in determining a clear relationship between a beach sample and the MSL. Depositional shore platforms produced by the supply of marine sediments (sand, shingle, or shells) to the shore have been described by Zenkovich (1967) and called improperly "shore terraces"; broad coastal plains characterized by many low shelly ridges that run roughly parallel to the shore, like the "cheniers" in coastal Louisiana (Shepard and Wanless, 1971), also belong to the depositional shore platforms category. Their sea-level indications are similar to those provided by beaches.

Marine-built terraces develop near sea level and are made of accumulations of marine materials removed by shore erosion. Their landward part may be capped by alluvial deposits.

The term beachrock applies to beach sediments cemented by calcium carbonate in the intertidal zone (often in the upper part of it). Beachrocks are generally limited to areas of warm or temperate waters. Their upper surface usually shows a superimposition of beachrock slabs, each showing the same seaward slope as the nearby beach, delimited landward by basset edges. A beachrock is generally a good indicator of sea level, with a vertical uncertainty depending on the local tidal range. However, radiometric ages of beachrock samples (shells, coral debris) would provide only maximum dates for the sea level at which lithification occurred, because beach sediments may be reworked.

Reef flats are stony expanses of reef rock with a flat surface. They are generally situated in the lower part of the tidal range and capped by calcareous algae, patches of sand and coral debris, and occasionally a few coral colonies living in shallow pools or depressions. In the absence of moating phenomena, the uppermost corals in growth position, often appearing as microatolls, correspond to the spring low-tide level. When the reef flat surface is made of coral conglomerate, its elevation may be at any level in the intertidal range or in the reach of regular waves. The low-tide level at the time of the conglomerate lithification can be determined by petrological analysis as the vertical boundary between the former marine phreatic and marine vadose environments for the first generation of intergranular cements (Montaggioni and Pirazzoli, 1984).

Speleothems, such as stalactites or stalagmites, are usually formed in caves above sea level by the evaporation of mineral-rich water. When submerged in sea-flooded karst systems, the depth of speleothems indicates minimum sea-level rise. In the fortunate case of a marine biogenic cover capping the speleothem, both the marine bioconstruction and the speleothem deposits can be dated radiometrically.

In glacio-isostatically uplifted areas, the highest marks of marine action may be identified from the lower limit of perched glacial boulders, till and continuous terrestrial deposition, or from the upper limit of shore deposits, beach ridges, and *in situ* marine fossils.

Lastly on the continental shelves, seismic stratigraphy gives a picture of the way the rock strata have been piled on one another. Each transgressive–regressive cycle removes some sediment and leaves piles of new sediment, producing recognizable patterns such as erosional unconformities. These features can be used to identify the best places to collect borings to interpret sea-level changes. In the laboratory, diagenetic products and intergranular cementation identified by analysis of depositional material may also provide evidence of former marine zonation related to sea-level positions.

SEA-LEVEL RISE, EFFECT

Rising sea level is gradually inundating wetlands and lowlands, eroding beaches, exacerbating coastal flooding, raising water tables, and increasing the salinity of rivers, bays, and aquifers. In coastal areas where the human influence is slight, these effects are usually unimportant, as ecosystems and geological systems simply shift upward and inland with the rising water levels. Human systems, however, do not move inland so readily. As a result, the advancing sea and human activities are on a collision course in many developed areas. Caught in the middle, are the intertidal marshes, mangroves, beaches, and mudflats, as well as the plants and animals, that depend on them for their existence.

All of these effects may be accelerated in the coming decades if global warming accelerates the rate of sea-level rise. Global sea level rose approximately 18 cm in the last century, but warmer temperatures could increase that rise to 30–100 cm (see *Changing Sea Levels*).

Physical effects of sea-level rise

Coastline retreat: inundation and erosion

The most obvious implication of a rise in sea level is that land that is barely above sea level would be below sea level, and hence would be directly inundated if no measures were taken to hold back the sea. The easiest way to get a rough sense of the vulnerability to a large rise in sea level is to examine a topographic map to determine which areas are close to sea level. The first published assessment of the impacts of global warming on the US coast simply obtained estimates of the land below the 4.5 m (15-foot) contour, and assumed that those areas would be completely lost if the sea were to rise 4.5 m (Schneider and Chen, 1980).

Land elevations do not tell the whole story. Erosion can cause relatively high ground to be lost even if the sea does not rise enough to inundate it; and wetland accretion can allow marshes and swamps to persist even when the sea rises more than enough to inundate them. Moreover, depending upon the tide range in a given area, land whose elevation is greater than the projected sea-level rise might still be flooded by the tides. Finally, human activities can hold back the sea.

Inundation of low areas. Although the concept of inundation is simple enough, the quality of elevation information is insufficient to reliably estimate the amount of land, for example, within 1 m of mean high water. As Table S6 shows, topographic maps in most nations lack the vertical resolution necessary to estimate the land that could be inundated by a 1-m rise in sea level, and in many nations the elevation data is so poor that interpolations are probably meaningless. In the United States, the contour interval for the widely available topographic maps varies, generally from 1.5 to 6 m (5–20 ft). For much of the coast, better maps exist, but they are tucked away in government offices that created the maps for specific uses, such as flood insurance rates and the design of municipal drainage systems. A second problem is that available digital elevation data is usually much less precise than the printed topographic maps. In the United States, for example, the digital line graphs that contain the topographic information of the printed map, are available for a few states, but in most cases, the available digital elevation

model data provides modeled elevations based on interpolations between various points along a grid (Titus and Richman, 2001).

A recent study by the US Environmental Protection Agency developed maps of lands below the 1.5- and 3.5-m contours along the US Atlantic and Gulf coasts (Titus and Richman, 2001). The areas with the greatest amounts of land at risk include Florida, Louisiana, North Carolina, and the shores of Chesapeake and Delaware Bays (see Figure S14) Approximately 56,000 km^2 lie below the 1.5-m contour, while another 32,000 km^2 are found between the 1.5- and 3.5-m contours. Table S7 illustrates the current uses of the land below 1.5 m, which is about 75% wetlands, 20% farms and forests, and only 5% urban and residential. The land between 1.5 and 3.5 m, by contrast, is approximately 31% wetlands, 33% forest, 23% agricultural, and 13% urban and residential. Approximately 2,000 km^2 of low developed lands are on the bay sides of barrier islands, where people often filled wetlands with just enough sand to elevate the land above mean spring high water (Titus *et al*., 1991). Approximately two million people reside below the 1.5 m contour.

Other nations have begun to assess vulnerability to sea-level rise. Table S8 summarizes those studies. China, United States, Bangladesh, the Netherlands, and Nigeria have the greatest amounts of very low land, in part because those nations all have major river deltas. On a percentage basis, however, coral atoll nations such as Marshall Islands, Kiribati, and Tuvalu (not shown) are the most vulnerable.

Wetlands. The majority of very low land is already inundated by high tide. Coastal marshes and swamps are generally found between the highest tide of the year and mean sea level. Because wetlands collect sediment and produce peat on which they can build, they have largely been able to keep pace with the historic rate of sea-level rise. Wetlands expanded inland as new lands were inundated, but because of sedimentation and peat formation, their seaward boundaries did not always retreat. Thus, the area of dry land just above the wetlands is less than the area of wetlands. The results in Table S7 corroborate this hypothesis: The dry land appears to be uniformly distributed at the low elevations. But the 42,000 km^2 of wetlands found below the 1.5-m contour is 30% more than the *total* area of land between 1.5 and 3.5 m . Therefore, *if* sea level rises more rapidly than wetlands can accrete, there will be a substantial net loss of wetlands (Figure S15). This loss could be further aggravated by increased wave erosion from deeper waters, and saltwater intrusion into freshwater swamps, which would tend to convert the swamps to open water.

Will wetlands be able to keep pace with sea-level rise? Published reports provide conflicting answers. As Figure S16 shows, the current rate of sea-level rise already appears to be too great for the marshes of Blackwater National Wildlife Refuge on the Eastern Shore of Chesapeake Bay in the United States, where one-third of the wetlands have eroded in the last few decades. Studies by Ellison and Stoddart (1991), Ellison (1993), Ellison and Farnsworth (1997) during the early 1990s concluded that Carribean and Bermudan mangroves could not accrete with a rise in sea level faster than about 1.5 mm/yr. Callaway *et al.* (1997) by contrast, concluded that mangroves are currently more than keeping up with higher rates of sea-level rise along the Gulf of Mexico. Parkinson *et al*. (1994) suggest that Carribean mangroves have recently shown accretion rates of 3.7 mm/yr, but that compaction could eventually reduce the net accretion to less than 2 mm/yr.

While scientific uncertainty about vertical accretion impairs our ability to forecast the landward retreat of the *seaward* boundary of coastal wetlands, economic and political uncertainty prevent us from projecting the inland advance of their *landward* boundary. If coastal areas are developed and protected from the rising sea, wetlands will not be able to advance inland, and in some cases, they will be squeezed between a rising sea and the protective structures.

Deltas are a special case. Large amounts of sediment can allow for unusually high accretion rates. At the same time, human activities that divert the sediment may prevent the sediment from reaching the wetlands. In Louisiana, flood control levees, the navigation infrastructure, and other human activities have disabled the natural processes with which the Mississippi Delta could otherwise keep pace with rising relative sea level; as a result, Louisiana is currently losing about 60 km^2 of wetlands per year (Louisiana Wetland Protection Panel, 1987). Dams along the Nile and Niger river have caused drastic erosion along the deltas in Egypt and Nigeria (Awosika *et al*., 1992; El-Raey *et al*., 1995). Future water management structures may have similar effects on Bangladesh, Iraq, Gambia, and other deltaic nations.

Erosion. A rise in sea level can cause an ocean beach to retreat considerably more than the retreat attributable to inundation alone (see Figure S17). The Danish coastal engineer Per Bruun (1962) demonstrated why: Beaches follow a characteristic profile determined primarily by the sediment size and the wave climate. The waves and winds regularly transport sand throughout the entire beach system, which extends from the dunes out to a depth of 10–30 m or so. Storms may erode the dunes and upper part of the beach; calm swell waves return sand back to the beach. If the sea rises 1 m, the profile will maintain its same shape with respect to the water level, which elevates the shore bottom by one 1 cm. This occurs because the swell that pushes sand from the bottom back onto the visible part of the beach can only reach so far below the surface. If the surface is 1 cm higher, the elevation down to which that swell can reach is also 1 cm higher. Hence, less sand is carried back onto the beach than would have been the case if the sea was not rising.

Bruun (1962) showed that beach profile adjustment requires the shore to retreat by an amount equal to sea-level rise divided by the average slope of the beach profile. Pure inundation, by contrast, equals sea-level rise divided by the slope of the land just above sea level. Because the beach just above sea level tends to be much steeper than the submerged portion, total coastline retreat is more than what one would expect considering only inundation. Studies applying the Bruun Rule have estimated that a 1 cm rise in sea level will generally cause beaches to erode 50–100 cm from New England to Maryland (Everts, 1985; Kyper and Sorenson, 1985), 200 cm along the Carolinas (Kana *et al*., 1984), 100–1,000 cm along the Florida coast (Bruun, 1962), 200–400 cm along the California (Wilcoxen, 1986), 40–100 cm along the beaches of Alexandria, Egypt (El-Raey *et al*., 1995), 25–600 cm along the beaches of Senegal (Niang-Diop, 1995), and 15 cm in the area around Recife, Brazil Erosion was less in the Brazilian site because of the natural protective features of coral reefs. In Senegal, erosion seems likely to account for only 1% of the potential land loss from a 1-m rise in sea level (Niang-Diop *et al*., 1995), whereas it could account for 75% of the loss in Uruguay (Volonte and Nichols, 1995).

The importance of erosion does not result from its share of projected land loss so much as its universality. Much of the world's coasts are currently eroding, and rates are often fast enough to be noticed by coastal residents. The 30-cm rise in sea level likely along most coasts in the next 50–60 years would erode most sandy, muddy, and pebble shores 15–50 m. Because shorefront development tends to be less—and sometimes much less—than 30 m from the high water mark, projected erosion is likely to require a human response along the vast majority of developed coasts in the next few decades.

Barrier islands. Some of the most economically important vulnerable areas are the recreational resorts along the coastal barrier islands and peninsulas of the US Atlantic and Gulf coasts. Typically, the oceanfront block is 2–5 m above high tide; but portions of the bay side may be less than 1.5 m above high water. Many of these low bay sides are filled wetlands.

If human activities do not interfere, a barrier island can respond to sea-level rise by either (1) washing over landward and remaining intact, or (2) breaking up and drowning in place. Figure S18 provides a cross section of a barrier island washing over. This landward migration of the barrier island is analogous to erosion from the Bruun Rule, except that

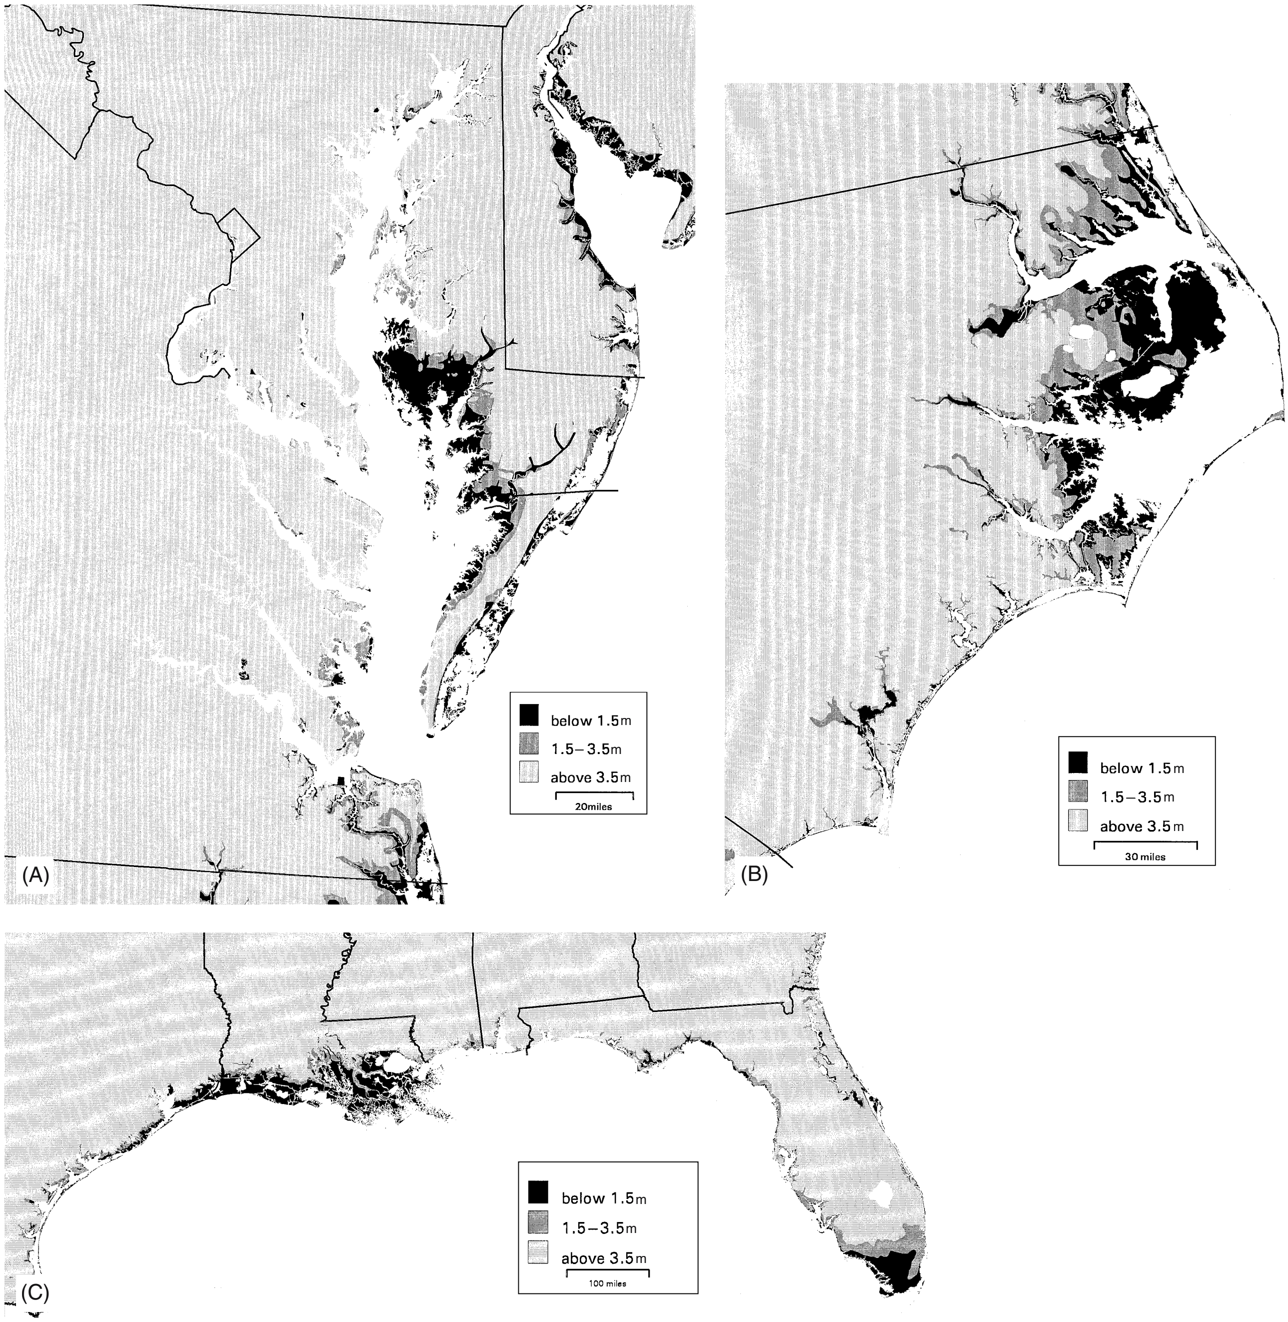

Figure S14 Maps of US lands close to sea level. These maps show the land below the 1.5- and 3.5-m contours along the coasts of (A) Chesapeake Bay, (B) North Carolina, and (C) the Gulf of Mexico. These maps are based on modeled elevations, not actual surveys or the precise data necessary to estimate elevations at specific locations. The map is a fair graphical representation of the total amount of land below the 1.5- and 3.5-m contours; but the elevations indicated at particular locations may be wrong. Although the map illustrates elevations, it does not necessarily show the location of future coastlines. Coastal protection efforts may prevent some low-lying areas from being flooded as sea level rises; and coastline erosion and the accretion of sediment may cause the actual coastline to differ from what one would expect based solely on the inundation of low land. These maps illustrates the land within 1.5 and 3.5 m of the National Geodetic Vertical Datum of 1929, a benchmark that was roughly mean sea level in the year 1929 (Titus and Richman, 2001).

the beach profile in this case goes all the way over the dune crest, across the island, to the bay, and maintenance of this more complicated profile requires sand to be washed landward. Generally, a barrier island erodes from the ocean side until it reaches a critical width, generally about 400–700 ft (Leatherman, 1979), after which the erosive forces of storms tend more to push sand landward onto the bay side of the island. The net effect of the washover process is similar to rolling up a rug; as the island rolls landward, it builds upward and remains above sea level. By contrast, Figure S19 illustrates the fate of Isle Derniere in Louisiana, which was unable to keep up with the (subsidence-induced) relative sea-level rise of 1 m per century.

Whether a particular island will break up or wash over depends on sediment supplies, the depths of the bays behind the island, and the rate of relative sea-level rise. For developed islands, however, the distinction between washover and breakup is largely academic: Most are much wider than the critical width necessary to permit island migration, and thus the islands would both erode from the ocean side and bay side. Moreover, development tends to impede landward migration: structures

block the landward transport of sand, and after storms deposit sand onto the streets, local public works departments generally bulldoze it back onto the beach, rather than allowing it to blow or wash to the bay side.

Flooding

Rising sea level increases the vulnerability of coastal areas to flooding for several reasons. By providing a higher base for storm surges, a 1-m rise in sea level (for example) would enable a 15-year storm to flood many areas that today are only flooded by a 100-year storm (Kana *et al*., 1984; Leatherman, 1984). Moreover, beach erosion and wetland loss leave some properties more vulnerable to storm waves. Finally, higher surface- and groundwater levels reduce drainage and thereby increase flooding from rainstorms (Titus *et al*., 1987).

All of these problems are already being experienced to some extent. The increased storm vulnerability resulting from erosion has led many states to fortify dunes; Louisiana has fortified entire undeveloped barrier islands (Louisiana Wetland Protection Panel, 1987). The more subtle problems of decreased drainage and higher water tables are also evident in the low parts of many low islands, where some of the streets and private lots are flooded each time it rains.

Many coastal areas are protected with levees and seawalls and would not necessarily experience inundation, erosion, or flooding. However, these structures have been designed for current sea levels; higher water levels would threaten the integrity of these coastal structures. For example, higher storm surges might overtop seawalls, and erosion could undermine them from below. In areas that are drained artificially, such as New Orleans, the increased need for pumping could exceed current pumping capacity (Titus *et al*., 1987).

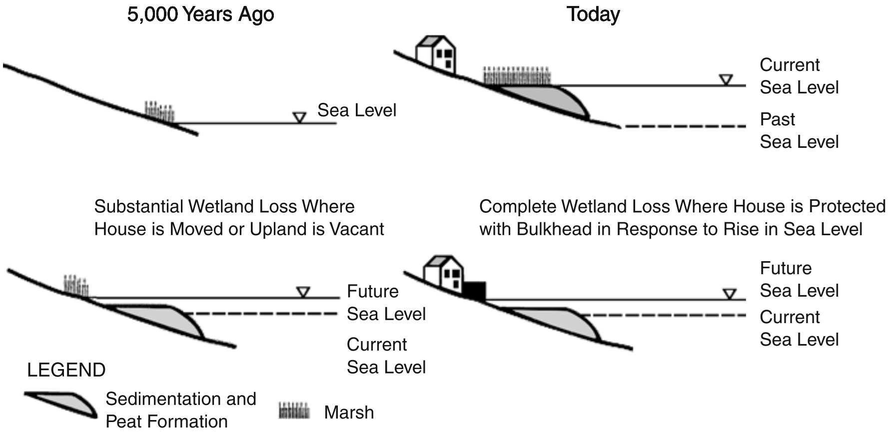

Figure S15 Evolution of a marsh as sea level rises (Titus *et al.*, 1991).

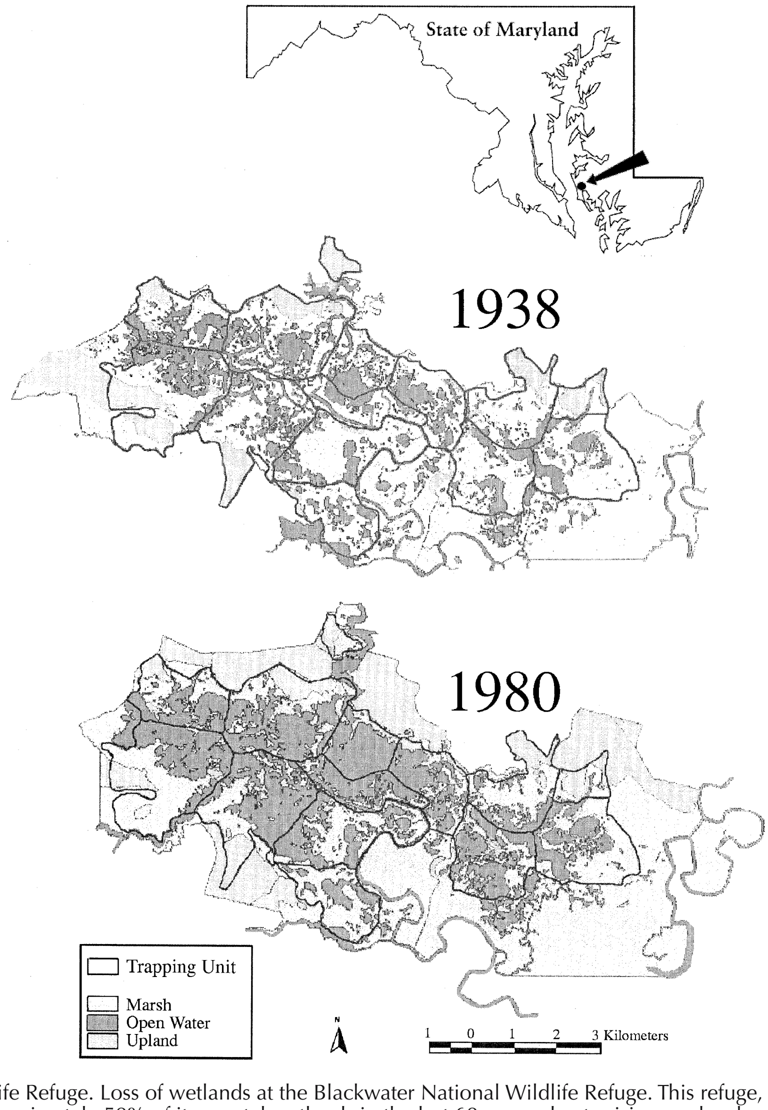

Figure S16 Blackwater Wildlife Refuge. Loss of wetlands at the Blackwater National Wildlife Refuge. This refuge, along the eastern shore of Chesapeake Bay, has lost approximately 50% of its coastal wetlands in the last 60 years, due to rising sea level, erosion, and saltwater intrusion. These maps show a 30% loss between 1938 and 1980. The extent of the loss is most evident when one focuses on particular trapping units within the refuge (trapping units are outlined in black and were delineated under land grants before the refuge was created). The increase in land area outside the trapping units resulted from land acquisition by the refuge (with permission of court J. Stevenson).

Saltwater intrusion

Rising sea level sends saltwater inland and upstream in rivers, bays, wetlands, and aquifers. New York, Philadelphia, and much of California's Central Valley rely on freshwater intakes that are slightly upstream from the point at which the water is salty during droughts. Residents and farmers in central New Jersey rely on the Potomac–Raritan–Magothy aquifer, which could become salty if sea-level rises (Hull and Titus, 1986). Miami's Biscayne aquifer is recharged by the freshwater Everglades, which are just inland of the salt-tolerant mangroves of South Florida. Although parts of the Everglades are a few meters above sea level, portions of the Everglades are less than 1 m above mean high water. If those areas become salty, a substantial part of the Biscayne aquifer would follow suit. The South Florida Water Management District already spends millions of dollars each year to prevent saltwater intrusion into the Everglades (Miller *et al.*, 1989).

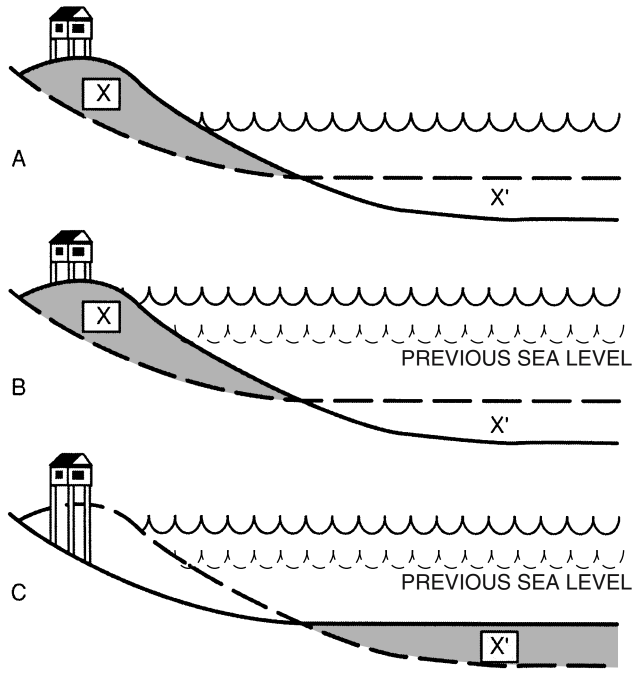

Figure S17 The Bruun Rule, (A) Initial condition; (B) immediate inundation when sea level rises; (C) subsequent erosion due to sea level rise. A rise in sea level immediately results in shoreline treat due to inundation; shown in a and b. However, a 3-foot rise in sea level implies that the offshore bottom must also rise 3 feet. The sand required to raise the bottom (X′) can be supplied for beach nourishment. Otherwise, waves will erode the necessary sand (X) from upper part of the beach as shown in (C).

Responses to sea-level rise

Structures to hold back the sea

For over five centuries the Dutch have used dikes to hold back the North Sea. These impermeable earthen walls protect the coast from storm surges, and lands below sea level from permanent inundation as well. Lands below sea level also require means to remove rainwater: An early solution was to dig ditches, and use windmills to pump water from the ditch up to a nearby canal. In many cases, tide gates keep water in the canal slightly below sea level by opening during low tide and closing the rest of the time. The Dutch approach has been applied in New Orleans (USA), Shanghai (China), and the Fens (UK). Storm-protection dikes protect land above sea level in many other areas. London, Providence (USA), and several other coastal cities are protected by large tide gates known as "storm surge barriers," which close only during storms.

To protect a shore from erosion, a structure need not be impermeable, but it must either block waves from hitting the shore or retain sediment in place. Vertical seawalls and bulkheads, and piles of rock placed at an angle—known as "revetments"—do both. Breakwaters limit the size of the waves that hit the shore, while groins can trap sand moving along the shore, albeit at the expense of erosion elsewhere.

Employing structures to hold back the sea can have adverse effects on the environment and public access to the shore. Any time a bulkhead or revetment is built between a developed area and a retreating shore,

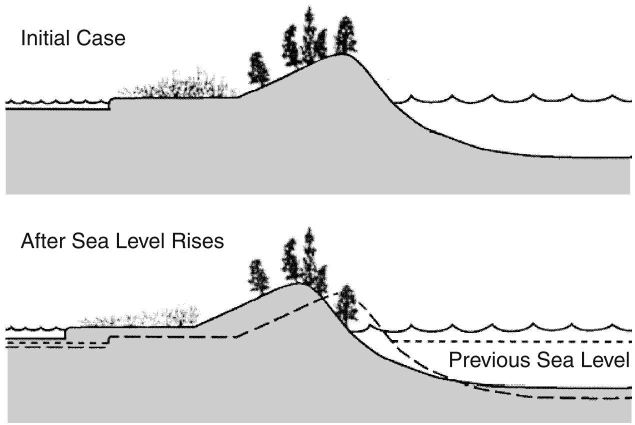

Figure S18 Overwash: the natural response of narrow barrier islands to rising sea level. As sea level rises, sand is washed to the bay side of the island, which increases the elevation of the island and allows it to migrate in land (Titus, 1990).

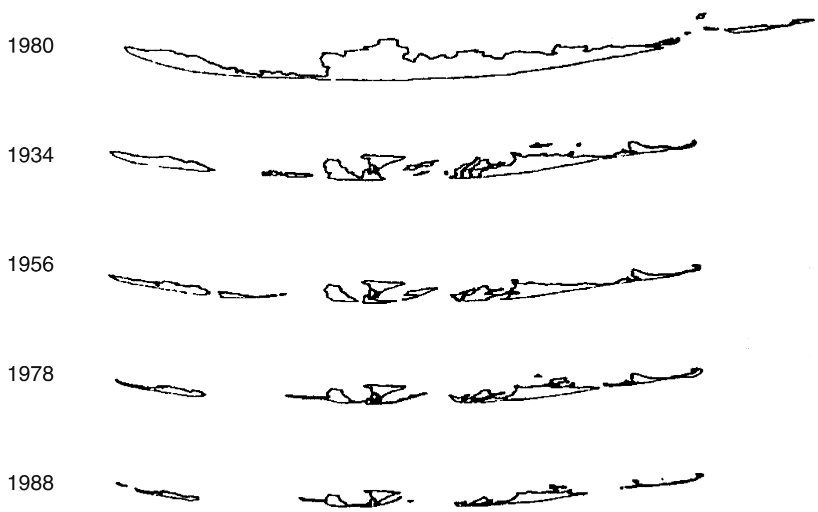

Figure S19 The breakup of Isle Derniere, Louisiana (now Isles Dernieres) (Louisiana Geological Survey).

eventually the wetlands, beaches, and mudflats between the dry land and the sea will be eliminated. Marshes and swamps are important habitat for many species or birds and fish, and also provide organic material to an estuary. Beaches and mudflats provide important habitat for horseshoe crabs and shorebirds. Estuarine beaches are particularly vulnerable because they are often only a few meters wide.

The public has a legal right to access along the intertidal wetlands and beaches under the "public trust doctrine," which is recognized by nations that follow common law and the civil law (Slade, 1990). Therefore, eliminating these lands can have the effect of preventing public access, effectively transferring ownership of the coast from the public to private landowners. Even where wetlands and beaches are not eliminated, dikes block the view of the waterfront and impair pedestrian access to the water. In the United States, people value access to ocean beaches more than estuarine shores; hence, most states prohibit coastline armoring along the ocean (and Gulf of Mexico) while allowing it along estuarine shores (Titus, 1998).

Elevating beaches and low dry land

Communities can retain natural shores and protect developed lands by placing additional soil, sand, or gravel onto the beaches and low land. After the 1900 hurricane killed 6,000 people, most of Galveston, Texas was elevated a few meters. Parts of Miami may have to be elevated because the soils are too permeable for effective pumping (Miller *et al.*, 1989) Land reclamation projects in San Francisco and Hong Kong (Nicholls and Leatherman, 1995) now include a safety margin for accelerated sea-level rise. Placing sand onto beaches is the most common response to erosion along developed ocean beaches in the United States.

A case study of Long Beach Island, New Jersey concluded that raising the entire island in place would be more feasible than encircling the island with a dike or allowing the island to retreat landward (Titus, 1990) (see Figure S20). A number of communities are gradually being elevated, although not necessarily as a conscious response to sea-level rise: Flood-prevention programs provide subsidies to elevate old homes on pilings. Communities undertake beach nourishment to elevate their

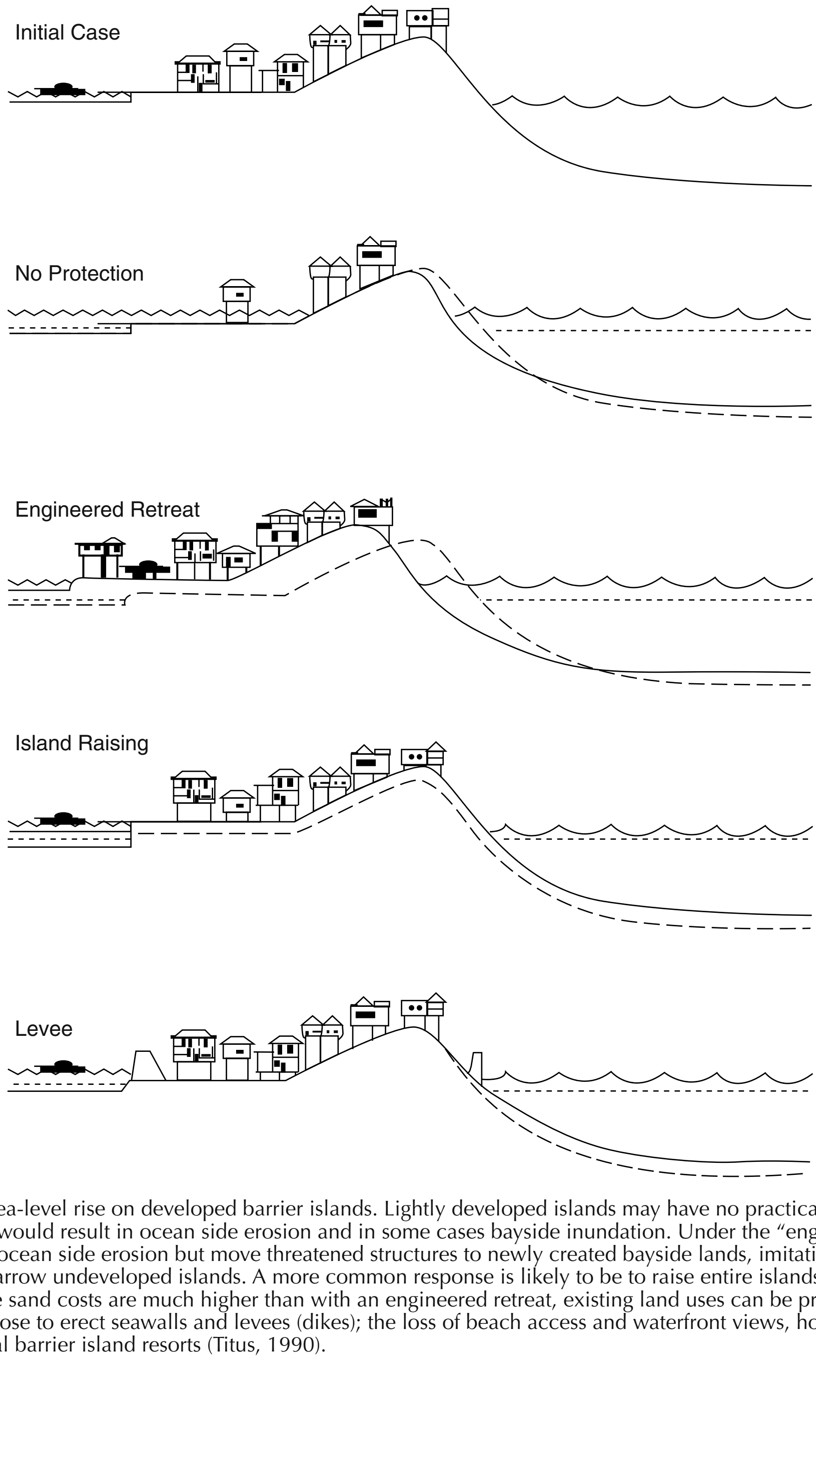

Figure S20 Responses to sea-level rise on developed barrier islands. Lightly developed islands may have no practical choice other than the "no protection" option, which would result in ocean side erosion and in some cases bayside inundation. Under the "engineered retreat" option, a community might tolerate ocean side erosion but move threatened structures to newly created bayside lands, imitating the natural overwash process that occurs with narrow undeveloped islands. A more common response is likely to be to raise entire islands as well as their beaches; although the sand costs are much higher than with an engineered retreat, existing land uses can be preserved. Finally, wide urbanized islands may choose to erect seawalls and levees (dikes); the loss of beach access and waterfront views, however, make this option less feasible for recreational barrier island resorts (Titus, 1990).

beach profiles. Finally, repaving projects elevate streets by tens of centimeters. The higher street often leaves surrounding home lots lower than the street, so that rainwater no longer drains from their yards into the street. As a result, homeowners bring in soil or gravel to elevate their lots enough so that they will drain into the street.

Allow shores to retreat

In lightly developed areas where land values are low relative to the cost of holding back the sea, nature simply takes its course. In most cases, the landowner bears the cost. However, the US flood insurance program sometimes pays for the cost of the lost structure (but not the land), and Australia directly compensates some landowners. The more difficult question arises if private erosion-control costs are low relative to property values, but the community wants to ensure that structures do not block the inland migration of coastal wetlands and beaches. The two primary approaches are:

(1) *Setbacks*, which prevents development of areas likely to be eroded; and
(2) *Rolling* easements, which allow development subject to the condition that the property will not be protected from rising water levels (Titus, 1998).

Setbacks are currently used to mitigate pollution runoff and to ensure that homes are safe from current flood risks. Several US states currently require an additional erosion-based setback, in which new houses are setback by an extra 20–60 times the annual erosion rate. The long-run success of this approach may be limited, however, because eventually the shore will erode to any setback line. The larger setback required to prevent development in any area threatened by rising sea level would require governmental compensation (Titus, 1998).

Rolling easements avoid these problems, by allowing development while informing property owners today that they will not be allowed to build bulkheads or fill the currently dry land if the effect in the future is to destroy wetlands or the public's right to the intertidal shore (Titus, 1998). This option requires neither a specific estimate of future sea-level rise nor large public land purchases, and it is economically efficient because it does not prevent owners from using their land unless the sea actually rises enough to inundate it. Moreover, incorporating this type of foresight into land-use planning can substantially reduce the economic costs of sea-level rise (Yohe *et al*., 1996).

Texas common law has recognized rolling easements for decades along its open coast. Maine has had regulations since 1987 explicitly informing homeowners that their houses will not be allowed to block the landward migration of wetlands or dunes even if the sea rises 3 ft. South Carolina's Beachfront Management Act, passed in response to the risks of a 1-foot rise in sea level, has been was modified to require rolling easements in some locations.

SEDIMENT BUDGET

Definition

As it pertains to coastal sedimentary systems, the sediment budget can be defined as the balance between changes in the volume of sediment stored in the system and the sum of the volumes of sediment entering or leaving the system. Examples of coastal sedimentary systems include estuarine areas composed of fine (mud-size) sediments and open-coast littoral systems most typically composed of sand-sized sediments. The focus here is on sedimentary systems of the littoral zone, the region of coast for which sediment transport is dominated by incident wave processes. This zone ranges from the intermittently dry beach (where wave swash dominates) to water depths of roughly 10–20 m (where the seabed first feels the impact of waves). A focus on the littoral zone reflects the objective of most sediment budget studies: to understand and/or predict long-term changes in the position of the coastline, the interface between the subaerial and subaqueous portions of the littoral zone.

Bowen and Inman (1966) provided one of the earliest sediment budget definitions for sandy coasts: "The procedure, sometimes referred to as the budget of sediments, consists of assessing the sedimentary contributions (credits) and losses (debits) and equating these to the net gain or loss (balance of sediments) in a given sedimentary compartment." In essence, the sediment budget is a sediment volume continuity equation with three terms that sum to zero: sediment flux in, sediment flux out, and volume rate of change within the system. Solving the sediment budget is, in principle, simply a matter of determining two of the terms and solving for the third. Komar (1996) provides a recent review of modern sediment budget techniques.

Spatial and temporal scales of the sediment budget

Although there are no absolute limitations on the spatial and temporal scales considered for sediment budget investigations, in practice spatial scales are on the order of tens of kilometers of coast or greater and temporal scales are on the order of tens of years or longer. In general, these are the scales relevant to the long-term management of coastal erosion. The sediment budget is thus concerned with the large-scale and long-term net result of all processes that transport sediment in the littoral zone and affect the position of the coastline. Individual sediment transporting events, such as storms, may not be relevant unless they contribute to long-term change in coastline position.

The littoral cell

Fundamental to the determination of the sediment budget is the identification of the sedimentary system, and in particular the boundaries of the system. In terms of the continuity equation, this is analogous to the definition of a control volume; for sediment budget studies the control volume is usually referred to as a littoral cell. No universally accepted standards exist for defining the littoral cell for all coasts—the coastal characteristics, the study objectives, and the method of sediment budget solution are all important factors in making this determination. One pragmatic, but broadly applicable, definition simply refers to littoral cells as "semi-contained entities where one can better develop a budget of sediments" (Komar, 1996, p. 18).

The placement of littoral cell boundaries is typically guided by the focus of most sediment budget studies: to understand and/or predict coastline change. In principle, the littoral cell encompasses the region of littoral sediments for which sediment volume changes are closely linked to coastline changes, while regions external to the littoral cell act as sediment source or sink areas for littoral cell gains or losses, respectively. In practice, it can be very difficult to objectively place littoral cell boundaries, with problems unique to defining the longshore, landward, and seaward boundaries.

Ideally, the longshore boundaries of the littoral cell are defined to minimize sediment exchange with other littoral cells along the coast. A classic example is a pocket beach bounded by rocky headlands that are presumed to act as barriers to littoral transport (Figure S21). Along many coasts, the longshore boundaries of the littoral cell are far less clear, especially on long stretches of sandy coast interrupted only by tidal inlets. If the littoral cell is chosen to encompass a large enough area, an assumption of no sediment exchange with adjacent littoral cells may be realistic. However, if a littoral cell defined in this way includes sections of coastline with widely differing rates of erosion or accretion, the value of the sediment budget as a tool for understanding and/or predicting coastline change will be limited. In practice, these larger cells are usually broken into smaller subcells to isolate sections of coast with quasi-uniform rates of change (e.g., Jarrett, 1991), with the underlying assumption that the processes acting within these smaller sections of coast are also quasi-uniform. Cell boundaries may thus lie within an uninterrupted section of coast, with the solution of the sediment budget requiring a simultaneous solution for all subcells with shared boundaries.

The landward boundary of the littoral cell is typically chosen as the base of an upland feature such as the toe of a dune or cliff, thus isolating littoral zone sediments from upland reservoirs of sediment that may serve as sources or sinks relative to the littoral cell. Although this is generally one of the most straightforward cell boundaries to define, significant erosion or accretion of the coastline over the time period of interest may require a moving cell boundary, with the associated complication that sediments may be repeatedly recycled between the littoral cell and upland features such as dunes.

The seaward boundary of the littoral cell can be especially difficult to define, in part because the processes of sediment transport in this environment are poorly understood. Typically, the seaward limit of the littoral cell is chosen on the basis of several simplifying assumptions. First, it is assumed that the littoral cell encompasses a coastal profile that maintains a constant form, generally known as an equilibrium profile (Dean, 1991), as the coast advances or retreats. With this assumption, littoral cell volume changes can be equated to coastline changes through a simple geometric relationship (e.g., Jarrett, 1991). It is further assumed that there is a seaward limit of significant sediment transport (Hallermeier, 1981), at a depth roughly corresponding to the seaward limit of the equilibrium profile. This depth, typically judged to be 8–15 m on the ocean coast, is often referred to as the "closure depth," a term

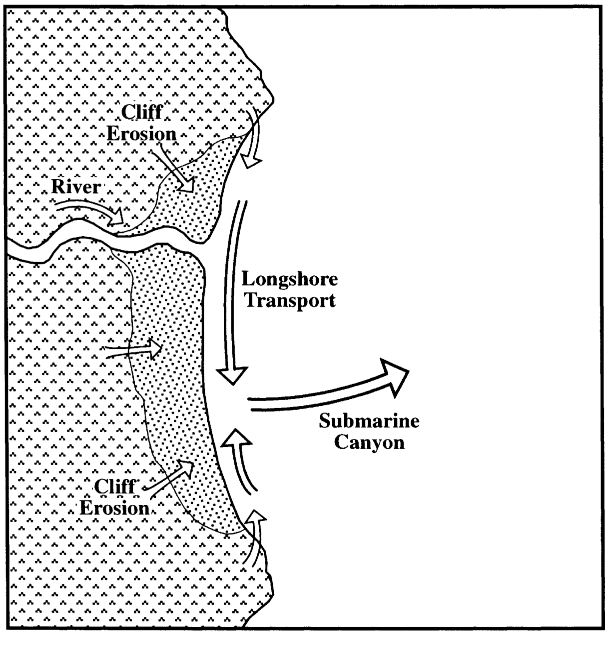

Figure S21 Schematic of a simple littoral cell consisting of a sandy pocket beach bounded by rocky headlands. Arrows represent pathways for sediment transport (after Komar, 1996).

derived from the depth at which sequential coastal profiles seem to "close," or exhibit no significant change over time. Although some profiles have been shown to maintain a reasonably constant form over many decades and simple equations exist for determining the closure depth as a function of the wave climate and sediment grain size (Hallermeier, 1981), profile data are typically inadequate for testing these assumptions rigorously in most study areas. Nevertheless, these simplifications provide an operational method for defining the seaward boundary of the littoral cell in the absence of more rigorous alternatives.

Quantifying sediment gains and losses within littoral cells

Regardless of the way in which the littoral cell is defined, a key challenge for all sediment budget studies is the determination of the sediment flux across cell boundaries. At each of the cell boundaries—longshore, landward, and seaward—there are many physical processes with the potential to add or remove sediment from the littoral cell. Although few of these processes are understood well enough to permit the direct calculation of the cross-boundary sediment flux integrated over the sediment budget timescale, a critical first step for all sediment budget studies is to identify the important sediment transport processes in the region examined. In most cases it is also useful to identify the sources and sinks of sediment associated with these processes, that is, the areas outside the littoral cell that either supply sediment to the littoral cell or store the sediment leaving the littoral cell. Quantifying sediment volume changes within these source or sink areas is often the most reliable method of quantifying gains or losses to the littoral cell. Table S9 summarizes the principal natural and anthropogenic processes responsible for sediment flux across littoral cell boundaries, and the typical sources and sinks of sediment associated with these processes.

Longshore transport

Waves breaking at an angle to the coast result in the longshore transport of sediment, also known as the littoral drift (see Komar, 1990 for review). This transport can occur both on the subaerial beach under the influence of wave swash, as well as in deeper water where steady longshore flows are generated by breaking waves. Perhaps one of the most important components of the sediment budget, the net longshore

Table S9 Principal processes of sediment transport and associated sources and sinks of sediment relevant to the sediment budget

Sediment transport processes resulting in littoral cell gains or losses	Sediment sources (for littoral cell gains)	Sediment sinks (for littoral cell losses)
Longshore transport	Adjacent littoral cells; inlet sand bodies	Adjacent littoral cells; inlet sand bodies
Cross-shore transport	Offshore areas; cliffs, dune scarps; inlet sand bodies	Offshore areas; washover fans; inlet sand bodies
Riverine transport	Upland areas	
Aeolian transport	Coastal dunes; washover fans	Coastal dunes
Gravity flows	Cliffs, scarped dunes	Submarine canyons
Biogenic processes	Calcareous sand of biogenic origin	
Human interventions	Offshore and upland areas used as a source for beach nourishment; updrift sand delivered by inlet bypassing	Dredge disposal sites; industrial uses of sand from beach mining; sand bodies trapped at structures including groins, jetties, and dams; reduction in source from naturally eroding upland features (e.g., cliffs and dunes); artificial dunes constructed by beach scraping

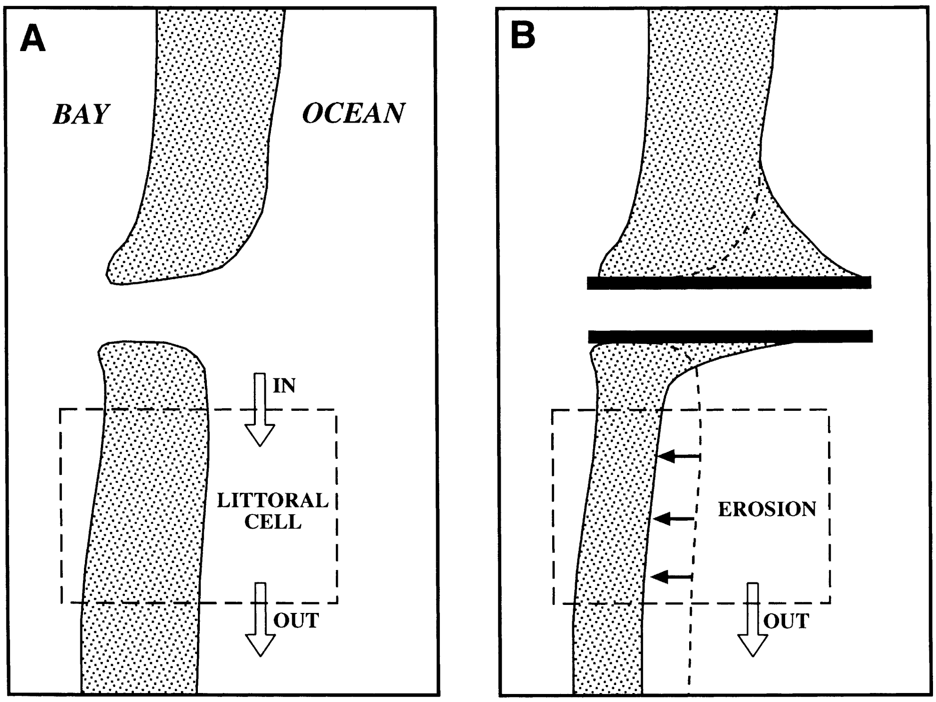

Figure S22 Application of the sediment budget on a barrier island coast. In (A) the rate of sediment transport out of the littoral cell is balanced by the rate of sediment bypassing of the inlet and the coastline is stable. In (B) the construction of inlet jetties has eliminated the transport into the littoral cell, causing a net loss to the littoral cell and coastal erosion.

transport is often readily apparent at coastal structures (e.g., jetties, groins) where sediment may be impounded (Figure S22(B)).

Two main approaches have been employed for estimating the littoral cell gains or losses due to longshore transport. A modeling approach employs empirically derived equations that relate the incident wave characteristics, in particular the wave height and direction, to the rate and direction of longshore transport (Komar, 1990). To provide estimates relevant to the sediment budget, the longshore transport must be integrated over the timescale of the sediment budget. Both the gross sediment transport (total, irrespective of direction along the coast) and the net transport may be of importance to the sediment budget depending on the nature of the littoral cell boundary. For example, in Figure S21, the gross longshore transport near the location of the submarine canyon is important if it is assumed that sand transported from either direction is trapped by the canyon. Alternatively, in Figure S22 only the net transport at the longshore boundaries of the littoral cell may be relevant to volume changes within the cell.

Unfortunately, these transport estimates are generally highly uncertain due to uncertainties in the equations themselves or simply because quality wave information is lacking. Frequently, this approach is used only to estimate the difference in the longshore transport between the longshore boundaries of the littoral cell, with the absolute magnitudes of transport adjusted so that the observed volume changes within the cell are explained (e.g., Jarrett, 1991).

As an alternative approach, littoral cell gains or losses due to longshore transport can be estimated, in some cases, by measuring changes in the volume of sediment contained in source or sink areas external to the littoral cell. For example, the growth of a terminal spit on a barrier island or the impounding of sediment updrift of a recently constructed barrier to longshore transport (e.g., Figure S22(B)) may provide quantitative information on the volume of sediment transported, or prevented from being transported, across a littoral cell boundary.

Cross-shore transport

Waves and current also transport sediment in the cross-shore direction, with the potential for net transport across the landward and seaward boundaries of the littoral cell. Although cross-shore transport can significantly influence the sediment budget, quantification of the gains and losses due to this process can be extremely difficult. Of the many important processes of cross-shore transport, few, if any, are understood to the degree that modeling or empirical approaches can provide quantitative estimates for the sediment budget. A further complication is that, for many of the relevant processes, the net transport across the littoral cell boundaries may be an extremely small fraction of the gross transport, yet this small net transport may still represent a major component of the sediment budget when integrated over the relevant timescale.

At the landward boundary of the littoral cell, wave swash—the up- and down-wash of waves breaking on the subaerial beach—represents one of the dominant cross-shore transporting processes. Wave swash can transport large quantities of sand onshore or offshore depending on many factors, including the sand texture and the continually changing characteristics of incident waves. Because much of this transport is cyclic (with sediment typically carried offshore during storms and onshore during fair weather) and does not result in net transport across littoral cell boundaries, the sediment budget contribution from wave swash may be minimal under most conditions. With increasing storm intensity, however, wave and water levels may become high enough to intersect upland features such as dunes and cliffs, resulting in erosion of these features (e.g., Ruggiero *et al*., 1997). With the aid of gravity-induced slumping or debris flows, this results in a direct transfer of sediment from the upland feature to the adjacent littoral cell, a process that is not readily reversible (with the exception of aeolian transport, see below).

Quantifying the sediment budget contribution from the erosion of upland features is usually accomplished through a source and sink approach. With data on the topographic change of an upland feature, the volume of sediment delivered to the littoral cell can be estimated (e.g., Komar, 1983). However, as noted by Komar (1996) the volume of sediment delivered does not necessarily equal the volume of sand retained by the littoral cell if a component of the eroding sediment has a grain size incompatible with the littoral cell sediments (e.g., a silt or clay fraction will not remain in the littoral cell). In this case, only a fraction of the eroding upland feature volume can be assumed to contribute to the sediment budget.

When storm water levels and waves are high enough to overtop coastal dunes on barrier islands, offshore transport by wave swash may be replaced by onshore transport driven by both waves and steady currents associated with storm surge. The most common expression of this transport is a washover deposit or fan, consisting of sand removed from the littoral cell and deposited either on land or within the bay landward of a barrier island (e.g., Dolan and Hayden, 1981). As the storm intensity increases, the waves and currents associated with washover fans may become focused at a particular point along the coast, opening a new tidal inlet through the barrier island. Although new inlets are typically reclosed rapidly by natural processes or human intervention, large quantities of sand may be transported onshore though these temporary openings, forming deposits in the back-barrier bay similar to washover fans. Washover fans and deposits associated with new inlets represent a loss of sand from the littoral cell, which can be quantified by measuring the thickness and areal extent of such deposits (e.g., Kochel and Dolan, 1986). Estimating the long-term contribution from all storms over the timescale relevant to the sediment budget can be difficult, as washover and inlet deposits from past storms may be difficult to identify, both in terms of their volumes and their ages.

New inlets that remain open will subsequently develop a characteristic morphology consisting of ebb- and flood-tidal deltas on the seaward and landward side of the inlet channel, respectively. The processes of sediment redistribution associated with changes at tidal inlets are complex, involving both longshore and cross-shore transport, and may have a significant impact on the sediment budget of adjacent littoral cells (Rosati and Kraus, 1999). Quantifying the sediment budget terms associated with tidal inlets can be exceedingly difficult. Perhaps the most straightforward approach is the use of bathymetric change to quantify the volume of sand trapped (or released) by the inlet over the time period relevant to the sediment budget being formulated. Unfortunately, adequate bathymetric data are seldom available, and are of limited use for predicting the impact of major inlet changes (e.g., inlet opening, inlet closing, construction of inlet jetties, etc.). Frequently, assumptions are made of the efficiency of an inlet at trapping the gross longshore transport in order to arrive at an estimate of the inlet's sediment budget impact (Rosati and Kraus, 1999).

At the seaward boundary of the littoral cell, determining the sediment gains or losses due to cross-shore transport is generally extremely difficult. At present, sediment transport knowledge is inadequate for quantitative predictions, although studies suggest, at least qualitatively, that offshore areas can act as both sources (e.g., Williams and Meisburger, 1987) and sinks (e.g., Niedoroda *et al*., 1985) of sediment relative to the littoral cell. Because quantification is difficult, it is often assumed that sediment transport is negligible seaward of the predicted closure depth, making the determination of sediment budget gains or losses at this littoral cell boundary unnecessary (in principle). As an alternate approach, some studies have assumed that major imbalances in the sediment budget—after accounting for all the sediment budget components that can be quantified—are attributable to sediment flux at the seaward boundary (e.g., Inman and Dolan, 1989). In almost all cases, however, this important component of the sediment budget remains a source of great uncertainty and warrants much further research.

Riverine sediment transport

The delivery of sand to the coast by rivers can represent a major component of the sediment budget. This is especially true on steep gradient coasts, such as typically found on the leading edge of continental plates, where rivers deliver their transport load directly to the coast. In contrast, the river valleys of low gradient, trailing edge coasts may be drowned, trapping sediment from rivers in estuaries before it can reach the coast.

A variety of techniques have been developed to estimate the sediment budget contribution from rivers, although all are associated with a high degree of uncertainty due to the difficulty of directly measuring the sediment load of a river integrated over the timescale relevant to the sediment budget. Komar (1996) reviews many of the methods that have been used, and makes the further point that, as in the case of sediment eroded from cliffs, only the fraction of delivered sand with a similar size as found in the littoral cell will contribute to the sediment budget.

Aeolian sediment transport

In many coastal areas, wind plays an important role in the flux of sediment across the landward boundary of the littoral cell. Upland features that are not well stabilized by vegetation, such as washover fans, may provide a source of sediment in areas dominated by offshore directed wind. In many areas, however, aeolian transport results in the formation of coastal dunes, which by their existence indicate that the net effect of wind transport is landward—a loss to the littoral cell. As for most sediment transport processes affecting the sediment budget, the direct calculation of aeolian transport's contribution to the sediment budget is not feasible, and a source and sink approach, whereby changes in dune volume are inferred to represent a littoral cell loss, may be the best available method (e.g., Inman and Dolan, 1989). Because coastal dunes are typically vulnerable to erosion by wave processes (see above), any sediment budget for which coastal dunes are important must take into account the possibility that dunes can represent a net source to the littoral cell, despite their earlier formation as a sink.

Gravity flows

At both the landward and seaward boundaries of the littoral cell, sediment transport driven primarily by the direct influence of gravity may represent another significant contribution to the sediment budget. At the landward boundary, slumping and other forms of mass wasting of cliffs or scarped dunes can deliver sediment almost instantaneously to the littoral cell. The processes initiating this transport are varied and complex, but in many cases the cross-shore transport of sediment by waves plays a key role (e.g., Everts, 1991). As described above, the contribution to the sediment budget can be estimated by quantifying the volumetric loss to the upland feature and accounting for the percent of eroded material expected to be size compatible with littoral cell sediments (e.g., Komar, 1983).

At the seaward boundary of the littoral cell, submarine gravity flows can cause significant losses to the sediment budget, especially along narrow-shelf coasts where submarine canyons extend landward into the littoral cell (e.g., Lewis and Barnes, 1999). These gravity flows are initiated when longshore transport delivers sand to the head of the canyon; periodically the deposit becomes over steepened to the point where it slumps and flows down the canyon as a turbidity current. The most straightforward means of quantifying the volume of sand lost from the littoral cell is by determining the volume change in the sediment sink area at the bottom of the canyon. Often, however, the necessary bathymetric change information is lacking and inferences about the volume of sediment lost through this process must be made by considering the balance of other sediment budget components.

Biogenic processes

In tropical and subtropical regions, a significant component of beach sand may be of biogenic origin, composed of calcium carbonate grains, rather than derived from terrestrial erosion (largely quartz or other silicate minerals). In these areas, the sediment budget may be strongly influenced by the biogenic production of carbonate material, such as corals, shells, and foraminiferal tests, which is reworked by physical processes into sand of the littoral cell. As described by Komar (1996), estimating the volumetric contribution to the sediment budget is difficult, because the mere presence of carbonate sand does not give the rate at which it is being produced and lost due to abrasion. Although some techniques have been developed (see Komar, 1996, for a description), much further research is needed to develop a reliable means of estimating this sediment budget component.

Human interventions

Along many coasts, the influence of human activities is becoming increasingly significant and must be accounted for in balancing the sediment budget. Human activities take many forms, but can be broadly categorized into activities that interfere with natural processes, and activities that move sediment directly. Interferences in natural processes typically result in the reduction or elimination of a sediment source, representing a loss to the littoral cell (tabulated as the creation of new sediment sinks in Table S9). The construction of dams can trap sediment in upland reservoirs, greatly reducing the riverine transport of sediment to the littoral cell. Armoring of eroding upland features, such as cliffs and dunes, prevents transporting processes such as gravity flows and cross-shore transport from delivering sediment that otherwise would have nourished the adjacent littoral cell. Groins and inlet jetties are designed to interrupt longshore sediment transport, creating new updrift sediment sinks for longshore transport (Figure S22). Estimating the impact on the sediment budget as a result of these engineering structures is, in many cases, more straightforward than for purely natural processes, as the volume of sediment impounded (or prevented from being eroded) can often be directly measured.

Human activities that move sediment directly may also result in sediment losses or gains to the littoral cell. Sediment gains include beach nourishment, whereby sand is placed within the littoral cell using a source area external to the littoral cell; and inlet bypassing, whereby sand on the updrift side of a tidal inlet is pumped to the downdrift side (representing a loss to the updrift littoral cell). Sediment losses include inlet channel dredging when the disposal site is outside the littoral cell, the mining of beach sand for industrial uses (becoming rare), and beach scraping following storms, whereby sand is bulldozed off the beach foreshore to form artificial dunes. The best available estimate of the sediment budget contribution of these engineering activities is, in most cases, the contractor's estimate of sediment volume delivered.

Effect of sea-level rise

Because sediment budget timescales are generally long, on the order of decades or longer, a rise in sea level relative to land has the potential to significantly influence coastline position. Though neglected in most sediment budget studies, sea-level rise occasionally has been treated as an agent of coastal change operating independently of other processes affecting the sediment budget (e.g., Inman and Dolan, 1989). The most common method of relating sea-level rise to coastline change is through a simple geometry-based model known as the Bruun Rule (Bruun, 1962), in which a rise in sea level results in an upward and landward translation of the equilibrium profile with a redistribution of sediment from onshore to offshore. If the redistribution of sediment is assumed to occur within the bounds of the littoral cell, the amount of coastline change predicted by the Bruun Rule can be removed, in principle, from consideration when balancing the sediment budget (Inman and Dolan, 1989).

Unfortunately, the approach of attributing a distinct component of coastline change to sea-level rise is not well founded by either field observations of the long-term profile response or through a processes-based modeling approach. In most cases, the uncertainty level in the overall sediment budget is enough to account for the component of coastline change that may be attributable to sea-level rise. Also, there is little justification for considering sea-level rise as an independent process, as sea-level rise by itself has no capacity to transport sediment. Rather, sea-level rise undoubtedly acts as a modifier of many transport processes influencing the sediment budget, although our understanding of these processes is currently too limited to quantify the effect of sea-level rise on coastline position. With the potential to be a significant and pervasive agent of long-term coastal change, sea-level rise clearly warrants much further research.

The balance: coastline change

In principle, the sediment budget can be balanced by summing the volumetric contributions of all relevant sediment transporting processes, giving the net volumetric change within the littoral cell. Coastline change can then be predicted from volume change by invoking the equilibrium profile assumption, whereby the profile maintains a constant form out to the closure depth while translating landward (erosion) or seaward (accretion). In many cases, however, great uncertainties remain in most sediment budget components, as described above, and only the end result—littoral cell volume change or the coastline change itself—is known with any degree of certainty. For this reason, the observed volume or coastline change is frequently used to adjust or calibrate the most uncertain terms in the sediment budget. The sediment budget is then used to make predictions of coastline change given expected changes in specific sediment budget components, most often those induced by human activities. Several simple examples are given below.

In the case of Figure S21, the most uncertain sediment budget component might be the down-canyon loss of sediment through gravity flows. By measuring the volume change within the littoral cell directly through bathymetric comparisons, or by estimating volume change from coastline change using the equilibrium profile assumption, the down-canyon loss can be estimated if the other important components of the sediment budget—here river input and cliff erosion—are reasonably well known. The utility of the sediment budget is then in making predictions of coastline change given a modification of a sediment budget component. For example, if cliff erosion is arrested by armoring a modification to the rate of coastline change can be predicted if it is assumed that the other sediment budget components remain unchanged after cliff armoring.

In another example, the construction of inlet jetties might interrupt the sediment bypassing a tidal inlet as in Figure S22. If a preconstruction sediment budget has been established, including estimates of longshore transport and any other significant components, then the impact of jetty construction on coastline change can be estimated by assuming a total or partial interruption in the longshore transport reaching the littoral cell, and again assuming that other components of the sediment budget remain unchanged.

Despite their uncertain nature, the sediment budget often represents the best available tool for gauging the impact of human interventions, as well as changes due to natural processes, on the rate of coastline change. Also, as stated by Komar (1996, p. 25), “the formulation of a sediment budget can also serve to organize what is known about a coastal area or littoral cell, and where the chief gaps still exist in our understanding, thereby providing a guide for future research.”

SEDIMENT SUSPENSION BY WAVES

Suspended sediment under waves is defined as sediment that is picked up (entrained) from the seabed by the water and is kept entrained by the motion of the water. The suspension occurs as a result of the moving water entraining loosely consolidated sediments such as sand and carrying them up into the water column away from the seabed. When the water stops moving, the sediments eventually settle back down to the seabed under the influence of gravity. However, moving water can counteract the effects of gravity by exerting stress on the sediments and effectively dragging them up into the water column against gravity’s pull. On the coast, waves arriving from the deeper ocean provide the necessary movement of water to lift sediments up off the seabed and transport them around.

Sediment transport processes

When waves interact with the seabed, they mobilize sediment and progressively change the shape of the coastline over time. The mobilization of sediment by waves may be thought of as taking place in two principal ways (Bagnold, 1963): (1) as a result of collisions between individual sediment grains, and (2) as a result of fluid stresses on individual sediment grains, both of which may maintain the motion of the sediment. The first process is termed bedload and commonly occurs with large sediments such as sands, gravels, and pebbles. These large-sized sediments tend to bounce off one another because the water would have to be moving quickly for sustained periods of time to keep them suspended. The second process is termed suspended load and commonly occurs with sand and smaller-sized sediments. These sediments are small enough for the water to drag them into suspension. Sediments like silt and clay that are smaller than sand size may be suspended for long periods of time and carried by the water over long distances before settling back to the seabed. These sediments form a subset of suspended material referred to as washload because they are suspended for long enough periods that they are washed away. Waves reaching coastlines are typically energetic enough to suspend sediments smaller than sand size and wash them away into deeper water.

Historically, bedload was considered to be the principal process in sediment transport and to account for the volumetric majority of sediment moved since it included the movement of large sediments. Recent work (e.g., Neilsen *et al.*, 1979; Sternberg *et al.*, 1989) has indicated that suspended load is the major contributor to sediment transport. Sediment carried in suspension can account for upwards of 80–90% of the volume of wave-transported sediment. So, even though bedload moves large sediments, the accumulated volume of smaller sediments moving in suspension comprises a significantly greater volume of sediment moved than bedload. Thus, the suspension of sediments under waves is an important factor in the redistribution of sediment and coastal evolution.

Sediment suspension mechanisms

In order to better understand the suspension of sediments under waves, several mechanisms have been proposed to account for the observed characteristics of suspension. Initially, diffusion, analogous to the mixing of concentrations at the molecular level in chemistry, was proposed as the mechanism for the suspension of sediment by Rouse (1937). By

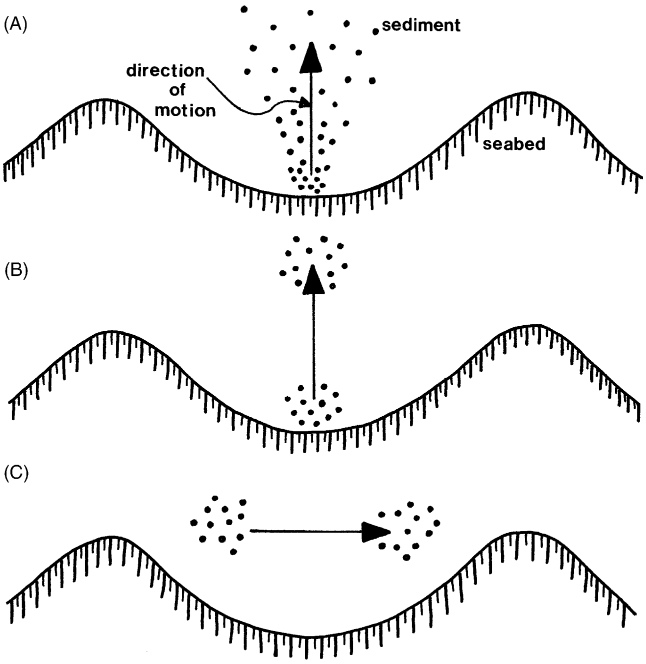

Figure S23 Mechanisms of sediment suspension: (A) diffusion, (B) convection, and (C) advection.

this mechanism, sediment grains behaved like molecules and moved down concentration gradients from areas of high concentration to areas of low concentration. Sediment suspension thus resulted from the movement of sediment away from the seabed (high concentration of sediment) into the water column (low concentration of sediment). Figure S23 represents the concept of diffusion showing the general pattern of motion of the water-sediment mixture. Currently, a molecular-type diffusion mechanism is commonly accepted for horizontal transport of sediments but is no longer accepted for vertical transport since the rate of diffusion in still water is not strong enough to overcome the force of gravity alone. However, diffusion can occur in moving water where the motion of the water counteracts gravity.

Additional mechanisms associated with the turbulent motion of the water were then proposed to supplant the molecular diffusion mechanism. These mechanisms, referred to as convection and advection, are represented in Figures S23(B) and (C), respectively. Convection and advection occur as a result of the drag of moving water on stationary particles towing the particles along with the water. This drag is referred to as a Reynolds stress and is a velocity-dependent force imparted on the sediment grains by the moving water. The faster the water, the greater the stress on the sediment. Convection occurs as a result of vertically directed Reynolds stresses that carry the water and sediment mixture upwards away from the seabed. The sediment is maintained in suspension by these fluid stresses that counteract the force of gravity. Advection occurs as a result of horizontally directed Reynolds stresses that carry the water and sediment back and forth across the seabed. Again the sediment is maintained in suspension by fluid stresses that counteract the force of gravity. Over rippled seabeds, convective and advective suspension of sediment are an extremely important factor due to near-seabed turbulence as water passes over the bedforms.

Flow separation and vortex propagation

The near-seabed turbulence that causes convective and advective suspension of sediment is influenced by the presence of bedform-induced flow separation. Flow separation occurs as a direct result of the conservation of energy within the water. Water energy is commonly described using the Bernoulli equation, which equates the total energy of the water as equivalent to the sum of the pressure of the water, the kinetic energy (related to water velocity) and the potential energy (related to the elevation of the water and gravity). Figure S24 illustrates the dynamics of flow separation over a bedform under unidirectional flow (after Honji *et al.*, 1980). In the figure, water is assumed to be flowing from left to right.

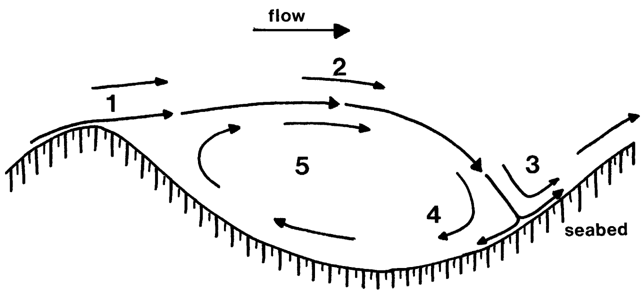

Figure S24 Schematic of flow separation and generation of a sediment suspending vortex (after Honji *et al.*, 1980).

Immediately over the ripple crest (1) the flow of water just above the seabed expands as the water column deepens into the trough of the ripple. Flow velocity decreases into the trough since there is a greater depth through which the same volume of water must travel than over the crest. In order to conserve energy in the direction of flow, the pressure of the water at the seabed increases to compensate for the decrease in velocity. If the water is moving fast enough, the increase in pressure at the seabed lifts the water upwards as a result of a pressure gradient away from the seabed and the flow separates. If the water is not moving fast enough, the change in pressure is not sufficient to lift the water away from the seabed. The flow of water (streamline) lifted off the seabed by the pressure difference (1) begins to accelerate as it is no longer slowed by the friction of the seabed (2). As the flow accelerates, velocity increases and, to compensate and conserve energy, pressure decreases. The decrease in pressure reduces the pressure gradient away from the seabed and the streamline reattaches (3). The streamline from 1 to 3 creates a free shear layer beneath which flow reverses (4) relative to the direction of the flow above the layer and forms a vortex of rotating water (5) in the lee of the ripple crest. The free shear layer has increased momentum relative to the surrounding water due to its larger velocity thereby creating a momentum gradient toward the seabed. The momentum gradient traps the rotating flow in the lee of the ripple where it entrains sediment.

Under a wave-dominated environment, the free shear layer that traps the suspended sediment forms and decays twice each wave cycle since the horizontal component of the oscillatory flow becomes zero twice each wave cycle. When the free shear layer decays, the vortex at the seabed is no longer trapped. The vortex generally has larger velocities than the water above and a momentum gradient is established away from the seabed. The upwards directed momentum gradient causes the vortex to rise away from the seabed, suspending sediment up into the water column (Tunstall and Inman, 1975). The vortex is both convected and advected away from the seabed and it diffuses over time into clouds of suspended sediment that are transported with the flow. The diffusion occurs down the concentration gradient from the vortex to the surrounding water. As the vortex decays, the Reynolds stresses suspending the sediment decay as well and the suspended material begins to settle out. The formation and subsequent ejection of vortices from the bed is an important mechanism for suspending sediment under waves and results in intermittent injection of suspended sediment into the water throughout a complete wave cycle.

Wave cycle model of sediment suspension

The intermittent nature of sediment suspension through vortex creation and ejection, or shedding, is significant because it leads to strong temporal variations in concentration and hence strong temporal dependencies in sediment transport. The temporal variations occur over the timescale of a complete wave cycle since the mechanisms controlling vortex shedding vary with the passage of each wave. The wave cycle model of sediment suspension is based on a model of periodic flow separation and vortex propagation over a rippled seabed that incorporates this intermittent suspension of sediment (Sleath, 1982). Figure S25 represents this conceptual model over various stages, or phase angles, of a wave cycle. The motion of water under a wave at the water surface is generally orbital, molecules of water traveling through a 360° orbit between wave crests. The wave orbit becomes flatter toward the seabed as the vertical motion of the water is muted and the water generally flows horizontally first in one direction as a wave crest passes and then horizontally in the other direction as the wave trough passes. This change in flow direction is referred to as oscillatory flow. Given this oscillation, the phase angle of the wave cycle may be referenced relative to the 360° of one complete

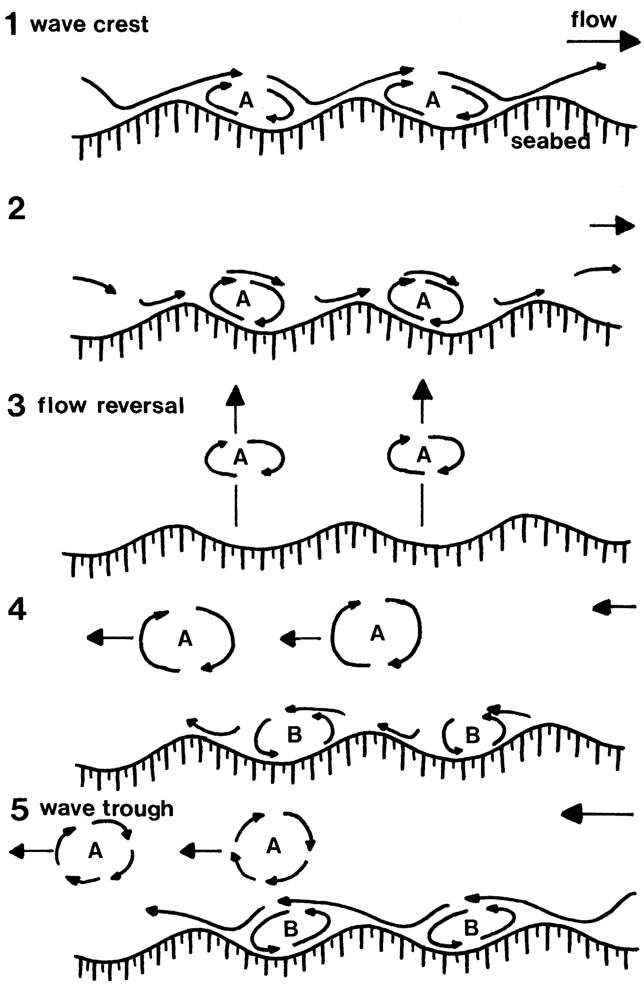

Figure S25 The wave cycle model of sediment suspension (after Sleath, 1982).

wave cycle. The start of the wave cycle may be set anywhere in the cycle but is commonly assigned to a maximum velocity in one direction under the wave cycle model. In Figure S25, the start of the wave cycle has been arbitrarily set to occur with the passage of a wave crest (1).

At the beginning of the wave cycle (1), phase angle $\theta = 0°$, the horizontal velocity of the flow is at a maximum to the right. Flow has separated over the lee slope of the ripple and has generated a vortex downstream of the crest (A). The vortex is trapped at the bed by the large momentum gradient directed toward the seabed from the free shear layer. The vortex entrains sediment from the seabed while trapped and reaches its maximum size and velocity. At this point, velocity is large but the suspended sediment concentration in the water column is small since the vortex is trapped at the seabed. As the horizontal flow to the right decreases in velocity (2) with the passage of the wave crest, phase angle $\theta = 45°$, the free shear layer decays resulting in a momentum gradient directed upwards away from the seabed. The vortex carries the entrained sediment as it begins to rise. When the horizontal velocity reaches zero (3) at the midpoint in the wave between the crest and the trough, phase angle $\theta = 90°$, the flow is on the point of reversal and the free shear layer has vanished. The vortex is ejected from the seabed by the upwards transfer of momentum and carries sediment into suspension. At this point, velocity is small and suspended sediment concentration in the water column is large since the vortex has been released upwards. With the collapse of the free shear layer the vortex is no longer constrained and the suspended material begins to diffuse under viscous and gravitational forces.

Once through the point of reversal, horizontal flow increases to the left (4) with the approach of the wave trough, phase angle $\theta = 135°$. The vortex ejected during the previous phase (A) is transported in the opposite direction to the flow which generated it. This vortex is deflected higher into the water column by the generation of a new free shear layer on the ripple slope opposite to the slope above which it formed. As the vortex (A) rises it diffuses into the water column and is advected across the bed by the water that is now flowing to the left. At the seabed a second vortex (B) is generated under the newly developing free shear layer. When the horizontal velocity reaches a maximum to the left (5) with the arrival of the wave trough, phase angle $\theta = 180°$, the flow of water is in the opposite direction to the flow at a phase angle $\theta = 0°$ (wave crest) and the second vortex (B) reaches its maximum size and velocity while trapped at the seabed. The velocity is now large again but suspended sediment concentration in the water is now dependent on the diffusing and advected vortices generated earlier in the wave cycle.

The second half of the wave cycle covering the passage of the wave trough and the arrival of the next wave crest, phase angles $\theta = 180°$ to $\theta = 360°$, go through these same five stages as the flow reverses from the left to the right. The second vortex (B) is ejected into the water column in the same manner as the first vortex (A) at the next flow reversal. The first vortex continues to diffuse and to be transported back and forth above the seabed so long as the fluid turbulence can maintain the sediment in suspension against the pull of gravity.

Not all waves will be large enough to generate flows at the seabed that will result in separation. The size of the wave needed to suspend sediment at the seabed will depend on the depth of water. If a series of waves pass by in succession, and each generates flows strong enough to develop vortices at the seabed, sediment suspended by the first wave may be kept in suspension until all the waves have passed. Such a series of waves is known as a wave group. Successive waves in a wave group inherit some turbulence from the preceding waves. This inheritance of turbulence leads to the suspension of sediment for periods of time longer than a single wave cycle. The extended suspension events result in the individual vortices coalescing into clouds of suspended material above the bed. Video observations (e.g., Dyer, 1980) of sediment suspension under wave groups show the formation of these suspension clouds and their subsequent decay once the wave group has passed.

Modeling sediment suspension

Given the conceptual wave cycle model of sediment suspension, it is clear that the marked spatial and temporal variations in sediment suspension are critical in determining overall sediment transport. Bailard (1984) developed a model for sediment transport based on energetics principles proposed by Bagnold (1963) but recognized that the use of time-averaged terms were a significant weakness to the model's predictive ability. The weakness is due to the fact that time-averaged terms do not represent the physical processes well (e.g., Osborne and Greenwood, 1993). The process of vortex shedding acts as a strong control on the suspension of sediment into the water column and provides a significant influence on the resulting concentration profile. Additionally, the time at which concentration reaches a maximum is out of phase with the time at which velocity reaches a maximum. The energetics approach relies on the velocity and concentration maximums occurring together.

Ideally, any model that is developed to predict sediment suspension under waves should account for the suspension characteristics outlined in the wave cycle concept of suspension. Neilsen (1993) investigated several different models for predicting sediment suspension under waves and concluded that simple models worked better than complex models. Simple models work better than complex models because the contribution of many of the variables in the process of sediment suspension is poorly understood as are the interrelationships between the variables. However, the simplest model, where sediment suspension is predicted from the value of the flow velocity, also fails to provide reasonable predictions because suspension maximums occur at a different phase to velocity maximums. Neilsen (1993) concluded that the shift in phase between velocity and concentration had to be included in the derivation of a model.

Atkins (1993) used the wave cycle model of sediment suspension to suggest that a simple model for sediment suspension could be derived as a function of the flow velocity shifted with respect to the suspended sediment concentration by a time lag equivalent to the phase shift between the two variables. The model predicted total suspended sediment concentration as the sum of convective, advective, and diffuse components. The components were predicted from the flow velocity using simple sinusoidal relationships. In experimental tests, the model was able to explain nearly 80% of the variation in sediment suspension measured under a synthesized irregular wave spectrum. Both peaks and lows in suspended sediment concentration were reasonably well predicted both in magnitude and through time. The success of the model suggests that the wave cycle model of sediment suspension under waves is an adequate starting point for further research into suspension mechanisms.

Conclusions

Sediment suspension under waves is a complex interplay between the currently identified mechanisms of convection, advection, and diffusion.

This interplay results in strong temporal relationships between water velocity and the concentration of suspended sediment. A group of successive waves energetic enough to suspend material can keep sediment suspended for extended periods of time. The predictive successes of simple models based on the physical mechanisms provides strong evidence that simple functional relationships between velocity and concentration may be used to predict sediment suspension under waves. A better understanding of the processes controlling the mechanisms of sediment suspension, their time dependencies, and their inter-relationships will lead to better predictive models of suspension and, ultimately, better models of sediment transport. Better models of sediment transport would then allow for better predictions of coastal evolution and increase our understanding of how and why coastlines change.

SEDIMENTARY BASINS

Regional subsidence in coastal areas is mainly due to the occurrence of sedimentary basins. Figure S26 indicates the major deltas of the world (Fairbridge and Jelgersma, 1990); many situated on top of sedimentary basins. Before giving some examples of basins situated in the coastal zone some information should be given about the origin of those basins.

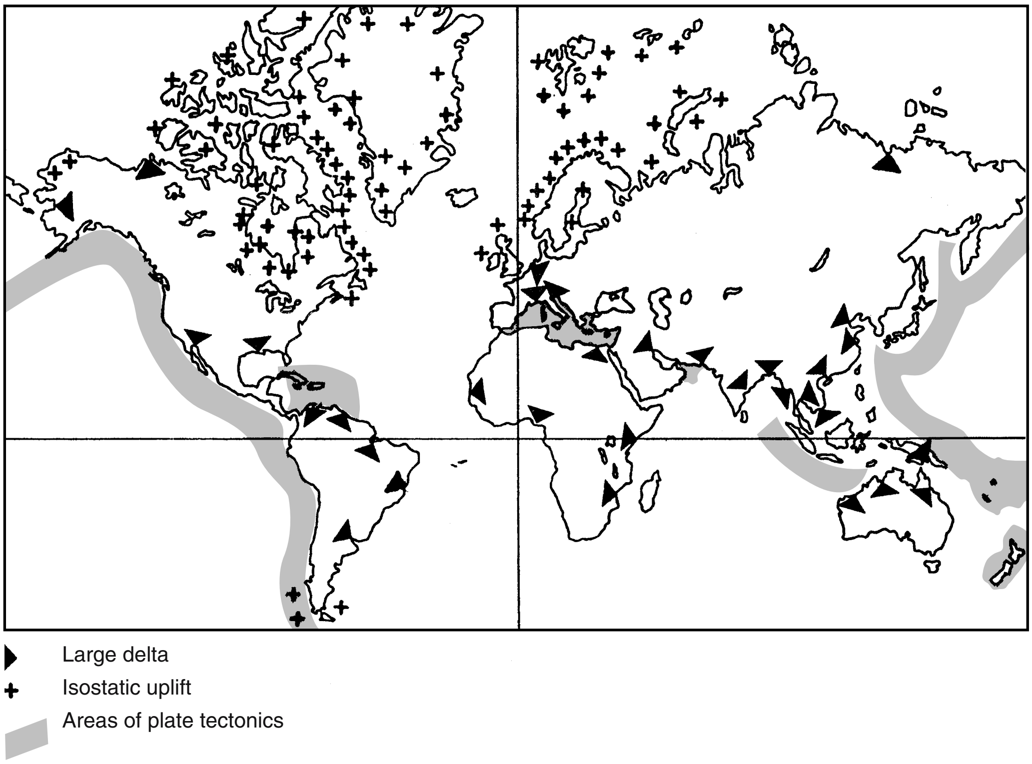

Figure S26 Location map of coastal instability (from Fairbridge and Jelgersma, 1990; with the kind permission of Kluwer Academic Publishers).

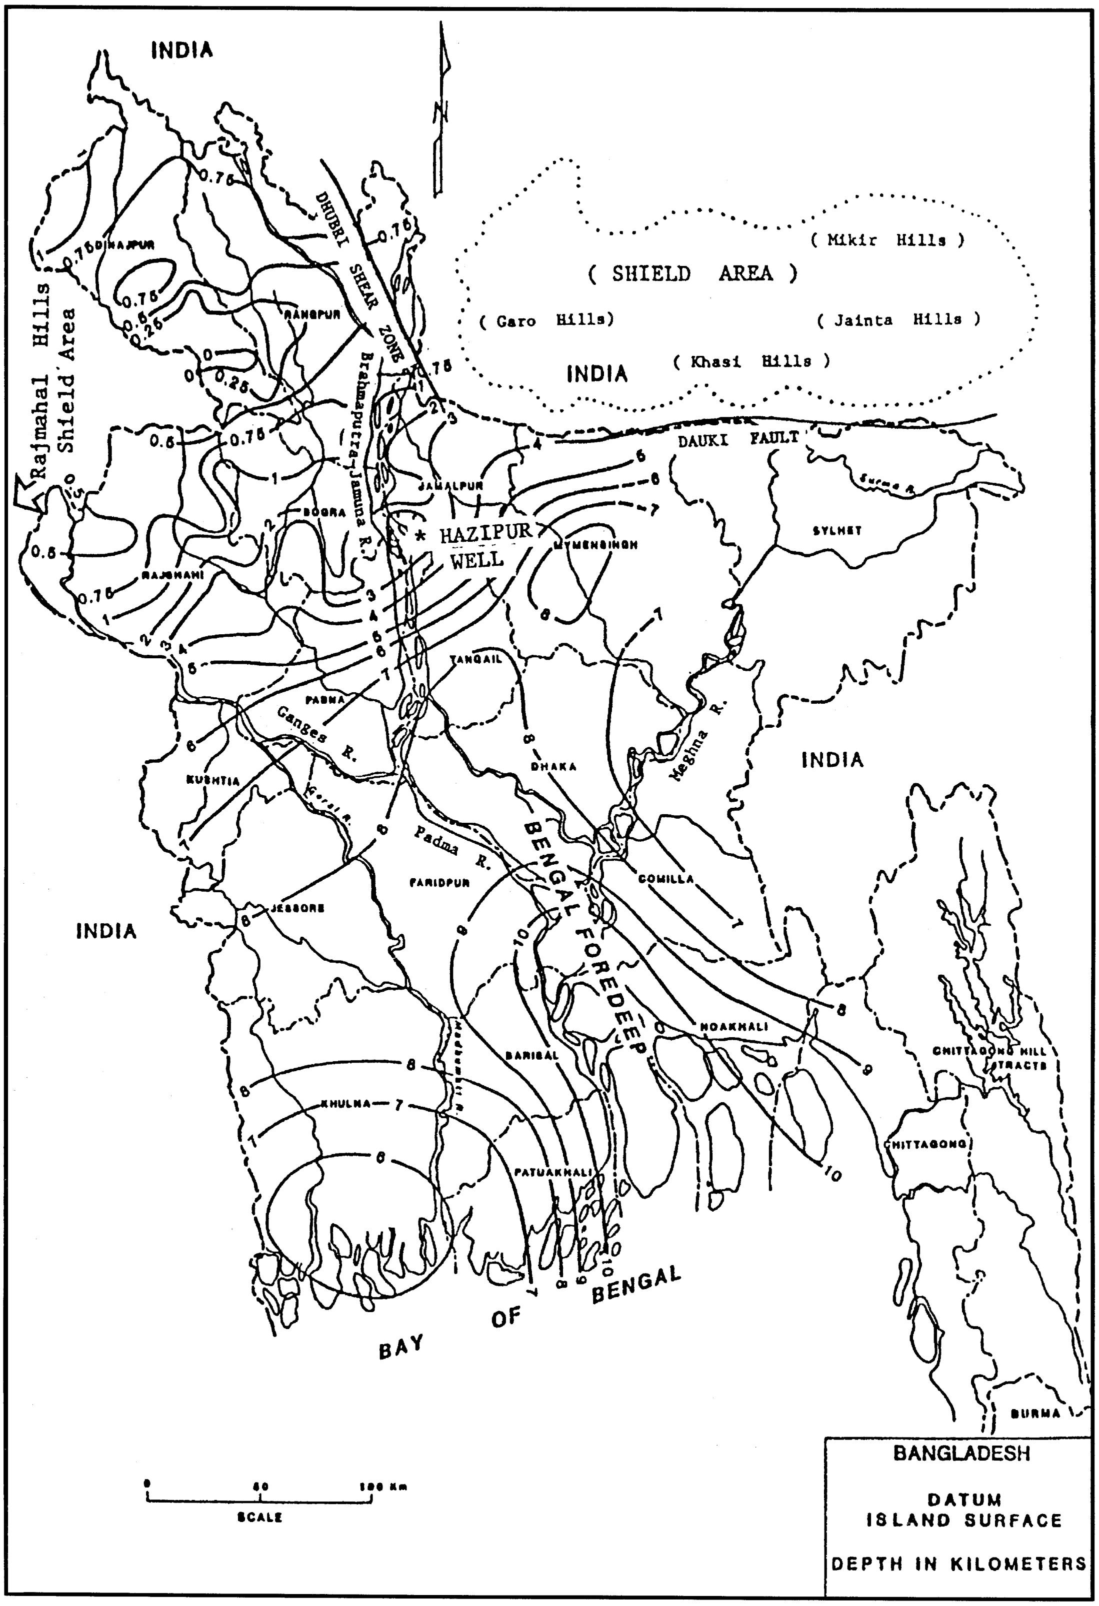

Figure S27 Depth to basement in the Bengal basin of Bangladesh (from Alam 1996; with the kind permission of Kluwer Academic Publishers).

Sedimentary basins are places of prolonged slow subsidence in general, compensated by sediment input of rivers and the sea. In recent time, however, this sediment input in several deltas was strongly reduced due to the construction of dams and reservoirs in the upstream area of the river and to other human interference. This so called "sand starvation" results in surface lowering and consequently in shore erosion. The subsurface layers of sedimentary basins have been subject to intensive investigations, many studies have been made of their stratigraphic sequences and their relation to sea-level changes.

During the last decades the concept of plate tectonics has given a more detailed idea as to how these basins are formed. The lithosphere consists of a number of plates which are in motion. Accordingly, sedimentary basins exist in an environment of the motion of these plates. Basins can either be formed by collision of plates or by lithospheric stretching of the plates. The first mentioned activity gives rise to basins due to flexures, they are present as foreland basins at the foot of mountain belts. The Bengal basin of Bangladesh and the Po basin of Italy are examples of these flexures and will be discussed below. Lithospheric stretching of plates causes fault zones which become later, due to thermal cooling, important areas of subsidence. Examples of these rift basins are the North Sea basin and the Niger basin. Another genetic class of rift basins are associated with strike-slip deformation. The Tertiary rift basins onshore and offshore of Thailand and Malaysia are associated with this phenomenon. A few samples of sedimentary basins present underneath important deltas are presented below.

The Po delta

The river plain overlying the Po–Veneto sedimentary basin is enclosed by the Alpine mountain chain in the north and by the Apennines in the south. Collision of the African plate with the European plate in the Late Cretaceous was responsible for this landscape. The Po–Veneto basin came into being and due to the slow but continuous subsidence, thick layers of sediment were deposited. Mapping the base of the Pliocene–Quaternary sequence has indicated several fault zones in the southest part of the plain. The Quaternary deposits reach a thickness of more than 1,000 m.

In geological terms, the lobate Po delta is a very young phenomena which came into being in historical time by an increase in sediment discharge caused by deforestation in the uplands and an increase in precipitation (Little Ice Age). In recent time reforestation, construction of dams and reservoirs, and human activities in the delta itself have caused sediment starvation, subsidence, and consequently shore erosion.

Ganges–Brahmaputra delta

The Bengal basin is a product of the collision of the Indian plate with the Burmese and Tibetan plate. From the Cretaceous onwards thick layers of sediments have been laid down in this basin due to tectonic and isostatic subsidence. The uplift and erosion of the Himalayas mountain range are the main sources of the sediments filling the basin. The thickness of the sedimentary sequences is demonstrated in Figure S27 by a contour line on the depth of the basin (Jones, 1985; Alam, 1996). Subsidence rates are thought to be 2–5 cm/century.

The Ganges–Brahmaputra delta and plain of India and Bangladesh have many fault zones which may have contributed to the shifting of river courses and the differences in surface lowering. Other tectonic phenomena are the occurrence of many earthquake epicenters. The Meghna fault zone, NE–SW direction, continues offshore in the Bay of Bengal and ends in the canyon of the Swatch of no Ground.

The alluvial and deltaic plain are subject to seasonal flooding by rivers and cyclonic surges. Due to the high tidal range the delta can be classified as tide-dominated.

Niger delta

The Niger delta has been developed since the Cretaceous when tectonic events culminated in seafloor spreading between the African and South American lithospheric plates. The post-drift period was characterized by instability and subsidence, due to thermal cooling, in the rift valleys and the rift margins. Due to this subsidence more than 8,000 m of Tertiary and Quaternary sediments are present (Figure S28) in the Niger sedimentary basin (Whiteman, 1982). Like all deltas in the world the recent delta sediments consist of a wedge of fine-grained sediments formed as a result of the post-glacial rise in sea level.

The coast of the delta is formed by small barrier islands separated by inlets and backed by an extensive area of mangrove swamps. The delta can be classified as wave-dominated with important input of river sediment. The latter has compensated for the subsidence but in recent time due to the construction of several dams and reservoirs the sediment supply is strongly reduced. This sediment starvation in the delta

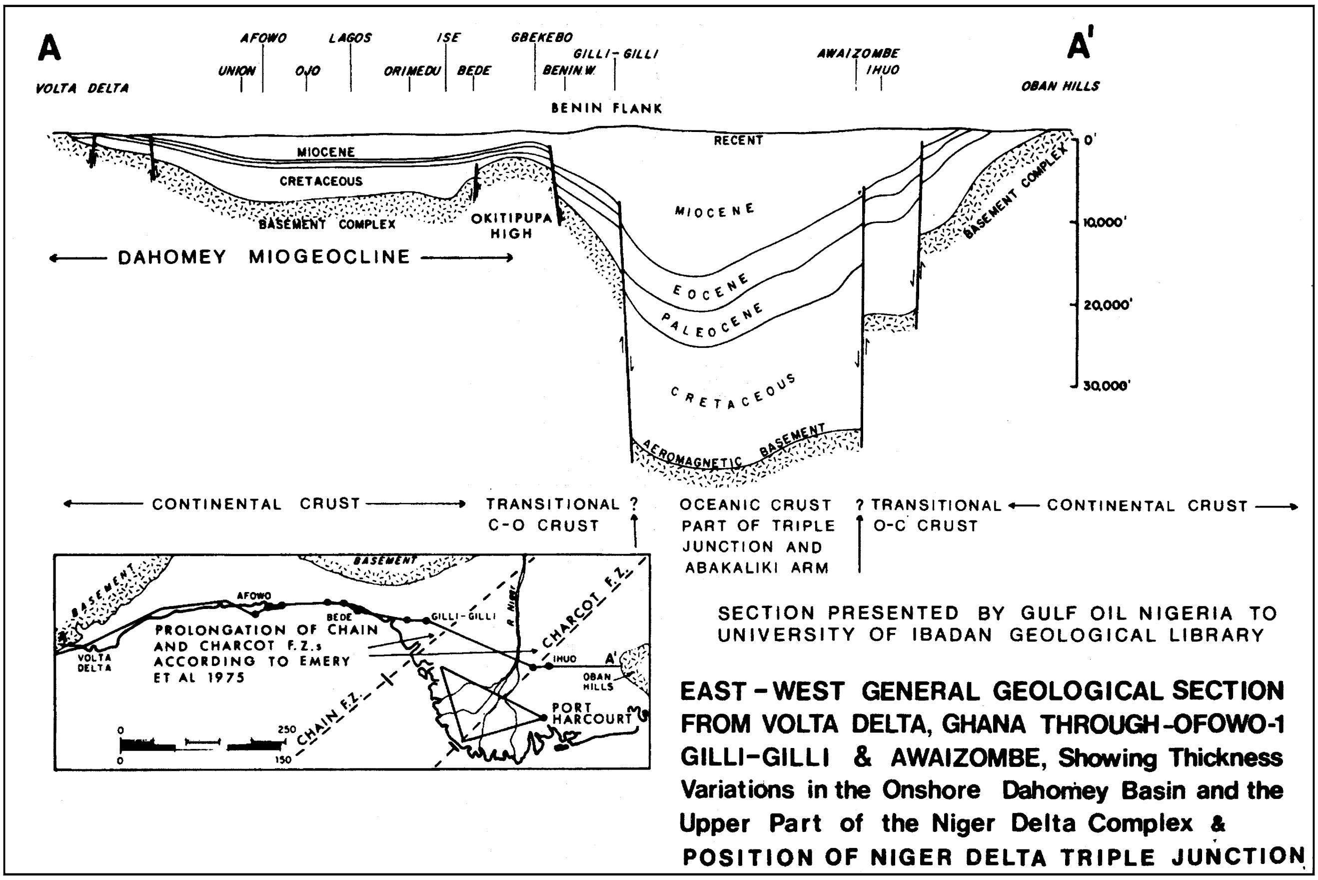

Figure S28 Cross-section of the Niger sedimentary basin (from Whiteman, 1982; with the kind permission of Kluwer Academic Publishers).

and the shore has resulted in important coastline retreat. Human activity in the delta, mining of gas, oil and water, has also contributed to surface lowering.

North Sea basin

The North Sea sedimentary basin developed during Late Cretaceous and Early Tertiary rifting phases marking the onset of seafloor spreading in the Arctic North Atlantic between the European and the North American–Greenland plate. At the same time the early phases of the Alpine orogeny took place.

Thermal cooling in the rift systems of the Early Tertiary caused important subsidence. Consequently, thick layers of Cenozoic sediments could be deposited. As demonstrated in Figure S29, the Cenozoic series reaches a maximum thickness of 3,500 m of which the Quaternary reaches a maximum of 1,000 m (Ziegler and Louwerens, 1977; Jelgersma, 1980). The Netherlands and NW Germany are situated on

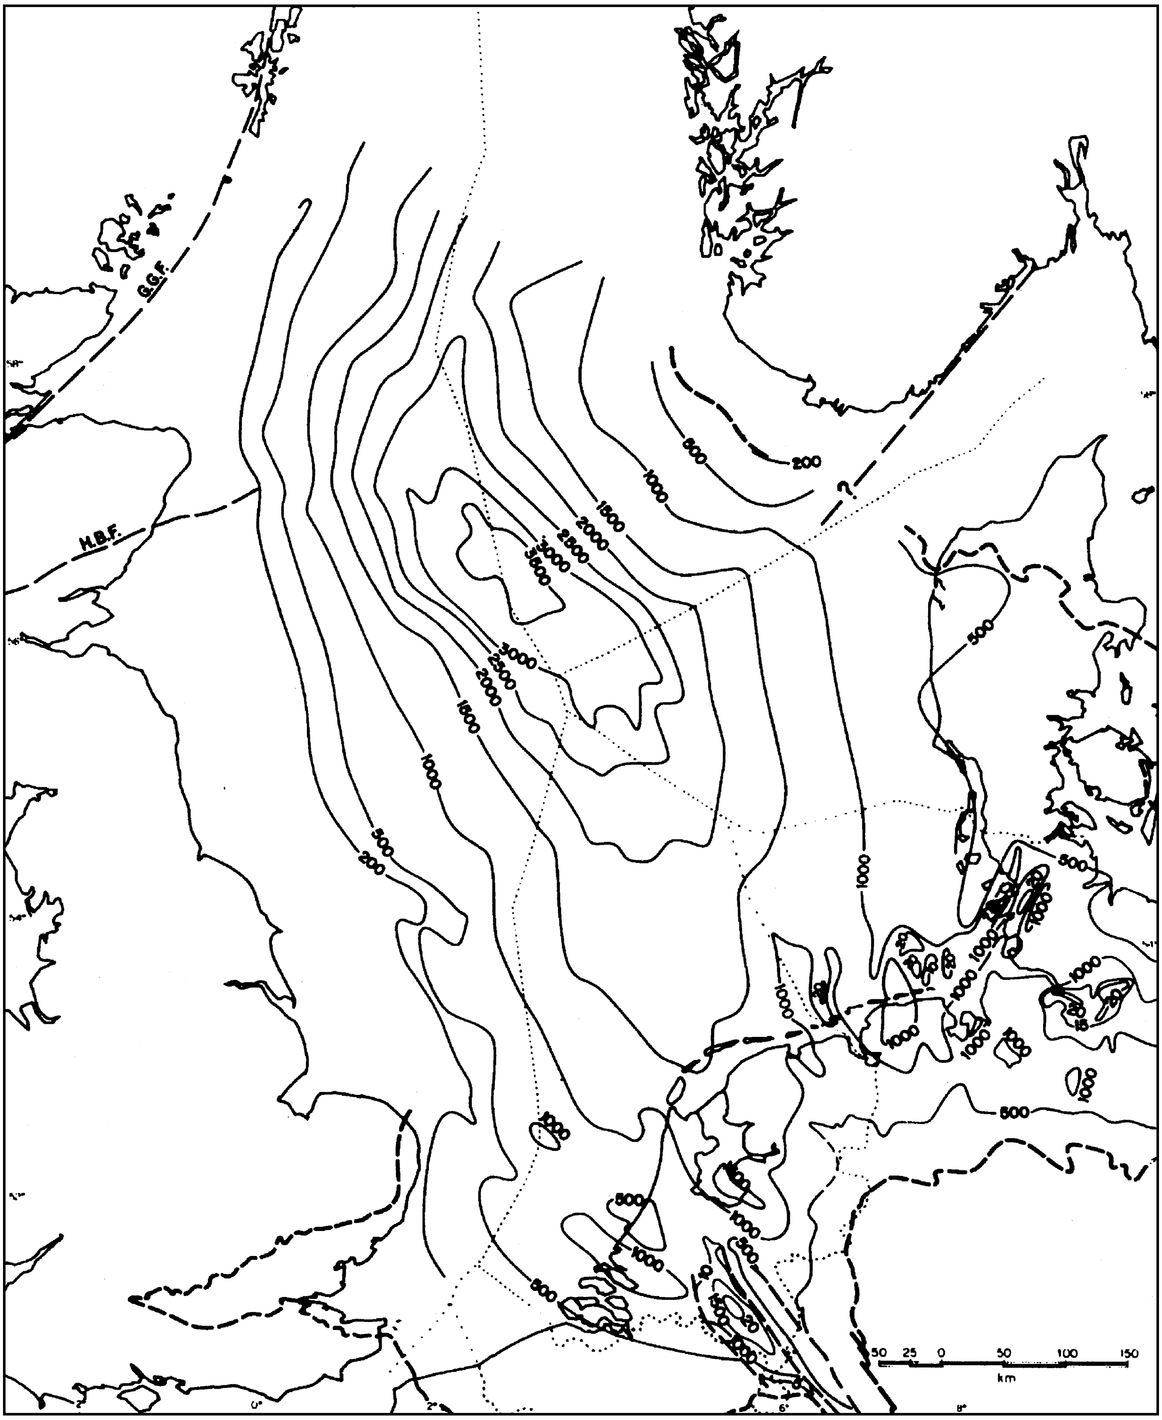

Figure S29 Depth contour of the base of the Tertiary (from Jelgersma, 1980, reproduced with permission of John Wiley & Sons Limited).

the edge of the subsiding North Sea basin. Tectonic subsidence occurs in these areas, contributing to a relative sea-level rise. The combined effect is measured by tide gauges, its amount being between 15 and 20 cm/century.

Mississippi delta

Sedimentation in the northern Gulf of Mexico has taken place since the end of the Cretaceous in a series of depocenters on the edge of the continental shelf. Sediment accumulation in the depocenters during the Neogene and the Quaternary reached high values as demonstrated in Figure S30 by the depth contour line of the base of the Pleistocene and a cross section of the depocenter (Woodbury *et al.*, 1973; Jelgersma, 1996).

The present Mississippi delta consists of a wedge of soft sediment deposited during the post-glacial rise in sea level. The river delta can be classified as river-dominated; the tidal range is nearly absent and serious wave attack occurs only during hurricanes.

Subsidence rates in the delta are locally very great; this is mainly due to human interference. Accordingly, much of the marshland surrounding the river delta itself has changed into lakes.

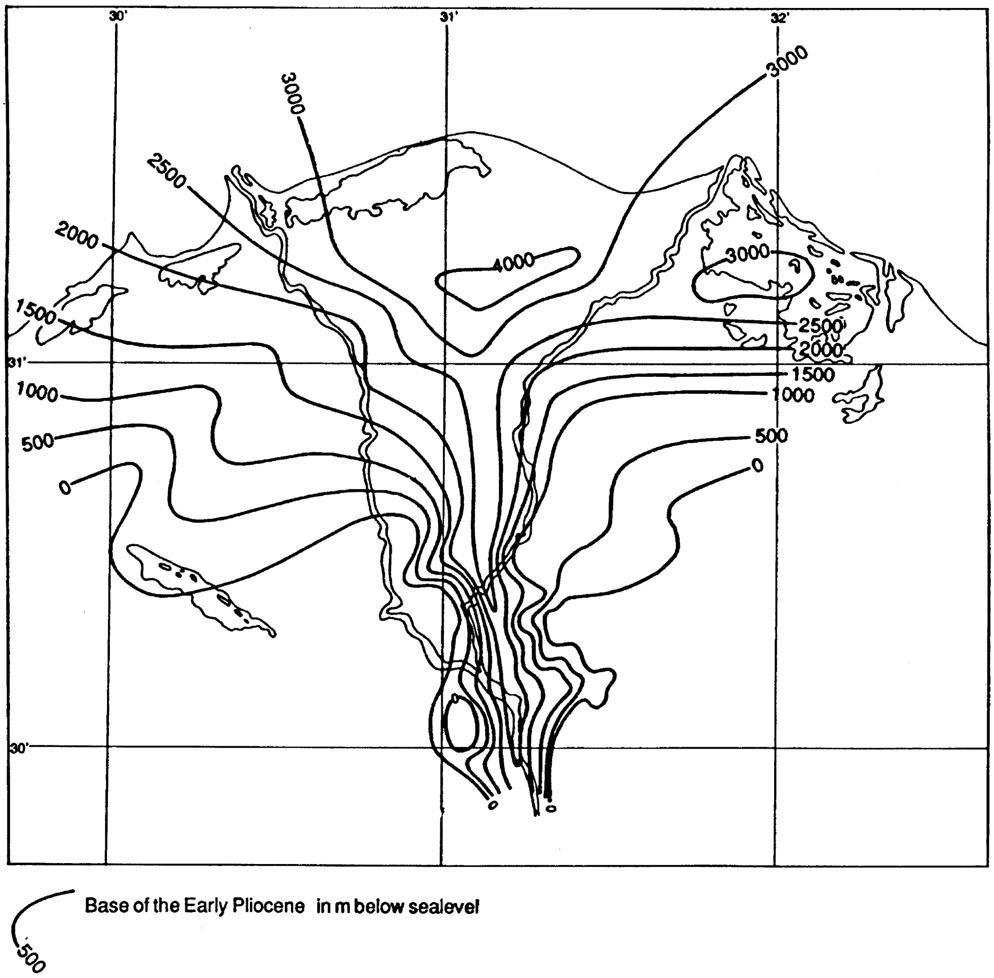

Figure S31 Depth contour of the base of the Early Pliocene in the Nile delta (from Jelgersma, 1996; with the kind permission of Kluwer Academic Publishers).

Nile delta

Crustal movements in the western Mediterranean during the Late Miocene obstructed the connection between the Atlantic Ocean and Mediterranean in the Straits of Gibraltar. The interrupted inflow from the Atlantic led to a gradual desiccation of the Mediterranean. Due to this lowering of the base level a deep canyon was cut down in the area of the recent Nile delta. This Late Miocene channel reaches in the northern embayment of the delta to a depth of 4,000 m. In the beginning of the Pliocene, a renewed opening between the Atlantic and the Mediterranean took place. The inflow of ocean water restored the level of the Mediterranean, consequently the Nile canyon was flooded and a thick layer of Pliocene, Pleistocene, and Recent deposits could be formed and is present in the subsurface of the delta.

In Figure S31, a contour map of the base of the Pliocene is presented; the Pliocene and the Quaternary deposits dip northwards reaching a thickness of 4,000 m (Said, 1981; Jelgersma, 1996). It is evident that in the northern embayment the subsidence reaches high values, probably caused by fault zones. The Nile delta has been a river-dominated delta; the input of river sediment compensating for the basin subsidence. During the last decades, due to the construction of the High Aswan dam, sediment input in the delta has been strongly reduced. This resulted in serious shore erosion and salt-water intrusion. The delta then changed from river- to wave-dominated.

SEISMIC DISPLACEMENT

When topographical changes are produced by an earthquake or a succession of earthquakes, a distinction is usually made between precursory displacements that occurred before the event (preseismic), the coseimic displacements during the event, and postseismic changes shortly later, often accompanying after-shocks.

Seismic displacements have a horizontal and a vertical component. The horizontal component is often clearly visible along fault lines activated by the earthquake, though more or less regular horizontal deformation may extend along the surface of nearby crustal blocks. In coastal areas, the vertical component is easily measurable and most important from a geodetic point of view, because it changes the relation to sea level.

As noted by Vita-Finzi (1986) earthquakes were being documented long before progressive uplift or depression attracted the attention of geologists. Several past events, important for their casualties and destructions, have been reported by ancient writers. Most past observers tend to say little or nothing about any ground movements accompanying an earthquake. Nevertheless, some exceptions exist that mention sudden seismic changes in the past, though seldom separating the effects of an earthquake from those of its after-shocks. According to several historical sources (Guidoboni *et al.*, 1994) in the summer of BC 426, when an earthquake struck the Gulf of Malia, in Greece, the central part of Atalante, near Euboea, was split open to the extent that ships could pass through, and some of the plains were flooded as far as 20 stades (ca. 4 km). It is also reported that in a winter night in BC 373, after a violent earthquake, the city of Helice, in the Gulf of Corinth, was drowned by the sea with all of its inhabitants. (Schwartz and Tziavos, 1979).

From ancient Japan, several examples of seismic displacements in coastal areas are reported by Imamura (1937). In AD 684, at the time of the Tosa earthquake in Shikoku Island, cultivated ground to the extent of 8.25 km^2 is said to have sunk beneath the sea. On September 4, 1596, at the time of a series of earthquakes, the island of Uryû-jima, slightly off the present city of Oita, with an area of 4 km N-S by 2.3 km E-W and a population of 5,000, sank beneath the waves, where it now lies at a depth of 30–40 fathoms.

Seismic changes in land level are often mere effects of the tilting of crustal blocks. In Shikoku Island, during the 1707 earthquake, subsidence at Kochi reached nearly 2 m, and upheaval 2.1–2.4 m near Yoshiwara, while two belts of subsidence occurred in the western half of the province, indicating that two contiguous crustal blocks had tilted, both of which dipping north.

Important seismic vertical displacements have been reported also from coastal regions in other parts of the world. In the delta area of the river Indus, at the time of the Kutch earthquake, on June 19, 1819, a fault scarp 3 m high appeared, extending for a distance of 80 km parallel to the coast. The region SE of this locality, about 5,200 km^2 in area began to sink, and within 3 h after the earthquake had changed into a sea.

In Chile, after the Valparaiso earthquake on November 19, 1822, the coast had risen 1 m, while at Quintero, some 24 km northwards, it was 1.2 m. According to Lyell (1875), the whole country from the foot of the Andes was raised on this occasion, the maximum rise being at a distance of about 3.2 km offshore.

Rigorous measurements of topographical changes produced by earthquakes started to be carried out toward the end of the 19th century. The geodetic investigation of ground deformation immediately after an earthquake, though often logistically problematic, offers the advantage that the area to be surveyed can be identified without much difficulty. The first post-event triangulation was done in Sumatra in 1892. The second survey was executed after the 1897 Indian earthquake and found a maximum vertical displacement of 3.6 m. Repeated leveling surveys carried out in seismic areas before and after a major earthquake, have helped to clarify the local pattern of crustal deformation. Tide gauge records, when located in areas affected by earthquakes, can also provide very precise, continuous information on all the preseismic–coseismic–postseismic sequence. Recently, complete control of land displacements can be furnished all over the world by satellite geodesy.

For the past, coastal coseismic displacements deduced from stepped elevated coastlines have been reported from several seismically active parts of the world. In some cases, detailed analysis of closely dated fossil coastlines (Figure S32) promises to reveal regional forms of the geoid

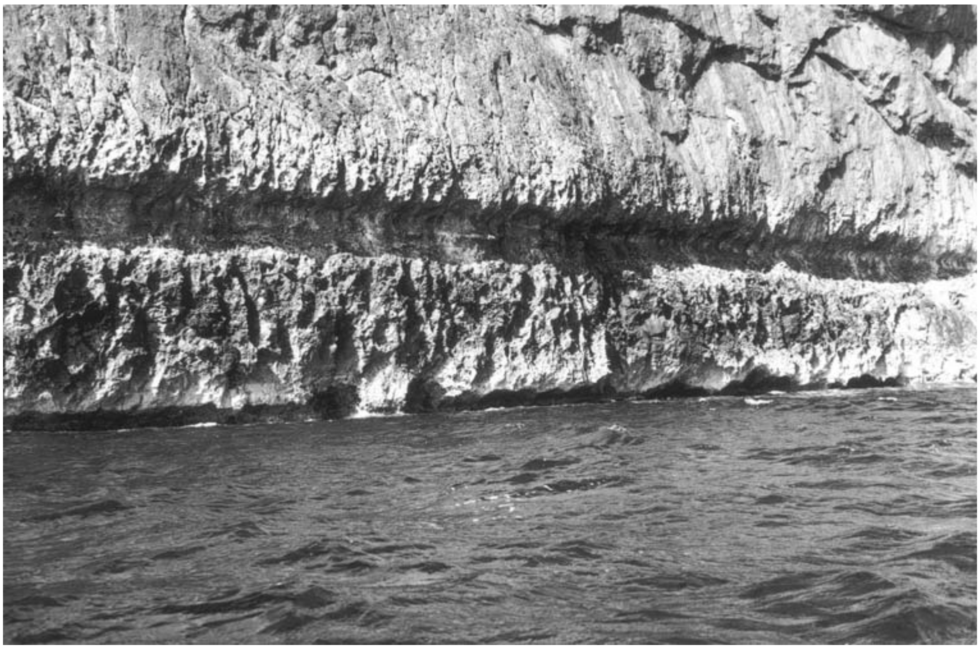

Figure S32 A crustal block approximately 200 km long, including all the western part of Crete and the nearby Antikythira Island (Greece), was uplifted and tilted coseismically by a great earthquake, probably on July 21, 365 AD. The upheaval reached 9 m in the southwestern part of Crete island (Pirazzoli *et al.*, 1996). In this photograph (No. 3980, Oct. 1977), taken near Piper Eliá, on the east side of Gramvousa Peninsula, Crete, continuous erosional marks left by the sea level before the uplift are well visible on the limestone cliff at about 5 m in elevation.

at successive time intervals and thus extend the brief period spanned by satellite data into the Holocene and possibly beyond.

Preseismic displacements are difficult to demonstrate for past events, as well as in historical times. This is because, in most cases, they are not reported. Preseismic movements are unexpected, may last for decades, and be sufficiently slow to escape notice, also in coastal areas. Such was the case, for example, for Cefalonia Island (Greece), before the 1953 earthquake that caused coseismic uplift of 30–70 cm along the south coast of the island. In the 1990s, however, a survey carried out along the uplifted coast (Pirazzoli *et al*., 1994) was able to demonstrate that, near Karavomilos, a slow 15 ± 5 cm preseismic submergence must have occurred within a few years before the earthquake, therefore preceding the coseismic uplift that reached about 50 cm at this site.

SEQUENCE STRATIGRAPHY

Sequence stratigraphy is an informal chronostratigraphic methodology that uses stratal surfaces to subdivide sedimentary successions. Unlike most traditional lithostratigraphic units (NACSN, 1983), which are defined as regionally mappable packages (members, formations, groups) of similar lithologies (rock types), sequence stratigraphic units trend across traditional lithostratigraphic boundaries (Figure S33). This methodology owes its origins to the pioneering work of Caster (1934), Sloss (1963), Campbell (1967), and Asquith (1970). All of these workers documented that stratal surfaces trend across traditional lithostratigraphic boundaries, and concluded that stratal surfaces represent time-significant boundaries that can be used to define coeval packages of strata contained within different lithostratigraphic units (Figure S33).

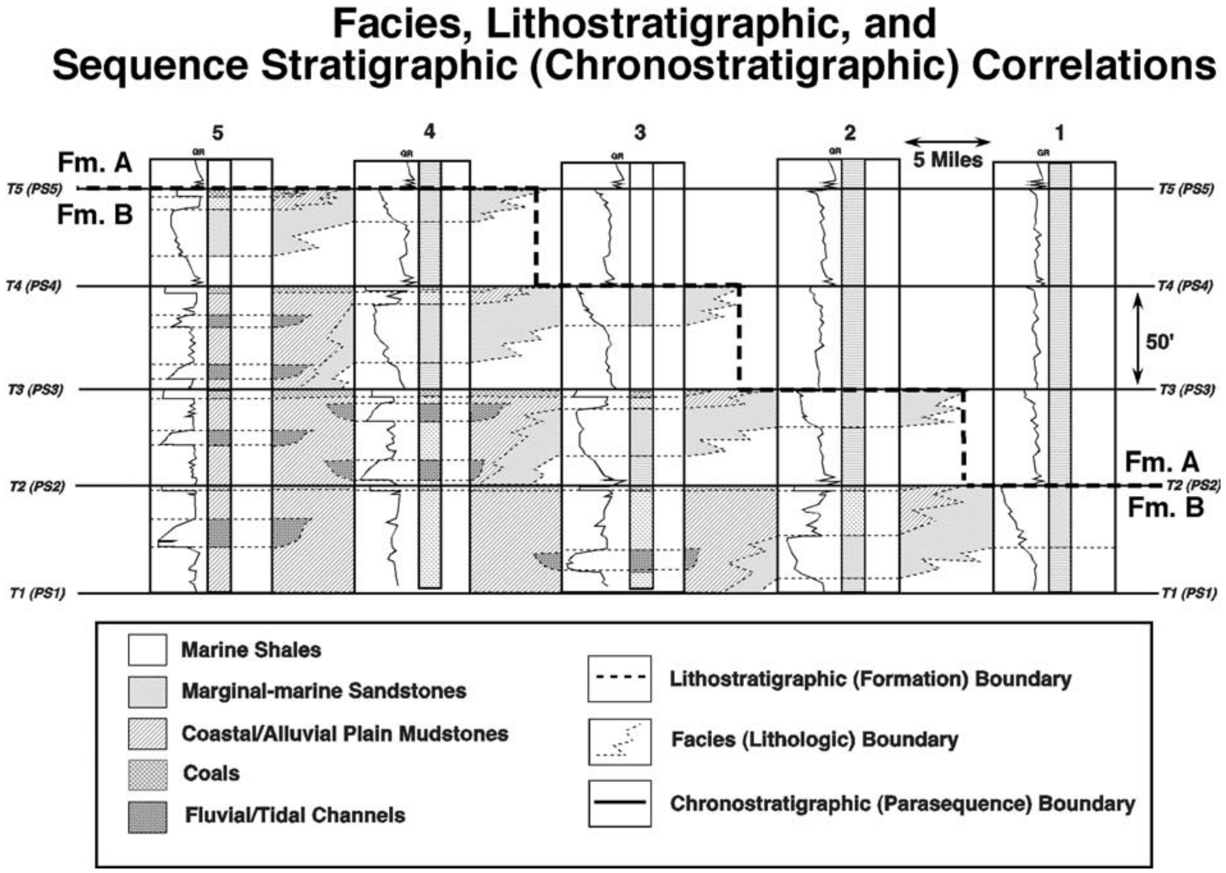

Figure S33 Idealized well-log cross section that illustrates the differences among facies, lithostratigraphic, and sequence stratigraphic (chronostratigraphic) correlations. Based on detailed correlation of well-log markers, five (5) regional flooding surfaces (parasequence boundaries) were identified. The parasequence boundaries represent chronostratigraphically significant surfaces that separate older strata below from younger strata above. Each parasequence contains a coeval facies succession that is dominated by marine shales downdip and coastal/alluvial plain deposits updip. The chronostratigraphic framework provided by the stratal (parasequence) correlations document that the traditional lithostratigraphic (formation) boundaries are time-transgressive. In the example provided, the lithostratigraphic boundary between Formation A (marine shale) and Formation B (marine shales, marginal marine sandstones, coastal plain mudstones, coals, and fluvial/tidal channels) occurs at time T2 (PS2) in Well 1 and time T5 (PS5) in Well 5.

The original concept of a sequence, a stratigraphic unit bounded by unconformities and their correlative conformities, was outlined by Sloss (Sloss *et al*., 1949; Sloss, 1963). Using the Phanerozoic sedimentary succession of the North American craton as an example, Sloss defined six interregional unconformities and six unconformity-bounded units which he termed sequences. While this methodology gained little interest among most geoscientists in the 1950s, 1960s, and early 1970s, it did find a niche following among petroleum geologists who were using seismic data to determine subsurface stratigraphy. With the publication of the landmark “Memoir 26” on seismic stratigraphy by the American Association of Petroleum Geologists (AAPG) in 1977 (Payton, 1977), however, sequence stratigraphic methodology and concepts became an active topic of research and debate among geoscientists. Contained within this volume is the now classic 11-part paper written by researchers at Exxon Production Research Company (Vail *et al*., 1977a). This entry outlined the fundamentals of seismic stratigraphy and offered the Depositional Sequence as the basic unit for stratigraphic analysis. Please note that while the unconformity-bounded sequence of Sloss (1963) covered thousands of feet and were typically a hundred million years in duration, the depositional sequences of Vail and others (1976) were commonly hundreds of feet thick and a million years in duration. As defined by Mitchum (1977), the *Depositional Sequence* is “… a stratigraphic unit composed of a relatively conformable succession of genetically related strata and bounded at its top and base by unconformities or their correlative conformities.” The basic premise behind this methodology was the observation that “… primary seismic reflections are generated by physical surfaces in the rocks, consisting mainly of stratal (bedding) surfaces and unconformities with velocity-density contrasts.” Furthermore, Vail and Mitchum (1977) concluded that since “… all the rocks above a stratal or unconformity surface are younger than those below it, the resulting seismic section is a record of the chronostratigraphic (time-stratigraphic) depositional and structural patterns and not a record of the time-transgress lithostratigraphy (rock stratigraphy).” Using datasets from the Cretaceous of North America and the Tertiary of South America, Vail *et al*. (1977d) illustrated that seismic stratigraphic surfaces trend oblique to traditional lithostratigraphic boundaries and define coeval facies successions among adjacent formations. Sequence stratigraphic analysis, as defined by Vail and Mitchum (1977), was based on the identification of stratigraphic units composed of a relatively conformable succession of genetically related strata termed depositional sequences. The upper and lower boundaries of depositional sequences are surfaces defined by unconformities and their correlative conformities. These surfaces are termed *Sequence Boundaries*. Vail and others (1976) believed that sequence boundaries (Figure S34) could be objectively identified on seismic as through-going surfaces defined by stratal (reflection) terminations both below and above. Stratal (reflection) terminations beneath sequence boundaries included truncation and toplap, while stratal (reflection) terminations above sequence boundaries included onlap and downlap (Mitchum, 1977). It should be noted, however, that in subsequent sequence stratigraphic publications (Van Wagoner *et al*., 1990) downlap was no longer utilized as criteria for sequence boundary identification. It is now believed that downlap more commonly occurs within sequences, and should be used to define compartments (systems tracts) within sequences.

Because the characteristics of sequence boundaries and sequences appeared similar in a wide variety of basins through geologic time, Vail *et al*. (1977b) concluded that cycles of relative sea-level change were the primary controlling factor in sequence development. In the seismic stratigraphic methodologies outlined in Vail *et al*. (1977b), relative sea-level rises were interpreted by (coastal) onlap, relative sea-level stillstands by (coastal) toplap, and a relative sea-level falls by a downward (basinward) shift in (coastal) onlap (Figure S34). Within this paradigm, the physiographic break “*shelf edge*” along the basal sequence boundary serves as a major reference point for a given sequence. This shelf edge (Figure S34) permits delineation of lowstands, the interval of time when sea level (coastal onlap) is interpreted below the shelf edge, and highstands, the interval of time when sea level (coastal onlap) is interpreted above the shelf edge (Vail *et al*., 1977b).

One final premise contained within the paper by Vail *et al*. (1977) is that global cycles of sea-level change are evident throughout the Phanerozoic, and that these cycles are globally synchronous. This contention was based on the belief of the Exxon researchers that the depositional sequences they defined on different continental margins were coeval and of similar magnitude (Vail *et al*., 1977c). They concluded that these interpreted global cycles were records of geotectonic, glacial, and other large-scale processes and reflected major events of the Phanerozoic history. Based on this paradigm, Vail *et al*. (1977c) offered preliminary cycle charts to document the timing of the global (eustatic) events that controlled sequence development. Haq *et al*. (1987, 1988), as well as deGraciansky *et al*. (1998), have subsequently published updated versions of “The Cycle Charts.”

With the publication of SEPM Special Publication Number 42 in 1988 (Wilgus *et al*.), seismic stratigraphy evolved into sequence stratigraphy. This volume also contained numerous articles by Exxon researchers who presented updated sequence models based on more modern seismic, as

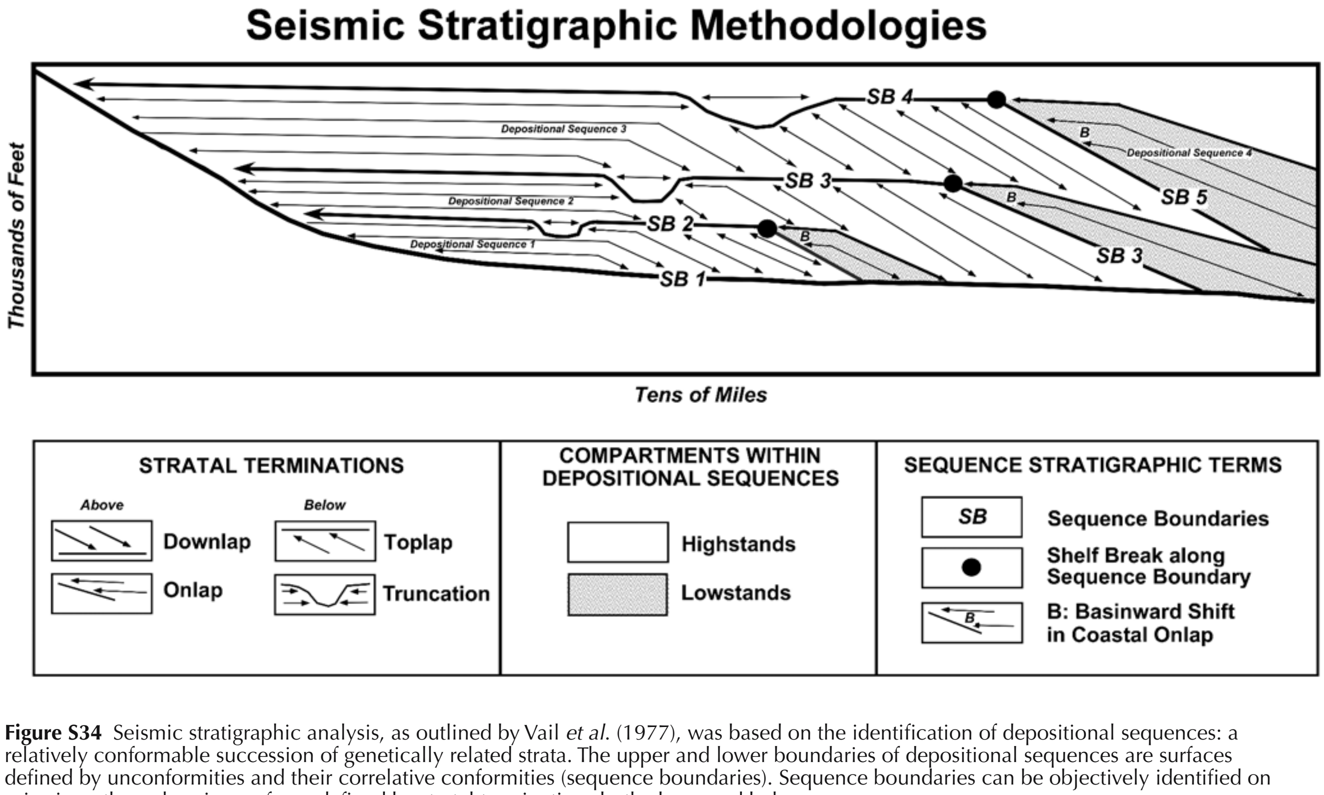

Figure S34 Seismic stratigraphic analysis, as outlined by Vail *et al*. (1977), was based on the identification of depositional sequences: a relatively conformable succession of genetically related strata. The upper and lower boundaries of depositional sequences are surfaces defined by unconformities and their correlative conformities (sequence boundaries). Sequence boundaries can be objectively identified on seismic as through-going surfaces defined by stratal terminations both above and below.

well as the integration of outcrop, core, and well-log data. A third publication by Exxon researchers (Van Wagoner *et al*., 1990) continued to refine sequence stratigraphic methodologies based on outcrop, core, and well-log data. In this volume, Van Wagoner *et al*. (1990) proposed a hierarchy of stratal surfaces (beds, bedsets, parasequence, parasequence sets, sequences) all of which had chronostratigraphic significance. While the depositional sequence continued to be the fundamental stratal unit in sequence stratigraphy, parasequences were identified as the building blocks of sequences. *Parasequences* were defined as relatively conformable succession of genetically related strata bounded by marine-flooding or correlative surfaces (Van Wagoner *et al*., 1990). Parasequence sets were defined as a succession of genetically related parasequences that form a distinctive stacking pattern (Van Wagoner *et al*., 1990). Based on outcrop and subsurface observations Van Wagoner *et al*. (1988, 1990) proposed three basic compartments or *systems tracts* (lowstand, transgressive, and highstand) within sequences (*Figure* S35). These systems tracts were defined by major stratal boundaries, parasequence set stacking, as well as temporal and spatial position within sequences. Surprisingly, they were not defined by interpreted sea-level variations as their names might suggest. The lowermost compartment the *lowstand systems tract* is bounded by the sequence boundary at its base and the transgressive surface at its top (*Figure S35). The transgressive surface* is defined as first significant marine-flooding surface (parasequence boundary) across the shelf within a depositional sequence. In higher-relief basins (Figure S34), where the basal sequence boundary displays a well-defined "shelf break" (slope of 3–6 degrees), the lowstand systems tract consists of a basin-floor lowstand fan, a basinally restricted lowstand wedge, and an incised valley system that extends updip across the shelf, landward of the lowstand wedge (Van Wagoner et *al., 1990). In lower-relief "ramp-type" basins, where the basal sequence boundary lacks a well-defined "shelf break" (slope,* 1 degree), lowstands lack basin-floor fans (Van Wagoner et al., 1990). The lowstand wedge consists of aggrading parasequences that onlap at or below the depositional shelf break of the underlying sequence boundary. The *transgressive systems tract* is the middle compartment within sequences. It is bounded below by the transgressive surface, and above by the maximum flooding surface. The *maximum flooding surface* is defined as the maximum marine incursion (transgression) within a sequence. Parasequences within the transgressive systems tract form a distinctive retrogradational pattern. The *highstand systems tract* is the uppermost compartment within a sequence. It is bounded below by the maximum flooding surface and above by the overlying sequence boundary. Parasequences within the highstand systems tract form an aggradational and then progradational parasequence set.

As outlined by Van Wagoner *et al*. (1990) sequence boundaries, sequences, and systems tracts can be interpreted in terms of cycles of relative sea-level change. Sequence boundaries are interpreted to be the result of relative sea-level falls (Van Wagoner *et al*., 1990). If slope failure, canyon development, and fluvial capture occur during this fall, mass transport complexes followed by submarine fans complexes can be locally deposited along the basin floor (Van Wagoner *et al*., 1990). As the rate of relative sea-level fall decreases, reaches a stillstand, and slowly rises, fluvial incision and submarine fan deposition ceases. Coarse-grained braided fluvial and/or estuarine deposits aggrade within the incised valleys, and a lowstand wedge is deposited below the depositional shelf break of the underlying sequence boundary (Van Wagoner *et al*., 1990). When the relative rate of sea-level rise increases toward its maximum, retrogradational parasequences of the transgressive systems tract are deposited (Van Wagoner *et al*., 1990). As the rate of relative sea-level rise begins to slow and reach a stillstand, aggradational followed by progradational parasequences of the highstand systems tract are deposited (Van Wagoner *et al*., 1990). As relative sea level falls once again, the next sequence boundary forms by fluvial incision, slope failure, and canyon development.

Since the publication of AAPG Memoir 26 in 1977, sequence stratigraphy has become a major research topic in sedimentary geology. Inclusion of industry, government, and academic researchers has produced healthy debate in a number of areas. From day one, a major issue of debate (Miall, 1986, 1992) was the contention by Vail *et al*. (1977c) that depositional sequences are the product of eustacy, and therefore form globally synchronous cycles that can be used as a basis for global chronostratigraphy (The

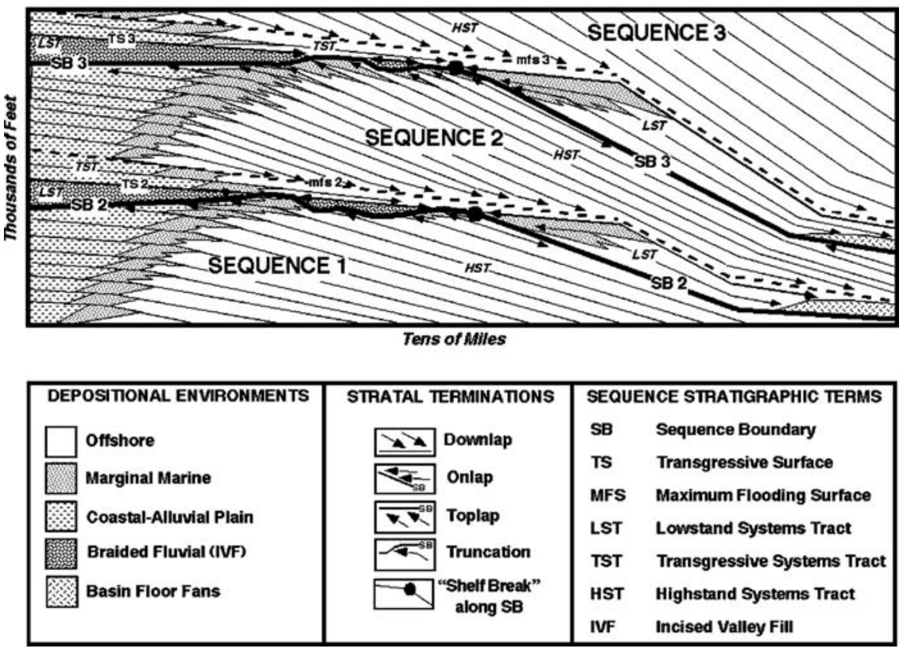

Figure S35 Idealized Model of a Depositional Sequence for a basin with distinct physiographic relief ("shelf break model"). In this updated sequence stratigraphic model, first proposed by Van Wagoner *et al.* (1988), three basic stratal compartments (systems tracts) were proposed: lowstand, transgressive, and highstand. The *lowstand systems tract* is the lowermost compartment within a sequence. It is bounded by a sequence boundary at its base and a transgressive surface at its top. The *transgressive surface* is defined as first significant marine-flooding surface (parasequence boundary) across the shelf within a depositional sequence. The lowstand systems tract typically consists of a basin-floor fan, a basinally restricted lowstand wedge (aggrading parasequence set) that onlaps the "shelf break" of the underlying sequence boundary, and an incised valley that extends updip across the "shelf-profile" of this sequence boundary. The *transgressive systems tract* is the middle compartment within a sequence. It is bounded below by the transgressive surface, and above by the maximum flooding surface. The *maximum flooding surface* is defined as the maximum marine incursion (transgression) within a sequence. Parasequences within the transgressive systems tract form a distinctive retrogradational parasequence set. The *highstand systems tract* is the uppermost compartment within a sequence. It is bounded below by the maximum flooding surface and above by the overlying sequence boundary. Parasequences within the highstand systems tract form an aggradational and then progradational parasequence set.

Cycle Charts). Discussions on the utility of defining and mapping sedimentary cycles (sequences) based on subaerial unconformities (*Depositional Sequences*: Van Wagoner *et al*., 1990), maximum flooding surfaces (*Genetic Sequences*: Galloway, 1989), or transgressive surfaces (*T–R Sequences*: Embry, 1993) has also occurred. Even among practitioners of "depositional sequences," differences in sequence stratigraphic methodologies has arisen. The classic Exxon papers in AAPG Memoir 26 and Methods in Exploration Number 7 (Mitchum *et al*., 1977; Van Wagoner *et al*., 1990) defined sequences and systems tracts purely by stratal geometries. Within this context, interpreted sea-level variations, facies, or increments of geologic time were not considered in sequence boundary or system tract definition. Posamentier *et al*. (1992), however, based sequence boundary placement and system tracts definition on interpreted sea-level variations. Plint and Nummedal (2000) defined sequence boundaries by stratal termination, but systems tracts by interpreted sea level variations. Mellere (1994) based system systems tracts on facies change, not stratal compartments. Erskine and Vail (1988) based sequence boundaries and system tracts on interpreted cycles of geologic time. Finally, while Van Wagoner *et al*. (1990) contended that transgressive erosion was not a significant process in the rock record, others such as Plint and Nummedal (2000), strongly argue that transgressive erosion can significantly erode and modify highstand, as well as lowstand, depositional patterns.

SETBACKS

Coastal management strategies reduce the risks associated with coastal hazards and protect coastal infrastructure, habitat, water quality, recreation values, and aesthetic properties. A *setback* is one type of regulatory method used by all levels of government to mitigate risks to coastal structures and to protect coastal resources. For example, following Hurricane Luis in 1995, three island territories in the eastern Caribbean (Antigua and Barbuda, Nevis, and St. Lucia) developed a shoreline (defined here as the high water line) management strategy involving the establishment of setbacks (Cambers, 1997).

What is a setback?

Taken literally, setbacks are a type of regulatory restriction that require coastal construction projects to "set back" a landward distance from a predetermined reference feature on the beach. This arrangement provides a buffer between a hazard area or natural area and coastal development. Setback lines often parallel (but are situated some distance inland from) a reference feature such as the high water line, vegetation line, dune crest, contour elevation, or cliff edge. Reference features are usually determined by the geomorphic and ecologic properties of a particular reach. The setback is the measured horizontal distance from the reference feature to the setback line. The method used to establish the horizontal distance is a key component in the process of establishing setbacks because coastal structures are permitted landward of the setback line, but not seaward without a variance. Therefore, setbacks can have substantial implications for state and local governments, managers, planners, developers, and citizens.

The overall purposes of a setback are to:

- provide a buffer between coastal development and coastal hazards, for example, flooding and erosion;
- protect or establish natural resources such as conservation areas;
- facilitate sustainable coastal development;
- ensure public access to the beach;
- maintain the aesthetic character of the coast.

Components and types of coastal setbacks

Coastal setbacks require one or more of the following components:

- a reference feature
- a feature deemed worthy of protection (for example, a natural resource)
- a method for establishing a setback line.

Reference features

Reference features provide a starting point from which to establish a setback distance. Reference features can be stationary (relatively permanent) or dynamic. Stationary reference features can include a surveyed elevation, dune toe or crest, vegetation line, road or other cultural feature (for example, lighthouse). Dynamic reference features typically include the shoreline (i.e., the intersection of the land and sea), a proxy for the shoreline (for example, high water line, HWL; mean high water line, MHWL; ordinary high water line, OHWL; normal water line, NHWL; etc.) or a cliff (also called bluff) edge. For example, Florida employs a setback from the seasonal high water line (SHWL) for coastal permitting. Wisconsin uses a statewide setback of 75 ft (22.9 m) from the ordinary high water mark (OHWM) and 75 ft (22.9 m) from the cliff edge to protect structures from cliff erosion.

Natural resources

Setbacks provide one method of managing coastal resources including their features, processes, and characteristics (Clark, 1974). Natural resources in the coastal zone can include coastal habitats and ecosystems (wetlands, estuaries, beaches, dunes, uplands), sand and gravel, small-town characteristics, visual openness and surf (Houlahan, 1989; Nelson and Howd, 1996; Klee, 1999). According to the US Fish and Wildlife Service (1995), more than 45% of all species listed as endangered or threatened reside within coastal habitats.

Setback line methods: fixed setbacks

"Fixed" setback lines are rigid in the sense that they do not depend on *a priori* measurements, but rather on a uniform, standard, or fixed distance landward of a reference feature. In this case, setback distances are determined prior to a permit application (Houlahan, 1989). For example, Delaware places setback lines 100 ft (30.5 m) landward from the seawardmost 7 ft (2.1 m) elevation above the national geodetic vertical datum (NGVD). In the Technical Belt of Poland, the Maritime Administration employs a setback of 200 m landward of the dune ridge or 100 m inland of the upper edge of a cliff. However, a case study conducted in Essex, England claimed that, along reaches of varied topography, a rigid setback line would have no topographical or planning relevance since the artificial boundary can bisect natural ecosystem and hydrologic boundaries (Bridge and Salman, 2000). Additionally, Klee (1999) considers fixed setbacks a "weak" approach because coastal construction can occur at existing setbacks regardless of current potential hazards.

Setback line methods: floating setbacks

"Floating" or variable-rate setbacks use a dynamic (nonrigid) natural phenomenon to determine setback lines and can change according to the topography of an area or by measurements of shoreline movement over time. Thus, floating setbacks reflect site- or reach-specific coastal processes and, in theory, allow for natural erosion to occur. Floating setback distances usually are established after a permit request (Houlahan, 1989). In most applications of variable-rate setbacks, setback lines typically are positioned in a landward direction of the reference feature by multiplying an "average annual erosion rate" (AAER in feet or meters per year) by a constant (time in years of setback protection). For example, the setbacks for single-family dwellings (defined as buildings with a floor area $<5{,}000$ ft^2 or 464.5 m^2) in North Carolina are determined by multiplying the AAER by 30 with a minimum 60 ft (18.3 m) setback. The constants and minimum setbacks can vary with building size, anticipated life-expectancy of a structure, or duration of a mortgage.

The setback distance, obtained by the variable-rate AAER method, is based on a prediction of a future shoreline position. This method for producing a setback requires accurate assessments of historical shoreline changes, usually in the form of a shoreline rate-of-change statistic. In some cases, erosion rate data are averaged or "smoothed" along the length of a coast and/or grouped into blocks of similar rate values to produce a representative rate for a segment of coast. When using a dynamic setback approach, shoreline change data must be updated periodically to reflect current and historical conditions. However, this approach may not explicitly account for extreme events such as storm surge.

Setback line methods: combined fixed and floating setbacks

Some US states require a combination of the two setback types to increase the setback a fixed distance landward of the distance given by the erosion rate. This strategy is used along the U.S.' Great Lakes (e.g., Michigan) to protect a cliff face and along some US Atlantic coastal states such as New Jersey and North Carolina to safeguard areas prone to severe erosion.

Methods used to establish "erosion rate-based" setbacks

Floating setback distances (in meters or feet) are obtained from extrapolating historical shoreline or cliff-line migration erosion rate or trend lines (in meters per year or feet per year) to a predetermined target date (in years). The goal of extrapolation is to provide the best estimate of a future shoreline or cliff-line position. In theory, the calculated setback distance reflects the actual distance the shoreline will migrate landward, year by year, over a number of years. The precision with which estimates of shoreline rates-of-change reflect actual changes and predict future changes depends on:

- the accuracy of the techniques used to identify and record historical shoreline positions (e.g., shoreline identification and rectification on historical maps, vertical aerial photographs, or Geographic Positioning Systems, GPS),
- the quality of the data base (e.g., map and photograph quality, number of maps and photos of shoreline positions available and used in the computation, the time period between measurements, the total time span of the record),
- the mathematical and statistical method used to calculate an historical shoreline rate-of-change—especially when faced with nonlinear, cyclic, or chaotic shoreline migration trends,
- the temporal variability of shoreline movement,
- the proximity of the observations to actual changes in the trend (sampling bias),
- the quantitative techniques used to predict a future shoreline position based on historical trends, and
- an analysis and understanding of the coastal processes and human-induced shoreline modifications that govern shoreline migration trends.

The data used to determine erosion rate-based setbacks consist of a number of shoreline positions obtained from historical maps, maps compiled from aerial photography, aerial photographs and GPS. Analyses of historical shoreline movement trends begin by overlaying a set of georeferenced maps and/or rectified aerial orthophotographs for a coastal area. Next, transects or monuments of known geographic coordinates are established perpendicular to a baseline and, preferentially, to the shoreline (i.e., estimate error is minimized as the baseline and shoreline become more parallel). At each transect or monument, a data set is produced of shoreline positions at specific dates from which trends or shoreline rates of change can be delineated.

Shoreline changes occur over a wide range of nested time scales. At one extreme, shorelines move in response to eustatic sea-level fluctuations and tectonism; at the other, changes result from the constant fluctuations of wind, wave, and tidal action. The shoreline position at any given time (and the ensuing direction and magnitude of shoreline movement) is a cumulative summary of all long- and short-term processes. However, aerial orthophotographs record instantaneous positions of the shoreline at a specific time, and maps often record shorelines surveyed from instantaneous to longer, but unknown time periods. Consequently, each recorded shoreline time/position data point possesses a degree of gross, systematic, or random error arising from attempts to locate precisely the shoreline datum (typically the HWL) from photographs and maps. This situation leads to erosion rates that contain various degrees of uncertainty. Historical shoreline rate-of-change statistics are, therefore, relatively long-term, linear summaries of several instantaneous, error-prone geographical shoreline positions. Dolan *et al*. (1991) discussed four methods used to calculate shoreline rates of change and showed how the potential sources of error can bias the final statistics.

Erosion-rate based setbacks are obtained by extrapolating the slope of a trend line (a rate-of-change statistic) which passes through a few (usually <10) historical shoreline position/time data points. In most cases, when setback distances are predicted from a line calculated by a linear regression, the y-intercept is omitted, the slope (rate-of-change) is retained, and the line is adjusted to pass through the most recent data point (not needed for predictions based on an end-point rate).

The accuracy of a shoreline prediction depends on the accuracy of both the data and the historical trend estimates based on those data (Fenster *et al*., 1993; Douglas and Crowell, 2000; Galgano and Douglas, 2000). The challenge of establishing accurate setback lines comes from (1) using a limited number of error-prone shoreline position data to delineate actual historical trends and (2) knowing when to rely on a 30 year or more projection of a shoreline positions based on an historical *linear* erosion rate estimate. A rate-of-change statistic computed from shoreline position/time data sets implicitly assumes that shoreline movement is constant and uniform (i.e., linear) through time—often not the case in reality. In fact, shoreline movement can be linear, nonlinear, cyclic, or (perhaps) chaotic (Eliot and Clarke, 1989; Fenster *et al*., 1993). The popularity of linear extrapolation for setback determination is due chiefly to its simplicity. As with any empirical technique, no knowledge of or theory regarding the sand transport system is required. Instead, the cumulative effect of all the underlying processes is assumed to be captured in the position history. Thus, an assumption implicit in the procedure for delineating erosion-rate setback lines is that the observed historical rate-of-change is the best estimate available for predicting the future. Regardless of the potential limitations of this assumption, the use of linear models to predict the future avoids problems (such as overfit, underfit, and/or accelerations) that arise when using nonlinear models to extrapolate. Thus, it is best to constrain projections of shoreline position to a line or series of lines.

The NRC (1990), Morton (1991), and many others have discussed the highly nonlinear nature of processes that transport sediment in the coastal zone. For shorelines that experience short-term fluctuations in shoreline migration or longer-term migration nonlinearity, linear estimation methods will vary in their ability to approximate the long-term historical trend. Fenster *et al*. (1993) developed and demonstrated a method to employ nonlinear models, when called for by statistical significance tests of historical shoreline trend data, as an intermediate step to find the best line, or range of lines, with which to estimate future shoreline positions. Moreover, they investigated techniques for extrapolating shoreline behavior and discuss what constitutes a significant change in shoreline trend (especially in the absence of structures or processes known to have altered the underlying system). The goal of this shoreline prediction technique was to allow assessment of the stability of a long-term trend relative to intermediate (the 50 years of aerial photography) and short-term (decennial) trends, thereby best relating past shorelines to those which can be expected in the future. In this way, *linear* predictions using a pair of lines representing the range of probable future shoreline positions (and the degree of prediction uncertainty) can be based on linear *or* curvilinear historical shoreline migration trends. This approach, used in concert with knowledge of the process-response system (if known), was designed to avoid problems associated with using nonlinear models for predictions and to provide a probabilistic basis for predicting future shoreline locations. Crowell *et al*. (1997) conducted a thorough review of this technique and found, using average annual sea-level data as a surrogate for a few instantaneous shoreline positions, that a simple linear regression surpasses other forecasting methods unless known physical changes have occurred to the system. Douglas and Crowell (2000) and Galgano and Douglas (2000) have examined errors associated with common shoreline forecasting methods.

Although process information for a coastal reach is critical to understanding long-term geomorphological changes, often these data are not available. In addition, the relative contribution of all the process variables that contribute to shoreline erosion or accretion may be difficult to determine. For these reasons, coastal management strategies have relied mostly on extrapolating shoreline migration data that use time as a surrogate for the processes that produce shoreline change. Other deterministic shoreline modeling routines lack universal reliability (e.g., Theiler *et al*., 2000). Research efforts should strive to produce reliable process-based models that can predict shoreline erosion from the synergistic processes that produce changes to the sediment budget.

Several attempts have been made to identify and isolate the processes responsible for producing shoreline changes (the signal) and deviations from the signal (noise). For example, Leatherman *et al*. (2000) asserted that global eustatic sea-level rise drives coastal erosion and that a relationship exists between long-term average rates of shoreline erosion and the rate of sea-level rise (i.e., the shoreline retreat is 150 times the rate of sea-level rise). However, arguments posed by Pilkey *et al*. (2000), Sallenger *et al*. (2000), and Galvin (2000) that question this relationship underscore the difficulty involved in isolating specific oceanographic processes with their coastal (i.e., shoreline) responses.

The fundamental difficulties involved in relating hydrodynamics to sediment transport are further illustrated by recent research dealing with the relationship between tropical and extratropical storms and the long-term shoreline migration history of a coastal reach. Douglas and Crowell (2000) and Honeycutt *et al*. (2001) contend that, despite the fact that large storms can cause enough beach erosion to require a decade or more for recovery, it is appropriate to eliminate storms from shoreline change data bases. On the other hand, based on analyses of a reach along the wave-dominated Outer Banks of North Carolina, Fenster *et al*. (2001) concluded that the exclusion of storm-influenced data points is neither warranted nor prudent because such values do not constitute outliers, and they do not increase substantially the range of uncertainty surrounding predicted future shoreline positions. In addition, the added value of reducing uncertainty with the inclusion of more data points outweighs the potential advantages of excluding storm-influenced or storm-dominated data points.

Spatial considerations

The spatial considerations involved in establishing erosion-rate based setbacks stem from the need to project the setback line some landward distance from a continuous reference line. Therefore, extrapolations must occur at some predetermined spacing (transects) along a shore-parallel baseline that contains an infinite number of points. This situation raises a question, namely, where along a shore-parallel baseline, that is, at what spacings, should extrapolations occur? Although Geographic Information Systems (GIS) and high-speed digitizing techniques allow investigators to assemble almost unlimited samples for assessments of along-the-coast patterns of variation, there is value in knowing the relationship between sample size (e.g., number of digitized points) and the accuracy of an average rate-of-change estimate for a particular reach or an unspecified location along-the-shore. Rate-of-change values will be more useful for erosion-rate based setback delineation and are less likely to be contested when obtained by a scientifically and statistically sound approach. Although many coastal management agencies use arbitrary transect spacings (e.g., 50 m, 100 m), Dolan *et al*. (1992) used geostatistics (i.e., the theory of regionalized variables) to provide nomograms by which optimal sample sizes can be determined. In this case, optimal sample size is defined as the amount of data required to support the inferences of a particular study. Too few data produce inconclusive results; oversampling is inefficient. This study showed, in part, that the confidence in estimation of rate-of-change values in the spatial domain (due to spatial continuity) far exceeds the confidence in rate values calculated at a sample location in the temporal domain because along-the-shore rate-of-change values exhibit a high degree of spatial autocorrelation (nearest neighbor effect). In fact, the 50 m spacing of transects along Hatteras Island, North Carolina provides an excellent estimate of rates between transects (accurate to ± 0.5 m/yr).

Administration and setback implementation

In addition to differences in the type of setback used by a particular agency, variations exist among nations and states with respect to how setbacks are administered and who administers them. Additionally, the technical standards and methods for establishing those standards vary widely. For example, some US states apply setbacks only to new construction, while others apply to both new and old development. Also, some states differentiate among classes of buildings (e.g., single-family dwelling, multi-family structures, and industrial/commercial buildings). For example, North Carolina uses data averaging of similar shoreline recession rates at neighboring transects to produce a single shoreline recession rate for a "block" of shoreline. On the other hand, Massachusetts calculates recession rates every 100 m along the shore.

Twenty-three of the twenty-nine US coastal states and territories (including American Samoa, Guam, Marianas Islands, Puerto Rico, and Virgin Islands) utilize regulatory setbacks as a coastal zone management tool (Bernd-Cohen and Gordon, 1998). According to the Heinz Center Report (2000), ten US states use fixed methods (43.5%), five use floating methods (21.8%), and four use a combination of the two (17.4%). All five US territories used fixed setback methods. Most of the US coastal states use state-controlled setbacks, although two states exclusively use local setbacks (California and Washington) and five states have no setbacks (Heinz Center, 2000). In most cases, states with setback programs use local government agencies to administer the program. These setback programs can be administered on either a mandatory or a voluntary basis.

In Europe, the use of setback policies is increasing in erosion-prone coastal nations. In a study of national policy and legislation in selected European Union and Baltic States, Bridge and Salman (2000) discuss the use of setback lines in the management of coastal zones for nine selected nations and list three types of setback methods in practice within Europe: (1) shore-parallel linear (fixed); (2) contour (a distance from a shore reference feature based on elevation); and (3) Exclusive Economic Zones (offshore protection). Of the nine listed nations, eight have established fixed setbacks: Denmark, Finland, Germany, Norway, Poland, Spain, Sweden, and Turkey. The buffer zone varies widely from 5 m to 3 km. England stands as the exception with no formal coastal setback policy in place. As in the United States, the types and implementation of setbacks within the European Union and Baltic nations vary. Among the cities and regions located along the Russian Baltic Sea coast, a lone local statutory regulation establishes a 1 km wide setback for the economically and militarily strategic Kaliningrad region. No other setback policy is in place within Russia's coastal zone.

Advantages and disadvantages

The advantages of using setbacks as a regulatory method include:

- prevent structural loss and damage from erosion
- protect coastal habitat and water quality
- provide open space for natural shoreline environment
- provide recreation and beach access
- allow natural erosion/accretion cycles to occur
- can contribute to sustainable management of coastal systems.

The disadvantages are:

- may not provide adequate protection, for example, fixed methods may not account for topography or variations in coastal erosion processes, buffer zone may not mitigate impacts
- may limit tax base (economically restrictive)
- erosion-rate based data have accuracy limitations
- may not address existing structures
- a strategy is needed to deal with structures located near "old" long-term predictions
- shore-parallel, linear setback lines do not include the marine zone
- enforcement may depend on cultural attitudes and administrative context.

SHARM COASTS

A sharm coast is a type of irregular but mostly broad embayment with a limited extension inland, which can be found along the coast of the Red Sea; best developed in the southern part of the Sinai peninsula (Sharm el Sheikh) or in the middle part of the Saudi Arabian coastline (Schmidt, 1923; Bird, 2000). The sharms do interrupt broader coral-reef belts, but may be decorated with small reef benches. Mostly the inner parts of the sharms show beaches (often with beachrock) at the end of dry valleys (wadis), but at some places sharms exist without a connection to valley-like forms inland. There are several interpretations for the formation of the sharm embayments, and most probably several of them together are responsible: the lack or interruption of coral reefs maybe explained by sediment discharge and suspension at the mouth of the wadis, or by too much freshwater impact (possibly in the form of groundwater seepage). Other explanations include cutting of a former reef body by fluvial erosion during sea-level lowstands in glacial times, or overdeepening of the seabed in front of valley mouths where coral reef growth could not keep up with the rising sea-level in postglacial times. Some of the sharms are simply ria-like forms, that is, drowned lower parts of former valleys; others may be formed by slumping or sliding of oversteepened fringing reef bodies or submarine slopes, but no evidence for this process has ever been checked out in the Red Sea.

SHELF PROCESSES

Introduction

The low slopes and gentle relief of most continental shelves immediately suggest that they were formed through some combination of marine erosion and sedimentation. Although this is largely true, the specific modes of origin are often complex. The processes of marine sedimentation and erosion are episodic and strongly related to the water depth. Seaward of the zone of breaking waves, these processes are generally related to storm activity. As a consequence, the timescale of change is long compared to the timescale at which significant changes in sea level are known to occur. In many areas, the timescale of tectonic change is also similar. This means that the continental shelves of the world have been alternately submerged and exposed throughout the numerous sea level excursions of the Pleistocene and earlier geologic epochs. The overall topographic characteristics and local relief features of most continental shelf areas result from a combination of subaerial and submarine processes.

The large-scale geologic setting and the long-term history determine the overall configuration of the shelf. The processes of the erosion and sedimentation can be effective in modifying features caused by tectonic warping or faulting. Depending upon the intensity of the wave-current climate, range of water depths, and degree of consolidation, the shelf processes can be effective in forming both broad scale and local relief.

The hydrodynamic regime

A discussion of shelf processes logically begins with a description of the behavior of waves and currents, with special attention to how they bring about marine sediment transport. The actual processes of marine sediment transport are complex, and a detailed discussion is beyond the scope of this entry. Briefly, we paramaterize the entrainment of bottom sediment by the fluid shear stress acting on a unit of bed area. This shear stress is proportional to the vertical gradient of fluid velocity acting immediately above the seabed. Thus, both the magnitude of the flow and its vertical structure contribute to its ability to entrain bottom sediment. Shelf currents arise from various combinations of tide, surface wind stress, and internal pressure gradients. Normally, the current bottom boundary layer is meters to tens of meters in thickness. Waves, on the other hand, have boundary layers that are generally less than 10 cm in thickness because the flow reverses during each wave cycle. The wave boundar layer is thin and it readily produces large shear stress acting on the seabed.

There are many factors that distinguish the marine environment from other environments with active sediment transport. Unlike rivers, the magnitude and direction of currents on the shelf are constantly changing. At the same time, the size and period of the waves are also varying. The orbital motion of the waves decreases exponentially with water depth and becomes insignificant at depths equal to half the deepwater wavelength. Inside of this depth, both waves and currents contribute to the shear stress acting on the bottom sediments. In many cases, especially during storms, the major stress results from the waves. A common condition is that the waves are primarily responsible for entraining the bottom sediment, and the currents determine the magnitude and direction of the sediment transport. There is no distinct depth limit for shelf sediment transport due to waves and currents. Instead, the frequency at which storm events are powerful enough to cause sediment entrainment simply diminishes with increasing water depth across the whole width of most shelves.

When waves and currents occur together there is an interaction because turbulence is generated by the intense shear in the wave boundary layer which interacts with the turbulence in the bottom boundary layer of the current. The effect is that the current experiences greater drag than would occur without the waves. Entrainment and transport of bottom sediment are also enhanced.

Marine sediment dynamics

Several factors related to the condition of the seabed influence how sediment is entrained. Local bottom roughness, which may result from the presence of sand ripples, worm burrows, or shell fragments, produce more drag on the current. Part of this enhanced shear is applied to the sediment surface and part results from drag that does not act directly to entrain particles. Thus, identical currents passing over adjacent seafloor segments with different bottom roughness characteristics will apply different magnitudes of bottom shear stress.

The bottom sediments may be granular or cohesive. Granular sediments are stabilized in their "at-rest" positions only by gravity. As a general rule, sediments with less than 10–15% clay particles exhibit granular behavior (Metha *et al*., 1989). Sediments with higher concentrations of clay particles, or significant amounts of organic material, tend to resist entrainment because of binding effects.

Empirical relationships have been developed to relate the entrainment of granular bottom sediment to the fluid shear stress acting on the bed. At present there is no method to predict the onset of entrainment of cohesive sediments without direct measurements, either in the field or in specially equipped laboratory flumes.

Once the waves, currents, or a combination of both entrains the bottom sediment, it is subject to transport and deposition. As in rivers, the sediment is transported as suspended load, bedload, and dissolved load. But because waves play an important role in marine sediment dynamics, and because current conditions change rapidly, the sediment transport processes are noticeably different in shelf environments. Pure bedload transport is restricted to medium and coarser sand. These particles settle rapidly and are rarely a significant fraction of the suspended load outside of the nearshore zone.

There is no physical limit to the water depth at which bedload transport occurs. There are some places where bedload sand transport happens in mid-shelf and outer-shelf environments. However, the necessary high fluid stress rarely occur in the ordinary conditions in shelf environments. Only in certain places are tidal or wind-driven currents fast enough to cause this form of sediment transport.

Suspended sediment transport is the dominant mode in most continental shelf environments. Under most conditions, active deposits of medium and coarser sand are restricted to the beach, surf zone, and shoreface environments (Dean, 2001). Mud, silt, and fine sand sediment, entrained from the seabed, are dispersed upward into the shelf water column by turbulent eddies in the boundary layer of the currents and waves. In a stable transport condition, the turbulence and the vertical profile of the concentration of suspended sediment particles act to cause an upward flux that balances the settling speed of the suspended sediment. If the flow intensifies, more sediment will be entrained and both the concentration and height of the suspended layer will increase. The reverse of these processes cause deposition.

The presence of suspended particles alters the structure of the bottom boundary layer. The vertical concentration gradient acts to suppress the turbulence which, in turn, reduces the stress applied to the seafloor. The presence of a vertical density gradient, brought about by the vertical gradient in the concentration of suspended particles, can severely limits the thickness of the suspended layer. Both numerical model results and scale model observations have shown that the boundary layer of large storm waves can become saturated with suspended sediment. A sharp density gradient develops at the top of the boundary layer and prevents the sediment from escaping upward into the mean flow.

In most shelf environments suspended sediments are repeatedly entrained, transported, and redeposited until they are finally buried and protected (Niedoroda *et al.*, 1989). Cohesive deposits generally undergo an aging process after their burial that strongly affects their susceptibility to reentrainment. New deposits have high water contents and are weak. Over periods of days to months these sediments dewater and are bioturbated. Both of these effects make these sediments more resistive to reentrainment.

The intensity of boundary layer turbulence is also significantly reduced where the seafloor is covered by a smooth mud layer. The absence of boundary roughness allows a laminar boundary layer to develop to a significant thickness. This tends to suppress the shear stress transmitted to the bottom sediment. The entrainment of the sediment is thus suppressed.

Shelf sediment transport processes

The combined effects of waves and currents dominate shelf sediment transport. In most places, currents alone are inadequate to entrain the bottom sediment. Thus, under calm conditions there is little to no sediment transport. Shelf sediment transport is mainly accomplished during storm events. The magnitude of the transport is a nonlinear function of the intensity of the bottom currents and size of the waves. The magnitude of sediment transport rises sharply as these two forcing parameters increase. A major storm can be responsible for more sediment transport than occurs in many smaller storms. Because patterns of waves and currents do not repeat themselves exactly in a succession, the net transport of sediment over long time intervals results from the sum of individual displacements during each individual storm event. This makes the dispersion of sediment particles in most shelf environments quite complex.

There are cases where sediment is entrained and transported primarily by shelf currents. The shear stresses that are imparted to the bottom sediments on the open shelf by hurricane-driven currents can be large enough to affect significantly entrained sediment (Murray, 1970). In some locations around the British Islands strong tidal currents routinely cause sediment transport (McCave, 1972). In other places, such as the shelf off southeast Florida, a strong offshore current provides sufficient stress to continuously transport sediment.

There continues to be some dispute about whether density-driven bottom currents, similar to turbidity currents, occur on continental shelves. It has been proposed by Hayes (1963), that as a storm-surge return-flow floods back over barrier islands, it becomes sufficiently sediment charged to persist as a density-driven flow as far as the mid-shelf region. The Texas shelf, where these storm deposits have been observed, has been re-examined by Snedden and Nummedal (1989). They found that the beds associated with Hurricane Carla are better explained as resulting from a more normal downwelling flow in the latter portion of the storm.

A form of gravity-driven sediment-laddened bottom flow has recently been observed. Using a combination of direct measurements from an instrumented tripod and acoustic images, it was possible to show that fine sediment was entrained within the wave boundary layer during major storms on the Eel River shelf. The sediment was suspended by the intense shear in the wave boundary layer at a concentration that inhibited vertical mixing across the top of the boundary layer. Gravity, acting down the bottom slope, propelled the sediment suspension across the shelf to near the shelf edge. This is a wave-entrained bottom flow rather than a classic turbidity current because the source of intense turbulence is the waves rather than the mean flow.

Mass gravity flows in the form of mudflows and related turbidity currents are known to develop in shelf environments off major river deltas (Coleman and Prior, 1982). These can be associated with the venting of natural gas, or as a result of liquefaction due to excitation by surface storm waves. In either case large pockets of mud become unstable and flow downslope (Bea *et al.*, 1983). Mudflows of this type are capable of triggering turbidity currents (Niedoroda *et al.*, 2003b).

Hyperpycnal flows are density currents caused by sediment-ladden flows from a river mouth entering still water bodies. These have been observed in reservoirs (Syvitski *et al.*, 1998). These authors show that hyperpycnal flows are rare in continental shelf situations because the density contrast between saltwater and river water causes the river plumes to be buoyant.

Coastal plumes are an important sediment transport and dispersal mechanism on shelves. Depending on the size of the river watershed, the flood discharges may or may not be associated with local storm conditions. In small watersheds the correlation of storm conditions and a river flood plume is stronger. Under these conditions the plume is often driven along the shore by the storm winds, and temporary deposits form beneath it. Subsequent storm events that are not associated with river floods then shift the temporary deposits from the inner-shelf to the outer-shelf. This process has been well documented on the Eel River shelf (Wheatcroft *et al.*, 1999).

Sediment-rich flood plumes from large river systems often arrive at the river mouth during ordinary weather conditions. Because of the effects of the earth's rotation these discharges tend to turn cum sole (to the right in the Northern Hemisphere) and become dynamically coupled to the coastline. These plumes of brackish water with high concentrations of suspended sediments commonly persist for hundreds of kilometers along the Louisiana-Texas coast, the coast of the central United States, the south coast of the northern and many other places.

Temporary mud patches have been observed in the mid-Atlantic Bight off New Jersey and Long Island. These form during the calmer summer months on the mid- and inner-shelf. It is thought that under prolonged calm conditions an initial mud deposit begins to collect in a sheltered deeper area within the ridge and swale bottom topography. The presence of even a thin layer of mud makes the bottom hydrodynamically smooth. This inhibits the production of turbulence in the bottom boundary layer and promotes additional settling of suspended particles. The initial mud patch can thus grow. These persist until the stormy winter season.

Thicker, more persistent and extensive deposits of soft mud have been observed on the inner- and mid-shelf off Louisiana and east Texas (Suhayda, 1977). The water content of the mud is high so that it develops wave motions when forced by storm waves in the overlying water column. The wave energy is dissipated in the moving mud to the point that shelf areas behind these mud deposits are sheltered from the storm waves. Local fishermen are known to utilize these refuges in storms.

At high-latitudes ice is an agent of shelf sediment transport. The Canadian Atlantic shelf, the shelves of some of the large islands in the High Canadian Arctic and the shelf around Antarctica (Anderson, 1989) are places where a significant amount of ice-rafted sediment is deposited. This sediment comes from the melting of icebergs that have calved from glaciers. Stranded ice produces one of the oddest modes of shelf sediment transport that is important only very locally. Ice keels, either from icebergs or from the undersides of sea ice ridges, rake through the shelf sediments and produce distinctive gouges (scours) that can be several meters deep, tens of meters wide, and kilometers long (Niedoroda, 1991; Weeks *et al.*, 1991).

Shelf sedimentary sources

Sediment that is transported on the shelf originates either from land sources or from the reworking of previous deposits. Shelves in tectonically active areas tend to derive most of their sediment from the land. Shelves in stable tectonic areas are generally sediment-starved because rising sea level has caused the river sediments to be trapped within large coastal plain estuaries (Swift *et al.*, 1991).

On most coasts the coastline provides a line source of sediments to the adjoining continental shelf. The sediment is moved alongshore in the surf zone, in coastal plumes and in the accelerated flows of the upper shoreface. Coastal engineers have adopted the concept of a depth-of-closure (Hallermeier, 1978) for use in planning beach nourishment programs. This concept is based on the observation that the changes of beach and nearshore profiles are constrained within an envelope. The upper and lower envelope limits converge towards each other at the seaward extent suggesting that all of the sand simply exchanges between the beach and offshore bars without net loss. Actually, there generally is a net loss, but it is small compared with the large profile changes brought about by the cycle of storm flattening and recovery during quiet periods. Along coastlines undergoing net erosion this small loss to the upper shoreface provides a line source of sediment to the shelf.

Many of the discrete coastal sediment sources (rivers, tidal inlets, estuaries) have been discussed above. There is often a perturbation in the shelf sedimentary regime adjacent to these sources in the form of shoals, tidal sand waves or shifting deposits of sediment. In most cases, shelf processes spread the sediment delivered from these sources. Because shelf flows forced by the tide and wind are dominantly shore-parallel within a few kilometers of the coastline, this dispersal of sediment is also dominantly in the coast-parallel direction.

Much of the sediment on broad, sandy continental shelves results from the reworking of preexisting deposits. Where coastal systems are retreating in the face of rising sea level the mid-shoreface exposes older strata (Swift *et al*., 1991). As the coastal system migrates landward these exposed strata become buried by lower shoreface deposits. This is the origin of a transgressive sand sheet that extends across the entire shelf. It is a common feature of broad sandy shelves and is formed by a combination of shoreface retreat and storm the reworking over the period since the last glacial maximum.

Shelf morphodynamics

Most continental shelves and their major features are composed of unconsolidated sediments. As these are exposed to considerable fluid power, in the form of waves and currents, it is predictable that the morphology of shelf features, and the shelves themselves, represent a time-averaged morphological adjustment of the climate of waves and currents. Niedoroda and Swift (1981) have shown that, although all unconsolidated shelves have a concave-upwards profile, the steepness of the inner shelf profile and the distribution of depths in the mid-shelf correlate with the general intensity of the wave-current climatology. The profile of shelves in stormy areas have a steeper inner-shelf shelf and overall greater depth.

The shoreface is defined according to the concept that it represents the time-averaged response of the shelf surface to the controlling hydrodynamics acting on a sloped surface (Niedoroda and Swift, 1981; Niedoroda *et al*., 1985a,b). It has been recognized that the shoreface profile translates landward in the face of sea-level rise with little change to its overall shape (Bruun, 1962; Cowell *et al*., 1995). Moody (1964) measured shoreface adjustments to severe storms off the Delaware coast and showed that the profile alternately steepened and flattened about a mean shape. Niedoroda and Swift (1981) argued that the shape of the shoreface was maintained by a time-averaged balance of sediment transport processes that involved the action of downwell and upwelling storm flows, the corresponding timing of maximum wave conditions during the storm events, the offshore bias caused by the bottom slope and diminished sediment suspension with depth and an onshore bias to sand transport during the period between storms. Measurement programs by Niedoroda *et al*. (1984), Wright *et al*. (1994), and have demonstrated the action of these components, but a complete balance of processes has yet to be successfully demonstrated.

The mode of origin and maintenance of some of the major shelf features has recently been studied. Sand waves are very common in the mid-shelf ridge and swale morphology in the North Sea, Canadian and American Atlantic shelf, and the northeast Gulf of Mexico, among other areas. Recent work by Nemeth *et al*. (2001) has examined these features with stability analyses. A system of equations covering both the shelf hydrodynamics and sediment dynamics has been developed. These are used to show that, under a range of current and wave conditions, a flat shelf surface is not stable. Differential sediment transport tends to produce a "bumpy" surface due to an interaction between the vertical velocity and turbulence profiles and the shape of shelf surface. Over time, only the bottom shape perturbations (bumps) within a narrow range of spacings (wavelengths) will grow. These become the sand waves. The characteristic timescale for producing these features in an energetic mid-shelf location is on the order of centuries to millennia. Once produced, the sand waves persist because they are the stable configuration of the shelf surface to the time-averaged wave-current climate of the area. Nemeth *et al*. (2001) have shown that, in areas where there is a net bias to the shelf flows the sand waves slowly migrate while maintaining their forms. Without this bias, sand waves can remain fixed in location and form.

Calvete *et al*. (2001) have used a similar mathematical method to explain the existence of shoreface connected sand waves. Their analyses show that these features are the stable response mode of the seafloor in the lower shoreface region to the wave–current climatology weighted according to the scale of the induce sediment transport events. The timescale for developing these features is in the range of centuries to millennia. They can be stable or they can migrate longshore (usually in the direction of the apex of the angle their axes make with the shoreline) and shoreward as the shoreface retreats.

The time-averaged morphodynamics of the shelf and shoreface profiles have been represented in numerical models (Niedoroda *et al*., 1995, 2001, 2003a; Stive and deVriend, 1995; Zhang *et al*., 1997, 1999; Carey *et al*., 1999). In these studies the physics of shelf sediment transport are represented in time- and space-averaged forms so that individual events, such as storms, are not resolved. Both depth-averaged cross-shelf (1D-V) and plan-view (2D-H) representations have been developed. These models are in part based on the concept proposed by Clarke *et al*. (1983). This states that provided the characteristic sediment particle transport excursion distance in individual events (typically storms) is small relative to the scale of the shelf, then the time-averaged sediment transport can be represented as a Fickian process similar to turbulent diffusion, but at very large time- and length-scales. Thus the effects of individual storm flows, tidal currents, currents due to shelf waves and internal waves, and other fluctuating currents are represented by time-averaged diffusion coefficients, and all results are limited to terms that are long compared with the timescale of characteristic shelf sediment transport events.

These models have been able to reproduce the dependence of the shelf profiles on the major parameters that include the storm climate, sediment supply, and rate of sea-level rise (or fall). The characteristic responses to changes of these parameters are shown to vary from hours in the surf zone to millennia in the mid- to outer-shelf zones. The controlling parameters are the same as the "Sloss parameters" identified by Swift *et al*. (1991) based on more empirical observations.

This work that resulted in this entry has been assisted by the ongoing research in the ONR EuroStrataform Project (Contract Number N00014-03-C-0134).

SHELL MIDDENS

Shell midden refers to anthropogenic deposits containing noticeable amounts of shell, that is, calcareous invertebrate tests. Such deposits are common in marine coastal areas from subarctic to tropical latitudes throughout the world. They also occur along rivers and lakes, where freshwater molluscs comprise the shell consitutents.

Shell midden is not an analytically rigorous term in the sense of human activity, but a descriptive label that identifies the most superficially recognizable constituent of the deposit. *Shell-bearing site* is a more accurate label, although cumbersome and not likely to be adopted (Claasen, 1991). *Midden* originally meant domestic refuse deposited around a house, but shell-bearing sites in the label further obscures the importance of other constituents of the deposit. These sites do not solely represent shell-gathering activities by people. Other food remains such as fish or plants may be very abundant and may, in fact, represent a more significant economic activity at that location, but such remains generally require screening or microscopic analysis of samples to identify.

One sense in which shell middens or shell-bearing sites are a meaningful category is in terms of the depositional and preservational environment represented. As deposits, shell middens share the attributes of having increased porosity, permeability, and alkalinity (Stein, 1992). The alkaline environment created by the leaching of calcium carbonate from the shell and the neutralizing of groundwater, which is generally weakly acidic, creates excellent preservation for organic materials such as shell, bone, and antler, Also, because shell middens are located near aquatic habitats, they frequently are affected by saturation by water (Stein, 1992).

History of research

Investigations of shell middens in Europe, North America, and other continents began in the mid to late 1800s by naturalists, but once they were recognized as anthropogenic, became largely the domain of archaeologists in the 20th century (Classen, 1991; Stein, 1992). In the early part of the 20th century, it was not uncommon for shell middens to be excavated simply to recover artifacts for determining culture historical sequences, essentially disregarding the shell constituents. Most research, however, has focused on the unique aspects of shell middens, their rich invertebrate content, their relationship to coastal resources, and the unique depositional and postdepositional processes that affect them. By far the greatest amount of work has been expended on reconstructions of subsistence and diet, and relating this to the development of marine adaptations among human groups. Closely related is methodological research concerning appropriate sampling and quantification strategies for characterizing midden contents and methods for determing seasonality of deposits. Interest in how shell midden deposits were formed, in terms of the human behavioral components, began with the earliest observations, but studying formation and diagenesis from a geoarchaeological point of view is a more recent development. Middens have always been viewed as informing on ancient environments and habitats, from the position of the coast to the nature of the neritic environment, but the integration with studies of coastal ecology, geomorphology, and neotechtonism has increased dramatically in recent years. Studies of middens have been applied in legal cases concerning the traditional subsistence practices and territories of native peoples.

Behavioral component of shell deposition

A century of research at shell-bearing sites, combined with ethnohistoric and ethnoarchaeological studies around the world (Wessen, 1982; Trigger, 1986; Waselkov, 1987; Claasen, 1991) has resulted in the recognition of a great deal of variability in the cultural activity that created shell-bearing sites. Layers with dense shell may be deposited in association with major village settlements, annually re-used seasonal encampments, temporary wayfaring encampments, or specialized nonhabitation resource procurement sites. Shell middens commonly have more than 20 different taxa of marine invertebrates, each of which is deposited as the result of a distinct chain of activities. Multiple harvesting methods for multiple taxa might be employed at a specific location, and several different marine habitats might be exploited from a single base camp on foot or by watercraft. Shellfish might have been collected regularly, only seasonally, or incidentally to the procurement of other resources, and again, this is different for each taxa represented. They may have been consumed immediately or preserved for storage or trade, or used as bait rather than as food (Claasen, 1991). Processing ranged from eating shellfish raw to a variety of methods of roasting, steaming, boiling, drying, and smoking. These activities leave a wide variety of thermal features from pits to surface pavements of stone used as heating elements.

Shell refuse was disposed of in various ways. It was sometimes burned, and might be discarded adjacent to the habitation area, into the intertidal zone, or over a riverbank. In a short-term occupation, living areas and refuse discard areas might be discreet, but when a location was re-used over hundreds or thousands of years, these areas might shift, so that houses and other structures were built into former refuse areas or refuse disposed of in former house areas. In a shore setting the midden accumulation itself might make a significant contribution to accretion and become the most desirable place for habitation as it built up above the water level. Midden areas were sometimes later used as cemeteries, which adds to the impetus for protecting these resources against erosion and development.

Industrial, in contrast to domestic, uses of shell also create or contributed to shell accumulations, Marine shells have been widely used for making ornaments, such as beads and pendants, or as an inlay materials. They have also been used as musical instruments, for example, Aztec conch shell horns, and as a trading standards (e.g., wampum). Use of shell to manufacture tools is less common, but includes the manufactures of mussel shell knives and whaling harpoon heads in northwest North America, fishhooks in the Polynesian areas, and heavy pounders and adzes made from huge *Tridacna* shells in the Pacific. Tools and ornaments of marine shell were made not just for local consumption, but were traded far inland on all continents. Ground shell was used as ternper in some preshistoric pottery wares. Shell also was used as a raw materials in construction (Blukis Onat, 1985). Crushed, it makes a permeable substrate, and in Mesoamerica was ground to make lime for plaster and cement. In the Pacific Islands, it was common for people to extend their land by building bulkheads, and then fill behind them with a mixture of refuse and materials dredged up from the reef flats (thus aiding in keeping canoe channels clear as well) which included coral and shells. Shell industries that involved mining shell for construction, or processing shells for non-subsistence trade items, likely created distinctive types of shell middens.

Anthropogenic versus natural shell accumulations

Recognition of the anthropogenic origin of some shell beds began with observations by naturalists in the 19th century. Criteria for distinguishing cultural shell accumulations from other fossils shell beds has continued to be an area of interest as archaeologists have continued to encounter regionally specific nonanthropogenic shell deposits and develop additional criteria to aid in field recognition. Locally dense accumulations of shell can result from activities of animals such as birds or otters that repeatedly break and leave shells in localized areas, or through beach processes that sort sediments by size, shaped, and density. Natural death assemblages in subtidal marine deposits are less similar, but can be confusing when these are elevated relative to contemporary sea levels. A further problem is the recognition of cases where cultural middens are redeposited by shore processes or by later cultures (Ceci, 1984).

A typical shell midden is likely to have associated artifacts such as tools, ornaments, and manufacturing waste, although these are often quite sparse. Thermally altered rocks, a ubiquitous byproduct of many food processing activities, are often abundant. Other evidence of thermal processes can include ash lenses, charcoal, lenses of oxidized sediment, and calcined shell and bone. The fine matrix in a midden is typically very dark, from charcoal and decomposed organic materials, although there may also be lenses of wood ash, or oxidized soil. The microstratification present in most middens reflects different dumping events as well as constructed features such as surface hearths, roasting or steaming pits, pavements of rock used as heating elements under drying racks, or postholes from large structures such as houses or small structures such as drying racks.

The faunal assemblages in most prehistoric shell middens are diverse, and at the same time, highly selected. The diverse array of marine invertebrates may well represent multiple habitats. Yet not all the locally available invertebrates were collected, and generally a limited size range of individuals. Selectivity is also indicated in the varying compositions of the strata and lenses of the deposit, which are dominated by different associations of taxa representing specific harvesting events. Numerous species of birds, fishes, and mammals can also be present. Flotation to recover carbonized plant remains has rarely been applied, but can reveal a diverse array of wood charcoal and edible plant tissues.

Shells in middens may be whole or fragmented, depending on how they were collected and processed, and depending also on postdepositional alterations such as trampling, or deliberate use for engineering purposes. Fragmentation often follows specific patterns that indicated particular processing methods, such as splitting chiton plates to remove them. Also, the fragmented edges are sharp and angular, not rounded. Attachments of other animals are not found on the interiors of shells, indicating the organisms were alive shortly before deposition. Pieces of weathered shell may occur, but as minor constituents.

Cultural middens can be found in a wide range of geomophological conditions because their deposition is not causally related to shore processes in the way that beach deposits are. Humans may transport shells to a location elevated above the shore, or toss refuse shells into the subtidal zone. Size varies, from small lenses that resulted from a single episode of harvesting and processing, to sites hundreds of meters in length, and thicknesses of over 10 m.

Of the traits described above, associated artifacts and constructed features are the most consclusive for recognizing *in situ* cultural midden deposits, but also the least likely to be observable in a field survery situation without extensive exposure. When observations are limited to shell scattered over a surface or a limited vertical exposure in a cut bank, the criteria of matrix color presence of thermally altered rock and charcoal, and diversity of faunal remains are often more useful. The fragmentation, weathering, rounding, and other alternation of the shells is particularly useful in distinguishing different transportation mechanisms, and the length of time elapsed between death of the organism and deposition. Natural death assemblages in marine deposits exhibit the least degree of movement, often including articulated shells with little fragmentation or mechanical damage. They also typically represent a single habitat, and include abundant juveniles. Beach deposits may incorporate some very fresh shells, but generally contain a significant amount of shells that died some time ago and are essentially part of the sediment load. These will be whole or fragmentary shells that are surface abraded and rounded on the exterior and exposed interior anatomical surfaces, as well as on fractured edges. Older shell may also have been used as substrate for other animals, indicated by attachment of animals such as barnacles, sponges, or bryozoa, on both interior and exterior surfaces. Animals with indications of death by predators, such as drill holes, are more common than in a cultural deposit. The diversity of taxa in a shell midden will be underestimated in field observations (compared with screened samples), but this criteria is usually sufficient to distinguish middens from accumulations of shells created by animals, which tend to focus on a more limited range of species.

Recent shell middens, that is, those formed in the historic period, are potentially quite different from prehistoric ones. Colonization of many areas by people of European descent and changes in traditional diets have led to very different uses of shellfish. Disposal practices are different, too, including incinerating and burying materials in back yards, and use of municipal garbage dumps. The practice of aquaculture, mass production for distant markets, and the use of mechanical equipment results in a different signature characterized by high selectivity, perhaps even a single species. Historic-era middens are most definitively identified by the presence of introduced shellfish species or associated artifacts of recent vintage. In some areas, prehistoric shell middens were mined for shell for use in road construction, for making lime, or as soil amendment, creating extensive secondary deposits. Microstratification and the pressure of constructed features are the best criteria for showing that the deposit is *in situ* and has been redeposited.

Research issues

Shell middens have played a majore role in terms of attempting to understand the evolution of maritime adaptations around the globe, yet the degree to which humans exploited or relied on marine intertidal resources at different points in human development is less well known than for terrestrial resources because changing sea levels have biased the archaeological record, drowning much of the Pleistocence and early Holocene record (Bailey and Parkington, 1988). The extensive record at the Klasies River Mouth site in South Africa shows use of marine resources, including molluscs, beginning 60,000 years ago (Thackeray, 1988), and a number of shell-bearing sites older than 20,000 years have been documented in Europe, Asia, and Africa (Claasen, 1991). Yet most recorded shell middens are Holocene in age. This is interpreted as evidence of increasing resource intensification in the last 10,000 years, correlated with increased population growth and decreasing mobility and territory size during which human groups turned from high-ranked resources such as large herbivores and incorporated more resources that are low-ranked in terms of energy return such as molluscs and other invertebrates into their subsistence (Bailey, 1978, 1983).

Reconstruction of prehistoric subsistence through the quantitative analysis of midden contents has been a major theme since the mid-20th century. Much of this research suffers from methodological problems such as inadequate sampling and assuming all shellfish represent food, and estimates of the human population derived from shellfish quantities are particularly flawed (Claasen, 1991). Related efforts have focused on determining the seasonality of harvesting shellfish, and by extension, the season of occupation. A number of studies have estimated season of death for species with annual growth rings by determining the proportion of the annual growth that had been achieved, using thin sections or surface measurements of ring width. The validity of the estimates of season of death suffers from reliance on modern samples, and the extension of these seasonality estimates to estimating the seasonality of habitation is weakened by inadequate attention to sampling and assuming that shellfish were harvested for immediate consumption as food, ignoring the possibility of storage and of nonfood uses (Claasen, 1991). A focus on the food value of the animal remains in middens continues (Erlandon, 1988), but archaelogists are more cautious about generalizing from small samples and make more use of comparative regional information.

Sampling problems are considerable, and not easily resolved. A relatively small excavation may remove, from primary context, hundreds of thousand of pieces of shell, all essentially artifacts. The information context of the shell itself becomes redundant long before the information content of other aspects of the site, such as features, bird bones, tools, is adequately sampled. Because of the high cost of collecting and analyzing shell and other small midden constituents (Koloseike, 1970), archaeologist commonly retain limited samples of the excavated materials. Results are frequently noncomparable between projects because of variation in sampling intensities and size fractions. Strategies for selecting the samples spatially are frequently non-probabilistic and not based on the growing understanding of the internal spatial structure of shell middens. For example, the use of a few column samples to characterize the midden, and especially to discuss, changes over time, is questionable given research by Campbell (1981) which shows that the shell composition of middens may vary as much horizonatally as vertically. In the analysis process, archaeologists variously choose weight, number of identified specimens, and minimum number of individuals to quantify the relative abundance of taxa, adding to the noncomparability of samples. Each measure provides different estimates of abundance, even changing rank order, because of differential fragmentation and recognizability of parts of different taxa.

Geoarchaeological approaches to shell midden formation

The use of geoarchaeological methods to understand the physical processes involved in the deposition and diagenesis of shell deposits is a much more recent endeavor. Examination of physical traits of midden sediments, such as sediment texture, clast orientation, soil chemistry, and surface weathering on particles is increasingly being used to interpret the physical process of transportation, bioturbation, and leaching (Stein, 1992). Diagenetic changes, especially those related to saturation can create apparent stratification that has been misinterpreted by archaeologists interpreting culture history.

Environmental reconstruction

The role of shell middens in reconstruction of coastal paleoenvironments ranges from simply using them as indicators of paleo-coastlines to inferring nearshore habitals from the molluscan species present, to using them as a means of dating geological deposits that reflect coastal accretion or neotectonic events (Grabert and Larsen, 1973). The need for caution and independent evidence to sort out changes due to habitat versus those due to cultural effect is widely recognized. Molluscan assemblages in coastal sites are indicators of coastal ecology and habitat as determined by substrate, exposure, salinity, and water temperature (Rollins *et al*., 1990) but they also reflect human selection. The most effective work is interdisciplinary and uses multiple lines of independent evidence (e.g., Sanger and Kellogg, 1989; Shackelton, 1988).

Shell middens are playing a growing role in coastal geomorphological and neotectonic research because they are a specific type of deposit that can be assumed to represent a coastal position, although not causally related to a specific short position as a beach deposit might be. Shell middens contain abundant datable material, including historically diagnostic artifacts (McIntire, 1971), radiocarbon datable organic material, and shells datable by isotope analysis (Thackeray, 1988) and have been used to provide bracketing dates for subsidence events and tsunami deposits.

Summary

Despite the methodological caveats that plague research on shell middens, they have been shown to reveal a wealth of information on prehistoric adaptations and on coastal paleoenvironments. Interdisciplianary research efforts are increasing and new analytic techniques are being developed. Unfortunately the rate of destruction of these unique coastal resources is likewise increasing due to development. Although shell middens, like other archaeological sites, are protected by cultural resource protection and management laws in most countries, enforcement is inconsistent or nonexistent. With the increased rate of development added to the natural erosion processes that have always affected coastal sites, we are in danger of losing much of this nonrenewable resource. It is not only a scientific data base for interpreting prehistory and paleonenvironments, but also a historic record and direct physical connection to traditional places and practices for native peoples in many coastal areas.

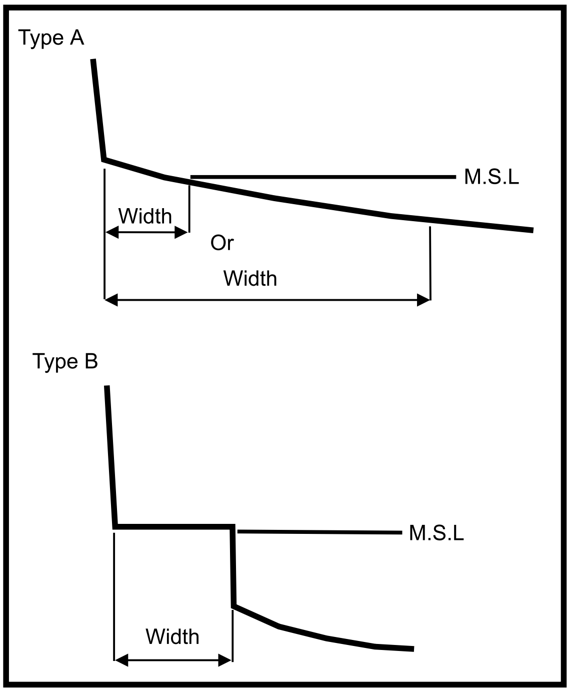

Figure S36 Two morphologies of shore platforms, Type A and Type B (adapted from Sunamura, 1992).

SHORE PLATFORMS

Shore platforms are horizontal or gently sloping surfaces backed by a cliff, eroded in bedrock at the shore. The erosional origin of these surfaces is evident because they cut across and expose geological structures. Shore platforms have long been classified using a tripartite scheme with respect to elevation in relation to the tide. Thus high-tide, intertidal, and sub-tidal platforms have been identified. Another classification uses the two most common profile forms, either the sloping platform (commonly 1–5°) or the horizontal platform. In recent times these have been referred to as Type A and Type B platforms, respectively (Figure S36). Shore platforms are common along much of the world's coastline occurring in all but the very highest coastal latitudes, as well as lakes. However, the total percentage of coastline composed of shore platforms is unknown. Associated with shore platforms are a variety of coastal features such as sea caves, ramps, notches, potholes, ramparts, and low-tide cliffs.

Many different terms synonymous with shore platform have been used, often having quite different genetic and morphological meanings. Such terms include: rock bench, high-water rock platform, Old Hat Type platform, abrasion platform, shore bench, storm-wave platform, marine bench, sloping wave-bench, intertidal platform, sea-level shore platform, wave-cut terrace, surf-cut terrace, coastal platform, bench, abrasion bench, denuded bench, tidal bench, wave-cut bench, rock platforms, high-water rock ledges, wave ramp, wave-cut platform, wave-cut terrace, wave-cut shore platform and bedrock platform. Clearly, the wide variety of terms used reflects different interpretations of morphology and processes by individual workers, and of the relationship between a surface and sea level. The term "shore platform" has been the most widely used, because it has no genetic connotations and is the most appropriate term since the development of shore platforms and the processes involved are still not fully understood.

The origin of shore platforms has been the subject of debate for 150 years. This debate is concerned with the relative roles of marine and subaerial processes in the development of shore platforms. Advocates of a marine origin have often referred to shore platforms as "wave-cut" platforms. The marine origin for shore platforms has dominated the literature but there is little quantitative evidence to support such a mode of development. The same is also true for subaerial weathering. Little quantitative research of either mechanism has occurred. Investigators have too often relied on interpretative approaches based on morphological features, despite numerous warnings of the ambiguity of morphology as an indicator of process. Subaerial weathering has often been ascribed a secondary role in platform genesis. It has been proposed that the remarkably horizontal nature of some shore platforms results from a secondary plantation of the surface by subaerial processes following initial cutting by marine forces. A small group of researchers have suggested that weathering is a primary process. In this scenario, waves serve only to remove the debris formed by weathering, but without the weathering there would be no platform. A third view is that both marine and subaerial processes play strong roles, but very few workers have suggested both processes are equally important.

Mechanical wave erosion includes impact forces, cavitation, hydrostatic pressure, and compression of air in joints spaces. Air compression results from the sudden inrush of water into a crack or space and causes an explosive shock upon the sudden release of the compressed air. Cavitation occurs when high water velocities at the bed cause a drop in pressure. If vapor pressure is attained then the rock surface can be damaged by the sudden formation and destruction of vapor pockets. Hydrostatic pressures increase with the depth of water. Since depth changes frequently under waves, variations in pressure occur at the bed, but for these variations to cause erosion the force exerted must exceed the strength of the rock. It remains to be determined whether or not these variations cause erosion. Impact forces include shock pressure and water hammer but these are restricted in extent because specific circumstances are required for them to operate effectively. Water hammer is the impact between a body of water and a solid and only operates if no air is trapped between the water and solid. The generation of shock pressures require the trapping of an air pocket by the front of a breaking wave as it impacts against a vertical structure. Shock pressure and water hammer are also dependent on the occurrence of breaking waves impacting directly on a platform or against the cliff. Since water depth determines the position of wave-breaking relative to the shore, true impact forces from breaking waves seldom operate on shore platforms. Larger waves break in deeper water further from the shore so that it is even less likely very large storm waves generate these forces. Only in situations where the depth of water in front of a platform is exactly suited to the breaking, water depth relationship, is there any likelihood of shock pressure and water hammer occurring and then only at the seaward edge of a platform. Water depths on platforms at high tide and even during storm and wave setup do not permit large breaking waves to impact directly against the cliff. More common is for the bore of a broken wave to shoal across a platform surface. While forces exerted are less than those generated by shock pressure and water hammer the greater frequency of air compression in joint spaces is likely to mean that it is the most important of marine processes. Associated with marine processes is abrasion, which is the wearing away of bedrock by the to and fro movement of sediments under wave action. Under more violent conditions sediments can be hurled against cliffs, acting like missiles. The effectiveness of abrasion relies on a suitable sediment and thickness of deposit. Harder sediment lying over softer bedrock will be more effective than sediments similar in nature to the platform rock. When sediments are too thickly deposited on a platform a protective role occurs. Wave tank experiments have provided some evidence that breaking and broken waves are capable of initiating shore platforms in blocks made of sand and plaster. Ice grounding by wave action and wind has be identified as an important development process on shore platforms in high latitudes.

Studies utilizing the Schmidt Hammer test have confirmed weathering occurs on platforms. Subaerial weathering includes both mechanical and chemical processes, such as solution, salt weathering, and wetting and drying. Some evidence exists to link higher erosion rates with greater numbers of wetting and drying cycles. The number of cycles is determined largely by the tide and varies with change in elevation within the tidal range. Salt spray, wave splash and rainfall contribute to and prevent wetting and drying depending on the timing in relation to the tidal cycle. The number of wetting and drying cycles also show seasonal variations with more in summer months than winter since drying is facilitated by higher temperatures. The growth of algae on platform surfaces reduces the number of cycles by preventing drying, especially in winter months. A subaerial process often identified is water-layer weathering. This involves a combination of weathering processes but seems to be most reliant on wetting and drying and to a lesser degree salt weathering and solution. Water layering morphology occurs where pools of water accumulate and are afforded time to evaporate and the surface dry. Pools up to several meters in diameter are surrounded by raised rims 2–5 cm high that occur along fracture lines the rock. These ridges develop along fissures because they hold water and undergo fewer cycles of wetting and drying. Water-layer weathering operates wherever seawater can accumulate and evaporate. Thus, it can occur from the low-tide level and has been reported as high as 24 m above sea level where spray accumulates. In high latitudes frost shattering has been proposed as significant in platform development. Although frost shattering is not limited to higher latitudes, it has been reported as a significant process on chalk platforms on the southeast coast of England.

Biological activity on shore platforms causes erosion but also inhibits other erosion processes. Bio-erosion can be subdivided into mechanical and chemical. Solution processes operate where biota release CO_2 into seawater, lowering the pH and in turn causing calcium carbonate to convert to calcium bicarbonate which has the effect of weakening the rock. Algae probably contribute significantly to erosion relative to other organisms. Endolithic algae have a wide vertical distribution at the shoreline and weaken rock by boring. Both endolithic and epilithic algae cause variations in the chemistry of water through metabolic functions and probably cause chemical erosion. Algae also serve as food for grazing organisms such as chitons and gastropods. Molluscs that graze on endolithic algae can achieve considerable erosion on coastal bedrock. Some chitons and gastropods carve out home scars that appear as impressions similar in size to their own shell in rock surfaces. The protective role of biota on shore platforms has been recognized but it is poorly understood. Dense and continuous mats of algae often cover significant areas of shore platforms during winter months in temperate environments. During warmer months desiccation removes these algae exposing the platform. Algae coverage protects the substrate from mechanical wave erosion and reduces some weathering processes by preventing drying. Thick growths of kelp such as *Durvillea antarctica* on the seaward edge of platforms dissipate wave energy through motion but also contribute to erosion when they are removed. Holdfasts thrown upon platforms often contain sizable pieces of rock.

Shore platform morphology can be characterized as being either near horizontal or gently sloping. Sloping platforms (Type A) grade into the sea whereas horizontal platforms (Type B) terminate at the seaward edge with a marked cliff that drops into the sea. This drop is sometimes referred to as the low-tide cliff. Platform morphology is largely controlled by geological factors. Evidence suggests that platform type is a function of the compressive strength of rock, with Type A platforms developed in softer rock than Type B. However, wave energy also appears to play a role with Type B platforms subjected to higher wave energy than Type A platforms. A demarcation between the two morphologies can be made based on the relative differences in the magnitude of the wave energy and rock strength. Variation in the gradient of platforms has been attributed to tidal range with steeper gradients generally occurring where the tide range is the greatest. This relationship holds best for platforms in macro-tidal environments and weakens as tidal range becomes smaller. So that platforms in micro-tidal areas have the lowest gradients although sloping Type A platforms are common. However, explanations for platform gradient employing tidal range ignore the role of geology.

Platform elevation is an important, if poorly understood, component of morphology. This is surprising given the wide use made of raised platforms for reconstructing sea level and tectonic histories in many coastal settings. Traditionally the view has been that platforms develop down to the low-tide level. To date it is unknown to what elevation platform surfaces develop in relation to the sea. This problem is more complicated because of the tendency of some platforms to be located at or above the high-tide level while others are intertidal. It becomes difficult to determine whether higher platforms have developed at that elevation in relation to the present sea level or if they have emerged or relate to a higher stand of sea level. Attempts have been made to link elevation with wave energy and geology. Interestingly the field evidence does not show a consistent relationship between elevation and wave energy. Some examples occur where higher platforms are found on headlands and lower ones in embayments, examples showing no such relationship have also been reported. Again this reflects the role of geology in determining platform morphology. Platform elevation has been found to increase as the compressive strength of the rock increases. The depth of water in front of platforms has also been shown to be an important control on platform elevation. This is because water depth controls the type of wave arriving and therefore the amount of energy delivered to the platform. If both geology and wave energy are considered together better explanations of platform elevation can be made.

Width is taken as the horizontal distance from the edge of a platform exposed at low tide to the cliff platform junction, and has often been associated with exposure to wave energy. Wider platforms might be expected where exposure to wave energy is greatest. A number of examples exist to support this proposition, but examples can also be found that show an opposite relationship with wider platform in sheltered embayments. The lack of a clear relationship reflects the strong influence geology has in determining morphological characteristics. Narrower platforms have been found to occur in rock with higher compressive strengths. The expectation that there should be a relationship between width and wave energy is reliant on a marine origin for shore platforms. The absence of a clear association between width and the wave environment may also reflect the role of subaerial processes. The distance to the seaward edge of a platform is largely irrelevant to weathering processes. The wave energy needed to removed weathered debris is significantly less than that required to erode rock from *in situ*, so that platforms could be much wider than under a wave energy control model of platform width. Understanding platform width is also made difficult because there is uncertainty that the seaward edge of a shore platform retreats landward. This is important because if the edge does not retreat then it marks the original position of the coastline. It might be reasonable to expect that platform width is limited by wave attenuation across the widening platform. Widening ceases when waves are no longer capable of removing weathered debris or erosion of the cliff, the platform can be said to be in static equilibrium. If, however, the seaward edge does retreat then the width is determined by the relative rates of erosion of the cliff and the seaward edge. Initially the rate of retreat of the cliff should be greater than the seaward edge to allow a platform to develop. Increasing width would attenuate wave energy and cause cliff recession to slow and could not increase until the seaward edge retreat allowed wave energy to do more work by reducing the width of the platform. It has been suggested that once a platform has developed both the cliff and edge of a platform erode at the same rate so that the entire profile retreats landward in a type of dynamic equilibrium.

The rates at which shore platforms develop are of considerable interest since these may provide an indication of the ages of platforms. Determining the age is necessary since it is possible that some platforms are polygenetic, having developed previously when sea level was at a similar position as today, or a platform that initially developed at a lower sea level has emerged to be coincident with the present sea level and reactivated. There are two components to be considered with respect to the rate of development. The retreat of the cliff backing the platform and rate of vertical lowering of the platform. It remains to be determined whether or not the seaward edge of a platform retreats landward. Cliff retreat rates vary considerably both spatially and temporally, but commonly occur at less than 1 m a^{-1}. Vertical lowering rates have only been measured at a few locations worldwide and with only a few exception over short time periods of about two years. Generally rates are in the range of 0.5–1.5 mm a^{-1} with a mean of 0.95 mm a^{-1}. Although there is considerable variation in these rates depending on location on the platform, season, and rock type. On tropical limestone, mean rates of lowering of 1.97 and 1.25 mm a^{-1} have been reported. Mean erosion rates on temperate limestone and mudstone of 1.13, 1.48, and 1.53 mm a^{-1} were recorded. Erosion rates on schist and greywacke 0.625 and 0.37 mm a^{-1}, respectively, have been measured. The publishing of mean erosion rates belies the fact that there is a considerable range in the measured rates, in some instances rates as high as

10 mm a^{-1} have been reported. In settings where seasonally driven weathering processes such as wetting and drying are important higher erosion rates occur in summer compared with winter. In those setting where winter storm activity is dominant higher erosion rates have been measured in winter. Two studies have extend the length of vertical lowering records beyond 10 years. Both presented erosion rates that were the same order of magnitude as short-term studies. One based on an 11-year period was cautious about extrapolating short-term erosion rates while the other based on a 20-year period suggested that short-term data can be extrapolated at least to the decadal scale. Another difficulty is that all vertical lowering rates are only measured at a scale of millimeters. There are no reports of large block disintegration thus the contribution of erosion at larger scales is unknown.

Numerous attempts have been made to numerically model platform development. These fall into two categories. Those based on the Gilbertian notion that platform development only begins when the erosive force of waves (F_W) exceeds the resisting force of rock (F_R) so that development begins when $F_W \geq F_R$. The second approach is based on empirical field evidence. Models from both approaches have attempted to elucidate the types of equilibria, elevation, width, and gradient that platforms attain. Attempts have also been made to model the effect of sea-level fluctuations and wave forces on platform development. A fundamental problem is that all modeling attempts are based on the view that platforms are wave cut. Not surprisingly these models are then used to support the view that platforms have a wave-cut origin. As yet no model has been developed that is based on a subaerial origin. A number of models have also produced contradictory results. In some instances the equilibrium form predicted is dynamic while other models suggest a static form of equilibrium will be reached. This difference in equilibrium type arises because different assumptions about erosion of the seaward edge of the shore platform were used. Platform gradient has been modeled as a function of tidal range in some examples while others have used wave height, water depth in front of a platform, and rock strength.

SHORE PROTECTION STRUCTURES

Shore protection in its widest usage refers to the reduction or elimination of damage to the shore and backland as might be caused by flooding, wave attack, and erosion. The shore may consist of cliffs, reefs, beaches, and artificial or engineered structures that form part of the water and land interface. Shore protection structures can be classified as hard, soft, or a combination. Soft structures or soft methods of shore protection usually involve placement of beach-quality sediment, typically sand, directly on the beach, a process called beach nourishment or beach fill. The beach fill may be placed across the upper beach profile and as a dune system. In such designs, the beach berm protects the dune against erosion, and the dune protects the backland from flooding and wave attack. Another type of soft shore protection structure is a "nearshore berm," referring to placement of material in an approximate linear form along the shore to break storm waves and to feed material to the beach during times of accretionary wave conditions (Hands and Allison, 1991; McLellan and Kraus, 1991). Information about beach fill design for shore protection can be found in Dean (2003) and in Coastal Engineering Manual (2003).

This entry principally concerns hard shore protection structures designed to reduce erosion of sandy beaches. Hard structures should usually be placed together with beach fill, as emphasized below with respect to preservation of the neighboring beaches. The generic forms of hard shore protection structures are groins, detached breakwaters, and seawalls, and these have several variations.

Elements of planning and coastal sediment processes

In considering local shore protection, the neighboring shore is also a concern and must be included in considerations because waves and currents transport sediment along the coast. Shore protection actions taken at one section of coast will usually have consequences for neighboring sections, and the timescales of the change induced may be short (months) or long (decades). Therefore, a regional approach is best considered that includes understanding of the sediment budget for the coast. Information about shore protection in the wider sense is available in Marine Board (1995), Komar (1998), Coastal Engineering Manual (2003), and Dean and Dalrymple (2002).

Shore protection is part of coastal zone management in which the uses and functions of the shore, as well as the benefits and costs of maintaining it, are evaluated. Such an evaluation is usually done by an associated group of stakeholders, including property owners, regulatory agencies, and other organizations with interest in preserving the property, environment, and functionality of the particular shore in question.

In approaching a shore protection design to mitigate beach erosion, the cause of the erosion should first be identified to determine the general approach and optimal design. For example, a rule of thumb is that if high-tide shoreline recession is greater than 1–2 m/year for a long stretch of shore, beach fill alone is probably not cost effective. Local areas of the shore experiencing significant beach erosion as compared with the adjacent shore are called erosional hot spots (Kraus and Galgano, 2001). Structures may be an effective hot-spot countermeasure under certain situations. Both initial costs of construction and the maintenance costs should be considered. Shore protection is a form of infrastructure; therefore, maintenance of the structures and beach fill is part of the project life cycle.

It is convenient to classify sediment transport as being directed either alongshore or across shore. Longshore sediment transport occurs throughout the year, with storms often creating the most transport. For an observer standing on the coast, it is convenient to define left- and right-directed longshore sediment transport. The net transport is then defined as the difference of the right- and the left-directed transport, and the gross transport rate is defined as the sum of the left- and right-directed transport. Changes in the high-tide shoreline position, or erosion and accretion, are caused by differences in net transport from one location to another on the coast.

Cross-shore transport is directed either onshore or offshore. Offshore transport occurs during storms, when the beach is eroded and sediment transport is transported seaward to create a storm bar. Sediment may also be transported onto the land (overwash), and this material is called washover. After a storm and during summer or mild wave conditions, sand that is stored in storm bars is moved onshore to widen the beach. In the following, the predominant direction of transport enters in consideration of the action of a shore protection structure.

Groins

Groins are shore-normal structures (Figure S37) emplaced for the purpose of either (1) maintaining the beach behind them, or (2) controlling the amount of sediment moving alongshore. Because modern coastal engineering practice includes a regional perspective that incorporates the stability of downdrift beaches, groin construction is normally done together with beach nourishment so that sediment impounded by the groin or groins is replaced in the total system. If beach fill is not included with groin construction and maintenance, downdrift beaches may suffer (Nersesian *et al*., 1992). Groins have varied shapes, such as the simple groin, spur or L-shaped groin, and T-head (Figure S38). These shapes were developed to better retain sediment by reducing offshore transport by the rip current that tends to form at the stems of groins, and by providing a sheltered region from waves.

Groins are designed to operate where there is appreciable longshore sediment transport. Groins will not function well if cross-shore transport is strong, such as in the US Great Lakes, where steep waves tend to move sand offshore that can then bypass the groins by transport along longshore bars. Groins are often placed as a system or a field. Figure S39

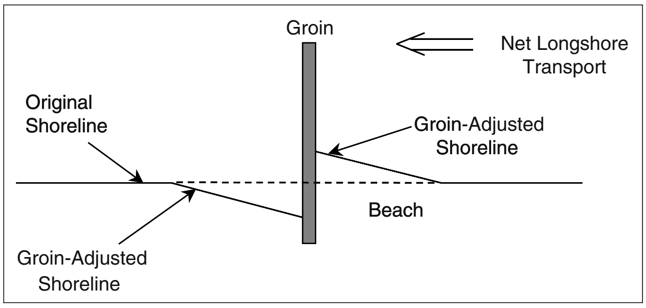

Figure S37 Definition sketch for beach response to a groin.

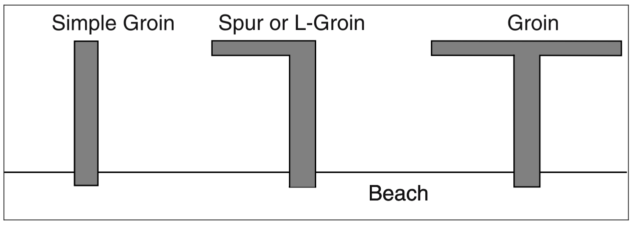

Figure S38 Examples of types of groins.

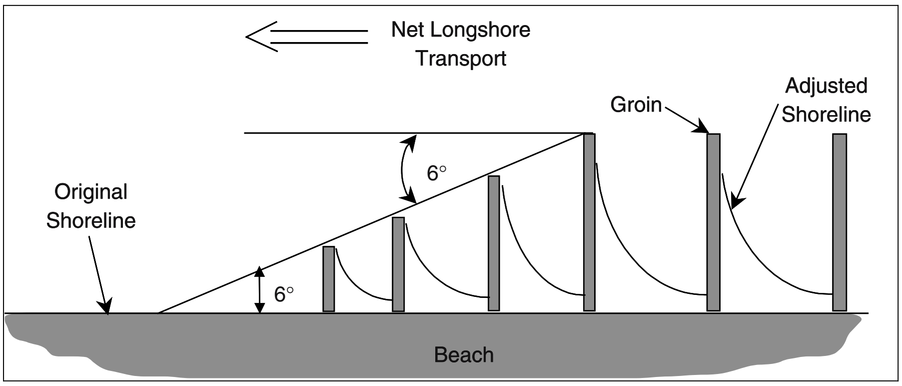

Figure S39 Tapered groins.

shows a schematic of a tapered groin field, with shortening of the groins in the direction of net transport to transition into the beach without structures.

Groin functioning and design can be parameterized in a numerical simulation model through three key processes (Kraus *et al*., 1994) as (1) sediment bypassing around the seaward end of the structure, (2) structure permeability in allowing sediment to go through or over the groin, and (3) ratio of net to gross longshore transport rate, which controls in great part high-tide shoreline recession and advance at a groin, as schematically shown in Figure S39. Groin length determines the amount of bypassing. Typically, a groin will be shorter than the average width of the surf zone. A long groin will intercept too much sand moving alongshore and cause erosion of the downdrift beach by impounding or blocking sediment on the updrift side.

Groins may be a possible component of a shore-protection project and sand-management program under the following situations:

1. Where there is a divergent region of longshore transport, such as at the center of a crenulate-shaped pocket beach, or where the curvature of the coast changes greatly.
2. Where there is no source of sand, such as the downdrift side of a large harbor or inlet with jetties.
3. Where intruding sand is to be managed, such as to retain sand on the updrift side of a harbor to prevent shoaling of the channel and to stockpile the sediment for bypassing by land transport.
4. Where the sand transport rate is to be controlled or gated, such as to prevent undue loss of beach fill to unwanted areas.
5. Where an entire littoral reach is to be stabilized, such as on a spit, near a submarine canyon.
6. Where stabilization of the high-tide shoreline is required under extreme conditions.

Groins cannot prevent sand from moving offshore, such as during storms. For such situations, detached breakwaters serve better for shore protection.

Groins may be made porous or low to allow some amount of sediment to bypass them. Also, groins may be notched at the shoreward end to allow sand to pass through them that is being transported near the high-tide shoreline (Kraus, 2000). Such designs are intended to balance the amount of material bypassed to the amount retained under certain wave conditions and water level. Also, permeable and notched groins tend to minimize abrupt change in high-tide shoreline position on the sides of the groins, promoting a straight shoreline.

Detached breakwaters

Detached breakwaters are sometimes referred to as offshore breakwaters. They function to reduce wave energy on their landwards sides. Sediment will accumulate in the wave-sheltered region because the water is calmer and the longshore current behind the detached breakwater weaker than on adjacent shore that is open to full wave energy. Detached breakwaters are often constructed to be partially submerged, for example, at higher tide, to allow wave transmission over and, sometimes, through them. In this way, a certain amount of wave energy reaches the sheltered region and promotes sediment transport alongshore. Detached breakwaters are often built in groups, and this configuration is referred to as a segmented detached breakwater system. Detached breakwaters may be an appropriate shore protection measure in areas where cross-shore transport is large, or where wave energy must be reduced, such as at a change in orientation of the coast.

The response of the beach to detached breakwaters is controlled by at least 14 variables (Hanson and Kraus, 1990), making these structures more difficult to design than groins. The response of the beach to the presence of a detached breakwater (Figure S40) may be as a tombolo, for which the high-tide shoreline reaches the structure, or as a salient that describes a cuspate morphologic form that grows toward, but does not reach the structure. The type of beach response is determined by design requirements. Typically, it is desired to allow some amount of sediment to pass alongshore behind the structure. A potential design deficiency for detached breakwaters is to place them too far offshore. In such a case, the high-tide shoreline will show no response.

Main design parameters for detached breakwaters are distance offshore, length of structure, and transmission (depends on elevation of structure and its composition). The design takes into account the prevailing wave climate at the site and the desired beach response. For segmented detached breakwaters, the gap width between structures is also a key design parameter. Empirical design procedures have been developed that incorporate the geometric parameters of detached breakwaters (Pope and Dean, 1986; Rosati, 1990), whereas numerical simulation

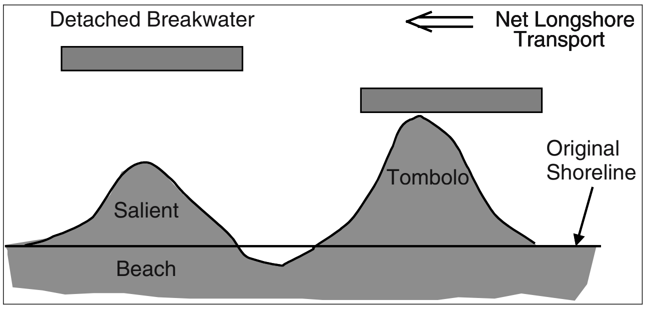

Figure S40 Definition sketch for beach response to detached breakwaters.

models can be applied to account for a wide range of conditions, including wave transmission (Hanson and Kraus, 1990). As depicted in Figure S40, a detached breakwater built closer to shore will tend to create a tombolo. Erosion or high-tide shoreline recession between structures can occur and must be accounted for in design.

Submerged detached breakwaters are sometimes called reefs, particularly if they have a broad crest. Reef breakwaters allow transmission, the wide crest reducing wave height behind them. Reef breakwaters often serve as an offshore retaining structure for sediment near the beach, acting to perch or elevate the beach.

Headland control is a variation of detached breakwaters, in which hard points or shore-connected detached breakwaters are constructed, often with orientation parallel to the crests of the predominant incident waves (Silvester and Hsu, 1993; Hardaway and Gunn, 1999). In this way, a curved headland beach, or a pocket beach if bounded laterally by two such structures, will form. The intent is to developed isolated beach compartments that will lose a minimum amount at their longshore ends, letting the high-tide shoreline achieve a form in equilibrium with the predominant direction of the incident waves.

Seawalls

Seawalls are constructed to prevent inland flooding from major storms accompanied by high water levels (storm surge) and large waves. Seawalls also fix the position of the land sea boundary if the sea reaches the structure. The main functional element of a seawall is the elevation to minimize overtopping from storm surge and wave runup. A seawall is typically a massive, stone and concrete structure with its weight providing stability against sliding forces and overturning moments. Whereas groins and detached breakwaters are constructed with preservation of the beach as a design goal, the purpose of seawalls is to protect the backland. Knowledge on seawalls and their interaction with beaches is compiled in a collection of papers found in Kraus and Pilkey (1988), and the literature on the subject has been brought up to date by Kraus and McDougal (1996).

Seawalls have many counterparts in nature, as do groins and detached breakwaters. Wiegel (2002a,b,c) gives an account of many types of seawalls and their performance.

SHOREFACE

Introduction and origins of the term

The shoreface, a relatively steep surface that slopes away from the low-tide shoreline and imperceptibly merges with the flatter inner shelf or basin plain ramp, is an integral feature of nearly all clastic coasts (Figure S41). The term has been applied in a facies context in many geological interpretations of ancient coastal deposits in the rock record. This usage commonly invokes additional attributes that are unrelated to the morphologic feature and commonly unfounded.

Barrell (1912) coined the term "shore face" to describe the transition between the subaerial and subaqueous plains of a deltaic topset system: "The shore face is the relatively steep slope developed by breaking waves, a slope which separates the subaerial plain above form the subaqueous below." Johnson (1919) consolidated the term ("shoreface") and redefined it as the zone between the low-tide shoreline and the more nearly horizontal surface of the offshore. He expanded its usage to other types of coasts, as "the steeper, landward portion of the shore profile of equilibrium, of which the profile of the gently sloping subaqueous plain is the seaward continuation."

Development and maintenance of the shoreface

Early in the history of the concept, it was recognized that the shoreface is part of an equilibrium profile generated by shoaling waves. Many

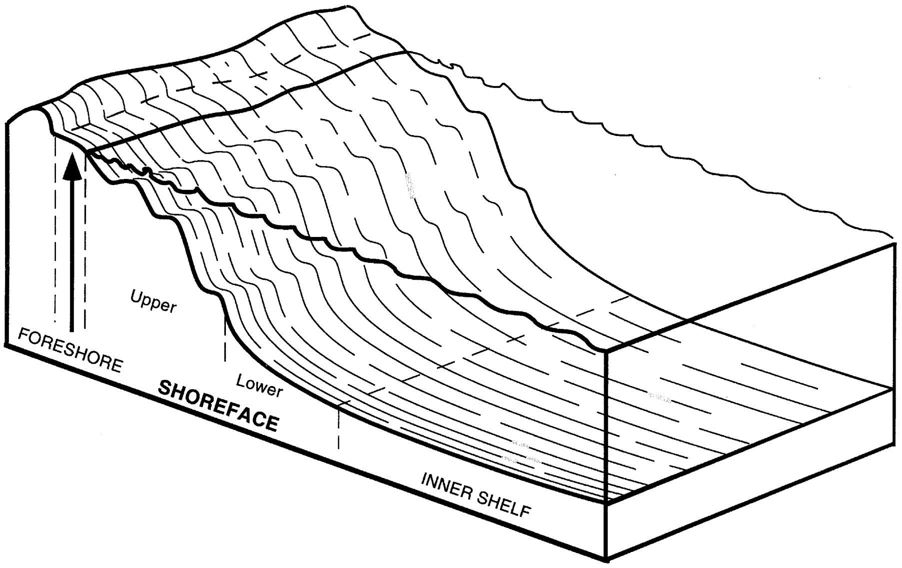

Figure S41 Sketch showing the character of a simple (progradational) shoreface. Shore-parallel breaker-bars, which may not occur on all shorefaces, are here used to separate it into "upper" and "lower" parts, which may be the only components recognizable in ancient shoreface deposits.

workers have assumed that the base of the shoreface is defined by fair weather wave base, but as Johnson noted in 1919, the two are unrelated. Wave base is commonly taken as a water depth equal to half of the length of the passing waves. As such it is primarily dependent on wave period. On the Pacific coast of the United States, long period ($\geq$10 s) waves are common under fair-weather conditions, and their wave base lies in water depths of 78 m or more, well beyond the shoreface. On coasts receiving shorter period waves, the base of fair-weather waves lies in shallower water (e.g., about 20 m for 5 s waves), but coincidence of fair-weather wave base and the bottom of the shoreface is just that: a coincidence.

Although unrelated to wave base as such, the development and maintenance of a shoreface is at least partly controlled by aspects of shoaling waves. Niedoroda and Swift (1981, see also Niedoroda *et al.*, 1984) provide a plausible explanation for the maintenance of the shoreface, that balances the onshore transport of sand under (mostly) fair-weather conditions with the offshore transport during storms. In shallow water, the oscillatory flow of water induced by passing waves becomes asymmetric, with short relatively strong landward flow under the crest of a wave and a more prolonged weaker, seaward flow under the trough. This orbital velocity asymmetry drives sediment in a landward direction, building the shoreface. Storms sporadically interrupt this process and seaward flowing rip and geostrophic currents erode the shoreface. Much of the eroded sediment is subsequently returned to the shoreface during fair weather, maintaining its concave-up profile. Evidence for this combination of processes will be presented in a following section "Sedimentologic aspects of the shoreface."

Shoreface profiles

The shape of the shoreface profile on constructive (progradational) coasts differs from that of erosive (or transgressive) coasts. Progradation occurs where high rates of sediment supply (relative to base level change) cause a coastline to build laterally into the adjacent basin. Sediment is sufficient to provide a bottom profile in equilibrium with the shoaling waves. A simple concave-up profile typically results (Figure S42) that resembles the theoretical curve for landward increase in bottom orbital velocity asymmetry generated by shoaling waves (Figure S43). Because of the large volume of sediment available, the relief of progradational shorefaces reflects the energy of the coastal waves. On high-energy coasts like the southern coast of Washington State, the shoreface extends to a depth of 10 m (Figure S42(C)). On coasts with lower wave energy (e.g., the Gulf coast at Galveston, Texas), the shoreface bottoms out in shallower depths (Figure S42(A)).

Most coasts today are still in a transgressive or erosional phase, where the volume of sediment is insufficient to create a simple equilibrium profile. Commonly on such coasts, older deposits crop out on the shoreface, where they resist erosion by waves and coastal currents. Differential erosion creates irregularity in the shoreface profile (Figure S44), although many such profiles contain a simple "wave-tuned" component in their upper part, either because that is where unconsolidated sediment is concentrated or simply owing to intensified wave erosion in the shallowest water (Figure S45). Because transgressive coasts typically lack an abundance of sediment, the depth to which they extend reflects in part the topography crossed by the transgression. The relief of transgressive shorefaces is highly variable (Figures S44 and S45), but can exceed 20 m (Figure S44(C)).

Sedimentologic aspects of the shoreface

The textural character and sedimentary structures of shorefaces differ with energy and provenance. Typically, wave energy reaches a maximum in the shallower part of a shoreface, and coarse sand and gravel, if available, are concentrated in the active breaker zone adjacent to the shoreline (the coarsest typically being at the very base of the foreshore). The grain size typically decreases to seaward across a shoreface to fine or very fine sand at it base.

In some areas, the base of the shoreface marks the transition between sand and mud (Figure S42(A)), but in many places sand continues well out onto the inner shelf. On the coast of southwestern Washington State, for example, fine to very fine sand extends to water depths of 60 m or more. Although some geologists refer to the entire sandy part of a shoaling-upward coastal succession as shoreface deposits, there is no general basis for this interpretation. The proportion of sand, silt, and mud, depend on the sediment available and the wave-energy regime (Galloway and Hobday, 1996) and are not specifically related to the shoreface morphology.

An exception to the generally seaward-fining on most shorefaces occurs where gravel is present. Studies of modern gravel-bearing shorefaces (Shipp, 1984; Howard and Reineck, 1981) show a scattering of gravel at the base of the shoreface and the immediately adjacent inner shelf. Vertical successions of ancient gravelly shoreface deposits typically have a distinctive facies composed of scattered small pebbles in a matrix of fine- to very fine-grained sand in the interval 2–3 m below cross-bedded nearshore gravelly sand. The gravel at the base of the shoreface probably results from a combination of erosion of a shoreface during storms and its subsequent rebuilding in the storms aftermath as suggested by Niedoroda and Swift (1981). Gravelly sand eroded from the upper shoreface is carried seaward by rip currents or geostrophic flow and deposited at or near the base of the shoreface. Waves following the storm rework and winnow this material and transport the finer component landward. The coarsest part (typically small pebbles) is left behind as a "post storm lag."

The sedimentary structures of a shoreface depend on both wave energy and sediment texture. The shallower part consists of the

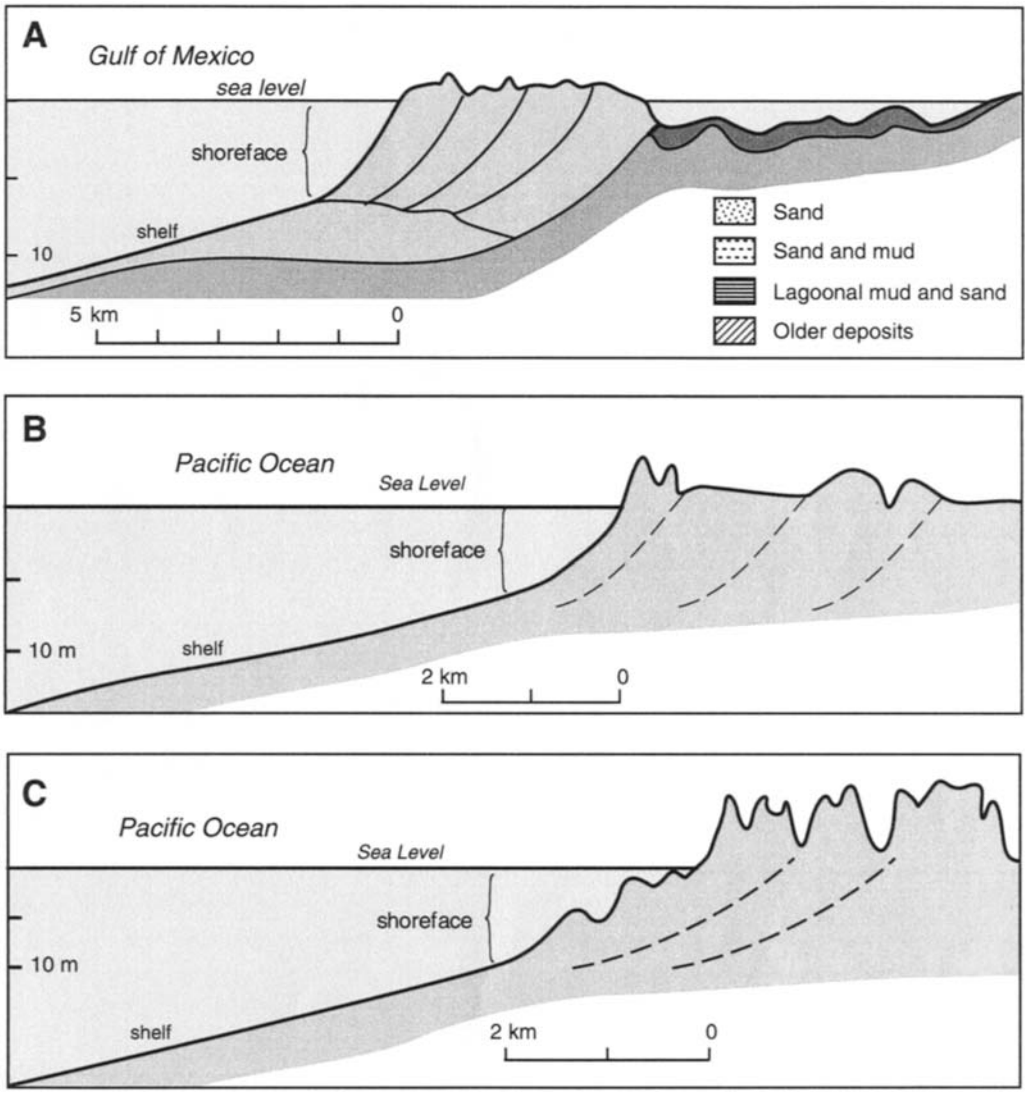

Figure S42 Shoreface profiles on progradational coasts, showing simple concave-up character. (A) Galveston, Texas, Gulf of Mexico (after Morton, 1994). (B) Nayarit coast of Mexico, Pacific Ocean (after Curray *et al.*, 1969). (C) Long Beach, Washington, Pacific Ocean (after Dingler and Clifton, 1994). Note differences in scale.

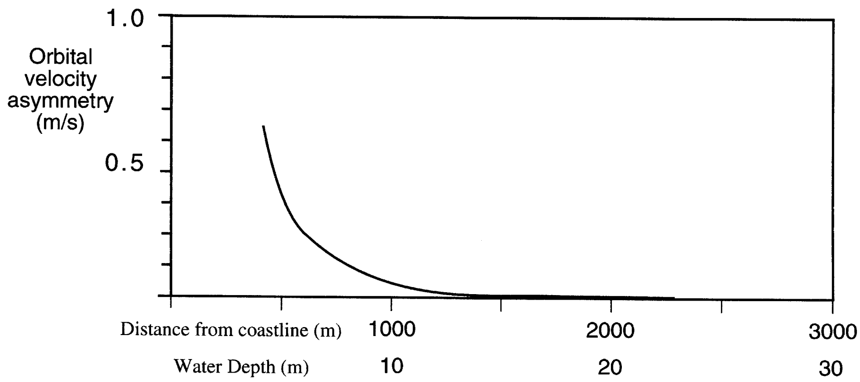

Figure S43 Predicted orbital velocity asymmetry (difference between the bottom velocities under the crest and trough of a shoaling wave, using Stokes second order wave theory) under 10-s waves with a deepwater wave height of 1.0 m over a bottom with a uniform slope of 1 : 100. Water depth at which velocity asymmetry becomes noticeable approaches the depth of the base of the shoreface off the Long Beach, Washington (Figure S41(C)) where these wave conditions obtain during fair weather.

(C) South Padre Island (after Morton, 1994). Topographic irregularity below "wave-tuned" portion in A and B presumably due to differential erosion of older deposits exposed on the shoreface during transgression. Note differences in scale.

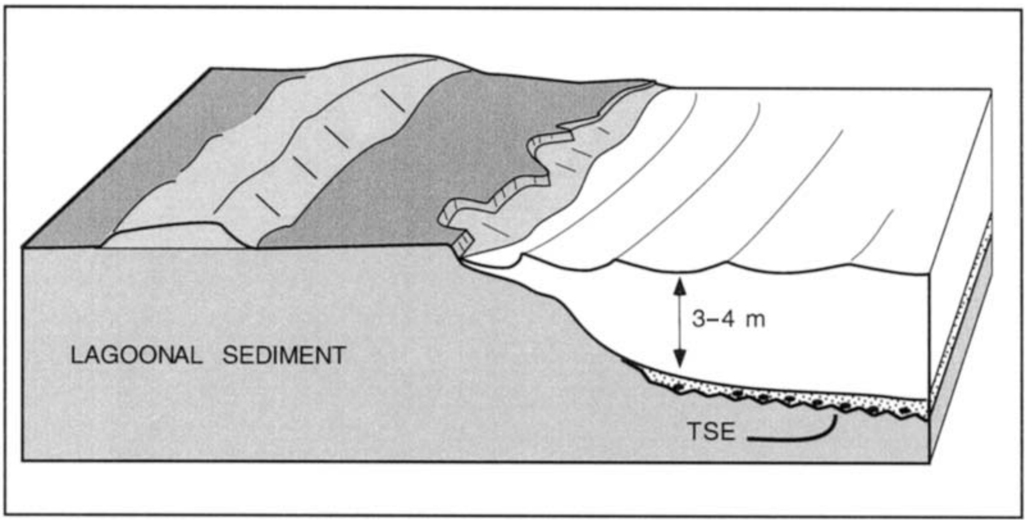

Figure S45 Erosional shoreface on a transgressing coast, Cape Romaine, South Carolina (after Hayes, 1994).

nearshore, in which bedforms are generated by passing waves or by longshore and rip currents of the nearshore circulation cell. Bedform size, shape, and orientation differ as a function of wave size and direction of approach and the grain-size of the sea bed material (Clifton and Dingler, 1984). Storms may generate hummocky or swaley cross-stratification. Guttercasts are a characteristic shoreface feature. Shore-parallel or other breaker bars are common features on the upper part of many shorefaces (Figure S41) and can serve to focus longshore and rip currents. Depending on infauna and sediment texture, bioturbation can obliterate much of the physical structures on the outer part of a shoreface.

Shoreface subdivisions

Many workers divide the shoreface into upper, middle, and lower components. Galloway and Hobday (1996) define the upper shoreface as the inner surf zone, the middle shoreface as the portion occupied by breaker bars systems and the lower shoreface as the area to seaward where the shoreface merges with the inner shelf. Howard and Reineck (1981) recognize three principal zones without relating them to shoreface morphology: a *nearshore* made up of clean sand in which physical sedimentary structures predominate, a *transition* in which fine and silty sand contain a mixture of biogenic and physical structures, and an *offshore* composed of sandy silt with only remnant stratification.

Shoreface zonation is less evenly applied to the stratigraphic record. Although geologists commonly subdivide ancient shoreface deposits into upper, middle, and lower facies (and some subdivide these further into proximal and distal components), they generally agree only on the character of the upper shoreface as an interval with abundant cross-bedding and other physical structures. This would probably include the middle shoreface of Galloway and Hobday (1996) where currents focused by bar-trough systems produce structures that resemble those of the surf zone. Deposits on the lower part of a shoreface may be indistinguishable from those on the adjacent inner shelf, unless gravel is present.

Otherwise the most realistic facies subdivision is that of an upper shoreface overlying a lower shoreface/inner shelf transition.

SIMPLE BEACH AND SURF ZONE MODELS

Definition

Beach and surf zone models refers to conceptual models which provide some basic insight on the dynamic interaction between waves and beaches. In this entry, only simple aspects of these models will be discussed.

Background

The physical processes that mold beaches and that are at work in the surf zone are anything but simple. The best scientific minds that study these processes often disagree on what are the important cause and effect relationships at work in this complex and dynamic area. However, there are some relatively simple models which are useful for understanding important aspects of how beaches respond to waves, such as erosion and accretion. Beach erosion falls into two general categories: (1) When the littoral transport of sand, or possibly other sediment, to the beach is less than the littoral transport of sand from the beach, that is, a net loss in the longshore transport of sediment. (2) When sand moves from the subaerial (above water) beach to the submerged beach or the movement from the submerged beach to the subaerial beach. It is this latter category of offshore and onshore sand movement, referred to as cross-shore sediment movement, which will be regarded as erosion or accretion, respectively in this entry.

Summer beach–winter beach model

The simplest model for onshore and offshore sediment movement is commonly referred to as the summer beach–winter beach concept. By the 1950s, coastal scientists became aware of a strong seasonality of beaches in California. Generally, during winter storms waves would remove sand from the subaerial beach and deposit it offshore typically in bar formations. Milder wave conditions, during summer, would move the bars onshore and ultimately they would attach to the shore and rebuild the wider berm associated with the "summer beach." Figure S46 shows the profiles of a reflective and a dissipative beach. Using the terminology of Wright and Short (1984) reflective and dissipative beaches correspond roughly to summer and winter beaches, respectively. In interpreting Figure S46, note that there is very high vertical exaggeration.

Weather patterns in many parts of the world undermine the simple concept of a summer/winter beach pattern, and even in California, the concept is not too reliable. The important insight of the concept, that wider beaches are associated with a prolonged period of mild wave conditions and narrower beaches are associated with storm waves, is true.

U_t Beach index model

The U_t parameter was developed by Ahrens and Hands (2000) and it can be used like an index to classify wave events on beaches as either erosion or accretion. U_t can be calculated in terms of a sediment mobility number, N_{so}, and the deepwater wave steepness, H_{so}/L_o. The mobility number is defined: $N_{so} = H_o/\Delta d_{50}$, where H_o is the deepwater wave height offshore of the beach in question, d_{50} is the median grain diameter of sediment in the surf zone, and Δ is the relative density of the sediment given by, $\Delta = (\rho_s - \rho)/\rho$, where ρ_s and ρ are the density of the sediment and water, respectively. Deepwater wave steepness is the ratio of the deepwater wave height to deepwater wave length, L_o, where $L_o = gT^2/2\pi$, T is the wave period and g is the acceleration of gravity. U_t can be defined:

$$U_t \equiv [(N_{so}/33)(H_{so}/L_o)^{0.57}/\exp(8.3(H_{so}/L_o))]^{1/2.2} \qquad \text{(Eq. 1)}$$

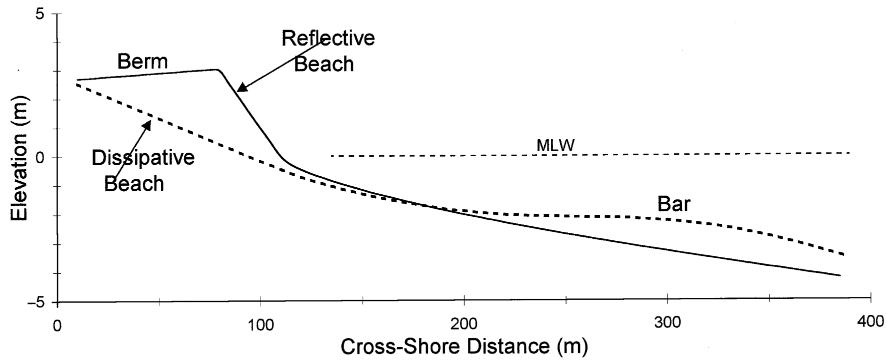

Figure S46 Typical profiles of the highest beach state, dissipative, and the lowest beach state, reflective.

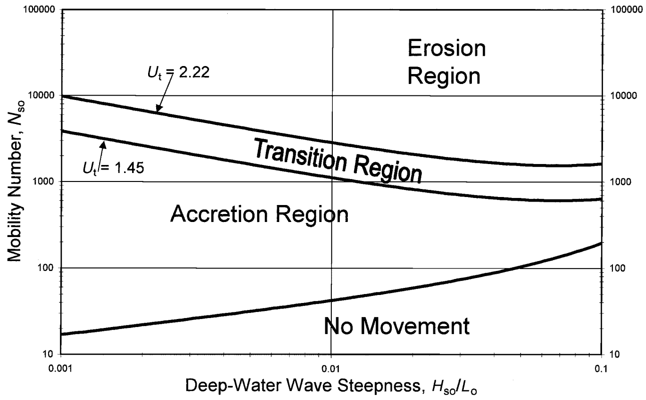

Figure S47 The U_t plane, showing erosion and accretion regions as defined by the U_t parameter.

The U_t parameter was calibrated using an extensive field data set of primarily qualitative observations of beach erosion or accretion, Kraus and Mason (1991). Data are from beaches all over the world, collected by many researchers, and include observations of 99 distinct wave events. The range of the parameter for this data set was, $0.42 \leq U_t \leq 6.56$, values of $U_t > 2.22$ were always observed to be erosion events and values of $U_t < 1.45$ were always observed to be accretion events. There was a transition region, $1.45 < U_t < 2.22$, where a mixture of erosion and accretion events occurred, but generally U_t did a good job of classifying events in the Kraus and Mason data set. Figure S47 shows the N_{so} versus H_{so}/L_o plane using the U_t parameter to determine various regions.

Certain features of Figure S47 should be noted because they provide insight into the erosion or accretion processes. Highly mobile sediment, that is, high mobility numbers, is associated with erosion and low sediment mobility is associated with accretion. The accretion region shrinks and the erosion region expands in going from low- to high-wave steepness. These are trends which are consistent with current understanding of erosion and accretion processes.

Antecedent beach conditions (ABC) model

There have been a number of attempts to develop a single parameter to quantify the tendency of sand to move onshore or offshore. The most useful simple parameter is the fall-velocity parameter given by $\Omega = H/wT$, where H is the wave height and w is the fall velocity of sediment in the surf zone. Some scientists have used the breaker height, H_b, on the beach to calculate Ω others have used the deepwater wave height, H_o, offshore of the beach to calculate Ω. Regardless of whether H_b or H_o is used, the principle is, if Ω is small, it indicates that sediment movement is predominately by bedload and there would be a net onshore movement of sediment. If Ω is large, it would favor offshore movement of sediment because there would be large quantities of suspended sediment which would be carried offshore by the bed return flow or, possibly, by rip-currents.

An interesting perspective on beach erosion and accretion can be gained by comparing the current value of the fall-velocity parameter, Ω(current), with the antecedent value, Ω(antecedent). Ω(current) is the average value of Ω for the day in question and Ω(antecedent) is a weighed average of Ω(current) starting yesterday and including the previous 30 days, Wright and Short (1984). The function is heavily weighted toward the recent past with the previous five days contributing 90% of the total weight. Wright and Short found that Ω(antecedent) correlated very well with the six fundamental beach states that they had identified. The six beach states can be ranked hierarchically from the highest state, dissipative, to the lowest state, reflective. Wave conditions which move a beach toward a higher state cause erosion and wave conditions which move a beach downstate cause accretion. These beach states have some very interesting quantum aspects which suggest analogies to quantum physics. Typical profiles for the end beach states are shown in Figure S46. A dissipative beach is the product of storm waves and has a flat beach face and a rather subtle bar or possibly subtle bars. A reflective beach is the product of a period of mild wave conditions and has a berm, steep beach face and no bars. Both dissipative and reflective beaches are relatively two-dimensional, although reflective beaches usually have pronounced cusps. The four intermediate beach states all have complex three-dimensional, dynamic topography, so, it is difficult to associate a single profile that is typical of intermediate states.

Figure S48 shows the Ω(current) versus Ω(antecedent) plane adapted from the model of Wright *et al.* (1985). The figure identifies the highest beach state, dissipative, and the lowest beach state, reflective, connected by a stable region. The stable region trends along the diagonal where $\Omega(\text{current}) = \Omega(\text{antecedent})$: that is, when the current conditions are approximately equal to the antecedent conditions, the beach state is stable. The stable connecting region contains the four intermediate beach states defined by Wright and Short (1984). Boundaries for the stable region shown in Figure S48 are approximate based on research by Wright *et al.* (1985). Also shown in Figure S48, are an erosion region and an accretion region. The erosion region is characterized by, $\Omega(\text{current}) > \Omega(\text{antecedent})$, and the accretion region by $\Omega(\text{current}) < \Omega(\text{antecedent})$.

To help illustrate the ABC model, a simple calm-storm-calm sequence is shown in Figure S48. Simple indicates that an extended calm period is interrupted as breaker heights increase monotonically from small values to large values during the height of the storm and decrease monotonically to small values as the storm wanes and another extended calm period begins. The sequence shown is not specific, but is consistent with breaker heights over an inshore bar, wave periods, and sand size that occur on the east coast of the United States or the coast of New South Wales, for example, $0.25 \leq H_b \leq 1.75$ m. Circles are shown along the path of the sequence to bracket one day intervals and arrows are used to indicate the time order of the sequence. The sequence starts at the lower left when a calm period is interrupted by the initial arrival of waves from a storm. With increasing breaker heights, the sequence quickly leaves the stable region and moves into the erosion region since Ω(current) quickly exceeds Ω(antecedent). As long as the storm intensity increases, Ω(current) increases causing Ω(antecedent) to increase too, this is the main period of erosion. However, at some point the storm intensity will start to wane and Ω(current) will start to decrease. During this initial waning period, Ω (antecedent) will continue to increase but the storm sequence will quickly leave the erosion region and drop into the stable region, and then into the accretion region. It is this initial waning period of the ABC model, when both Ω(current) and Ω(antecedent) are large, that is anomalous from the perspective of the

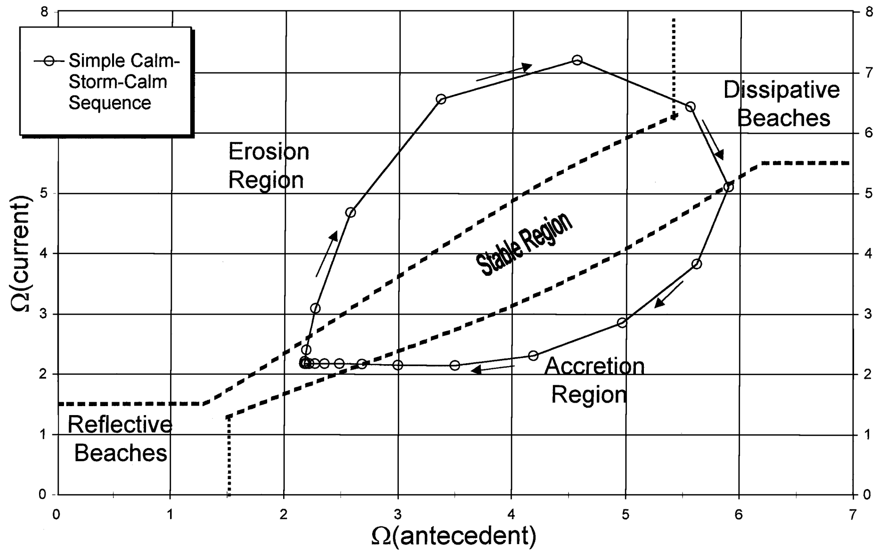

Figure S48 Current versus antecedent beach condition plane showing a "simple" calm-storm-calm sequence.

U_t Beach Index model and also other beach index models. The U_t model predicts that when wave conditions are energetic, $U_t > 2.22$, erosion will occur regardless of the antecedent beach conditions; the ABC model predicts that accretion will occur when Ω(current) is roughly 20% less than Ω(antecedent) regardless of how large Ω(current) is. These criteria can easily be in conflict during the early portion of a waning storm and current research indicates that the ABC model is the more realistic. As the storm continues to wane, the beach continues to rebuild, albeit slowly, until it returns to a stable condition similar to the condition at the beginning of the cycle.

Summary

Three models of beach and surf zone behavior are discussed. In order of increasing complexity they are: (1) summer–winter beach profiles, (2) the U_t Beach Index model, and (3) the antecedent beach condition (ABC) model. From a historical perspective, the summer–winter beach profile concept is interesting, but is certainly not a reliable model. The U_t model is a simple model to determine if beaches will erode or accrete for a given sediment size and wave conditions, but gives no information about beach profiles. The ABC is the most complex of the three models and is difficult to apply considering the level of information required. However, the ABC model is conceptually the most realistic and provides a great deal of information about beach and surf zone processes beyond erosion, accretion, and beach profiles (Wright and Short, 1984). The ABC model has also been widely accepted and generalized by other coastal scientists.

One of the most difficult aspects of the ABC model is to classify beaches and surf zones in the proper state. To help classify ABC beach states correctly, Lippmann and Holman (1990) developed computer enhanced video images of the surf zone to show bar and trough locations and shapes, and proposed some additional beach states. All of the models discussed are for microtidal beaches, that is, tide ranges less than 2 m. The ABC model has been generalized by Masselink and Short (1993) to include the influence of tides on beaches and surf zones and, therefore, to extend the usefulness of the ABC model to beaches with tide ranges greater than 2 m.

SMALL ISLANDS

Introduction

What is a "small island"?

The definition of a *small island* depends upon one's perspective. Any country in the family of nations can declare themselves a member of the Alliance of Small Island States (AOSIS). AOSIS nations include Antigua and Barbuda, Bahamas, Barbados, Belize, Cape Verde, Comoros, Cook Islands, Cuba, Cyprus, Dominica, Fiji, Federated States of Micronesia, Grenada, Guinea-Bissau, Guyana, Haiti, Jamaica, Kiribati, Maldives, Malta, Marshall Islands, Mauritius, Nauru, Niue, Palau, Papua New Guinea, Samoa, Singapore, Seychelles, Sao Tome and Principe, Solomon Islands, St. Kitts and Nevis, St. Lucia, St. Vincent and the Grenadines, Suriname, Tonga, Trinidad and Tobago, Tuvalu, Vanuatu; observer nations include American Samoa, Guam, Netherlands Antilles, and the US Virgin Islands. AOSIS is a political organization of the United Nations, stemming from the 1990 Second World Climate Conference, which recognized Small Island Developing States (SIDS) as having a unique need in a changing environment.

From a geographic perspective, it is clear that AOSIS member states, and SIDS in general, are found in each major ocean, semi-enclosed, or marginal sea (see Figure S49). Some "SIDS" are low-lying non-island coastal countries with a decidedly marine climate. They all share a number of common development issues including energy, coastal and marine resources, waste management, biodiversity, sustainable tourism, population growth, and climate change, among others. Their socioeconomic circumstance commonly includes a rapidly growing population, and small gross domestic products with which to mitigate the effects of natural disasters and anthropogenic hazards. Most islands in AOSIS, and SIDS in general, are positioned in low latitudes, and thus are susceptible to common meteorological hazards such as tropical storms and flooding.

Geologically islands can be separated into seven island types: arc system islands; barrier system islands; coral reef islands; diapiric islands; estuarine and deltaic islands; intraplate islands; precontinent islands; and rift islands. Many island types are associated with plate boundaries and fault zones (e.g., rift and diapiric islands), others are located at passive margins or in the coastal zone, while yet others are well within the boundaries of plates and may or may not have associated coral reefs. Their petrographic characteristics range from basalt for rift and intraplate islands, to metamorphic and clastic sand and clay sedimentation for precontinent and estuarine islands, respectively, to the classic carbonates of coral reefs and the andesite of island arc system islands. Thus the cause of each island type varies considerably too, including subduction, volcanism at boundaries and within plates, coastal hydrodynamics, riverine terminus, and biological colonization upon a substrate. Other classification schemes exist but the above serves to illustrate the diversity of geophysical settings.

Small islands also tend to have distinctly different meteorological environments. While tropical islands all tend to have sea level air temperatures in the range of 20–30°C, precipitation patterns differ widely. The lush vegetation and high annual rainfall (>200 cm yr^{-1}) of the islands of the western Caribbean Sea are in stark contrast to the near desert conditions of Aruba, Bonaire, and Curaçao, barely 1,000 km due east. Much of the interannual variability in low-latitude rainfall is related to the annual cycle of the intertropical convergence zone (the ITCZ), and this in many places is punctuated by ocean-basin scale events such as the El Niño–Southern Oscillation (ENSO). Extratropical islands have equally complex climatological variability, including extreme winter precipitation at high latitudes and the formation of sea-ice. Again, no commonality exists in the biogeography of complex island ecosystems, because their environmental settings vary widely.

The physical notion of a small island then is well beyond the geopolitical perspective of AOSIS or SIDS. Humankind tends to categorize natural systems, but in the case of small islands this is quite problematical. Setting limits on the area of an island as a definition of "small" is as arbitrary as specifying latitude or population density or biodiversity. Yet as a working definition, it might be most productive to consider their shared range of natural hazards and the common socioeconomic consequences of limited infrastructure and response strategies to events both anthropogenic and geophysical. In addition, the notion of sustainable development needs to be included in the definition as a focus for well being. These concepts are addressed in the next sections.

Natural hazards

Tropical and extratropical storms tend to be one of the most severe natural hazards to small islands, and yet such events are a major source of freshwater, especially in low latitudes. The West Indian Hurricane, the western Pacific Typhoon, and the Indian Ocean Cyclone are similar tropical storms with varying degrees of severity. All coastal areas are at risk from the high surface winds, which can exceed 100 m s^{-1} with attendant rainfall in excess of 30 cm in 24 h. Extreme wind damage and flooding are common aftermaths of these storms, and it is not uncommon for years to pass before the socioeconomic infrastructure is restored. Tropical ecosystems have evolved to include the tropical storm as part of the natural cycle, and indeed it can be argued that storm events are needed from time to time to exercise the coupled land–air–sea system that defines the biological health of a small island.

Most of the toll in human terms from tropical storms is associated with storm surge and flooding. Many oceanic small islands are essentially mountains protruding above the sea surface and have very steep offshore submarine topography and narrow shelves. For storm surge height to build to the 5 m level of Hurricane Andrew in south Florida in 1992, a long and continuous coastline is necessary. Thus AOSIS countries such as Belize and Cuba are highly prone to extensive coastal flooding and loss of human life through drowning, which is the primary cause of death from tropical storms. The catastrophic loss of life, probably exceeding 250,000 persons, in the estuarine and deltaic islands of

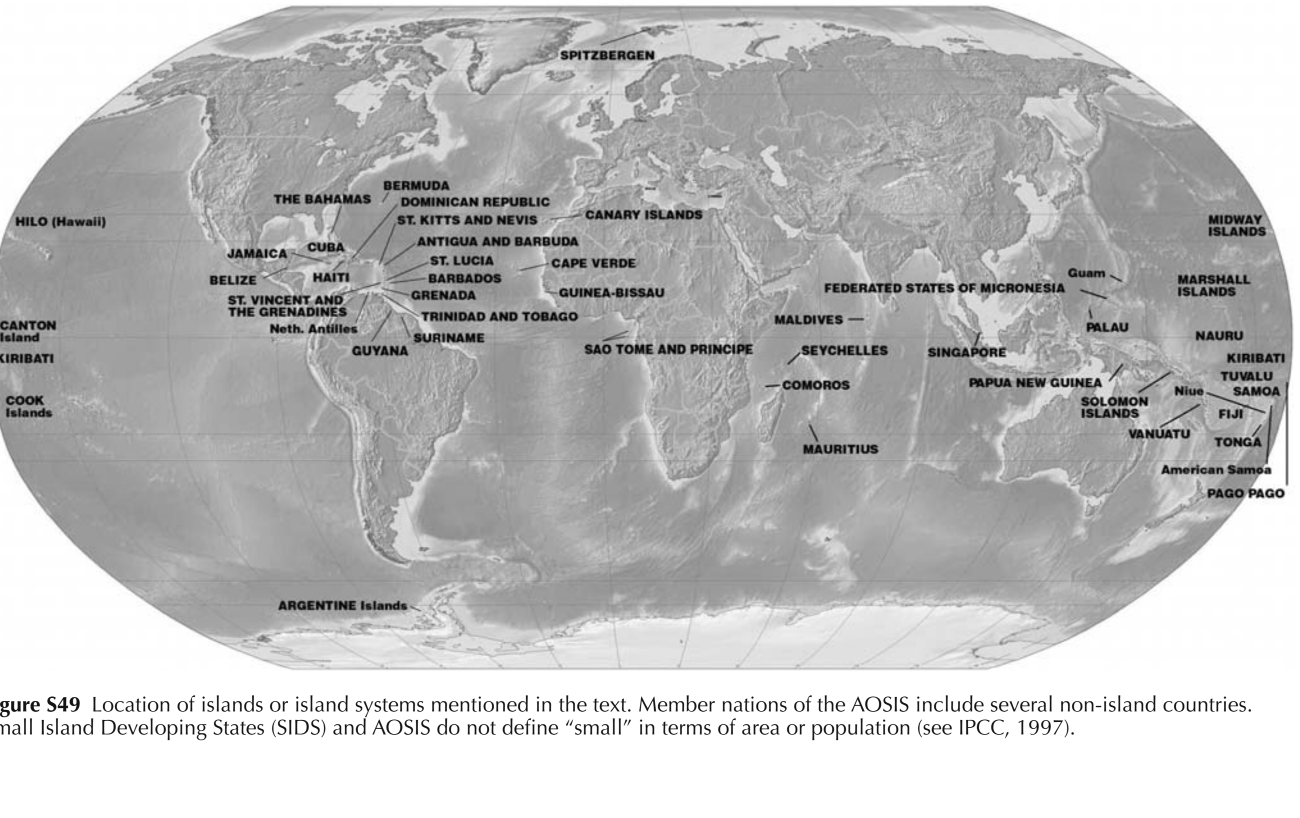

Figure S49 Location of islands or island systems mentioned in the text. Member nations of the AOSIS include several non-island countries. Small Island Developing States (SIDS) and AOSIS do not define "small" in terms of area or population (see IPCC, 1997).

Bangladesh in 1971, is not experienced on intraplate and island arc small islands due to the hydrodynamics of wind-stress induced storm surges. Modeling and observations suggest storm surges of 1–2 m, even in extremely powerful tropical storms, for small islands that are categorized as other than barrier islands, deltaic islands, or precontinent islands.

Many small islands are located in tectonically active regions, and thus are subject to numerous earthquakes. Many are volcanically active or were in their early history. The Hawaiian Islands are a classic example of intraplate islands that owe their existence to volcanism, and it is the basaltic base of these islands that offers corals the necessary substrate to colonize and grow. The low-lying atolls of the Midway Group represent the ultimate fate of Hawaii as it drifts to the northwest over the geothermal hotspot in the central Pacific that gives it genesis, and slowly subsides back into the deep. From a socioeconomic perspective, these and other tectonically active small islands require the necessary infrastructure to recover from a seismic event. It is an often-overlooked problem, especially in SIDS, to be able to recover from the aftermath of a major event, especially the control of fires, loss of electrical power, roads and bridges, and access to public health facilities for the rapidly growing human populations.

Seismic sea waves (tsunami) are another class of coastal hazard from a marine perspective. Although commonly thought of as a natural hazard of the Pacific Ocean, tsunamis are known to occur in all oceans, with historical references in the Mediterranean Sea as early as the 16th century BC. Most tsunami events are associated with strong, shallow focus, dip-slip submarine earthquakes, submarine or subaerial landslides or caldera collapse, submarine volcanoes, or asteroid impact. Not all of these geophysical events create a tsunami, it being especially difficult to forecast a tsunami from an earthquake alone. Small islands are particularly vulnerable to damage from tsunami events, and this has led to establishing warning systems facilitated by the Intergovernmental Oceanographic Commission of UNESCO and national agencies. In the Pacific, where major tsunami events seem to occur about every decade, an extensive array of seismometers, tide gauges, buoys, and communications systems can provide up to several hours of warning; in the Atlantic where the frequency of occurrence is perhaps twice a century, no warning system exists.

In the deep sea, a tsunami travels as a small-amplitude shallow-water wave with celerity $C = \sqrt{gH}$ where g is gravity and H is water depth. A typical celerity in the deep sea is 200 ms^{-1} and it can thus take 24 h for a tsunami to cross the Pacific Ocean, as did the wave from the 1960 Chilean earthquake. In smaller basins such as the Caribbean Sea, the total travel time will be an hour, or much less if the wave is locally generated, as was the case with the Virgin Islands tsunami of 1867. As the tsunami enters shallow water, conservation of energy requires that the amplitude of the wave must increase, and this has led to the great waves, some exceeding 30 m in height, rushing in to destroy coastal communities, ecosystems, and infrastructure. While wave height is a factor in the devastation, wave run-up is often the larger issue. Much like breaking surf on a beach rushes up the beach face, tsunami run-up has been recorded to reach 490 m. Immediate evacuation of the coastal zone is the only viable course of action if lives are to be spared.

Sea-level change on small islands varies as widely as the underlying geology. During the last 100 years or so, tide gauges have been operating to measure water level changes as is needed in tsunami warning systems, ENSO studies, and for determining the tides and chart datums. When the tide gauges are operated using accepted engineering practices including annual differential leveling surveys to juxtaposed benchmarks and regular visits by a trained observer, the long-term trend of relative sea level (RSL) can be discerned. It is the change of sea level relative to the land that is of socioeconomic consequence, and the local effects of vertical land motion, steric seawater changes, oceanic currents, atmospheric barometric pressure, wind-stress, and anthropogenic activities such as dredging and coastal construction complicate it. Many SIDS and member states of AOSIS have expressed great concern about global sea-level rise. For more information, see Pugh (2004).

Unfortunately, few small islands have information from quality-controlled water-leveling measuring systems to quantify relative sea level. Typically, a record-length exceeding three nodal tidal periods (18.61 years each) is needed to statistically discern change in relative sea level above the natural interannual variability associated with long-period tides and coupled atmosphere–ocean events such as ENSO, the Pacific Decadal Oscillation, or the North Atlantic Oscillation. A survey of RSL at selected small islands shows a wide variety of trends (see Figure S50), some showing sea-level rise, some sea-level fall, and some with no statistically significant change at all (see Table S10). Complicating the RSL issue is that even close-by islands can have very different trends, either upward or downward, especially intraplate small islands, deltaic islands, and those within island arc systems. It is simply not possible with current measurements to state unequivocally that small islands, or any coastal system, has an issue with relative sea level that can be attributed to global change, whether anthropogenic or geophysical.

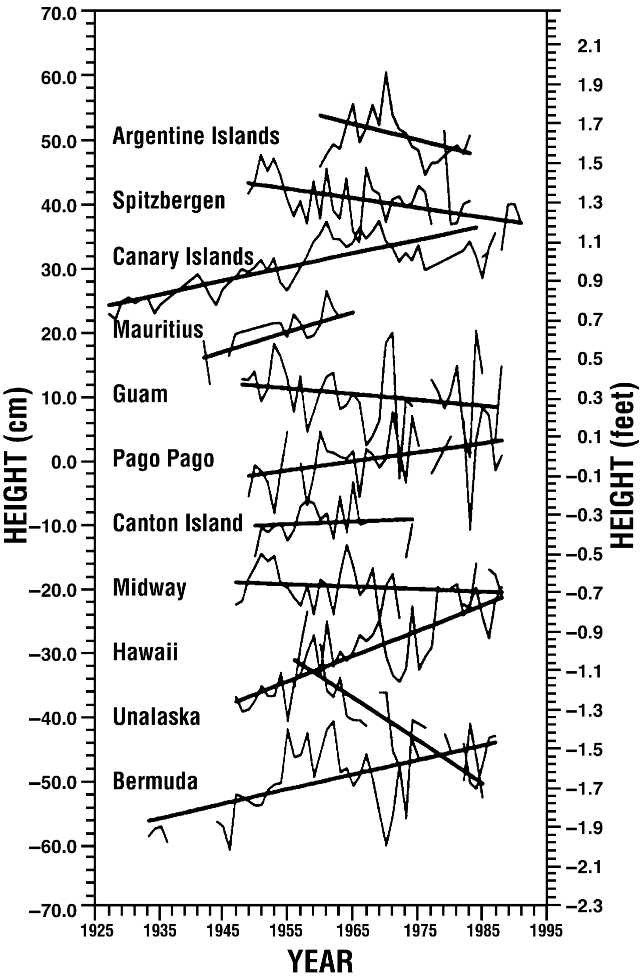

Figure S50 Relative sea level trends at selected small islands. The mean of each curve is offset by 10 cm for clarity. The heavy straight line is the linear least squares trend best fitting the annual mean values. See Table S11 for statistical summary and geographic coordinates. Redrawn from Maul (1996).

Anthropogenic hazards

The discussion of anthropogenic hazards on small islands, and especially to SIDS is meant to be no more exhaustive than the above material on natural hazards. For example the socioeconomic issue of RSL to a small island such as Key West, Florida, which has experienced a well documented 30 cm rise in sea level in the last 150 years (0.19 ± 0.01 cm yr^{-1}), is quite different to that of an equally sized island in say Micronesia. Key West is a highly developed community with significant financial resources to mitigate RSL, and in fact due to extensive coastal engineering, the area of Key West island *per se* has *grown* by some 25% in the century and a half since records have been maintained. Most all developing AOSIS nations would not have the same experience.

Of the anthropogenic hazards identified in many studies, growth of the human population, deforestation, waste management, and marine exploitation are often mentioned. Again, no single small island will have the identical human-caused "hazards" as neighboring islands, but for many SIDS especially in tropical climes, similar patterns seem to arise. While there is cause for concern regarding global change as an instrument of stress to the small island community, it appears that it is local populations causing local problems that will exacerbate environmental degradation for the foreseeable future.

Table S10 Summary of least squares linear trend sea-level change statistics from selected small islands shown in Figure S50

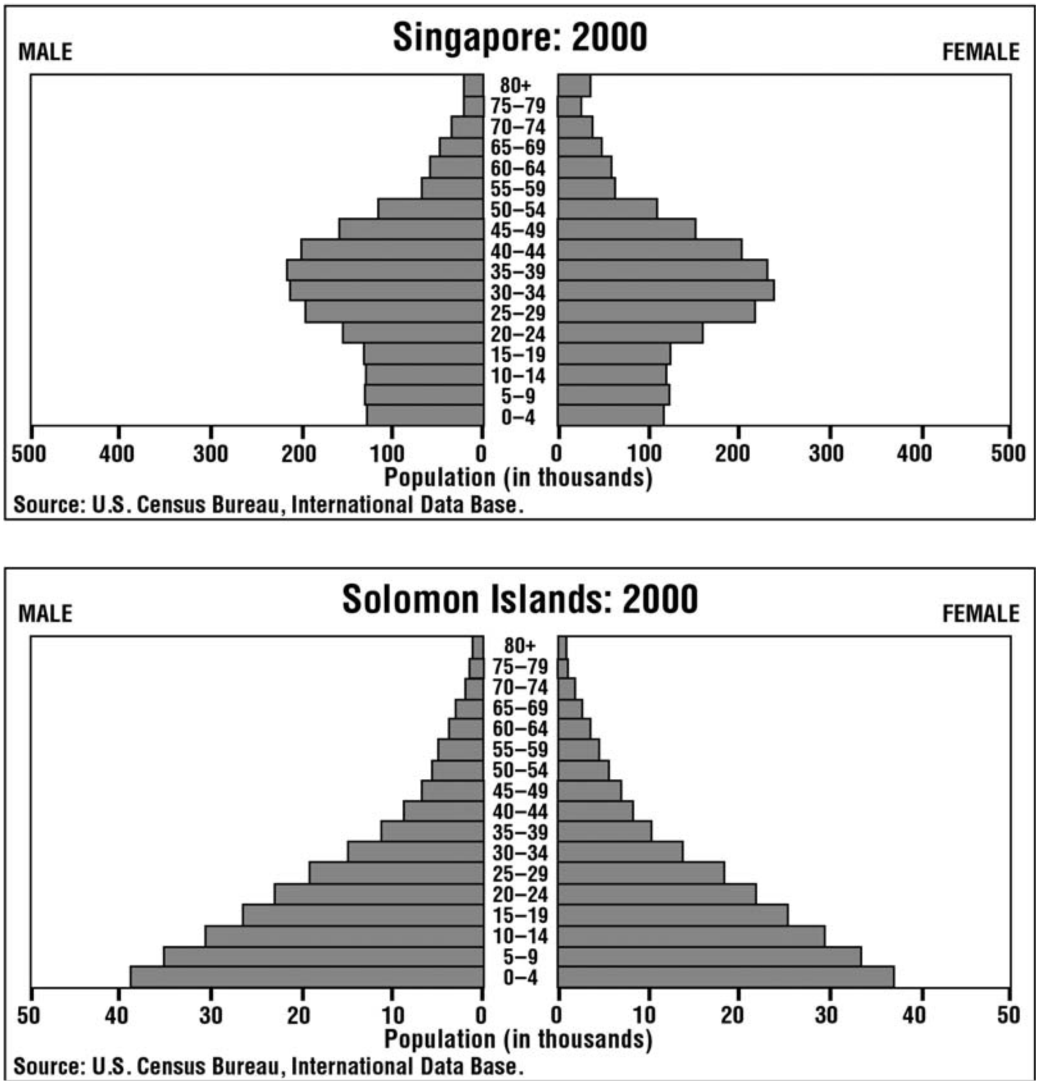

Figure S51 Population pyramid from two small island developing states. Upper panel shows a stabilizing population and the lower panel shows a rapidly growing population. Data from IDP (2000).

Demographics of many SIDS are characterized by a population pyramid that is wide at the base (i.e., many younger persons) and narrow at the apex (i.e., few older persons). In comparison, a society characterized by a population pyramid that is essentially cylindrical (i.e., the number of births, deaths, and distribution by age class are quasi-equal), is one of numerical stability (see Figure S51). Rapidly growing populations require matched growth in services such as education, medicine, food, freshwater, and infrastructure. Small islands are by definition limited in areal extent, and the rapid conversion of agricultural lands to housing, particularly in mountainous islands where cultivatable land is limited to the coastal zone, leads to marginalizing the ability of internal nutritional sustainability.

Deforestation is another consequence of anthropogenic pressure on small islands and other developing areas. Much of the deforestation is past history, such as the conversion of island forestlands to agriculture, as typified by the sugarcane industries of former European colonies in the Intra-Americas Sea. In tropical small islands, it has been the mangroves that have been affected by coastal forestry practices more than any other species. While in many cases mangrove trees have been used for construction, often they are simply removed for ascetic reasons associated with tourism. Not only has this severely impacted the role of these trees as the basis of the tropical marine food web, it has weakened the ability of the coast to resist erosion from tropical storms, tsunami, and sea-level rise.

Waste management in small islands is a critical issue. While in most cases the atmosphere will remove airborne pollutants, the oceanic circulation can cause waste to concentrate on the leeward side. Ship-generated waste, particularly that associated with the lucrative cruise ship trade, is a common problem in many small islands regardless of their latitude. Governmental agencies such as the International Maritime Organization and the United Nations Environment Programme have invested heavily in creating the facilities to manage such wastes, and yet with the growing pressure of other population-related activities on the environment, the coastal zones of small islands are increasingly stressing the marine ecosystem. Waste management of course is of a multiple nature, and while the focus herein is on the coast, the cause is both point-source and distributed.

Finally, considering anthropogenic hazards, the actions of human populations toward marine exploitation must be included. In the Caribbean Sea, for example, the actions of one nation upon another leads to political as well as environmental stress. Overfishing by one small island state upon another as a concerted practice has caused entire reef systems to become incapable of sustainable production. SCUBA divers have been known to sweep past an unprotected coral reef, and essentially remove the entire breeding population of numerous marine species. But the practice of using modern technology to efficiently scour a fishery is not limited to SIDS, as is quite evident in the regions of George's Bank and the Grand Banks. While overfishing has been used to illustrate the issue, souvenir hunting and jewelry harvesting of corals and other marine gems has equally led to exploitation of the marine environment well beyond a sustainable level.

Towards a sustainable environment

Small islands, in many cases, are tuned to the wealth associated with tourism. All the anthropogenic and natural hazards summarized above seem to converge on this central issue. The rugged beauty of isolated small islands, which were created by natural forces that would be considered catastrophic in a contemporary socioeconomic context, are just the scenery that lures visitors. James Mitchner's *Tales of the South Pacific* excites the imagination of fellow wanderers among the family of man. And it is that very attraction that stresses the ability of developing nations to sustain the economic growth necessary to support burgeoning human populations. Not achieving a stable population will lead to the failure of all services and sources of income. Ecotourism, while perhaps less lucrative than currently practiced tourism, is inherently sustainable and should be considered in the mix of solutions leading to sustainable economic development.

Two other critical issues seem to have arisen that cause and limit sustainability: sand mining and water availability.

Tourism and other growth industries require raw materials for construction and infrastructure development. All too often the most cost effective—at least at first—is inexpensive concrete products based on abundant beach sands. Healthy coral reefs in tropical small islands produce beach sands that balance the natural sediment transport to deepwaters as integrated over time. Parallel processes provide materials in other climes for development. Indigenous peoples used these supplies of nature without regard to over-exploitation because of low population densities in the coastal communities. This supply- and-demand balance is no longer viable within the context of exponential human population growth. Thus a paradigm shift is necessary for sustainability, not only regarding beach sand mining, but also for perhaps the most central human issue: freshwater supply.

Peoples of small islands, whether off the desert coast of Bahrain or the rain-forest coast of Singapore, or the frigid Argentine Islands, are focused on the supply of potable water. Sustainability requires that supply exceed demand. No human need except for air, at least on the diurnal-timescale, exceeds the requirement for safe and abundant drinking water. Earth does not have a water shortage problem; it has a cheap water shortage problem! Small islands are perhaps the quintessential expression of this issue. OTEC (ocean thermal energy conversion) and other ocean and coastal engineering solutions to the general issue of supply and demand of abundant freshwater through technology, have as yet realized their theoretical potential. While freshwater is the immediate issue, it is energy—inexpensive energy—that is the central issue, and it is not limited to SIDS.

Conclusions

Small islands are an enigma in many respects within the context of coastal science. They are subjected to storms of tropical and extratropical origin that seem to exacerbate the impact by anthropogenic coastal development. Sea-level change is seen to be extremely site specific, voiding the common perception that all such geographical entities are subject to inundation by external global forces beyond local control. Tsunami, the devastating seismic sea waves, are recognized as not just a Pacific Ocean hazard; highly populated coastal zones of the Atlantic Ocean being perhaps most vulnerable from a socioeconomic context. France and Portugal have recognized the danger of the next repeat of the 1755 Lisbon earthquake and tsunami by establishing a system to prevent a European catastrophe on the scale of the 1998 Papua-New Guinea tsunami.

Population density and pressure upon the coastal marine ecosystem by humankind is clearly a major issue of this quandary. Deforestation, mangrove forests in particular in tropical climates, has repercussions well beyond the erosion issues of sediment systems that provide the nourishment for tourism and other economic stimuli of developing island states. Development brings the inevitable issues associated with waste—what to do with all that stuff? Exploitation of the marine environment extends beyond coral reefs in the tropics, to include fisheries at all latitudes, tourism in pristine locales such as Antarctica, and turtles in the mid-latitude hatcheries of the beaches of east central Florida.

Next, there is the quandary of intellectual sustainability. Human population is, and has been for millennia, characterized by migration. The drain of educated young people not returning to their island homes all too often plagues SIDS. How is the international community of scholars going to create the social environment that encourages young professionals to share their knowledge in a developing nation? Educators in developed nations must encourage the return of the best and brightest scholars to homelands desperately in need of their skills, insight, and worldview perspective, and developing states must accept responsibility by creating policies for students sent abroad to want to return.

Finally there is the issue of "Who do you say is my neighbor?" How is the issue of life, liberty, and the pursuit of happiness, however, it is expressed in the social context of a particular small island society, executed? Clearly the "business as usual scenario" won't create a sustainable society. And in that context, small islands are not separable from the larger global continuum of humankind. Certainly AOSIS and SIDS provide a venue for discussing the special problems of societies with radically limited geographic boundaries. Geophysicists in the widest context can isolate the science peculiar to small islands. Solution of their peculiar problems truly requires a paradigm shift from the confrontational litigious nature of geopolitics to the notion of a shared destiny that does not extort funds and resources from one segment of humankind at the expense of another.

SOUTH AMERICA, COASTAL ECOLOGY

Geomorphologic and oceanographic characteristics of South America

South America (Figure S52) extends from tropical climatic zones (12°30′N) to cold polar zones (about 55°S), encompassing a great diversity of coastal and marine ecosystems. The tectonic history and geological factors, such as the present-day geomorphology and vertical motions of the coastline, influence the coastal and marine ecosystems of South America. Tectonically, South America is divided into two parts, the Andean chains to the west and a vast stable platform to the east, consisting of exposed Precambrian rocks and shallow sedimentary cover rocks (Kellogg and Mohriak, 2001). The Pacific Andean coastline is characterized by high relief, a relatively narrow shelf bordering a deep trench, small drainage basins, and rapid vertical motions of the coast. Low relief, broad shelf, and extremely large drainage basins and alluvial fans characterize the Atlantic coastline. Approximately 93% of South America's drainage is to the Caribbean and the Atlantic, away from the Andes, and provides the world's best example of continent-scale drainage control by plate tectonics (Kellogg and Mohriak, 2001).

The upper water circulation of Atlantic Ocean as a whole consists in its gross features of two great anticyclonic circulations or "gyres" separated over part of equatorial zone by the eastward flowing Equatorial Counter Current. In the South Atlantic, the upper-water gyre extends from the surface to a depth of about 200m near the Equator and to about 800 m at southern limits of the gyre at the Subtropical Convergence. The different portions of this gyre have different water properties. The South Equatorial Current flows west toward the American side of the South Atlantic. Part of the current crosses the equator into the North Atlantic, and is named the Guyana Current. The remainder turns south along the South American continent as the Brazil Current (Figure S52), which then turns east at about 30°S, at the Subtropical Convergence, and continues across the Atlantic as part of the Antarctic Circumpolar Current (Pickard and Emery, 1990). A contribution to the water in the South Atlantic comes from the Malvinas Current (or Falkland Current) flowing north from Drake Passage, up the coast of South America and reaches the Brazil Current at the Subtropical Convergence. The Brazil Current and Guyana Current are warm and saline, with a low concentration of nutrients, having come from the tropic region. The Malvinas Current is cold, with lower salinity and a higher concentration of nutrients, transporting subantarctic waters.

The circulation of the upper water of the Pacific is very similar in its main features to that of the Atlantic. In the South Pacific the superficial currents flow northward, from the Antarctic Circumpolar Current, forming the Peru (or Humboldt) Current (Figure S52). The Peru Coastal Current is closest to the coast and confined to the uppermost 200 m depth, transporting cold water (14–16°C) in summer (Pickard and Emery, 1990). The Peru Oceanic Current (down to 700 m depth) reaches higher velocities than Peru Coastal Current. Between these currents, the weak and irregular southward flow of the Peru (Humbouldt) Subsurface Countercurrent is usually sub-superficial but occasionally reaches the surface (Pickard and Emery, 1990). Along the Pacific coast of South America, an upwelling area extends from 4°S to 42°S. Peruvian coastal upwelling is peculiar because winds sustain the upwelling process throughout the year. The coastal upwelling system, which hardly comprises 0.02% of the total ocean surface, is of great significance because it determines the enormous productivity of Peruvian and Chilean coastal waters, representing almost 20% of the world's landings of industrial fish (Tarazona and Arntz, 2001). Wind intensity and persistence are highest in winter and lowest in summer. Wind stress, and consequently upwelling strength, has intensified over the last decades (Pickard and Emery, 1990). The oceanographic conditions along the Pacific coast are influenced by an interannual variability known as El Niño–Southern Oscillation (ENSO), which consists of a cold period (La Niña) and a warm period (El Niño), with anomalous warming of the eastern Pacific during about three months. El Niño occurs every 2–7 years, causing a deepening of the pycnocline and thus rendering the upwelling process inefficient (Tarazona and Arntz, 2001).

These complex assortments of geomorphologic and oceanographic characteristics result in very diversified environmental settings, allowing the occurrence of many different coastal ecosystems in South America. The occupation of coastal environments is expanding very fast, and in most cases, without adequate planning. The rising rates of coastal resources exploitation, the threat of global changes and sea-level rise and the economic losses due to environmental degradation, on the one hand making the coastal management a hard task, and on the other hand, these events evidence the urgency of planning the uses and conservation of these environments.

Simone Rabelo da Cunha

Sandy beaches ecosystems in South America

Sandy beaches constitute a dynamic interface between the land and the sea that stretch from the base of the dunes to the low tide mark or lower limit of the swash zone. Dunes, beaches, and surf zones are closely linked by the interchange of sand. The morphology of these dynamic and harsh environments is defined by the interaction of waves, tides, sediment characteristics, and topographic features, which combined characterize the morphodynamics of a beach (Short, 1996) (see *Beach Processes* and *Sandy Coasts*). Sandy beaches dominate ocean and estuarine shores of the South American coast. Pacific sandy beaches display a variety of morphodynamic environments. Venezuela, Colombia, and Ecuador present a narrow discontinuous stretch of pocket sand beaches, alternating with rocky shores and mangrove swamps. In Peru, which constitutes the southern extreme of mangrove swamps in the beginning of the warm-temperate Pacific coast, alternating exposed and sheltered beaches, together with active sand dunes, become prevalent. Chilean beaches are mainly found from 19°S to 42°S. Exposed sandy beaches with different morphodynamics alternate with rocky shores in the north (19–30°S) and intertidal sand flats at the mouth of rivers in south-central regions (38–42°S) (Jaramillo, 2001). Atlantic sandy beaches also display wide variations in morphodynamics. Sheltered, pocket beaches are found between Venezuela and northern Brazil, up to Cabo Frio (23°S). Pebble beaches, with a variable amount of rocky fragments, are also found. Southwards, within the warmtemperate biogeographic province, sandy beaches become more exposed and reflective, with coarse sands and steep slopes. A continuous (640 km) exposed, dissipative and microtidal (astronomic tides 0.5 m) sandy beach is found from Rio Grande do Sul (southern Brazil: ca. 29°S) to northeastern Uruguay (Barra del Chuy: 33°45′S), with fine to very fine, well-sorted sands, gentle slopes, well-developed frontal dunes, heavy wave action, a wide surf zone and large barometric tide ranges (Calliari *et al.*, 1996). The physiognomy of this coastline is mainly determined by the prevailing winds and wind-driven surf off the South Atlantic. Southwards, the exposure of beaches is ameliorated by the estuarine effect of the Río de la Plata, between Punta del Este and Montevideo (Uruguay) and also in the northeast of Buenos Aires Province (Argentina). Beyond the estuarine influence of the Río de la Plata River and up to the gulfs of northern Patagonia (around San Matías Gulf/Valdés Península: ca. 41°S), beaches are mainly characterized by fine sands and gentle slopes. These gulfs define the southern limit of the warm-temperate southwestern Atlantic province, which also demarcates a biotic transition in faunal composition. The cold-temperate coastlines south to 43°S, Patagonia, are mainly sand flats, pebble beaches, and long, high cliffs of Cenozoic marine sediments.

Pacific beaches of northern Chile and Peru present surf zones characterized by upwelling, high detrital inputs from kelp beds and the absence of surf diatoms (Arntz *et al.*, 1987). Contrastingly, exposed dissipative beaches of the Atlantic coast of southern Brazil, Uruguay, and Buenos Aires Province are characterized by non-periodic events of high concentrations (7×10^8 cells L^{-1}) of brown colored patches produced by surf zone diatoms such as *Asterionellopsis glacialis* (Odebretch *et al.*, 1995). Favorable surf circulation patterns promote greater retention of particulate primary production, thus allowing the beach/surf zone ecosystem of dissipative coastlines to function as semi-closed ecosystems (McLachlan, 1980). Long dissipative beaches of moderate to high

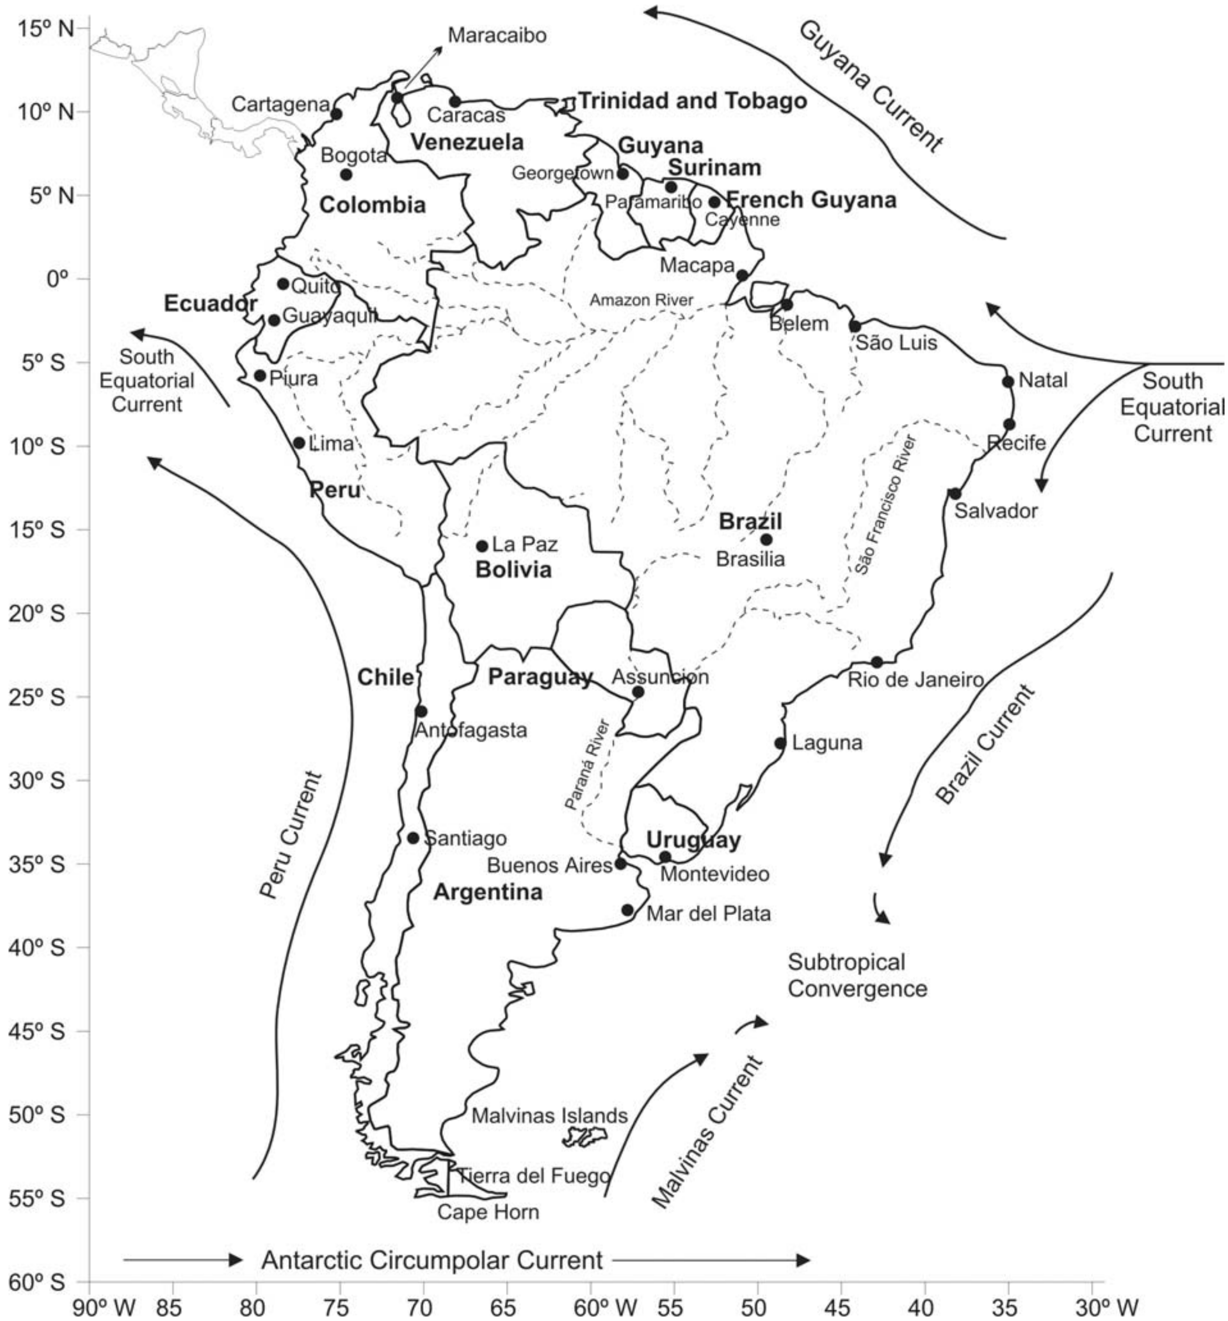

Figure S52 South America countries, showing larger rivers and main oceanographic currents.

energy, rip current activity and an associated dune system providing nutrients by groundwater flow, constitute suitable conditions primarily met in southern Brazil and Uruguay (Defeo and Scarabino, 1990). Abundant suspension feeders play an important role as efficient mineralizers, providing ammonium sources for surf diatoms. Phytoplankton at exposed reflective and sheltered shores is much less abundant, and food for macrofauna mainly comes from the sea as living and nonliving particulate organic matter, while debris and carrion are transported shoreward through the surf zones (McLachlan, 1980). Warm-temperate Atlantic beaches are also subject to seasonal blooms of toxic dinoflagellates. The strong dynamics of oceanic waters and the influence of the Río de la Plata also produce several toxic outbreaks (Méndez *et al.*, 1996).

Research on sandy beaches of South America has been mainly focused on macrofauna (community and population levels), particularly on exposed coastlines. Concerning communities, investigations deal with structure, seasonal dynamics and distribution patterns at spatial scales ranging from macro (km) to meso (individual beaches). Crustaceans, mollusks, and polychaetes are the most diverse groups. A review of existing information does not provide support to the well-known worldwide pattern of increasing number of species from temperate to tropical latitudes. The concurrent effects of morphodynamics, variations in tide amplitude and beach length, as well as the presence of localized areas with extremely high productivity due to upwelling events, mask the recognition of latitudinal trends. Indeed, the reverse pattern was found by Jaramillo (2001) in 3,000 km of Chilean coastlines (20–42°S): species richness increases southwards, from 15 (20–23°S) to 28 (40–42°S). Similar trends were reported by Dexter (1992) for 284 beaches around the world, who found an increase in species richness from tropical to cold-temperate beaches. Moreover, the number of species is not directly related to beach length or tidal amplitude: the greatest species richness in the Atlantic coast was recorded in pocket (short) sheltered and very sheltered beaches with sand sediments mixed with rock fragments (pebbles and cobbles), along São Sebastião

Channel, southeastern Brazil (23°43′S), where 31 species of crustaceans, 35 of mollusks, and 24 of polychaetes were documented for only one beach (Engenho d'Água; e.g., see Nucci *et al.*, 2001). Species richness, abundance, and biomass vary with beach morphodynamics: flat dissipative beaches have more diversity, abundance and biomass than reflective ones (Defeo *et al.*, 1992; Jaramillo, 1994). Intertidal suspension feeders are typical inhabitants in these high-energy dissipative beaches. On the contrary, only supralittoral species (insects, ocypodid crabs, some talitrid amphipods, and cirolanids) remain in truly reflective beaches.

Sandy beaches of South America display across-shore zonation of their macrofauna. In general, the upper shore or supralittoral of tropical and subtropical beaches is characterized by crabs (Ocypodidae), whereas on temperate beaches talitrid amphipods and cirolanid isopods prevail. The upper littoral or mid-shore fringe is dominated by cirolanid isopods and polychaetes, whereas the lower littoral and shallow sublittoral are mainly occupied by cirolanids, amphipods, bivalves, and hippid crabs of the Genus *Emerita*. Concerning tropical coastlines of Venezuela (ca. 10°N), the supralittoral tends to be dominated by the brachyuran *Ocypode quadrata*, talitrid amphipods and the cirolanid isopod *Excirolana braziliensis* (also on the middle shore), whereas the midlittoral is mainly occupied by anomurans of the genus *Emerita* and *Lepidopa*, the mollusks *Donax denticulatus*, *Tivela* sp., *Terebra cinerea*, and *Olivella verreauxi*, and the polychaetes *Glycera* sp. and *Sthenelais limicola*. The shallow sublittoral is dominated by the gastropod *Mazatlania aciculata*, the echinoid *Mellita quinquiesforata* and the starfish *Astropecten marginatus* (e.g., see Penchaszadeh *et al.*, 1983). In Colombia, Pacific beaches with fine sands have higher species richness and abundance than the Atlantic counterparts with coarser grains (from 3°N to 11°N). Both coasts are dominated by the isopods *E. braziliensis* and *Exosphaeremona diminutum*, as well as the polychaetes *Scolelepis agilis* and *Hemipodus armatus* (Dexter, 1974). Sandy shores of Peru (about 8–12°S) are dominated by a low number of species with high biomass, notably the suspension feeders *Mesodesma donacium, Donax peruvianus* and *Emerita analoga* in the shallow intertidal (Arntz *et al.*, 1987). Other members are (Penchaszadeh, 1971): the sand crab *Ocypode gaudichaudii* and the cirolanid *E. braziliensis* (supralittoral and upper/mid-littoral), the polychaetes *Hemipodus triannulatus, Nephtys monilibranchiata*, and *Nephtys multicirrata* (mid-littoral) and the anomurans *Blepharipoda occidentalis* and *Lepidopa chilensis* (lower littoral and shallow sublittoral). In Chile, the most common species are the insect *Phalerisida maculata* (supralittoral) the cirolanid isopod *E. braziliensis* (supralittoral and upper littoral), the anomuran crab *E. analoga*, the bivalve *M. donacium*, and the polychaete *Nephtys impressa* (swash zone and shallow sublittoral), all of which occur between 20°S and 42°S (Jaramillo, 2001). The supralittoral ocypodid *O. gaudichaudii* found in northern Chile (20–23°S) is replaced by the talitrid amphipod *Orchestoidea tuberculata* in south-central Chile (32–42°S), as a result of latitudinal gradients in rainfall and sediment temperature.

On Atlantic coastlines, coarse sandy beaches in Surinam (ca. 6°N) show an impoverished fauna characterized by the presence of *O. quadrata* in the supralittoral (Swennen and Duiven, 1982). Sheltered sandy beaches of northern Brazil are dominated by crustaceans, mollusks, and polychaetes, commonly found on channels from Bahia to Rio Grande do Norte. The supralittoral is dominated by *O. quadrata* and the peracarids *Orchestia* spp. and *E. braziliensis*. Lower fringes present a low number of crustaceans and mollusks, depending on tidal exposure and the existence of reefs or freshwater runoff. Southwards (Rio de Janeiro State: ca. 23°S), exposed reflective/intermediate beaches harbor an average of 7 species, notably the talitrid amphipod *Pseudorchestoidea brasiliensis* (supralittoral), the isopod *E. braziliensis* (supralittoral and upper littoral), and the anomuran *Emerita brasiliensis* (lower littoral and shallow sublittoral), which together represent 95% of the macrofauna (Veloso and Cardoso, 2001). For roughly the same latitude, some 90 species of mollusks, crustaceans, and polychaetes appear in Engenho d'Água beach, along São Sebastião Channel (Brazil: ca. 23°42′S). The high species richness in these sheltered unconsolidated marine beaches, with rocky shores inundated by sand, is associated with higher habitat heterogeneity: rocky fragments form small tide pools and moist and shady microhabitats, which may widen the presence of some intertidal species (Denadai *et al.*, 2001). In one of the few comprehensive studies that included sublittoral fringes, Borzone *et al.* (1996) showed a marked increase in the number of species from the intertidal to sublittoral of sandy beaches of Parana, Brazil (25°30′S), particularly in reflective beaches.

Sandy beaches between Southern Brazil (29°S) and Argentina down to Golfo Nuevo (ca. 43°S) show a gradient from warm-temperate to cold-temperate faunistic composition, where the Río de la Plata acts as an effective ecological barrier (Escofet *et al.*, 1979). The wide chain of wave-exposed beaches along southern Brazil and Uruguay show maximum species richness (at least 23), density and biomass at the long chain (640 km) of dissipative beaches of fine sands and flat slopes, while the lowest values (5 species) occur in reflective beaches of Uruguay, with coarse sands and steep slopes (Defeo *et al.*, 1992). Crustaceans are the most represented (nine species), followed by mollusks (six), insects (five) and polychaetes (three). The cirolanid isopod *Excirolana armata* dominates in numbers, whereas the suspension feeders *Mesodesma mactroides*, *Donax hanleyanus*, and *E. brasiliensis* dominate in terms of biomass. The highest beach levels are occupied by *O. quadrata* (only juveniles are sporadically found in Uruguay), the amphipod *P. brasiliensis*, insects and the cirolanid isopod *E. braziliensis*. The polychaetes *Euzonus furciferus* and *Scolelepis gaucha* are found at mid-beach levels, together with the isopod *E. armata*. The higher intertidal levels are dominated by the amphipods *Bathyporeiapus ruffoi*, *Phoxocephalopsis zimmeri*, and *Metarpinia* sp., and the suspension feeders *M. mactroides, D. hanleyanus*, and *E. brasiliensis*, whereas the lower ones are occupied by the isopods *Macrochiridotea giambiagiae, Macrochiridotea lilianae*, and *Macrochiridotea robusta*, the polychaetes *Hemipodus olivieri* and *Sigalion cirriferum*, and the gastropods *Olivella formicacorsii, Buccinanops duartei, Olivancillaria vesica auricularia* and *Olivancillaria teaguei*. On Brazilian coastlines, *Callianassa mirim* (Callianassidae) is also found in this fringe (Gianuca, 1983).

Species richness and abundance decrease towards Río de la Plata (ca. 35–36°S), as a result of high salinity variability and decreasing exposure. Low abundances of *P. brasiliensis* and *E. armata* co-occur with some brackish water species. In Buenos Aires Province (ca. 37°S), the supralittoral species *O. quadrata* and *E. braziliensis* are not found, and *Orchestia platensis* and *P. brasiliensis* are rarely present. The intertidal is inhabited by the isopod *Cirolana argentina*, the clams *M. mactroides* and *D. hanleyanus*, and gastropods of the genus *Buccinanops* and *Olivancillaria* (Escofet *et al.*, 1979). The supralittoral of beaches of north Patagonian gulfs is inhabited by *O. platensis*; the upper littoral by *C. argentina*, the bivalve *Darina solenoides*, polychaetes *Scoloplos* sp., *Travisia* sp., and *Onuphis dorsalis*, and amphipods Haustoriidae and Phoxocephaliidae. The lower littoral and shallow sublittoral are represented by the bivalves *Tellina petitiana* and *Bushia rushi*, the gastropods *Olivella* sp., *Buccinanops globulosum, Olivancillaria arcellesis, Olivancillaria uretai* and *Olivancillaria urceus*, the isopod *Serolis gaudichaudii*, several amphipods (*Monoculopsis valentini, Stephensia haematopus*, Haustoriidae and Phoxocephaliidae) and polychaetes. *Callianasa* sp. and the polychaete *Arenicola brasiliensis* appear in sheltered beaches (Escofet *et al.*, 1979).

Faunistical zones across the beach also showed important variability, with aperiodic (even daily) and seasonal components (Brazeiro and Defeo, 1996). The across-shore position of patches varies according to the different susceptibility of each species to environmental variations. Generally, species richness increases from upper to lower beach levels in dissipative beaches, whereas in very reflective beaches the lower fringes tend to disappear. One or two faunistical belts are found in reflective beaches, and three or four in dissipative ones (Defeo *et al.*, 1992).

Life history traits, dynamics, and structure of sandy beach populations show clear geographical patterns. In one of the few large-scale studies conducted in South America, Defeo and Cardoso (2002) analyzed macroecological issues of the intertidal mole crab *E. brasiliensis* along some 2,700 km between Urca (Rio de Janeiro, Brazil: 22°57′S) and Arachania (Uruguay: 34°36′S). Most (11 from 14) life history traits of the crustacean *E. brasiliensis* were significantly correlated with mean water temperature of the surf zone, which could be summarized as follows: (1) a shift from continuous to seasonal reproductive and recruitment events from subtropical to temperate beaches; (2) an increase in individual sizes of the smallest ovigerous female, fecundity at size, predominance of females and individual weights from subtropical to temperate beaches; and (3) a decrease in male sizes, growth, and mortality rates towards temperate beaches. The concurrent effect of morphodynamics at a regional scale was also detected and in some cases masked clear latitudinal trends.

Lifespans appear to be also related to temperature, ranging from 1 to 3 years for the small, warm water species to >10 years in some cold-temperate clams (e.g., *M. donacium* in Chile), but most species live for 1–4 years and have relatively rapid growth to maturity. Wide seasonal growth oscillations occur in southern populations, with lowest rates during autumn and winter (Gómez and Defeo, 1999 and references therein); alternatively, tropical populations show continuous growth throughout the year.

Sandy beach populations are labile to climatic variability, which generates resurgences and mass mortalities. Arntz *et al.* (1987) showed dramatic fluctuations of the suspension feeders *D. peruvianus, M. donacium*, and *E. analoga* in Peru, as a response of the strong (ENSO) event of

1982–83. Following the mass mortalities of the dominant *M. donacium* as a response of a strong increase in sea surface temperatures during ENSO, *D. peruvianus* increased from 5% to 60–100%, and *E. analoga* increased from <1% to 29%. This suggests differential responses to climatic events and also potential interspecific interactions because of competitive release of resources by dominant macrofauna members. Variations in species composition along the Chilean coast have also been related to latitudinal gradients in rainfall and sediment temperature (Jaramillo, 2001).

Beach morphodynamics affect biodiversity on sandy coastlines. An increase in species richness, abundance, and biomass from reflective to dissipative beaches has been reported (Defeo *et al*., 1992). However, a large-scale study conducted in Chile (Jaramillo, 2001 and references therein) showed that species richness, abundance, and biomass are higher at intermediate beaches, some of them located near areas of persistent upwelling. Populations that co-occur in contrasting environments are less sensitive to variations in beach morphodynamics, as revealed by comparisons of abundance, reproduction, recruitment, fecundity, growth, mortality, and burrowing time between reflective and dissipative beaches (Gómez and Defeo, 1999; Defeo *et al*., 2001).

Most sandy beach populations have strong and persistent distribution patterns in response to an environment that is spatially and temporally structured by sharp, small-scale gradients (Defeo and Rueda, 2002). Specific habitat preferences across the beach generally determine significant correlations between abundance and mean grain size, beach face slope, sediment moisture and penetrability. Aggregations persist in time, but, in contrast to sessile species, the position of the patches varies according to the different susceptibility of each species to variations in physical (e.g., sediment moisture and temperature), and biological (swimming ability and burying) factors (Giménez and Yannicelli, 2000).

Unpredictable and strong short-term increase in tide ranges (i.e., up to sand dunes) generated by storm surges, wind-driven surf off the ocean and barometric tides could be a source of mortality. This mortality in many cases is size-dependent, as smaller intertidal organisms are more susceptible to being stranded in the upper littoral. Mass mortalities at dissipative beaches probably occur at a higher frequency than on reflective ones, where wave intrusion is mitigated by the steep slope on the lower shore.

Intra- and interspecific interactions are important in structuring sandy beach populations and communities. Results from long-term and large-scale field experiments, together with laboratory observations and field monitoring, suggest that population fluctuations in dissipative sandy shores are produced by the intertwined forces of environmental, density-dependent, and human-induced factors operating together at different spatial and temporal scales (Defeo, 1996a). Concurrent field sampling and laboratory experiments with cirolanid isopods showed that intra- and interspecific interactions would be of importance in population regulation (Defeo *et al*., 1997). Local populations tend to present density-dependent growth and mortality. Density-dependent and density-independent forces acting together can jointly explain population fluctuations over time, as shown for the yellow clam *M. mactroides* in Uruguay (Lima *et al*., 2000) and the guild of suspension feeders *M. donacium, D. peruvianus*, and *E. analoga* in Peru. The fact that density-dependent mechanisms are often manifested in dissipative beaches, with highest values of species richness and abundance, suggests that biotic interactions should be of utmost importance in these systems, whereas reflective beach populations should be mainly regulated by individual responses to the environment. Considering that these populations are highly spatially structured, potential compensatory and overcompensatory mechanisms have been shown to occur at small spatial scales in dissipative beaches with highest macrofauna abundance (Defeo, 1996a). Other studies, however, suggest that environmental harshness leaves limited scope for competitive interactions, as suggested for Chilean beaches (Jaramillo, 2001).

Predation by birds, gastropods, crabs, fishes, and insects usually generates high rates of size-dependent mortality, particularly at dissipative beaches with high macrofauna biomass. Research efforts were mainly focused on food habits of juvenile fishes in the inner surf zones of dissipative sandy beaches (e.g., Monteiro-Neto and Cunha, 1990). Predation could act as a selection pressure determining body size of macrofauna, and thus higher growth rates should be directed to diminish predation risks. An active selection of the site could also be invoked to decrease predation and desiccation risks.

Sandy beach ecosystems receive a variety of increasing anthropogenic impacts such as forestation, exploitation of coastal species, coastal development, pollution (disposal of liquid and solid wastes, freshwater discharges from wide plain basins used for agriculture and cattle rearing, agro-chemicals), and unplanned recreational use (Lercari and Defeo, 1999).

Sandy beach fisheries in South America rely on species with different life histories. Harvested stocks are the intertidal clams *Mesodesma* and *Donax*, mole crabs *Emerita* and supralittoral ghost crabs *Ocypode*. The main artisanal/recreational fisheries are based on the extraction *M. mactroides* (handpicking: Brazil, Uruguay and Argentina) and *M. donacium* (handpicking and diving: Peru and Chile). These fisheries have shown to be notoriously difficult to manage, because ocean beaches are open and extended systems readily accessible to commercial and recreational users, but also to unauthorized harvesters. Management measures are difficult to enforce and appear to be beyond the finances of most management agencies. High uncertainty in stock estimates, lack of basic biological knowledge, improvements in fishing power, low operating costs and a risk-prone management attitude, determined a trend towards overexploitation (Castilla and Defeo, 2001). Nevertheless, a successful management experiment was documented for *M. mactroides* of Uruguay, which included the experimental manipulation of the system based on a fishery closure for 32 months (Defeo, 1996a, 1998). The long-term study (8 years) showed that abundance, age composition, age-specific survival, fertility, and population growth rate of the yellow clam were significantly affected by adult density, recruitment variability, and fishing intensity (Brazeiro and Defeo, 1999). Population structure of the sympatric clam *D. hanleyanus* showed inter and intra-annual fluctuations of recruits and adults, with uneven periods of abundance related to fluctuations in the fishing effort targeted on *M. mactroides* (Defeo and de Alava, 1995). Operational management tools based on area-specific management plans (legal sizes and catch per fisher and fishing ground) were implemented in Chile through "Management and Exploitation Areas," defined as concessions allocated to fisher communities (Castilla and Defeo, 2001).

Disposal of liquid and solid wastes, accidental oil spills and deposition of mine tailings (Castilla, 1983) modify community composition, abundance, population structure, fecundity, and zonation of macrofauna in South America. Freshwater discharges from man-made canals also affected the habitat, community structure and abundance, fecundity and growth rates of *D. hanleyanus* (Defeo and de Alava, 1995) and *E. brasiliensis* (Lercari and Defeo, 1999). Mechanical disturbance of sands occasioned by recreational users during the summer seems to have little effect on macrofauna (Jaramillo, 2001).

Information is comparatively scarce or absent for plankton, meiofauna, vagile megabenthos, and nekton of the surf zone, as well as for birds and sub-terrestrial fauna inhabiting sand dunes. An ecosystem approach is needed for modeling networks of interactions between different components of food webs. Other processes and mechanisms affecting structure and functioning of sandy beach macrofauna (e.g., predation, commensalism, parasitism, and mutualism) are still little documented. There is considerable scope to elucidate the role of competition in structuring sandy beach communities, and its relative contribution according to morphodynamic states, exposure, and tidal regimes.

Biogeographic patterns in life history traits have not been adequately assessed in sandy beach ecology. Further research should be directed to clarify large-scale patterns, the relative contribution of factors influencing beach fauna and to decipher cause–effect relationships. At present, our knowledge of how dissimilar responses of populations could also result from locally adjusted genotypes or a combination of plastic and genetic responses is limited, and should be addressed by genetic studies throughout biogeographic ranges. Little is also known about dispersive abilities of meroplanktonic larval phases, and the mechanisms influencing larval distribution and connectivity between populations are still poorly understood (Defeo, 1996b). Research should also focus on planktonic stages and physical-oceanographic information (e.g., nearshore hydrodynamics) to determine the spatial scales at which the population dynamics is to be considered an open process, that is, if it is more related to the arrival rates of larvae than to post-settlement processes.

Long-term studies are scarce at both the community and population levels, and the consequences of natural or human-induced disturbances on the structure and dynamics of macrofauna are poorly known. Recent mass mortalities that occurred on a geographical range have been poorly documented and understood. Different approaches are needed to perform well-designed experimental and field studies directed to critically assess environmental impacts in these fragile ecosystems. This should be complemented by laboratory (microcosm) experiments to understand ecophysiological effects of pollutants and responses to abiotic factors coming from different human sources.

Sandy beach populations may be partially regulated by density-dependent processes of unknown extent. Future work should emphasize scale-dependent experimental manipulations of abundance, both through field and laboratory experiments. The spatial analysis of populations and the environment should be useful for monitoring changes in abundance, structure, and dynamics of populations.

Accumulation of toxins, such as those associated with algal blooms of toxic algae, can cause mass mortalities of suspension feeders or render them unsafe for human consumption. This limits the potential utilization of many species and creates the need for careful monitoring and management. As human impacts on coastal waters continue, blooms of toxin-producing phytoplankton could affect beach suspension feeders more. This should be a focus for future studies.

Omar Defeo and Anita de Alava

Rocky shore ecosystems in South America

Rocky shores are important ecosystems along the South American coast because of the great diversity of species and economic importance of some of these species, such as oysters, mussels, crabs, and fish. As a transitional ecosystem between terrestrial and marine environments, the rocky shore can be divided into three parts. The first, upper part of the rocky substrate is permanently exposed to the air (the supralittoral zone), the second part is only exposed during low tides (the intertidal or mid-littoral zone), and the third part is always submerged (the sublittoral zone). While the rocky substrate does not permit organisms to burrow, crevices, pits, and the accumulation of boulders create a three-dimensional matrix that provides different microhabitats for many kinds of organisms. Most of the organisms attach to the rock surfaces, thus providing additional microhabitats on which other organisms may settle. The sessile fauna on the intertidal zone is usually distributed in horizontal belts of dominant species, giving the zone a striped appearance called zonation. In the sublittoral zone, this distribution is much less marked and only some species show a depth zonation (see *Rock Coast Processes*).

On the Atlantic side of South America, traveling along the coast from north to south, rocky-shore communities first appear in the Santa Marta area of Colombia (11°13′N 74°14′W–11°20′N 74°05′W). For the most part, the coastal mountains, part of the Sierra Nevada de Santa Marta, plunge abruptly into the sea. However, a low and narrow rock (phyllite or quartz-diorite) platform exists, at least in the bays, which are often split up into small promontories and islands. The spatial distribution of this community was studied by Battaström (1980), who described the zonation as follows: the supralittoral is inhabited only by the gastropods *Littorina ziczac, Littorina angustior, Nodilittorina tuberculata*, and *Tectarius muricatus*; the upper intertidal zone has a bare appearance but is covered by blue-green algae and represents an impoverished upper part of the lower barnacle–vermetid zone; the lower intertidal zone is a narrow zone formed by barnacles (*Tetraclita* sp., *Chthamalus angustitergum, Megabalanus stultus*) and/or vermetids (*Petaloconchus varians, Spiroglyphus annulatus*); the sublittoral fringe is covered by a mixture of algae (*Ralfsia expansa, Sargassum* sp., *Laurencia papillosa*, and *Ectocarpus breviarticulatus*) and invertebrates (barnacles, chitons, limpets, boring organisms, and a multitude of crabs and snails living inside the algae); the sublittoral zone is characterized by the presence of encrusting coralline algae overgrown by a mat of macroalgae (most important are the rhodophyceans *Amphiroa* sp., *Jania* sp., *Hypnea* spp. *Ceramium nitens, Centroceras* sp., and *Laurencia* spp.) and many sessile and semi-sessile invertebrates (sponges, horny and scleractinian corals, the zoanthids *Palythoa* sp. and *Zoanthus* sp., sea anemones, scattered barnacles and chitons, the gastropods *Fissurella angusta* and *Acmaea* spp., the bivalves *Isognomon radiatus* and *Isognomon bicolor* and the ascidians *Styela canopus, Herdmania momus,* and *Pyura vittata*).

In Venezuela, rocky shores are present in the regions of Trinidad and the Paria Peninsula (11°N), but they are apparently poorly studied and no literature was found describing this area. Rocky shores are absent from the delta of the Orinoco River to the northern coast of Brazil, where the littoral is covered by a mangrove formation.

A few rocky shore ecosystems exist along the northeastern Brazilian coast, but hard substrates are commonly available as sedimentary rocky fringes along the shallow coast. Algae, coral communities, and other sessile invertebrates such as sponges, tunicates, bryozoans, and cnidarians usually inhabit these fringes. One of the few granitic rocky formations already studied is an intertidal and shallow sublittoral platform of boulders and gravel at Ponta Cabo Branco, Paraíba (7°S), which joins the fringing sedimentary reefs along the coast. These rocks form a unique ecosystem in the area composed of a rich sessile community of sponges (*Chondrilla nucula, Haliclona* sp., *Tedania ignis, Halichondria* sp.), tunicates (*Didemnum duplicatum, Didemnum psammatodes, Polysyncraton amethysteum, Eudistoma* spp.), cnidarians, macroalgas (*Ulva* sp., *Gelidium* sp.), oysters (*Crassostrea rhizophorae*) and associated fauna. In the sublittoral, corals (*Siderastrea stellata, Mussismilia hartti, Mussismilia hispida, Montastrea cavernosa, Agaricia agaricites*, and *Porites astreoides*) and the zoanthids *Palythoa* sp. and *Zoanthus* sp. are common invertebrates.

From central Brazil (Espírito Santo, 20°S) to Laguna in the south (Santa Catarina, 28°S), rocky shore environments are formed by granitic or basaltic rock, resulting from the erosion of the border of the Serra do Mar mountain chain, which lies parallel to the coastline. It is not a continuous ecosystem, but forms more or less extended outcroppings between sandy beaches. This is the principal rocky shore ecosystem along the coast of Brazil and also the most known. The first published descriptions of the community appeared between late 1940s and early 1950s (Oliveira, 1947, 1950; Joly, 1951, 1957) and since then, information on species distributions and communities has been found through many species surveys and ecological studies.

The following synthesis provides an overall picture of the community, and is based on work by Joly (1951, 1957), Oliveira (1947, 1950), Nonato and Pérès (1961), and Oliveira-Filho and Paula (1983). The supralittoral mostly comprises bare space used by the periwinkle gastropods *L. ziczac* and *Nodilittorina lineolata*, which are the most common and characteristic organisms at the lower part of this zone. Isopod crustaceans of the genus *Lygia* are also very common at the supralittoral.

The upper intertidal contains a dense belt of the barnacle *Chthamalus bisinuatus*, while *Tetraclita* and *Megabalanus* are found lower in the intertidal zone, but are not dominant space occupiers. Below the *Chthamalus* belt, *Brachidontes solisianus* is the dominant in terms of space used. However, in sites exposed to waves, *Perna perna* mussels can form dense beds in the mid and lower intertidal. More recently, *I. bicolor* has invaded the southeastern and southern coasts of Brazil and is replacing *B. solisianus* in some areas. The mid-intertidal zone is also colonized by many algae, such as *R. expansa, E. breviarticulatus, Centroceras clavulatum, Jania adhaerens, Acantophora spicifera*, and *Ulva* spp. On wave-exposed sites one can add *Porphyra* spp. (in winter), *Chaetomorpha antennina*, and many species of fleshy macroalgae, and coralline algae both articulated and encrusting. On the low intertidal and sublittoral the oyster *C. rhizophorae* can be abundant and common algal species are *L. papillosa, A. spicifera, Jania capillacea, Amphiroa fragillisima, Hypnea cervicornis, Rhodymenia pseudopalmata*, and *Corallina officinalis*. In many sites along the coasts of São Paulo, Paraná and Santa Catarina, the sabelariid polychaete *Phragmatopoma caudata* forms extended sandy reefs along the low intertidal zone. In the latter two states, the colonial ascidian *Eudistoma carolinense* forms a narrow belt below *Phragmatopoma* and comprises an important intertidal microhabitat for more than 117 species (Moreno and Rocha, 2001). Among the vagile invertebrates characteristic of the intertidal zone are some herbivorous mollusks, such as the limpets *Collisella subrugosa* and *Fissurella clenchi*, besides the periwinkles, which can migrate down from the supralittoral zone; the predator whelks *Stramonita, Pisania*, and *Leucozonia*; and the crabs *Pachygrapsus gracilis* and *Pachygrapsus transversus*.

A dense *Sargassum* spp. bed usually marks the upper sublittoral fringe and is probably the most abundant macroalgae in both tropical and subtropical sublittoral zones. It forms dense beds usually covering a thin layer of encrusting coralline algae, which are dominant space occupiers in many sublittoral sites, especially at places where grazing pressure is high. The most important herbivores at the sublittoral are the urchins *Arbacia lixula, Echinometra lucunter, Lytechinus variegatus*, and *Paracentrotus gaimardi*; chitons; gastropod mollusks of the genera *Aplysia, Astraea*, and *Tegula*; and fish, such as damselfish (*Stegastes* sp.), surgeons (Acanthuridae), and parrotfish (Scaridae). Sessile invertebrates common to the sublittoral zone are cnidarians of the genera *Palythoa* and *Zoanthus*, which form large encrusting colonies, and a variety of small arborescent hydrozoan colonies. Sponges are also very common and diverse—more than 120 species are known within the merely 25 km long São Sebastião Channel on the north coast of the State of São Paulo (Hajdu *et al*., 1996). The most conspicuous bryozoan is the encrusting *Schizoporella*, but many small arborescent colonies are frequent, especially from the genus *Bugula*. Common ascidians are the encrusting colonial didemnids and the solitary pyurids and stylelids (Rodrigues *et al*., 1998).

The southern coast of South American, between Rio Grande do Sul (Brazil) and Rio de la Plata estuary is formed basically by a long sandy beach of 750 km in length. Very little rocky substrate is available along this coast that could represent an important geographical barrier for sessile organisms. Close to the borderline between Santa Catarina and Rio Grande do Sul (29°S), there is a small rocky outcropping formed by very tall volcanic rocky structures, called Torres ("towers" in English) because of the height of the rocks. Artificial rocky substrates are also present, such as the rocky jetties at the entrance of Lagoa do Patos, which also supports a diverse encrusting community.

Very few experimental studies have been undertaken to understand the dynamics of both intertidal and sublittoral rocky shore communities along the Brazilian coast. Caging experiments showed that littorinid grazing activity controls the abundance of microalgal populations in the supralittoral zone (Apolinário *et al*., 1999). Experimental analysis of succession on cleared substrates in the intertidal zone revealed that *C. bisinuatus* recruits more on the *Brachidontes* zone and prefers granitic to basaltic substrates (Tanaka and Duarte, 1998). On the belt formed by *Sargassum cymosum* var. *nanum* in the low intertidal zone, succession is maintained in its earlier stages due to desiccation stress causing widespread algal mortality during the early summer (Paula and Eston, 1989). Experimentally cleared areas of the sublittoral zone revealed that *Sargassum stenophyllum* was both the competitive dominant with slow growth and an opportunist colonist (Eston and Bussab, 1990).

South to the Rio de la Plata River estuary in Argentina, there are loess platforms separated from a coastal cliff of 7–8 m by sand strips. The upper intertidal is inhabited by crusts of blue-green algae, while the mytilid bivalve *Bachidontes rodriguezi* is the dominant space occupier in the mid-intertidal zone with densities up to 33,000 ind m^{-2} and an associated community of around 40 species. The cause of this dominance is not only competitive abilities but also the absence of important predators at the intertidal zone (Lopez Gappa *et al*., 1990). The barnacles *Balanus amphritite* and *Balanus glandula* are present in areas with fewer *Balanus rodriguezi*. The first species appears in Quenquén Harbor (38°34′S; 58°42′W) and the second has become abundant in Mar del Plata Harbor (38°0′S; 57°32′W) in recent years. There are no periwinkles in the Mar del Plata region, where they are replaced by the gastropod *Siphonaria lessoni*, which is abundant in both the intertidal and supralittoral zones.

Community distribution in the southern region of Argentina, the Chubut Province, is as follows: the supralittoral covered by various blue-green algae with the chlorophyte *Enteromorpha intestinalis* and the mollusks *S. lessoni* and *Brachidontes purpuratus* in tide pools; in the upper intertidal there is a striking absence of barnacles and the most important inhabitant is the gastropod *S. lessoni*; in the mid-intertidal there are three well-marked belts: *B. purpuratus*, the coralline alga *Corallinetum officinalis* and the phanerogams *Spartina montevidensis* and *Salicornietum ambigua*; the low intertidal is occupied by a mytilid belt (*Mytilus edulis platensis, Aulacomya ater*, and *B. purpuratus*); the sublittoral does not include the usual phaeophytes but instead has a wide belt of the chlorophytes *Codium fragile* and *Codium vermilara* establishing its upper limit (Olivier *et al*., 1966).

Chile has an extended coast, about 2,600 miles long, which can be topographically divided into two very different regions: south of Chiloé (41°29′s), the coast is discontinuous, with mountains along the shore rising up to 3,000 m, comprising an eroded tectonic pattern of glaciated and non-glaciated fjords. North of Chiloé the coastline is very regular and fully exposed to the prevailing winds and waves, but there are geological differences: from Chiloé up to Navidad (33°57′S) the coastal range is made up of metamorphic shale of low elevation, from Navidad to Antofagasta (23°38′60S) it is mainly granitic rock, and north of Antofagasta it consists of volcanic rocks with sedimentary intrusions (Stephenson and Stephenson, 1972; Santelices, 1991).

Along the southern coast of Chile, south to Chiloé Island, the bad weather conditions and the limited access result in a lack of knowledge about the intertidal and sublittoral communities in these wave-exposed open coasts. Nevertheless, community descriptions are available from sheltered islands in the southernmost tip of South America. For instance, in the Beagle Channel the supralittoral zone contains several bands of lichens and the upper intertidal is covered by a mixture of algae (*Bostrychia mixta, Hildenbrandia lecannellieri, Pilayella littoralis, Adenocystis utricularis, Enteromorpha* spp., *Porphyra* spp., *Spongomorpha* spp.). Next, the mid-intertidal has mussels and barnacles together with high densities of the gastropods *Acmaea, Collisella, Nacella*, and *Siphonaria*, while the low intertidal is covered by pink encrusting coralline algae and high densities of *Nacella magelanica* and *Nacella mytilina*, with the brown alga *Lessonia vadosa* marking the lowest limit of the intertidal zone. The sublittoral communities of these habitats consist of belts of *Macrocystis pyrifera* in sheltered and semi-sheltered sites (Santelices, 1991).

In central Chile the supralittoral inhabitants are barnacles (*Jehlius cirratus*) in reduced densities, aggregations of *Littorina araucana* and *Littorina peruviana*, the algae *Porphyra columbina* and dark-red crusts of *H. lecanellieri*. The upper intertidal is covered by pure or mixed stands of chthamaloid barnacles (*Chthamalus scabrosus, J. cirratus*), while the mid-intertidal usually contains a belt of the mussel *Perumytilus purpuratus* mixed with the algae *Centroceras clavulatum, Enteromorpha compressa, Iridaea laminarioides, Ulva rigida*, and *Polysiphonia* spp. (Santelices, 1991).

Towards the northern coast of Chile, this same pattern of species distribution is observed for wave-exposed rocky habitats, but there is a northward reduction in the number of belt-forming algae species. *Macrocystis pyrifera* disappears north of Concepción (36°49′60S) where the dominant algae are *Lessonia trabeculata* in the sublittoral and *Lessonia nigrescens* along the sublittoral–intertidal fringe (Santelices, 1991). Rocky sheltered communities have not been well studied and the only description available is from Guiler (1959) in which the intertidal biota in Antofagasta Bay was studied. There the rocks are shale that forms a wide erosion platform covered by an association of *Pyura praeputialis* and *Corallina chilensis* immediately below the barnacle belt. The lower limit of the *Pyura* belt might be controlled by predation by the starfish *Heliaster helianthus* and *Stichaster striatus*. At the lower intertidal *Ulva* replaces *Corallina*; the large barnacle *Austramegabalanus psittacus* occurs in the lowest part of the *Pyura* belt and both organisms are covered by *Ectocarpus confervoides* and *Halopteris hordacea*. *Pyura chilensis* is widespread along the coast of Chile and do not form belts as *P. praeputialis* in Antofagasta region (Santelices, 1991).

Much experimental work has been done to examine species distributions in both the intertidal and sublittoral zones of the Chilean coast. *P. praeputialis*, for instance, maintains its dense intertidal beds by intraspecific self-facilitating mechanisms that enhance recruitment to the border of previously settled individuals (Alvarado *et al*., 2001). The intertidal rocky community in Mehuin (39°25′60S), in the southern coast, is regulated by herbivory and competition; there are apparently no intertidal carnivores capable of controlling herbivore densities and high herbivore densities can destroy the red alga *Iridaea boryana* cover; depending on the season of the disturbance, the community may be dominated by the alga or by barnacles plus crustose algae (Jara and Moreno, 1984). In the sublittoral zone, experimental kelp canopy removal revealed that *M. pyrifera* control the species composition of understory algal community (Santelices and Ojeda, 1984), and, in central Chile, the removal of *L. nigrescens* results in a community of calcareous crustose alga *Mesophyllum* sp. in the presence of herbivory and large patches of *Gelidium chilense* in the absence of herbivory (Ojeda and Santelices, 1984). In northern Chile, the abundance of herbivores, algae morphology, plant density, water movement, and the egg case of elasmobranches which tie plant stipes together are the most important ecological factors for the persistence and stability of *L. trabeculata* beds (Vasquez, 1992).

A high degree of eco-geographic isolation seems to be a general characteristic of the intertidal and shallow sublittoral rocky communities of Chile. The result is a high degree of endemism and several of the endemic species occupy unique ecological niches with unknown parallels in comparable habitats elsewhere (Santelices, 1991). The causes of this isolation, and factors limiting the distribution of these species and communities are unknown and offer an important area of future research.

Oceanographic conditions and upwelling are strong influences on the coastal communities of Peru. This upwelling area associated with highly productive waters stretches from 4°S southward to 40°S, in central Chile, but the most intensive effects are seen in the Peruvian coast, especially during the winter (Tarazona and Arntz, 2001). Because of the upwelling process, intertidal and shallow sublittoral zones of northern Chile and Peru have high species diversity. In Peru, the forest-forming kelps (*Lessonia* spp. and *M. pyrifera*), the mussel *Argopecten purpuratus*, the gastropod *Thais chocolata*, the crabs *Cancer setosus, Cancer porteri*, and *Platyxanthus orbignyi*, and the sea urchin *Loxechinus albus* all occur in great numbers with a large biomass. Kelp forests form a sublittoral belt about 15 m wide and harbor numerous associated species. Mussels (*Perumytilus purpuratus, Semimytilus algosus*) also form beds in the intertidal zone, with more then 70 associated species. The structure of these communities tends to be controlled by grazers and predators, while the population dynamics of the algae *Macrocystis* is influenced by the upwelling and El Niño events (Tarazona and Arntz, 2001). As an example of this influence, the intense El Niño event of 1982–83 caused mass mortality of key species like the mussel *Semimytilus* and brown algae (*Macrocystis* and *Lessonia*) along the Peruvian rocky shores (Tarazona *et al*., 1988).

In Colombia, the tectonic processes along the Pacific coast have given origin to abundant steep cliffs (>45° slope) and rocky shores with more gently sloping platforms, composed of boulders, pebbles, and gravel from cliff erosion. Along the northern coast and in the interior of Buenaventura Bay (3°52′60N), species have the following distributional patterns: desiccation-tolerant blue-green and green algae, a lichen species, periwinkles (*Austrolittorina aspera, Littoraria zebra*), the crab *Grapsus grapsus*, and the isopod *Lygia baudiana* inhabit the supralittoral.

About 20 species occupy the upper intertidal zone, among them the periwinkle *L. zebra*, the crab *Pachygrapsus transversus* on less wave-exposed cliffs, while barnacles (*Tetraclita, Chthamalus*), limpets (Fissurellidae, Acmaeidae, Siphonariidae), crabs (*G. grapsus*) and some green algae occur on exposed cliffs. The mid-intertidal zone is dominated by bivalves (*Brachidontes* sp., Isognomidae, and oysters) and the associated fauna is comprised by crabs of the families Xanthidae (*Eriphia squamata*) and Grapsidae (*P. transversus*), and the red coralline alga *Lithothamnion*. In the lower intertidal zone it is possible to find barnacles, anemones, sponges, the gastropods *Acanthina brevidentata* and *Thais kiosquiformis*, and some crabs. At this level an increasing number of boring organisms (bivalves of the families Pholadidae, Petricolidae, and Mytilidae and the ghost shrimp *Upogebia tenuipollex* contribute to the bioerosion of the rocky cliffs. Erosion rates can be as much as 300 $cm^3\ m^{-2} month^{-1}$ for igneous rocky cliffs and 450 $cm^3\ m^{-2}\ month^{-1}$ for sedimentary rocky cliffs (Cantera and Blanco, 2001).

The most important stresses on rocky shores are the trampling effects of tourists and fisherman, oil and sewage pollution, and selective collecting for food and obtaining mussel seeds for cultures. All these processes have been studied in different rocky shore ecosystems and showed marked influences in the intertidal community structure. Although many rocky shore ecosystems are located in protected areas inside ecological reserves, usually the goal of the reserve is to protect either the terrestrial or the underwater ecosystem while neglecting the intertidal zones. One of the few well-studied reserves is the Estación Costera de Investigaciones Marinas (ECIM) in Las Cruces (33°30′S), Chile, with a 5 ha human-exclusion exposed shore established in 1982. The intertidal community changes and food-web cascading effects, which occurred inside the reserve, showed that humans act as an efficient and selective keystone predator (Castilla, 1999).

The rocky shore communities throughout the South America coasts are reasonably well described. Yet, almost no information exists on the Patagonian coast of Argentina and the Ecuadorian coast. On the other hand, mechanisms of community structure are best studied in Chile and, very recently, Brazil. Apparently, the conservation of rocky shores has not been of primary importance for most countries environmental conservation policies. The few well-monitored known marine reserves are located in Chile.

Rosana Moreira da Rocha

Coral reefs ecosystems in South America

Coral reefs are highly diverse ecosystems that have been compared with the tropical rain forest. They are formed by coelenterates that secrete a calcium skeleton as well as by other calcium secreting organisms such as mollusks, corallinae algae, and sponges (see *Coral Reefs*). The structure formed by these organisms offer shelter and support for an incredible diversity of life, making coral reefs crucial to the culture and livelihood of millions of people in tropical coastal environments. Corals have on their living tissue symbiotic algae called zooxantelae that contribute with oxygen and organic compounds and receive protection from the coral colony. The phenomena known as bleaching is caused when the zooxantelae leaves the coral, usually due to stress related causes. In the last decades, mass bleaching events that have caused the death of many coral reefs have been reported from several parts of the world. These events, related to climate change, have added to other anthropogenic stresses, which are causing an alarming rate of degradation of coral reefs. The concerns with the health and conservation of coral reefs have led government and organizations to establish several programs for monitoring and protecting these ecosystems. The Global Coral Reef Monitoring Network (GCRMN) was established in 1995 with the objective of encouraging and coordinating monitoring of coral reefs at the government, community, and research levels around the world. Brazil, Colombia, and Venezuela are part of the Node of GCRMN for southern tropical America, together with Panama and Costa Rica (Wilkinson, 2000).

Coral reef formations in tropical South America are more developed in the Atlantic coast, as several important cold upwelling areas inhibit reef development in the Pacific coast. Coral reef formations on the Pacific side are found in a few reef patches on the coast of Colombia and on offshore islands. The Atlantic coast of South America is under strong continental influences, which introduces large amounts of sediment and inhibits the development of extensive coral reef formations in some areas, especially around large rivers such as the Amazon, Orinoco, and Magdalena. Coral reefs occur along the Atlantic coast of Colombia, Venezuela, and Brazil.

Colombia is the only South American country with both Pacific and Atlantic coasts and coral reefs. There are about 2,700 km^2 of coral reefs in the Caribbean waters, of which 75% are located in oceanic reef complexes. Along the mainland coast, there are fringing reefs on rocky shores such as the Santa Marta and Urabá areas (Garzon-Ferreira *et al*., 2000).

In Venezuela, reefs occur along three Caribbean areas out of total 2,875 km of Caribbean and Atlantic coastline. Along the continental coast of Venezuela, the more developed coral formations occur in the Morrocony National Park and adjacent reefs, where more than 30 coral species can be found. The best reef formations are found 100 km offshore at Los Roques Archipelago, with 57 coral species and reefs growing up to 50 m depth (Garzon-Ferreira *et al*., 2000).

Brazil is located in the central-oriental portion of South America with approximately 7,408 km of coastline running from 4°25′N to 33°45′S. Coral reefs are sparsely distributed along almost 3,000 km of coast (Maida e Ferreira, 1997), and their distribution and location is still poorly known (Castro and Pires, 2001). Laborel (1969) provided the most thorough qualitative description of Brazilian reefs (see also Maida and Ferreira, 1997 and Castro and Pires, 2001 for reviews). The Brazilian coast can be divided into three biogeographical realms. Intertropical (northern coast): comprises the northern coast from the French Guyana border to Cabo de São Roque. Tropical: the largest portion of the Brazilian coast, from Cabo de São Roque to Cabo Frio, Rio de Janeiro State. Subtropical: from Cabo Frio to the border with Uruguay. Reef formations, including some that are not true coral reefs, are present mostly along the tropical Brazilian coast (northeastern coast), although some coral growth also occurs at the northern region and in the southeastern coast up to São Paulo State. Coral diversity is low, with only 18 hard coral species, but 10 of these are endemic to Brazil. Of those, three species have an even more restricted distribution, only occurring on the reefs of Bahia State. Brazilian reefs present only one species of reef-dwelling soft coral, *Neopongodes atlantica*, which is an endemic form (Maida e Ferreira, 1997).

Reef formations such as those that are typical of the northeastern Brazilian coast are rare elsewhere, not displaying the distinctive zones generally observed in reefs around the world (Leão *et al*., 1988). One of the main characteristics of the Brazilian reefs, are the constructions made by calcareous algae, from the group of the Melobesiae, and vermetid gastropods of the genus *Petaloconchus* and *Dendropoma*. These formations can be found on crystalline and eruptive rock, but are especially common on the seaward side of sandstone banks and coral reefs. They grow in the upper part of the reef front forming structures that are similar to the algal ridges of the Indo-Pacific reefs (Laborel, 1969). Endemic species like *Favia leptophylla, Mussismilia braziliensis, Mussismilia hartii*, and *Mussismilia hispida*, that among the principal reef builders, are archaic forms, the remnants of a tertiary fauna that was preserved in a refugium provided by the seamounts of Abrolhos bank during the last glaciation (Leão *et al*., 1988).

On the northern coast the main geographic feature is the immense Amazonian estuary with a width of more than 350 km. The water of the Amazonian estuary, loaded with vast amounts of sediments, is transported by littoral currents to the north up to Guyana, forming an extensive barrier for coral reef development. According to Laborel (1969), the region has no reefs, only scattered coral growth, but further down the coast, about 80 km off São Luís, the capital of Maranhão State, lays a large coral bank called Parcel de Manuel Luis, whose existence has been known to navigators since the 17th century, mostly because of the danger it represented to navigation.

Reef formations are present along the northeastern coast from Cabo do São Roque (Rio Grande do Norte state) to the south of Bahia State. In Cabo de São Roque there is a group of oval shaped reefs located a few miles from the coast. These reefs are simple structures, usually formed by numerous pinnacles in a shallow sandy base. On the reef flat only two species of coral occur, *Siderastrea stellata* and *Favia gravida*. Calcareous algae Melobesiaea and the vermetid gastropods form an algal ridge. The seaward crest is dominated by *Millepora alcicornis*, followed by *M. hartii* on the slope and *Montrastea cavernosa* at greater depths. According to Laborel (1969) the main reef builder in this region is *S. stellata*.

In this region, from Natal to São Francisco River, the principal characteristics are the coastal sandstone banks and superficial coral reefs, disposed in various lines running parallel to the coastline along more than 600 km. The sandstone banks and superficial coral reefs form lines that are not continuous, and in the places where these formations are interrupted, the coast takes the form of small bays, normally with mangrove swamps whenever creeks and rivers are present (Maida e Ferreira, 1997). The sandstone banks are structures that can reach up to 10 km in length and 20–60 m wide. They can appear directly adjacent to the beach, or as submerged formations on the high tides (Dominguez *et al*., 1990). In some areas up to three lines of reefs can be seen at one coastline, forming an effective protection to the shore. The length of each reef varies from 1 to 4 km, for the reefs that are exposed at low tide, and up to 10 km for the submerged reefs, such as the reefs located off Itamaracá Island, north of Recife (Dominguez *et al.*, 1990). The depth of surrounding waters is seldom greater than 10 m. In this area, the region of more extensive coral development is located between Recife and Maceió Cities. The Tamandare reef complex is the most studied area due to the presence of the Oceanographic Institute in Recife, established in 1958 by the Federal University of Pernambuco, and due to the work of Laborel (1969), who presented a detailed description of the area (Maida e Ferreira, 1997). Coral reefs in the area present a distinctive feature, given by their growth as isolated columns of 5–6 m high and expanded laterally on the top. Where the growths of these reef columns are dense, the reefs coalesce at their tops creating large structures with open spaces below the surface, forming a system of interconnected caves (Maida e Ferreira, 1997). The coral fauna of the reefs in this region is richer than up north. From the 18 species of stony coral described for the Brazilian coast, 9 species were described for this coast. The main reef builders in this region are the species *M. hartii* and *M. cavernosa*. The fish fauna is similar to the Caribbean fauna, but less diverse, with basically the same families but less species.

Further south, reefs disappear in the area around the mouth of the São Francisco River. The São Francisco River, with an average run-off of 3,300 $m^3 s^{-1}$, discharges large quantities of fine material and exerts considerable variation in salinity in the seawater for several kilometers off and along the coast, forming a large barrier for coral reef development over 100 km wide.

Coral formations are observed again south of the river mouth, along the coast of Bahia State. This coast has the higher diversity of reef formations, presenting superficial reefs; fringing reefs; large isolated mushroom shaped pinnacles, called "chapeirões," and large platform bank reefs (Leão *et al.*, 1988; Dominguez *et al.*, 1990). *M. braziliensis*, an endemic species to the Bahia coast, is the most important coral species, and the main reef builder. In the coast of Bahia State the continental shelf widens up, reaching over 200 km in the southern part of the coast. In this region, "Abrolhos," the largest and more diverse reef complex on the Brazilian coast, is located. Coral reef formations in the Abrolhos area are spread over an area of 6,000 km^2, up to 15 km long and 5 km wide. The whole region has been a National Marine Park since 1983, being the first Marine Park established in Brazil. A special permit is required from IBAMA (Brazilian Environmental Institute) and the Brazilian Navy to land on these islands. In Abrolhos there is observed the highest diversity of corals in Brazil. All hermatypic scleractinian corals and hydrocorals found in the Brazilian Coast are present in Abrolhos, from which seven species, including the principal constructors, are endemic forms. Two of the Brazilian species of scleractinian corals, *M. braziliensis* and *Favia leptophylla*, and the hydrocoral *Millepora nitida* only occur in the coast of Bahia.

South of Abrolhos, variations in water temperature are greater throughout the year, and there is a greater vertical temperature gradient. Reefs gradually disappear on the northern coast of Espirito Santo State in Rio de Janeiro State, few scattered points of coral growth are found in Cabo Frio, Angra dos Reis, and Ilha Grande, between the barriers represented by the cold upwelling waters around Cabo Frio, and the mouths of the rivers São Mateus, Mucuri, and Doce. The southern limit of coral growth is São Paulo State.

As in most regions of the world, anthropogenic impacts have been the main cause of degradation on coral reefs in South America. The human related activities that affect reefs in the region are the same that threaten most coral reefs around the world, such as land use practices that increase sedimentation, industrial, domestic and agricultural pollution, mining, over-exploitation of reef resources, and uncontrolled tourism. Coral reefs in the region support important biodiversity reservoirs and an expanding tourism industry (Garzon-Ferreira *et al.*, 2000). According to the report of the Status of Coral Reefs of the World (Wilkinson, 2000), bleaching events appear to have increased in frequency, but decreased in severity, throughout the 1990s, due to the global warming phenomena.

Beatrice Padovani Ferreira and Mauro Maida

Mangrove ecosystems in South America

Mangroves are transitional ecosystems between land and sea. Mangrove plants are adapted to salinity variation, waterlogged and hypoxic or reduced mud sediments (see *Mangroves*). Mangrove forests show best development in tropical protected shores, where low wave energy and abundant freshwater supply allow deposition and accumulation of fine organic mud and salinity range between 5 and 35 (Lugo and Snedaker, 1974). The extension of forests inland depends on tidal range and topography, and large forest belts can extend several kilometers landward from the sea. Under these optimal environmental conditions and humid areas, mangroves can attain their maximum growth and productivity. Examples of these are reported for Ecuador and Colombia, where red mangrove (*Rhizophora*) trees reach 40–50 m in height and more than 1.0 m in diameter (Lacerda *et al.*, 1993), and for coasts of Surinam, French Guyana, and northern Brazil, where black mangrove (*Avicennia*) trees reach 30–45, m in height and 0.7–1.0 m in diameter (Lacerda and Schaeffer-Novelli, 1992). The productivity of these systems, in terms of litterfall, varies from 3 to 10 metric ton $ha^{-1} year^{-1}$ (Lacerda *et al.*, 1993; Twilley *et al.*, 1997). Seaweeds can play an important role to mangrove productivity, representing 10–45% of total primary production of mangroves, not only in South America (Peña, 1998; Cunha, 2001), but also elsewhere (Steinke and Naidoo, 1990; Rodriguez and Stoner, 1990). Microalgae are certainly important, though not quantified. The high primary production, together with habitat heterogeneity, can sustain a large and diversified fauna, including transient and resident animals. Many of these are economically important, especially for artisanal users of mangrove. Around the world, many people are supported by mangroves' goods and services, as economic or food source (Hamilton and Snedaker, 1984; Saenger *et al.*, 1983).

South America mangroves, as much as New World mangroves, have a reduced number of tree species, contrary to Southeast Asia, which has nearly one hundred taxa of true mangrove trees (Tomlinson, 1986). There are only four genera: *Rhizophora* (Rhizophoraceae), *Avicennia* (Avicenniaceae), *Laguncularia*, and *Conocarpus* (Combretaceae). The species *Rhizophora mangle, Avicennia schaueriana, Avicennia germinans, Laguncularia racemosa*, and *Conocarpus erecta* have wide distribution. The species *Rhizophora harrisonii* and *Rhizophora racemosa* are more restricted to northern places of South America (Cintron and Schaeffer-Novelli, 1992). *Avicennia* is the most tolerant genus to environmental stress, sometimes dominating highly saline substrates or low-temperature areas, being able to attaining greater structural development in low salinity, disturbance-free environments (Cintron and Schaeffer-Novelli, 1992). Many plant species occur associated with mangrove forests, and the diversity can vary due to climatic conditions and proximity of other ecosystems, like rain forests. Despite this, some species frequently appear to be associated with mangroves around the world, including Atlantic and Pacific coasts of South America. The Malvaceae *Hibiscus tiliaceus* and the fern *Acrostichum aureum* are the most widespread (Cintron and Schaeffer-Novelli, 1983). Macroalgae occur colonizing roots and trunks of mangrove trees, rocks, stones, or shell fragments into the mangrove. Red algae of the genera *Bostrychia, Caloglossa, Catenella*, and *Polysiphonia* and the green algae of the genera *Cladophoropsis, Rhizoclonium*, and *Bloodleopsis*, dominate the macroalgal communities. However, other genera can also occur, especially in northern areas, where water transparency and salinity are high (Cordeiro-Marino, 1992).
